REVIEW OF PARASITE FATE AND TRANSPORT IN KARSTIC AQUIFERS

William J. Blanford
Louisiana State University
Baton Rouge, Louisiana

Every year in the United States cases of waterborne illness are generally characterized by gastrointestinal problems (vomiting, diarrhea, etc.). However, these same symptoms can be more serious and even fatal in certain groups, such as the young, elderly, and those with compromised immune systems. Furthermore, *viral pathogens* found in groundwater are linked to chronic diseases such as adult onset diabetes and myocarditis. Recognizing that preventing contamination of water sources is the first step in the multiple barrier approach to drinking water protection, the Interim Enhanced Surface Water Treatment Rule (IESWTR) and the Disinfectants/Disinfection Byproducts Rule (DBPR) were released in 1999. The two rules will provide additional protection of public water supplies and address microbiological contamination. The rules address the risks of the trade-offs between disinfection necessary for *microbial inactivation* and disinfection byproducts. The requirements of 40 CFR 141.72(b) are consistent 99.99% removal and/or inactivation of viruses and 99% removal of *Cryptosporidium oocysts*. The code gives public water suppliers the option to demonstrate compliance through pilot plant studies or other means that combine filtration techniques with *disinfection* as in EPA 1999 Microbial and Disinfection Byproducts Rules Simultaneous Compliance as in Guidance Manual.

Presently, only surface water systems and systems using groundwater under the direct influence of surface water are required to disinfect their water supplies. Although historically considered free of microbial contamination, most recent research has shown that aquifers can be readily contaminated by pathogens. To lessen the requirement for disinfection and to protect water resources, water suppliers have sought to use natural systems to treat *Cryptosporidium*. Thus, there is a critical need for information regarding the transport and fate of pathogens during water infiltration into subsurface systems.

Highly porous limestone aquifers are the primary water supply for about 25% of the U.S. population, including several large municipalities such as Atlanta, Austin, Miami, Nashville, San Antonio, and Tampa. After discussion with the water utilities and regulators in some of these cities, we found that there was tremendous concern about microbial contamination from parasites such as *Cryptosporidium*. Their concern was from the lack of information needed to determine the potential for *Cryptosporidium* and other pathogens to travel through their limestone aquifers from septic fields, wastewater treatment plants, and agricultural feedlots to the wells and springs from which they derive their water supplies. Through our discussion, we determined that a contaminant transport model compatible with existing models for limestone systems is needed. To produce the model, extensive laboratory tests are needed to garner transport parameters, and field tests are needed to evaluate the performance of the model. A recent report by the National Research Council on the role of science and technology in countering terrorism reached similar conclusions (1). Section 8.15 of that report states,

> research should be undertaken on water sampling schemes to determine what types and population of data points are required for a spatiotemporal network and on intelligent decision processing to be able to reliably recognize the patterns of attack indicators vs. natural hazards. Such research would require that priority attention be given to the development of simulation models that would both analyze and simulate events and serve to train operators in systematic recovery, emergency response, and evacuation.

REVIEW OF PARASITE FATE AND TRANSPORT IN KARSTIC AQUIFERS

William J. Blanford
Louisiana State University
Baton Rouge, Louisiana

Every year in the United States cases of waterborne illness are generally characterized by gastrointestinal problems (vomiting, diarrhea, etc.). However, these same symptoms can be more serious and even fatal in certain groups, such as the young, elderly, and those with compromised immune systems. Furthermore, *viral pathogens* found in groundwater are linked to chronic diseases such as adult onset diabetes and myocarditis. Recognizing that preventing contamination of water sources is the first step in the multiple barrier approach to drinking water protection, the Interim Enhanced Surface Water Treatment Rule (IESWTR) and the Disinfectants/Disinfection Byproducts Rule (DBPR) were released in 1999. The two rules will provide additional protection of public water supplies and address microbiological contamination. The rules address the risks of the trade-offs between disinfection necessary for *microbial inactivation* and disinfection byproducts. The requirements of 40 CFR 141.72(b) are consistent 99.99% removal and/or inactivation of viruses and 99% removal of *Cryptosporidium oocysts*. The code gives public water suppliers the option to demonstrate compliance through pilot plant studies or other means that combine filtration techniques with *disinfection* as in EPA 1999 Microbial and Disinfection Byproducts Rules Simultaneous Compliance as in Guidance Manual.

Presently, only surface water systems and systems using groundwater under the direct influence of surface water are required to disinfect their water supplies. Although historically considered free of microbial contamination, most recent research has shown that aquifers can be readily contaminated by pathogens. To lessen the requirement for disinfection and to protect water resources, water suppliers have sought to use natural systems to treat *Cryptosporidium*. Thus, there is a critical need for information regarding the transport and fate of pathogens during water infiltration into subsurface systems.

Highly porous limestone aquifers are the primary water supply for about 25% of the U.S. population, including several large municipalities such as Atlanta, Austin, Miami, Nashville, San Antonio, and Tampa. After discussion with the water utilities and regulators in some of these cities, we found that there was tremendous concern about microbial contamination from parasites such as *Cryptosporidium*. Their concern was from the lack of information needed to determine the potential for *Cryptosporidium* and other pathogens to travel through their limestone aquifers from septic fields, wastewater treatment plants, and agricultural feedlots to the wells and springs from which they derive their water supplies. Through our discussion, we determined that a contaminant transport model compatible with existing models for limestone systems is needed. To produce the model, extensive laboratory tests are needed to garner transport parameters, and field tests are needed to evaluate the performance of the model. A recent report by the National Research Council on the role of science and technology in countering terrorism reached similar conclusions (1). Section 8.15 of that report states,

> research should be undertaken on water sampling schemes to determine what types and population of data points are required for a spatiotemporal network and on intelligent decision processing to be able to reliably recognize the patterns of attack indicators vs. natural hazards. Such research would require that priority attention be given to the development of simulation models that would both analyze and simulate events and serve to train operators in systematic recovery, emergency response, and evacuation.

KARSTIC LIMESTONE AQUIFERS

Karstic landscapes cover approximately 15% of the earth's land surface and are characterized by caves, sinkholes, and springs. Karstic aquifer systems occur throughout the United States and are particularly significant for groundwater resources in Texas and Florida, the second and fourth most populous states. There is significant interchange between surface and subsurface features, fluids, and waterborne materials. In many unconfined karstic aquifers, groundwater and surface water behave as a single body of water (2). The Edwards and Trinity aquifers are the only significant water sources for semiarid south central Texas, including San Antonio, the eighth largest city in the United States. The Edwards aquifer is one of the most permeable and productive carbonate aquifers in the world. It provides a public water supply to more than 2 million people, water for agriculture and industry, and discharges into major springs. These springs support recreation and business, provide flow to downstream users, and are a habitat for several threatened and endangered species. Its high porosity and permeability result in part from the development of secondary porosity and fracturing. The Trinity aquifer, by contrast, is much less permeable or productive than the Edwards. Its lithologies contain significantly more clay minerals and other siliciclastics, as well as minor evaporites. Nevertheless, it supplies water to scattered communities, ranches, and individual wells north of the Edwards in an area of rapid urbanization and growth.

Karstic limestone aquifers are characterized by three primary types of porosity: intergranular matrix porosity, fracture porosity, and the development of cavern conduits (3). A conduit is defined as any interconnected pathway for water of sufficient size to permit turbulent flow. Resistance to flow in conduits is much less than in the adjacent matrix, and, as a consequence, most regional flow is concentrated in conduits. Similarly, most local matrix flow is toward the nearest conduit. Thus, hydrodynamic gradients can vary significantly between conduit recharge and regional flow.

Contaminant dispersion would take place by a variety of methods using this model. Contaminants within conduits travel much more rapidly than those within the matrix, which follow Darcy's law and the advection–dispersion equation. However, exchange of contaminants between the two can occur under a variety of naturally occurring cycles, such as floods versus droughts. Thus the system should be modeled as a network of conduits embedded in a porous matrix (4). The complex depositional environments that produce carbonate rocks, their pronounced digenetic susceptibilities, and the fabric controls related to tectonic alteration of large carbonate units result in groundwater systems that are highly heterogeneous and poorly understood. Regional bedrock karstic limestone aquifers cannot be understood without critical information on the geologic boundary conditions.

CRYPTOSPORIDIUM

Cryptosporidiosis has been recognized as a human disease since 1976 (5). The first diagnosed waterborne outbreak of cryptosporidiosis in the world occurred in Braun Station, Texas, in 1984 (6). The first report of the disease associated with a contaminated municipal water supply was in 1987 in Carrollton, Georgia, where 13,000 became ill (7). This water system met all state and federal drinking water standards. In Milwaukee, Wisconsin, in 1993, municipal drinking water infected 400,000 people with *Cryptosporidium* and resulted in approximately 50 deaths (8,9). Subsequently, the Texas Department of Health reported a more recent water outbreak in Brushy Creek, Texas, in 1998. Overall, there have been 12 documented waterborne outbreaks of cryptosporidiosis in North America between 1985 and 1997; in two of these (Milwaukee and Las Vegas), mortality rates in the immunocompromised ranged from 52% to 68% (10).

Cryptosporidium parvum is a protozoan tissue parasite and is an agent of enterocolitis in mammals (11). *Cryptosporidium* has a complicated and extensive life cycle. The environmental stage is an oocyst, which is a metabolically dormant protective phase (12). The oocysts are nearly spherical and have a diameter of 4.5 to 5.5 μm. Their surfaces are slightly negative to neutrally charged in natural waters (13,14), and their density is close to that of water at 1.025 to 1.070 (14). The oocyst encases four sporozoites, each capable of infecting a host cell. Ingestion of as few as 10 oocysts can lead to infection; the feces of infected mammals may contain as many as 10^7 oocysts/mL (15).

Cryptosporidium can enter the environment via human and animal wastes. It has been found in marine water and bathing beaches in the vicinity of a nearby sewage outfall (16). Cryptosporidiosis has been reported in many domestic animals, especially cattle. An infected calf can excrete 10^{10} oocyts per day. In a study of farm drains, Kemp et al. (17) found 0.06 to 19.4 oocysts per liter, which can result in contamination of surface waters. Typical concentrations of *Cryptosporidium* in untreated domestic wastewaters are between 1 and 10 oocysts/mL (18) and in polluted streams, are between 0.1 to 100 oocysts/mL (19). *C. parvum* forms a hardy oocyst that can survive chlorine disinfection as commonly practiced in conventional water treatment (20,21). Furthermore, Chauret et al. (22) concluded oocysts exposed to environmental conditions are as resistant to inactivation by chlorination as freshly shed oocysts. *C. parvum* oocysts have also survived for weeks in surface waters (23).

Mawdsley et al. (24) quantitatively monitored the movement of *Cryptosporidium parvum* oocysts from livestock waste through low-permeability silt clay loam soil in laboratory column and box studies. In their box studies, livestock waste was applied to a portion of the surface of 20 cm deep by 80 cm long blocks of undisturbed low-permeability silt clay loam soil. The soil was contained within a tilted box and water was applied for 70 days. Oocysts were found in leachate in numbers ranging from 10^4 to 10^6 oocysts. Postsoil core analysis found decreasing numbers of oocyst with distance from inoculation.

Brush et al. (25) and Harter et al. (11) performed laboratory column studies of *Cryptosporidium parvum* oocyst transport and fate. Brush et al. examined oocyst transport through columns containing glass beads, well-sorted sand, and shale aggregates. In these short-duration studies, approximately 50% of the oocysts were retained in the sand and roughly 40% in the glass beads and shale. Despite the losses within the column, oocysts were eluted during the same timeframe as the conservative tracer chloride in the sand and glass beads. The velocity of *C.*

parvum oocyst through the shale aggregate was slightly faster than chloride ions. Brush et al. (13) suggest that this was due to size exclusion and not charge exclusion because of the nearly neutral surfaces of the oocysts. Brush et al. modeled the movement of oocyst with a one-dimensional convective–dispersion transport equation. Sorption was described as instantaneous equilibrium sorption where the relationship between sorbed and aqueous concentrations was linear. All loss processes, including decay, sieving, impingement, and settling, were modeled as a single (i.e., lumped) first-order rate process. The results of their modeling efforts indicated that oocysts experienced less shear and turbulence than dissolved chloride ions and that the oocysts did not adhere to the porous media.

Harter et al. (11) investigated the influence of pore-water velocity and sand grain size on the transport and fate of *Cryptosporidium parvum* oocysts. They used 10 cm long columns, groundwater of medium ionic strength (100 to 150 mg/L TDS), and bovine *Cryptosporidium parvum* oocysts. Their results indicated no trend between sand size and oocyst recovery in the three studies. They found that oocysts arrived before chloride and the elution of oocysts continued after chloride for all column studies. In a limited number of extended studies, tailing of oocyst concentration was observed until the end of the experiment (250+ pore volumes). The early breakthrough, as with Brush et al., was attributed to size exclusion. The tailing in oocyst elution was attributed to reversible deposition.

Harter et al. (11) used a more complex one-dimensional transport model to simulate their data. Filtration was modeled as a first-order irreversible process calculated from the physical properties of the soil (grain size, porosity, and bulk density), water (density, viscosity, pore velocity), and microbial colloid (density, size, diffusion coefficient). Sorption was modeled as a first-order, rate-limited reversible process. Half of the loss was attributed to irreversible filtration, but rate-limited reversible sorption could account for the early breakthrough and partially account for the extended tailing. Harter et al. called for further experimental and theoretical research to measure and explain the long-term elution behavior of *Cryptosporidium parvum* oocysts.

GIARDIA

Giardia lamblia is the cause of the most frequently identified intestinal disease in the United States (26). Humans become infected by ingesting giardia cysts, which are the environmentally resistant stage of giardia (27). Giardia cysts can survive for prolonged periods. For example, Bingham et al. (28) documented cysts surviving in distilled water for 77 days at 8 °C. In another study, cysts of *Giardia muris* (a species that infects mice but is often used as analogue for *Giardia lamblia*), survived 28 and 56 days in lake water at depths of 4.5 meter (19 °C) and 9 m (6.6 °C), respectively. In cold river water (0–2 °C), cysts survived for 56 days (28). Typical concentrations of *Giardia* are between 1 and 100 cysts/mL in untreated domestic wastewater (18) and about 1 cyst/mL in polluted streams (19).

The *Giardia* cysts, which are 8–16 μm in diameter, are somewhat resistant to typical levels of wastewater treatment methods. During primary settling, only 0–53% of cysts are removed. Secondary treatment with clarification can remove 98.6–99.7% of cysts (28). Advanced tertiary treatment can further reduce the numbers of cysts by physical filtration and precipitation.

MICROSPORIDIUM

Microsporidia are unicellular protozoan parasites that infect a wide variety of animals, from insects and fish to every class of mammal, including humans. The vehicle for transmitting these organisms is its spores, which are shed from infected individuals (animal and human) via the urine, feces, respiratory sputum, and upon death and decay. Human infections are of concern in immunodeficient patients, especially those who are HIV+, and may infect a broad range of tissues. *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are the most common species of microsporidia isolated from patients with chronic diarrhea attributed to microsporidiosis (29,30). Exact routes of transmission for human microsporidial infection have not been confirmed, but considerable evidence supports fecal–oral, sexual, respiratory, and waterborne routes (29–31).

The potential for waterborne transmission of spores is the focus of our research. At least two published studies have detected the presence of *E. bieneusi* (32) or *E. bieneusi, E. intestinalis*, and *Vittaforma corneae* (another human pathogenic microsporidium) (33,34) in surface water using the polymerase chain reaction (PCR). Hutin et al. reported in a case-controlled risk factor analysis of HIV+ individuals in France that the greatest risk for intestinal microsporidiosis was use of a swimming pool in the prior 12 months.

At least one outbreak of microsporidiosis has been described and attributed to contaminated drinking water originating from a particular treatment plant. According to Cotte et al. (31), an outbreak of intestinal microsporidiosis in the summer of 1995 affected 200 people (all apparently HIV+), or about 1% of the HIV+ population in the study area. Additionally, 15% of the 361 patients from whom microsporidia were identified during the 3-year study had no known immunodeficiency condition. The clustering of residences of infected individuals in the town of Lyon, France, led the authors to suggest that a water treatment facility serving the area may have been a contributing factor to these cases. This plant employs flocculation, ozoflotation, and filtration but not chlorination in the treatment process and uses surface water as a water source.

A few studies have described the susceptibility of human-pathogenic microsporidial spores to drinking water treatment methods and environmental conditions. Laboratory studies by Kucerova-Posisilova et al. (35) indicate that *E. intestinales* spores retain infectivity for at least 2 weeks at temperatures up to 33 °C. However, information on the viability of spores concentrated from the environment has yet to be published to our knowledge. A very recent study by Wolk et al. (36) determined that a chlorine concentration of 2 mg/L with exposure for at least 16 minutes resulted in a 99.9% reduction in the viability of *E. intestinalis* spores. Microsporidia were detected in four recreational water samples from Arizona; one was confirmed as *E. intestinalis*. In addition to the three recreational water samples, three irrigation water samples from Mexico and two from Arizona were positive for microsporidia. One of the samples from Mexico was confirmed as *E. intestinalis. V. corneae* spores were identified from irrigation water from Costa Rica and from secondary sewage from Tucson, Arizona (37).

In summary, mounting evidence demonstrates that microsporidia are found in water, may originate from human and animal reservoirs, and need to be considered as potential waterborne pathogens. As such, more information is needed on the incidence and survival of spores in the environment and through the treatment process.

BACTERIOPHAGE

Several bacteriophage transport studies have been conducted under well-characterized conditions [see recent review by Schijven and Hassanizadeh (38)]. The bacteriophages PRD-1 and MS-2 are often employed as surrogates for viruses of concern in human health (39,40) because of the hazards and costs associated with human viruses.

CALCULATING FLOW IN KARSTIC LIMESTONE AQUIFERS

In karstic limestone aquifers, groundwater often flows through highly permeable flow paths formed by dissolution along faults, fractures, bedding plane partings, or stratigraphic features. Compared with diffuse flow through granular aquifers, groundwater velocities in karstic systems can be very high, often in the range of miles per day. Consequently, karstic aquifers require a much larger wellhead protection area than common for wells in sand and gravel.

Multiple options exist for modeling flow and transport in karstic aquifers. For simple applications requiring only global water balances in steady-state conditions, existing modeling tools such as MODFLOW have served adequately. For modeling responses to storms or contaminant movement, more advanced models involving explicit flow features (40), irregular grids, and/or multiple interacting flow systems (41) are needed. Software tools necessary for explicit modeling of karst features have recently appeared (42).

TRANSPORT MODELS

Models for microbe transport and of colloid transport in general are analogous to solute transport models nonideal sorption terms account for rate limitations in the attachment/detachment processes. The relevant physical processes include advection, dispersion, attachment/detachment, physical filtration, inactivation, and advection facilitated by sorption on other types of colloids (38). Early models of microbe transport in saturated porous media used the equilibrium sorption assumption and an empirical distribution coefficient to model microbe attachment/release (43,44). These equilibrium sorption models performed poorly in case studies (45) and fail to reproduce the results of experiments that show unretarded breakthrough and slow (nonequilibrium) release (50). Modern models of microbe transport and of colloid transport in general use kinetic models for attachment/release. Single-site kinetic models are often used (46–49). Bales et al. (50) use a two-site model with one set of sites in equilibrium and the other kinetically controlled. Bhattacharjee et al. (55) and Schivjen et al. (56) use two-site models wherein attachment to both types of sites is kinetically controlled but with different rate constants. Schivjen et al. (56) analyze several laboratory experiments and clearly demonstrate that a two-site kinetic model is necessary to reproduce the measured breakthrough curves.

Most previous studies use the first-order rate law. Second-order rate laws have been used to model sorption of inorganic colloids (49) and microbes (55). In either case, attachment rates may be empirical or determined from mechanistic models of colloid filtration (46,49). Combinations of empirical rates and mechanistic rate models have also been used (48). When mechanistic models are used to calculate the attachment rate, models for colloid filtration in packed-bed reactors (50) are the usual choice.

Transport facilitated by other colloids is another process to be considered. Schivjen and Hassanizadeh (38) note that the removal rate for viruses declines with increasing travel distance, and that this nonlinear removal may be due to partial attachment to other colloidal particles. Colloid-facilitated transport is of particular concern in karst systems that often have large amounts of suspended sediments whose attributes are favorable for facilitating transport (51,52). Two studies (48) have addressed the effect of random spatial variability of hydraulic conductivity on microbe transport. These studies clearly provide important insights into the effect of spatial variability on microbe transport but are better suited to granular aquifers, where spatial variability can be more readily represented as a simple random space function.

PARTICULATE REMOVAL

Rasheed Ahmad
Khafra Engineering Consultants
Atlanta, Georgia

Coagulation is used in water treatment plants as a pretreatment step to remove particulate matter (such as clay and silt particles, bacteria, viruses, and protozoan cysts) and dissolved materials, especially natural organic material (NOM). Although the removal of particulate matter continues to be an important reason for using coagulation, recent concern about carcinogenic byproducts has emphasized that a coagulation process must also optimize the removal of NOM to reduce the formation of disinfection byproducts. Coagulation is a process for enhancing the tendency of particulate matter in aqueous suspension to attach to one another and/or to attach to collector surfaces. Coagulation promotes destabilization of surface charges on colloidal particles. Destabilization and aggregation of particulate matter and precipitation or adsorption of NOM in subsequent solid–liquid separation processes are the primary functions of a coagulation process. The coagulation process involves two steps: (1) the addition of chemical coagulants to destabilize particulate matter and react with NOM and (2) physical transport of collisions among particulate matter resulting in their aggregation or floc formation. In the water treatment literature, coagulation refers to all reactions and mechanisms that result in aggregation, and the physical transport step of producing interparticle aggregation is called flocculation. In water treatment plant operation, coagulation is achieved by rapid or flash mixing of coagulants followed by flocculation.

The other example of particle alteration and particle production process technology is chemical oxidation. The main application of this process is in iron and manganese removal. Iron and manganese are relatively soluble under reducing conditions, for example, in groundwater, stagnant surface water, and certain lakes. Dissolved iron and manganese are usually removed from water by oxidizing them under engineered conditions to their insoluble forms by adding an oxidant and removing the precipitated ferric hydroxide and manganese dioxide by sedimentation and filtration. The oxidants used most often for this are oxygen, chlorine, permanganate, chlorine dioxide, and ozone.

Sedimentation is a particle separation process (Fig. 1). In conventional water treatment systems, it follows flocculation and precedes filtration. Its purpose is to enhance the filtration process by removing particulate matter. Sedimentation requires that water flow through the basin at a slow enough velocity to permit the particulate matter to settle to the bottom of the basin before the water exits the basin. The equipment required for this process includes a rectangular, square, or circular settling basin. The basin includes provisions for inlet and outlet structures and a sludge collection system. In addition, sedimentation systems are optionally equipped with tube or plate settlers to improve performance. The settling velocity of the particles or particulate matter is governed by the particle size, shape, density, and water viscosity (which varies with temperature). The surface overflow rate is the primary design parameter for sizing sedimentation basins. This rate is defined as the rate of inflow (Q) divided by the tank surface or floor area (A). Units are typically rated in gallons per day per

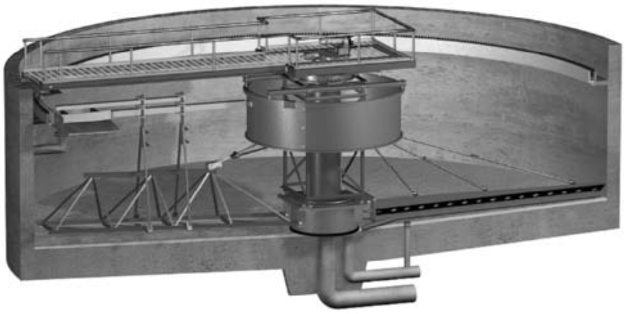

Figure 1. Circular sedimentation tank (*Source*: U.S. Filter).

square foot, gallons per minute per square foot, or cubic meters per hour per square meter. Design hydraulic overflow rates vary with the nature of the settling solids, water temperature, and hydraulic characteristics of the sedimentation basin. The settling efficiency for ideal conditions is independent of the depth and dependent on the tank plan or surface area. In reality, depth is important because it can affect flow stability if it is large and scouring if it is small.

In a conventional water treatment process train, filtration follows sedimentation. Particulate matter that is removed by this process includes microorganisms (bacteria, viruses, and protozoan cysts), clay and silt particles, colloidal and precipitated humic substances and other organic particulates from natural decay of vegetation, precipitates of aluminum or iron coagulation processes, calcium carbonate and magnesium hydroxide precipitates from lime softening, and iron and manganese precipitates. A number of different types of filters are used in water filtration, and they are described by various classification schemes. The most common filtration technologies used in water supply systems are rapid sand filtration, slow sand filtration, package plants, diatomaceous earth filtration (precoat filtration), membrane filters, and cartridge filters. High-rate granular filters or rapid sand filters are most widely used in conventional treatment and direct filtration (Fig. 2). Granular medium filtration is a water treatment process that uses a porous medium through which water passes to remove particulates or suspended solids. For granular medium filtration to be effective, source water must be pretreated. Chemical destabilization is an essential prerequisite for effective filtration. Chemicals used for particle destabilization are limited primarily to metal salts or cationic polymers as primary coagulants. Pretreatment may also include aeration or introducing an oxidant if water treatment aims to remove iron or manganese. Sometimes, a filter aid polymer is added in the influent to the filter to improve particle capture efficiency. Filtration by granular media consists of three principal mechanisms: (1) transport, (2) attachment, and (3) detachment. *Transport* mechanisms move a particle into and through a filter pore so that it comes very close to the surface of the filter medium or existing deposits where *attachment* mechanisms retain the suspended particle in contact with the medium's surface or with previously deposited solids. *Detachment* mechanisms result from the hydrodynamic forces of flow acting so that a certain portion of the previously attached particles, less strongly adhered to others, is detached from the filter medium or previous deposits and carried further, deep into or through the filter.

Flotation can be described as a particle separation process. It is a gravity separation process in which gas bubbles attach to solid particles to make the apparent density of the bubble–solid agglomerates less that of water, thereby allowing the agglomerate to float to the surface. The floated material (float) is removed from the surface, and clarified water is taken from the bottom of the flotation tank. Different methods of producing gas bubbles give rise to different types of flotation processes, which are electrolytic flotation, dispersed-air flotation, and dissolved air flotation (Fig. 3). Flotation is employed mainly for treating nutrient-rich reservoir waters that may contain heavy algal blooms and for low-turbidity, low-alkalinity waters.

In recent years, there has been considerable interest in using ultrafiltration (UF) or microfiltration (MF) membranes for particle separation in potable water treatment (Fig. 4). Similar to depth filtration, the performance of membrane filtration units is likely to be affected by the concentration and size of particles in raw water as well as the dissolved organic carbon

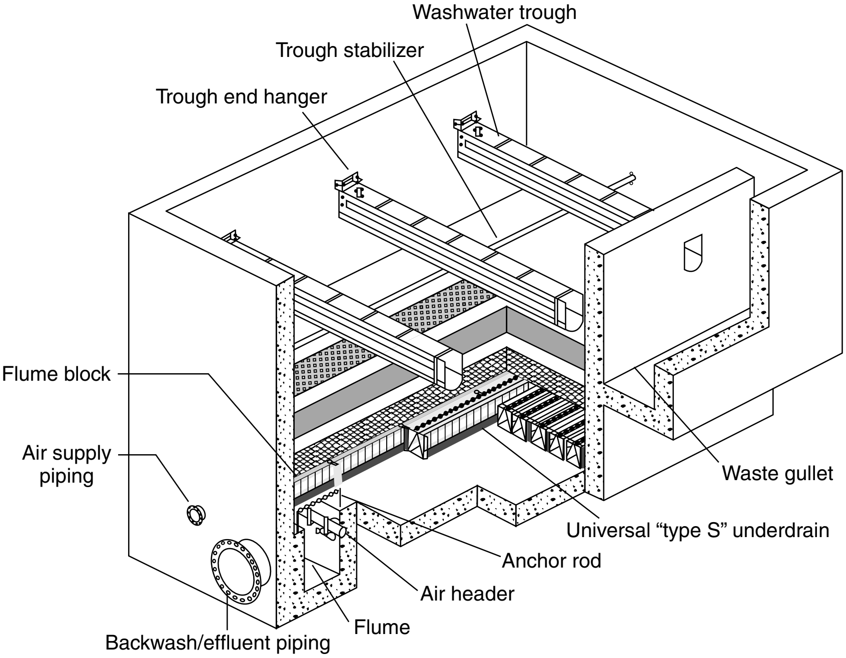

Figure 2. Rapid gravity filter box (*Source*: F.B. Leopold Co.).

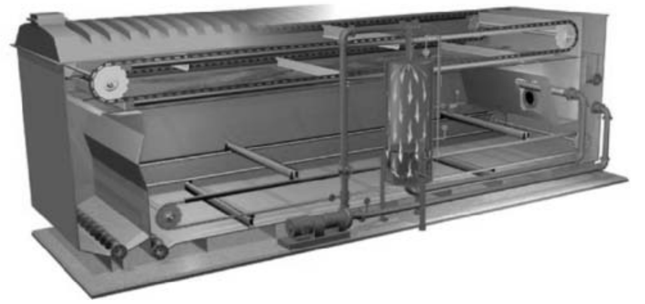

Figure 3. Dissolved air flotation (DAF) system (*Source*: U.S. Filter).

Figure 4. Membrane filtration system (*Source*: PALL).

(DOC). Particles of an effective size larger than the minimum pore size (or membrane cutoff) will be removed by the membrane. Permeate flux is closely related to the pressure drop across the membrane filter. Materials that accumulate on the membrane filter produce an additional layer of resistance to flow that is manifested as an increase in head loss or pressure drop across the membrane. A frequent backwash (every 15 min to 1 h) removes the cake formed on the membrane surface. In a conventional UF or MF process, the driving force to produce filtrate can work in two ways: Positive pressure moves fluid through the fibers; negative pressure moves fluid through fibers under vacuum pressure. The conditions under which membrane filtration processes might be preferable to granular medium filtration or conventional treatment are still largely unknown.

The selection of particulate removal technologies should be based on treatment objectives and control requirements. This process involves a number of basic data and other considerations, including effluent requirements, influent characteristics, existing system configuration, required investment, operation and maintenance (O&M), additional pretreatment and posttreatment processes, and waste management.

PHARMACEUTICALS IN WATER SYSTEMS

Kelly Pollack
Oladele Ogunseitan
University of California
Irvine, California

THE EMERGING PROBLEM OF PHARMACEUTICALS IN THE ENVIRONMENT

As the demographic pattern in most regions of the world changes in response to epidemiological transition, life expectancy is lengthened, and human reliance on medications to maintain the quality of life intensifies. It is now indisputable that widespread use of pharmaceutical products results in their release into the environment. This occurs primarily through the excretion of partially metabolized doses and the disposal of expired or unused medication (1–3). It is inevitable that that these fugitive releases lead to exposures of aquatic organisms and other natural ecosystem components. However, the driving force behind recent concerns is the potential for large-scale human exposures through natural drinking water recycling processes. Historically, most investigations of anthropogenic chemicals in the environment have focused on acutely toxic industrial chemicals from mining, energy, and agricultural industries. The environmental impacts of products emanating from the pharmaceutical industry have largely been excluded from scrutiny. The U. S. Geological Survey conducted the first national survey of pharmaceutical products in natural water systems in 2000. The results of that study confirmed prior suspicions about the widespread contamination of aquatic systems by these products (4).

The conclusions of several investigations of pharmaceuticals in the environment have now demonstrated an urgent need for rigorous ecological evaluation of potentially harmful prescription and over-the-counter products. These include hormones, antibiotics, analgesics, steroids, and their bioactive metabolites that are continuously introduced into the environment from the disposal of partially treated domestic wastewater. The fate of these compounds in the aquatic ecosystem depends in part on their chemical structure and physicochemical characteristics, including solubility in water and lipids, adsorption to soil particles, volatility, and potential biodegradability. These characteristics determine whether the chemicals will bioaccumulate through the foodweb, partition into sediments, mobilize through groundwater, or impact drinking water resources (5).

Information is sparse on the ecological effects of pharmaceutical products in the environment because the mode of action, dose response, and pharmacokinetic metabolism in humans are not fully understood for many medications. Therefore, it is difficult to predict with reasonable certainty, how specific pharmaceutical products will affect the myriad species that may become exposed following the release of pharmaceutical chemicals into the environment. However, there is a growing body of evidence that subtle, chronic effects from low-level exposures are occurring. These effects are occurring, in particular, from hormonal products and from chemicals that are known to induce the expression of phylogenetically conserved genes and the production of key metabolic enzymes (3).

For nontarget (e.g., aquatic) organisms whose chemical receptors are similar to those found in humans, it is possible to predict unintentional physiological effects of exposure to pharmaceutical products such as growth and reproductive hormones. In fact, estrogen receptors have been designed to monitor the occurrence and distribution of estrogenic pharmaceutical compounds in the environment. However, the sensitivity of such monitoring systems means that they can recognize chemicals from sources other than the pharmaceutical industry (6). Although understanding chemical interactions with biological receptors has been very useful for predictive modeling of the ecosystemic effects of pharmaceutical products, there is only rudimentary knowledge of potential synergistic and additive effects due to human or wildlife exposure to multiple pharmaceutical products found in many contaminated systems. In addition, unlike persistent organic pollutants from other industrial sectors, pharmaceutical contaminants do not necessarily have to be persistent to exert major physiological effects. This is due in part to the trained potency of their actions and the fact that concentrations in receiving waters are constantly replenished through the disposal of contaminated wastewater effluents (7). To initiate a thorough understanding of which pharmaceutical products are most likely to pollute water systems and which products are likely to provoke disturbances to ecosystemic and public health, either alone or in interactions with other chemicals, it is important to evaluate the societal distribution of pharmaceuticals with respect to prescription volume, doses, and disposal.

DISTRIBUTION OF PHARMACEUTICALS IN THE UNITED STATES

The pharmaceutical industry is a major contributor to the global economy; annual commercial transactions in prescription drugs in the United States approach $300 billion. In the year 2001, approximately 3.1 billion pharmaceutical prescriptions were filled for several thousand different medicinal chemicals in the United States alone (8). The top-ranked pharmaceuticals products prescribed in 2002 are presented in Table 1. The identity of popular prescriptions and their associated medical functions provides a reasonable summary of the societal burden of diseases. Attention to the quantity of drug doses multiplied by the number of each prescription is also a reasonable estimate of the quantity of potent drugs that enters the domestic sector annually. Very little attention has been paid to the question of what happens to the drugs after they leave the human body. In general, many drugs are prescribed at doses that can be supported by human metabolic capacity. Quite frequently, administered drugs and their partial metabolites leave the human body through excretion in urine and feces soon after ingestion. The period of excretion for some drugs may last for days (2,3). The list of products in Table 1 does not include those used in the agricultural industry, although they are important contributors to the distribution of pharmaceuticals into the environment, particularly antibiotics (9). Veterinary pharmaceutical products are routinely dispersed into the environment through the same pathways as human medications, but in many cases, there is no benefit of sewage treatment to reduce the concentration of influent pharmaceuticals because animal wastes can contaminate surface waters directly (2).

The top 20 pharmaceutical products found in streams during a reconnaissance project conducted by the U.S. Geological Survey between 1999 and 2000 are shown in Table 2. The data are limited by the narrow scope of chemicals investigated, compared to the main categories of prescriptions drugs presented in Table 1. Caffeine, the fourth ranked most commonly found organic chemical in surface waters, is the first in the list to be associated with pharmaceutical products, although its main source is dietary. Caffeine is an inducer of cytochrome P450 enzymatic activity in humans and in wildlife. Its presence in water systems is due to its resistance to biodegradation in many wastewater treatment processes. Therefore, caffeine has been used as a reliable tracer of wastewater effluent discharge, and it has been proposed as a monitoring sentinel for the distribution of pharmaceutical products in the environment (10,11).

FATE OF PHARMACEUTICALS IN SEWAGE TREATMENT FACILITIES

The capacity of human physiological systems to metabolize pharmaceutical products varies greatly from complete breakdown of a compound into various metabolites to excretion by the consumer in an essentially unaltered free form. The degree of metabolism is a function of chemical characteristics; the genetic, physiological, and dietary potential of the consumer; and the timing of the dose (2). Some pharmaceutical degradation products can be more bioactive than the parent compound, and the nontoxic conjugates can later be converted by microbial action to the original bioactive parent compound (4). It is also possible for microbial action to convert certain pharmaceutical products into chemicals that could resemble pollutants from other industries, thereby confusing monitoring programs and enforcement regulations. For example, (Fig. 1) shows the hypothetical pathway for the biodegradation of clofibrate, a hypolipidemic medicinal product commonly found in contaminated water systems when it enjoyed a

Table 1. Characteristics of Top Prescription Pharmaceutical Products in the United States[a]

Drug Category, 2001 Rank Order	Total Prescriptions for 2000, Millions	Leading Product	Manufacturer	Function	Prescriptions per Year (1999) (Millions)	Quantity per Dose, mg	Human Metabolite, % Excreted	Conc. in Surface Water, μg/L[b]
Codeine and combinations	124.2	Hydrocodone	Watson Laboratories	Pain reliever; antitussive and opioid analgesic	30.4	5–7.5	Codeine and morphine up to 10 μg/mL in urine	0.1–1.0 (codeine)

high prescription rate in the 1980s. Human metabolism of clofibrate produces clofibric acid, which is excreted in feces and disposed of into the domestic sewer system. The structure of clofibric acid suggests that heterotrophic bacteria can cleave the side chain to produce chlorobenzoate and/or chlorobenzene, which are chemicals commonly associated with the petrochemical solvent industry.

Pharmaceutical products, their synthetic precursors, and biotransformation products are continuously released into the environment through consumer excretion and through the disposal of unused or expired medications. Although sewage treatment facilities are the most obvious sinks for pharmaceutical products, municipal landfills are also important sinks for solid products that are disposed of with domestic solid waste (3). In addition, episodic leakage of sewer lines and overflow of veterinary solid waste contaminated with pharmaceuticals may lead to the release of completely untreated medicines into the environment (5). In the United States, about a million homes do not have sewage treatment systems but instead rely on direct discharge of raw sewage into streams by “straight-piping” (3). Some Canadian cities reportedly discharge 3.25 billion liters per day of essentially untreated sewage into surface waters and the ocean (3).

Sewage treatment generally processes human waste in three steps: primary (clarifying), secondary (aerobic biodegradation of organic matter), and tertiary (finishing step to reduce the concentrations of specific pollutants such as nitrates and phosphorus to acceptable standards). The liquid effluent is generally discharged by release into surface freshwater systems or the ocean. Waste from biomass and other precipitated solids are treated as sludge, which is used in many different ways. Most domestic sewage treatment facilities are not designed to process specialty chemicals such as pharmaceutical products. It is also possible that certain pharmaceutical products may be sufficiently toxic to inhibit the action of activated sludge microorganisms that are responsible for degrading organic materials in sewage. If undegraded pharmaceutical products in sewage are precipitated, they may end up in the sludge material. This is sometimes used to fertilize soils, raising the complex issues of soil contamination, groundwater infiltration, and human exposure through agricultural products. In addition, many municipalities do not process sewage completely through the tertiary stage, and the effluent is used for landscape irrigation, again raising the possibility of human and ecosystemic exposures. Finally, the process of chlorinating completely treated sewage and recycling the water for drinking is increasingly attractive as many regions experience water shortages. Chlorination of pharmaceutical products may produce highly toxic chemicals. For example, there is some evidence that the chlorination of caffeine will result in the production of chlorocaffeine, a potential mutagen (10,11).

Many pharmaceutical compounds survive biodegradation in sewage treatment plants. Some products are as persistent as more widely studied organochlorine pollutants, but only few large-scale studies have been completed. The removal efficiencies of pharmaceuticals in

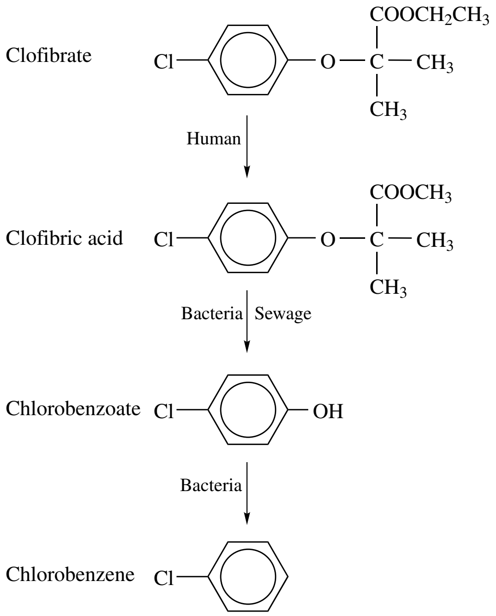

Figure 1. The production of chemical pollutants usually attributed to other industries may result from human and microbial metabolism of pharmaceutical products. The example shows the hypothetical degradation of clofibrate to chlorobenzene.

Table 2. Top 20 Organic Contaminants (Including Pharmaceuticals) Found in Streams in 39 States from 1999–2000 in the United States[a]

Rank	Chemical Compound	Source
1	Coprostanol	Fecal steroid/Hormone
2	Cholesterol	Human steroid
3	*N*-*N*-diethyltoluamide	Insect repellent
4	Caffeine	Dietary stimulant, pharmaceutical additive
5	Tri (2-chloroethyl) phosphate	Fire retardant
6	Triclosan	Antimicrobial disinfectant
7	4-Nonylphenol	Nonionic detergent metabolite
8	4-Nonylphenol monoethoxylate	Nonionic detergent metabolite
9	Ethanol, 2-butoxy-phosphate	Plasticizer
10	4-Octylphenol monoethoxylate	Nonionic detergent metabolite
11	Bisphenol A	Plasticizer
12	Cotinine	Tobacco cigarettes (nicotine metabolite)
13	4-Nonylphenol diethoxylate	Nonionic detergent metabolite
14	5-Methyl-1H-benzotriazole	Anticorrosive agent
15	Fluoranthene	Polyaromatic hydrocarbon oils
16	1,7-Dimethylxanthine	Caffeine metabolite
17	Pyrene	Polyaromatic hydrocarbon oils
18	Trimethoprim	Antibiotic
19	1,4-Dichlorobenzene	Deodorizer
20	Diazinon	Insecticide

[a] Reference 4.

treatment plants are still largely unknown (4). However, a study in Germany demonstrated that the removal efficiencies of pharmaceuticals by sewage treatment might be as low as 60% (2). There are many possible reasons for the low efficiency. Most pharmaceutical products are designed for metabolism at the human body temperature of 37 °C, which is not usual in sewage treatment facilities or anywhere else in nature. The identification of metabolic products is difficult because different metabolites can result under different environmental conditions and standard reference compounds are difficult to synthesize (2). The ability of treatment facilities to degrade pharmaceuticals can also change on the basis of operational state and seasons. Wet weather runoff and overflows from plant failure or overcapacity can also lead to direct release. Finally, influent concentrations of most pharmaceutical products may be so low that the microbial enzymes that degrade them are either not induced, or other more abundant substrates compete for their actions (2).

In the most comprehensive reconnaissance project that has been conducted to date, the U.S. Geological Survey investigated the occurrence of medicines, hormones, and other organic wastewater contaminants in a network of 139 streams across 39 states (4). Whereas previous research has shown that antibiotics, prescription drugs, and nonprescription drugs can be present in streams, this was the first study to examine their occurrence in a wide variety of hydrogeologic, climatic, and land-use settings across the United States. Although the data covered only a limited number of pharmaceutical compounds, it is reasonable to assume that many other compounds survive wastewater treatment and biodegradation and are ultimately released into water systems.

DETECTION OF PHARMACEUTICALS IN WATER SYSTEMS THAT RECEIVE EFFLUENT

There is a paucity of data on the distribution and fate of pharmaceuticals in natural water systems because, until recently, there have been few analytical methods that are sufficiently sensitive to detect these compounds at the expected low concentrations (4). In addition to sensitivity, analytic methods specifically developed for pharmaceutical products must also be able to discriminate among anthropogenic and natural constituents. For example, the use of artificial reproductive hormones as birth control pills and to control osteoporosis in postmenopausal women is widespread and has probably contributed significantly to the environmental distribution of these human hormones. However, it is sometimes difficult to discriminate between the artificial variety from the pharmaceutical industry and natural hormones excreted by humans, especially after partial metabolism by microbial action (2). The pending creation of mass spectral libraries for environmental pharmaceutical products and their degradation products will facilitate the development and reliability of methods in this direction. Ecotoxicological assessment of pharmaceutical products in the environment also requires developing sentinel and monitoring species that are expected to concentrate certain chemical moieties reliably or to respond to their effects at the physiological level (2).

In the USGS study, five analytical methods were used to measure concentrations of 95 organic wastewater contaminants (of which pharmaceuticals were a major part) in water samples. The methods used for measuring contaminants in the water included solid-phase extraction (SPE) with liquid chromatography/mass spectrometry positive-ion electrospray [LC/MS-ESI (+)] analysis and whole-water continuous liquid–liquid extraction (CLLE) with capillary gas chromatography/mass spectrometry (GC/MS) analysis (5). Although sampling locations were biased toward locations that were downstream of urban centers and livestock production, organic wastewater contaminants were still present in 80% of the streams that were sampled. There was a median of 7 and as many as 38 contaminants found in the water samples. Nonprescription drugs were found at the greatest frequency. Antibiotics, other prescription drugs, and reproductive hormones were found at relatively similar frequencies. It was hypothesized that the greater frequency of detection for nonprescription drugs might have been due in part to suspected greater annual use compared to other compounds. Measured concentrations rarely exceeded drinking-water guidelines, drinking-water health advisories, or aquatic-life criteria. However, most of the 95 contaminants do not have guidelines or established safe-level concentrations because not much is known about the ecotoxicological effects of the contaminants investigated (5).

ECOLOGICAL EFFECTS OF PHARMACEUTICALS IN WATER SYSTEMS

Acute toxicity is one of the many possible ecotoxicological end points of the exposure of nontarget species to pharmaceutical products synthesized strictly for human consumption. The low levels of pharmaceuticals found in polluted waters that contain many different species is not a reason for complacency in the expectation of toxicity (2). The low concentrations may not always pose acute risk, but the cumulative risks of prolonged exposure to low levels of chemicals is known to represent considerable hazard in animal studies and human epidemiology. Laboratory studies that do not simulate simultaneous exposures to multiple pharmaceutical products are likely to underestimate their ecotoxicological impacts. In most cases, there is limited information on which receptors in nontarget organisms are sensitive to chemical exposure. For these organisms, the most important threats are subtle behavioral modifications or genetic alterations that can lead to profound long-term changes in ecosystemic structure and function. Many such subtle effects have been demonstrated in wildlife as a result of chemical exposures. These include reversal of attraction, boldness, contact avoidance, feeding and mating disturbances, and confused directional sensing (2).

The environmental distribution of antidepressants and chemical regulators of obsessive–compulsive behavior can have subtle effects on nontarget organisms at chronic low doses. Serotonin reuptake inhibitors are a major component of widely prescribed antidepressants, including Prozac, Zoloft, Luvox, and Paxil. In addition to playing an important role in mammalian neurotransmission, serotonin is involved in a wide array of physiological regulatory functions in many species. In bivalves, serotonin regulates reproductive functions, including spawning, oocyte maturation, and parturition. At molar concentrations of 10^{-4} to 10^{-3}, serotonin induces spawning. Serotonin stimulates the release of neurohormones in crustaceans. Prozac and Luvox induce spawning and spawning behavior in zebra mussels at very low concentrations. In lobsters, serotonin causes behavioral reversal by stimulating subordinates to engage in fighting against dominants by reducing their propensity to retreat (2).

Kolpin and co-workers (4) detected compounds in water systems known or suspected to have weak hormonal activity and the potential to disrupt normal endocrine function. These compounds were detected in practically all streams investigated during the study. The expected low levels of exposure (<0.001 μg/l) to specific hormonally active compounds can adversely affect the reproduction of aquatic species. Other potential ecological problems of pharmaceutical exposure include increases in the incidence of cancers and the proliferation of antibiotic-resistant bacteria.

In addition to possible ecotoxicological effects, the prospects of human health effects from ingesting subtherapeutic doses of multiple pharmaceuticals from every intake of drinking water or through inhalation of volatilized products from every bath raises substantial concern. For many pharmaceutical products, the potential effects on humans and aquatic ecosystems are not clearly understood. Many drugs currently detected in aquatic waters already have known effects on nontarget organisms. Synthetic oral contraceptives (17α-ethynylestradiol) generally occur at concentrations lower than 7 μg/liter in effluents from publicly owned waste treatment facilities. In combination with steroidal estrogens 17β-estradiol and estrone, exposures to 17α-ethynylestradiol, it is believed, causes feminization in male fish, as observed in sewage treatment lagoons in the mid-1980s (2).

The consolidation and proliferation of resistance to multiple antibiotics in pathogenic microorganisms is an increasing threat to human reliance on antibiotics for treating dangerous infectious diseases. Acquired antibiotic resistance may remain stable indefinitely, even after the sources of exposures are removed. This means that the threats posed by microbial antibiotic resistance can only grow in the future, even if strict controls are placed now on the environmental release of antibiotics. For example, bacterial isolates from wild geese that have never been treated with antibiotics were resistant to ampicillin, tetracycline, penicillin, and erythromycin (2). Sufficiently high concentrations of multiple antibiotics can also have ecotoxicological effects on microbial communities that sustain global biogeochemical cycles and many local ecosystem functions, including the detection of indicators of fecal contamination in water systems.

REGULATORY STRATEGIES FOR CONTROLLING PHARMACEUTICAL PRODUCTS IN WATER SYSTEMS

Pharmaceutical products target more than 500 distinct biochemical receptors in the human body. Many of these receptors are also found in aquatic organisms (2). However, current guidelines for approving the effectiveness and metabolic fate of pharmaceutical products do not necessarily include testing across phylogenetic branches or documenting potential bioaccumulation and biodegradation. Even among humans, unrecognized genetic polymorphisms may make certain individuals much more sensitive to the effects of certain drugs, to the extent that a "zero tolerance" guiding principle for pharmaceuticals in domestic water supplies does not appear unreasonable. However, such broad regulatory goals are deemed too expensive to be implemented effectively.

Although the risks posed by inadvertent exposures to pharmaceutical products are not specifically controversial, only a limited number of federal agencies are responsible for managing the release of pharmaceuticals into the environment. In Europe, the Organization for Economic Cooperation and Development (OECD), an intergovernmental organization that has representatives in 29 countries, regularly publishes "Test Guidelines" for assessing the hazards of chemicals, including pharmaceuticals, in various environmental contexts (2). The problems of pharmaceutical products in the environment were first recognized widely in Europe, and the leading edges of regulatory issues appear to be evolving similarly from Europe. The European Union (EU) first expressed concern for the release of veterinary pharmaceuticals and their metabolites into the environment in the early 1980s because these products, it was perceived, have a much more direct route of introduction to the environment than medications prescribed for humans. The EU established two assessment levels to determine if a veterinary drug is dangerous to the environment. The first level considers the potential for release; the second level evaluates fate in various environmental compartments and investigates effects on specific biota that are likely to be exposed. All new applications for veterinary pharmaceuticals must include an environmental impact report based on the two levels of assessments. Regulatory guidelines for human pharmaceuticals are pending ratification by the EU (2).

In the United States, the Food and Drug Administration (FDA) and the U.S. Environmental Protection Agency (EPA) have separate roles regarding the distribution and release of pharmaceutical products in the environment. The FDA is responsible for assessing the risk to the environment caused by the manufacture, use, and disposal of human and animal drugs (5,12). FDA approval for new medications requires the submission of Environmental Assessment (EA) reports under the National Environmental Policy Act of 1969. As with the European Commission, the concern for new drugs rests primarily on acute and chronic effects, as measured by traditional toxicity tests (2). Much less concern has been given for more subtle behavioral effects. The FDA uses a tiered approach, similar to that of the EU, to determine if regulatory action is required. Generally, an Environmental Assessment report is required if the expected environmental concentration of the active ingredient of the drug in the aquatic environment exceeds 1 ppb (5,12). More recently, published literature and various conferences have indicated that in addition to the EA reports, pharmaceutical chemicals might have long-term effects on various wildlife species, but firm regulation will require additional research to evaluate these effects (12).

One of the top five goals of the EPA's Strategic Plan 2000 is identifying emerging risks of previously unknown, unrecognized, unanticipated, or unsuspected chemical pollutants in the environment (2). The EPA regulates emissions and effluent discharges from pharmaceutical manufacturing facilities, which are subjected to various restrictions or schedules of compliance regarding processed or raw effluent discharges (5,6). Despite considerable progress in recognizing and regulating risks posed by pharmaceuticals in water systems, important shortcomings remain in the current approaches used to determine ecological risk. Additive, synergistic, or antagonistic impacts of similar drugs or different classes of drugs that affect the same receptors are not currently being evaluated or considered part of regulatory principles. Additionally, the FDA's expected environmental concentration limit of 1 ppb for any given drug could easily be exceeded when the cumulative concentrations of similar-mode-of-action medications are considered. This regulatory loophole may allow potentially damaging chemicals to skip through the environmental assessment process.

In conclusion, the multidisciplinary demands of understanding and regulating the design, approval, consumption, metabolism, excretion, disposal, and environmental fate of pharmaceutical products in water systems requires developing innovative strategies in academic and regulatory institutions. These strategies may be consolidated under the umbrella of a new subdiscipline entitled "pharmecology" whose ultimate mission is protecting the environment from the chemical hazards associated with the pursuit of human health.

POINT-OF-USE/POINT-OF-ENTRY SYSTEMS (POU/POE)

Zacharia Michael Lahlou
Technical Assistance Consultant

Numerous households use point-of-use/point-of-entry (POU/POE) systems primarily to deal with aesthetic concerns, such as taste and odor. These treatment devices are installed just as their name implies—at the point where water enters a household or where it is used, such as a faucet. In certain situations, however, using POU/POE systems to provide safe drinking water to a system's customers is not an individual's choice, but that of the water system cooperating with regulatory authorities. Therefore, this "Tech Brief" only discusses POU/POE treatment options that meet Safe Drinking Water Act (SDWA) water quality requirements.

WHAT IS THE ROLE OF POU/POE SYSTEMS?

Some small water systems find complying with U.S. Environmental Protection Agency (EPA) maximum contaminant level (MCL) requirements difficult. Installing expensive treatment technologies may be the largest obstacle for these systems. In many cases, obtaining water from some other source may not be an option. In these situations, POU/POE water treatment systems may provide a low-cost alternative to centralized water systems.

Water system personnel can install POE treatment units at individual households where water lines enter the home, alleviating the expense of treating large amounts of water at a central facility. An even less expensive alternative is the POU system, as these systems only treat the water at an individual tap.

POU/POE systems are used to control a wide variety of contaminants in drinking water and often use the same technology concepts employed in centralized treatment—but at a much smaller scale. This technology is applied to reduce levels of organic contaminants, control turbidity, fluoride, iron, radium, chlorine, arsenic, nitrate, ammonia, microorganisms (including cysts) and many other contaminants. Aesthetic factors, such as taste, odor, or color, can be improved with POU/POE treatment.

In addition to treating raw water, POU/POE systems can be used to treat finished water that may have degraded during distribution or storage. They insure that susceptible consumers, such as the very young or immunocompromised, receive safe drinking water.

POU/POE can save many small communities money where individual households have private wells. The community then does not have to build a treatment plant or install and maintain water distribution mains. Many states, however, have concerns about POU/POE treatment devices, such as:

- how well the units treat drinking water,
- the potential health risk posed by not treating all the water in the house, and
- water system officials' ability to properly monitor and maintain the equipment.

WHAT REGULATIONS AFFECT POU/POE SYSTEMS?

The 1996 SDWA lists POU/POE systems as options for compliance technologies. When a water system uses this technology to comply with a National Primary Drinking Water Regulation (NPDWR) the SDWA identifies requirements that must be met. The SDWA states the public water system or a person under contract with the public water system shall own, control, and maintain the POU/POE system to ensure proper operation, maintenance, and compliance. The act also states that the treatment mechanism should be equipped with mechanical warnings that automatically notify customers of operational problems.

Other conditions in the SDWA include: "If the American National Standards Institute has issued product standards applicable to a specific type of POE/POU treatment unit, individual units of that type shall not be accepted for compliance with a MCL or treatment technique unless they are independently certified in accordance with such standards."

POU devices are listed as compliance technologies for inorganic contaminants, synthetic organic contaminants, and radionuclides. POU devices are not listed for volatile organic contaminants because they do not address all routes of exposure.

WHAT ARE THE TYPES OF POU/POE SYSTEMS?

No single type of residential water treatment system is available to remove all water quality problems. Therefore, selection of one or more technologies may be necessary to solve multiple water quality problems. The following is a short summary of different types of POU/POE available (see also Table 1). Additional information and guidance is available from manufacturers, distributors, and public health agencies to help select the appropriate treatment technologies to remove specific water contaminants from water.

FILTERS

Water passes through the filter media (usually in a cartridge in smaller units), which either adsorbs or physically screens various contaminants. Common filter media include:

Table 1. Summary of POE/POU Systems and Costs (NSF, 1999)

Technology	Some Contaminants Removed	Initial Cost	Operating Cost	Operating & Maintenance Skills
Chlorine	Microbial	**$**	**$**	**$**
UV, Ozone	Microbial	**$$**	**$**	**$$**
Cartridge	Protozoa			
Filter	Bacteria	**$**	**$ to $$**	**$**
Reverse Osmosis	Microbial, Inorganic Chemicals and Metals Radium, Minerals, Some Organic Chemicals	**$$**	**$$$**	**$$$**
Distillation	Microbial, Inorganic Chemicals and Metals, Minerals, Some organic Chemicals, Radium, Uranium	**$$**	**$$**	**$**
Activated Carbon	Organic Chemicals, Radon, Odors (solid block can filter protozoa and some bacteria)	**$$**	**$$ to $$$**	**$**
Packed Tower Aeration	Radon, Volatile Organic Chemicals, Tastes, Odors	**$$**	**$**	**$$$**
Ion Exchange	Inorganic Chemicals, Radium, Nitrate	**$$**	**$$ to $$$**	**$$**
Activated Alumina	Arsenic, Selenium, Fluoride	**$$$**	**$$$**	**$$$**
		$ Low	**$$ Moderate**	**$$$ High**

- Granular activated carbon (GAC) is used for taste and odor control and to remove radon and regulated organic compounds.
- Solid block carbon treats the same contaminants as GAC, but also to removes lead, asbestos, various bacteria, cysts, and sediment particulates.
- Ceramic or synthetic fiber microfilters treat various bacteria, cysts, and sediment particulates.
- Activated alumina treatment is most often used for fluoride, selenium, silica, and arsenic removal.

REVERSE OSMOSIS

Water passes through a synthetic, semi-permeable membrane that filters all pathogens and most organic and inorganic contaminants. Reverse osmosis units must have a means of discharging filtered matter to a drain. The discharge line should be installed with an air gap so a cross-connection between wastewater and drinking water will not occur.

DISTILLATION

Distillers heat water in one chamber and turn it into steam. The steam then passes into another chamber where it is cooled and condensed to a liquid. Distillation can effectively remove microorganisms, dissolved minerals, metals, nitrates, and some organic contaminants. Distillation units require a dependable supply of electricity and usually produce only small amounts of drinking water.

ION EXCHANGE

Ion Exchange, commonly known as water softening, is used to treat all household potable drinking water. Ions of either sodium or potassium, stored in the softener's "resin bed" are exchanged for ions of the calcium and magnesium hardness minerals. Ion exchange can be used for dealkalization and to remove iron and manganese, heavy metals, some radioactivity, nitrates, arsenic, chromium, selenium, and sulfate.

DISINFECTION AND OXIDATION

Oxidizing chemicals, such as chlorine and ozone, are added to water through a feed system that controls the concentration and allows appropriate contact time. These chemicals break down organic contaminants and destroy pathogens.

Ultraviolet light (UV) is a popular disinfection method in combination with other treatment techniques. UV uses rays of ultraviolet light to deactivate pathogens. UV light damages a pathogen's DNA and prevents it from reproducing. One of the major advantages of UV disinfection is that it disinfects without the addition of chemicals; therefore, it does not generate taste, odor, or chemical by-products.

AIR STRIPPING OR AERATION

Air stripping has been used in POE systems to remove volatile organic compounds, hydrogen sulfide, and radon from water. Air stripping is a treatment method that exposes water to air. This treatment process removes or "strips" volatile organic contaminants from groundwater as air is forced through the water, causing the compounds to evaporate. GAC alone can remove volatile organics but can only be operated for short periods before the carbon has to be replaced. For these applications, it is important to vent gases adequately to avoid creating an air pollution hazard inside the home.

POU/POE OPERATION AND MAINTENANCE

Selecting POU/POE systems does not eliminate the need for evaluating treatment efficiency before the units are installed. For systems that employ cartridges (e.g., GAC columns or activated alumina), source water pilot testing may be necessary to develop valid estimates of the unit's service life.

Effective operation, maintenance, and monitoring programs are especially significant for POU/POE systems. Many homeowners assume their systems will perform properly once installed and do not understand the level of effort required to ensure proper operation. For this reason, when POU/POE systems are installed for regulatory purposes, water utilities or regulatory agencies must provide programs for long-term operation, maintenance, and monitoring.

Proper installation is the first step in effective long-term operation and maintenance (O&M) of POU/POE systems. Experienced contractors or installers whose products conform to applicable plumbing codes should be the only personnel who install the units. Qualified installers:

- carry liability insurance for property damage during installation,
- are accessible for service calls,
- accept responsibility for minor adjustments after installation, and
- give a valid estimate of the cost of installation.

After installation, POU/POE systems should have a well-defined program of O&M for continued production of high quality drinking water. The equipment manufacturer's recommended O&M requirements can serve as the basis for the O&M program. Equipment dealers may provide maintenance for a limited time period as part of an installation warranty. A local plumbing contractor, a POU/POE service representative or equipment dealer, a water service company, the local water utility, or a circuit rider may carry out a long-term maintenance program.

Monitoring programs need to be site specific and reflect the contaminant or contaminants being removed, the equipment used, the number of POE/POU units in service, and the logistics of the service area.

Minimum sampling frequencies and types of analyses should be established in cooperation with the local health department, the state regulatory agency, and the treatment system.

Monitoring programs generally include:

- raw and treated water sample collection,
- meter reading,
- field analyses (measuring pH, dissolved oxygen concentration, and other parameters),
- shipment of samples to a laboratory, and
- recordkeeping.

The use of state-approved sampling methods and certified laboratories is a requirement for regulatory compliance.

Remote monitoring and control is becoming a more practical option for small communities and could be part of an O&M agreement developed by a POU/POE vendor. Remotely monitoring operating parameters could provide an attractive alternative to fixed sampling and O&M schedules, thus, allowing customized customer service of the POU/POE device.

A POU/POE vendor could use remote telemetry equipment to review several installations and reduce the number of unnecessary system checks and visits. Remote telemetry also may be used to better schedule routine O&M, trouble-shooting problems, and emergency situations.

SELECTING AN APPROPRIATE POU/POE SYSTEM

The selection of POU/POE treatment units should be based on how well a particular type of unit removes specific contaminants from drinking water. Therefore, the selection process involves:

- an evaluation of the quality and type of source water,
- type and extent of contamination,
- treatment requirements, and
- waste disposal requirements.

The treatment requirements are usually compared based on operation and maintenance requirements, cost, and institutional requirements.

For a guarantee that a water treatment unit will perform and remove contaminants that the manufacturer claims, look for certification or registration labels on the treatment units. Two private organizations, the National Sanitation Foundation International (NSF) and the Water Quality Association (WQA), provide product testing. However, manufacturers are not required to test their products under these programs.

NSF INTERNATIONAL LISTING PROGRAM

NSF International is a nonprofit, independent testing and research group that provides standards for drinking water treatment components and tests home and personal water treatment devices to determine their ability to improve the aesthetic quality of water and remove health-related contaminants. NSF International has a certification laboratory that can conduct a full range of physical, microbiological, radiological, inorganic, and organic analyses.

NSF uses expert committees to develop its technology standards. The committee includes representation from industry, government, and consumer groups. The committee also receives input from a council of public health consultants and a certification council that has expertise in test methods.

Once an NSF committee develops a standard, the NSF applies to have it certified by the American National Standards Institute (ANSI). An ANSI designation means that only one standard exists for that type of product in the U.S. and that the standard follows all of ANSI's guidelines.

WQA Voluntary Product Validation Program and Voluntary Certification Program WQA, a nonprofit international trade association, awards its Gold Seal to water treatment equipment that passes testing under industry standards for performance, capacity, and durability. WQA does not evaluate claims for removing health-related contaminants. However, WQA has a certification program for POU/POE devices. But remember, WQA is a trade association for POU/POE equipment manufacturers, and although the association provides educational material to the consumer, they also promote the use of treatment equipment.

WHAT ABOUT SAFETY AND TERRORISM?

Recent events confirm that bioterrorism is no longer a threat, but a reality. POU filtration systems can reduce many biological warfare agents. POU systems, rated for their ability to remove waterborne biological agents, are available in a range of sizes from individual use to those capable of delivering thousands of liters of water per hour.

HAVE *YOU* READ ALL OUR *TECH BRIEFS?*

Tech Briefs, drinking water treatment and supply fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) publication *On Tap* for more than seven years.

A package of *Tech Briefs* is now available as a product. A three-ring binder holds all the current *Tech Briefs* in print. New selections can easily be added to the package as they become available. To order this free product, call the NDWC at (800) 624-8301 or (304) 293-4191 and ask for item #DWPKPE71.

You also may order online at ndwc_orders@mail.nesc.wvu.edu or download fact sheets from our Web site at www.ndwc.wvu.edu. (Additional copies of fact sheets are free; however, postal charges may be added.)

Z. Michael Lahlou holds a doctorate in environmental and natural resource economics and a master's in civil and environmental engineering. Formerly the technical assistance coordinator for the National Drinking Water Clearinghouse, Lahlou now resides in Huntington Beach, California.

ASSESSING THE BACTERICIDAL EFFICIENCY OF POLYDEX FOR THE DISINFECTION OF DRINKING WATER IN RURAL AREAS OF SOUTH AFRICA

M. N. B. Momba
N. Makala
A. Okeyo
University of Fort Hare
Alice, South Africa

INTRODUCTION

In developing countries, a large number of people lack access to adequate water supply. They, therefore, are forced to use surface water drawn from polluted rivers, irrigation canals, ponds, and lakes without prior treatment. For small rural communities, groundwater remains the main water supply source. Some communities receive their drinking water directly from uncovered or covered boreholes and wells, whereas for others, the water is drawn from the boreholes (using an engine) to a reservoir, and from the reservoir, it is then delivered to the people through a public standpipe system. In both cases, groundwater is distributed to the community without any purification. However, inadequate design, construction, operation, and maintenance of wells and boreholes can lead to quality problems related to groundwater. Poor sanitary sealing is more generally a common cause of microbiological quality deterioration (1). The failure to periodically drain and clean water supply holding tanks to remove sediments provides opportunities for heterotrophic bacterial colonization and biofilm development (2).

Polluted waters are an important vehicle for the spread of disease as they are carriers of disease-causing organisms such as pathogenic bacteria and viruses. Thousands of people in developing countries become ill each year through contact with contaminated water. The full impact of contaminated water on health is difficult to determine because of poor recording of diseases. A crucial need exists for scientifically sound answers to the problems of the contamination of water sources with potentially hazardous microbial organisms and the assessment of the risks posed by such pollution. Where public health is concerned, disinfection is the most important step in any process involving drinking water treatment.

Disinfection—by application of chlorine—is the most widely used treatment for bacteriological water quality improvement. However, its efficiency is limited to the presence of an adequate chlorine residual in potable water. Once the latter depletes, any drinking water system will experience a correlation between increase in bacterial numbers and the distance away from the point of treatment. This increase has been termed regrowth and is recognized as a major problem within many water systems (3). The identification of other disinfectants and the understanding of their modes of action should be stepped up in order to improve the microbial quality of drinking water from the point of treatment to the consumers.

Polydex is the result of extensive research and development in the search for a healthier microbial control and protection of potable water and wastewater. Polydex is a Pest Management Regulatory Agency (PCPA) registered product, which is designed for use in ponds, dugouts, and potable water tanks for the control of algae and bacteria (4). Polydex is also used in agriculture for the control of noxious gases and odors in animal waste and in slaughterhouses for reducing the risks of *E. coli* contamination, such as the one which claimed several lives in Walkerton, Ontario (5). The active ingredient in Polydex is a biologically active form of the copper ion (Cu^{2+}). Polydex contains a unique hydrotropic and colloidal mineral matrix, which effectively captures and carries copper ions (Cu^{2+}) evenly throughout water in high concentrations under a wide variety of water conditions.

The biocidal effects of copper have been used for centuries. The early Greeks and Romans made water storage and drinking vessels out of this metal. More recently, copper has been used in hospital, recreational, drinking, and industrial water systems. Unlike chlorine, copper does not result in dangerous halogenated organic byproducts, such as trihalomethane (THM), chloramines, and chloroform, and this ion is stable, making it easier to maintain an effective residual (6).

The disinfection action is attributed to the positive charge of copper ion. Positively charged copper ion has an affinity for electrons and, when introduced into the interior of a bacterial cell, they interfere with electron transport in cellular respiration systems. Metal ions will bind to the sulfhydryl, amino, and carboxyl groups of amino acids, thereby denaturing the proteins, which renders enzymes and other proteins ineffective, compromising the biochemical process they control. Cell surface proteins necessary for transport of materials across cell membranes also are inactivated as they are denatured. Finally, copper will bind with the phosphate groups that are part of the structural backbone of DNA molecules, which results in unraveling of the double helix and consequent destruction of the molecule (6,7).

It is also important to consider how copper in water can be advantageous to humans, animals, and plants. Our daily diet must provide specific trace amounts of copper for a number of reasons in order to maintain human health. The essential role of copper in maintaining normal health in both animal and humans has been recognized for many years. Normally, copper is readily available in a range of foods, and normal balanced diets should provide adequate daily amounts without the need for additional supplements. Dietary copper intake will vary considerably with the type of food consumed, the condition of the soils (e.g., copper content, pH, etc.) from which certain foods are produced, and drinking water characteristics. The average daily dietary requirement for copper in the adult human has been estimated at 2 mg and for infants and children at 0.05 mg/kg bw (8–10). The NRC (11) reported "estimated safe and adequate" daily dietary intakes of copper ranging from 0.5 to 0.7 mg/for infants 6 months of age or less and up to 2–3 mg/day for adults. In cases where individuals have a change in their everyday eating habits or decide to indulge in a limited medically controlled diet that may result in an inadequate intake of copper, water treated with Polydex may come in handy in supplying the body with needed copper.

Although several tests have shown the effectiveness of copper in killing bacteria, our preliminary experiments revealed that its effectiveness was limited in raw water with high turbidity when considering the initial dose recommended by the suppliers (1 part of polydex into 60,000 parts), which automatically showed that the quality of raw water remains one of the most important parameters in determining the efficiency of polydex. It was therefore vital to re-evaluate the bactericidal efficacy of polydex by considering various types of water sources and determining the disinfectant (polydex) demand of the water. Coliform bacteria were used as the main parameters with references to South African Water Quality Guidelines–Domestic use (12,13). Total coliforms are frequently used to assess the general hygienic quality of water and to evaluate the efficiency of drinking water treatment and the integrity of the distribution system. They should not be detectable in treated water. When found, they suggest inadequate treatment, post-treatment contamination and/or aftergrowth, and an excessive concentration of nutrients. In some instances, they may indicate the presence of pathogens responsible for the transmission of infectious diseases. The total coliform group includes bacteria of fecal origin and indicates the possible presence of bacterial pathogens such as *Salmonella spp., Shigell spp., Vibrio cholerae, Campylobacter jejuni, C. coli, Yersinia enterocolitica*, and pathogenic *Escherichia coli*, especially when detected in conjunction with other fecal coliform (13). The study aimed at generating valuable information in regard to the bactericidal efficiency of polydex for the disinfection of drinking water in rural communities.

MATERIALS AND METHODS

The experimental study was conducted on the basis of five replicates for each type of test water, and the effectiveness of polydex was evaluated every hour for the period of 7 h. Microbiological analyses were conducted in aseptic conditions under a laminar flow cabinet in the laboratory. Turbidity and pH were also considered, as both factors play a significant role in the disinfection process. All microbial and physicochemical tests were performed before and after disinfection.

Sampling Sites

Raw, filtered (water after flocculation, sedimentation, and filtration), and surface water samples were collected at the Alice water purification system (Alice, Eastern Cape), Umgeni water (Durban, Natal), Rand water, (Vereeniging, Gauteng), and in Thohoyandou water purification systems (Venda, Limpopo). Groundwater samples were also collected in Alice, Vereeniging, and Thohoyandou. Test waters were collected in clean sterile 5l polyethylene bottles.

Disinfection of Test Waters

The bactericidal effect of polydex was determined using two different initial doses:

1. Dose indicated by the manufacturer: 1 part of polydex into 60,000 parts of test water to give one part per million biologically active copper ions. Therefore, 0.083 ml polydex (approximately 3.9 mg/l copper) was used to disinfect 5l of test water with turbidities ranging between 0.59 NTU and 8 NTU.
2. 5.4 mg/l copper (corresponding to 2 × 0.083 ml) was used for the disinfection of surface water with higher turbidity (>9NTU).

Physicochemical Analyses

Turbidity and pH were measured using the microprocessor Turbidity Meter (HACH Co., Model 2100P) and pH Meter, respectively, and copper (Cu) concentrations were determined according to the spectroquant NOVA 60 manual (1998) using photometric test kits (Merck).

Microbiological Analyses

Total coliforms, presumptive *E. coli*, and *Salmonella* species were detected by the membrane filtration technique using filters with 0.45 μm pore size and 47 mm diameter (Millipore). Different volumes (10 and 100 ml) were filtered depending on the type of water used. Saline water was used as a diluent for the 10 ml volumes to spread the bacteria evenly over the filter membrane. The membrane filters were placed on Chromocult agar (Merck) plates and incubated for 24 h at 37 °C. Analyses were carried out in triplicates. Water samples were analyzed for the above micro-organisms using internationally accepted techniques (14).

RESULTS AND DISCUSSION

Characteristic of Raw Surface Water Before and After Disinfection with An Initial Dose of 3.9 mg/l Polydex

Figure 1 summarizes the counts of indicator bacteria before and after disinfection and the impact of turbidity and pH on the effectiveness of this disinfectant. There was a gradual decrease in all indicator micro-organisms after an hour of disinfection, which continued throughout the 7 h of the study period. Although presumptive *Salmonella* and presumptive *E.coli* were removed at a percentage of 100% within 1 h and 5 h, respectively, in all raw water samples, the removal of total coliforms in water samples from Venda, Rand water, and Alice ranged between 90–91% throughout the 7 h of the study period. However, complete removal of total coliforms occurred 5 h after disinfection of Umgeni water, which appeared to have lesser turbidity compared with other test waters. Although all raw water samples were disinfected with the same initial copper concentration of 3.9 mg/l, copper residual was more slowly depleted in Umgeni water than in the other raw water samples. The average copper residuals in Venda, Rand, and Alice waters after 7 h were 1.02 mg/l; 1.20 mg/l, and 1.12 mg/l, respectively, whereas samples from Umgeni water still maintained the copper residual concentration of 1.71 mg/l, which gave a clear indication that higher turbidities hinder the effectiveness of polydex as a disinfectant.

Characteristics of Filtered Surface Water Before and After Disinfection with an Initial Dose of 3.9 mg/l Polydex

The effectiveness of polydex was further proved by the dramatic decrease in numbers of all indicator micro-organisms in filtered water samples with reasonably low turbidities after disinfection (Fig. 2). Complete removal of presumptive *Salmonella,* presumptive *E. coli*, and total coliform bacteria occurred after 1 h, 2 h, and 4 h of disinfection in all the water samples, respectively. Although all filtered water samples maintained copper residuals ranging between 2.06 mg/l and 2.44 mg/l after the 7 h of the study period, the water samples from Umgeni water purification system had a higher residual (2.44 mg/l) than those from Venda, Rand, and Alice water supplies, which had residuals of 2.11 mg/l, 2.20 mg/l, and 2.06 mg/l, respectively. There was an indication of a slight decrease in pH after disinfection in all samples (raw surface water, raw groundwater, filtered surface water); however, this appeared not to have any effect on the effectiveness of polydex—or public health—as the pH values obtained were within the limits recommended for potable water, which are 5–9.5 (12).

Characteristic of Raw Groundwater Before and After Disinfection with An Initial Dose of 3.9 mg/l Polydex

Initial total coliform bacterial counts of 68 cfu/100 ml, 46 cfu/100 ml, and 82 cfu/100 ml were noted in Venda, Rand, and Alice groundwaters, respectively. These bacterial counts gradually decreased to 0 cfu/100 ml after 4 h in Venda and Rand water when the copper residuals were 2.43 mg/l and 2.96 mg/l, respectively. Although this was not the case with Alice water samples, the total coliform bacterial counts were found to be within the South African recommended limits for no risk (0–5 cfu/100 ml) (13). Although a complete removal of presumptive *E. coli* occurred 3 h after disinfection in all types of water, no presumptive *Salmonella* was recorded in Venda and Alice water samples within 1 h (Fig. 3).

Characteristic of Raw Groundwater Before and After Disinfection with An Initial Dose of 5.4 mg/l Polydex

There was a notable decrease in coliform bacterial counts when the initial dose of 5.4 mg/l polydex was used for

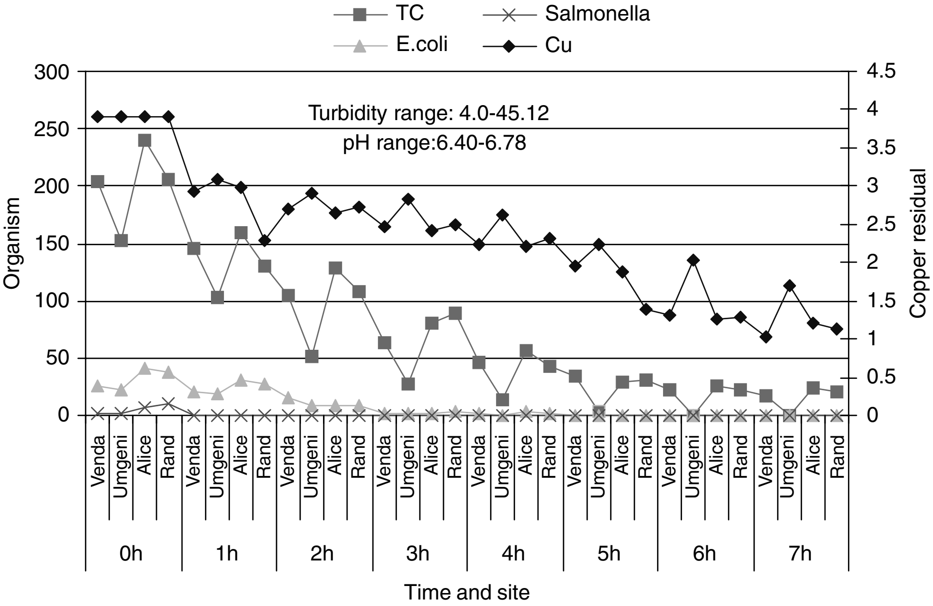

Figure 1. Average counts of indicator bacteria in raw surface water samples before and after disinfection with an initial dose of 3.9mg/l copper.

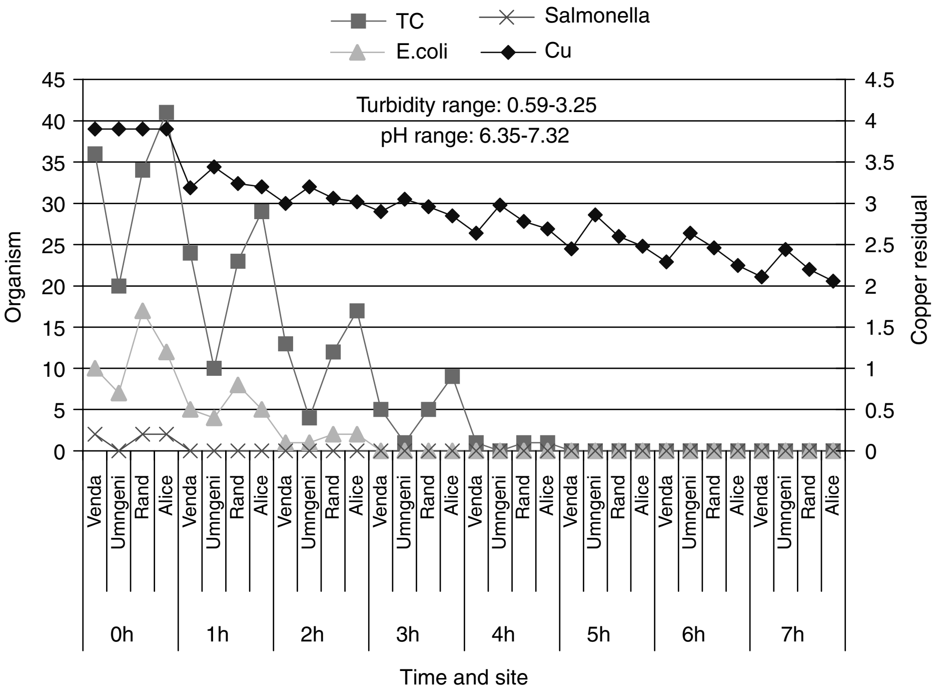

Figure 2. Average counts of indicator bacteria in filtered water samples before and after disinfection with an initial dose of 3.9 mg/l copper.

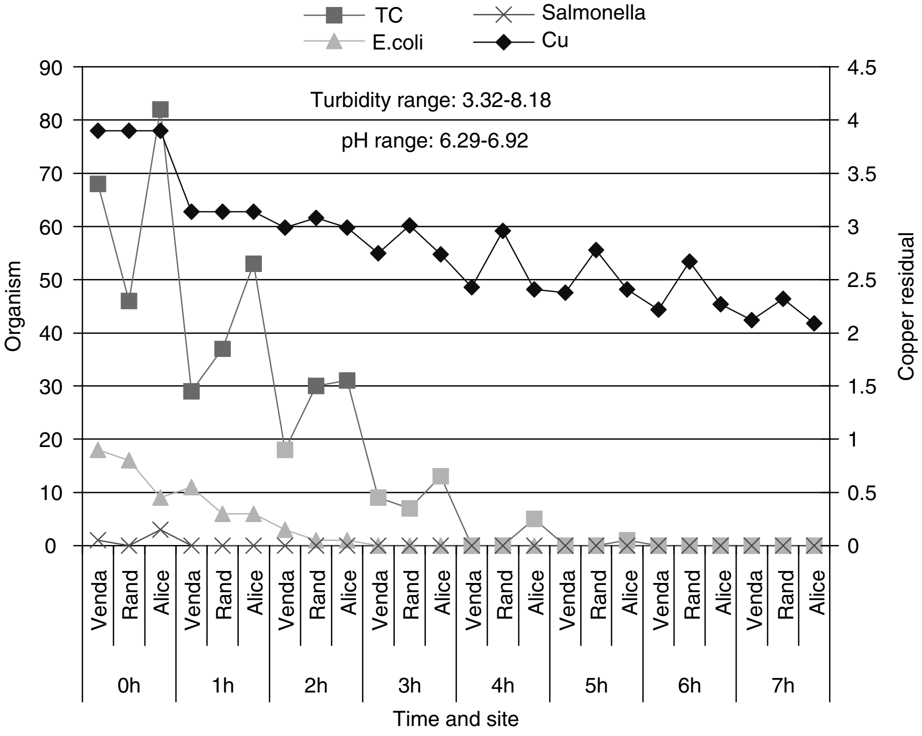

Figure 3. Average counts of indicator bacteria in groundwater samples before and after disinfection with an initial dose of 3.9mg/l copper.

the disinfection of water samples with higher turbidities. Complete removal of total coliforms occurred 6 h after disinfection of Venda and Alice water samples. Although the removal of bacteria was not complete in Rand water samples within this time, the number of total coliforms was within the limits of South African Water Quality Guidelines for no risk (0–5 cfu/100 ml) (12,13), after which the complete removal of coliforms occurred 7 h after disinfection (Fig. 4). The above observations further confirmed that polydex is highly effective in less turbid waters and, therefore, calls for an increase in dosage in highly turbid waters.

As indicated in Fig. 4, the total removal of presumptive *E. coli* in all test waters was recorded 3 h after disinfection.

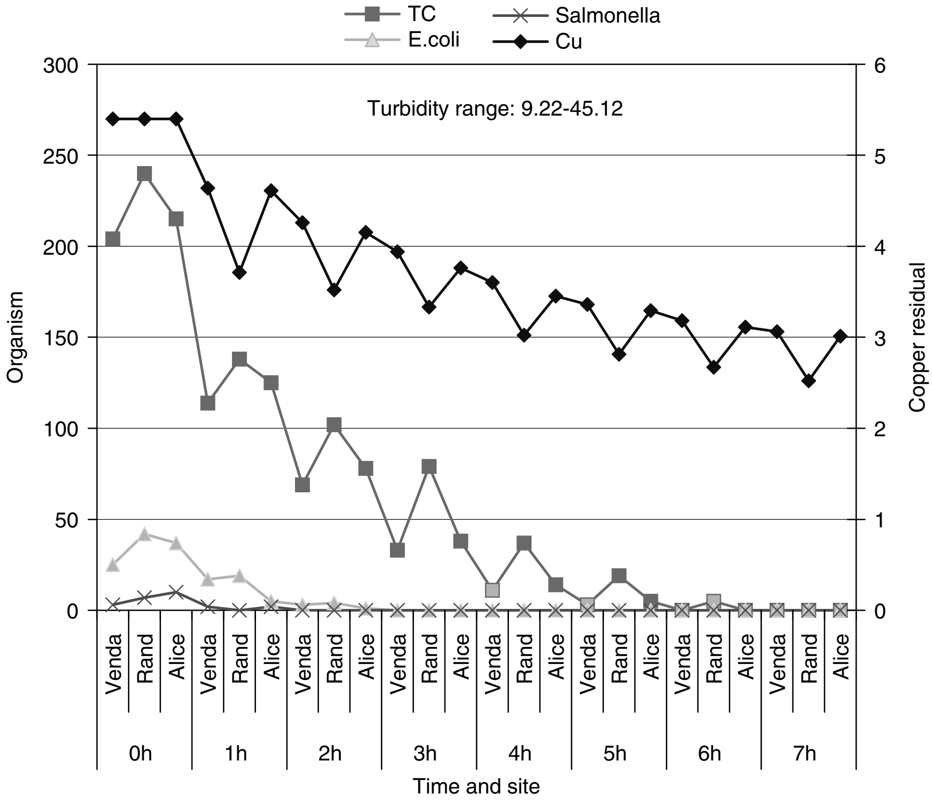

Figure 4. Average counts of indicator bacteria in water samples with high turbidity before and after disinfection with an initial copper dose of 5.4 mg/l.

In Rand water samples, the removal of presumptive S*almonella* was observed within 1 h after disinfection, and in Venda and Alice water samples, complete removal of this bacteria species occurred after 2 h.

CONCLUSIONS AND RECOMMENDATIONS

The study has revealed that polydex was effective for the removal of indicator micro-organisms. However, the turbidity of water remains one of the most important factors that can have a negative effect on its bactericidal efficiency. The dose of 3.9 mg/l appeared to be suitable for the disinfection of water samples with turbidity values ranging between 0.59 NTU and 8.18 NTU; however, this dose is not sufficient for the disinfection of highly turbid waters (>9 NTU). A dose of 5.4 mg/l is recommended for these waters as it completely removes the indicator micro-organisms thereafter leaving residuals of 2.52–3.06 mg/l after 7 h, which are within the recommended limits for potable water.

Based on the present investigations, it is important to filter highly turbid waters or increase the dose in order to increase the effectiveness of polydex. Consequently, this study suggests the followings:

- Polydex can be recommended as a disinfectant for drinking water as limits allowed by South African Water Quality guidelines are reached when this disinfectant is used: (0–5 counts/100 ml total Coliforms, 0 counts/100 ml Faecal Coliforms) (13).
- The dose of 3.9 mg/l is recommended for water with turbidity values ranging between 0.59 NTU and 8.18 NTU, and 5.4 mg/l is recommended for highly turbid waters (>9 NTU).
- The product is also recommended because the residual disinfectant ranges between limits allowed by South African Water Quality Standards (target water quality range 0–3 mg.l^{-1}).

Acknowledgment
The authors wish to express their thanks to Sibambene Trade & Services (Pty), Ltd, who sponsored this investigation. The effort of some personnel of the University of Venda, Umgeni Water, and Rand Water, especially for the collection of water samples, are immensely appreciated.

PRIVATE SECTOR PARTICIPATION, MARKETING AND CORPORATE STRATEGIES IN MUNICIPAL WATER SUPPLY AND SEWERAGE

David Lloyd Owen
Envinsager
Llangoedmor, Ceredigion,
United Kingdom

INTRODUCTION—PRIVATE SECTOR PARTICIPATION: DEFINITION AND DRIVERS

The entry will describe how financial, commercial, and technical services are being mobilized to enable economic and social services to be provided and improved by water sector organizations in the North (the developed economies) and the South (developing economies). These needs are different because the policy contexts (politics and governance), standards, and risks experienced by entities installing and improving water services in the North and the South are different. It will be shown that the international water sector companies have evolved a diverse suite of financial and contractual arrangements often in association with international financial institutions (e.g., the World Bank). It will also be shown that the water sector is evolving as new companies shape their financial and technical competence to operate and compete internationally.

Private sector participation (PSP) refers to the formal provision of municipal water and sewerage services by the private sector. This involves providing these services commercially, where infrastructure work is funded by private capital or through a combination of finance from private investors and multilateral agencies.

There are two principal drivers for PSP. In the developed economies of North America, Western Europe, and Southeast Asia, PSP is primarily used to shift the financial burden of upgrading and extending municipal water and sewerage services from central and local government to the private sector. In developing economies, PSP is being employed to finance and manage the development and operation of the water and sewerage infrastructure on commercial lines to mobilize funding from a variety of sources.

The World Water Council's 'World Water Vision for 2025' seeks to address the current lack of access to water provision, sewerage, and sewage treatment by 2025 (1). To provide universal access to water and sewerage services, Vision 2025 calls for investment in new water and sanitation assets to rise from $30 billion in 1995 to $75 billion pa and for investment by industry and for environmental protection to increase from $10–15 billion in 1995 to $75 billion pa between 2000 and 2025 (2). Vision 2025 anticipates that national private companies will contribute 45% of this investment, against 15–21% in 1995; international finance will increase from 5–6% to 24% (3). Such a financial commitment will not take place unless adequate investment conditions exist, and these require private sector participation to manage these services (4).

HISTORY OF PSP

The first formal example of private sector participation in water provision—as opposed to municipal corporations and religious foundations—dates from 1582 when Peter Morris was granted a 500-year lease to pump water from a station underneath London Bridge (5). Early private sector water companies were concerned with providing water to individual buildings not directly served by watercourses and wells as urbanization and industrial development emerged. London's New River Water Company, incorporated in 1619 (6) was the earliest example of a corporate entity, surviving today as Thames Water, part of Germany's RWE. Typically, these companies were taken over as European municipalities developed and were given statutory obligations regarding water provision and sewerage. In the United Kingdom, a series of Acts of Parliament passed between 1867 and 1894 brought the majority of these entities under municipal control (7). Between 1850 and 1914, economic development and urbanization in Europe and the Americas brought about a new wave of water company formation (Table 1). In Europe and Latin America, these companies were usually set up to integrate water provision and distribution contracts for an entire city as opposed to localized undertakings in the United States. York Water Company, the earliest extant company in the United States was incorporated in Pennsylvania in 1816.

Economic and political considerations between 1914 and 1945 caused many European companies to be nationalized or concessions to be revoked. In the United States, the market ceased to expand, but there were a

number of concession awards in Mexico. Except for France and Spain, where lease and concession awards were made from the 1950s, PSP continued to play a peripheral role, if at all, until the late 1980s. Between 1988 and 2002, there has been a fourfold increase in PSP and a reappraisal of its role in various economies.

FORMS OF PSP

PSP contracts can be gained outright through a bidding process, or they can evolve from contacts established through private sector consulting, construction, or engineering activities. The characteristics of the main types of water and wastewater privatization contracts are outlined in Tables 2 and 3.

These two types of contracts do not delegate full financial responsibility to the private operator, especially with regard to private capital investments. Operations and maintenance (O & M) contracts operate on a fixed fee basis and cannot address problems of municipal inefficiency.

The municipality controls the assets, and the private sector controls their operation. Risk elements start emerging because the private sector now deals directly with customers.

Table 2. Operations and Management (O & M) and Lease Contracts

Time horizon	2–5 years, up to 10	Ownership	Public
Customer	Government/ Municipality	Investment	Public

Construction risk	None	Tariff collection	Private
Regulatory risk	Medium		

Concessions

Concessions involve the private sector operation of assets to pay for new or upgraded facilities and upgrading work. Build-own-operate (BOO) and build-operate-transfer (BOT) contracts involve specific services to the municipality in relation to a specific program of capital improvements, whereas the full utility concession contract embraces all aspects of service provision and capital spending (Table 4). Concessions require a much more specific regulatory environment to account for the elements of risk involved. The concession company controls the service provision entity, but the municipality retains control of the asset owning entity. The latter entity is subsequently responsible for the extant assets, and new assets are vested into this entity at an agreed date. Dalton (9) discusses the political risk involved in developing concessions in developing economies.

A BOO/BOT project's cash flows are usually contractually predetermined and often have government backing. BOT/BOO projects are an effective means of rapidly organizing private capital and management toward a narrow range of services. However, some of the simpler project-oriented contracts do not affect the utility's management and operation; thus underlying problems such as leakage (and illegal interception), overstaffing, and tariff collection may not be addressed.

In full utility concessions (Table 5), existing revenues can be used immediately to service debt, thereby mitigating construction risk. During a period of time, a utility can benefit from a steady flow of revenues from a diversified customer base. A more robust balance sheet can be created, allowing for internal finance as well as the use of capital markets to sell long term debt. The operator is responsible for upgrading and operating

Table 4. BOOT/BOT/BOO Concession

the services, while developing new assets to hand over to the municipalities in the longer term.

Asset sale is the most dramatic and politically contentious form of privatization (Table 6). To date, it has been used in the 1989 sale of the English and Welsh water and sewage companies (WASCs) and in Chile. The assets are in private hands, but the license to operate them can be subject to renewal. In the case of the U.K. WASCs, a 30-year operating license was awarded to each entity in 1989. In the United States, companies developed the assets in the first place (Table 7).

THE ‘BRITISH’ AND ‘FRENCH’ MODELS

The World Bank calls delegated water management through concession awards the ‘French model.’ The ‘French model’ is typically used to contrast it with the ‘British model’ of asset sales. The real ‘French model’ is the Affermage lease as traditionally used in private sector contracts in France.

Initial Public Offerings

Initial public offerings (IPOs) of a corporatized utility take place when all or part of the shares of a water or multiutility company are listed on the local stock exchange. Since 1976, 48 municipal entities have been privatized by this method; all but nine took place since 1989. Twelve involved outright share sales, but municipalities retain a majority holding in the other 36. In addition, seven privately held water utilities have had IPOs since 1991, along with the water activities of two larger conglomerates. Prime Utilities (Malaysia, 1994) has subsequently left the sector; Azurix was bought back by Enron, its majority holder in 2001, and its main asset, Wessex Water, was in turn acquired by YTL of Malaysia in 2002. One, Northumbrian Water of the United Kingdom was privatized in 1989, acquired by Suez in 1996, and refloated in 2003.

EXTENT OF PSP

In 1988, PSP was restricted to its ‘traditional’ markets in the United States (asset owning companies); England and Wales (statutory water companies); and France, Italy, and Spain (concessions and lease contracts). The World Bank noted eight PSP water and sewerage contracts in developing economies between 1984 and 1989 (10) against 97 between 1990 and 1997 (Table 8) (11).

The total number served by the private sector in 1998 is estimated at 93 million. Since 1988, it is estimated that PSP has reached a further 302 million people through privatizations; 64 million were added through service extension and population growth within contracts, along with minor contract awards, to cover a total of 460 million people, or 8% of the global population. This includes 7.2 million people in six contracts, which subsequently have been returned to municipal ownership (Table 9).

Table 10 is based on 97 water and sewerage privatization awards identified by the World Bank during the first 8 years of the 1990s involving a total investment of $24.95 billion (12) from banks and multilateral agencies.

O&M contracts do not mobilize new sources of private sector investment. Greenfield operations are typically site specific, involving the construction of a water or sewage treatment facility, as seen in the Scottish sewage treatment construction in the United Kingdom. In recent years, a number of greenfield contracts have been awarded in areas earmarked to become new housing or industrial zones. This approach has had some popularity in the Philippines. Divestitures have been seen in Chile. The concession approach, allied with the splitting of water and sewerage entities into operating and asset holding companies has become the favored approach toward water privatization in many countries (Table 11).

CORPORATE STRATEGIES

A variety of relationships have developed between companies and within companies with regard to global

water and sewerage contracts. None of the water company linkages existed before 1992; only Veolia (then called Generale des Eaux) and Suez (then called Lyonnaise des Eaux) were operating as private sector multiutility companies at that time

Power and Gas Utilities Entering the Sector

The attraction of the water market for these companies is that it represents an extension of their abilities in client management, asset maintenance, and development and in dealing with regulation and politics. Many of these companies have been publicly owned until relatively recently. Power companies across Europe have entered the sector either by acquiring companies in their home markets or internationally.

Municipal Multiutilities

To date, one German and six Italian municipal multiutilities have been partially floated. In these cases, the water activities account for a minority of group turnover, which tends to be dominated by power activities.

Multiutilities active in seeking water contracts or investments include United Utilities (UK: North West Water/NORWEB), VE (France: Veolia Water/Cofreth & Esys Montenay), Suez (France: Ondeo/Tractabel & Elyo), RWE (Germany: Thames Water/RWE), ACEA (Italy: Acqua Italia/ACEA), and Amga (Italy: Acque Genova/Amga).

From $4.8 billion in investment in 1990–2004 against $24.3 billion in 1995–1999, it is evident that the pace of investment increased in the latter half of the decade, although only $5.1 billion was invested in 1998–1999, as a result of economic problems in Asia during those 2 years. Typically, equity investment provided by the companies involved in operating concessions is equivalent to 30% of the total investment, indicating that the private sector invested $12.2 billion during the period 1990–1999, a total investment of $41.3 billion.

CONSTRUCTION AND WATER

Constructing water and wastewater facilities and their operation have always been closely interlinked. In Vivendi Environment and Suez, the water companies have branched into construction, as has been more erratically seen in the English and Welsh water companies during the past 13 years. Usually, the construction company is attracted to the services concessions, having built the facilities. Bouygues, one of the leading French construction companies, acquired Société d'Aménagement Urbain et Rural (SAUR, founded in 1933) in 1984. FCC (originally Focsa) was founded as a construction company in 1900 and gained the Barcelona sewerage contract in 1911. Dragados, a Spanish construction company, has extensive experience in water supply and sewerage projects. Dycagua, Urbaser's water tendering arm, was set up in October 1994 and has won a number of concessions. Ferrovial has adopted a similar approach through its Ferroser subsidiary.

JOINT VENTURES

Joint ventures for international water/sewerage contracts typically include a company that has experience in the water sector and has a significant presence in the target market(s). Examples include International Water (Edison/Bechtel/United Utilities—all non-U.S. markets), Sino-French Holdings (Suez/New World Developments - China, HK & Macao), VE/Hyundai (South Korea), and Proactiva (VE/FCC-Latin America) (Table 12).

It is evident that the two pioneering companies, Suez and Veolia Environment, continue to lead this market. That dominance is now being challenged, especially by Germany's RWE and a number of British companies.

PUMPS

VIPIN BHARDWAJ
NDWC Engineering Scientist

BETHANY REED
NESC Graphic Designer

From start to finish, pumps play an important role in all water distribution systems. They are used to transfer raw water to the treatment plant; they supply water to sections of a distribution system where it is not possible to supply it by gravity; they add appropriate chemical doses during treatment; and they transfer sludge from settling chambers for further treatment and disposal. Pumps will provide long-term efficient service if they are properly operated and maintained

PUMPS IN WATER DISTRIBUTION SYSTEMS

Pumps are an important part of any water distribution system. At the source, they help deliver raw water to the treatment plant. In the plant, pumps add chemical solutions at desired dosages for treatment processes, and other pumps remove sludge from sedimentation facilities for further treatment and disposal. Within distribution systems, pumps discharge water under pressure to the pipe network and lift water where it cannot go by gravity, especially to water towers.

PUMP APPLICATIONS

Different types of applications require different types of pumps. Pumps are selected based on system requirements, discharge pressure required, flow capacity required, and availability of space. The two most common pumps in the water industry are: centrifugal pumps, used most often in water distribution, and positive-displacement pumps, most commonly used in treatment plants for chemical dosing.

TYPES OF PUMPS USED IN WATER SUPPLY

Three kinds of pumps are most often found in water distribution systems: the aforementioned centrifugal pumps, used to move water, vertical turbine pumps, used at the intake, and submersible pumps, used in wells.

Centrifugal Pumps

Centrifugal pumps are the most common type used in water distribution. Centrifugal pumps have a circular "fan/turbine-shaped" structure called an impeller that is mounted on a centrally supporting structure called the shaft. The motor rotates the shaft and can be powered by electricity or diesel fuel. Water enters at an opening in the center called the suction. The rotating impeller imparts a high velocity to the water, and it is circulated and thrown outward (See Fig. 1). A circular-shaped covering called casing surrounds the impeller. The casing is shaped like a spiral so that the water slows down, and the velocity head is converted to pressure head as it flows out of the casing. At the junction of the casing and shaft, a seal or packing rings are provided to prevent leakage. A packing gland presses against the rings to maintain a tight seal.

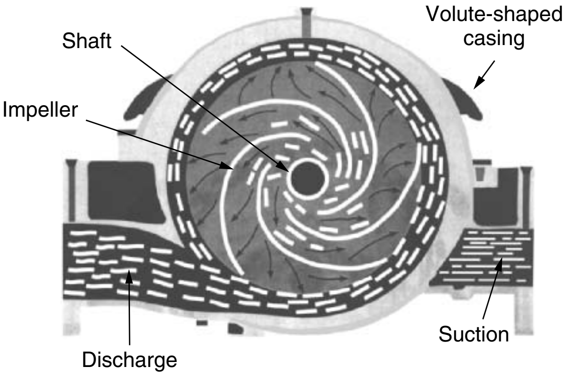

Figure 1. Volute centrifugal pump schematic. Adapted from AWWA *Water Transmission and Distribution: Principles and Practices of Water Supply Operations,* 2nd Edition.

GLOSSARY OF PUMP TERMS

Head—(1) A measure of the energy possessed by water at a given location in the water system expressed in feet; (2) a measure of the pressure or force exerted by water expressed in feet.

Velocity Head— A measurement of the amount of energy in water due to its velocity or motion.

Pressure Head—A measurement of the amount of energy in water due to water pressure.

Impeller—The moving element in a pump that drives the fluid.

Efficiency—A ratio of total energy output to the total energy input expressed as a percent.

Priming—The action of starting the flow in a pump or siphon. With a centrifugal pump, this involves filling the pump casing and suction pipe with water.

Source: American Water Works Association. 1996. *Water Transmission and Distribution: Principles and Practices of Water Supply Operations*, 2nd Edition. Denver, CO: AWWA.

Different flow rates and outlet pressures can be generated by this type of pump, depending on the size of the pump and the space between the casing and the impeller. Impellers can also have varying shapes. These pumps can be used either as a single unit or can be coupled with another similar pump in series to generate more output pressure. When more than one pump is used, it becomes a multistage pump. The pressure desired in the distribution system determines the number of stages required. If a single stage pump is not enough to supply water at adequate pressure, multiple stages are used. Centrifugal pumps can achieve an output pressure of up to 250 feet for each stage. Centrifugal pumps are used to supply large volumes of water at a constant output pressure. The pressure generated by a centrifugal pump is less compared to other types of pumps, such as a reciprocating (positive-displacement) pump.

According to the American Water Works Association's *Water Transmission and Distribution: Principles and Practices of Water Supply Operations*, some of the advantages of centrifugal pumps are:

- wide range of capacities that range from a few gallons per minute [gpm] to 50,000 gpm. Heads of five to 700 feet are generally available;
- uniform flow at constant speed and head;
- simple construction (small amounts of suspended matter in the water will not jam the pump);
- low to moderate initial cost for a given size;
- ability to adapt to several drive types—motor, engine, or turbine;
- moderate to high efficiency at optimal operation;
- no need for internal lubrication;
- little space required for a given capacity;
- relatively low noise level; and
- ability to operate against a closed discharge valve for short periods without damage.

Some of the disadvantages are:

- an efficiency that is limited to a narrow range of discharge flows and heads;
- low capacity that is greatly dependent on discharge pressure;
- generally no self-priming ability;
- potential for running backward if stopped with the discharge valve open; and
- potential for impeller to be damaged by abrasive matter in water, or clogged by large quantities of particulate matter.

During startup, centrifugal pumps require a procedure called “priming” in which the pump is filled with water before turning the switch on. This insures that when the impeller starts rotating it starts pumping water, and energy imparted to the impeller is not lost. If a centrifugal pump is not primed, it does not operate efficiently (i.e., it does not pump water even when it is turned on). Generally, pumps have an adjacent chamber, called the priming chamber, that sucks in water when the pump is turned on and keeps the impeller submerged.

Vertical Turbine Pumps

In vertical turbine pumps, the water flows vertically through a channel of uniform cross-sectional area. The impeller is positioned in the center along the axis in the channel. The blades of the impeller are shaped so that the water flows in a radial direction (See Fig. 2). The casing has diffuser vanes, shaped so that they guide water and make it flow either into the discharge or through diffuser bowls into inlets of succeeding stages. Vertical turbine pumps are used most often at raw water intakes and at booster stations in the distribution system to augment the pressure required for service. Vertical turbine pumps are relatively more expensive than centrifugal pumps for the same capacity and require more maintenance.

According to the American Water Works Association’s *Water Transmission and Distribution: Principles and Practices of Water Supply Operations,* some of the advantages of vertical turbine pumps are:

- uniform flow at constant speed and head;
- simple construction;
- individual stages capable of being connected in series, thereby increasing the head capacity of the pump;
- adaptability to several drive types—motor, engine, or turbine;
- moderate to high efficiency under the proper head conditions;
- little space occupied for a given capacity; and
- low noise level.

The main disadvantages are:

- high initial cost;
- high repair costs;
- the need to lubricate support bearings located within the casing;
- inability to pump water containing any suspended matter; and
- an efficiency that is limited to a very narrow range of discharge flow and head conditions.

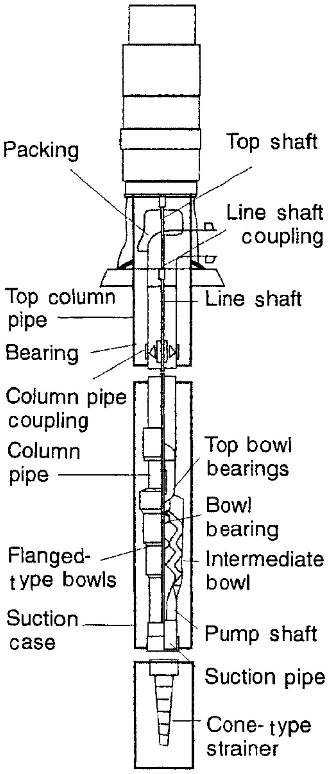

Figure 2. Verticle turbine pump. Adapted from AWWA *Water Transmission and Distribution: Principles and Practices of Water Supply Operations,* 2nd Edition.

Submersible Pumps

Submersible pumps, as the name implies, are placed below the water level (See Fig. 3). They are used mostly for pumping groundwater from wells. The pump is basically a multi-stage centrifugal pump. The impellers of the pump are mounted on a vertical shaft. Each impeller passes water to the next stage through a diffuser shaped so that the water flows vertically to the next diffuser. Each impeller and diffuser is called a stage. The desired output pressure determines the number of stages.

The pump is driven by an electric motor placed adjacent to the pump and is constructed for submerged operation. The wiring of the electric motor is such that it is waterproof. The motors are manufactured to ensure water does not cause it to fail by grounding or shorting out. However, most failures of submersible pumps are due to electrical problems with the motors.

Positive-Displacement Pumps. Positive-displacement pumps are used in water supply operations for feeding chemicals at various stages of the treatment process. They displace a certain volume of water in each stroke

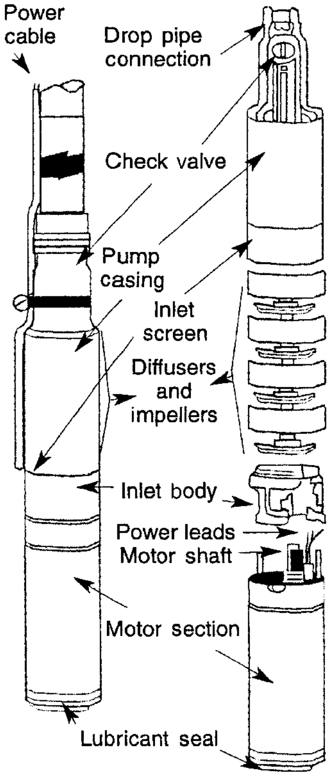

Figure 3. Submersible pumps. Adapted from AWWA *Water Transmission and Distribution: Principles and Practices of Water Supply Operations,* 2nd Edition.

as they operate. These pumps are not suitable for pumping large volumes of water, they are more suited for high pressure and low flow service. There are two types of positive-displacement pumps: reciprocating pumps and rotary pumps.

Reciprocating Pumps

Reciprocating pumps have a piston that moves back and forth in an enclosing cylinder. The arrangement of rotating shaft, connecting rod, and joint pushes the volume of the fluid in the cylinder through an outlet valve. The liquid enters and leaves the cylinder through check valves. Reciprocating pumps are suitable for applications where very high pressures are required, or where abrasive fluids, such as acids or viscous liquids, have to be pumped.

Rotary Pumps

In rotary pumps, the impeller rotates within an enclosing structure and imparts energy to the water. The impeller can be in the shape of a gear, screw, or lobes. For rotary pumps, the output is continuous and smoother compared to reciprocating pumps. Rotary pumps are better suited for lower pressures than reciprocating pumps because of slippage at higher pressures. Rotary pumps can jam if any solids enter the small clearance spaces between the impeller and casing. Rotary pumps are suitable for handling fluids of varying viscosities and are used in water treatment for chemical dosing.

OPERATION OF CENTRIFUGAL PUMPS

Because centrifugal pumps are so widely used in water distribution and because so many brands are available, the individual procedures for proper operation vary. Most manufacturers supply instructions, guidelines, or manuals with a new pump. Users must follow these instructions while operating pumps.

Pump Starting and Stopping

During pump startup, check the lubrication of the motor bearings and prime the pump. After priming, the pump must be started with the discharge valve fully closed. The discharge valve must then be opened slowly to allow any air in the system to escape. The pump discharge valve must be opened and closed slowly to prevent water hammer in the system. (For more information about water hammer, see the *Tech Brief* in the Winter 2003 *On Tap*.)

During power failure (when the motor stops running), the discharge valve can remain open. This might be a problem because the water can actually flow backward. On large pumps, emergency power operated valves are provided to prevent the impellers from running in reverse. On smaller pumps, check valves are provided.

If the pump will be shut down for longer periods, additional steps should be taken. In cold weather, for example, all water must be drained out from the pump to prevent freezing. The pump packing or seal must be removed if the pump is to be stored idle for longer periods.

Centrifugal Pump Maintenance

Centrifugal pumps require regular inspection and maintenance. Bearings on the motor may become worn and must be checked and kept well lubricated. The packing or seal can wear out due to friction resulting in leakage from the pump. These should be checked regularly. Bearing and motor temperatures must be monitored. If a surface is substantially hotter than normal, the unit should be shut down and the cause of excessive heat investigated. In case of any unusual noises or vibrations from the pump, it must be stopped and the cause investigated.

WHAT ABOUT SAFETY?

Safety instructions provided by the manufacturer must be followed. Pumps should always be switched off before any maintenance. All liquids must be drained out before servicing. People must stand away from any moving parts. Safety precautions must be taken regarding electrical motors. Maintenance personnel must wear rubber gloves and use insulated tools while servicing electrical motors. A record of all maintenance work must be maintained.

Concern that the water supply could be vulnerable to terrorist attacks has understandably been heightened by recent world events. Knowledge, planning, and preparedness helps relieve this concern. It is crucial now to regularly inspect the location, accessibility, and operation of all the pumps in the distribution system. A large-scale disruption in water supply for a large water system can happen because of pump failure at a key location. After gathering complete and accurate information on all the pumps in the system, the utility manager can run through "what if" scenarios to determine where a contaminant is likely to move. Workers can also learn how water movement can be controlled by running or shutting down pumps or other utility operations.

HAVE YOU READ ALL OUR TECH BRIEFS?

Tech Briefs, drinking water treatment and supply fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) publication *On Tap* for more than seven years.

A package of *Tech Briefs* is now available as a product. A three-ring binder holds all the current *Tech Briefs* in print. New selections can easily be added to the package as they become available. To order this free product, call the NDWC at (800) 624–8301 or (304) 293–4191 and ask for item #DWPKPE71.

You also may order online at *ndwc_orders@mail.nesc.wvu.edu* or download fact sheets from our Web site at www.ndwc.wvu.edu. (Additional copies of fact sheets are free; however, postal charges may be added.)

RADIONUCLIDES

National Drinking Water
Clearinghouse

Radionuclide contamination of drinking water is a significant, emerging issue. Until now, manmade radioactivity in drinking water has not been a major problem. Natural sources have been the primary cause of contamination. However, the potential for contamination exists throughout the country as releases from medical facilities or nuclear power plants may wind up in drinking water. Because of their potential health effects and widespread occurrence, natural radionuclides—including radon, radium, and uranium—cause much concern.

WHERE DO RADIONUCLIDES OCCUR, AND WHAT ARE THE PUBLIC HEALTH RISKS?

Radionuclides occur naturally as trace elements in rocks and soils as a consequence of the "radioactive decay" of uranium-238 (U-238) and thorium-232 (Th-232). This decay happens because radioactive atoms have too much energy. When radioactive atoms release or transfer their extra energy, it is called decay. The energy they release is called ionizing radiation, which may be alpha particles, beta particles, or gamma rays. This energy is transmitted through space or another medium in waves (e.g., x-rays or gamma rays) or particles (e.g., electrons or neutrons) and is capable of either directly or indirectly removing electrons from atoms, thereby creating ions, which are electrically charged atoms.

Radon-222, radium-226, radium-228, uranium-238, and uranium-234 are ions of the U-238 and Th-232 decay series. They are the most common radionuclides found in groundwater. Other naturally occurring radionuclides tend to be environmentally immobile or have short half-lives, meaning they are far less likely to be found in significant amounts in groundwater.

When ionizing radiation strikes a living organism's cells, it may injure the organism's cells. If radiation affects a significant number of cells, the organism may eventually develop cancer. Or at extremely high doses, it may even die.

Radon. Radon is a naturally occurring radioactive gas that emits ionizing radiation. National and international scientific organizations have concluded that radon causes lung cancer in humans. Ingesting drinking water that contains radon also presents a risk of internal organ cancers, primarily stomach cancer. The U.S. Environmental Protection Agency (EPA) and the U.S. Surgeon General recommend testing indoor air for radon in all homes and apartments located below the third floor. If you smoke and your home has high indoor radon levels, your risk of lung cancer is especially high.

Tap water only emits approximately 1 to 2 percent of the radon found in indoor air. However, breathing radon from this source increases the risk of lung cancer over the course of a lifetime.

Radium. Radium-226 and radium-228 are natural groundwater contaminants that usually occur at trace levels. At high exposure levels, radium-226 and radium-228 can cause bone cancer in humans and are believed to cause stomach, lung, and other cancers as well.

Uranium. Uranium is a naturally occurring radioactive contaminant that is found in both groundwater and surface water. At high exposure levels, uranium is believed to cause bone cancer and other cancers in humans. EPA also believes that uranium can be toxic to the kidneys.

Table 1. What Regulations Govern Radionuclides?

Radionuclide National Primary Drinking Water Regulations						
		EPA Standards				
Contaminants	Drinking Water Health Effects	Proposed Maximum Contaminant Level Goal MCLG	Proposed Maximum Contaminant Level (MCL)	Current MCL	Sources	Best Available Technology (BAT)[2]
Radium-226	Cancer	Zero	20 pCi/L	5 pCi/L combined with radium-228	Naturally occurring	Ion Exchange (IE); Lime Softening (LS); Reverse Osmosis (R0)
Radium-228	Cancer	Zero	20 pCi/L	5 pCi/L combined with radium-226	Naturally occurring	IE; LS; RO
Radon-222	Cancer	Zero	300 pCi/L	–	Naturally occurring	Aeration
Uranium	Kidney toxicity, Cancer	Zero	20 ug/L[3]	–	Naturally occurring	Coagulation/ Filtration; Anion exchange; LS; RO[4]
Adjusted gross alpha emitters	Cancer	Zero	15 pCi/L	15 pCi/L	Naturally occurring and manmade	RO
Gross beta and photon emitters	Cancer	Zero	4 mrem ede/yr	4 mrem ede/yr any organ or whole body	Naturally occurring	IE; RO

1. *PicoCuries per liter* (pCi/L) is an activity measurement of radioactive decay (1 pCi/L = 2.2 disintegrations per minute); *micrograms per liter* (μg/L) is a mass measurement; *mrem* is measurement of effective radiation dose to organs.
2. Except as noted, BAT for the purpose of issuing variances is the same as BAT for compliance.
3. 20 μg/L is based on kidney toxicity. 20 μg/L is the equivalent of 30 pCi/L.
4. *Coagulation/Filtration* and *Lime Softening* are not BAT for small systems (those with fewer than 500 connections) for the purpose of granting variances.

Note: EPA recognizes that most radionuclides emit more than one type of radiation as they decay. The lists of compounds labeled “alpha” or “beta” emitters identify the predominant decay mode.
Note: In this document the unit mrem ede/yr refers to the dose ingested over 50 years at the rate of 2 liters of drinking water per day.
Source: U.S. Environmental Protection Agency, 1991.

Gross Alpha. Alpha emitters naturally occur as radioactive contaminants, but several come from manmade sources. They may occur in either groundwater or surface water. At high exposure levels, alpha emitters are believed to cause cancer in humans.

Beta and Photon Emitters. Beta and photon emitters are primarily manmade radioactive contaminants associated with operating nuclear power plants, facilities that use radioactive material for research or manufacturing, or facilities that dispose of radioactive material. Some beta emitters occur naturally. Beta and photon emitters primarily occur in surface water. At high exposure levels, beta and photon emitters are believed to cause cancer in humans.

WHAT ARE THE TREATMENT TECHNOLOGIES FOR RADIONUCLIDES?

Whether or not a particular treatment technology effectively removes radionuclides from drinking water depends on the contaminant’s chemical and physical characteristics as well as the water system’s characteristics (e.g., source water quality and water system size). Other considerations include cost, service life, and co-treatment compatibility.

Table 2. Technologies for Radionuclides

Unit Technology	Limitations (See Footnotes)	Operator Skill Level Required[1]	Raw Water Quality Range and Considerations[1]
1. Ion Exchange (IO)	(a)	Intermediate	All groundwater
2. Point of Use (POU) IO	(b)	Basic	All groundwater
3. Reverse Osmosis (RO)	(c)	Advanced	Surface water usually requires prefiltration
4. POU RO	(b)	Basic	Surface water usually requires prefiltration
5. Lime Softening	(d)	Advanced	All water
6. Green Sand Filtration	(e)	Basic	
7. Co-precipitation with Barium Sulfate	(f)	Intermediate to Advanced	Groundwater with suitable water quality
8. Electrodialysis/Electrodialysis Reversal		Basic to Intermediate	All groundwater
9. Pre-formed Hydrous Manganese Oxide Filtration	(g)	Intermediate	All groundwater

[1] National Research Council (NRC). "Safe Water from Every Tap: Improving Water Service to Small Communities." National Academy Press. Washington, DC. 1997.

Limitations Footnotes

a. The regeneration solution contains high concentrations of the contaminant ions. Disposal options should be carefully considered before choosing this technology.

b. When POU devices are used for compliance, programs for long-term operation, maintenance, and monitoring must be provided by the water utility to ensure proper performance.

c. Reject water disposal options should be carefully considered before choosing this technology.

d. The combination of variable source water quality and the complexity of the chemistry involved in lime softening may make this technology too complex for small surface water systems.

e. Removal efficiencies can vary depending on water quality.

f. This technology may be very limited in application to small systems. Since the process requires static mixing, detention basins, and filtration; it is most applicable to systems with sufficiently high sulfate levels that already have a suitable filtration treatment train in place.

g. This technology is most applicable to small systems that already have filtration in place.

Source: Environmental Protection Agency, 1998.

EVALUATION OF TECHNOLOGIES

The following treatment technologies were evaluated for their ability to remove radionuclides from water:

- ion exchange (IE);
- point-of-use (POU) IE;
- point-of-entry (POE) IE;
- reverse osmosis (RO);
- POU RO; POE RO;
- lime softening (LS);
- greensand filtration;
- co-precipitation with barium sulfate;
- selective sorbents;
- electrodialysis/electrodialysis reversal (ED/EDR); and
- preformed hydrous manganese oxides (HMOs).

Ion Exchange. Small systems may readily use IE treatment, which removes approximately 90 percent of radionuclides. The effluent must be regularly monitored and the resin must be frequently regenerated to ensure that breakthrough does not occur. Ion exchange units may be controlled automatically, requiring less of the operator's time. However, it is necessary to employ a skilled operator to determine when regeneration is needed and to troubleshoot. Also, disposal of concentrated radionuclides can be expensive.

Ion exchange treatment generates wastes that include rinse and backwash water, and the resin. The rinse and backwash liquid waste includes brine, radium, and any other contaminants that the process removes.

Cation Exchange. A cation is a positively charged ion. Cation exchange resins exchange like-charged ions equally with protons—sodium ions (Na+), or in sodium-restriction cases, potassium ions (K+)—to remove undesirable cations from water. Cation exchange is often used to remove calcium and magnesium cations, and to treat hard water.

The amount of waste (rinse and backwash) that cation exchange typically generates ranges between 2 and 10 percent of the treated water.

Lime Softening. Lime softening can be used to remove radium from drinking water with 80 to 95 percent efficiency. Also, adding lime or lime-soda ash to water increases the pH of the water and induces calcium carbonate and magnesium hydroxide precipitation. Lime softening also is used to treat hard water.

Lime softening generates wastes that include lime sludge, filter backwash liquid and sludge, and sludge supernatant.

Reverse Osmosis (RO). Reverse osmosis effectively removes many inorganic contaminants, including heavy metals and radionuclides, such as radium and uranium. RO can remove 87 to 98 percent of radium from drinking water. Similar elimination can be achieved for alpha particle activity and total beta and photon emitter activity.

When using an RO system to remove radionuclides, performance depends on a number of factors, including pH, turbidity, iron/manganese content of the raw water, and membrane type. The pretreatment design depends on the quality and quantity of the source water. Existing treatment plants may already provide much of the required pretreatment—for example, coagulation/filtration of highly turbid surface water or iron removal for well waters. RO can be cost effective for small systems.

TECHNOLOGIES FOR RADIONUCLIDE REMOVAL NOT PROPOSED AS BAT IN 1991

Greensand Filtration for Radium Removal

Greensand filtration technology consists of a conventional filter box with manganese greensand replacing the traditional filtration medium. Studies indicate that greensand filtration removes up to 56 percent of radium.

This process generates wastes that include sludge and supernatant from the filter backwash, and eventually the greensand media must be disposed of.

PREFORMED HYDROUS MANGANESE OXIDE (HMO) FILTRATION

Costs for HMO treatment can be quite low, if filtration is already in place.

HMO filtration is similar to oxidation/filtration in its complexity and the operator skill it requires. Proper dosages must be determined, and if water quality varies, the dosage must be recalibrated. Once the proper dose is determined, dosing is relatively easy. HMO filtration requires simple equipment and is fairly inexpensive. Filters must be backwashed, which may require intermediate operator skill. Radium containing wastes include HMO sludge, filter backwash, and sludge supernatant.

CO-PRECIPITATION OF RADIUM WITH BARIUM SULFATE

Adding a soluble barium salt—such as barium chloride—to radium and sulfate contaminated water causes co-precipitation of a highly insoluble radium-containing barium sulfate sludge. This process has primarily been used for wastewater treatment. Mine wastewater treatment data indicates that this process removes up to 95 percent of radium.

This process generates wastes that include the barium sulfate precipitate sludge, filter backwash, and sludge supernatant.

OTHER TECHNOLOGIES

Some other technologies also are available that may remove radionuclides from drinking water. However, these technologies have not been fully tested for drinking water treatment or have only been used in industrial or experimental situations. Examples of processes that remove radium include selective sorbents (e.g., acrylic fibers or resins impregnated with manganese dioxide) and non-sodium cation exchangers (e.g., hydrogen ions and calcium ions).

HAVE YOU READ ALL OUR TECH BRIEFS?

"Tech Briefs," drinking water treatment fact sheets have been a regular feature in the National Drinking Water Clearinghouse (NDWC) newsletter *On Tap* for more than four years. NDWC Technical Assistance Specialist Mohamed Lahlou, Ph.D., researches, compiles information, and writes these very popular items.

To order, call the NDWC at (800) 624-8301 or (304) 293-4191. You may also order online at ndwc_orders@mail.estd.wvu.edu or download fact sheets from our Web site at *www.ndwc.wvu.edu.*

Additional copies of fact sheets are free; however, postal charges may be added.

For further information, comments about this fact sheet, or to suggest topics, call Lahlou at one of the above numbers or contact him via e-mail at mlahlou2@wvu.edu.

USE OF REDOX POTENTIALS IN WASTEWATER TREATMENT

Enos C. Inniss
University of Texas
San Antonio, Texas

INTRODUCTION

Effective process control requires an understanding of where the process is with respect to reaction potential and completion. Online measurements allow for greater monitoring of the state of the process from flowrates to chlorine residuals. A measure of dissolved oxygen in the system is useful until anoxic and anaerobic conditions are encountered. Once those environmental conditions are achieved, as is the case with biological nutrient removal (BNR), the ability to measure a wider range of conditions may be achieved with oxidation–reduction potential (ORP).

BASICS OF OXIDATION–REDUCTION REACTIONS

Oxidation–reduction reactions also referred to as redox or oxido reduction involves the transfer of electrons and provides microorganisms with their free energy during transformations. The energy exchange is usually in the form of ATP (adenosine triphosphate), where the energy is in the bonds between the phosphoryl groups. Both aerobic and anaerobic metabolism produce ATP, but the anaerobic rate of production is much lower than that of the aerobic process.

The redox reaction typically transfers electrons from an electron donor (ED) to an electron acceptor (EA), where two half-reactions (or redox couples) can be derived to show the movement of the electron (Fig. 1). By taking the electron, the EA gains a net negative charge, while the ED loses an electron and gains a net positive charge.

THE NERNST EQUATION

The redox potential (ΔE) can be viewed as the electron pressure or the degree of tendency for electrons to be transferred and is defined by the Nernst equation (Fig. 2). The standard redox potential, ΔE°, is defined as the difference between the reduction potentials of the electron acceptor and donor when all components are in their standard state ($\Delta E^\circ = E^\circ_{\mathrm{EA}} - E^\circ_{\mathrm{ED}}$). This reduction potential is measured with respect to the hydrogen half-reaction.

Biochemical standard state (E° at pH 7) for the hydrogen half-reaction is -427 mV (negative 427 millivolts).

$$\mathrm{EA} + e^- \rightleftharpoons \mathrm{EA}^{(-)} \quad \text{reduction}$$

$$\mathrm{ED} \rightleftharpoons \mathrm{ED}^{(+)} + e^- \quad \text{oxidation}$$

Figure 1. Generic reduction and oxidation half-reactions (1).

$$\Delta\varepsilon = \Delta\varepsilon^\circ - \frac{RT}{n\mathscr{F}} \ln\left(\frac{[\mathrm{ED}^{(+)}][\mathrm{EA}^{(-)}]}{[\mathrm{ED}][\mathrm{EA}]}\right)$$

where
R = universal gas constant,
T = temperature,
n = 1 mole of electrons, and
$\mathscr{F}$ = faraday, the charge of 1 mole of ?

Figure 2. The Nernst equation for redox potential (1).

The more positive the half-reaction, the greater the tendency for the oxidized form to be reduced and therefore the electron acceptor is defined (1).

TYPICAL RANGES FOR REDOX POTENTIAL IN BIOLOGICAL SYSTEMS

The wastewater treatment process involves a multitude of environmental conditions in order to achieve complete treatment of influent constituents. Each of these general environmental conditions may be defined by several ranges of redox potentials (Fig. 3). As a general rule of thumb, readings taken with an ORP electrode that are less than -200 mV are indicative of anaerobic or reducing conditions. ORP readings between approximately -200 and $+200$ mV are for anoxic conditions. Aerobic or oxidative conditions are present above $+200$ mV.

The typical wastewater processes for the anaerobic range include sulfate reduction, occurring primarily in the collection system, and methanogenesis and fermentation, which are more typical of the anaerobic digestion process. This range is defined by sulfate as the primary terminal electron acceptor. The anoxic range is useful for biological nutrient removal, where nitrate serves as the dominant terminal electron acceptor. The aerobic range involves the activated sludge process and disinfection, where oxygen or the disinfectant serves as the terminal electron acceptor (2,3).

NUTRIENT REMOVAL

For biological nutrient removal (BNR), there is a need to switch between anaerobic/anoxic conditions and aerobic

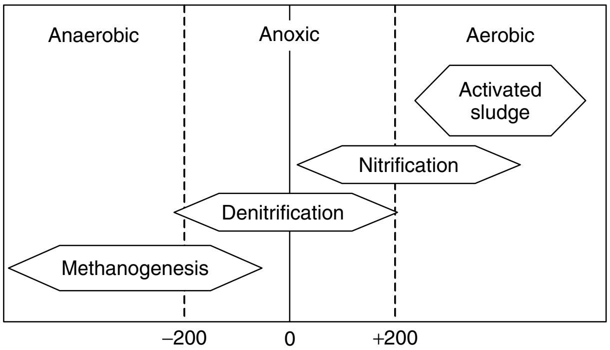

Figure 3. Redox potential ranges (mV) for typical wastewater processes. (Modified from References 2 and 3).

conditions to achieve complete removal of nitrogen and phosphorus compounds from the water. For phosphorus removal, anaerobic conditions result in a release of orthophosphate to gain energy by using up ATP. The higher energetics of aerobic metabolism then causes phosphorus uptake, so that the microorganisms can store the energy. Similarly, anoxic/anaerobic conditions allow for the conversion of nitrate and nitrite to nitrogen gas, while aerobic conditions allow for the oxidation of ammonia to nitrite and nitrate. Controlling these two processes, denitrification and nitrification, respectively, requires the ability to switch and establish the proper environmental conditions. ORP readings afford the operator greater control over these conditions (4–6).

OTHER POTENTIAL APPLICATIONS

Other applications for ORP monitoring and control are currently being researched and implemented. Waste-activated sludge hydrolysis may be enhanced to increase its bioavailability during sludge handling (7–9). Dosing may be controlled in the disinfection process (10). Aeration may be controlled and thus the organism growth influenced in the activated sludge process (11).

CONCLUSION

With increasingly better electrode technology and online monitoring and data storage capability, process control using ORP has a future in reducing operational cost and improving operational efficiency.

REPAIRING DISTRIBUTION LINE BREAKS

VIPIN BHARDWAJ
NDWC Engineering Scientist

Occasionally, water systems encounter situations where they must repair distribution system pipes. Corrosion and tuberculation (i.e., buildup of sediment, dirt, or rust) may have caused small leaks in the lines, or worse, a major line break may occur, creating an emergency situation. This Tech Brief discusses ways to manage these situations and outlines steps a utility may take to repair the distribution system.

WHAT CAUSES PIPES TO BREAK?

Distribution lines can break for a variety of reasons. Excessive weight, such as increased traffic continuously running over a buried pipe, can trigger a line break. Also, extremely cold temperatures can cause breaks because when water freezes, it expands. But environmental conditions are not the only reason a line may break.

Sometimes utility workers may unknowingly install pipes that have defects from the manufacturing process, and they are not strong enough to handle high-pressure surges. Consequently, the pipes may split or crack. Other times pipes may not have been properly installed into the trench, creating a situation where it's only a matter of time before a line bursts.

Corrosion and tuberculation are two more reasons that pipe can rupture. Corrosion may cause breaks or leaks because acidic conditions can cause pitting or holes in a metallic pipe. In addition, tuberculation can cause high-pressure pockets in some areas of pipe, because water that's under pressure may not be able to easily move beyond the area of buildup.

WHEN ARE REPAIRS NEEDED?

Over time, even small leaks can waste a substantial amount of water, which is expensive. When water system personnel detect a leak, they should repair it immediately—no matter how small it is.

When water comes out of the ground, it is obvious a leak exists nearby and its location is fairly easy to determine. However, scheduling periodic leak detection exercises helps water systems determine where and when they should make repairs in situations that aren't so obvious.

Because most leaks are not visible, all a utility worker may know is that the system is losing water. Someone then has to find the leak. This involves using listening devices, such as Geophones® or other electronic equipment. (For more information about leak detection, see the *Tech Brief* in the Spring 2001 *On Tap*, and the article, “On the Trail of the Elusive Water Leak” in the Summer 2003 *On Tap*.)

One of the best ways to trace water loss is to conduct a water audit. A water audit helps systems keep unaccounted for water loss to the recommended 15 percent or less of the total water a system produces. Conducting a water audit and following up on the results can help the utility control its water losses. (For more information about water audits, see the Fall 2002 *On Tap* article, “The Economics of Water Loss: What is unaccounted for water?”).

To conduct a water audit, utility workers will need to take flow measurements over a 24-hour period. This task will require pressure gauges. Utility workers also should make sure to check meters on main lines first to see if they are accurate and calibrated. As water flows from main lines into smaller lines, utility workers take flow measurements at a number of points in the smaller lines. Large, unaccounted for nighttime flows indicate a leak.

EMERGENCY REPAIRS

Sometimes leaks aren’t small. Sometimes they gush. If a main breaks, utility workers must repair it immediately. To avoid too much stress, utilities need to have a plan of action ready that details the necessary equipment, personnel, and procedures. This plan is usually referred to as an emergency response plan (ERP) and should involve law enforcement, fire protection, and city officials because utility personnel must first figure out if the leak poses a hazard to life or property.

As soon as a major break is detected, utility workers should notify customers that their water will be turned off while workers make repairs. Valves must first be shut off in the area to isolate the break and to prevent further water loss.

More often than not, valves can become hard to close or may even break if they are not used on a regular basis. Systems should have regular valve-exercising and hydrant-flushing programs to alleviate this problem. (For tips about developing a valve-exercising program, see the article, “Why bother with a valve-exercising program?” in the Winter 2004 *On Tap*. For more information about hydrant flushing, see “Fire Hydrant Operation and Maintenance,” in the Fall 2002 *On Tap*).

If possible, repair the leak without shutting off the entire water supply. Figure 1 shows a section of a distribution system with an arrangement of four valves. The leak is near a corner before valve 2. Water flow is from left to right through the loop. When making repairs, close valve 4, valve 3, and valve 2, keeping valve 1 open till the very last minute (Fig. 3). Valve 1 is then closed slowly. Utility workers then make repairs on the leak and turn the water back on immediately. Closing the valve nearest the leak at the last minute allows the line to remain under pressure, preventing back siphoning and back pressure that can cause contaminants to get sucked in through the leak.

If, however, the valves cannot be opened and, consequently, the water cannot be turned off, one practice is to open several fire hydrants in the area. While this method will not stop the water, it will lower the water pressure enough that utility workers can repair the leak. Once the repairs have been completed, workers then slowly turn the water back on. Turning the water back on slowly ensures that water hammer will not become a problem.

Water hammer is a hydraulic shock that happens when a sudden change in velocity occurs, such as quickly closing a valve. Shock waves occur within the pipes, which travel back and forth and cause a “bang” within the pipe. This bang is the hammer that can cause pipes to burst. (See the *Tech Brief* about water hammer in the Winter 2003 *On Tap*.)

When a line is under pressure, less probability exists for contaminants to get in through the break. But if contamination does occur, the utility should take the appropriate actions to inform the public through local radio, TV, or other new service. Notification should outline

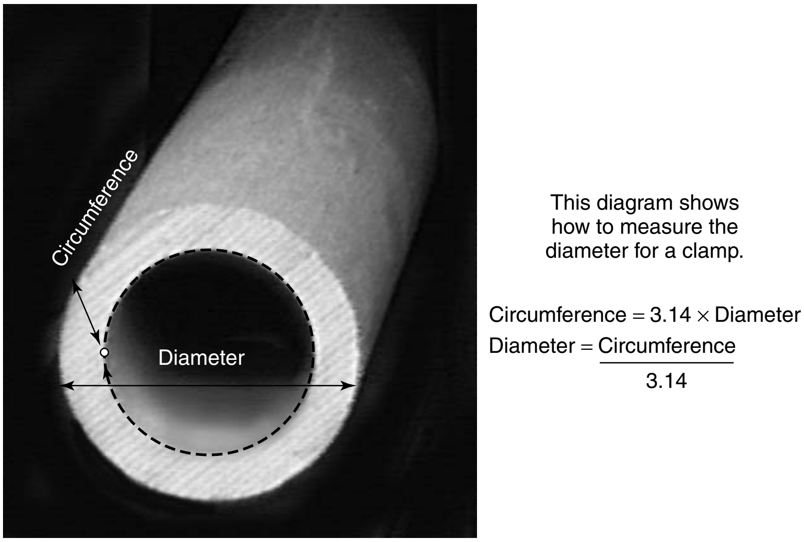

Figure 1. Calculating diameter from circumference. *Source*: *Water Transmission and Distribution*, AWWA, 2nd Edition.

steps customers can take to be sure their water is safe. In case of an emergency, utilities should refer to their ERP that should specifically outline what they need to do. For example, they also may need to notify state primacy agencies, depending upon what level of action they need to take.

DIGGING UP THE PIPE

Once utility workers detect the leak, they have to dig up the pipe. The trench must be parallel to the pipe on both sides and be deep enough that a person can work around the pipe to repair it. Workers must calculate the trench's depth and width based on pipe size. Water will collect in the pit and will have to be pumped out.

Utility workers also should remember that it's an Occupational Safety and Health Administration (OSHA) rule to shore the trench if it's five feet or deeper—or less than five feet if the conditions warrant it, such as extremely sandy or muddy soil.

REPAIR METHOD

If the break in the pipe is very large, that portion of the pipe will have to be cut off and a new section put in place. Cutting a pipe requires saws, pipe cutters, welding equipment (if the pipes are made of steel), pipe wrenches, couplings, and other hand tools.

If the break in the pipe is small, such as a rupture across the pipe, utility workers can wrap a flexible clamp or sleeve on it, which acts like a bandage for the pipe. Wrapping a coupling around the pipe, which is a device that holds two separate pieces of the pipe together in a "covering" device, is another way to repair a small break (see Fig. 2).

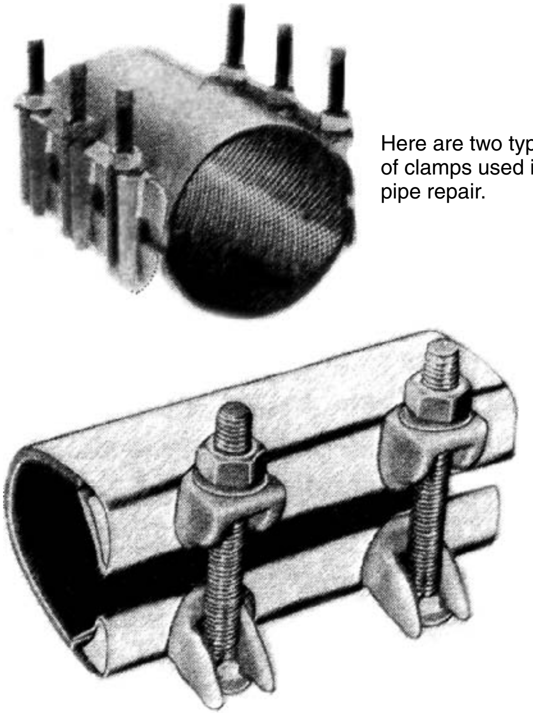
A clamp installed on the pipe has a gasket (usually made of rubber) that covers the ruptured section and helps to maintain a secure fitting. There is an arrangement of screws (preferably stainless steel) that are tightened around the clamp. Utility workers will need to clean and scrape corrosion and dirt from the pipe surface and then disinfect it with bleach.

In addition, they should measure the outside circumference of the pipe to determine the exact diameter of a coupling. (The diameter is equal to the circumference divided by 3.14159.)

After the pipe is repaired, workers should turn on the water slowly to check if there are any remaining leaks. The trench is typically covered with filling material, such as sand, crushed stone, or processed material, and compacted. The workers should ask system customers to turn on their taps and allow the water to run for some time because the water may or may not have sediment in it.

BEING PREPARED

A water utility should have an emergency vehicle, such as a pickup truck, stocked with essential tools, including pipe cutters, wrenches, shovels, traffic control equipment, barricades, flashers, cones, and flashlights. This preparation will save time in an emergency. They should keep the truck's gas tank full and not loan out tools or equipment. Qualified individuals should be on call for emergency response at all times, including scheduled holidays.



Here are two types of clamps used in pipe repair.

Figure 2. Types of clamps. *Source*: *Water Transmission and Distribution*, AWWA, 2nd Edition.

LAYING NEW PIPES

In some situations, a utility may have to replace an entire pipeline. New pipes may have to be hauled in and installed. Care must be taken to prevent pipes from breaking during shipping or storage, and the pipes must be installed correctly. Approvals or permits from the relevant state or local agency must be obtained before starting a new project.

Pipes should be placed where they will be installed before digging out the trench. One end of a pipe is shaped like a bell, and the other end is straight. Pipes are joined together straight end into bell end and secured with a gasket. Pipes should have their bell-shaped ends placed in the direction in which the installation of the pipe will proceed.

Excavating the earth to install pipes is the most expensive part of many replacement projects. Before beginning the repair project, other utility installations, such as sewer and gas lines, must be located. In addition, utility workers must notify nearby property owners and the general public.

Once the project is underway, utility workers must:

- determine the trench's width according to the pipe size required,

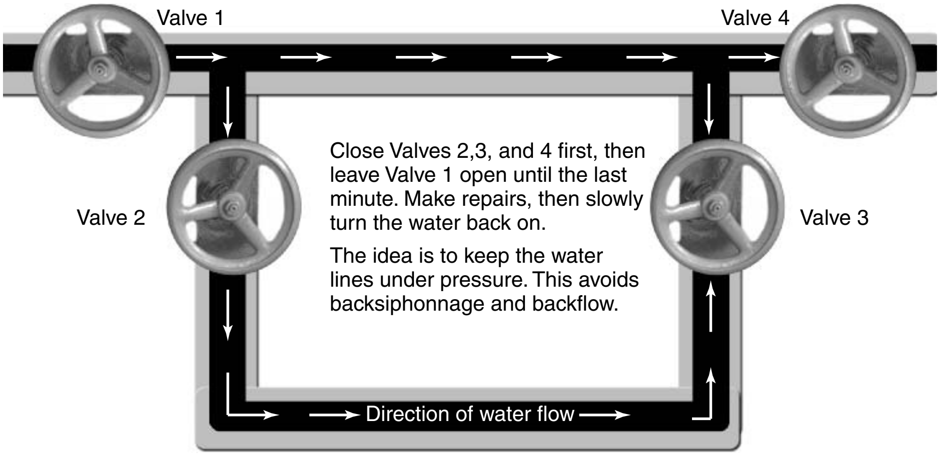


Figure 3. Overhead view of a distribution system. *Source*: *Operator Basics* CD, Montana Water Center.

- lower pipes carefully into the trench using ropes,
- dig out additional soil at the bell ends so that the pipe is supported along its entire length, and
- add some backfill material or bedding to the trench to support the pipe.

Pipes have gaskets on the bell-shaped ends. When laying new pipelines:

- the gasket must be clean, and
- pipes must be pushed all the way into the bell of an adjoining pipe to make a tight fit.

COMPLETING REPAIRS

Once workers have completed repairs, they should turn the water back on and check for leaks before backfilling the trench. The new lines should be disinfected and thoroughly flushed to remove all sediment and dirt.

According to the American Water Works Association's standards, water samples should be taken every 1,200 feet following a new installation. Samples must be bacteria free before the line can be put back into service. Workers should be sure to keep a record of where the repair needed to be made and its cause.

ROLE OF SMALL WATER RESERVOIRS IN ENVIRONMENT

Janusz Guziur
University of Warmia and
Mazury in Olsztyn
Olsztyn, Poland

> Motto:
> 'Water ... you are the greatest treasure ever existing in all the world'.
>
> (Antoine Saint-Exupery)

The earth's fresh water supplies are diminishing at a terrifying rate. The loss of fresh-water supply per capita has reached 40% since 1970.

The annual gross supply of water in the world per person is 10,000 m^3, 1500 m^3 in Poland, 2400 m^3 in Germany, and 2800 m^3 in France. These data converted into the water availability index in cubic meters daily per capita in some European countries are presented in Fig. 1 (1,2).

Melioration works (land improvement) completed in the past 50 years in many countries in Europe, Asia, or America have focused mainly on enlarging areas of farmland (increasing food production). They were intended to drain off water rapidly and dry and reclaim land. As a result, many natural watercourses have been replaced by drainpipes (ditches) and simple canals. Other water features have also disappeared, for example, small natural lakes and other small waterbodies, natural flood waters, midfield trees, and coppices. In Poland, 80% of small ponds and water mill dams have also been liquidated (3). Natural water retention potential has been distorted. As a result of declining available freshwater supplies in many areas of the world, interest is increasing in expanding the use of small water reservoirs.

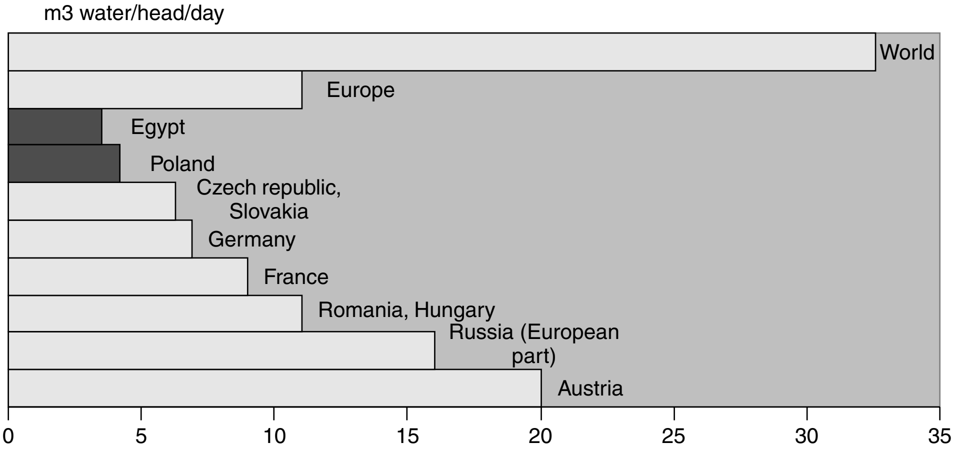

Figure 1. Water availability index in different European countries in cubic meters water per person daily (1).

The present situation calls for urgent action to reclaim lost properties in the natural environment. Natural landscape reclamation can be attained in two ways:

- *Natural Measures (Proecological, Nontechnical)*: by preserving small water reservoirs and cave-in lakes, natural wetlands and floodplains, village ponds and alike, as well as by planting forests, trees, and shelter belts in degraded areas.
- *Technical Measures*: by water retention, especially so-called small retention objects.

Natural retention means

- increased potential for water self-purification, accompanied by enriched landscape values.
- enhanced landscape attractiveness, which stimulates the development of ecotourism and also encourages the local population to enjoy living in more comfortable surroundings.

Of about 28 types of small natural inland water reservoirs and water ecosystems (4,5), wetlands known as marshes (swamps, bogs, wetlands, fens, mires) play a key role in the environment and water management. They are structural and functional waterlogged ecosystems that are transitional forms between typical land and typical water ecosystems. Features common to all marshy ecosystems are permanent or temporary waterlogging of the substrate, the presence of hydrophilous plants (hydrophytes), and specific soils. Such ecosystems are inhabited by rare plant and animal species and function as important flight paths for seasonally migrating birds as well as water plant habitats for nomadic species (6). They are also nesting and breeding areas for some rare species, frequently those on the verge of extinction (including endemic species). Owing to their specific soils and flora, marshes are often nicknamed 'kidneys of the landscape' or small wastewater purification plants (7).

The sanitary impact of wetlands on the environment is gaining in importance due to considerable contamination of surface and underground waters. A waterlogged area can function as a trap, source, or transformer of matter reaching it from the outside; each role depends on the type, age, and use of the ecosystem. Wetlands become traps mainly in spring and early summer. They are a source of phosphorus (P) when the vegetative season is ended (disappearing assimilation). Depending on the hydrologic type of supply, waterlogged areas are divided into four types (7):

- *Ombrogenic*: present in watershed zones, at the highest points, represented by high and transitional moors;
- *Topogenic*: present on lowlands and near lake areas as low, oligotrophic moors;
- *Soligenic*: marshy grounds in valleys near terraced parts of river valleys;
- *Fluviogenic*: riparian marshes, subject to the erosive impact of rivers, heavily bogged, with highly trophic (fertile) river sediments.

These types of wetlands have an exceptionally beneficial influence on the hydrologic regime of the terrain. In particular, they help retain water in the catchment, improve its water balance, and retain water in the countryside, which involves preventing water outflow from the catchment and rational time distribution of water (2,8). Wetlands also have an indirect positive effect on agricultural production (plant production) and pond fish culture (9).

In some countries, marshes and bogs cover large areas. In Poland, for example, natural and transformed marshes cover 13.1% of the country's total area (more than 4.3 million ha), of which 10.2% belongs to open (not forested) marshes, preserved in a nearly natural state.

More than 56% of Poland's natural and transformed marshes are contained in the European system ECONET Poland (European Ecological Network), where they constitute 16.7% of the total network area. The ECONET-PL network is composed of international and national core areas (that have a wealth of habitats and species) and ecological corridors. The latter are situated mainly in river valleys, providing links between core areas (7).

The most effective and currently desirable is the type of water retention that involves retaining the largest

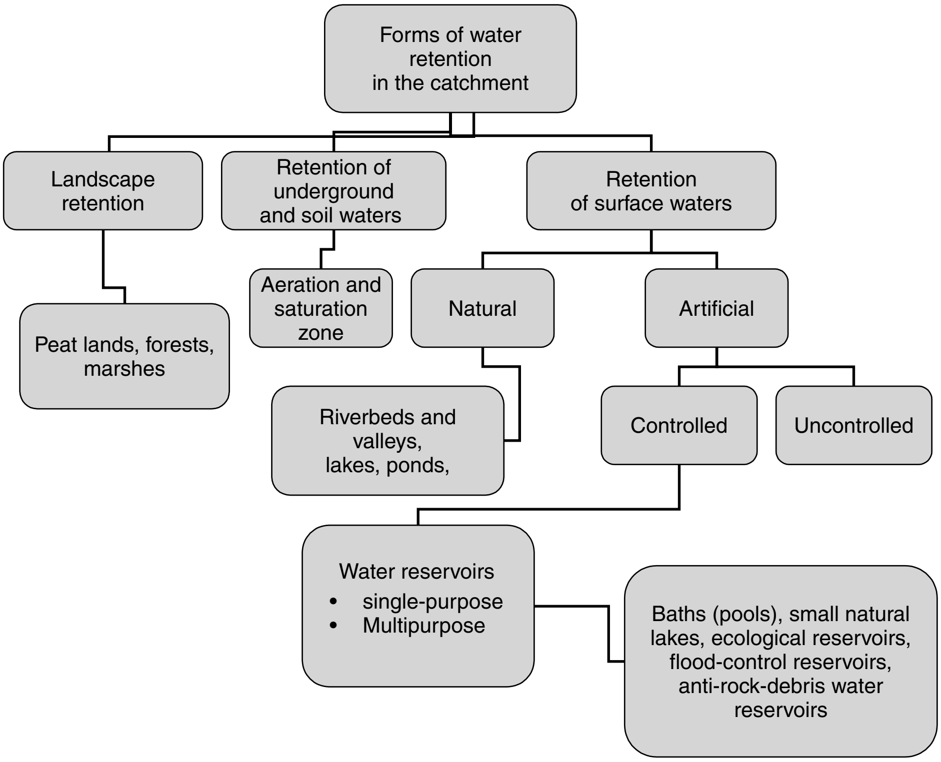

Figure 2. Basic forms of small retention in a catchment (10).

amounts of water possible in surface and near-surface water circulation systems using different measures. In short, the objective is to prevent unproductive water flow to the sea.

The total retention capacity of a catchment is the sum of individual elements that comprise many constituent forms of the catchment (Fig. 2). Economically, retention can be divided into natural and artificial forms (10). The major forms of natural retention include

–retention by river beds and valleys,

–retention by peatlands, marshes, and wetlands,

–retention by soil, underground, and surface waters,

–retention by stagnant waters—especially forest and soil retention.

Forest and soil retention are difficult to quantify. Estimates suggest that an increase in soil retention by 20 mm across 50% of the agricultural lands in Poland amounts to an additional 2 billion m^3 of water (11,12).

Artificial water retention consists mainly of retaining water in artificial reservoirs (e.g., dammed reservoirs in lowlands and mountains) and less often of lake retention obtained by artificial water lifting in natural lakes. Two types of retention are distinguished—uncontrolled and controlled. The latter is represented by artificial reservoirs of constant water lifting equipped with regulation devices, which enable water circulation control (10).

Small water retention relies mainly on waterbodies of different types. Waterbodies improve the water balance of a catchment; depress the level of flood waves, high water (after torrential rains), and thaw waves (in spring); increase low flows (summer drought seasons); and increase air humidity and soil moisture, thus improving the microclimate and conditions for arable crops.

Water reservoirs are objects that can be described by using measurable and nonmeasurable parameters. The following are most often used to compare waterbodies: size of retention (ha, m^3), runoff compensation ratio, type of regulation and discharge facilities, and hydraulic and economic functions (Table 1).

Development of water retention is an important element of integrated water management, particularly in terms of maintaining quality of water supplies and producing a positive effect on the outflow and levels of water from its surface, which in turn has some influence on the formation and shape of flood tides.

In addition, retention objects perform a variety of other tasks and functions, of which the most important are

- industrial water supply (e.g., water intake),
- fire protection
- relaxation, sports, and recreation,
- fisheries (professional and amateur),
- landscape and environmental management.

Surface water retention is attained through the following activities:

- construction and reconstruction of water reservoirs,
- construction of water lifting installations in rivers,
- filling fish ponds (especially larger pond complexes),
- water retention in amelioration installations and systems,

Table 1. Classification of Storage Reservoirs[a]

Classification Criteria	Size and Type of Reservoirs			
Retention size	**Small**		Medium	Large
Height of a dam (m)	From **5**		5 to 15	Over 15
Water capacity (m^3)	to **100,000**		to 500,000	Over 500,000
Runoff compensation (below the reservoir)	Long-term	Seasonal	Annual	Daily
Number of functions	Single-purpose[b]		Multipurpose[c]	
Hydraulic devices (discharge)	Uncontrolled : dry		Controlled: of a defined (set) water lifting level	

[a] References 10 and 13.

[b] Retention function (general).

[c] Potable water retention, flood control, irrigation of arable crops, recreational and water sport reservoirs, land melioration, electric power, sailing reservoirs, etc.

- water lifting in natural waterbodies (lakes),
- protection and management of small water reservoirs and cave-in lakes,
- flooding of valley depressions (bogs and marshes, cutoff meander lakes, old riverbeds).

The following water retention methods seem best for the natural environment:

Higher Water Retention on Areas Previously Ameliorated or Planned To Be Ameliorated

The primary objective is reconstruction of weirs on drainage ditches, which brings large contributions to water supplies [in Poland, about 500 million m^3: (11)]. The second stage comprises construction of small retention reservoirs at the end points of amelioration systems, that is, before water outflow to a river or sea. Some experts on hydrology and hydraulic engineering, however, claim that large retention reservoirs should not be built as long as 'all possibilities of constructing small retention reservoirs have not been exhausted.' It is also important to abandon amelioration of peat bogs or waterlogged meadows and pastures, which further improves water retention potential.

The most superior natural values are attributed to nonregulated rivers in undeveloped valleys. Such valleys contain a mosaic of different water ecosystems: cutoff meander lakes (old riverbeds), peat bogs, dry and moist meadows, and the so-called alder carrs (8,9). Flood control involves several methods that help preserve these unique natural water ecosystems. Of the two possible flood protection strategies—increasing water flow capacity of river valleys (hydraulic installations) or increasing water retention in the whole watershed—most specialists opt for the latter solution as more favorable for the natural environment (12,14,15). Of all methods for increasing water retention, the following seem recommendable from the viewpoint of preserving the natural environment:

Maintaining and Increasing Water Retention on Lands Used for Agricultural Production

The most important activities include doing without heavy agricultural machinery (which compacts arable layers of soil), plowing across the slope, creating terraces, not burning grass and stubble, and re-creating midfield water ponds.

Increasing Water Retention in Forested Areas

There is an array of activities available, including afforestation of lands with forest polycultures (monocultures have inferior water retaining capacity), safe transportation of felled trees (soil erosion risk), use of cable trains for transporting felled trees in mountainous areas, biological consolidation of streams, and no planning or building of main roads near streams and rivers. Despite numerous controversies, forests in river valleys are largely categorized as water protecting forests and therefore subject to less intense forest management practices.

Maintaining and Increasing Water Retention in River Valleys

It should be remembered that nonregulated rivers that have undeveloped valleys provide the highest natural values. Water retention measures undertaken in river valleys should be integrated with flood control. A partial solution that could reconcile flood control requirements with natural protection is the construction of so-called polders, waterlogged and nonreclaimable depressions. There are two types of polders: overflow polders that are flooded each time the water level rises (more favorable for protecting nature), and control polders (better for flood protection). Such solutions are used, for example, in Germany in the Rhine river valley near the water step in *Iffezheim* (16). Of all types of dammed reservoirs, dry reservoirs, which cause minimal changes in the hydrologic regime, are responsible for the smallest losses in river valley ecosystems. As far as wet reservoirs are concerned, small retention reservoirs are least damaging. According to Lewis and Williams (17), the least damage to the environment is caused by those wet reservoirs that are located in a river valley and are connected to the river by an inflow and an output canal.

To preserve ecosystems below a large reservoir, it is necessary to cause artificial floods (lasting a few days) that discharge large amounts of water in the spring. Natural and hydrologic effects of an artificial flood on the Colorado River in the United States (1996) are now a subject of wide research, so far yielding positive and promising results (18).

The water retention effects of the aforementioned measures are quite varied and, apart from typical retention reservoirs, rather limited. Their capacity for storing water (known as retention capacity) is usually measured in hundreds of thousands cubic meters of water (less frequently in millions of m^3). In Poland, objects whose capacity is less than 5 million m^3 are referred to as small retention objects (3,19).

Fish ponds—An Undervalued Element of Small Retention

Ponds are shallow artificial retention reservoirs, built in less fertile areas, usually waterlogged and agriculturally useless. Fish ponds make aquaculture possible, and they also facilitate ecological use of water and systematic water alimentation (permeation, leakage), more intense alimentation occurs when water is discharged in spring and summer and during the autumn fish catch. Pond objects are localized in the upper parts of a catchment and are supplied with water from small streams and by precipitation. Ponds significantly delay water outflow and make water flow more uniform in the whole watercourse (9,20) (Fig. 3).

Large fish pond objects and ponds of higher capacity (more than 1–2 thousand ha) located in lower parts of a catchment make it possible to store water and summer flood tides (so-called St John's floods—rains in midsummer), thus successfully alleviating the course of floods. In Europe, such pond complexes are found in the region of Milicz near Wrocław (5 thousand ha), and near Čs. Budějovic (22 thousand ha) in the south of the Czech Republic. The largest ponds in those complexes (regions) cover 100 to 700 ha (2,4,5,21,22).

The water retention potential of such pond, lies in the fact that they store water in those periods when it would otherwise flow away fruitlessly. Ponds are filled with water when the water level in rivers is the highest, meaning that it does not collide with the water uptake by other users (consumers). On the contrary, it has a positive effect on the whole water management in the catchment (23), and, particularly, on flood control. A clear example of the beneficial influence and protection against floods is the Czech pond Rožemberk (711 ha), built at the end of the sixteenth century and used for fish farming until today. In 1889 (and more recently in August 2002), it protected the town of Třeboň from a devastating flood and complete damage by spilling its waters over an area of 2,000 ha and storing more than 50 million m^3 water (3).

Figure 3. Small retention—fish ponds in Ostróda, Poland.

In Poland, for instance, there are about 71 thousand ha of fish ponds, including small ponds at farmsteads, which store about 900–950 million m^3 water, one-third of the country's total water retention (2). Regardless of these figures, many countries of central Europe pay little attention to the role of ponds and possible inclusion of fish ponds in water and amelioration systems when planning water management, and local water retention projects, in particular (4). Such notorious underestimation of the nonproductive value of fish ponds results from an erroneous assumption that fish ponds are exclusively fish production reservoirs. The truth is that, apart from their fish breeding function, they have more than 50 positive characteristics in terms of water management, agriculture, environmental protection, landscape values, water sports, angling, and professional or economic stimulation of the local population (5,22,24–27). Therefore, such merits can often exceed the primary fish breeding value of ponds in their economic assessment (28).

In general, dammed retention reservoirs significantly alter the river valley landscape, although they can also create suitable nesting and feeding areas for fish and birds, once islets and shallow shores are formed. This effect can partly compensate for the losses in the natural environment caused by construction of dammed reservoirs.

It should be added that the European Union has accepted the 'Habitat Directive' to preserve, nearly unchanged, valleys of large rivers and adjacent small reservoirs and floodplains with their wealth of ecosystems. The high diversity of species in such areas is further protected by the Convention on Biodiversity Protection, signed in 1992 by many European countries, including Poland (7,15).

RESERVOIRS, TOWERS, AND TANKS DRINKING WATER STORAGE FACILITIES

VIPIN BHARDWAJ
NDWC Engineering Scientist

CHRIS METZGAR
Graphic Designer

After water leaves the treatment plant but before it reaches the customer, it must be adequately and safely stored. This Tech Brief explores the various aspects of water storage.

A water distribution system transports water from the treatment facility to the user. The distribution system should supply water, without impairing its quality, in adequate quantities and at sufficient pressures to meet system requirements.

The facilities that make up the distribution system include finished water storage; pumping, transmission and distribution piping supply mains; and valves.

Storage facilities—such as reservoirs, towers, and tanks—provide storage for treated water before it is distributed. The water distribution system should have storage so that it is capable for basic domestic purposes, commercial and industrial uses, and to accommodate the flows necessary for emergencies such as fire fighting.

STORAGE RESERVOIR FUNCTIONS

Service reservoirs provide the following functions:

- provide a reserve of treated water that will minimize interruptions of supply due to failures of mains, pumps, or other plant equipment;
- help maintain uniform pressure;
- provide a reserve of water for fire fighting and other emergencies;
- act as a relief valve on a system of mains supplied by pumping;
- permit a reduction in the size of distribution mains below that which would be required in the absence of a reservoir; and
- allow pumping at the average rather than peak flow rate.

CLASSIFICATION OF STORAGE REQUIREMENTS

Storage volume requirements are classified by function: operating, equalizing, fire and/or emergency, and dead-storage volumes. Engineers must consider these individual volume components in combination to determine the total volume of storage capacity that is required for any system. The total storage required is typically the sum of all these functions.

Rather than requiring both fire and emergency storage, some local fire and state agencies allow systems to use the larger of either fire or emergency storage volumes.

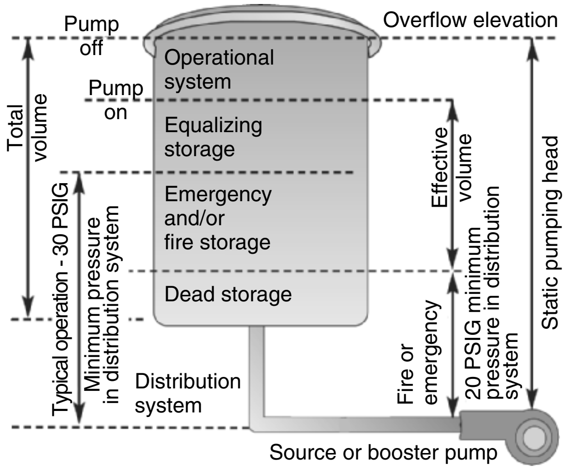

Figure 1. Storage volume classification. Source or booster pump.

These local agency requirements need to be determined on a case-by-case basis before designing a storage reservoir. Figure 1 illustrates the different components of the total storage volume.

Operating Storage—This is the difference in volume between the "pump on" and "pump off" levels when the tank is normally being used and the sources of supply pumps to the storage tank are off.

Equalizing Storage—This storage component is used when the source pump capacity is less than the peak system demands. The storage is needed so that water production facilities can operate at a relatively constant rate. Daily peak rates determine the volume, compared to the average daily demand and source capacity.

Fire Storage—The volume of water stored within the water system for fighting fires is known as "fire storage." The storage volume required varies with the size of city and with the size, type, and classification of construction within the service area. Storage volume requirements for fire fighting should be determined based upon state and local fire districts and municipalities. Fire authorities often refer to the latest edition of the *Guide for Determination of Required Fire Flow*, published by the Insurance Services Office to determine local fire flow requirements.

The typical minimum municipal fire flow requirement is 500 to 1,000 gallons per minute (gpm) for two hours for single family residential areas. Commercial and industrial areas fire flows can be as high as 8,000 gpm or more for many hours. Typical fire storage requirements are shown in Table 1. Engineers should base the actual capacity needs upon local fire flow requirements.

Emergency Storage—This storage is used to provide water to the system during other unusual or emergency conditions. Emergency storage volume depends upon the likelihood of supply interruption and the time required to make repairs or arrange for an alternative water supply.

Dead Storage—Storage in tanks or reservoirs that cannot be drawn out or used beneficially because of piping elevations or low pressures is known as dead storage. Dead storage is typically most significant in tall standpipe-type tanks where water in the bottom of the tank cannot be used because of low system pressure.

Table 1. Typical Range of Storage Requirements for Fire Protection

Type of Development	Storage Volume, Gallons	Storage Volume, ML
Low-density residential, 2 hr at 500 gpm	60,000	0.23
Built-up residential, 2 hr at 1,000 gpm	120,000	0.45
Light commercial, 4 hr at 2,000 gpm	480,000	1.8
Commercial, 4 hr at 4,000 gpm	960,000	3.6

Storage Volume Dedicated to Contact Time—Finished water stored in clearwells at water treatment plants is sometimes used to meet the disinfection contact time. In these cases, the amount of fixed volume used to meet the disinfection requirement should also be considered in the total volume and operational limits of the reservoir.

DAILY STORAGE VOLUME USE VARIES

Water use is greater during daylight hours—typically peaking in the mid-morning and early-evening hours. Stored water is withdrawn during these peak demand hours of the day and is replenished during minimum-demand times in the late-night and early-morning hours.

Figure 2 illustrates the hourly variation in daily water use (diurnal variation) that might occur in a typical residential community on the day of maximum water use for the year.

The shape of the diurnal curve of water demand will vary significantly between different cities because of differences in climates and local economies. Local design data should be obtained for each water system to determine storage needs. However, with an adequate source of supply capacity, equalizing storage of approximately 22 percent of the maximum daily demand is typical for small residential areas.

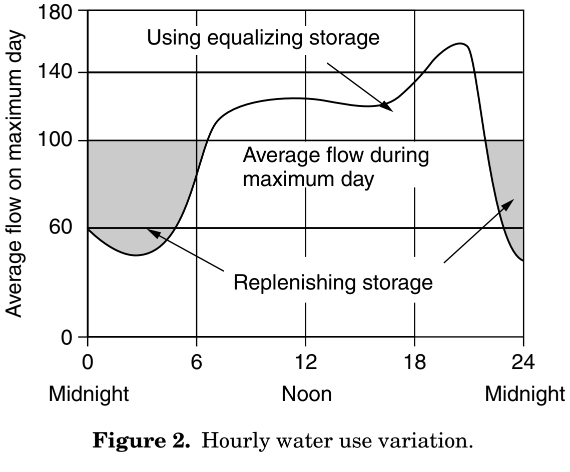

Figure 2. Hourly water use variation.

STORAGE TANK SHAPE AND VOLUME

Water towers can be made of concrete or steel and can take various forms. The most suitable form for concrete towers is a cylinder with a curved shaped bottom or with a flat bottom. Steel tanks may have a spherical or dome shaped bottom. The shape chosen is usually a compromise between function, construction and maintenance costs, and aesthetics.

The lowest water level in the tank is determined according to the pressure requirements in the pipeline. The pressure in the pipelines may vary depending on the type of community and pressure needs of different areas in a city. Typically, minimum acceptable water system pressures are 35 to 40 pounds per square inch (psi) and maximum pressures are 100 to 120 psi.

To keep pumping costs low, water depth in the tank is generally kept small. Due to structural considerations, the depth is kept equal to the diameter.

LOCATING STORAGE RESERVOIRS

A service reservoir stores the water and supplies it at the required pressure to the farthest point in the area. In view of the cost of pipelines and uniform pressure distribution, the reservoir should be located near the center of the service area.

In flat areas, it is relatively easy to build the water tower at the center. In hilly areas, however, it may be more advantageous to select the highest point for the construction of an elevated tank, which may lie at one end of the area instead of the center.

Apart from the center, the tank or tower can be situated between the area and the source of supply (pumping or gravity flow). When the service reservoir lies between the area and the source, all the water must pass through the elevated tank before flowing through the area (see Fig. 3a).

The pressure in the water supply system depends upon the water level in the service reservoir. A water supply system needs to guarantee a minimum pressure even at the most remote point in the area. Therefore, it is essential that the hydraulic gradient line always be above the required pressure.

When water is supplied from an impounded high-level reservoir, the service reservoir may function as a pressure-reducing device (see Fig. 3b). This reduces the possibility of damage to the pipes due to high hydrostatic pressure.

When the area lies between the source and the service reservoir, then most of the requirements are met by direct pumping and the excess water flows to the service reservoir (see Figs. 3c and 3d). In this system there may be larger fluctuations in the supply pressure.

CONSTRUCTION MATERIALS

Most states permit steel and concrete construction materials. All piping, joints, and fittings should conform to American Water Works Association (AWWA) specifications. Welded steel water tanks should confirm to American National Standards Institute (ANSI)/AWWA Standard D100. Factory-coated bolted steel tanks should confirm to ANSI/AWWA D103. Wire and strand wound, circular, prestressed concrete tanks should confirm to ANSI/AWWA Standard D110.

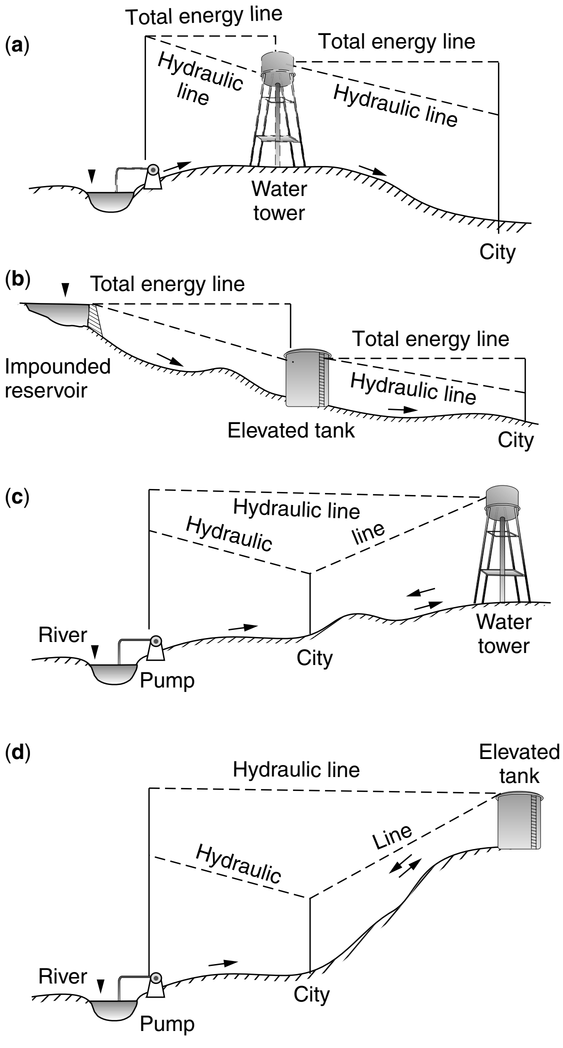

Figure 3. Service reservoir.

The storage tanks should be painted or have cathodic protection. The AWWA standards for painting exclude the use of paints that might add toxic materials to the stored water. The paint, both external and internal, should comply with the standards prescribed by AWWA D101 and D102.

OTHER CONSIDERATIONS

All water reservoirs should be covered to protect the stored water against contamination. Overflow pipes should be brought down near the ground surface and discharged to minimize erosion. The storage structure should be designed so that there is water circulates. There should be a convenient access to the interior for cleaning, maintenance, and sampling. Rigid storage reservoirs should be vented.

WATER TREATMENT PLANT RESIDUALS MANAGEMENT

National Drinking Water
Clearinghouse

Water treatment plants produce a wide variety of waste products as well as safe drinking water. These residuals may be organic and inorganic compounds in liquid, solid, and gaseous forms depending on the source of raw water and the type of treatment processes, commonly, coagulation/filtration, precipitative softening plant, membrane separation, ion exchange, granular activated carbon.

The differences between the unit processes of the five plant types listed above characterize the type of residuals generated at a given facility. In the current regulatory climate, a complete management program for a water treatment facility should include the development of a cost-effective plan to remove and dispose of residuals. The following steps need to be considered when developing a comprehensive water treatment residuals management plan:

- Characterize form, quantity, and quality of the residuals;
- Determine appropriate regulatory requirements;
- Identify feasible disposal options;
- Select appropriate residuals processing/treatment technologies; and
- Develop a residuals management strategy that meets both the economic and noneconomic goals established for a water treatment facility.

WHAT ARE THE RESIDUALS CATEGORIES?

Water treatment plant residuals form when suspended solids in the raw water react with chemicals (e.g., coagulants) added in the treatment processes and associated process control chemicals (e.g., lime). Some potable water treatment processes generate residuals that are relatively easy to process and dispose of. For example, leaves, limbs, logs, plastic bottles, and other large floating debris separated from water during the initial screening process can be disposed of at conventional solid waste landfills. However, most other treatment processes produce more complex residual waste streams that may require advanced processing and disposal methods to protect human health and the environment.

The four major types of residuals produced from water treatment processes are:

Major Treatment Processes and Types of Residual Solids Treatment Processes (Robinson and Witko, 1991)

Typical Residual Waste Streams Generated	Typical Contaminant Categories	Typical Disposal Methods	Regulation Covering Disposal Method
Coagulation/Filtration			
Aluminum hydroxide, ferric hydroxide, or polyaluminum chloride sludge with raw water suspended solids, polymer and natural organic matter (sedimentation basin residuals)	Metals, suspended solids, organics, radionuclides, biological, inorganics	Landfilling Disposal to sanitary sewer/WWTP Land application Surface discharge	RCRA/CERCLA State and local regulations RCRA, DOT NPDES (CWA), state and local DOH
Spent backwash filter-to-waste	Metals, organics, suspended solids, biological, radionuclides, inorganics	Recycle Surface discharge (pumping, disinfection, dechlorination) Disposal to sanitary sewer/WWTP	State and local DOH NPDES (CWA), state and local regulations State and local regulations
Precipitative Softening			
Calcium carbonate and magnesium hydroxide sludge with raw water suspended solids and natural organic matter	Metals, suspended solids organics, unreacted lime, radionuclides	Landfilling Disposal to sanitary sewer/WWTP Land application	RCRA/CERCLA, state and local regulations State and local regulations RCRA, state and local regulations, DOT
Spent backwash filter-to-waste	Metals, organics, suspended solids, biological, radionuclides, inorganics	Recycle Surface Discharge (pumping, disinfection, dechlorination) Disposal to sanitary sewer/WWTP	State and local DOH NPDES (CWA), state and local regulations State and local regulations
Membrane Separation			
Reject streams containing raw water suspended solids (microfiltration), raw water natural organics (nanofiltration), and brine (hyperfiltration, RO)	Metals, radionuclides, TDS, high molecular weight contaminants, nitrates	Surface discharge (pumping, etc.) Deep well injection Discharge to sanitary sewer/WWTP Radioactive storage	RCRA, NPDES, state and local regulations RCRA, NPDES, state and local regulations State and local regulations RCRA, DOT, DOE
Ion Exchange			
Brine stream	Metals, TDS, hardness nitrates	Surface discharge Evaporation ponds Discharge to sanitary sewer/WWTP	RCRA, NPDES, state and local regulations RCRA, NPDES, state and local regulations State and local regulations
Granular Activated Carbon			
Spent GAC requiring disposal and/or reactivation, spent backwash, and gas-phase emissions in reactivation systems	VOCs, SOCs (nonvolatile pesticides), radionuclides, heavy metals	Landfill Regeneration (on/off site) Incineration Radioactive storage Return spent GAC to supplier	RCRA, CERCLA, DOT State and local air quality regulations (CAA) State and local air quality regulations (CAA) DOT, DOE
Stripping Process (Mechanical or Packed Tower)			
Gas phase emissions	VOCs, SOCs, radon	Discharge to atmosphere GAC adsorption of off-gas (contaminant type and concentration dependent)	State and local air quality regulations (CAA)
Spent GAC if used for gas-phase control	VOCs, SOCs radionuclides	GAC adsorption of off-gas (contaminant type and concentration dependent) Return spent to GAC to supplier	State and local air quality regulations (CAA)

Chart Key

CAA = Clean Air Act
CWA = Clean Water Act
CERCLA = Comprehensive Environmental Response, Compensation and Liability Act
DOE = Department of Energy
DOH = Department of Health
DOT = Department of Transportation
GAC = Granular Activated Carbon
NPDES = National Pollutant Discharge Elimination System
RCRA = Resource Conservation and Recovery Act
RO = Reverse Osmosis
SOC = Synthetic Organic Chemical
TDS = Total Dissolved Solids
VOC = Volatile Organic Compound
WWTP = Wastewater Treatment Plant

- *Sludges* (i.e., water that contains suspended solids from the source water and the reaction products of chemicals added in the treatment process). Presedimentation, coagulation, filter backwashing operations, lime soften-ing, iron and manganese removal, and slow sand and diato-maceous earth filtration all produce sludge.
- *Concentrate* (brines) from ion exchange regeneration and salt water conversion, membrane reject water and spent backwash, and activated alumina waste regenerant.
- *Ion exchange resins,* spent granular activated carbon (GAC), and spent filter media (including sand, coal, or diatomaceous earth from filtration plants).
- *Air emissions* (off-gases from air stripping, odor control units, or ozone destruction).

The chemical characteristics and contaminant concentration levels in these residual waste streams often impose the ultimate disposal options. Furthermore, it is reasonable to expect that as drinking water quality is increasingly regulated, higher removal efficiencies of more contaminants will be required. To achieve these higher efficiencies, water treatment plants (WTPs) will need to use more sophisticated treatment technologies. Of particular concern are cases in which residuals are characterized as either hazardous or radioactive waste. Depending on the raw water quality and treatment process removal efficiency, hazardous or radioactive characteristics could be exhibited in potentially any residual waste stream mentioned on page 1.

WHAT REGULATIONS GOVERN MANAGEMENT OF WATER TREATMENT PLANT RESIDUALS?

Identifying the regulations that affect various management practices may be difficult for water treatment utility managers. The difficulty is due to the many different types of wastes produced by WTPs and various types of waste disposal: direct discharge, discharge to wastewater treatment plants, disposal in landfills, land application, underground injection, disposal of radioactive waste, and treatment of air emissions.

At the federal level, the U.S. Environmental Protection Agency (EPA) has not established any regulations that are specifically directed at WTP residuals. Applicable regulations are those associated with the Clean Water Act (CWA); Criteria for Classification of Solid Waste Disposal Facilities and Practices (40 CFR, Part 257); the Resource Conservation and Recovery Act (RCRA); the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) or Superfund; and the Clean Air Act (CAA). The CWA limits direct discharges into a water course while the other legislation governs other methods of use and/or disposal of wastes. Most states are responsible for establishing and administering regulations that will meet the requirements of these acts. The regulation of wastes, therefore, is the responsibility of the states.

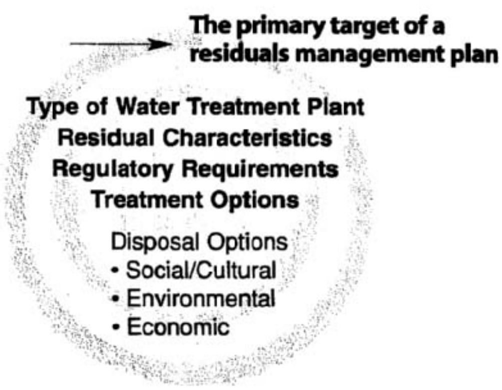

Figure 1. *Source*: Management of Water Plant Residuals.

HOW ARE RESIDUALS MANAGEMENT PLANS SELECTED?

To develop a residuals management plan, the WTP manager may start with a broad array of residuals processing and disposal options that can be narrowed through considering specific residuals characteristics and associated regulatory requirements. A focus on available disposal options further narrows the management alternatives.

Figure 1 illustrates the need for practical disposal options and treatment processes that will take into account economic and noneconomic factors of concerns to the community. The technical criteria used to select the final management plan differ from user to user; economic, cultural, social, and environmental factors are also site-specific, and are typically included in any final selection.

REVERSE OSMOSIS, PROCESS CHEMISTRY

Robert Y. Ning
King Lee Technologies
San Diego, California

INTRODUCTION

The application of membranes to purify water provides a powerful means of producing high-purity water. In the total treatment of raw water, reverse osmosis (RO) is an important midstream process for fractionating feedwater into high-purity water and brine. The brine may be used to feed cooling towers and evaporators.

The RO process is sensitive to upstream treatments and itself impacts downstream operations. The almost infinite variety of contaminants that enter the membrane systems with the feedwater and the economic necessity to expend minimal resources on raw water pretreatment pose a major challenge to RO process chemistry design and control. RO process chemistry itself is important in understanding and controlling the quality of the product permeate water which may be further polished to remove trace contaminants to meet the ultrapure specifications needed in industries such as pharmaceuticals, microelectronics, and power generation. Presented here are the chemistry of feedwater membrane fouling mechanisms, composition of foulants, and chemicals used to prevent fouling.

FEEDWATER CHEMISTRY

Water that enters reverse osmosis systems comes from all imaginable sources. Presented in Table 1 is a list of sources that are differentiable by their quality and the significant chemistry in these waters that impacts the performance of RO systems.

Major physical occurrences in natural waters are the processes of erosion of the rocks that generate sand (50 microns −2 mm), silt (5–10 microns), clay (<5 microns), and submicron colloidal particles. Just as active a physical process is the growth, excretion, death, and decay of animals and microorganisms.

Table 1. Sources of Feedwater and Significant Chemistry that Impacts RO

Source Water	Significant Chemistry
1. Rain	Oxidation–reduction (e.g., $O_2 + NO_x$), acid–base (e.g., $CO_2 + H_2O$)
2. Springs	Dissolution, acid–base (acid rain + carbonate rocks)
3. Ponds, Lakes	Complex interactions of living and nonliving matter
4. Wells, aquifers	Dissolution–precipitation (e.g., $CaCO_3$, $CaSO_4$, $SrSO_4$, $BaSO_4$, silicates, iron and aluminum salts, sulfides), relatively low in organic matter
5. Rivers, municipal and industrial wastewater	Complexation interactions, precipitation
6. Oceans (99.4% of the earth's water including 2% as ice)	Biotic life, complexation interactions, precipitation

Some significant chemical processes occurring in these waters can be enumerated. Rain extracts oxygen, oxides of carbon, sulfur and nitrogen, and organic aerosol particles from the atmosphere. Spring water dissolves soluble matter, and the acidity of rainwater is neutralized by alkaline rocks such as limestone. Ponds and lakes are biotic reactors in which biomass is produced and accumulated, and complexation interaction of organic matter with inorganic particles occurs. Much of this particulate matter is retained in upper zones of the ground as water enters aquifers. The large surface areas of contact and the long times available for dissolution and precipitation allow water in aquifers to be equilibrated and fully saturated with respect to the composition of the minerals they are in contact with. Thus it is from the deep well source water that the greatest scaling potentials from foulants such as calcium carbonate, calcium sulfate, strontium sulfate, barium sulfate, silica, iron, and aluminum exist. We can compare the water in the lower sections of rivers to municipal and industrial waste streams in which complexation interactions of organic and inorganic particles predominate.

The chemistry of seawater is particularly interesting to note. It reflects the equilibrated end point of the processes that began in the surface waters just mentioned. Interestingly, the chemistry in the water undergoing concentration within RO systems models the transition of surface waters to highly saline seawater with respect to coagulation of colloidal matter. Heavy precipitation of biomass coagulated with silt and clay occurs in the delta region of major rivers. The quantity of the different components in seawater is not proportional to the quantity of the components that river water pours into the sea but is inversely proportional to the facility with which the components in seawater are insolubilized by chemical actions in the sea (1). Complexation interactions, precipitation of particles, and crystallization of salts of low solubility that began in ponds and lakes continue in the ocean.

Some of the types of colloids that exist in natural water, especially in the sea, are listed in Table 2. Polyphenolic complexes such as humic acid, lignin, and tannin are decay

Table 2. Colloidal Matter in Natural Water

- Microorganisms
- Biological debris (plant and animal)
- Polysaccharides (gums, slime, plankton, fibrils)
- Lipoproteins (secretions)
- Clay (hydrous aluminum and iron silicates)
- Silt
- Oils
- Kerogen (aged polysaccharides, marine snow)
- Humic acid/lignins/tannins
- Iron and manganese oxides
- Calcium carbonate
- Sulfur and sulfides

products of woody tissues of plants that are particularly noticeable in surface waters due to their tendency to foul RO membranes by themselves or coagulate with other foulants (2). Polysaccharides that constitute cell walls of microorganisms and plants and are excreted variously as gums, slimes, and biofilms are prominent in membrane fouling. In the ocean, they are added to polysaccharides from sea organisms, especially planktons (3), which become kerogen upon aging. It is believed that white materials called "marine snow" that has been observed falling in the deep oceans are these aged and ubiquitous polysaccharides (4).

MEMBRANE FOULING MECHANISMS

Feedwaters to RO systems typically are concentrated by a factor of 2–10 (50–90% recovery) during production of permeate water. For simplicity in classification, three classes of fouling (5–11) can be said to occur.

First, there is scaling. The solubility limits of various dissolved salts in the brine stream may be exceeded, leading to deposition and growth of crystals in the flow channels and membrane surface of the RO elements. This type of fouling is referred to as scaling. Most common examples of scales are calcium carbonate; sulfates of calcium, strontium, and barium; and calcium fluoride. In the examination of foulants (2) under the microscope, crystals have well defined shapes. Inhibitors injected into feedwaters to suppress crystallization are called antiscalants.

Second, there is colloidal fouling. Particulate matter that preexists in feedwater can aggregate and adhere to the membrane and brine flow channels due to increased concentration, salinity, compaction, flocculation, surface interactions, and other physical and chemical factors. The particles, such as silt, carbon fines, coagula, and microbial clusters, may be large enough to be removed by 1 to 5 micron RO prefilters, or they may be colloidal particles that escape filtration even with the standard 0.45-micron filters used in silt density index measurements. The colloids can be organic or inorganic or composites. Ferric, aluminum, and calcium hydroxides and silicic acid grow to increasing particle sizes by polymerization. Cross-linking and complexation of organic and inorganic polymers produce gels and amorphous foulants commonly seen on membranes (2,12). Biotic debris such as polysaccharides and dead cellular matter contribute largely to this type of foulant. We have found that anticoagulants and antideposition agents show promise in inhibiting this fouling process. Antifoulants then can be a term applied specifically in this particulate fouling context. In a broader sense, the term antifoulant is used in the field to include antiscalants as well (6).

Third, biofouling is a prominent source of fouling. True of all water treatment and distribution systems is the growth and anchoring of microorganisms. At times, moderate temperatures and minimal nutrient levels in RO waters can support explosive growth of microorganisms. Bacteria capable of cell division in 20 minutes can grow from a normal count per unit volume of water to millions in an 8-hour shift. Due to the tendency of bacteria to secrete polymers that anchor themselves to surfaces to facilitate growth as a biofilm, this fouling mechanism is unique and poses a serious threat to operation of RO systems (13). This threat is compounded by the great difficulty of treating and completely removing a biofilm from membrane surfaces.

COMPOSITION OF FOULANTS

The chemical composition of foulants correlated with their sources are given in the Reverse Osmosis, Membrane Foulants.

ANTIFOULANT DESIGN AND APPLICATION

The term antifoulant is used here in its broadest meaning covering scaling, particulate fouling, and microbial fouling—the three classes of fouling mechanisms discussed before. Strategies aimed at controlling each type of fouling are summarized here.

For scale control, the development and application of antiscalants is well known and reviewed in the field of boiling water and cooling water chemistry (6,14–16) and applied to boilers, evaporators, cooling towers, and cooling systems. Anionic polymers, polyphosphates, and organophosphorous compounds, sometimes referred to as threshold inhibitors and dispersants, are used in substoichiometric amounts, usually in the range of 1–5 mg/L in RO systems (17). By binding to surfaces of growing crystal nuclei, the rates of crystallization from supersaturated solutions are retarded, and crystal packing orders are modified. By this mechanism, crystallization rates are so retarded that although supersaturation of solutes in the water will eventually equilibrate through crystallization within the residence time of the water in the system, there is little or no scale formation. The uniqueness of RO among water conditioning systems is that residence time is very short (a few seconds), concentration of seed crystals is low, and temperature is constant. For this reason, higher levels of supersaturation without crystallization are possible. On the other hand, the limits of saturation and rates of scaling are hard to model, measure, and predict. Interference comes from other solutes in the water, organic or inorganic. Assumptions of RO fouling limits vary considerably among practitioners.

Controlling fouling by preexisting particulate matter is much more challenging due to the variety of types of potential foulants and the complexity of their interactions (1,2,8,10,12), with each other in the same water and with the membrane. The stability and agglomeration of colloidal particles is a subject of major importance in natural water (1) as well as in treating process water (16). Drawing on the basic science of colloids and testing of model foulants suggested by RO foulant analysis data (2), progress is made steadily by the development of antifoulants.

The literature on preventing and managing biofouling in water treatment systems, is extensive. Much of the art and science found useful generally is applicable to RO systems as well. Several factors peculiar to the RO system can be mentioned. Chemicals used to sanitize and clean the system have to be chemically compatible with the thin, salt-rejecting, polyamide barrier membrane. It is of prime concern that accumulation and exponential growth of microorganisms should not be allowed to occur within the system. Pretreatment of feedwater, adequate maintenance of upstream unit operations, continuous flow of water through the RO unit, a good monitoring and sanitization program, and use of preservatives during downtime (18) are important to this end. Normalized flow and differential pressure in the system are sensitive indicators of biofouling.

To prevent irreversible fouling, trend charting of normalized permeate flow, differential pressure, and salt rejection, and readiness to perform adequate cleaning are important aspects of system operation (see Reverse Osmosis, Membrane Cleaning). Immediate assistance should be sought when cleaning has been inadequate. Powerful new cleaners are now available that provide alternatives to membrane replacement in the worst cases of fouling.

REVERSE OSMOSIS, MEMBRANE FOULANTS

Robert Y. Ning
King Lee Technologies
San Diego, California

INTRODUCTION

Periodic cleaning of reverse osmosis (RO) membranes is generally accepted as a necessary routine maintenance operation in running water purification plants (1–3). Common foulants found in RO membrane elements include calcium carbonate, calcium sulfate, strontium sulfate, barium sulfate, calcium fluoride, calcium phosphate, ferric hydroxide, aluminum hydroxide, silica, silt, polymers from natural sources, and synthetic polymers used in pretreatment. These foulants may occur singly or in most cases, in complex combinations. Single foulants are simpler to address in prevention and dissolving (except for barium sulfate) during cleaning. Complex foulants usually resulting from coagulation of colloidal particles, offer the greatest challenge in prevention and removal during cleaning.

A large body of data and observations from troubleshooting RO systems is summarized here. Complex foulants are extracted from membrane elements sent from plants across the world that need assistance. Qualitative tests and quantitative elemental analyses of these foulants, combined with a thorough review of the pretreatment chemistry, provide insights into the nature and the source of the foulants. Experience with the pattern of responses to various cleaners and successful resolution and elimination of fouling problems confirm the conclusions regarding the source of foulants and the mechanisms of formation in each specific situation. The following generalizations have been helpful in solving fouling problems and in selecting the most appropriate cleaning chemicals:

1. Organic matter usually contributes more than 10% of the mass of foulants; the majority of the samples contain 50–100% organic matter.
2. Biomass constitutes the major part of the organic content of the foulants.
3. Synthetic polymers used in water pretreatment can often be differentiated from biomass in foulants.
4. Anionic polymers used as antiscalants and dispersants can deposit on membranes and act to concentrate high valence metal ions (Fe, Al, Ca) on the membrane surface.
5. Colloidal silica and clays have complex and variable content of iron, aluminum, calcium, and magnesium.

6. Elemental phosphorous is associated with biomass, phosphate, and phosphonates.

The six generalizations separately presented below are derived from a synthesis of foulant analysis data and correlation with plant process chemistry and responses to cleaners. Positive outcomes in the plants have consistently been realized by applying them.

ORGANIC MATTER

Organic matter is defined as carbon-containing matter. Each foulant is washed by decantation with pure water, then dried at 120–130 °C. It is gravimetrically analyzed for carbon, hydrogen, and nitrogen (C,H,N) content by standard methods of pharmaceutical analysis, along with a quantitative ash test (furnace at 400–450 °C) to determine the percentage of inorganic matter. The percent total volatile or combustible elements (C,H,N and oxygen) from the ash test is considered organic matter, and it correlated well with C,H,N values along with the general oxygen atom content of biological and synthetic organic polymers commonly used in water pretreatment. The organic matter in 22 foulant samples analyzed by these methods, during a recent period has the values shown in Table 1. From the table, it is interesting to note that all samples contained at least 10% by weight of organic matter and that 73% of the samples contained 50–100% by weight of organic matter. Note that the foulants analyzed are representative of the more difficult to clean types of foulants. Foulants such as calcium carbonate, calcium sulfate, and ferric and aluminum hydroxides that are readily cleaned with generic acid cleaners are not represented. Organic matter, which includes biomass and polymers used in pretreatment, usually makes the foulant difficult to remove.

BIOMASS

Biomass refers to organic matter arising from living or dead organisms. In colloidal form, it can enter the RO system with the feedwater and then coagulates and accumulates on membrane elements. A more severe source of biomass is the exponential growth of viable organisms within the system (4) and the accumulation of the biofilm in the system due to the difficulties in removal (5). Such accumulation is usually promoted by inadequate maintenance sanitization procedures of the entire water processing system and stagnation during frequent or prolonged downtimes without preservative. Severe growths are often detectable by odor or slime on the internal surfaces in contact with water. Milder growths are detectable by microbial culturing and enzyme activity tests. Natural surface waters (lakes, rivers and sea), especially in warm regions, have very high levels of decaying or excreted plant and animal matter. High biomass content of foulants in the samples examined correlated with the factors mentioned, in the feedwater and in the plant.

Table 1. Organic Matter in RO Foulant Samples

Organic Matter (% by weight)	Number of Foulants Analyzed	
0–10%	0	
10–20	3	
20–30	2	
30–40	0	
40–50	1	27%
50–60	3	
60–70	3	
70–80	4	
80–90	5	
90–100	1	73%
Total:	22	100%

SYNTHETIC POLYMERS

Synthetic polymers used in water pretreatment can often be differentiated from biomass in foulants. The absence of the characteristics of biomass—odor, visual and microscopic appearance, color, slime, microbial count, enzyme activity, presence of phosphates, sodium and potassium in ash—and the presence usually of a thin and even coating of colorless to tan gel suggest synthetic polymers. Severe flux reduction accompanied by an almost invisible film of organic material is the hallmark of poisoning by cationic polymers. Using Fourier transform infrared spectroscopy (FT-IR), if the reference spectrum of the suspect pretreatment polymer is available and the foulant spectrum is uncluttered, positive identification through "fingerprinting" is possible. Carryover of high molecular weight synthetic cationic, anionic and nonionic polymers used as coagulants in pretreatment often is flocculated with colloidal particles of complex compositions, carries more mass, and is less readily identifiable. Lower molecular weight polymers used as antiscalants often participate in these complexes and are deposited as foulants. Even in the absence of polymeric coagulants, low molecular weight polymers, used as antiscalants and dispersants, can and will deposit on membranes at a slower rate (see following section).

ANIONIC POLYMERIC ANTISCALANTS

Anionic polymers used as antiscalants and dispersants are known to be quite intolerant of multivalent cations such as ferric and aluminum ions. These ions act as ionic cross-linkers, causing even polymers in the molecular weight range of 1,000 to 2,000 daltons to flocculate. By a combination of gradual deposition and accumulation due to incomplete removal during routine cleaning, such foulants build up over several years and gradually concentrate high valence cations as an ion exchange resin would. As an example, the elemental composition of such a foulant is given in Table 2. This sample contains 52% volatile organic matter (C,H,N,O) and 48% inorganic ash. The carbon and hydrogen content of the foulant (23.67% and 3.73%, respectively) are in reasonable agreement with the theoretical polyacrylic acid composition (at 52%) of 26.4% carbon, 2.9% hydrogen, and 23.4% oxygen. Smaller amounts of coagulated nitrogen-containing polymers or biomass can account for the nitrogen content. The inorganic composition of the foulant is revealed by scanning electron microscopy with energy diffusive X-ray analysis (SEM-EDX). The instrument is calibrated to quantitate elements between the atomic numbers of 12–42, which correspond to magnesium to molybdenum in the periodic table. The lighter elements such as B,C,H,N,O, and F are not measured, so the percentage by weight values are relative for the range of atoms measured. As shown, the predominant cation is iron (44% relative), followed by calcium, aluminum, chromium, and magnesium. Bridging to phosphate, silicate, and sulfate anions is apparent.

COLLOIDAL SILICA AND CLAYS

Colloidal silica and clays refer to preexisting siliceous particles in the feedwater, which coagulate during passage through the reverse osmosis system and become deposited on the membrane as a foulant (1,6,7). Colloidal silica, also known as nonreactive silica, results in natural waters from the polymerization of silicic acid and reactive oligomeric species, which as a population is termed reactive silica. Reactivity is measured by and often referred to as reactivity toward molybdate ions by the same type of condensation reaction. Condensation of reactive silica with aluminum, iron, and calcium hydroxides forms clays. Clays in feedwaters result mainly from the erosion of rocks, however. It is stated (8) that the chemical composition of most clays is similar to the composition of the earth's crust: oxygen 49.9%, silicon 26.0%, aluminum 7.3%, iron 4.1%, calcium 3.2%, sodium 2.3%, potassium 2.3%, magnesium 2.1%, and all other elements 2.8%. Following erosion is sand (50 microns −2 mm), silt (5–10 microns), and clay (<5 microns), differentiated by particle sizes.

Depending on the extent of clarification and prefiltration of feedwaters, silt and clays often end up on the membranes. The silt density index (SDI) is a means of measuring particle load in the feedwater by timing the fouling of 0.45-micron test filters. In practice, feedwater with an SDI value greater than 5 would lead to high fouling rates in plants. The 0.45-micron filters are nominal filters, so it is likely that a significant fraction of clay entering with the feedwater is not detected by SDI monitoring.

Table 2. Elemental Composition of an Iron Acrylate Foulant

Component	Percent by Weight	
By gravimetric elemental analysis:		
Carbon	23.67	(absolute)
Hydrogen	3.73	
Nitrogen	3.26	
Ash (inorganic)	48.08	
By SEM-EDX (at. no. 12–42, Mg–Mo):		
Iron	44.0	(relative)
Calcium	15.0	
Phosphorous	13.0	
Silica	9.9	
Aluminum	8.8	
Sulfur	4.2	
Chromium	1.8	
Magnesium	1.7	
Total:	98.4	

Table 3. Elemental Composition of a Colloidal Silica Foulant

Component	Percent by Weight	
By gravimetric elemental analysis:		
Carbon	1.15	(absolute)
Hydrogen	0.67	
Nitrogen	0.02	
Ash (inorganic)	92.46	
By SEM-EDX (at. no. 12–42, Mg–Mo):		
Silicon	90.0	(relative)
Iron	3.6	
Aluminum	2.7	
Potassium	1.3	
Sodium	0.8	
Calcium	0.8	
Magnesium	0.6	
Sulfur	0.5	
Chlorine	0.3	
Total:	100.6	

Colloidal silica and clays are often encountered in analyses of foulants. They frequently appear in the presence of organic matter and accumulate in the flow channels of the membrane elements in significant masses. Occasionally, colloidal silica can severely foul membranes in amounts almost too minute to sample physically. The composition of one such example is given in Table 3.

PHOSPHOROUS

Phosphorous is detected in foulant samples by SEM-EDX. Relative amounts in the inorganic portions of 20 recent foulants surveyed ranged from 0–58% of the elements measured in these samples (mean = 14.6%, SD = 15.7%). Sources of phosphorous-containing matter can be correlated with a number of sources. Biomass generally contains measurable amounts of phosphates. Algal biomass in natural waters reportedly contains almost 1% elemental phosphorous (9). Phosphates, except those of sodium, potassium, and ammonium, are generally only slightly soluble in water. If phosphates are present in a feedwater to any appreciable extent, phosphate scales will likely form in a reverse osmosis system unless the water is acidified (2). Calcium phosphate has limited solubility at neutral pH and an even lower solubility at higher pH. Phosphates are widely used in agriculture and in laundry products, so it is common to find phosphate in silt and agricultural runoff. Municipal wastewater has phosphate concentrations usually in the range of 15–30 mg/L of phosphate ion (about 5–10 mg/L as phosphorous) (11). In addition to calcium phosphate, ferric and aluminum phosphates are particularly insoluble and can enter the reverse osmosis system in clay or colloidal form.

Other sources of phosphorous are found in the environment of the membrane itself. High pH membrane cleaners widely used for removing organic foulants are often formulated with trisodium phosphate and sodium tripolyphosphate (10). Incomplete cleaning is likely to deposit insoluble phosphates with residual foulants which accumulate over time. Another source is the commonly used generic antiscalant sodium hexametaphosphate (SHMP). Solutions of SHMP are hydrolytically unstable and generate phosphate ions and phosphate foulants (2). Even phosphonates can precipitate with high levels of calcium, iron, and aluminum and can participate in fouling.

CONCLUSIONS

These conclusions regarding the formation of RO foulants have been the basis of resolving many operating problems in RO plants. Hopefully, they will serve as a framework for further insights into making RO systems more stable in operation.

REVERSE OSMOSIS, MEMBRANE CLEANING

Robert Y. Ning
King Lee Technologies
San Diego, California

INTRODUCTION

Reverse osmosis membrane cleaning has been extensively addressed over the years (1–7). Severe concentration of dissolved and suspended matter occurs when water is purified by using reverse osmosis (RO) membranes. Permeate recoveries of 50–90% correspond to 2–10-fold concentrations in the reject brine. Precipitation or crystallization of foulants can occur in the narrow brine flow channels within the membrane elements, leading to reduced membrane flux or increased differential pressure across the system, or both. Crystallization of salts or precipitation of colloidal matter occur more toward the back end of the system, and preexisting silt and flocculated organic matter can clog the leading elements of the system.

LIMITATIONS OF CLEANING

A practical procedure for maintenance cleaning is limited to recirculating cleaning solutions through the membrane elements. By a patented method (8) of membrane reconditioning, spiral wound elements, whose hard casing is removed, are routinely used in selecting effective cleaners for cleaning by recirculation. This allows visual inspection of the membrane surface after each cleaning test. It is apparent that, except for easily soluble foulants such as calcium carbonate or ferric and aluminum hydroxides, nearly all RO foulants are only slightly dissolved in even the best matched cleaning solutions by extensive soaking. Removal requires high tangential flow velocities and is usually partially effective especially where flow channels are clogged and large patches within the elements are inaccessible to the recirculating solution. For this reason, the need for cleaning should be minimized or completely eliminated by the new antiscalants and dispersants now available and adequate pretreatment and pilot testing of process designs. When cleaning is necessary, it should be performed at the earliest stages of fouling.

WHEN TO CLEAN

It is generally agreed among membrane manufacturers and practitioners that RO systems should be cleaned before the following performance changes are reached:

1. Loss of 10 to 15% in normalized permeate flow rate.
2. Increase of 10 to 15% in differential pressure.
3. Decrease of 1 to 2% in salt rejection.

If a cleaning procedure fails to restore system performance fully to reference start-up values, it is certain that continued use of the same cleaning procedure will lead to an accelerating decline in system performance and increased cleaning frequency. For this reason, it is important to address two issues at this point: (1) find an improved cleaning procedure, or (2) investigate possible improvement of pretreatment to avoid membrane fouling. Continue cleaning and process improvement efforts until the RO performance is stable.

CHOOSING CLEANERS

Major membrane manufacturers generally define five types of foulants for which various generic chemicals

Table 1. Cleaning Solutions Formulated from Generic Chemicals in Concentrations Recommended by Major Membrane Manufacturers[a,b]

Types of Foulants-	Acid-Soluble Foulants	Biofilm, Bacterial Biological Matter	Oils and Organic Matter	Organic and Inorganic Colloids	Silica and Silicates
Fluid Systems	1% citric acid	1% STPP (TFC only) 1% EDTA.Na$^+$ 1% TSP 1% Borax (TFC only) 0.1% Triton X-100 (CA only)			–
Hydranautics	2% citric acid 0.1% Triton X-100 or Tergitol 8, etc.	2% STPP 0.26% SDDBS pH 7.5	0.5% Na Perborate 0.1% TritonX-100 or Tergitol 8 etc.	2% STPP 0.8% EDTA.Na$^+$ 0.1% Triton X-100 or Tergitol 8, etc.	–
Filmtec	0.2% HCl or 0.5% H_3PO_4 or 2.0% citric acid or 0.2% sulfamic acid	1% EDTA.Na 0.1% NaOH to pH = 12 or following pH = 12 solutions: 0.05% Na-DDS or 0.1% STPP + 1% EDTA.Na, or 0.1% TSP + 1% EDTA.Na		0.1% NaOH 0.05% Na-DDS pH = 12	–
Desal	HCl pH = 3 or citric acid pH = 2	1% TSP 1% STPP 0.1% Na-DDS 1% EDTA.Na pH = 8–11.5			–
Permasep	0.5% HCl (pH 2.3 min) or 0.5% H_3PO_4 (pH 2.3 min) or 0.2% sulfamic acid or 2% citric acid, pH = 4 or 2% citric acid 2% Na_2EDTA NH_4OH to pH = 4 or 1% $Na_2S_2O_4$ or 1% NaHMP	1% Na_2EDTA 0.1% NaOH pH = 11 max	0.3% NaPerborate 0.25% Na-DDBS pH = 10 or 1% Na_2EDTA 1% STPP 1% TSP, pH = 11 or 2% STPP 0.25% Na-DDBS pH = 10 or 1% NaHMP	0.3% NaPerborate 0.25% Na-DDBS pH = 10 or 2% STP 0.25% Na-DDBS pH = 10 or 1% NaHMP	0.5% NaOH, pH = 11 or 1% Na_2EDTA 0.1% NaOH, pH = 11 or 0.3% Naperborate 0.25% Na-DDBS pH = 10 or 2% STPP 0.25% Na-DDBS pH = 10

[a] Reference (10).

[b] STPP = sodium tripolyphosphate; EDTA.Na = sodium salt of ethylenediaminetetraacetic acid; TSP = trisodium phosphate; Triton X-100 and Tergitol 8 = nonionic surfactants; Na-DDS = sodium dodecylsulfate; Na-DDBS = sodium dodecylbenzenesulfonic acid; Na_2EDTA = disodium salt of ethylenediaminetetraacetic acid; NaHMP = sodium hexametaphosphate.

are recommended for blending at the site where cleaning solutions are prepared. The five types of foulants are (1) acid-soluble foulants, (2) biofilm/bacterial slime/biological matter, (3) carbon-containing oils/organic matter, (4) dual organic and inorganic coagulated colloids, and (5) silica and silicates. The recommended generic chemicals and concentrations in the cleaning solutions to be prepared are given in Table 1 for the five respective types of foulants. Proprietary booster cleaners are commercially available to fortify the effectiveness of these generic cleaners that are formulated at the site. For convenience and technical support, a large variety of proprietary RO membrane cleaners are available from chemical suppliers that specialize in RO operations.

CLEANING STRATEGIES

Experience has shown that within the same class of foulants, responses to the same cleaning solution can vary considerably. Elemental analyses of foulants and cleaning studies have shown that more than one type of foulant can be present on the membrane at the same time, requiring sequential cleaning with different cleaners. Sometimes even the order of cleaners used would make a significant difference. All this is to say that the choice of cleaners and the cleaning procedure to be used is an empirical science. For a given set of conditions in a plant, cleaning efficiencies are improved by trials over time. The progress of improvement can be greatly accelerated by conducting off-line cleaning studies on single elements.

When a better cleaning method is needed in the plant, the following are the alternative strategies:

Strategy 1: The plant has a history of using generic cleaning chemicals, and modest improvement in effectiveness is needed. Consider purchase of proprietary booster cleaners.

Strategy 2: Significant cleaning improvement is needed. Look for a proprietary cleaner supplier who has cleaning expertise. Option 1:

Based on prior knowledge of the characteristics of the foulant on hand and consultation with the supplier, select a combination of cleaners for trial in the plant. Option 2: Send one to three fouled elements to a specialist for a cleaning study, foulant analysis, and a review of plant performance history and pretreatment processing. Document the findings and pilot cleaning results using a recommended improved cleaning procedure. Simultaneously, address recovery of the plant and avoidance of repeated fouling. Option 3: Send all fouled elements for off-site cleaning by a specialist.

Strategy 3: All cleaning efforts by recirculation of cleaning solutions have failed. Consider nonroutine methods such as using proprietary membrane conditioning liquids or a patented membrane reconstruction process by which the membrane bundle is unrolled, cleaned leaf by leaf, then restored with a new hard casing. Both methods are offered by King Lee Technologies (9).

ON-LINE CLEANING PROCEDURE

There are six steps in cleaning membrane elements in place in RO systems:

1. Mix cleaning solution.
2. Low flow pumping. Pump preheated cleaning solution to the vessels at a low flow rate (about half of that shown in Table 2) and low pressure to displace the process water. With the RO concentrate throttling valve completely open to minimize pressure during cleaning, use only enough pressure to compensate for the pressure drop from feed to concentrate. The pressure should be low enough that essentially no permeate is produced. Low pressure minimizes redeposition of dirt on the membrane. Dump the concentrate, as necessary, to prevent dilution of the cleaning solution.
3. Recirculate. After the process water is displaced, cleaning solution will be present in the concentrate stream. Recirculate the concentrate to the cleaning solution tank, and allow the temperature to stabilize.
4. Soak. Turn the pump off, and allow the elements to soak. Sometimes, a soaking period of about 1 hour is sufficient. For difficult to clean foulants, an extended overnight soaking period of 10–15 hours is beneficial. To maintain a high temperature during an extended soaking period, use a slow recirculation rate (about 10% of that shown in Table 2).
5. High flow pumping. Feed the cleaning solution at the rates shown in Table 2 for 30–60 minutes. The high cross-flow rate flushes out the foulants removed from the membrane surface by the cleaning; minimal or no permeation through the membrane avoids compacting the foulant. If the elements are heavily fouled (which should not be a normal occurrence), a flow rate 50% higher than that shown in Table 2 may aid cleaning. At higher flow rates, excessive pressure drop may be a problem. The maximum recommended pressure drops are 20 psi per element or 60 psi per multielement vessel, whichever value is more limiting.

   Note: In this cleaning mode, foulants are generally partially dissolved in the cleaner and partially dislodged physically from the membrane and flow channels without dissolving. An in-line filter removes the recirculated particles and should be monitored for cartridge replacement.
6. Flush out. Prefiltered raw water can be used for flushing out the cleaning solution, unless there will be corrosion problems such as seawater corroding stainless steel piping. To prevent precipitation, the minimum flush temperature is 20°C.

   Additional Notes: The pH should be monitored during acid cleaning. The acid is consumed when it dissolves alkaline scales. If the pH increases more than 0.5 pH units, add more acid.

Table 2. Recommended High Recirculation Flow Rates During Cleaning

Feed Pressure,[a] psig	Element Diameter, inches	Feed Flow Rate per Vessel (gpm)
20–60	2.5	3–5
20–60	4	8–10
20–60	6	16–20
20–60	8	30–40

[a] Dependent on the number of elements in the pressure vessel.

MULTISTAGE SYSTEMS

For tapered multistage systems, the flushing and soaking steps can be performed simultaneously in the entire array. The high flow rate recirculation step, however, should be carried out separately for each stage, so that the flow rate is not too low in the first stage and too high in the last. This can be accomplished either by using one cleaning pump and operating one stage at a time or by using a separate cleaning pump for each stage.

CONTROL AND IMPROVEMENT OF CLEANING PROCESS

To ensure complete recovery of membrane performance by cleaning, the system performance should be adequately controlled by trending of normalized flux, differential pressure, and salt rejection to (1) trigger cleaning when any monitored parameters change from normal baseline by 10–15%, (2) record the trended parameters before and after each cleaning, and (3) initiate improvement actions for better cleaning if membrane performance does not fully recover. A change in responsiveness to a previously effective cleaning process signals a change in the fouling pattern that requires immediate attention.

If partial cleanings are allowed to continue, the system performance will decline at an increasing rate and will become increasingly difficult to recover.

In-place cleaning processes are improved primarily by the choice of cleaning chemicals and the order of the application sequence. Depending on the composition of the complex foulants, when two or more cleaners are found necessary, often the order in which they are used is important. Also critical, but to lesser extents, are the variables of time, temperature, and cross-flow rate.

Through a thorough review of the water and pretreatment chemistry, analyses of the foulant composition and source, and customized selection of antiscalants, dispersants, and high performance cleaners, both fouling avoidance and reliable plant performance can be attained.

APPLICATION OF RISK ASSESSMENTS IN CRAFTING DRINKING WATER REGULATIONS

Bruce A. Macler
Toxicologist, U.S.
Environmental Protection
Agency
San Francisco, California

INTRODUCTION

Assessments of adverse health outcomes and estimations of health risks from contaminants of drinking water are used at several points in the overall development of U.S. drinking water regulations. They are applied during the extensive discussions surrounding consideration of a contaminant's risk and approaches to risk mitigation, and in the required elements of National Primary Drinking Water Regulation (NPDWR) proposals, support documents, and final rules. Risk assessments are of several types with substantially different intents and characteristics. No one approach fits all applications. The type of assessment chosen depends on the application and the nature and availability of relevant data.

The regulatory process starts with the identification of a constituent as either a possible contaminant of drinking water or as having some adverse toxicological or pathogenic properties. Available health data are then collected and analyzed, leading to the possible development of a toxicological profile of adverse health outcomes and dose–response characteristics. This is then coupled with occurrence data and exposure estimates to provide an estimate of national public health impact. If a decision is made to move forward on a NPDWR, more refined assessments are then used to develop maximum contaminant level goals (MCLGs). Separate assessments are used to help identify possible maximum contaminant levels (MCLs) or treatment techniques consistent with public policies. In some cases, risk assessments may comprise regulatory elements themselves, such as sanitary surveys or comprehensive performance evaluations. Finally, risk assessments are necessary as formal components of regulatory supporting documents to help estimate risk reductions and quantify public health benefits. Some of these assessments, particularly those associated with public health policies and legal requirements, are highly constrained in form and content. Additionally, while the art and science of environmental risk assessment continue to evolve, we still have substantial uncertainty and imprecision in these estimates. Effective interpretation of these risk products requires some understanding of their purpose and form. This chapter details these applications and presents some examples.

RISK ASSESSMENT APPROACHES FOR DRINKING WATER REGULATIONS

In risk management activities to ensure the safety of drinking water, assessments of health risk are performed to answer questions posed in the management process (Fig. 1). Examples include broad questions such as "What is the nature and magnitude of waterborne disease in the United States?"—answers to which can help define where the safety of drinking water fits into the overall considerations of public health, or identify particular situations (e.g., undisinfected wells, crossconnections) that are associated with disease. More familiarly, risk assessments can address narrower questions such as "What is the risk that oral ingestion of hexavalent chromium will cause lung cancer?" or "What is the likelihood of *Cryptosporidium* illnesses from a turbidity spike in an unfiltered surface water system?" where the answers might help define regulatory actions. Specific questions, such as "What is the likely differential number of cancers prevented between a MCL for arsenic at

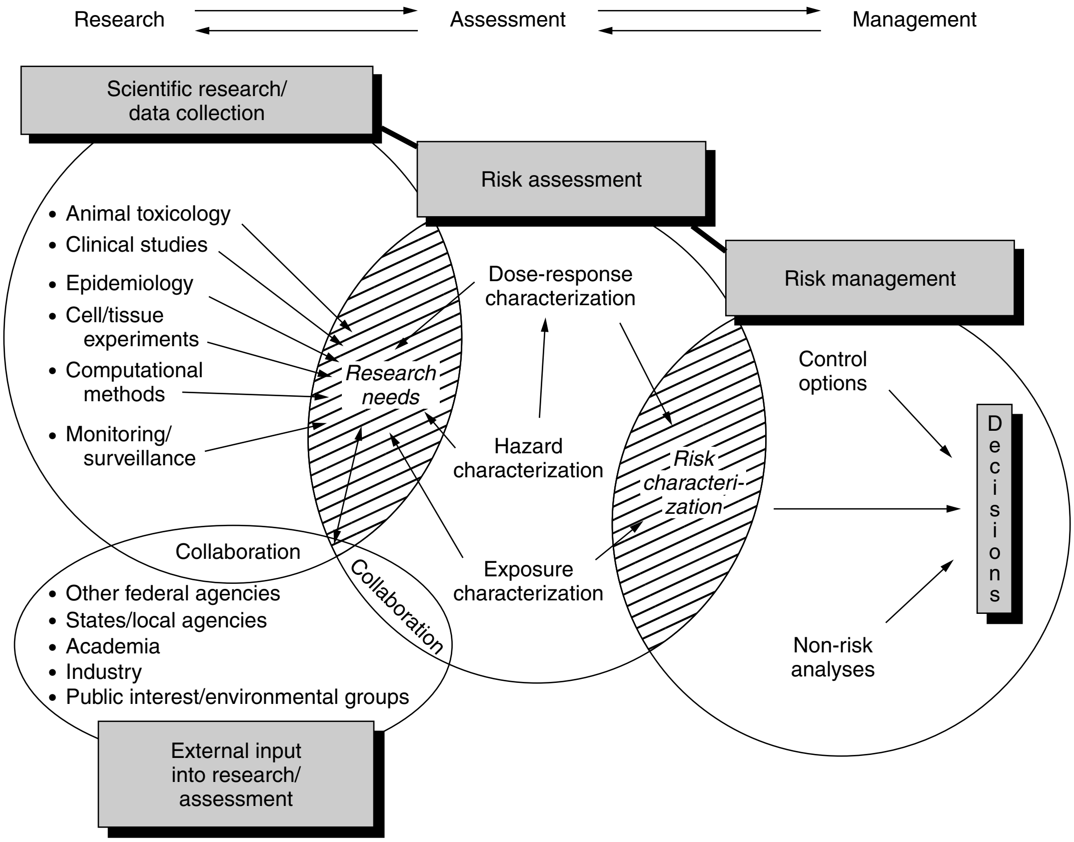

Figure 1. Integration of data collection, risk assessment, and risk management [*Source*: Farland (1)].

3 μg/L and one at 5 μg/L?” or “What are failure modes in the operation of an upflow clarifier?” may need to be answered to compare or determine possible solutions to the identified problems.

Risk assessment approaches for drinking water health and regulatory questions fall into three main types: those based on epidemiologic data, those calculated using mathematical risk models, and those based on analysis of systems and components. Epidemiologic and risk model approaches have been described more completely in earlier chapters, so only their applicability to regulatory development is addressed here. For this purpose, it is important to remember that there are substantial and important limitations to these approaches and that the conclusions from such assessments must be considered with due caution by those using the information. In addition, management decisions are often required in the face of uncertainty and lack of information. Risk assessments can provide useful information, but seldom give clear, unambiguous answers.

With respect to epidemiologic data, information from waterborne disease outbreaks, intervention studies, or controlled experiments on humans can be used directly to both quantitatively and qualitatively describe risks. However, the precision and accuracy of epidemiologic data typically limit these assessments to situations where excess risks (risks above background levels) are about 1% or greater. More often, epidemiologic studies of large groups or populations can describe only effects greater than 10–100% or more. In general, causal associations between contaminants and effects are considered significant only when effects are severalfold higher than background levels. Therefore, risk assessments done directly from these data can generally describe risks and answer risk questions only to this level of resolution. Because public health questions for drinking water often involve situations where risks are substantially below epidemiologic resolution, this approach is frequently inappropriate.

Perhaps the most familiar form of risk assessment is based on mathematical models used to extrapolate existing data to make quantitative estimates relevant to other situations. This well-known approach, first described by the National Academy of Sciences (NAS) in 1983 (2), organizes the process of human health risk assessment into four steps: hazard identification, dose–response assessment, exposure assessment, and risk characterization (Fig. 2). Hazard identification involves an evaluation of whether exposure to a substance would produce an adverse or otherwise undesirable effect. The data used to make such a determination usually come from animal studies. In some instances, human data may be available for the contaminant of interest. Dose–response assessment involves a more quantitative evaluation of the empirical evidence relating a specific exposure dose to the effect of interest. In particular, the available data are examined to determine the relationship between the magnitude of the exposure and the probability of the observed effect.

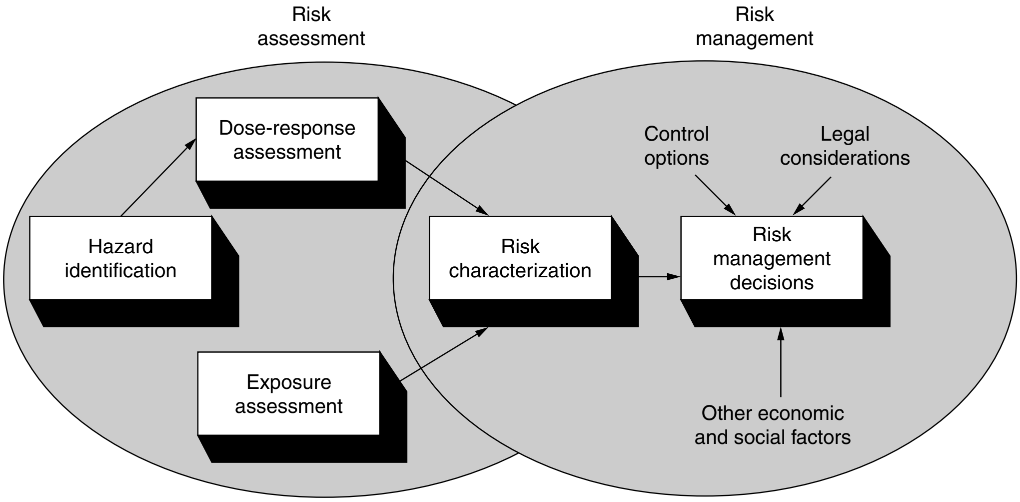

Figure 2. NAS risk assessment paradigm (left circle) and risk management (right circle) [*Source*: USEPA (3)].

Exposure assessments involve an evaluation of contaminant occurrence data, characterization of the environmental fate and transport of the contaminant from the source to the exposed population by different media (e.g., air, water, food), and physiological considerations of different exposure routes (e.g., ingestion, inhalation, dermal contact).

These toxicity and exposure products are combined in the risk characterization. The risk characterization describes the overall nature and magnitude of risk posed to human populations exposed to a particular contaminant. Included in the description is a discussion of what is known and not known about the hazards posed by the substance, what models were used to quantify the risk and why they were selected, assumptions and uncertainties associated with the qualitative and quantitative aspects of the assessment, and general level of confidence in the assessment.

A caution with these is that, while the calculated results are often presented as point value expressions of risk, it must be recognized that the farther the extrapolation from the original data, the more uncertainty and less precision in the results. The animal data themselves result from what are essentially small, highly controlled epidemiologic studies, and thus have the resolution limitations noted above. In addition, experimental variation may be 10% or greater. Because these studies are most often conducted with high exposures to the contaminants of interest and generate high risks, models are used to extrapolate the data to answer questions about lower environmental exposures and/or risks. These models have inherent limitations that magnify uncertainties. Exposure estimates likewise have substantial variation and uncertainty. The net result is that quantitative estimates of risk cannot describe a defined point risk for a certain exposure, but instead a range of possible risks. These ranges tend to increase with increasing model complexity to frequently span orders of magnitude. Most often, the range includes zero.

A third approach to risk assessment is based on analysis of an entire system or operation to identify vulnerabilities that could allow contaminants to reach the consumer. It is based on standard engineering design assessment approaches used to identify failure modes, judge probabilities of occurrence, and describe consequences. These have been adapted to focus on vulnerabilities in systems or operations that could result in human exposure to contaminants. This approach begins with a full description of the system or flow diagram of the process. Points where contamination can occur are identified. The likelihood and consequences of contamination at these points are described. From such an assessment, management actions can focus on controlling high-impact situations (Fig. 3). In the food industry, hazard assessment critical control point (HACCP) programs have been put into place to protect the public from, among other things, contaminated shellfish and other food items. Sanitary surveys, source water vulnerability assessments, and comprehensive performance evaluations (CPEs) are examples of this type seen in the drinking water industry. This is also the approach used for water system security and counterterrorism assessments. As currently practiced, these are qualitative, rather than quantitative in nature. Once the system is described and vulnerabilities identified, probabilities and consequences are typically rated on the basis of best professional judgment and using categories such as “high, medium, or low” or “minor, significant, or catastrophic.” The end result may be a list of vulnerabilities with some rankings for risks and consequences. Managers can use this information to identify problem areas and prioritize activities. Although not commonly practiced, it should be noted that such system analysis approaches are open to quantification of risks (4).

RISK MANDATES FROM THE SAFE DRINKING WATER ACT

The Safe Drinking Water Act (SDWA), as amended in 1986 and 1996 (5) has language that directs the U.S. Environmental Protection Agency (USEPA) to establish

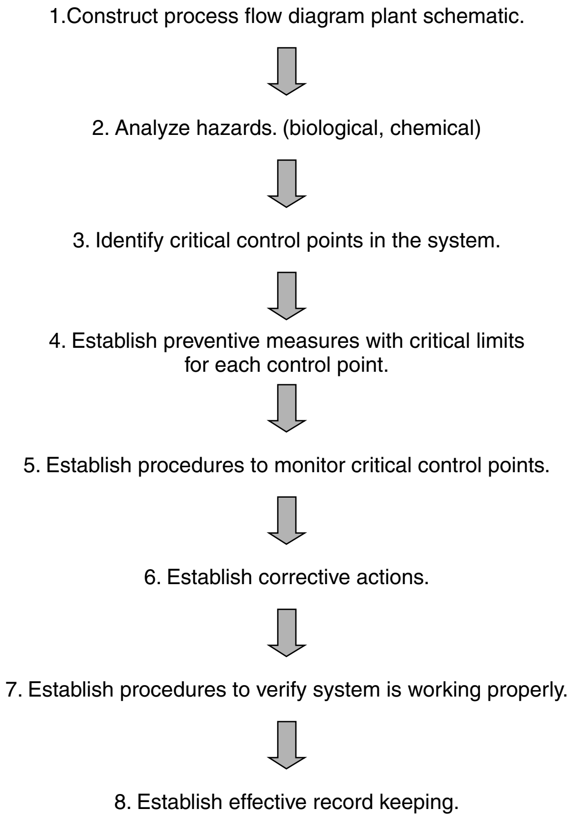

Figure 3. Hazard assessment critical control point (HACCP) risk assessment approach.

MCLGs for contaminants of public health concern for drinking water: “Each maximum contaminant level goal established under this subsection shall be set at the level at which no known or anticipated adverse effects on the health of persons occur and which allows an adequate margin of safety.” These goals, which are not enforceable themselves, are to be used to set the enforceable NPDWRs (5):

> Each national primary drinking water regulation for a contaminant for which a maximum contaminant level goal is established under this subsection shall specify a maximum contaminant level for such contaminant which is as close to the maximum contaminant level goal as is feasible. . . . For the purposes of this subsection, the term “feasible” means feasible with the use of the best technology, treatment techniques and other means which the Administrator finds, after examination for efficacy under field conditions and not solely under laboratory conditions, are available (taking cost into consideration).

In addition, a provision added to the Act in 1996 specifies priorities for selecting contaminants for rulemaking to

> take into consideration, among other factors of public health concern, the effect of such contaminants upon subgroups that comprise a meaningful portion of the general population (such as infants, children, pregnant women, the elderly, individuals with a history of serious illness, or other subpopulations) that are identifiable as being a greater risk of adverse health effects due to exposure to contaminants in drinking water than the general population.

In addition, the Act specifies that USEPA shall document health risks, opportunities for risk reductions, and benefits and costs of mandating these reductions and make these available for public comment. This health risk reduction and cost analysis (HRRCA) is a required component of the regulatory process.

By this and other language, Congress described both the necessary characteristics of risk assessments for drinking water regulations and the broad principles for managing these risks. It can be seen that by their words, Congress established a precautionary policy with regard to drinking water safety. The MCLG was to be set conservatively with respect to risk to more vulnerable individuals. The MCL was to be set to reflect the MCLG, with the additional considerations for technical feasibilities and costs.

These broadly stated goals set directions, but were not sufficiently described to be used for specific regulatory decisions. USEPA evolved operational interpretations of Congressional intentions for both the MCLG and for the acceptable public health risks associated with MCLs and treatment techniques following the 1986 amendments. These have been used consistently for NPDWRs from that time. Following the 1996 amendments, USEPA developed additional approaches for the benefit and cost analyses for the HRRCA.

DEVELOPING MCLS AND TREATMENT TECHNIQUES

The SDWA grants the USEPA Administrator the authority to publish a MCLG and promulgate a NPDWR for a contaminant if the contaminant may have an adverse effect on the health of persons, the contaminant is known or likely to occur in drinking water with a frequency or level of health concern, and there is a meaningful opportunity for health risk reduction. Development of a NPDWR normally begins with the identification of a drinking water contaminant. As provided in the SDWA, USEPA must list candidate contaminants for regulation on a periodic basis (6). Following listing, more detailed health, occurrence, exposure, and treatment technology information is gathered. When adequate information becomes available, a determination is made on whether to go forward with development of a NPDWR proposal (7). This determination uses a protocol developed and recommended to USEPA by the National Drinking Water Advisory Council (NDWAC). The health risk information is combined with occurrence data (levels, frequency, national distribution, persistence, etc.) and exposure estimates to predict the national number of individuals exposed above advisory levels. This risk assessment forms the basis for USEPA’s determination if regulation would provide a meaningful opportunity for health risk reduction.

Maximum Contaminant Level Goals

Once the decision is made to move forward, the MCLG is determined. MCLGs are risk assessment products developed by USEPA Office of Water and Office of

Research and Development. MCLGs are strictly health-based levels. They are developed and set at contaminant levels believed to be without appreciable health risk to individuals, to be consistent with the provision "set at the level at which no known or anticipated adverse effects on the health of persons occur." Additionally, they must address the concern for the protection of sensitive subpopulations. Therefore, risk assessments used to develop MCLGs must at a minimum provide an estimate for a zero-risk exposure level for humans who may be more sensitive to the contaminant. While these risk assessments are caveated to be upper bounds for estimated risks, such that the true risks may be less or even zero, the assessments do not have to, nor are they designed to, estimate the full range of true risks to the average individual.

MCLG risk assessments use the available toxicologic and epidemiologic health study data. The data are evaluated with respect to the nature of the adverse health effects from the contaminant, the strength of evidence for causal relationships, and their quality. Depending on the outcome, a dose–response estimate is made. As noted above, these data are almost always limited in quantity and quality, yielding substantial ranges for uncertainty. USEPA has chosen as a matter of policy to work to risks at the more conservative end of these ranges, in order to comply with the provision that the MCLG "allows an adequate margin of safety" in the face of these uncertainties. Therefore, poorer-quality data will lead to more stringent quantitative descriptions of risk.

For chemicals that produce adverse health effects and are not considered to be carcinogenic (noncarcinogens), the MCLG is based on the *reference dose* (RfD), which is defined as an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population (including sensitive subgroups) that is likely to be without an appreciable risk of deleterious effects during a lifetime. In practice, the RfD is set at a plausible zero-risk level. USEPA assumes that a physiological threshold exists for noncancer health effects from chemical contaminants, below which the effect will not occur. Thus the MCLG will be a nonzero number.

Depending on the quality of the available toxicity data, the RfD is usually derived from an experimental no-observed-adverse-effect level (NOAEL), identified as the highest dose in the most relevant study that did not result in a known adverse effect. The adverse effects chosen may themselves be mild and without clinical significance, but typically represent early stages in progression to more serious disease. In order to extrapolate from the data to human exposures protective of sensitive subpopulations, the NOAEL is divided by various uncertainty factors to derive the RfD. These uncertainty factors conservatively account for the variation in human response to the contaminant, extrapolation to human responses if animal data were used, the nature of the studies, data quality, and relevance. The result of this is that the RfD may differ from the NOAEL by as little as a factor of 3 (e.g., nitrate, arsenic) or as much as $\geq$1000 (e.g., methyl bromide, chlorobenzene). The RfD takes the form of dose ingested per unit body weight per day (μg kg^{-1} day^{-1}). RfDs that have been reviewed and agreed on by consensus within USEPA are listed in USEPA's Integrated Risk Information System (IRIS).

The RfD, which is based on the total daily amount of contaminant taken up by a person on a body weight basis, is converted to a drinking water equivalent level (DWEL) concentration and adjusted for the percentage contribution of other sources [relative source contribution (RSC)] of the contaminant besides drinking water (air, food, etc.) to arrive at the MCLG. This calculation traditionally assumes a lifetime consumption of 2 L of drinking water per day by a 70-kg adult, which is about the upper 90th percentile consumption level. More recent USEPA regulatory risk assessments, such as those for arsenic, have considered different drinking water consumption rates in addition to this default value to represent specific populations (infants, agricultural workers) and situations (8).

A different approach is taken for contaminants that may be carcinogenic. USEPA assumes as a default position that no toxicity threshold exists for induction of cancer and thus, there is no absolutely safe level of exposure. Until relatively recently, once it was determined that a contaminant is a known or probable human carcinogen, the MCLG was automatically set at zero. USEPA has now revised its guidelines for cancer risk assessments to reflect the increasing understanding of the several steps in the progression of cancer (9,10). Some contaminants have been reevaluated for their carcinogenicity using the current draft version of these guidelines. A good example is chloroform (6), which is now considered a carcinogen only at very high exposures associated with tissue damage, such that a threshold is indicated. This allows calculation of a nonzero MCLG using a margin of exposure (MoE) approach. As with RfDs, these determinations of carcinogenicity and their associated dose–response assessments that have been reviewed and agreed on by consensus within USEPA are listed in IRIS.

An alternative approach is used for situations where the data on carcinogenicity of a contaminant are equivocal or too scanty to make a clear judgment. These contaminants are termed "possible human carcinogens." For these, the MCLG may be derived from their relevant noncancer health effects as described above. The resulting RfD is divided by an additional uncertainty factor of 10 as a margin of safety for the possible carcinogenicity.

In a vein similar to that for carcinogens, microbial pathogens and indicator organisms are also assigned a MCLG of zero as a matter of policy, from the consideration that one infective unit (oocyst, cyst, virus particle, bacterium) could be sufficient to cause an infection. The available data on infectivity are supportive for this assumption for the pathogenic viruses studied and for the protozoa, *Giardia* and *Cryptosporidium*. While it is less clear that this is so for pathogenic bacteria, the data cannot exclude this possibility.

Identifying Candidate MCLs

Once the MCLG is established, it is combined with information on contaminant occurrence, treatment technologies, and analytical methods to suggest and evaluate possible regulatory criteria for further discussion. Although the MCLG is a regulatory value, it is not enforceable; the NPDWR is the enforceable regulatory element.

One element in the standard setting process is to determine whether the NPDWR should be a MCL or a treatment technique. An enforceable MCL can be established to control exposure to a contaminant when appropriate analytical methods exist to quantify the contaminant and determine compliance at the MCL. When methods are not available, as for certain microbial exposure situations, treatment techniques may be established that do not directly measure exposure, but use other indicators for compliance.

Two risk considerations come into play in the process of setting a MCL to reduce a contaminant as close as feasible to the MCLG. The first has to do with MCLGs of zero. It is impossible to quantify a contaminant or confirm treatment to a zero exposure. Therefore, MCLs must be above zero, and thus have some risk. A risk benchmark is used to identify appropriate safe drinking water exposures. These guide selection of analytical techniques, treatment approaches, and, ultimately, the MCL choices. This benchmark is based on a consideration of de minimus or “acceptable” risk. As a matter of policy, USEPA Office of Water has used an acceptable risk range for chemical carcinogens from one additional cancer per million people to one additional cancer per 10,000 people exposed to the contaminant over a lifetime (8,11). For pathogenic microorganisms, an acceptable risk of one additional infection per 10,000 people exposed per year has been used (12,13).

These allowable exposures are estimated from the associated dose–response curves. For carcinogens, this dose–response assessment uses models to extrapolate from the available data to zero exposure–zero risk, defining a curve that is essentially linear at low exposures. The resulting “cancer slope factor” allows for a convenient probability analysis of risks to individuals associated with different exposures. The exposures for the acceptable risk range are taken directly from the curve. However, as noted above, the uncertainties increase substantially in these extrapolations. USEPA traditionally uses the 90th percentile upper bound of the modeled results to minimize the possibility that risks in this exposure range are not greater than estimated. The end result of this is that the risk from a lifetime consumption of water at a given level is unlikely to be greater than estimated, is more likely substantially less, and may be zero.

A similar probabilistic risk approach is used for microbial contaminants. The dose–response models used for microbial risk assessments are somewhat more complex in that they must be selected to account for the particulate nature of the infective material in the environment. The modeled exposures are then used for further risk management.

For contaminants with noncancer health risks, the MCLG is used as the starting point for determining a MCL. Because this uses a “bright line” reference point (the DWEL), exposures need only be estimated and compared to the MCLG. However, since this is nonprobabilistic, alternative MCLs cannot be considered on the basis of risks. For most noncarcinogens, the MCL is set equal to the MCLG.

The estimated risks associated with different exposures are then matched against the existing environmental exposure levels to determine the magnitude of the public health problem to be solved. As discussed in other chapters, the additional considerations for treatment technologies and their feasibility and the availability of appropriate analytical methods are factored in at this point.

Health Risk Reduction and Cost Analysis

The second application of risk assessment in the development of a MCL or treatment technique is in the estimation of public health benefits to be gained by regulation. This is used in the management discussions leading up to a regulatory proposal. Under the SDWA of 1986, it was necessary to consider only analytical and treatment feasibility in establishing the MCL. However, a cost benefit assessment was produced as an element of the regulatory impact analysis (RIA). The 1996 revisions to the SDWA required USEPA to explicitly consider costs and benefits in determining the MCL. Therefore, an expanded HRRCA is now required as part of a regulatory proposal. To estimate benefits for different MCLs or treatment requirements, the risks to an individual at the resulting exposure levels must be multiplied by estimates of the number of individuals in the United States exposed to the different levels. In practice, a relationship between the number of individuals exposed versus exposure level is first produced, then further manipulated to account for existing and proposed treatment controls. This relationship may be calculated stepwise or by using Monte Carlo simulations based on exposure distributions. From this, the number of cancers or microbial illnesses avoided at a given regulatory level can be estimated. These “body counts” can be matched with information on the costs of treating the associated diseased and the dollar value of avoiding illness to give quantitative information on the monetary benefits of the regulation. These benefits are then matched against the implementation and compliance costs to utilities and oversight agencies (14). From a risk assessment perspective, it must be remembered that carcinogen dose–response curves represent upper-bound risks; thus estimates of the number of cancers based on these curves are also upper-bound values for any given exposure level.

This approach is most useful for benefits from reducing cancer or microbial illness risks. This is both because these disease endpoints are recognizable and definitive and because the impacts are quantifiable from their probabilities. This is not so for noncancer risks from chemicals. Because these are described by nonprobabilistic, zero-risk DWELs associated with subclinical health effects of indeterminate public health importance, it is difficult to quantify or assign monetary value to the benefits of reducing exposures to these chemicals.

Risk Assessments as Regulations

Risk assessments can comprise regulatory elements themselves. These may apply directly to utilities or secondarily through requirements on primacy agencies. The type of risk assessments currently required in NPDWRs are all qualitative system analyses. These include treatment system sanitary surveys found in the Total Coliform Rule (15) and Interim Enhanced Surface Water Treatment Rule (IESWTR) (16), the watershed sanitary surveys in the Surface Water Treatment Rule (SWTR) (12), and the CPEs, also in the IESWTR. These all require on-site evaluations to determine sources of contamination and vulnerabilities to failures that could compromise water quality. These analyses are similar to the HACCP process used by the National Aeronautics and Space Administration (NASA) and U.S. Department of Agriculture (USDA) to protect foods.

Australia has taken a more formal HACCP approach to protect their drinking water. Termed the "framework for management of drinking water quality," it is to be incorporated into the Australian Drinking Water Guidelines (17). The approach includes a systematic and comprehensive analysis of the entire route of water from source to tap (Table 1). This analysis leads to identification of hazards, sources of hazards, and associated risks. These are addressed in the subsequent institution of protective measures to yield multiple barriers to contamination. The emphasis of the HACCP approach is on proactive protection, rather than reactive responses.

Regulatory Reviews of NPDWRs

The 1996 SDWA Amendments required that USEPA review all existing NPDWRs every 6 years to determine if information available subsequent to promulgation would support regulatory revision. Congress stipulated that all such revisions must maintain, or provide for greater, protection of the health of persons. USEPA, working with the NDWAC, developed a protocol for these reviews, driven largely by reevaluations of health risk information (7). USEPA principally considered whether any new evaluation of oral ingestion risks could lead to revision of the MCLG. This approach allows the Agency to use up-to-date risk assessment approaches in its reevaluations, which will include a wider range of possible adverse health outcomes (reproductive and developmental) and better characterizations of carcinogenicity. The potential here is that some carcinogens would be reclassified in such a way that their MCLs could be relaxed while maintaining the same level of health protection to the public. The reclassification of chloroform as a threshold carcinogen is an example. This would recognize that improved risk assessments could reduce the scientific uncertainties that led to excessively stringent NPDWRs.

System analysis and management
Assessment of the drinking water supply system
Planning preventive strategies for water quality management
Implementation of operational procedures and process control
Verification of drinking water quality
Incident and emergency response
Supporting requirements
Employee awareness and training
Community involvement and awareness
Research and development
Documentation and reporting
Review
Evaluation and audit
Review and continual improvement

FUTURE OUTLOOK

Risk assessments are used both formally and informally at several points within the regulatory process. They serve specific purposes and mandates and may have severe constraints on their representations of risk. While assessments may be qualitative or quantitative in nature, they are always limited by the available information and our current abilities to understand disease processes and predict outcomes. They will always be inexact. Recognizing and accepting their limitations is important for making sound regulatory decisions. An increased awareness of how risk assessments may be used will improve future regulatory discussions.

POTENTIAL RISKS OF WATERBORNE TRANSMISSION OF *ESCHERICHIA COLI* O157:H7

Escherichia coli O157:H7 can be transmitted by any route where fecal contaminated material is ingested. These routes may include foodborne, waterborne, person-to-person, and animal-to-person. Epidemiological investigations during outbreaks have identified that only a small number of organisms is needed to cause infection (i.e., 10–200 organisms) (3). This low infectious dose combined with the possibility of *E. coli* O157:H7 infections that do not show symptoms allows direct person-to-person transmission via poor hygiene.

The most well-documented route of *E. coli* O157:H7 transmission is foodborne. Several outbreaks have occurred from consumption of undercooked ground beef either in restaurants or within individual homes. In addition to meat, other foods have been implicated, including mayonnaise, unpasteurized apple juice, fermented hard salami, lettuce, vegetable sprouts, yogurt, and milk. Contamination of these foods may have occurred due to improper hygiene among food handlers or by contact between uncooked foods and raw meats contaminated with *E. coli* O157:H7. There is also the possibility of direct contamination of produce in the fields with manure from infected animals (4).

An increasingly common route of transmission is waterborne via recreational or municipal water sources. Several *E. coli* O157:H7 outbreaks have been linked to use of recreational waters. Typical sources of recreational water outbreaks may be fecal contaminated material entering a lake and lake water ingested by swimmers or by children with diarrhea contaminating pool water, usually with an insufficient level of chlorine. Outside Portland, Oregon, 59 individuals were infected after swimming in a recreational lake in 1991 (5). A water park outbreak in Georgia in 1998 resulted in dozens of infections and the death of one child. The outbreak was linked to contamination from a child with diarrhea combined with low chlorine levels in the pool water (6).

In addition to these recreational water outbreaks, several incidents have occurred with drinking water. A list of outbreaks linked to contaminated drinking water is shown in Table 1.

The first municipal waterborne *E. coli* O157:H7 outbreak occurred in Missouri in 1989 (7); more than 240 people were infected, and four individuals died. It was suspected that the outbreak occurred from backflow during two water main breaks, leading to intrusion of the pathogen. The most publicized waterborne outbreak of *E. coli* O157:H7 occurred in May 2000 in Walkerton, Ontario, Canada. Approximately 1350 cases of gastroenteritis were reported in individuals exposed to Walkerton municipal water, and overall, it was estimated that the number of cases associated with Walkerton exceeded 2300 individuals. Stool samples confirmed 167 cases of *E. coli* O157:H7 infection; 65 individuals were hospitalized, and 27 individuals developed hemolytic uremic syndrome. Four deaths were directly due to the *E. coli* outbreak in Walkerton, and *E. coli* O157:H7 was a contributing factor leading to three additional deaths. During the outbreak, a supply source well was contaminated with coliform bacteria and *E. coli* O157:H7. This well was prone to surface contamination, especially following flooding conditions, which is what preceded the Walkerton incident. Furthermore, environmental testing of livestock farms, especially a farm adjacent to this well, indicated the presence of *E. coli* O157:H7 infections in the livestock (16,17).

This most common drinking water treatment is disinfection with chlorine. Susceptibility of various strains of *E. coli* O157:H7 to chlorine disinfection has

Table 1. Outbreaks of *E. coli* O157:H7 from Drinking Water

Year, Location	# Infected	Description	Reference
1989, Missouri, U.S.	243	Two water main breaks may have led to backflow in an unchlorinated municipal water supply leading to four deaths	(7)

been examined in several studies, and except for an occasional resistant strain (18), the organism can be rapidly inactivated by low levels of chlorine disinfectant and shows no unusual tolerance to chlorine.

According to a Water Quality Disinfection Committee survey (19), it was determined that United States water utilities must maintain a median chlorine residual of 1.1 mg/L and a median exposure time of 45 minutes before the point of first use in the distribution system. Based on these guidelines, it seems unlikely that *E. coli* O157:H7 would survive conventional water treatment practices in the United States at these levels of chlorination. Had appropriate chlorine residual levels been maintained, many of the aforementioned drinking water outbreaks, such as the Walkerton event, would have been avoided. In nondisinfected drinking water, *E. coli* O157:H7 demonstrates environmental survival and chlorine susceptibility similar to wild-type *E. coli* (20), which suggests that wild-type *E. coli* could be an adequate indicator organism for fecal contamination of water.

The United States Environmental Protection Agency regulates systems that operate at least 60 days per year and serve 25 people or more or have 15 or more service connections as public water systems under the Total Coliform Rule. This compliance monitoring of tap water for all public water systems can indicate whether the system is contaminated or vulnerable to fecal contamination, if it fails to identify specifically the presence of *E. coli* O157:H7. Existing detection methods for *E. coli* O157:H7 are intended for analyses of clinical specimens or food products, which are expected to contain large numbers of organisms. These methods lack sensitivity for detecting low numbers of contamination in environmental samples and typically require long (20–48 hour) incubation periods for analyzing small sample volumes. To ensure that public water systems can rapidly respond to contamination from this significant human pathogen, there is an urgent need for rapid detection methods for *E. coli* O157:H7 in water. The reader is referred to the article entitled "Understanding *Eschericia coli* O157:H7 and the need for rapid detection in water" by Bukhari, Weihe, and LeChevallier for further discussion of rapid methods for detecting *E. coli* O157:H7 in water.

SLOW SAND FILTRATION

National Drinking Water
Clearinghouse

First used in the U.S. in 1872, slow sand filters are the oldest type of municipal water filtration. Today, they remain a promising filtration method for small systems with low turbidity or algae-containing source waters. Slow sand filtration does not require pretreatment or extensive operator control—which can be important for a small system operator with several responsibilities

WHAT IS SLOW SAND FILTRATION?

Slow sand filtration is a simple and reliable process. Slow sand filters are relatively inexpensive to build, but they do require highly skilled operators (Fig. 1).

The process percolates untreated water slowly through a bed of porous sand, with the influent water introduced over the surface of the filter, and then drained from the bottom.

Properly constructed, the filter consists of a tank, a bed of fine sand, a layer of gravel to support the sand, a system of underdrains to collect the filtered water, and a flow regulator to control the filtration rate. No chemicals are added to aid the filtration process.

ADVANTAGES

Design and operation simplicity—as well as minimal power and chemical requirements—make the slow sand filter an appropriate technique for removing suspended organic and inorganic matter. These filters also may remove pathogenic organisms.

Slow sand filtration reduces bacteria, cloudiness, and organic levels—thus reducing the need for disinfection and, consequently, the presence of disinfection byproducts in the finished water. Other advantages include:

- Sludge handling problems are minimal.
- Close operator supervision is not necessary.
- Systems can make use of locally available materials and labor.

Slow sand filters also provide excellent treated- water quality (See Table 1). Slow sand filters consistently demonstrate their effectiveness in removing suspended particles with effluent turbidities below 1.0 nephelometric turbidity units (NTU), achieving 90 to 99 + percent reductions in bacteria and viruses, and providing virtually complete *Giardia lamblia* cyst and *Cryptosporidium* oocyst removal.

LIMITATIONS

Slow sand filters do have certain limitations. They require a large land area, large quantities of filter media, and manual labor for cleaning.

Table 1. Typical Treatment Performance of Conventional Slow Sand Filters

Water Quality Paramenter	Removal Capacity
Turbidity	<1.0 NTU
Coliforms	1–3 log units
Enteric Viruses	2–4 log units
Giardia Cysts	2–4 + log units
Cryptosporidium Oocysts	>4 log units
Dissolved Organic Carbon	<15–25%
Biodegradable Dissolved Organic Carbon	<50%
Trihalomethane Precursors	<20–30%
Heavy Metals	
Zn, Cu, Cd, Pb	>95–99%
Fe, Mn	>67%
As	<47%

Source: Adapted from Collins, M.R. 1998.

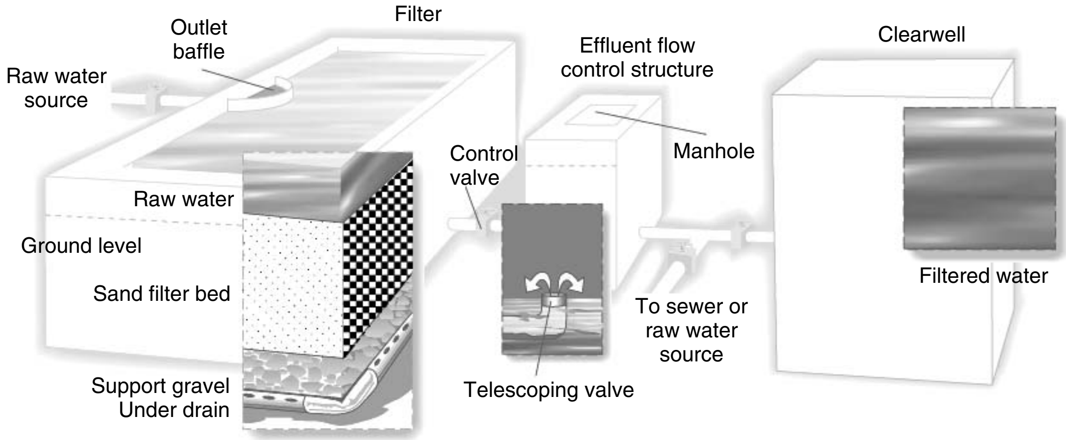

Figure 1. Slow sand filter.

Water with high turbidity levels can quickly clog the fine sand in these filters. Water is applied to slow sand filters without any pretreatment when it has turbidity levels lower than 10 NTU.

When slow sand filters are used with surface waters that have widely varying turbidity levels, infiltration galleries or rough filters—such as up- flow gravel filters—may be used to reduce turbidity.

Waters with a very low nutrient content may impair turbidity removal since some nutrients must be present that promote biological ecosystem growth within the filter bed.

Slow sand filters do not completely remove all organic chemicals, dissolved inorganic substances, such as heavy metals, or trihalomethane (THM) precursors—chemical compounds that may form THMs when mixed with chlorine. Also, waters with very fine clays are not easily treated using slow sand filters.

A granular activated carbon (GAC) sandwich filter is a modified slow sand filter that removes organic material. This filter uses a base sand layer that is approximately 1 foot deep, an intermediate GAC layer approximately 0.5 feet, and a top sand layer approximately 1.5 feet deep. This modified slow sand filter effectively removes pesticides, total organic carbon, and THM precursors.

Slow sand filters are less effective at removing microorganisms from cold water because as temperatures decrease, the biological activity within the filter bed declines.

PROCESS DESCRIPTION

Slow sand filters require a very low application or filtration rate (0.015 to 0.15 gallons per minute per square foot of bed area, depending on the gradation of the filter medium and the quality of the raw water). The removal action includes a biological process in addition to physical and chemical ones (Table 2).

A sticky mat of biological matter, called a "schmutzdecke," forms on the sand surface, where particles are trapped and organic matter is biologically degraded. Slow sand filters rely on this cake filtration at the surface of the filter for particulate straining. As the surface cake develops during the filtration cycle, the cake assumes the dominant role in filtration rather than the granular media.

Pilot testing is always necessary when designing slow sand filters. Currently, engineers are not able to predict the performance of a slow sand filter with a specific quality of raw water. Operation of a small pilot filter, preferably over several seasons of the year, will insure adequate performance of the full-scale plant.

Remember, after the designer sets the parameters—such as the plant filtration rate, bed depth, and sand size—there is little a plant operator can do to improve the performance of a slow sand filter that does not produce satisfactory water.

Slow sand filter pilot plant testing does not have to be expensive. Pilot plant testing has been done using manhole segments and other prefabricated cylindrical products, such as filter vessels.

Slow sand filter pilot facilities operate over long periods of time—up to a year—but the level of effort can be quite low, consisting of daily checks of head loss, flow rate, water temperature, and turbidity and taking coliform samples.

Since the purification mechanism in a slow sand filter is essentially a biological process, its efficiency depends upon a balanced biological community in the schmutzdecke. Therefore, filters should operate at a constant rate. When operation is stopped, the microorganisms causing bacteriological degradation of trapped impurities lose their effectiveness. Intermittent operation disturbs the continuity needed for efficient biological activity.

Allowing the filter to operate at a declining rate is one way of overcoming this problem. Declining rate filtration produces additional water, which is generally satisfactory. Moreover, the declining-rate mode may be applied during overnight operation, resulting in significant labor savings.

Storing filtered water is essential at a slow sand filter plant for two reasons. First, because of the importance of establishing biological activity, using chlorine ahead of the filter is inappropriate, and the operator must provide disinfectant contact time in a storage basin. Second, storage is needed for production equalization and demand.

Table 2. Design Summary of a Slow Sand Filter

Design Parameters	Recommended Range of Values
Filtration rate	$0.15\ \mathrm{m}^3/\mathrm{m}^2 \cdot \mathrm{h}$ ($0.1–0.2\ \mathrm{m}^3/\mathrm{m}^2 \cdot \mathrm{h}$)
Area per filter bed	Less than 200 m^2 (in small community water supplies to ease manual filter cleaning)
Number of filter beds	Minimum of two beds
Depth of filter bed	1 m (minmum of 0.7 m of sand depth)
Filter media	Effective size (ES) = 0.15–0.35 mm; uniformity coefficient (UC) = 2–3
Height of supernatant water	0.7–1 m (maximum 1.5 m)
Underdrain system	
Standard bricks	
Precast concrete slabs	Generally no need for further hydraulic calculations
Precast concrete blocks with holes on the top	
Porous concrete	
Perforated pipes (laterals and manifold type)	Maximum velocity in the manifolds and in laterals = .3 m/s Spacing between laterals = 1.5 m Spacing of holes in laterals = 0.15 m Size of holes in laterals = 3 mm

MONITORING AND OPERATION REQUIREMENTS

A slow sand filter must be cleaned when the fine sand becomes clogged, which is measured by the head loss. The length of time between cleanings can range from several weeks to a year, depending on the raw water quality. The operator cleans the filter by scraping off the top layer of the filter bed. A ripening period of one to two days is required for scraped sand to produce a functioning biological filter. The filtered water quality is poor during this time and should not be used.

In some small slow sand filters, geotextile filter material is placed in layers over the surface. In this cleaning method, the operator can remove a layer of filter cloth periodically so that the upper sand layer requires less frequent replacement.

In climates subject to below-freezing temperatures, slow sand filters usually must be housed. Uncovered filters operating in harsh climates develop an ice layer that prevents cleaning. Thus, they will operate effectively only if turbidity levels of the influent are low enough for the filter to operate through the winter months without cleaning. In warm climates, a cover over the slow sand filter may be needed to reduce algae growth within the filter.

Before cleaning a slow sand filter, the operator should remove floating matter, such as leaves and algae. When one unit is shut down for cleaning, the others are run at a slightly higher rate to maintain the plant output.

After cleaning, the unit is refilled with water through the underdrains. This water can be obtained from an overhead storage tank or by using water from an adjacent filter. When the clearwell is designed, the temporary reduction of plant output should be considered, ensuring that sufficient water is available for the users.

Once the filter is cleaned, the microorganisms usually re-establish and produce an acceptable effluent. In cooler areas, ripening may take a few days. Even then, if the effluent's turbidity is sufficiently low, the water supply can be resumed after one day with adequate chlorination.

Slow sand filter monitoring and operation is not complicated. Daily tasks include reading and recording head loss, raw and filtered water turbidity, flow rates, and disinfectant residual. If necessary, the operator should adjust the flow to bring water production in line with demand.

In addition, with the promulgation of the Surface Water Treatment Rule, each day the operator needs to use the flow data and disinfectant residual data to calculate contact time values and determine if disinfection is sufficiently rigorous. These duties may require one to two hours unless automated.

HAVE YOU READ ALL OUR TECH BRIEFS?

"Tech Briefs," drinking water treatment fact sheets have been a regular feature in the National Drinking

Water Clearinghouse (NDWC) newsletter *On Tap* for more than four years. NDWC Technical Assistance Specialist Mohamed Lahlou, Ph.D., researches, compiles information, and writes these very popular items.

To order, call the NDWC at (800) 624–8301 or (304) 293–4191. You may also order online at *ndwc_orders@mail.estd.wvu.edu* or download fact sheets from our Web site at www.ndwc.wvu.edu.

Additional copies of fact sheets are free; however, postal charges may be added.

For further information, comments about this fact sheet, or to suggest topics, call Dr. Lahlou at one of the above numbers or contact him via e-mail at *mlahlou2@wvu.edu.*

APPROACHES FOR SECURING A WATER DISTRIBUTION SYSTEM

Marsha A. Hosner
DHI
Newtown, Pennsylvania

The world focus on water security has been extremely heightened since the attack on the World Trade Center on September 11, 2001. The thinking behind the new focus is in response to terrorist threats on our drinking water and infrastructure in general. This heightened focus is generally a public response—citizens wanting something to be done to make them safer than they are currently. But water related security issues are not new.

INHERENT RISKS

Catastrophic events involving water have been taking place regularly throughout history. On April 1, 1913, hundreds of homes in Portsmouth, Ohio, were washed away when a 69-foot wall of water washed through from a flood on the Great Miami River. More than 120 people were killed, and there was a subsequent smallpox outbreak. On Cape Cod, Massachusetts, treated sewage disposal has formed a contaminated plume of ground water that today is slowly spreading into drinking water wells through the shallow gravel and sand soil composition. Droughts take place on a regular cycle related to various weather systems (1).

The possibilities of things that could go wrong are impossible to list—a fact that points to a reality that has to be faced. There is no way to stop things from happening to your water systems. And though there are a number of things you can do to reduce the risk, the most important step to take is preparing in advance for the time when something does happen.

DRINKING WATER SPECIFICS

Water arrives at the consumer through a network of pipes that ultimately link to the water supply or treatment facility. However, to achieve maximum control over the system, for instance, in case of pipe failures or unusual demand patterns (such as fire flows), water supply networks are generally designed as complicated, looped systems, wherein each individual tap may be capable of receiving water from several sources and intermediate storage facilities. This means that the water from any given tap can arrive through several different routes and can be a mixture of water from several sources. The routes and sources for a given tap can vary over time, depending on the pattern of water use (2).

The Association of State Drinking Water Administrators devised a security vulnerability checklist for a water distributor to use as a guideline for security (3). It includes a list of critical components, such as shown in (Fig. 1): ground water, surface water, purchased water, buildings, pumps, treatment equipment and supplies, laboratories, chemicals, storage tanks, power supplies, auxiliary power supplies, pipes, valves, buildings, computers, files, work vehicles, telephones, and dispatch radios.

Citizens have always been concerned about who is watching the water and how and when they would be told if something went wrong. In 1993, there was a an outbreak of *Cryptosporidium*—an intestinal protozoan—that infested the Milwaukee water supply and sickened more than 400,000 people (4). The cause of the infestation was not determined, but it is thought that it related to storm water runoff across pasture land that fed cattle—known for carrying this protozoan. *Giardia* is another germ that can often be found in the water supply.

Except for freak accidents or intentional attacks on the system, U.S. drinking water is thoroughly tested and is safe to drink. The maximum contaminant levels are frequently tested on a prescribed schedule, and it is treated with chlorine and chloramines to kill germs. Of course, people not on the public water supply need to take steps on their own to ensure that there are no contaminants. There are many countries that do not treat water or test it—and in those countries, the risk of serious disease is much higher.

The Danish government hired the Danish Hydraulic Institute (DHI) to secure the water system for their country. The end result of that study, again, was that it cannot be done (Fig. 2). So steps were then taken to prepare responses in case of accidental or intentional contamination. One of the methods being used there is called Artificial Recharge Technology—a mixing of water sources to dilute the supply, so that it can be flushed to reduce contaminants quickly and eventually to remove them (5).

GOVERNMENT ACTIONS

The states have had money available for loan for many years through the EPA Superfund. This is a loan that has to be paid back over 20 years. This money can be used for fencing, cameras, and other physical security and also for software models and other emergency action planning tools. By the year 2004, all water distribution utilities serving approximately 3000 customers or more

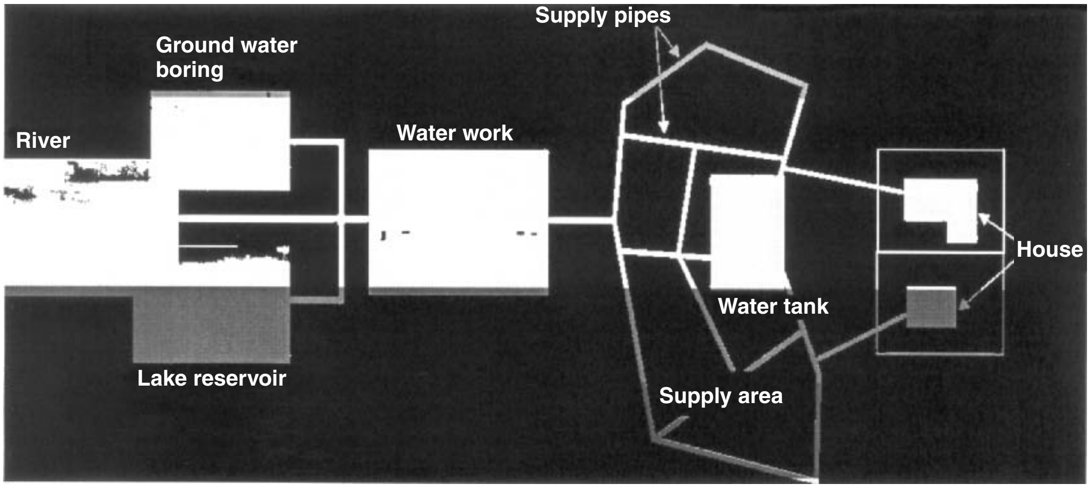

Figure 1. Components of a water system.

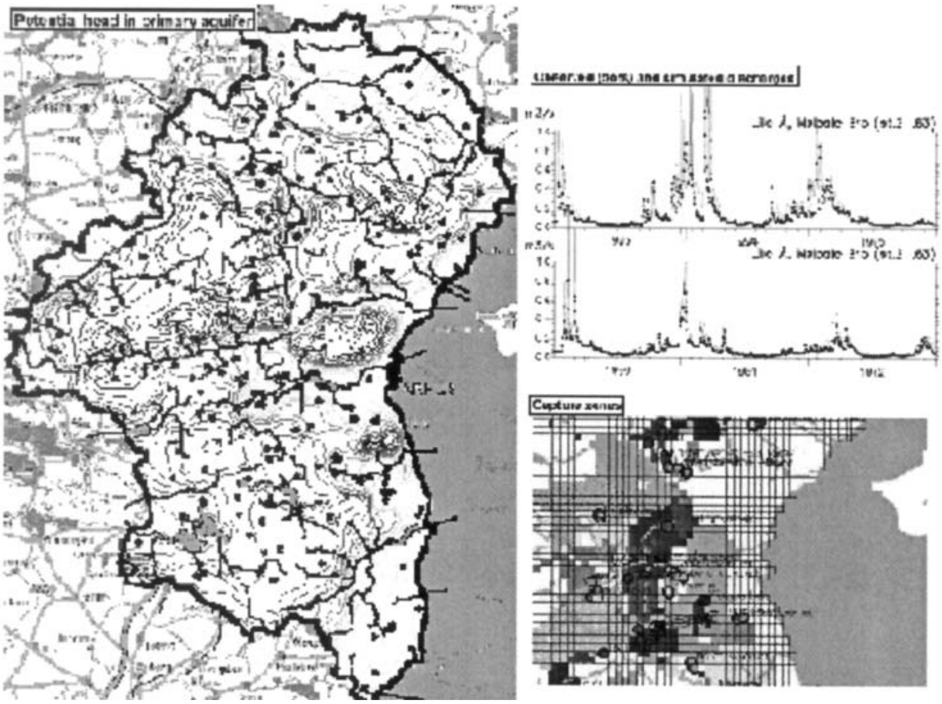

Figure 2. Aarhus, Denmark, water supply system data as seen in the emergency response planning software screen.

will be required to have written emergency action plans filed with the government.

These formal requirements for water utilities will be followed by formal requirements for wastewater utilities, and voluntary compliance by the wastewater utilities is expected to take place prior to formal implementation. In response to the need to establish these documents, many organizations have created written guidelines, as well as various training schemes. Sandia National Labs has been designated as the official resource for vulnerability assessment training (6). Many other private firms have been trained by Sandia to train others to perform these assessments.

Water security issues were addressed formally during the Clinton administration as just one part of a needed focus on all our infrastructure systems. In the White Paper printed by the U.S. Department of Justice, the Presidential directive states, “Critical infrastructures are those physical and cyber-based systems essential to the minimum operations of the economy and government . . . these infrastructures have become increasingly automated and interlinked. These same advances have created new vulnerabilities to equipment failures, human error, weather and other natural causes, and physical and cyber attacks. Addressing these vulnerabilities will necessarily require flexible, evolutionary approaches that span both the public and private sectors, and protect both domestic and international security. . .non-traditional attacks on our infrastructure and information systems may be capable of significantly harming both our military power and our economy" (7). Even in this document written in 1998, our government was requiring emergency action plans.

The Environmental Protection Agency (EPA) is, today, setting up the training, the grants, and the documentation for water agencies to meet their required vulnerability assessments and emergency action plans (8). Every water and wastewater agency is coming out with its own version of training aid documents, and commercial software packages are available from many companies to facilitate the planning process (Fig. 3). At least one commercial company, DHI, offers additional discounts to government buyers to hold down the cost of this compliance (www.dhigroup.com). There is also freeware available from the U.S. government. So lack of tools is not an issue for suppliers to prepare themselves.

TAKING ACTION

Whether it is a terrorist threat, flood, drought, earthquake, hurricane, or other natural catastrophe, there are logical steps to take to reduce the risk in any situation:

1. Identify the resources at risk and label them.
2. Determine who is responsible as a caretaker of each resource—and make sure they know it.
3. Measure the degree of risk.
4. Monitor the condition of the resource frequently.
5. Develop contingency plans.

First determine the water resources in your realm that are susceptible to loss or destruction—water supply, bridges, or treatment plants. Make an inclusive list. Figure 1 shows all the components of a water supply system—it is more than the waterworks plant. Be sure that the surrounding community is aware of the resources—posting signage, for example, that a water supply is not for dumping, and other things that might seem obvious to some are not so obvious to others. We are all caretakers of our environment. Many catastrophic events can be avoided simply by educating those who are in the area about proper care of their resources. Running out of water is a very scary possibility, and the public should be informed and trained in water conservation tactics—especially in time of droughts.

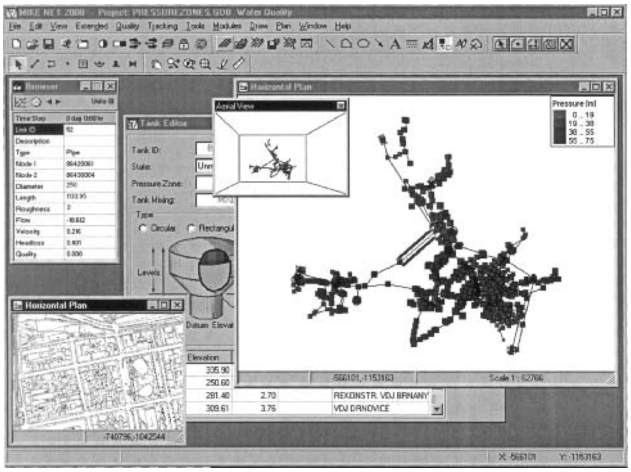

Figure 3. Use of a commercial software package to prepare action plans.

Second, identify the responsible person for each item you listed—it could be an organization, individual, or a department. Ensure that they know the full scope of their responsibility. They may know they are responsible, say, for water distribution—but have they been acknowledged as responsible for safety for that system? Ensure that they have been empowered to take needed steps to secure it. These are organizational issues generally that have to be met by some level of municipal government. The responsible parties must have the proper authority for exercising their duty.

Third, the responsible authority should measure the resource. They should get a firm grasp of the magnitude of their responsibility—both the physical size and the number of people involved. They need to know what condition it is in today. If steps can be taken to make them less vulnerable, they should be taken. It is impossible to improve the condition of anything if you do not know what condition it is in now. Measure it, and determine what shape it should be in to satisfy the community it serves (Fig. 4). Then take steps to get it in shape.

Fourth, monitoring the current condition can vary greatly depending on the vulnerability of the resource. If it is a condition that can be watched, then someone should be checking the vulnerability or watching for safety reasons. For instance, water quality samplers can be installed to check, at any interval desired, the condition of any water supply. Simple fences can keep out unwanted visitors. Periodic inspections to keep things at optimum condition are easily performed.

Fifth, contingency planning is multiphased. It should be determined if there are adequate resources, in the way of tools and manpower, to manage the system in the event of a catastrophe. Contingency plans should exist

Figure 4. Monitoring the data from a storm drain flow monitor.

that can be readily executed. Authorities should know of the contingency plans—how to locate them and how to execute them. Models can be developed of water supplies and wastewater collection systems that can then be used to show a multitude of "what if" scenarios. For water distribution systems, the use of a model is key to creating proper emergency response plans.

The American Water Works Association published the Manual of Water Supply Practices M19, which includes the section "Emergency Planning for Water Utility Management" (9). In chapter 5 of this document, it states that the basic principles of an emergency action plan are that it should "(1) use or reference existing resources, (2) be concise and logical, and (3) be coordinated with other agencies." There is a great push to implement SCADA (supervisory control and data acquisition) systems to watch the operation of a water system in real time—even monitoring the water quality, so it is important that these automated systems have built into them the ability to notify officials in case of sudden change and emergency. Many systems simply monitor and react without human notification. For introduction of toxins and protection of public health and safety, this would not be acceptable to the public, nor should it be.

In summary, I quote the AWWA from the *Security Analysis & Response for Water Utilities*: "A completed security assessment and response plan is useful only if the utility staff and supporting agencies maintain continued vigilance" (10). Ongoing training of staff, ongoing review of the emergency system, along with periodic drills of implementation of emergency actions are vital to successful performance of any emergency action planning.

WATER SECURITY: AN EMERGING ISSUE

Hemant J. Purohit
Sukumar Devotta
Environmental Genomics Unit,
National Environmental
Engineering, Research
Institute, CSIR
Nagpur, India

One of the most pressing global issues is the increase in world population and its impact on the availability of freshwater. Freshwater is generated, transported, and stored within confined river basins. In 1992, the Dublin conference, Assessment, CFWA, was considered, where water was regarded as an economic good, and in 1994, the United Nations Commission for Sustainable Development proposed that a comprehensive assessment of the freshwater resources of the world should be undertaken (1). Climate change adds further risks and uncertainties to the global picture, requiring adaptive management in water resources based on monitoring and re-evaluation (2). A global-scale assessment of water resources and their use was performed in the framework of the 1997 United Nations Comprehensive Assessment of the Freshwater Resources of the World (3). Since 1970, global water demand has risen at an estimated rate of 2.4% per annum, with much higher trends in developing countries because of increasing urbanization and water-intensive agricultural activities (4). Developing countries are home to the overwhelming proportion of the world's 2.6 billion people without access to clean water, a figure that is expected to significantly increase in the next decades (5). The relationships between water quantity and environment have been overlooked in the past. A need exists for a new dimension of the impending water crisis (6). For example, in India, it is expected that severe water crises will occur by the year 2025 (7).

MODELS FOR PREDICTION OF GLOBAL WATER AVAILABILITY

Identification of the links between rapidly growing populations and shrinking freshwater supplies is the essential first step in making water use sustainable. Various models are proposed for prediction of water usage based on climate data. Even water security has been correlated with food security by modeling (8). Yates (9) presented an integrated assessment model for continental scale runoffs where the limiting data for the spatial and temporal variability of freshwater resources is the constraint. An analysis of Western Europe's and Africa's freshwater runoff, which spans a range of climate variability, was performed at varying levels of spatial aggregation and at both monthly and annual time steps. Model results showed that regional runoff characteristics were lost beyond a data aggregation of 1° × 1° resolution. A macroscale hydrological model, designed to simulate stream flow from climatic inputs over a large geographic domain, has been proposed by Arnell (10). In the case of

Hydrological Model of WaterGAP 2 (WGHM), the model tuning has aimed at achieving a good representation of the long-term average discharges (11). It has a strong positive effect on the performance of all proposed water availability indicators.

WATER SOURCE AND RESOURCES

The prevention of water contamination is always a preferable scenario instead of attempting to remove contaminants once they have entered the aquatic environment. Although it is likely that some contamination events will always occur, a large proportion of water resources can be secured through protection and good water resource management; efficient design, operation, and management of water supplies; and regular and thorough surveillance activities. Water source protection is a mixture of case-specific measures of a particular area to protect individual sources. It also involves wider ranging measures, which are designed to protect the larger water resource bodies on a provincial, national, or regional (international) basis, which always requires guidelines such as state-level or provincial-level guidelines up to international treaties to ensure sustainable management of resources. Surface water sources and resources are far more open to contamination, and potential sources for contamination are generally far larger than for groundwater. Thus, any measures taken to protect surface water resources will generally encompass a far wider geographical region than measures designed to protect groundwater resources. At a global level, the advanced scientific methods, such as GIS applications and remote sensing techniques, quantify the existing water resources and help in formulating a sustainable management scheme by considering both water uses and environmental protection (12). Groundwater is an important source of drinking water. In its natural state, groundwater is generally of high microbiological quality with little or no contamination. The relative purity of groundwater in its natural state is largely a result of infiltration through the soil and unsaturated layers of rock, although some groundwaters do have high levels of harmful chemicals, such as fluoride and arsenic (7).

THREATS TO WATER RESOURCES

The water resources can be at threat because of natural geological disturbances or anthropological activities, which are making water unsafe for human consumption. Various anthropogenic activities exist that are making water resources unsafe, such as selenium pollution, which is a globally identified phenomenon and is associated with the most basic agricultural practices to the most high-tech industrial processes (13).

The prevention of contamination of groundwaters by persistent mobile contaminants is an essential element in the protection of groundwater resources. Generally, where aquifers are overlain by a substantial unsaturated zone and have high primary porosity and reasonable permeability, they tend to be less vulnerable to pollution. In industrial cities, initial development led to a decrease in the groundwater levels and subsequent accumulation of contaminants in the unsaturated zone. However, further developmental activities that have occurred there, or maybe elsewhere using different water sources, sometimes leads to a recovery of groundwater levels owing to desorption of contaminants and groundwater pollution, which has led the concept of “Groundwater Protection Zones” where acceptable land uses are defined in order to protect the underlying groundwater. Many factors exist that influence the shape of the zone: the nature of the aquifer (which are very rarely isotropic); the number of rivers in the zone; the condition of rivers (whether influent, effluent, perched, or changing); and the number and location of other abstraction points within the zone. The more rivers associated with the aquifer, the greater the distortion and extension of the zone.

In general, water can become contaminated at the original water source, during treatment, in the pipes that distribute water from a treatment facility to homes and businesses, or in containers. Surface water (rivers or lakes) can be exposed to acid rain, storm water runoff, sewage overflow, pesticide runoff, and industrial waste. This water is cleansed somewhat by exposure to sunlight, aeration, and micro-organisms in the water. Groundwater (aquifer) generally takes longer to become contaminated, but the natural cleansing process also may take much longer because it moves slowly and is not exposed to sunlight, aeration, or aerobic (requiring oxygen) micro-organisms. Groundwater can be contaminated by disease-producing pathogens, leachate from landfills and septic systems, careless disposal of hazardous household products, agricultural chemicals (fertilizers, pesticides, herbicides), industrial chemicals, and leaking underground storage tanks. Water distribution systems contain living micro-organisms and nutrients that enter a system with raw water during water treatment failures or from leaks, cross-connections, and back-flows. Bacterial growth may also occur at or near the pipe surfaces (biofilms), the interface with suspended particulates, and within the water itself. Besides microbes, other contaminates occurring in drinking water can include: (a) organics (trihalomethanes and other disinfection byproducts), which are formed when chlorine and other water disinfectants combine with naturally occurring organic matter; pesticides, including herbicides, insecticides, and fungicides; and volatile organic chemicals; and (b) inorganics (arsenic, barium, chromium, lead, mercury, and silver). The Centre for Science and Environment, New Delhi, India, has also expressed concern over the contamination of pesticides in bottled water.

WATER SECURITY AND ITS RELATION TO FOOD SECURITY AND AGRICULTURE

The International Food Policy Research Institute has developed a 2020 Vision of *a world where every person has economic and physical access to sufficient food to sustain a healthy and productive life, where malnutrition is absent, and where food originates from efficient, effective, and low-cost food and agricultural systems that are compatible with* *sustainable use and management of natural resources*. The major challenges observed to this Vision 2020 are ignorance to water security (14). The Indian national consultation program (15) also projected the World Water vision for the year 2025. Projections for world agriculture in the first half of the twenty-first century vary widely, largely depending on assumptions of yield growth. The pattern of yield growth for major crops is logistic, and not exponential. This pattern is consistent with ecological limits on soil fertility, water availability, and nutrient uptake (16).

Agriculture demands more water than any other activity. Although the total amounts of water made available by the hydrologic cycle provide enough freshwater for the world's current population, most of this water is concentrated in specific regions, leaving other areas water deficient. Therefore, the "Virtual water" concept has been introduced for water-short countries in recent years. These countries can minimize their use of water and achieve food security at the same time by importing a portion of their food requirements from other areas or countries where water resources are adequate and available at a lower cost (17). Similarly, a Water Poverty Index has been proposed, which integrates water stress and scarcity and physical estimates of water availability with socioeconomic variables (18). The effect of usage of virtual water has been analyzed nicely in a case study where, by taking six southern Mediterranean countries, the water-food challenges facing water-scarce countries and the implications for the world food economy have been discussed. By accounting for the volume of virtual water embedded in food imports into the countries concerned, a close relationship between water endowment and food import dependence has been elaborated. The results of this case study highlight that food imports are imperative for compensating water resource deficiency and that water scarcity-related food imports will continue to have an impact on food economy (19).

Globally, water is likely to become an increasingly critical resource issue in the developing world. In the coming time, the forces of globalization with technological revolution will influence the trans-boundary management of water as equity. The world is moving into a new kind of economy as well as into a new kind of society, where we need new mindsets and knowledge to resolve increasingly complex and interrelated continental issues. The water sector is no exception to this development.

GUIDE TO SELECTION OF WATER TREATMENT PROCESSES

Michael Muntisov
GHD Pty Ltd.
Melbourne, Victoria, Australia

Selecting the appropriate treatment process is a critical step in providing safe, reliable, good quality drinking water at a cost-effective price.

This article provides guidance in selecting appropriate treatment processes taking into account raw water quality and costs.

RAW WATER QUALITY AND TESTING

There is a need for raw water quality data covering an extended period sufficient to show seasonal and extreme events to make a sound decision on appropriate treatment processes.

Ideally, the parameters listed in Table 1 should have data collected as set out.

In practice, the extent of data set out in Table 1 is rarely available. In these cases, immediate intensive periods of testing are essential to develop as much understanding of the raw water characteristics as possible in advance of selecting treatment processes. Adjacent similar water sources are possible sources of indicative data. In addition, risk assessment techniques can identify potential hazard parameters even where sampling data are limited. For some possible contaminants, it is appropriate to assess risk rather than sampling because measurements may not be representative. This approach involves examining possible sources of contaminants in the catchment and then calculating the risk or approximate concentration that might occur in the raw water.

Before any process is finally selected, it is important to carry out treatability testing on the actual source water. All waters have subtle differences, and these can have a significant effect on process selection and performance. As a minimum, coagulation jar tests should be performed.

Testing is particularly important for correct sizing and cost analysis of competing options to take account of actual conditions. For example the amount of coagulant and other chemical usage can have a significant influence on the cost-effectiveness of a coagulant-based conventional process versus, say, microfiltration. Conversely, although it can be assumed that microfiltration achieves excellent particle and protozoa removal reliably, its performance in terms of fouling and sustainable flux rate can only be determined realistically by pilot testing the water to be treated. Pilot testing is always recommended, if feasible, particularly for large projects.

THE BENCHMARK PROCESS

To allow comparison between process options, particularly on a cost basis, it is appropriate to define a "benchmark" process.

The benchmark process is based on the most commonly used treatment configuration in the world, coagulation/clarification/granular media filtration.

A typical process flow schematic is shown in Fig. 1.

Within the benchmark, there can also be considerable variation between clarifier and filtration types. An indication of types of clarifier available and their basic characteristics are set out in Table 2.

Modern granular media filters typically operate at 10 to 15 m/h in postclarifier configurations, although there are examples of deep-bed higher rated filters operating under suitable conditions. There is a wide variation in granular media filter designs. Table 3 sets out some examples at both ends of the spectrum.

Table 1. Minimum Sampling Regime for Raw Water

Surface Water	Groundwater (Not Significantly Influenced by Surface Water)
Initially and then annually • Complete scan of WQ parameters. From this, additional parameters may be added or removed from the weekly/monthly testing regime. *Weekly* • Turbidity • True colour • Alkalinity • pH (at sample point) • Temperature (at sample point) • Conductivity *Monthly* • *Cryptosporidium / Giardia* • Total coliforms • *E.coli* • Iron • Manganese • DOC • Calcium (component of hardness) • Magnesium (component of hardness) *Special* • Short-term intensive testing of certain 'suspect' parameters depending on circumstances for example hourly measurement of turbidity on flashy river; pesticides or *Cryptosporidium* after storm;	*Initially and then annually* • Complete scan of WQ parameters. From this, additional parameters may be added or removed from the monthly/quarterly testing regime. *Monthly* • Turbidity • pH (at sample point) • Calcium (component of hardness) • Magnesium (component of hardness) • Iron • Alkalinity • Temperature (at sample point) • Conductivity *Quarterly* • True color • Manganese • Total coliforms (monthly if detected) • *E.coli* (monthly if detected) *Potential Concerns* • Parameters sometimes found in groundwaters include — Nitrate — Radionuclides — Hydrogen sulfide — Arsenic — Other suspect parameters, for example, pesticides

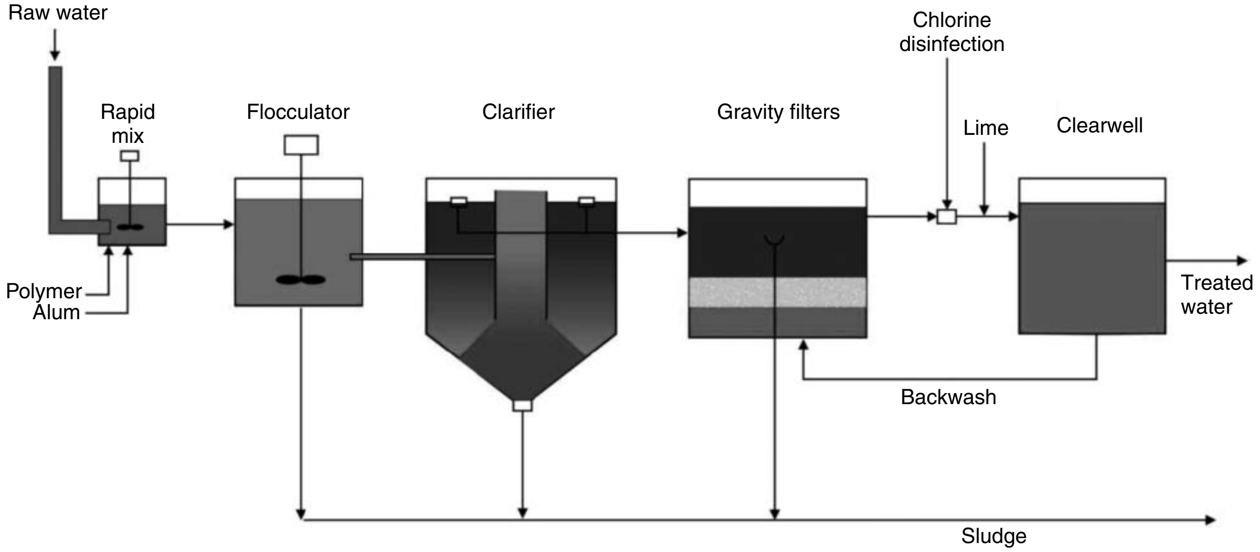

Figure 1. The "Benchmark" process.

Table 2. Clarifier Options in "Benchmark" Process

Clarifier Type	Typical Loading Rate m/hr	Minimum Flocculation	Comment
Horizontal flow sedimentation	1.5	2 stage, 15 minutes }	Sedimentation particularly suited to waters with high solids load
Radial flow sedimentation	1.5	2 stage, 15 minutes }	
Sludge blanket clarifier	2.5	NA }	
Sludge recirculation contact clarifier	3.0	15 minutes }	
Pulsation type	3.0	NA }	
Dissolved air flotation (DAF)	10	2 stages, 10 minutes	• Suited to colored, algal-laden, impounded raw water • Can be located in-filter
Tube settler	5	2 stages, 15 minutes	Loading rate depends on spacing and depth of tubes. Often retrofitted to increase plant capacity
Ballasted sand	30	1 stage, 10 minutes	Proprietary process
Sirofloc	10	2 stages, 10 minutes	Proprietary process

Table 3. Granular Media Filter Arrangements

Media	Typical Grading and Depth	Typical Loading Rate	Comment
Monomedia (sand)	600 mm of 0.6 m effective size	6 m/h	Typical old style rapid gravity filter designs
Monomedia (sand or anthracite)	2000 mm of 2 mm effective size	Up to 24 m/h	e.g., 3000 ML/day direct filtration plant at Prospect, Sydney, Australia
Dual media (typically anthracite/sand)	1500 mm of 1.5 mm anthracite on 300 mm of 0.8 mm sand	12–18 m/h	Also used in direct filtration configuration (i.e., no preclarification)
Dual media (typically anthracite/sand)	Wide range of anthracite sand combinations are in use	8–14 m/h	Finer grading used in postclarifier configurations

GUIDE TO PROCESS SELECTION

Table 4 provides a summary guide to selecting the most applicable treatment process, given particular water quality problems. The parameters covered focus on challenges that occur in raw waters. They do not include parameters that are created through treatment and distribution. Therefore, parameters such as disinfection by-products like trihalomethanes (THMs), lead (usually a corrosion product), and soluble aluminum (usually a residual of alum coagulation) are not included.

Table 4 focuses on primary treatment needs and does not consider residual disinfection requirements.

The "primary process candidates" focus on processes that can cost-effectively provide very good removal efficiency of the parameter in question, so that water

Table 4. Water Treatment Process Selection Guide

Water Quality Parameter	Primary Process Candidates	Relative Cost	Comments	Other Process Candidates
		Biological		
Bacteria	Chemical disinfection	0.1	Chlorine, chlorine dioxide, chloramine, and ozone are the main disinfectants. Cost is based on chlorine.	
	Ultraviolet disinfection	0.2	Good pretreatment often required.	
	Microfiltration	1.3		
Virus	Chemical disinfection	0.1		Reverse osmosis
	Ultraviolet disinfection	0.2	Some viruses can be relatively resistant	
Giardia	Benchmark	1.0	Filtered water turbidity of better than 0.3 NTU and preferably 0.1 NTU is required.	Reverse osmosis
	Chemical	0.1	Most practical choices are chlorine, chlorine dioxide, and ozone. Cost is based on chlorine.	
	Ultraviolet disinfection	0.2	Good pretreatment often required.	
	Microfiltration	1.3		
Cryptosporidium	Benchmark	1.0	Filtered water turbidity of better than 0.3 NTU and preferably 0.1 NTU is required.	Reverse osmosis
	Ultraviolet disinfection	0.2	Good pretreatment often required.	
	Microfiltration	1.3		
Algae	Benchmark	1.0	High algae levels needs a suitable clarifier process, e.g., DAF. See "Organics" for algal taste, odor and toxins.	
		Aesthetics		
Turbidity	Benchmark	1.0		Reverse osmosis
	Microfiltration	1.3		
Color	Benchmark	1.0		
	Ozonation	0.5	Practical limit to color removable	
	Nanofiltration	2.0	Pretreatment required	
Hardness	Lime softening	1.2		
	Ion exchange (cation)	0.7	Need also to consider pretreatment requirements, if any	
	Nanofiltration	2.0	Pretreatment required	
Iron	Benchmark	1.0		Lime softening
	Oxidation/filtration	0.8		Activated alumina
Manganese	Oxidation/benchmark	1.1	Potassium permanganate commonly used	Lime softening
	Catalytic filtration	0.8	Chlorination ahead of Mn-coated filter media	
	Benchmark/high pH	1.1	Coagulation at high pH	
Hydrogen sulfide	Aeration	0.3		
		Organics		
DOC	Benchmark	1.0		
	Ion exchange (anion)	0.9		
	Nanofiltration	2.0		
Algal tastes & odors	Granular activated carbon	0.6—1.0	Cost depends on bed life; bed life uncertain: testing required	
	Powdered activated carbon	0.2—0.4	Cost depends on dose and period of use	
	Ozonation	0.5	Sometimes used in conjunction with hydrogen peroxide	
Algal toxins	Chlorination	0.1	Effective on many hepatotoxins	Nanofiltration
	Ozonation	0.5	Sometimes used in conjunction with hydrogen peroxide	

(*continued overleaf*)

Table 4. (*Continued*)

Water Quality Parameter	Primary Process Candidates	Relative Cost	Comments	Other Process Candidates
	Ozone/biological activated carbon	1.0		
	Granular activated carbon	0.6—1.0	Bed life uncertain; testing required	
	Powdered activated carbon	0.2—0.4	Dose setting can be difficult	
Pesticides	Ozonation	0.5	Sometimes used in conjunction with hydrogen peroxide	Reverse osmosis
	Ozone/biological activated carbon	1.0		
	Granular activated carbon	0.5—2	Bed life uncertain	
	Powdered activated carbon	0.2—0.5	Dose setting can be difficult	
Organic chemicals generally	Aeration	0.3—1	Only for highly volatile compounds	
	Granular activated carbon	0.5—2	Cost highly sensitive to bed life; testing required	
		Inorganics		
Antimony	Benchmark	1.0		Reverse osmosis
Arsenic	Oxidation & benchmark	1.1		
	Oxidation & lime softening	1.3		
	Activated alumina	0.9		
	Ion exchange (anion)	0.9		
Barium	Lime softening	1.2		Reverse osmosis
	Ion exchange (cation)	0.7		
Beryllium	Benchmark	1.0		Reverse osmosis
	Lime softening	1.2		
	Activated alumina	0.9		
Boron	Ion exchange (anion)	0.9		
	Reverse osmosis	2.5		
Cadmium	Benchmark	1.1	Ferric coagulation at high pH	Reverse osmosis
	Lime softening	1.2		
Chromium (III)	Benchmark	1.0		
	Lime softening	1.2		
	Ion exchange (cation)	0.9	Anion for Cr(VI)	
	Reverse osmosis	2.5	OK for Cr(VI)	
Cyanide	Oxidation and benchmark	1.1		Reverse osmosis
Fluoride	Activated alumina	0.9		
	Reverse osmosis	2.5		
Mercury (inorganic)	Benchmark	1.0	Ferric coagulant preferred	Reverse osmosis
	Granular activated carbon	0.5—1.0	Cost depends on bed life	
	Lime softening	1.2		
Nitrate	Ion exchange (anion)	0.9		
	Reverse osmosis	2.5		
Sulfate	Ion exchange (anion)	0.9		
	Reverse osmosis	2.5		
Selenium	Ion exchange (anion)	0.9		Reverse osmosis
	Activated alumina	0.9		
Silver	Benchmark	1.0		
	Lime softening	1.2		
TDS	Reverse osmosis	2.5	Brackish water	
	Electrodialysis	3.0		
	Distillation	5.0	Very dependent on energy cost	
		Radiological		
Uranium	Benchmark	1.0	Waste disposal is an issue	
	Lime softening	1.2	Waste disposal is an issue	
	Ion exchange (cation)	0.9	Waste disposal is an issue	
Radon	Aeration	0.3		
	Granular activated carbon	0.5—1.0	Depends on bed life	
Radium	Lime softening	1.2	Waste disposal is an issue	
	Ion exchange (cation)	0.9	Waste disposal is an issue	
	Reverse osmosis	2.5	Waste disposal is an issue	

quality objectives can be met. Processes that provide only limited removal are generally not listed. The focus is also on the most readily available technologies.

The "relative cost" column indicates life-cycle cost in comparison with the "benchmark" treatment process. The cost relativity is indicative only and depends on plant scale, the site and local conditions, and costs. "Other process candidates" list potential processes which would not normally be selected for the water quality parameter in question but are listed to provide guidance if that particular process is also a good primary candidate for another water quality parameter of concern.

As a reference, the expected range of life-cycle cost for the benchmark process in developed countries is of the order of US$0.15 to US$0.40 per kL (2003); the variation depends mainly on scale—the larger scale plant has lower unit costs.

Examples of Application

Example 1: Braided River from Farming Catchment and High Base Flow. A source water drawn from a braided river suffers from elevated turbidity after storms and is suspected of *Cryptosporidium/Giardia* and bacteria/contamination from farming in the catchment.

From Table 4, microfiltration is suitable for all identified contaminants, as is the combination of the benchmark process plus disinfection (either chemical or UV). From this, the prime process candidates are therefore

- benchmark plus disinfection
- microfiltration

Example 2: Highly Turbid Tropical River in Unprotected Catchment. In this case, the water quality parameters of concern and corresponding process selections are

Cryptosporidium: benchmark, UV, MF
Turbidity: benchmark, MF
Color: benchmark, ozonation
Virus: disinfection, UV
Bacteria: disinfection, UV, MF
Iron: benchmark, oxidation/filtration.

Looking at these technology selections suggests selecting the benchmark process plus disinfection would most cost-effectively deal with all of the parameters of concern.

Example 3: Algal-Prone Surface Water Reservoir from a Compromised Catchment. In this case, the parameters of concern are turbidity, algae, DOC, color, *Cryptosporidium*, bacteria, virus, iron, manganese, taste and odor, and toxins.

Using the same procedure as previously highlights the potential to select a process train consisting of the benchmark process plus ozone/BAC.

Example 4: Groundwater. This groundwater has problems of elevated arsenic, iron, and manganese. From Table 4, the benchmark process with oxidation would be an appropriate selection.

Testing the most likely process selections obtained through the guidance process is always important to confirm achievable performance and likely actual costs. In evaluating the final short list of process options, factors like local skills, cost and availability of materials, level of support services, and waste management constraints, need to be taken into account.

SOURCE WATER ASSESSMENT

U.S. Geological Survey

FREQUENTLY ASKED QUESTIONS

What is a Source Water Assessment?

A source water assessment is a study and report, unique to each water system, that provides basic information about the water used to provide drinking water.

What Will My Assessment Tell Me?

- *Where My Drinking Water Comes From*. Source Water Assessments identify the area of land that most directly contributes the raw water used for drinking water.
- *What Could Pose a Threat to My Drinking Water Quality*. Assessments identify the major potential sources of contamination to drinking water supplies. This information is used to determine how susceptible the water system is to contamination.

Is This Information Available?

The results of an assessment will be provided to the public to help communities plan for protection activities. Information about the assessment will be included in the yearly consumer confidence report you receive from your water utility.

Does My Water System Have a Source Water Assessment?

Every state is moving forward to implement assessments of its public water systems, as required under a new

---

federal Safe Drinking Water Act program called the Source Water Assessment Program (SWAP). Assessments must be completed by 2003 for every public water system—for major metropolitan areas and the smallest towns, including schools, restaurants, and other public facilities that have wells or surface water supplies. Assessments will not be conducted for drinking water systems that have less than fifteen service connections or that regularly serve less than twenty-five individuals, since these are not considered public water systems.

Who is Paying for These Assessments?

Source water assessments and protection measures are eligible uses of the Drinking Water State Revolving Fund (DWSRF) set-asides. States may use the funds for a mixture of source water related local assistance activities. For example, funds are available for Land Acquisition and Conservation Easements.

SOURCE WATER ASSESSMENTS

The source water assessment programs created by states differ since they are tailored to each state's water resources and drinking water priorities. However, each assessment must include four major elements:

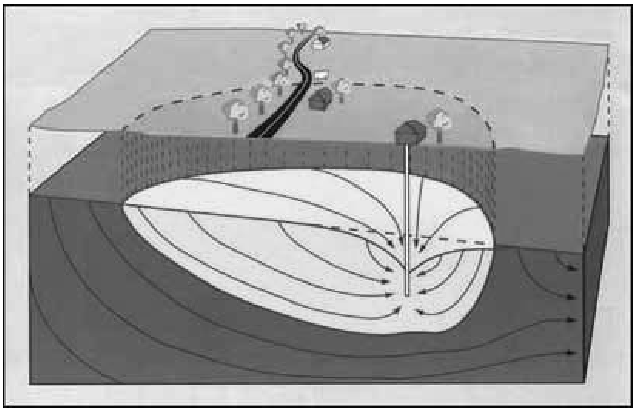
- delineating (or mapping) the source water assessment area,
- conducting an inventory of potential sources of contamination in the delineated area,
- determining the susceptibility of the water supply to those contamination sources, and
- releasing the results of the determinations to the public.

These steps are described in more detail below, with information on how citizens and organizations can join in the assessment process. More information about the SWAP program is available. Our SWAP Contact List has state specific contacts and links to State web sites.

Source Water Assessment Using Geographic Information Systems: This document provides guidance to states, municipalities, and public water utilities for assessing source waters using geographic information system (GIS) technology.

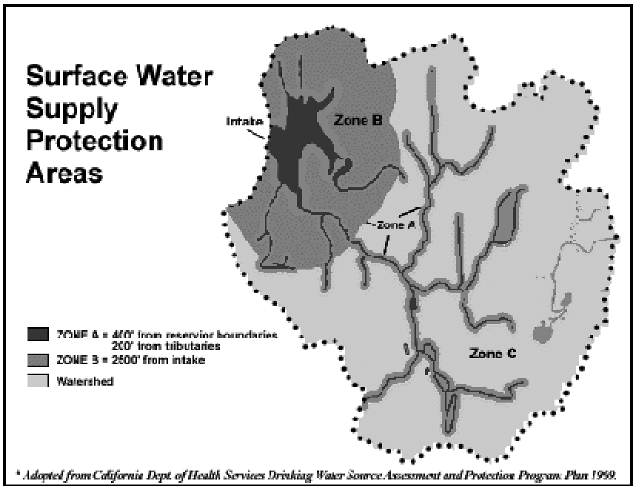
STEP 1: DELINEATE THE SOURCE WATER ASSESSMENT AREA

For each ground water well or surface water intake that supplies public drinking water, the land area that could contribute water and pollutants to the water supply must be delineated, or mapped. Significant potential sources of contamination will then be identified in this delineated area during Step 2 of the assessment process.



For ground water supplies, states commonly use information about the flow of underground water to delineate source water assessment boundaries. This results in a map of land areas where, if pollutants are spilled or discharged on the surface, they could filter through the soil to the ground water and be drawn into a particular well. Some states may use a simpler mapping approach, by drawing a circle of a certain radius around the well.

For a community that uses surface water from a stream, river, lake, or reservoir, the land area in the watershed upstream of the intake is identified on the map. A watershed boundary is drawn using a topographic map, and includes the land areas where rain or melted snow flows over or through the ground and eventually enters the water source upstream of the water system's intake.



* Adopted from California Dept. of Health Services Drinking Water Source Assessment and Protection Program Plan 1999.

Diagram2

Some states plan to divide the watershed area into segments—areas closest to the intake where most types of contamination sources can impact the water supply, and other more distant areas. The entire watershed up to the state's boundaries is required to be delineated, but the inventory of potential pollution sources may be more detailed in segments that are closer to the intake.

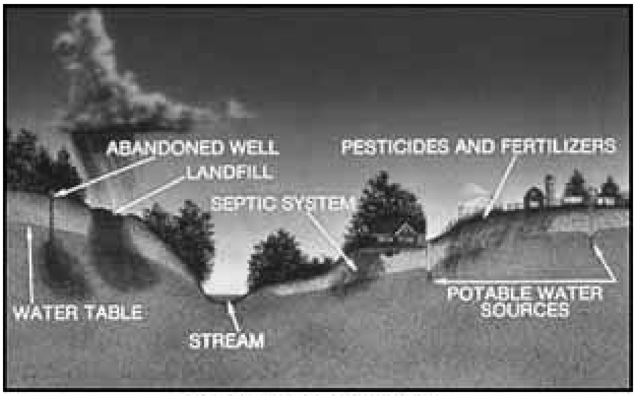
After the state has completed its assessment for a water system, the community may decide to undertake protection efforts for targeted sources of contamination. An initial step could be to expand upon the state's delineation process. Particularly for smaller ground water systems, where states may not have the resources to conduct a detailed delineation, additional scientific methods can be used to more accurately delineate the area that contributes ground water to the well.

Community members can seek assistance from the environmental sciences, geology, or engineering departments of local colleges, or from environmental consulting firms to assist in creating more detailed delineations. Sometimes these services are provided by professors, graduate students, or local firms for a reduced fee or none at all. In addition, local water resource information is often available from other sources such as the federal Natural Resource Conservation Service, the United States Geological Survey, and the state's Cooperative Extension Service.

For more information on delineation see Reliable Sources—Delineation.

STEP 2: CONDUCT AN INVENTORY OF POTENTIAL SOURCES OF CONTAMINATION

Community groups can become especially involved in the second step of an assessment—identifying potential sources of pollutants that could contaminate the water supply. This inventory usually results in a list and a map of facilities and activities within the delineated area that may release contaminants into the ground water supply (for wells) or the watershed of the river or lake (for surface water sources).



Contamination Sources

Some examples of the many different types of potential pollutant sources include landfills, underground or above-ground fuel storage tanks, residential or commercial septic systems, storm water runoff from streets and lawns, farms that apply pesticides and fertilizers, and sludge disposal sites.

Some states are asking communities to conduct the inventory themselves, in order to obtain detailed information about potential contaminant sources. Others will use computer databases and focus the inventory on land uses and activities that are currently mapped or regulated. Although this approach may not address sources of contaminants that are not currently regulated, such as smaller livestock areas or auto salvage yards, the database inventories could include industries and sewage treatment plants that discharge wastewater, hazardous waste sites, mining operations, particular land use categories (such as industrial, agricultural and urban areas), and various facilities that have environmental permits.

Community groups such as watershed organizations, local environmental committees or scout troops can enhance the state's assessment by conducting site-specific inventories of potential pollutant sources that may not be on state databases or maps. Local inventories may provide information on abandoned dump sites, businesses with septic tanks or floor drains such as dry cleaners or car repair shops, pesticide mixing and storage areas, golf courses, and other land uses that may release pollutants to ground water or surface water. Community groups can coordinate their local inventory with the state's assessment process or can enhance a completed assessment with a more detailed inventory.

A helpful document to aid community groups is EPA's "Drinking Water Contaminant Source Index" which is a list of potential contaminant sources and the pollutants they can release. Additional resources about contamination are available at Reliable Sources—Contaminant Source Inventory.

STEP 3: DETERMINE THE SUSCEPTIBILITY OF THE WATER SUPPLY TO CONTAMINATION

For the susceptibility analysis, the state combines the inventory results with other relevant information to decide how likely a water supply is to become contaminated by identified potential sources of contamination. This critical step makes the assessments useful for communities, since it provides information that local decision-makers may use to prioritize approaches for protecting the

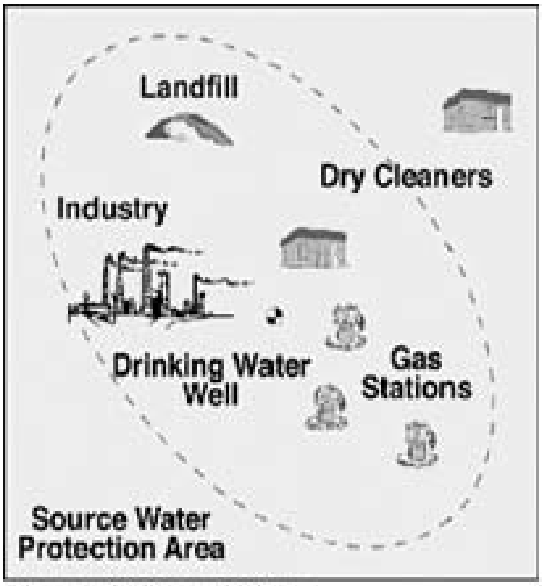


Diagram3: Ground Water

drinking water supply. Local information provided to the state by local community groups about contaminant sources, water resource characteristics, or environmental management practices may be used in the susceptibility determination process. Some states prioritize the potential for contamination from identified potential contamination sources or specific chemicals that could pollute the water. Other states assign susceptibility rankings of high, medium or low to the water sources.

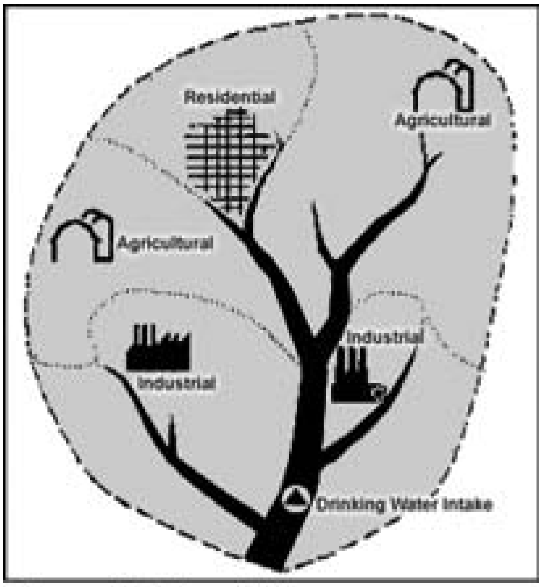

Diagram4: Surface Water

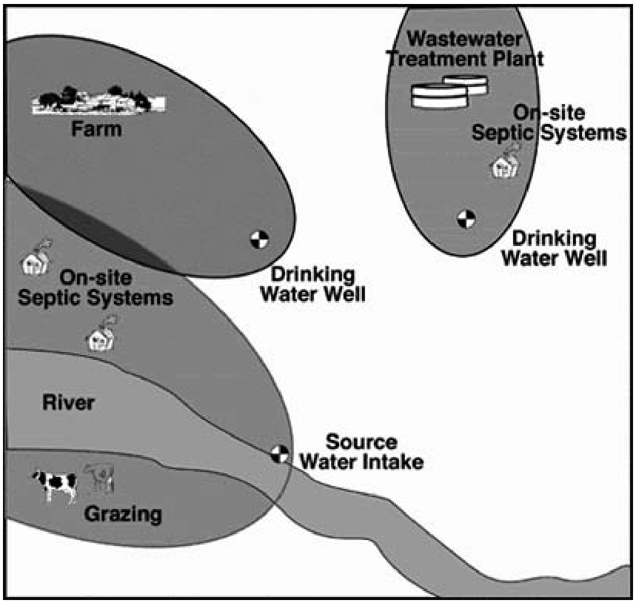
For more information on susceptibility see Reliable Sources—Susceptibility Determination.

STEP 4: RELEASE THE ASSESSMENT RESULTS TO THE PUBLIC

After a state completes the assessment of a particular water system, it will summarize the information for the public. Such summaries help communities understand the potential threats to their water supplies and identify priority needs for protecting the water from contamination. States will make the assessment summaries available to the public in a variety of ways. Some states plan to convene public workshops, while others will have copies available in public libraries and from local government offices or water suppliers. Many also plan to post the assessment summaries on the Internet. The results of the assessments will also be included in the annual water quality reports that community water systems are required to prepare for their customers. Community groups can convene local meetings to discuss the results and begin the process of protecting the drinking water source.

For more information on results see Reliable Sources—Public Availability.



USING THE ASSESSMENT

Whether using the state's assessment or expanding it into a more detailed local assessment, communities can use information gathered through the assessment process to create a broader source water protection program. Community groups and local officials, working in cooperation with local, regional, and state government agencies can plan how to manage identified potential contamination sources and prevent new contaminant threats in the source water assessment area.

Communities use a wide array of different source water protection methods to prevent contamination of their drinking water supplies. One management option involves regulations, such as prohibiting or restricting land uses that may release contaminants in critical source water areas. Along with regulations, many communities hold local events and distribute information to educate and encourage citizens and businesses to recycle used oil, limit their use of pesticides, participate in watershed cleanup activities, and a multitude of other prevention activities. Another aspect of a source water protection program can be the purchase of land or creation of conservation easements to serve as a protection zone near the drinking water source. For an effective protection program, communities should consider using a variety of prevention measures.

EPA's fact sheet, Community Involvement in Source Water Assessments, explains the four steps of source water assessments; how communities can participate in the assessment process; and how communities can utilize assessment information for source water protection. A downloadable version (PDF, 180 kb) is available.

HELPFUL CONTACTS

EPA, State and other contacts are also available to help you.

Your local water supplier may also have more information about opportunities to become involved in the source water assessment process. EPA can provide some local information about your drinking water system. You can also call the number on your water bill or contact your local health department for information on your water supplier.

HYDRAULIC DESIGN OF WATER DISTRIBUTION STORAGE TANKS

Rasheed Ahmad
Khafra Engineering Consultants
Atlanta, Georgia

Water distribution storage ensures the reliability of supply, maintains pressure, equalizes pumping and treatment rates, reduces the size of transmission mains, and improves operational flexibility and efficiency. Numerous decisions must be made in designing a storage tank, including size, location, type, and expected operation. There are several key considerations in the hydraulic design of water storage tanks.

Equalization is the primary purpose for constructing water distribution storage tanks. Water utilities like to operate treatment plants at a relatively constant rate, and wells and pumping stations generally work best when pumped at a steady rate. However, water use in most utilities varies significantly during the course of the day. These variations in use can be met by continuously varying source production, continuously varying pumping rates, or filling and draining storage tanks.

Filling and draining storage tanks is much easier operationally and is generally less expensive than other methods. Facilities that serve portions of a distribution system that has storage tanks generally need to be sized only to meet maximum daily demands; storage tanks provide water during instantaneous peak demands. Maintaining adequate pressure in a water distribution system is very important. To a great extent, the elevation of water stored in a tank determines the pressure in the pipes directly connected to the tank. The larger the tank volume, the more stable the pressure in the distribution system, despite fluctuations in demand or changes in pump operation. If distribution storage were not used, larger water transmission mains and larger treatment plant capacity would be required by most utilities to provide water needed for fire fighting. Especially in smaller systems, storage tanks are a much more economical and operationally reliable means for meeting the short-term large demands placed on a water supply system during fire fighting. In addition to fires, emergencies such as power outages, breaks in large water mains, problems at treatment plants, and unexpected shutdowns of water supply facilities can cause failure of the water system if sufficient water is not available in storage. Water storage tanks meet demands during emergencies.

Figure 1. Ground-level water storage tank (*Source*: Columbian TecTank).

Figure 2. Traditional multicolumn elevated storage tank (*Source*: Caldwell Tank, Inc.)

Besides equalization, pressure maintenance, and fire and emergency storage, other factors such as energy consumption, water quality, hydraulic transient control, and aesthetics should be considered in designing water distribution storage tanks. Tanks enable utilities to store energy as well as water for later use. To the extent that equalization storage slows down the velocity (and friction losses) in large transmission mains, the energy used to pump water is reduced by having distribution storage tanks that equalize pumping. Tanks may affect water quality in two general ways: (1) through chemical, physical, and biological processes that occur as water ages while stored in the tank and (2) through external contamination of water in tanks.

Figure 3. Composite elevated storage tank (*Source*: Caldwell Tank, Inc.).

Figure 4. Pedesphere elevated storage tank (*Source*: Caldwell Tank, Inc.).

Some water quality problems can be eliminated by proper design and maintenance. In recent years, because of the concern for microbial regrowth and formation of disinfection byproducts, protecting the water quality in the storage tanks has become increasingly important. Another important consideration in designing water distribution storage tanks is controlling hydraulic transients. Changes in velocity in water mains can result in "water hammer." A water storage tank is effective in dampening the extreme high or low pressure caused by a transient. Sometimes the aesthetics of storage tanks becomes important. Tanks should be designed to satisfy the aesthetic considerations of stakeholders without sacrificing the purpose of the tank and the efficiency of the system's operation.

Depending on the topography and local environmental conditions, storage tanks may be located above, on, or below the ground. Underground tanks or reservoirs are constructed of reinforced concrete. Small ground-level tanks are usually earth-lined with gunite, asphalt, or some synthetic membrane. Large surface tanks are concrete-lined (Fig. 1). Most large surface tanks are covered to prevent contamination by bird, animal, and human wastes. Elevated water storage tanks are usually constructed of steel or concrete. Common shapes for elevated storage tanks are illustrated (Figs. 2–4).

SYSTEM CONTROL AND DATA ACQUISITION (SCADA)

Zacharia Michael Lahlou
Technical Assistance
Consultant

As small water systems continue to struggle to become more efficient, technology provides good ways to improve operations. Nowhere is this more apparent than in the application of control and communications systems—namely SCADA [System Control and Data Acquisition]—and their ability to provide system and information management that can help utilities meet regulatory requirements, reduce operating costs, and improve customer service. A water distribution system transports water from the treatment facility to the user. The distribution system should supply water, without impairing its quality, in adequate quantities and at sufficient pressures to meet system requirements

WHAT IS SCADA?

A SCADA system consists of a computer placed at a central location, communications equipment, programmable logic controllers, sensors, and other devices that when put together, will monitor and control equipment and processes in a utility, such as a water system. Remote sites, equipped with remote telemetry units (RTUs), can be located as close as within the same building or as far away as across the country. RTUs measure a variety of conditions and parameters, including tank levels, temperature, voltage, current, volumes, and flow rates, and report back to a central processing unit (CPU). This technology is widely accepted in the water and wastewater industries as a reliable and efficient control system.

SCADA EQUIPMENT ENHANCES WATER OPERATIONS

Functions that the SCADA system can perform include: remote monitoring of well levels and control of their pumps, and monitoring flows, tank levels, or pressures in storage tanks. A SCADA system can also monitor water quality characteristics, such as pH, turbidity, and chlorine residual, and control the addition of chemicals. In the distribution system, SCADA can supervise and control the water pressure of networks, assure water pressure is uniformly distributed, lower the leakage rate, and store data for future analysis.

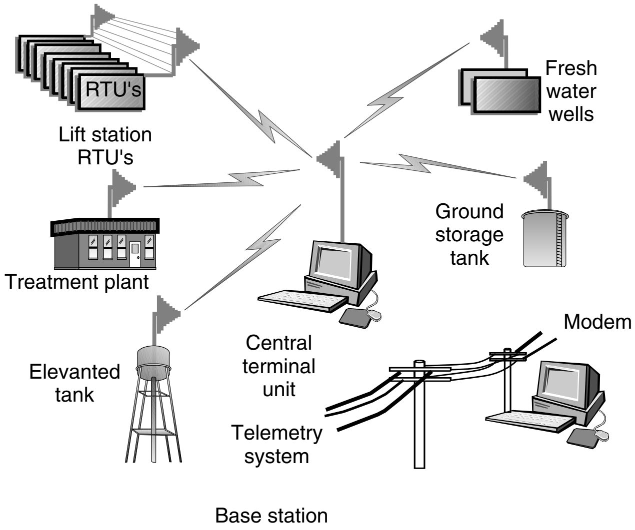
SCADA is not a new technology by any means, but significant innovations and improvements have been achieved since its introduction. By automating many routine tasks, a SCADA system frees the plant operator to perform other duties, such as addressing state and federal reporting requirements. In fact, SCADA can assist in mandated reporting because it can store various activities and information on the computer. Graphs and reports can be generated automatically using the data collected remotely from the field. These reports are important in inferring production and consumption patterns, data that help manage the water resources more efficiently. Stored information also proves invaluable when producing the annual Consumer Confidence Reports required under the 1996 Safe Drinking Water Act (SDWA) Amendments.

SCADA is useful in an emergency situation. Immediately following an incident, an operator can be notified via personal pager and increase response capability dramatically. SCADA provides multipurpose utility management, operating flexibility and more complex system control. SCADA keeps an eye on the entire system from one place.

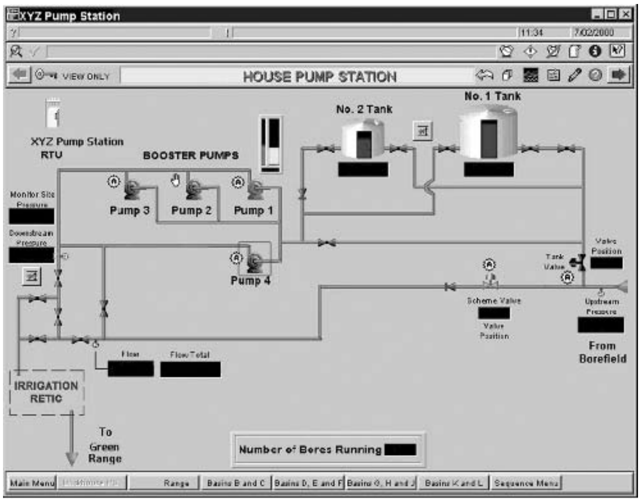
SCADA PROVIDES COST-EFFECTIVE CONTROL AND MONITORING FOR SMALL WATER SYSTEMS

Because of its cost, smaller systems often viewed SCADA as a luxury item. But water system management has become complex and SCADA has become more advanced yet, paradoxically less expensive, making SCADA a viable option. Initial installation costs, which are often high, typically pay for themselves in a short time through direct labor and vehicle cost savings, as well as increased efficiency.

Due to a low tax base, many small communities have limited financial resources for drinking water system management and operation. Thus, it is difficult for operators to maintain extensive manual monitoring to ensure the system complies with complex regulations. These small systems, therefore, frequently violate (monitoring/reporting violations) the SDWA and its amendments, according to the National Research Council.



SCADA system



SCADA allows water operators to monitor the entire distribution system from one location

One solution to keeping up with ever more stringent requirements is for several small communities to pool their resources. The U.S. Environmental Protection Agency is evaluating the option of using remote telemetry, called an “electronic circuit-rider,” that allows one qualified operator to monitor and control the operation of several small treatment systems from a centrally located computer. Using such a system can optimize the time spent taking daily readings out in the field. For onsite inspection and maintenance efforts, the RTS allows the operator to visit only the problematic systems. The results expected from an appropriately designed and successfully deployed remote monitoring and control system include enhanced water quality, compliance with existing water quality regulations, and reduced operating and maintenance costs for small communities.

SECURITY MEASURES ARE A CONCERN

Experienced computer hackers can access SCADA systems that operate over the Internet and deactivate process alarms, change chemical parameters, start and stop equipment, and so on. The results of such an intrusion can be devastating to the general public and to plant employees.

Many system managers installed protection as part of their “Y2K” contingency plans. The likelihood of a terrorist cyber attack is less likely than a cyber attack from a disgruntled employee. Fortunately, there are steps a system can take to minimize a security breech.

SCADA COMPONENTS AND TERMINOLOGY

Distributed Control System (DCS): An integrated system made up of many subsystems that are remotely located. Each subsystem can operate independently.

Modem (MOdulator DEModulator): Used to convert signals in one form to another. This is generally used for communication between computers and other devices over telephone lines or radio.

Programmable Logic Controller (PLC): A microprocessor-based controller, usually with multiple inputs and outputs and a program to perform control functions

Remote Telemetry Unit or Remote Terminal Unit (RTU): A microprocessor device with multiple inputs and outputs connected to field instruments and devices. The RTUs translate these signals to digital form and transmit the same to central location by radio or telephone lines.

The National Infrastructure Protection Center (NIPC), located in the Federal Bureau of Investigations headquarters in Washington, D.C., shares information with public and private sector owners and operators of critical infrastructures. The NIPC monitors, warns, and investigates unlawful acts involving computer and information technologies. The agency manages computer intrusion investigations and supports law enforcement related to cyber crimes.

Best practices regarding the security of SCADA operation include:

- Internal threats are usually the main security challenge. The key to managing internal threats is understanding who might do what and why.
- Log-ins should be traceable and a strong password authentication process used.
- Suggest that a utility consider fiber optics to each of its remote facilities. This is the best solution in terms of bandwidth and security.
- Suggest taking a look at commercially available tools for monitoring computers and having a security team review activity weekly to verify that only authorized users are accessing the system.

WHAT SHOULD BE CONSIDERED WHEN BUYING A SCADA SYSTEM?

Selecting the appropriate SCADA system software is all-important. The software program should be capable of performing every task needed to operate and maintain water treatment and the distribution system. Its use in many similar applications should prove its reliability. Make sure the hardware supplier and the software developer can guarantee prompt, efficient, and cost effective support. The manufacturer should have experience in the water and wastewater industry and be able to provide service, replacement parts, and support for the system when needed.

John Barkey, plant operator for Martin’s Ferry, Ohio, inspects the water levels of the system’s storage tanks from his desk

To expedite the selection of specific devices/components for an RTS that monitors and controls a small drinking water facility, prepare a list of features associated with the particular water treatment facility. Identify the water quality parameters and types of monitoring that are key to the specific operation. For example, monitor residual chlorine to verify disinfection operations. Next, review the regulatory compliance requirements and consider them when reviewing manufacturers’ specifications and discussing the applicability of their device or system. Finally, select the monitoring device.

It is important to document the pump characteristics, operational functions, and the physical dimensions of the treatment system before selecting components to monitor flow rates, pressure, electrical usage, or other process functions. Know facility specifications when contacting technical representatives of process monitoring/control devices. Component selection must be based on the plant’s operational characteristics.

Data acquisition and telemetry components can be purchased as package items, but again, identify an inventory of what devices will be used on line and what options exist for transmitting data in the locality of the treatment plant before contacting suppliers.

HAVE YOU READ ALL OUR TECH BRIEFS?

Tech Briefs, drinking water treatment and supply fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) publication *On Tap* for more than six years.

A package of *Tech Briefs* is now available as a product. A three-ring binder holds all the current *Tech Briefs* in print. New selections can easily be added to the package as they become available.

To order this product, call the NDWC at the numbers listed at the bottom of this ad and ask for item #DWPKPE71. **The item is free.** Additional copies of fact sheets are also free; however, postal charges may be added. You can also order copies of one or all of the free *Tech Briefs* listed below.

Tech Brief: Disinfection, item #DWBLPE47;

Tech Brief: Filtration, item #DWBLPE50;

Tech Brief: Corrosion Control, item #DWBLPE52;

Tech Brief: Ion Exchange and Demineralization, item #DWBLPE56;

Tech Brief: Organics Removal, item #DWBLPE59;

Tech Brief: Package Plants, item #DWBLPE63;

Tech Brief: Water Treatment Plant Residuals Management, item #DWBLPE65;

Tech Brief: Lime Softening, item #DWBLPE67;

Tech Brief: Iron and Manganese Removal, item #DWBLPE70;

Water Conservation Measures Fact Sheet, item #DWBLPE74;

Tech Brief: Membrane Filtration, item #DWBLPE81;

Tech Brief: Treatment Technologies for Small Drinking Water Systems, item #DWPSPE82;

Tech Brief: Ozone, item #DWBLPE84;

Tech Brief: Radionuclides, item #DWBLPE84;

Tech Brief: Slow Sand Filtration, item #DWBLPE99;

Tech Brief: Ultraviolet Disinfection, item #DWBLPE101;

Tech Brief: Leak Detection and Water Loss Control, item #DWBLPE102;

Tech Brief: Diatomaceous Earth Filtration for Drinking Water, item #DWBLPE108.

SETTLING TANKS

Nikolay Voutchkov
Poseidon Resources Corporation
Stanford, Connecticut

INTRODUCTION

Settling tanks (clarifiers) are an integral part of every wastewater treatment plant. These treatment facilities are used to remove solids from the wastewater by gravity sedimentation in quiescent conditions. Each settling tank has two functional zones—a clarification zone, where the process of gravity sedimentation occurs, and a thickening zone where the settled solids are accumulated forming a dense layer of sludge (sludge blanket). Settling tank effluent of low solids concentration is collected from the top of the clarification zone over overflow weirs into collection channels which convey the effluent to the tank outlet. The sludge collected at the bottom of the settling tank is removed for further treatment at the wastewater treatment plant’s solids handling facilities. The depth of the clarification zone is commonly referred to as a clear water zone (CWZ) depth, while the depth of the zone of sludge accumulation is named sludge blanket depth (SBD). The sum of the CWZ depth and the SBD is typically defined as a sidewater depth (SWD).

SETTLING TANK TYPES

Depending on their function settling tanks are categorized as primary and secondary. Primary settling tanks are located downstream of the wastewater treatment plant headworks and their main purpose is to remove the settleable suspended solids in the plant influent. Typically, primary settling tanks are also equipped with devices for removal of the floatable compounds (i.e., scum, oil and grease) in the wastewater influent which accumulate on the surface of the tanks during the sedimentation process. Secondary tanks are located downstream of the biological (secondary) treatment facilities of the wastewater treatment plant (such as activated sludge aeration basins or trickling filters) and are used to separate the biomass generated during the secondary treatment process from the treated plant effluent.

Depending on their geometrical shape, both primary and secondary clarifiers are classified in two main categories: rectangular and circular. Clarifier shape most suitable for a given application depends on a number of factors and has to be selected based on a cost-benefit analysis. Table 1 summarizes key advantages and disadvantages of rectangular and circular settling tanks.

Rectangular Settling Tanks

Rectangular settling tanks are long concrete structures which consist of individual basins (units) with common inner walls, and inlet and outlet channels (Fig. 1). Each individual tank basin is equipped with a separate sludge collection mechanism which transports the solids settled in the tank into a hopper for withdrawal or has a sludge suction collection mechanism which sweeps and removes solids accumulated at the tank's bottom. The length-to-width ratio of the individual tank basins is usually 3:1 to 15:1 (Fig. 1). The minimum settling tank length from inlet to outlet is typically 3 meters (10 ft). Tank depth is most frequently between 2 to 6 meters (6.6 to 20 ft). Rectangular tank unit width is usually selected based on available standard sizes of sludge collection mechanisms and varies between 2 to 6 meters (6.6 to 20 feet).

Circular Settling Tanks

Circular settling tanks are round facilities which consist of inlet structure, cylindrical clarification zone, conical sludge accumulation zone and effluent weirs (Fig. 2). The effluent weirs of these tanks are placed near the facility perimeter to create radially-directed flow pattern from the tank center towards the walls. The slope of the bottom

Table 1. Comparison of Rectangular and Circular Settling Tanks

Item	Rectangular Settling Tanks	Circular Settling Tanks
Advantages	Less land required for construction of multiple units. Potential construction cost savings because of use of common walls between individual tanks. Longer flow path minimizing short-circuiting. Higher effluent weir loading rates acceptable. Better sludge thickening.	Shorter detention time for settling sludge favoring use as secondary clarifiers. More simple sludge collection system. Easier to accommodate in-tank flocculation chamber—a benefit for activated sludge settling. Overall, lower maintenance requirements. Easier to remove heavy sludge.
Disadvantages	Longer detention time of the settled sludge—not favorable for plants with septic wastewater influent. Less effective for high solids loading conditions.	Higher short-circuiting potential. Higher flow distribution headlosses. Small circular tanks require more yard piping than do rectangular tanks of similar size.

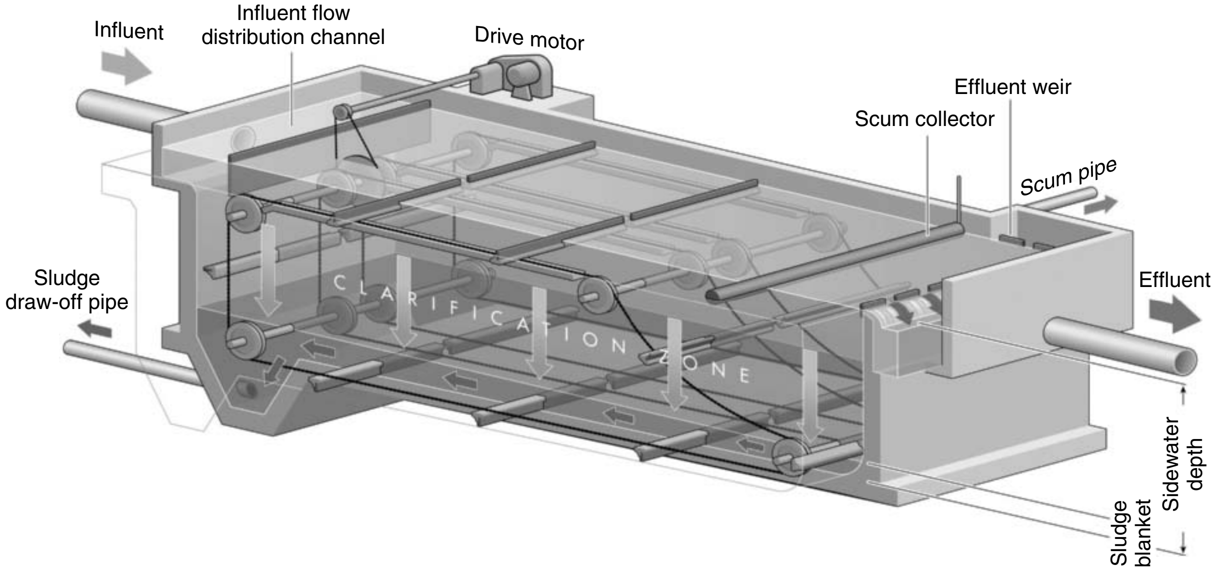

Figure 1. Rectangular settling tank.

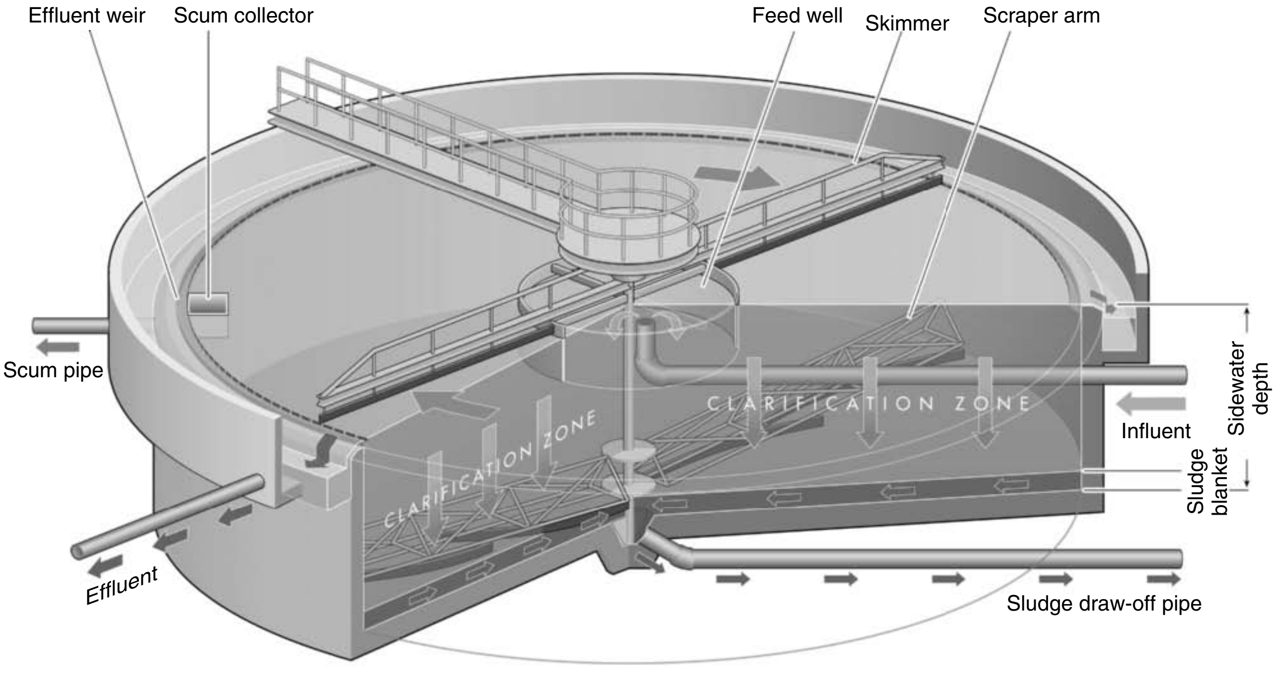

Figure 2. Circular settling tank.

conical floor is usually 1:10 to 1:12 and depends on the type of the sludge collection mechanism. Tank diameter ranges from 3 meters (10 ft) to over 100 meters (300 ft). Circular settling tanks are typically built in pairs of 2 or 4 to simplify the influent flow distribution between the individual units. Circular tank sidewater depth varies from 2.5 to 5 meters (8 to 16 feet).

Depending on the configuration of the tank inlet, circular settling thanks are classified as center feed and peripheral feed. Currently, the most widely used circular tanks are center feed type (see Fig. 2). In these tanks, influent flow enters though a feed pipe located in the center of the tank into a feedwell. The purpose of the feedwell is to provide uniform radial distribution of the tank influent and to dissipate the energy of the feed stream to a level adequate for efficient quiescent settling and uniform radial flow distribution. The conventional feedwells most widely used today are cylindrical metal structures with a diameter of 15 to 25% of the tank diameter which extend to 30 to 75% of the tank sidewater depth. Usually, conventional feedwells are designed for an average downflow velocity of 10 to 13 mm/s (2.0 to 2.5 ft/min) and maximum velocity of 25 to 30 mm/s (5.0 to 6.0 ft/min).

Settling Tank Enhancements

Inclined Plates and Ballasted Flocculation. Inclined plates and ballasted flocculation are used predominantly to enhance the performance of primary rectangular settling tanks. A typical inclined plate (lamella) system consists of bundles of parallel plastic tubes or metal plates inclined at 45 to 60° which are installed at the surface of the settling tank to a vertical depth of approximately 2 meters (6 feet). The distance between the individual plates is between 40 and 120 mm.

Ballasted flocculation combines the addition of coagulant and settling ballast (usually fine sand or sludge) to the tank influent with the installation of inclined plates in the tanks. A portion of the settled sludge or the recovered ballast is recycled to the primary clarifier influent to seed the influent. The addition of ballast increases the density of the influent floc particles by agglomeration. This enhancement typically yields three to five fold increase of the allowable clarifier surface overflow rate (SOR). Typically, conventional settling tanks are designed for SOR of 33 to 49 $m^3/m^2\cdot$ day (800 to 1,200 $gal/ft^2\cdot$ day). The use of high-rate ballasted solids separation technology allows increasing design clarifier SOR to at least 160 $m^3/m^2\cdot$ day (4,000 $gal/ft^2\cdot$ day). Because the ballast enhances solids removal, its use in primary clarification reduces the solids and organic loading of the downstream biological treatment processes.

Flocculating Center Feed Well. Flocculating center feed wells are used to enhance the performance of secondary settling tanks used for clarification of activated sludge. As compared to a conventional center feedwell which radius is approximately 10 to 13% of the tank radius, the flocculating feedwell's radius extends to 20 to 50% of the tank radius and the well size is designed to obtain a detention time of 20 to 30 minutes. The flocculating feedwell typically extends down to 40 to 50% of the tank depth. Some designs also include installation of mechanical mixers in the feedwell to enhance the flocculation process. The flocculating feedwell enhancement aims at creating optimum conditions for coagulation and flocculation of the incoming solids with the return activated sludge (RAS) recycled to the sedimentation tank. In the feedwell, the larger-size recycled RAS particles are given an ample time to attract and flocculate the smaller-size activated sludge particles conveyed form the aeration basins, thereby creating stronger and heavier solids particles that settle better and faster. More detailed design considerations for circular clarifiers with flocculating feedwells as well as a number of other available sedimentation tank process and equipment enhancements are presented elsewhere (1–3).

DESIGN CONSIDERATIONS FOR PRIMARY SETTLING TANKS

Performance efficiency of the primary settling tanks is affected by the upstream wastewater collection and treatment facilities and has a significant impact on downstream biological treatment and solids handling facilities. Primary settling tank performance is typically measured by tank's total suspended solids (TSS), biological oxygen demand (BOD), and phosphorus removal efficiencies and by the condition of the primary sludge (sludge septicity, concentration, and volume). Adequately designed and operated conventional primary settling tanks treating municipal wastewater typically remove 50 to 65% of the influent TSS; 25 to 35% of the influent BOD and 5 to 10% of the influent nitrogen and phosphorus. Clarifier TSS, BOD and nutrient removal efficiencies could be improved by chemical coagulation and flocculation of the influent wastewater solids prior to sedimentation (2–4).

Key design criteria used for sizing primary settling tanks are surface overflow rate and hydraulic detention time. Recommended values for these criteria according to various design guideline sources are presented in Table 2. Typically, primary sedimentation tanks are designed for effluent weir loading rates of less than 190 m^3/day per meter of length of the weir (5,000 gpd/ft) (Table 2).

Proper primary settling tank sludge collection, removal and withdrawal are of key importance for maintaining consistently high primary effluent quality and efficient and cost-effective solids handling. If primary settling tank sludge is retained for excessively long time in the tanks, the sludge could easily turn septic. Sludge septicity is accompanied with release of malodorous gases, which may disturb the normal sedimentation process as they travel from the tank bottom to the surface. Septic sludge is also more corrosive and more difficult to pump and dewater. Besides creating conditions for sludge septicity, maintaining relatively deep sludge blanket in the primary settling tanks may also make sludge collection and withdrawal more difficult and in extreme conditions, may cause damage of the sludge collection and withdrawal equipment (broken sludge collectors, plugged solids lines, and damaged pumps).

A widely accepted practice to prevent primary sludge septicity and its negative effect on settling tank performance is not to carry a sludge blanket, which is achieved by removing sludge continuously or very frequently from the settling tank's bottom. When not controlled appropriately, continuous sludge removal often results in pumping large quantities of diluted sludge or wastewater to the downstream solids handling facilities, which has a negative effect on their performance. In order to avoid over-pumping of diluted sludge to the downstream solids handling facilities and prevent the negative effects of excessively deep sludge blanket and associated sludge speticity, primary settling tank sludge blanket and concentration have to be maintained at optimum levels. The optimum primary sludge concentration is usually 3 to 5 percent and the most viable sludge blanket depth is typically between 1 and 3 feet. The optimum sludge blanket depth would vary seasonally and change during dry-weather and wet-weather conditions.

Table 2. Key Design Criteria for Primary Sedimentation Tanks

Design Guideline Source	Surface Overflow Rate (m^3/m^2/day)	Hydraulic Detention Time (hrs)
Metcalf and Eddy (5) (Primary Settling Followed by Secondary Treatment)	32–48 (at average flow) 80–120 (at peak hourly flow)	1.5–2.5
Randall et al. (4)	For SWD of 1.83–3.05 m: $\leq 2.184 \times \mathrm{SWD}^2$ (at average flow) $\leq 4.368 \times \mathrm{SWD}^2$ (at peak hourly flow). For SWD of 3.05–4.57 m: $\leq 6.672 \times \mathrm{SWD}$ (at average flow) $\leq 13.344 \times \mathrm{SWD}$ (at peak hourly flow)	NA
Great Lakes (6)	$\leq$ 40 (at average flow) $\leq$60 (at peak hourly flow) Tank surface area is determined based on the larger of the two SORs. Minimum SWD = 2.1 m	NA
Qasim (7)	30–50 (at average flow) 40 (typical at average flow) 70–130 (at peak hourly flow) 100 (typical at peak hourly flow)	1.0–2.0

Note: SWD—Sidewater Depth; 1 m^3/m^2/day = 24.542 gpd/ft^2.

DESIGN CONSIDERATIONS FOR SECONDARY SETTLING TANKS

The performance of the secondary settling tanks has a significant effect on the wastewater plant's effluent water quality, on the operational efficiency of the biological treatment system and on the solids handling facilities. The secondary clarifiers have two key functions: clarification of the biologically treated wastewater; and thickening and storage of the sludge from the biological treatment process. Main factors that impact secondary settling tank performance are: (1) the amount of solids retained in the tanks, which is determined based on the concentration of the solids removed from these tanks (return activated sludge (RAS)/waste activated sludge (WAS) concentration) and the sludge blanket depth; (2) the amount of solids in the aeration basins, which is established by measuring the MLSS concentration and the RAS flowrate; (3) the activated sludge settleability; and (4) the plant influent flow and waste load, significant fluctuations of which may result in shifting solids between the settling tank and the aeration basin, and ultimately in solids loss with the secondary settling tank effluent. The two key secondary settling tank design criteria are: the SOR; and the solids loading rate (SLR). Table 3 presents recommendations for determining secondary clarifier design SOR and SLR. The tank effluent weir loading rates are typically designed not to exceed 124 m^3/day per meter of length of the weir (10,000 gpd/ft).

The maximum allowable SLR of settling tanks for clarification of activated sludge could be determined for using solids flux analysis (2,3,5,8). This method is based on the fact that for an activated sludge of given settleablity, these is a maximum amount of solids that can be processed through the clarifier (limiting solids flux), above which the clarifier will not be able to operate in a steady-state condition in terms of sludge blanket elevation and effluent water quality. One of the main benefits of the solids analysis concept is that it allows to link the design and operation of the secondary clarifier and the aeration basin and to optimize their performance as one system.

The amount of solids retained in the sedimentation basins can be effectively monitored by frequent manual or automated measurements of the settling tank sludge blanket depth and the concentration of the sludge removed from the settling tanks. While keeping track of the sludge blanket and plant influent flow changes allows gaining a general understanding of the settling tank performance, it is also very advantageous to monitor sludge settleability as well. The Water Environment Research Foundation and the Clarifier Research Committee of the American Society of Civil Engineers have developed protocols for evaluating sludge settleablity and analyzing secondary clarifier performance (9). These protocols are suitable for operational assessment of existing secondary sedimentation tanks and for planning of new facilities.

TREATMENT FOR TECHNOLOGIES FOR SMALL DRINKING WATER SYSTEMS

National Drinking Water
Clearinghouse

INTRODUCTION

Small systems still face difficulties in meeting the requirements of the Safe Drinking Water Act (SDWA) because many technologies available to large systems may be too expensive or complicated for small systems to consider. Furthermore, trained operators and maintenance personnel may not always be available or affordable, leading to standards violations.

Overview of Some Treatment Technologies Used by Small Systems

When the SDWA was reauthorized in 1996, it addressed small system drinking water concerns and required the U.S. Environmental Protection Agency (EPA) to assess treatment technologies relevant to small systems serving fewer than 10,000 people. With this requirement, the SDWA also identified two classes of technologies:

- compliance technologies—which refer to affordable technologies or other treatment techniques (TT) that comply with the maximum contaminant level (MCL) and to technologies that satisfy a TT requirement. Options include package plants or modular systems, and point-of-entry (POE) or point-of-use (POU) treatment; and
- variance technologies—which refer to technologies that must reduce contaminants to levels that protect public health. These technologies may not achieve compliance with the MCL or TT requirement, but must achieve the maximum reduction or inactivation efficiency affordable to a system, considering its size and the quality of the source water.

With small systems' needs in mind, the National Research Council (NRC) recently published the results of a study—*Safe Water From Every Tap: Improving Water Service to Small Communities*—which found that continuous technical and financial assistance is still needed to help more than 54,000 small systems comply with changing regulations. In addition, the NRC study discussed some water treatment technologies that small systems may use to provide safe drinking water to their customers. These treatment technologies are also explained separately through Tech Briefs, four-page water treatment fact sheets, offered by the National Drinking Water Clearinghouse (NDWC). These fact sheets are available online at *www.ndwc.wvu.edu* or by calling (800) 624-8301.

DISINFECTION

The Surface Water Treatment Rule (SWTR) requires public water systems to disinfect water obtained from surface water supplies or groundwater sources under the influence of surface water. Primary methods of disinfection are chlorine gas, chloramines, ozone, ultraviolet light, chlorine dioxide, and hypochlorite.

Chlorine (Gas)

Chlorine gas removes almost all microbial pathogens and is appropriate as both a primary and secondary disinfectant. Chlorine is a dangerous gas that is lethal at concentrations as low as 0.1 percent air by volume. Adequate mixing and contact time must be provided after injection to ensure complete disinfection of pathogens.

Hypochlorites

Sodium Hypochlorite. is available as a solution in concentrations of five to 15 percent chlorine, but is more expensive than chlorine gas. Sodium hypochlorite is easier to handle than gaseous chlorine or calcium hypochlorite, but it is very corrosive and must be kept away from equipment that can be damaged by corrosion.

Calcium Hypochlorite. is a solid white substance, which is 65 percent available chlorine and dissolves easily in water. It is a corrosive material with a strong odor that must be kept away from organic materials, such as wood, cloth, and petroleum products because of the dangers of fire or explosion. Calcium hypochlorite readily absorbs moisture, forming chlorine gas so shipping containers must be emptied completely or carefully resealed.

Chloramines

Chloramines are formed when water containing ammonia is chlorinated or when ammonia is added to water containing chlorine. An effective bactericide that produces fewer disinfection byproducts, chloramine is generated onsite. It is a weak disinfectant and is much less effective against viruses or protozoa than free chlorine. Chloramine is appropriate for use as a secondary disinfectant to prevent bacterial regrowth in a distribution system. Nitrogen trichloride appears to be the only detrimental reaction. Adequate contact and mixing time must be provided.

Ozonation

Ozone is a powerful oxidizing and disinfecting agent formed by passing dry air through a system of high voltage electrodes. Requiring shorter contact time and a smaller dosage than chlorine, ozone is widely used as a primary disinfectant. Ozone does not directly produce halogenated organic materials unless a bromide ion is present. A secondary disinfectant, usually chlorine, is required because ozone does not maintain an adequate residual in water. The capital costs of ozonation systems may be high and operation and maintenance are relatively complex.

Ultraviolet Light

Ultraviolet (UV) radiation, which is generated by a special lamp, penetrates the cell wall of an organism, rendering it unable to reproduce. UV radiation effectively destroys bacteria and viruses. As with ozone, a secondary disinfectant must be used to prevent regrowth of microorganisms. UV radiation:

- is readily available,
- produces no known toxic residuals,
- requires short contact times, and
- is easy to operate and maintain.

Conventional UV radiation may not inactivate *Giardia lamblia* or *Cryptosporidium* cysts in a cost-effective way, and should be used only by groundwater systems not directly influenced by surface water and where there is virtually no risk of protozoan cyst contamination. UV radiation is unsuitable for water with high levels of suspended solids, turbidity, color, or soluble organic matter. However, microorganisms can be killed without generating byproducts of chemical oxidation or halogenation.

Chlorine Dioxide

Chlorine dioxide, although a powerful oxidant, may be more difficult to handle than other forms of chlorine. Chlorine dioxide requires trained staff to manage its use and is so reactive that it may not provide a residual disinfectant in the distribution system. Photochemical decomposition of chlorine dioxide in reservoirs may increase chlorate concentrations, and other factors, including the generation process used and water pH, can affect chlorate and chlorite levels.

FILTRATION

Federal and state laws require all surface water systems and systems under the influence of surface water to filter their water. Filtration methods include slow and rapid sand filtration, diatomaceous earth filtration, direct filtration, membrane filtration, and cartridge filtration.

Slow Sand Filtration

The filter consists of a bed of fine sand approximately three to four feet deep supported by a one-foot layer of gravel and an underdrain system. It is a low-cost, simple to operate, reliable technology, and it is able to achieve greater than 99.9 percent *Giardia* cyst removal. Slow sand filtration is not suitable for water with high turbidity. The filter surface requires maintenance. Extensive land is required due to low-flow operation. Biological processes and chemical/physical processes common to various types of filters occur on the surface of the filter bed. Slow sand filters do not require coagulation/flocculation and may not require sedimentation.

Diatomaceous Earth Filtration

Diatomaceous earth (DE) filtration, also known as precoat or diatomite filtration, relies on a layer of diatomaceous earth approximately 1/8-inch thick placed on a septum or filter element. Septums may be placed in pressure vessels or operated under a vacuum in open vessels. The filters are simple to operate and effective in removing cysts, algae, and asbestos. They have been chosen for projects with limited initial capital, and for emergency or standby capacity to service large seasonal increases in demand. This filter is most suitable for water with low bacterial counts and low turbidity. Coagulant and filter aids are required for effective virus removal. Since chemical coagulation is not required, small water systems have used DE filtration for many years.

Direct Filtration

Direct filtration systems are similar to conventional systems, but omit sedimentation. Effective direct filtration performance ranges from 90 to 99 percent for virus removal and from 10 to 99.99 percent for *Giardia* removal. Coagulation must be included for *Giardia* removal. Direct filtration is often used with steel pressure vessels to maintain the pressure in a water line to avoid repumping after filtration. Direct filtration is only applicable for systems with high quality and seasonally consistent influent supplies. Direct filtration requires advanced operator skill and has frequent monitoring requirements.

Membrane Filtration

More stringent water quality regulations and inadequate water resources are making membrane technology increasingly popular as an alternative treatment technology for drinking water. Capital, operation, and maintenance costs continue to decline, making membrane processes more viable.

Nanofiltration (NF). This membrane process employs pressures between 75 to 150 pounds per square inch (psi) for operation. While it provides removal of ions contributing to hardness (i.e., calcium and magnesium), the technology is also very effective for removing color and disinfection byproducts precursors.

Ultrafiltration (UF). Operational pressures range from 10 to 100 psi, depending upon the application. UF may be employed for removal of some organic materials from freshwater, and may be used for liquid/solid separation.

Microfiltration (MF). A major difference between MF and UF is membrane pore size. The primary applications for this membrane process are particulate and microbial removal.

Bag Filtration

Bag filtration systems are based on physical screening processes. If the pore size of the bag filter is small enough, parasite removal will occur. Unless the quality of the raw water precludes the need for pretreatment, EPA recommends pretreatment of the raw water using sand or multimedia filters, followed by preliminary bag or cartridge filtration, and the use of micron filters as final filters to increase particulate removal efficiencies and to extend the life of the filter.

Cartridge Filtration

Cartridge filters are an emerging technology suitable for removing microbes and turbidity. These filters are easy to operate and maintain, making them suitable for treating low-turbidity influent. They can become fouled relatively quickly and must be replaced with new units. Although these filter systems are operationally simple, they are not automated and can require relatively large operating budgets. A disinfectant is recommended to prevent surface-fouling microbial growth on the cartridge filters and to reduce microbial pass-through.

Backwashable Depth Filtration

Backwashable depth filters operate in part like cartridge filters. This method filters uncoagulated water and is designed to be backwashed when terminal head loss is attained or turbidity breakthrough occurs.

CORROSION CONTROL

Corrosion in a system can be reduced by adjusting pH and alkalinity, softening the water, and changing the level of dissolved oxygen. Any corrosion adjustment program should include monitoring as water characteristics change over time.

pH Adjustment. Operators can promote the formation of a protective calcium carbonate coating (scale) in water lines by adjusting pH, alkalinity, and calcium levels.

Lime Softening. Lime softening affects lead's solubility by changing the water's pH and carbonate levels. Hydroxide ions are then present, and they decrease metal solubility by promoting the formation of solids that protect the surface of the pipe.

Dissolved Oxygen Levels. The presence of excessive dissolved oxygen increases water's corrosive activity. However, removing oxygen from water is not practical because of the expense. The following strategies may be used to minimize the presence of oxygen:

- exclude the aeration process in groundwater treatment,
- increase lime softening,
- extend the detention periods for treated water in reservoirs, or
- use the correct size water pumps in the treatment plant to minimize the introduction of air during pumping.

ION EXCHANGE AND DEMINERALIZATION

Ion exchange and membrane processes are becoming used extensively in water and wastewater treatment. Ion exchange is primarily used to remove of hardness ions, such as magnesium and calcium, and for water demineralization. Reverse osmosis and electrodialysis, both membrane processes, remove dissolved solids from water using membranes.

Ion Exchange (IO)

IO units can be used to remove any charged (ionic) substance from water, but are usually used to remove hardness and nitrate from groundwater. Ion exchange effectively removes more than 90 percent of barium, cadmium, chromium, silver, radium, nitrites, selenium, arsenic, and nitrate. Ion exchange is usually the best choice for removing radionuclides.

Reverse Osmosis (RO)

RO systems are compact, simple to operate, and require minimal labor, making them suitable for small systems where there is a high degree of seasonal fluctuation in water demand. RO can effectively remove nearly all inorganic contaminants from water. Properly operated units will attain 96 percent removal rates. RO can also effectively remove radium, natural organic substances, pesticides, and microbiological contaminants. RO is particularly effective when used in series. Water passing through multiple units can achieve near zero effluent contaminant concentrations.

Electrodialysis

Electrodialysis is very effective in removing fluoride and nitrate and can also remove barium, cadmium, and selenium.

Some of the advantages are:

- all contaminant ions and most dissolved non-ions are removed,
- it is relatively insensitive to flow and total dissolved solids (TDS) level, and
- it may have low effluent concentration.

Some of the limitations are:

- high capital and operating costs,
- high level of pretreatment required,
- reject stream is 20 to 90 percent of feed flow, and
- electrodes require replacement.

Activated Alumina

Activated Alumina (AA) is a physical and chemical process in which ions in the feed water are sorbed to an oxidized AA surface. AA is used in packed beds to remove contaminants such as fluoride, arsenic, selenium, silica, and natural organic matter.

ORGANIC REMOVAL

The technologies most suitable for organic contaminant removal in drinking water systems are granular activated carbon (GAC) and aeration. GAC has been designated by the EPA as the best available technology (BAT) for synthetic organic chemical removal.

Granular Activated Carbon

Several operational and maintenance factors affect the performance of GAC. Contaminants in the water can occupy GAC adsorption sites, whether they are targeted for removal or not. Also, adsorbed contaminants can be replaced by other contaminants with which GAC has a greater affinity. Therefore, the presence of other contaminants might interfere with the removal of the contaminants of concern.

After a period of months or years, depending on the concentration of contaminants, the surface of the pores in the GAC can no longer adsorb contaminants. The carbon must then be replaced.

Aeration

Aeration, also known as air stripping, mixes air with water to volatilize contaminants (turn them to vapor), which are either released directly to the atmosphere or treated and released. Aeration is used to remove volatile organic chemicals (VOC) and can also remove radon. A small system might be able to use a simple aerator constructed from relatively common materials instead of a specially designed aerator system. Aerators include:

- a system that cascades the water or passes it through a slotted container,
- a system that runs water over a corrugated surface, or
- an airlift pump that introduces oxygen as water is drawn from a well.

Other Aeration Types

Packed Column Aeration (PCA). PCA or packed tower aeration (PTA) is a waterfall aeration process that drops water over a medium within a tower to mix the water with air. The medium is designed to break the water into tiny droplets and to maximize its contact with air bubbles for removal of the contaminant. Air is also blown in from underneath the medium to enhance this process. Packed columns usually operate automatically and need only daily visits to ensure that the equipment is running satisfactorily. Maintenance requirements include servicing pump and blower motors and replacing air filters on the blower.

Diffused Aeration. In a diffused aeration system, a diffuser bubbles air through a contact chamber for aeration. The diffuser is usually located near the bottom of the chamber where pressurized air is introduced. The main advantage of diffused aeration systems is that they can be created from existing structures, such as storage tanks. However, these systems are less effective than PCA and usually are employed only in systems with adaptable existing structures.

Multiple Tray Aeration. Multiple tray aeration directs water through a series of trays made of slats, perforations, or wire mesh. A blower introduces air from underneath the trays. Multiple tray aeration units have less surface area than PCA units and can experience clogging from iron and manganese, biological growth, and corrosion problems. Multiple tray aeration units are readily available from package plant manufacturers.

Shallow Tray Aeration (STA). STAs involve the use of shallow trays and are more efficient than multiple tray aerators. STAs increase the available area of mass transfer; thereby increasing the removal efficiency of most VOCs. However, because of the high air-to-water ratio, greater energy costs may be incurred.

Spray Aeration. Spray aeration is an accepted technology in which the contaminated water is sprayed through nozzles. The small droplets produced expose a large interfacial surface area through which VOCs can migrate from a liquid (water) phase to the gaseous (air) phase. Spray aerators have been used to effectively treat VOCs, but are not energy efficient and need a large operational area.

Mechanical Aeration. Mechanical aeration uses mechanical stirring mechanisms to mix air with the water. These systems can effectively remove VOCs. Mechanical aeration units need large amounts of space because they demand long detention times for effective treatment. As a result, they often require open-air designs, which can freeze in cold climates. However, mechanical aeration systems are easy to operate and are less susceptible to clogging from biological growth than PCA systems.

LIME SOFTENING

Lime softening is best suited to groundwater sources, which have relatively stable water quality. The combination of variable source water quality and the complexity of the chemistry of lime softening may make it too complicated for small systems that use surface water sources. Lime softening is unlikely to be suitable for treating

Surface Water Treatment Rule Compliance Technologies for Disinfection

Unit Technology	Limitations (see Footnotes)	Operator Skill Level Required	Raw Water Quality Range and Considerations[1]	Removals: Log *Giardia* & Log Virus w/CT's Indicated in ()[1]
Free Chlorine	(a, b)	Basic	Better with high quality. High iron or manganese may require sequestration or physical removal.	3 log(104) & 4 log(6).
Ozone	(c, d)	Intermediate	Better with high quality. High iron or manganese may require sequestration or physical removal.	3 log(1.43) & 4 log(1.0).
Chloramines	(e)	Intermediate	Better with high quality. Ammonia dose should be tempered by natural ammonia levels in water.	3 log(1850) & 4 log(1491).
Chlorine Dioxide	(f)	Intermediate	Better with high quality.	3 log(23) & 4 log(25).
Onsite Oxidant Generation	(g)	Basic	Better with high quality.	Research pending on CT values. Use free chlorine.
Ultraviolet (UV) Radiation	(h)	Basic	Relatively clean source water required. Iron, natural organic matter and turbidity affect UV dose.	1 log *Giardia* (80–120) & 4 log viruses (90–140) mWsec/cm2 doses in parentheses[2].

[1] CT (Concentration × Time), in mg-min/L, based upon 1989 Surface Water Treatment Rule Guidance Manual. Temp. 10 C, mid-pH range, unless otherwise indicated.

[2] UV dose is product of mW/cm2 (intensity) × sec (time); bases of viral inactivation ranges are rotavirus and MS–2 tests.

Limitations Footnotes

a. Providing adequate CT (contact time) may be a problem for some supplies.
b. Chlorine gas requires special caution in handling and storage, and operator training.
c. Ozone leaks represent hazard: air monitoring required.
d. Ozone used as primary disinfectant (i.e., no residual protection).
e. Long CT. Requires care in monitoring of ratio of added chlorine to ammonia.
f. Chlorine dioxide requires special storage and handling precautions.
g. Oxidants other than chlorine not detected in solution by significant research effort. CT should be based on free chlorine until new research determines appropriate CT values for electrolyzed salt brine.
h. No disinfectant residual protection for distributed water.

groundwater in systems serving 500 or fewer people unless those systems have access to a trained operator who can monitor the treatment process. Either hydrated lime or quicklime may be used in the softening process. The choice depends upon economic factors, such as the relative cost per ton of the two materials as well as the size and equipment of the softening plant.

What Are Other Softening Alternatives?

The selection of lime, lime-soda ash, or caustic soda softening is based on cost, TDS criteria, sludge production, carbonate and noncarbonate hardness, and chemical stability. Water containing little or no noncarbonate hardness can be softened with lime alone. Caustic soda softening increases the TDS of treated water, while lime and lime-soda ash softening often decrease TDS. Caustic soda softening produces less sludge than lime and lime-soda ash softening. Caustic soda does not deteriorate during storage, while hydrated lime may absorb carbon dioxide and water during storage, and quicklime may slake in storage causing feeding problems. The final selection is generally based on cost, water quality, and owner and operator preference.

FOR MORE INFORMATION

Small drinking water systems are more likely to violate SDWA regulations because when MCLs were set, they were based upon systems serving larger metropolitan areas. Thus, small systems must explore innovative technologies that they can afford. The NDWC's RESULTS (Registry of Equipment Suppliers of Treatment Technologies for Small Systems) database houses information related to small drinking water systems. The clearinghouse gathered this information from system operators, drinking water state offices, vendors, and others.

Database searches are available from the NDWC through combinations of site location, vendor name, type of technology, type of contaminant, and system size—and they include contact names and telephone numbers. Consulting engineers, local officials, private owners, and regulators may use RESULTS not only to understand technologies that small systems use, but

Surface Water Treatment Rule Compliance Technology for Filtration

Unit Technology	Limitations (see Footnotes)	Operator Skill Level Required	Raw Water Quality Range and Considerations[1]	Removals: Log *Giardia* & Log Virus
Conventional Filtration (includes dual-stage and dissolved air flotation)	(a)	Advanced	Wide range of water quality. Dissolved air flotation is more applicable for removing particulate matter that doesn't readily settle: algae, high color, low turbidity—up to 30–50 nephelometric turbidity units (NTU) and low-density turbidity.	2–3 log *Giardia* & 1 log viruses.
Direct Filtration (includes in-line filtration)	(a)	Advanced	High quality. Suggested limits: average turbidity 10 NTU; maximum turbidity 20 NTU; 40 color units; algae on a case-by-case basis.[1]	0.5 log *Giardia* & 1–2 log viruses (1.5–2 log *Giardia* w/coagulation).
Slow Sand Filtration	(b)	Basic	Very high quality or pretreatment. Pretreatment required if raw water is high in turbidity, color, and/or algae.	4 log *Giardia* & 1–6 log viruses.
Diatomaceous Earth Filtration	(c)	Intermediate	Very high quality or pretreatment. Pretreatment required if raw water is high in turbidity, color, and/or algae.	Very effective for *Giardia*; low bacteria and virus removal.
Reverse Osmosis	(d, e, f)	Advanced	Requires prefiltrations for surface water—may include removal of turbidity, iron, and/or manganese. Hardness and dissolved solids may also affect performance.	Very effective (cyst and viruses).
Nanofiltration	(e)	Intermediate	Very high quality of pretreatment. See reverse osmosis pretreatment.	Very effective (cyst and viruses).
Ultrafiltration	(g)	Basic	High quality or pretreatment.	Very effective *Giardia*, > 5–6.
Microfiltration	(g)	Basic	High quality or pretreatment required.	Very effective *Giardia*, > 5–6 log; Partial removal viruses.
Bag Filtration	(g, h, i)	Basic	Very high quality or pretreatment required, due to low particulate loading capacity. Pretreatment if high turbidity or algae.	Variable *Giardia* removals & disinfection required for virus credit.
Cartridge Filtration	(g, h, i)	Basic	Very high quality or pretreatment required, due to low particulate loading capacity. Pretreatment if high turbidity or algae.	Variable *Giardia* removals & disinfection required for virus credit.
Backwashable Depth Filtration	(g, h, i)	Basic	Very high quality or pretreatment required, due to low particulate loading capacity. Pretreatment if high turbidity or algae.	Variable *Giardia* removals & disinfection required for virus credit.

[2] Adham, S.S., Jacangelo, J.G., and Laine, J.M. "Characteristics and Costs of MF and UF Plants." *Journal American Water Works Association*, May 1996.

Limitations Footnotes

a. Involves coagulation. Coagulation chemistry requires advanced operator skill and extensive monitoring. A system needs to have direct full-time access or full-time remote access to a skilled operator to use this technology properly.

b. Water service interruptions can occur during the periodic filter-to-waste cycle, which can last from six hours to two weeks.

c. Filter cake should be discarded if filtration is interrupted. For this reason, intermittent use is not practical. Recycling the filtered water can remove this potential problem.

d. Blending (combining treated water with untreated raw water) cannot be practiced at risk of increasing microbial concentration in finished water.

e. Post-disinfection recommended as a safety measure and for residual maintenance.

f. Post-treatment corrosion control will be needed prior to distribution.

g. Disinfection required for viral inactivation.

h. Site-specific pilot testing prior to installation likely to be needed to ensure adequate performance.

i. Technologies may be more applicable to system serving fewer than 3,300 people.

Compliance Technology for the Total Coliform Rule

40 CFR 141.63(d)–Best Technologies or Other Means to Comply (Complexity Level Indicated)	Comments/Water Quality Concerns
Protecting wells from contamination, i.e., placement and construction of well(s) (Basic).	Ten State Standards and other standards (AWWA A100–90) apply; interfacing with other programs essential (e.g., source water protection program).
Maintenance of a disinfection residual for distribution system protection (Intermediate).	Source water constituents may affect disinfection: iron, manganese, organics, ammonia, and other factors may affect dosage and water quality. Total Coliform Rule (TCR) remains unspecific on type/amount of disinfectant, as each type differs in concentration, time, temperature, pH, interaction with other constituents, etc.
Proper maintenance of distribution system: pipe repair/replacement, main flushing programs, storage/reservoir and operation and maintenance (O&M) programs (including cross-connection control/backflow prevention), and maintenance of positive pressure throughout (Intermediate).	O&M programs particularly important for smaller systems needing to maintain water purity. States may vary on distribution protection measures. See also EPA's Cross-Connection Control Manual (#EPA 570/9-89-077).
Filtration and/or disinfection of surface water or other groundwater under direct influence; or disinfection of groundwater (Basic thru Advanced).	Same issues as cited above under maintaining disinfection residual; pretreatment requirements affect complexity of operation. Refer to Surface Water Treatment Rule Compliance Technology List; and other regulations under development.
Groundwaters: Compliance with State Wellhead Protection Program (Intermediate).	EPA/State Wellhead Protection Program implementation (per §1428 SDWA): may be used to assess vulnerability to contamination, and in determination of sampling and sanitary survey frequencies.

Technologies for Inorganic Contaminants

Unit Technology	Limitations (see Footnotes)	Operator Skill Level Required	Raw Water Quality Range
1. Activated Alumina	(a)	Advanced	Groundwaters, competing anion concentrations will affect run length.
2. Ion Exchange (IO)		Intermediate	Groundwaters with low total dissolved solids, competing ion concentrations will affect run length.
3. Lime Softening	(b)	Advanced	Hard ground and surface waters.
4. Coagulation/Filtration	(c)	Advanced	Can treat wide range of water quality.
5. Reverse Osmosis (RO)	(d)	Advanced	Surface water usually require prefiltration.
6. Alkaline Chlorination	(e)	Basic	All groundwaters.
7. Ozone Oxidation		Intermediate	All groundwaters.
8. Direct Filtration		Advanced	Needs high raw water quality.
9. Diatomaceous earth filtration		Intermediate	Needs high raw water quality.
10. Granular Activated Carbon		Basic	Surface waters may require prefiltration.
11. Electrodialysis Reversal		Advanced	Requires prefiltration for surface water.
12. Point of Use (POU)-IO	(f)	Basic	Same as Technology #2.
13. POU-RO	(f)	Basic	Same as Technology #5.
14. Calcium Carbonate Precipitation	(g)	Basic	Waters with high levels of alkalinity and calcium.
15. pH and alkalinity adjustment (chemical feed)	(g)	Basic	All ranges.
16. pH and alkalinity adjustment (limestone contactor)	(h)	Basic	Waters that are low in iron and turbidity. Raw water should be soft and slightly acidic.
17. Inhibitors		Basic	All ranges.
18. Aeration	(i)	Basic	Waters with moderate to high carbon dioxide content.

Limitations Footnotes

a. Chemicals required during regeneration and pH adjustments may be difficult for small systems to handle.
b. Softening chemistry may be too complex for small systems.
c. It may not be advisable to install coagulation/filtration solely for inorganics removal.
d. If all of the influent water is treated, post-treatment corrosion control will be necessary.
e. pH must exceed pH 8.5 to ensure complete oxidation without build-up of cyanogen chloride.
f. When POU devices are used for compliance, programs for long-term operation, maintenance, and monitoring must be provided by water utility to ensure proper performance.
g. Some chemical feeds require high degree of operator attention to avoid plugging.
h. This technology is recommended primarily for the smallest size category.
i. Any of the first five aeration technologies listed for volatile organic contaminants can be used.

Technologies for Volatile Organic Contaminants

Unit Technology	Limitations (see Footnotes)	Operator Skill Level Required	Raw Water Quality Range[1]
1. Packed Tower Aeration (PTA)	(a)	Intermediate	All groundwaters.
2. Diffused Aeration	(a, b)	Basic	All groundwaters.
3. Multi-Stage Bubble Aerators	(a, c)	Basic	All groundwaters.
4. Tray Aeration	(a, d)	Basic	All groundwaters.
5. Shallow Tray Aeration	(a, e)	Basic	All groundwaters.
6. Spray Aeration	(a, f)	Basic	All groundwaters.
7. Mechanical Aeration	(a, g)	Basic	All groundwaters.
8. Granular Activated Carbon (GAC)	(h)	Basic	All groundwaters.

[1] National Research Council (NRC). "Safe Water from Every Tap: Improving Water Service to Small Communities." National Academy Press. Washington, DC. 1997.

Limitations Footnotes

a. Pretreatment for the removal of microorganisms, iron, manganese, and excessive particulate matter may be needed. Post-treatment disinfection may have to be used.

b. May not be as efficient as other aeration methods because it does not provide for convective movement of the water thus limiting air-water contact. It is generally used only to adapt existing plant equipment.

c. These units are highly efficient; however, the efficiency depends upon the air-to-water ratio.

d. Costs may increase if a forced draft is used. Slime and algae growth can be a problem but can be controlled with chemicals such as copper sulfate or chlorine.

e. These units require high air-to-water ratios (100–900 m3/m3).

f. For use only when low removal levels are needed to reach a maximum contaminant level (MCL) because these systems may not be as energy efficient as other aeration methods because of the contacting system.

g. For use only when low removal levels are needed to reach an MCL because these systems may not be as energy efficient as other aeration methods because of the contacting system. The units often require large basins, long residence times, and high energy inputs, which may increase costs.

h. See the Synthetic Organic Compounds (SOC) compliance technology table for limitation regarding these technologies.

Technologies for Synthetic Organic Compounds

Unit Technology	Limitations (see Footnotes)	Operator Skill Level Required[1]	Raw Water Quality Range and Considerations[1]
1. Granular Actived Carbon (GAC)		Basic	Surface water may require prefiltration.
2. Point of Use GAC	(a)	Basic	Surface water may require prefiltration.
3. Powdered Activated Carbon	(b)	Intermediate	All waters.
4. Chlorination	(c)	Basic	Better with high quality waters.
5. Ozonation	(c)	Basic	Better with high quality waters.
6. Packed Tower Aeration (PTA)	(d)	Intermediate	All groundwaters.
7. Diffused Aeration	(d, e)	Basic	All groundwaters.
8. Multi-Stage Bubble Aerators	(d, f)	Basic	All groundwaters.
9. Tray Aeration	(d, g)	Basic	All groundwaters.
10. Shallow Tray Aeration	(d, f)	Basic	All groundwaters.

[1] National Research Council (NRC). "Safe Water from Every Tap: Improving Water Service to Small Communities." National Academy Press. Washington, DC. 1997.

Limitations Footnotes

a. When POU devices are used for compliance, programs for long-term operation, maintenance, and monitoring must be provided by water utility to ensure proper performance.

b. Most applicable to small systems that already have a process train including basins mixing, precipitation or sedimentation, and filtration. Site specific design should be based on studies conducted on the system's particular water.

c. See the Surface Water Treatment Rule compliance technology tables for limitations associated with this technology.

d. Pretreatment for the removal of microorganisms, iron, manganese, and excessive particulate matter may be needed. Post-treatment disinfection may have to be used.

e. May not be as efficient as other aeration methods because it does not provide for convective movement of the water thus limiting air-water contact. It is generally used only to adapt existing plant equipment.

f. These units are highly efficient; however, the efficiency depends upon the air-to-water ratio.

g. Forces may increase if a forced draft is used.

technologies that are affordable, appropriate, and reliable. Information in RESULTS may be obtained three ways: access the database through the NDWC's Web site located at *www.ndwc.wvu.edu*; call the NDWC at (800) 624–8301 or (304) 293–4191 and ask a technical assistant to perform a search for you.

Technologies for Radionuclides

Unit Technology	Limitations (see Footnotes)	Operator Skill Level Required[1]	Raw Water Quality Range and Considerations[1]
1. Ion Exchange (IO)	(a)	Intermediate	All groundwaters.
2. Point of Use (POU) IO	(b)	Basic	All groundwaters.
3. Reverse Osmosis (RO)	(c)	Advanced	Surface waters, usually require prefiltration.
4. POU RO	(b)	Basic	Surface waters, usually require prefiltration.
5. Lime Softening	(d)	Advanced	All waters.
6. Green Sand Filtration	(e)	Basic	
7. Co-precipitation with Barium Sulfate	(f)	Intermediate to Advanced	Groundwaters with suitable water quality.
8. Electrodialysis/Electrodialysis Reversal		Basic to Intermediate	All groundwaters
9. Pre-formed Hydrous Manganese Oxide Filtration	(g)	Intermediate	All groundwaters

[1] National Research Council (NRC). "Safe Water from Every Tap: Improving Water Service to Small Communities." National Academy Press. Washington, DC. 1997.

Limitations Footnotes

a. The regeneration solution contains high concentrations of the contaminant ions. Disposal options should be carefully considered before choosing this technology.

b. When POU devices are used for compliance, programs for long-term operation, maintenance, and monitoring must be provided by water utility to ensure proper performance.

c. Reject water disposal options should be carefully considered before choosing this technology. See other RO limitations described in the Surface Water Treatment Rule Compliance Technologies Table.

d. The combination of variable source water quality and the complexity of the chemistry involved in lime softening may make this technology too complex for small surface water systems.

e. Removal efficiencies can vary depending on water quality.

f. This technology may be very limited in application to small systems. Since the process requires static mixing, detention basins, and filtration; it is most applicable to systems with sufficiently high sulfate levels that already have a suitable filtration treatment train in place.

g. This technology is most applicable to small systems that already have filtration in place.

HAVE YOU READ ALL OF OUR FACT SHEETS?

Tech Briefs, drinking water treatment fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) magazine *On Tap* for several years. These very popular items are researched, complied, and written by NDWC staff.

For a complete listing of our Tech Briefs, visit our Web site at *www.ndwc.wvu.edu*. Additional copies of fact sheets are free; however, postal charges may be added. To order, call the NDWC at (800) 624–8301 or (304) 293–4191. You also may order online at *ndwc_orders@mail.nesc.wvu.edu*.

For further information, comments about this fact sheet, or to suggest topics, call the NDWC at one of the above numbers or contact Vipin Bhardwaj at *vbhardw2@wvu.edu*, Geri Ramiser at *gramiser@wvu.edu*, Kathy Jesperson at *kjespers@wvu.edu*, or Mark Kemp-Rye at *mkemp@wvu.edu*.

ULTRAVIOLET DISINFECTION

National Drinking Water
Clearinghouse

Using ultraviolet (UV) light for drinking water disinfection dates back to 1916 in the U.S. Over the years, UV costs have declined as researchers develop and use new UV methods to disinfect water and wastewater. Currently, several states have developed regulations that allow systems to disinfect their drinking water supplies with UV light. Running a UV light system requires a basic level of operator skill and relatively clean source water. On the down side, however, UV offers no residual disinfection within the distribution system.

WHAT IS UV DISINFECTION?

UV light, which continues to be a reliable means of disinfection, involves exposing contaminated water to radiation from UV light. The treatment works because UV light penetrates an organism's cell walls and disrupts the cell's genetic material, making reproduction impossible.

A special lamp generates the radiation that creates UV light by striking an electric arc through low-pressure mercury vapor. This lamp emits a broad spectrum of radiation with intense peaks at UV wavelengths of 253.7 nanometers (nm) and a lesser peak at 184.9 nm. Research has shown that the optimum UV wavelength range to destroy bacteria is between 250 nm and 270 nm. At shorter wavelengths (e.g., 185 nm), UV light is powerful enough to produce ozone, hydroxyl, and other free radicals that destroy bacteria.

The U.S. Department of Health, Education, and Welfare set guidelines for UV light disinfection in 1966. These guidelines require a minimum dose of 16 mWs/cm^2 [milliwatt seconds per square centimeter] at all points throughout the water disinfection unit.

However, the American National Standards Institute and the National Sanitation Foundation International set the minimum UV light requirement at 38 mWs/cm2 for class A point of use (POU) and point of entry (POE) devices that treat visually clear water.

The U.S. Environmental Protection Agency (EPA) lists UV disinfection as an approved technology for small public water systems. In addition, EPA is considering the following variations of conventional UV treatment as "emerging" technologies: pulsed UV, medium-pressure UV, and UV oxidation (i.e., used in combination with peroxide or ozone).

ADVANTAGES

Generally, UV is simple to install and requires little supervision, maintenance, or space. Improved safety, minimum service time, low operation and maintenance costs, and the absence of a chemical smell or taste in finished water are primary factors for selecting UV technology rather than traditional disinfection technologies.

UV treatment breaks down or removes some organic contaminants. UV achieves 1-log reduction of *Giardia lamblia* at an intensity of 80–120 mWs/cm^2, and 4-log reduction of viruses at an intensity of 90–140 mWs/cm^2. Only recently has the scientific community begun to accept UV as a highly effective tool for *Cryptosporidium* control.

UV light disinfection does not form any significant disinfection byproducts, nor does it cause any significant increase in assimilable organic carbon (AOC).

Research has confirmed that UV effectiveness is relatively insensitive to temperature and pH differences. In addition, researchers found that UV application does not convert nitrates to nitrites, or bromide to bromines or bromates.

Recent pilot studies show that UV-treated drinking water inhibits bacterial growth and replication in the distribution system; however, conditions within distribution systems, such as leaks, still require additional residual disinfection (e.g., free chlorine).

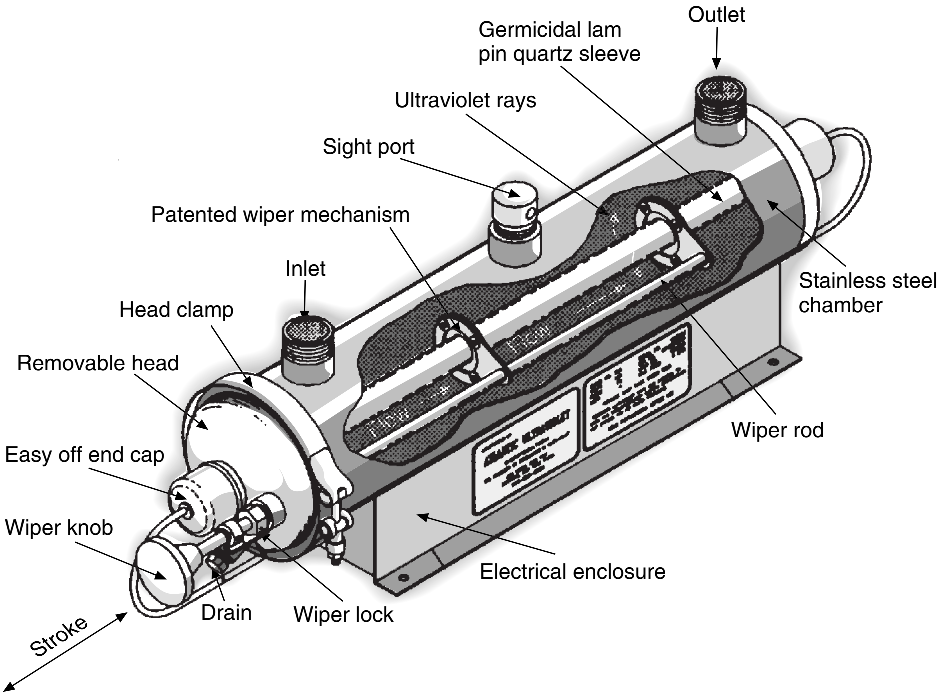
The advantages of using UV, rather than chemical disinfection, include:

- Has no known toxic or significant nontoxic byproducts;
- Has no danger of overdosing;
- Removes some organic contaminants;
- Has no volatile organic compound (VOC) emissions or toxic air emissions;
- Has no onsite smell and no smell in the final water product;
- Requires very little contact time (seconds versus minutes for chemical disinfection);
- Does not require storage of hazardous material;
- Requires minimal space for equipment and contact chamber;
- Improves the taste of water because of some organic contaminants and nuisance microorganisms are destroyed;
- Does not affect minerals in water; and
- Has little or no impact on the environment except for disposing of used lamps or obsolete equipment.

LIMITATIONS

Microbial and chemical characteristics are two major water quality factors that affect the UV unit performance. Microbial characteristics of water include type, source, age, and density. Chemical water characteristics include nitrites, sulfites, iron, hardness, and aromatic organic levels.

UV radiation is not suitable for water with high levels of suspended solids, turbidity, color, or soluble organic matter. These materials can react with UV radiation, and reduce disinfection performance. Turbidity makes it difficult for radiation to penetrate water.



Closed vessel ultraviolet reactor. *Reprinted with permission from the Atlantic Ultraviolet Corporation.*

Disadvantages of UV disinfection include:

- No disinfection residual;
- No technical database exists on how well UV systems perform for various water quality conditions; and
- No standardized mechanism measures, calibrates, or certifies how well equipment works before or after installation.

Systems also should consider using different kinds of microbial testing. Laboratories typically test for total coliform to judge microbiological activity in drinking water—but coliforms are sensitive to UV light. Because of this sensitivity, microbial tests for UV treated finished water should include a Heterotrophic Plate Count (HPC) test. HPC microorganisms may provide a better disinfection assessment than the UV sensitive coliforms.

PROCESS DESCRIPTION

UV light effectively destroys bacteria and viruses. However, how well the UV system works depends on the energy dose that the organism absorbs. If the energy dose is not high enough, the organism's genetic material may only be damaged rather than disrupted.

An effective dose is measured as a product of the lamp's intensity (the rate at which photons are delivered to the target), including radiation concentration, proper wavelength, exposure time, water quality, flow rate, and the microorganism's type, and source, as well as its distance from the light source.

At a minimum, drinking water systems should install two UV units, which are both capable of carrying the amount of water the system was designed to handle. Having two units in place assures continuous disinfection when one unit is being serviced. Two units also can ensure operation during low-flow demand periods.

Modular units designed for small drinking water systems are easy to install and operate (two plumbing connections per unit and one electrical hook-up). They should be equipped with automatic cleaners and remote alarm systems. For systems in isolated areas, operators should maintain and store a set of spare parts onsite, and consider a telemetry system for monitoring treatment.

Typical UV light components include:

- A stable high-voltage source of electricity because low-line voltage would result in a lower UV dose;
- A chamber made of stainless steel or any other material that is opaque and will not corrode;
- UV lamps that are properly secured inside quartz sleeves, easing installation, replacement, and maintenance;
- Quartz sleeves with sufficiently high transmission rates to deliver the UV energy produced by UV lamps;
- Mechanical wipers to maintain optimum transmission between scheduled cleaning and maintenance work;
- Sensors to monitor the UV intensity passing through the water. These sensors need to be connected to alarm systems to alert the operator in case of low UV intensity. The operator must have easy access to these sensors for necessary installation, replacement, calibration, and maintenance;
- Safety control to shut off UV lamps in case of low-flow levels and elevated lamp temperature;
- Arc and lamp-out monitors to alert the operator of system failure; and
- Electronic ballasts.

UV units are currently used as stand-alone treatment systems or as part of a series of other drinking water treatment processes or multiple barrier system. A common treatment that uses UV light to remove and disinfect contaminants from groundwater sources involves a combined ozone or hydrogen-peroxide process along with UV application. So, it is common to find that manufacturers of UV equipment also manufacture ozone equipment.

Furthermore, the drinking water treatment industry provides UV equipment (mainly closed chamber units) for short-term uses. Rental units are used in cleanup and emergency situations, such as if groundwater is contaminated by spilled toxic organic compounds.

MONITORING AND OPERATION REQUIREMENTS

Factors that affect UV light system performance are: lamp output, lamp aging, and plating or fouling of unit surfaces. To better control these factors, operators must ensure continuous dose measurement (i.e., accurate intensity and flow-rate measurement) and proper maintenance (cleaning as well as lamp and sleeve replacement regimes).

Technological advances have eliminated many of the operation and maintenance problems that were associated with earlier UV applications. Current systems are equipped with mechanical cleaners, ultrasonic cleaners, or some self-cleaning mechanism (mandatory if water fouling agents, such as iron, are present in the water entering the unit); lamps that are easy to install and replace; and alarm systems that indicate minor and major failure.

To ensure continued system operation, a maintenance schedule needs to be in place. This schedule should include periodic site inspections; changing lamps annually or when light transmission efficiency has decreased to 70 percent; inspecting and cleaning surfaces; inspecting or cleaning the UV chamber interior every six months; and inspecting and replacing ballasts, O-rings, valves, and switches.

Furthermore, the operator should monitor water turbidity and color since they are natural barriers to UV light transmission. And some dissolved minerals, such as calcium, have a tremendous negative effect on UV absorbance.

Since it may not be practical to provide instantaneous stand-by power during power outages, the system should be designed to automatically stop water flow or provide an alternate means of disinfection as a backup. Where the system is dependent on electrically powered pumps, this measure may not be necessary because the pumps will shut off when the power goes out. However, gravity flow systems may be vulnerable.

UV disinfection should have the following minimum operational controls and procedures:

- A central display indicating alarms for power failure, lamp failure, hours of lamp operation, low UV dosage, high lamp temperature, high ballast temperature, and high system flows;
- Methods that monitor lamp temperature, ballast temperature, and system water flows;
- A minimum of two photodiode sensors per unit to monitor UV dosage at 254 nm. These sensors must be calibrated using approved standards each time the lamps are cleaned or replaced or the UV chamber is serviced;
- Automatic UV system by-pass or shutoffs, which are activated whenever the system exceeds peak design flow rates, when UV dosage is low, or when lamp or ballast temperatures are high; and
- Two UV units should be installed so flow is not interrupted when one unit is out of service.

HAVE YOU READ ALL OUR TECH BRIEFS?

“Tech Briefs” drinking water treatment fact sheets have been a regular feature in the National Drinking Water Clearinghouse (NDWC) newsletter *On Tap* for more than four years. NDWC Technical Assistance Specialist Mohamed Lahlou, Ph.D., researches, compiles, and writes these very popular items.

A package of the Tech Briefs is now available as a product. A three ring binder holds all the current Tech Briefs in print. New selections can be easily added to the package as they become available. To order this product, call the NDWC at the numbers listed below and ask for item #DWPKPE71. The item is free.

To order, call the NDWC at (800) 624-8301 or (304) 293-4191. You also may order online at ndwc_orders@mail.estd.wvu.edu or download fact sheets from our Web site at www.ndwc.wvu.edu.

(Additional copies of fact sheets are free; however, postal charges may be added.)

For further information, to comment on this fact sheet, or to suggest topics, call Dr. Lahlou at one of the above numbers or contact him via e-mail at mlahlou2@wvu.edu.

ULTRAVIOLET IRRADIATION

M. SIDDIQUI
University of Utah
Salt Lake City, Utah

Ultraviolet irradiation (UV) is a potential alternative to chlorination for drinking water disinfection. UV provides disinfection without producing the problematic disinfection by-products of chemical disinfectants such as chlorine. During retrofitting of UV to an existing potable water treatment process or during design of a new installation, there can be significant benefits in reexamining the overall disinfection strategy for the treatment plant and the water distribution system (1).

MECHANISM

Light whose wavelengths are longer than 700 nm is in the infrared and radio emission range. Light of wavelengths shorter than 400 nm is in the ultraviolet range. This range is subdivided into UVA (320–400 nm) light, which is responsible for sun tanning, UVB (280–320 nm) light, which causes sun burning and the danger of skin cancer, and UVC (200–280 nm), which is absorbed by DNA and causes genetic damage and inactivates bacteria and viruses (2). UVC light is often called “germicidal” radiation. Organic molecules absorb energy primarily in the 200 to 300 nm range, and this range evidences the most disinfectant or germicidal properties. Bacterial disinfection is greatest at 260 nm, although other wavelengths also affect cells. A given individual microorganism is almost transparent to UV; it absorbs only a small fraction of the incident UV irradiance. Thus, germicidal effectiveness is directly proportional to the absorbance of the organism, which often peaks around 260 nm and accounts for the maximum germicidal effectiveness at that wavelength.

DNA is a nucleic acid polymer in a double-stranded helix linked together by a sequence of four constituent bases (adenine, cytosine, guanine, and thymine), which constitute the genetic code (2). Of these four bases, thymine undergoes a unique photochemical reaction when exposed to germicidal wavelengths of UV light. If two thymine bases are located adjacent to each other, absorption of a UV photon by one of the thymines leads to formation of a chemical bond between the two thymines (called a thymine dimer). This disrupts the structure of the DNA, so that if enough thymine dimers are formed, the DNA cannot replicate in cell mitosis. This is the fundamental mechanism of UV disinfection or inactivation.

UV DOSAGE

The amount of damage created by UV radiation and hence, the effectiveness of the disinfection process are related to the intensity of light and the exposure time to that intensity. UV dose is defined as the product of the average intensity of light within the reactor and the duration of exposure to that intensity (UV dose = average UV intensity × exposure time). The units of intensity are milliwatts per square centimeter, and those of exposure time are seconds. Dose therefore has the units of milliwatt seconds per square centimeter ($\mathrm{mW{\cdot}s/cm^2}$). Typical UV doses for drinking water range between 16 and 40 $\mathrm{mW{\cdot}s/cm^2}$ depending on the application, water quality, target disinfection level, etc.

MEASUREMENT AND ESTIMATION OF UV DOSE

In a UV reactor, UV irradiance at a certain point can be measured with a radiometer; however, the UV irradiance detected is only measured at a specific point, and only those photons that enter the detector from a narrow acceptance angle can be detected (3,4). This makes it difficult to obtain a direct “measurement” of the UV dose in a reactor configuration (3). Actinometry is a direct method for estimating UV doses. Actinometry measures UV light through a photochemical reaction for which the quantum yield (molecules of product formed per photon absorbed) is well established. A chemical mixture sensitive to UV light at the wavelength of interest is exposed, and the resulting photochemical changes are determined analytically. A quartz cell containing the chemical mixture is inserted into the reactor and exposed to the UV light. The chemical change produces a product over the period of exposure. From the product yield and the quantum yield, one can obtain the total photons incident at that point (3).

Several manufacturers also recommend employing mathematical models such as a multiple point source summation (MPSS) model for estimating UV doses (3,5). Most UV light sources are long narrow lamps. The light output from such a lamp may be approximated by a large number (n) of “point sources” equally spaced along the lamp axis. The light from each point source is assumed to radiate equally in all directions, and the irradiance across a small volume element, a section of an area to be irradiated, in the reactor is then obtained by summing the irradiance at that volume element from all n point sources. Proper account has to be taken of reflection, refraction, and absorption of a beam as it propagates toward the target volume element (3). Once the irradiance is calculated for each volume element in a large three-dimensional grid filling the reactor, the average irradiance is obtained by averaging the irradiance of each volume element over the entire grid. If more than one lamp is in the reactor, the irradiance at a given point is the sum of the irradiance from each lamp.

EFFECTIVENESS

UV irradiation is effective against bacteria at UV doses of 3 to 30 $\mathrm{mW{\cdot}s/cm^2}$ and against viruses at 30 to 100 $\mathrm{mW{\cdot}s/cm^2}$ (2). However, it was thought that protozoa such as *Giardia* and *Cryptosporidium* were unsusceptible to this approach. This inaccurate perception was linked to assays that evaluated UV treatments based on the physical damage they caused to the organisms' outer surfaces. Studies measuring infectivity, however, confirm that UV radiation penetrates the outer walls of *Giardia* and *Cryptosporidium*, causing internal damage and eliminating their threat, even when they are exposed to doses of 30 mW·s/cm^2 or less.

Generally, it has been found that the more complex the microorganism, the more sensitive it is to UV inactivation. Thus, viruses are the least sensitive, then bacterial spores, and finally bacteria are very sensitive. Until recently, protozoa, such as *Cryptosporidium parvum* and *Giardia lamblia*, appeared to go against this trend as it was thought they were very insensitive to UV because of difficulty in penetrating the shell in their cyst or oocyst state.

TYPICAL TREATMENT SYSTEM

A typical UV treatment system consists of a reactor vessel, where a UV lamp irradiates the flowing water. Ideally, uneven distribution is prevented by radial mixing within the reactor, so that all objects moving through it receive equivalent irradiation.

UV SOURCES

Light sources can vary widely. They encompass high- and low-vapor- pressure lamps, broadband sources covering the germicidal region from 200 to 300 nm, and narrowband emitters targeting sensitive wavelengths. UV light is most commonly generated by low- and medium-pressure mercury vapor lamps. In low-pressure mercury lamps, the energy is emitted primarily at 254 nm. A 4-foot, 40 watt (W) fluorescent lamp is a low-pressure mercury lamp with a "fluorescing" pigment on the inner surface. In medium-pressure mercury lamps, the emission is more widely distributed across the 200 to 600 nm range, and the power density is much higher. For example, a 4-foot lamp can carry as much as 30 kilowatts (kW) of electrical power.

FACTORS AFFECTING UV

Dissolved substances in the water—especially organic carbon and nitrates—can absorb UV light. Turbidity also plays a role in the transmittance of light, but mostly due to scattering or reflecting properties. In water, the particles that make up turbidity can also block or hide microbes (some of which can attach to a particle) and then prevent exposure to UV irradiation. However, until the turbidity reaches 5 NTUs (nephelometric turbidity units) or greater, this effect is usually negligible. Other factors include average UV intensity within the reactor received by the microbes in the water, hydraulic behavior of the fluid as it flows through the reactor and the amount of turbulence created, short-circuiting and retention time distribution, pretreatment processes prior to UV disinfection, particulate count and size distribution, and the microbial characteristics of the water to be disinfected (1).

CONCLUSION

UV technology is just beginning to be applied on a large scale to drinking water. The cost of obtaining a total biological barrier with UV disinfection is estimated to be same or less than traditional disinfection methods such as chlorination or ozonation. Because of this, UV disinfection of drinking water could become the most significant advance in protecting drinking water sources since the introduction of chlorination.

WATER DISINFECTION USING UV RADIATION—A SRI LANKAN EXPERIENCE

Niranjanie Ratnayake
University of Moratuwa
Moratuwa, Sri Lanka

BACKGROUND

Treated public water supplies are available in most urban areas in Sri Lanka. National Drinking Water Quality Standards have been established, based on WHO Guidelines for Drinking Water Quality, and usually the quality of water leaving the treatment plant is up to the Standards. However, for various reasons such as old pipelines, leaks in the distribution system, low pressure leading to back-siphonage and cross connections, the risk of subsequent contamination of the water is very high. In addition, many users depend on either overhead tanks, which are filled at night, or sump-pump-overhead tank arrangements to store the water, due to low pressure in the distribution system and unreliable supplies. Dual water supplies, where private surface or groundwater supplies are used to supplement the public water supply, are also common due to the inadequacy of the public water supply. Often, the same plumbing system is used for the two systems. The public water supply is treated, but the well water is usually untreated and is pumped directly into the sump or the overhead tank.

The risks of contaminating the drinking water in these situations are considerable. Residual chlorine doses applied at treatment plants are often insufficient to maintain the safety of the water, and many domestic consumers boil water before drinking it. Although boiling is a very reliable method of disinfection of small quantities of water, it is not practical for large-scale uses, such as hostels, canteens, hospitals, and factories. Even though bottled water is available in the market, it is expensive, and the reliability of the cheaper products is questionable. Therefore, it has become necessary to find an appropriate method for disinfecting such water supplies in the light of possible outbreaks of waterborne diseases among users, particularly where dual water supplies are used.

BREAK-POINT CHLORINATION

Chlorination is the most common disinfection method used in water treatment. Chlorine is used in the gaseous form, in solid form as calcium hypochlorite [Ca $(OCl)_2$], or in liquid form as sodium hypochlorite [NaOCl] solution.

Chlorine, a very strong oxidizing agent, reacts with many organic and inorganic substances in water, in addition to disinfecting water. The “chlorine demand” of these other substances has to be satisfied before excess free chlorine is available for disinfection.

Thus the total amount of chlorine added to water is not available for disinfection. Initially, the added chlorine is used immediately to oxidize inorganic and organic substances in reduced form. When this immediate chlorine demand is satisfied, the added chlorine combines with ammonia and similar compounds in the water to form chloramines. Chloramines in water are called “combined available chlorine,” because they are also effective in disinfection, although not to the same extent as free chlorine. Further addition of chlorine has the effect of oxidizing the chloramines formed, thus reducing the available chlorine. When all chloramines are oxidized, further addition of chlorine produces “free available chlorine”, which is the most effective form of chlorine for disinfection. The point at which all oxidation is completed and free available chlorine starts to appear is called the “break point,” and chlorination beyond this point is called “break-point chlorination.”

Thus, to produce a free chlorine residual which would be available to disinfect any contamination within the distribution system at the consumer’s premises, such as in the household plumbing system, overhead tank, or sump, sufficient chlorine should be added to achieve break-point chlorination.

UV RADIATION TECHNOLOGY

UV radiation has been established as an effective bactericide and viricide. UV radiation penetrates the cell wall and is absorbed by cellular nucleic acids. Radiation absorption prevents replication, thus killing the cell. However, the effectiveness of UV radiation in killing spore forming bacteria such as *Giardia lamblia* has not yet been established. UV radiation is not a chemical agent, so it produces no toxic residuals.

A special lamp is used to transfer electromagnetic energy to the target organism’s cells. Mercury arc lamps are the most commonly used type of lamp because about 85% of the energy output is of the 253.7 nm wavelength, which is within the optimum germicidal range of 250–270 nm.

The effectiveness of radiation is a direct function of the energy dose absorbed by the organism, which is measured as the product of the lamp’s intensity and the time of exposure. Intensity is the rate at which photons are delivered to the target organism. It is governed by the lamp’s power, the depth of water, and the presence of substances that absorb the energy, such as suspended solids, color, turbidity, and soluble organic matter. The radiation dose absorbed by the water is the water’s UV demand (which is similar to the chlorine demand) and is quantified as the absorption of UV energy (wavelength 253.7 nm) in a given depth of water. The energy dose also depends on the exposure time of the water to the UV radiation, although the required time is only seconds, rather than minutes, for effective disinfection. However, water that has high concentrations of substances like suspended solids, color, turbidity, and soluble organic matter may not receive an adequate radiation dose for effective disinfection.

If the radiation dose is not sufficient to destroy the target organism’s DNA macromolecules, but only damages them, disinfection would not be effective. Photoenzymatic repair, called “photoreactivation,” occurs from exposure to sunlight, incandescent, or fluorescent light for certain types of bacteria. Therefore, as a rule of thumb, the UV dosage is increased to more than that required to achieve the specified percentage of kill.

MAIN ADVANTAGES AND DISADVANTAGES OF UV RADIATION OVER CHEMICAL METHODS OF DISINFECTION

The main advantages of UV radiation over chemical methods of disinfection are the simplicity of the system for installation and operation, minimal space requirement, absence of any changes in the characteristics of the water and any residual by-products due to reactions in the water, and very short required contact time (seconds rather than minutes) for effective disinfection.

On the other hand, chlorination requires chemical handling and dosing equipment, and ozone and chlorine dioxide need to be produced at the site due to their chemical instability. All chemical disinfectants produce disinfection by-products, by oxidation, reduction, or disproportionation of the disinfectant itself and by reaction of the disinfectant with substances that are already in the raw water. For example, chlorination adds chloride ions to the water and produces trihalomethanes (THMs) and other halogenated organics, which are known to have harmful health effects, when the water contains organic matter. Chlorine dioxide produces chlorite and chlorate ions, which have been identified as harmful, and ozone is also known to produce some harmful by-products if certain organic substances, such as the pesticide heptachlor, are present in the raw water.

The major disadvantage of UV disinfection is the absence of a residual disinfecting mechanism left in the water to be used downstream, as would occur in chlorination and ozonation to some extent. Therefore, it is very important that the UV radiation is carried out as close to the point of consumption as practically possible to prevent recontamination of the treated water. Other disadvantages are the necessity of pretreatment to avoid shielding of microbiological cells by solids and the high cost of the equipment.

CASE STUDY

A UV water purification system that had a maximum flow rate of 60 L/h was used in the laboratory as a case study. The system consisted of an activated carbon filter unit and a UV light unit, as shown in (Fig. 1). Observations were also made on a system whose capacity was 300 L/h; it was installed at the University canteen.

The study was carried out for a period of 2 years. The main objectives of the study were

1. to find the potential of the UV water purification system to destroy pathogens at various flow rates for various sources of water;
2. to study the time taken by the UV equipment to produce disinfected water at the point of consumption; and
3. to compare the performance and cost of disinfection using UV radiation with that of chlorination using bleaching powder.

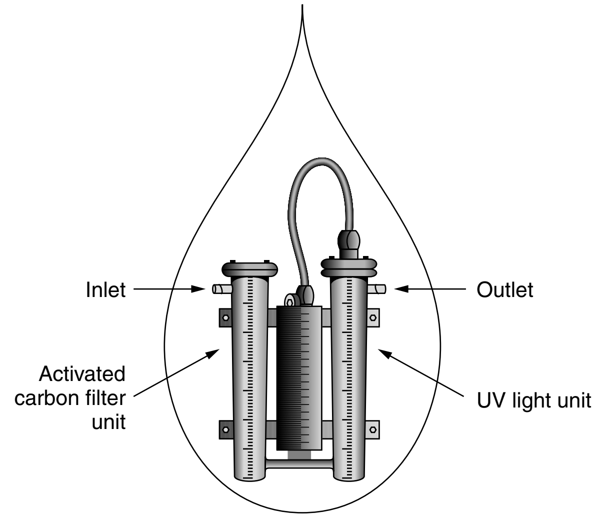

Figure 1. UV water purification system used in the case study.

Table 1. Typical Water Quality at the Water Sources Used in the Case Study

Water Quality Parameter	Location			
	Boat Yard	Ranmal	San Michele	University Well
Total coliform, per mL	167	127	510	97
Fecal coliform, per mL	134	116	481	92
Turbidity, NTU	4.1	3.7	5.7	1.1
DO, mg/L	5.7	6.3	7.7	5.9
Alkalinity, mg/L $CaCO_3$)	0.4	0.4	0.25	0.3
Ammonia, mg/L	1.04	0.56	0.28	1.20
Conductivity	218	1678	925	168.6
pH	7.14	7.43	7.45	7.5
Color, Hazen	40	20	15	5
Temperature, °C	29	29	28.5	29

A simple apparatus was set up using a ground level tank, a pump, a constant head overhead tank to feed the water through the UV purification system at a constant head, and devices to control and measure the flow rate and collect samples of raw and treated water for analysis at various times. Surface water from three locations of a large lake called Bolgoda Lake, several kilometers away from each other, and ground water from a dug well in the University premises were used as raw water sources. A map showing the locations of raw water sources for the case study is given in (Fig. 2). The typical water quality parameters at these water sources are given in Table 1.

Studies on the performance of the UV purification system in the laboratory showed that the total and fecal coliform numbers in the treated effluent from samples of raw water from all four sources, which initially contained high total coliform and fecal coliform, as shown in Table 1, were all zero after passing through the system. The tests were carried out at several flow rates, from as low as

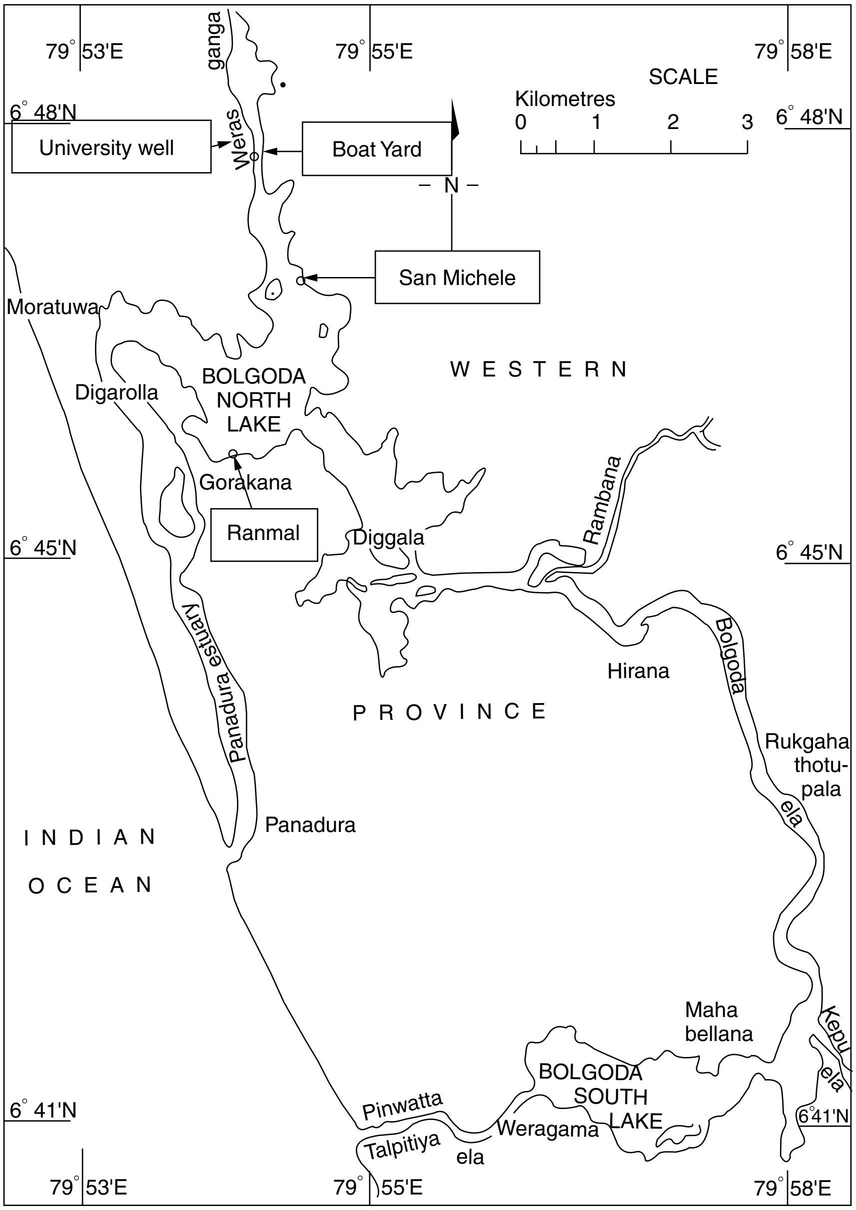

Figure 2. Map of locations of raw water sources taken for the case study.

10 liters per minute to 110 liters per minute, which is almost twice the maximum rate specified for the UV system. The resulting total and fecal coliform contents were always zero, when sampled after 5 minutes of UV lamp operation. The performance of the UV system when used for water from Bolgoda Lake at San Michele and Ranmal Hotel locations and the University well water are shown graphically in (Fig. 3). As can be observed, the total and fecal coliform counts were slightly reduced by the activated carbon filter, but the water cannot be considered safe because the coliforms were still present at all flow rates. However, when sampled 5 minutes after the UV lamp was switched on, none of the samples contained total or fecal bacteria. There is a slight improvement in the turbidity of the water after the activated carbon filter, but no significant change can be seen from the UV radiation.

During the first 5 minutes of system operation, initial studies showed that the coliform numbers do not immediately drop to zero but showed a gradual drop to zero, as shown in (Fig. 4). It was apparent that up to 4 minutes were needed to obtain water that was free from total and fecal coliform bacteria. However, further studies carried out using the same UV system showed that the total and fecal coliform numbers fall to zero when effluent samples are collected as early as after 30 seconds using the same water sources. Tests carried out using the larger UV system which is installed in the University canteen and has a design flow rate of 300 L/h, showed that the total and fecal coliform numbers in the water after passing through the system were zero when tested after 1, 2, 3, 4 and 5 minutes at the design flow rate, as well as double the design flow rate (600 L/h); this is the maximum flow rate possible from the tap. Thus, no

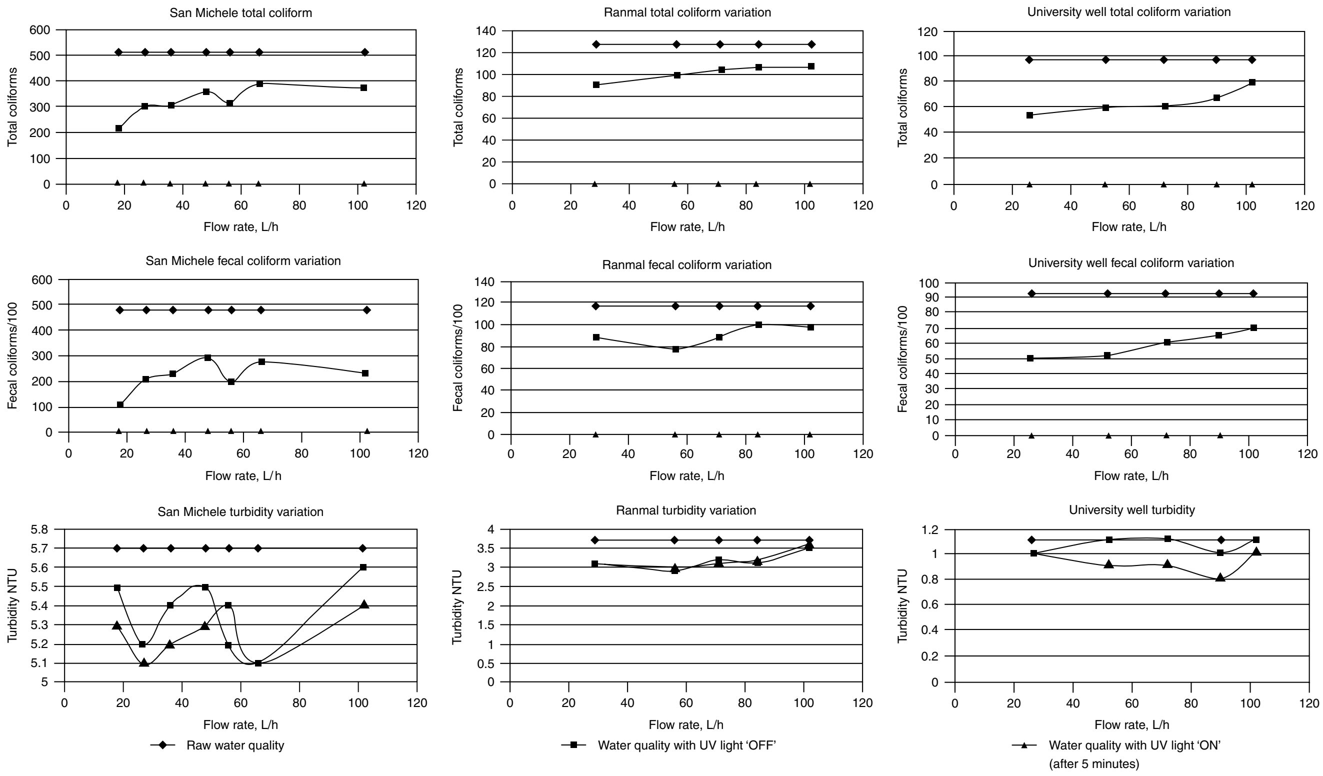

Figure 3. Performance of the UV system on water from different sources at different flow rates.

conclusive evidence could be gathered to determine the required lag time for the water. The time lag experienced earlier could be partly due to the time taken to replace the untreated water in the pipeline, particularly, at low flow rates.

When the system was used with the UV light in the "off" position, there was some improvement in the water quality, including a 20–40% reduction in the coliform content. However, this was not reduced to acceptable levels in any of the trials, and the reduction in total and fecal coliforms was lower at higher flow rates. Thus, it could be inferred that the 100% coliform removal obtained was due to UV radiation. Conversely, it is important to establish the fact that the water would not be safe from pathogenic organisms if the UV light were not turned "on." The function of the activated carbon filter is to remove turbidity, color, and organic matter in the raw water, so that the UV disinfection can be more effective.

A comparative study was done on the same source of raw water, to find the chlorine requirement of the water. It was attempted to find the "break point" for chlorination, but no clear break point was identified, presumably due to the low concentrations of ammonia that were present in the water sources. In raw water from the San Michele location of Bolgoda Lake, a slight depression of residual chlorine could be noticed (see Fig. 5) at an added chlorine concentration of 2.5 to 3.0 mg/L. However, at the Boat Yard location, there was no noticeable break point, but a high initial chlorine demand was noticed, probably due to the more polluted and stagnant status of the water at this location.

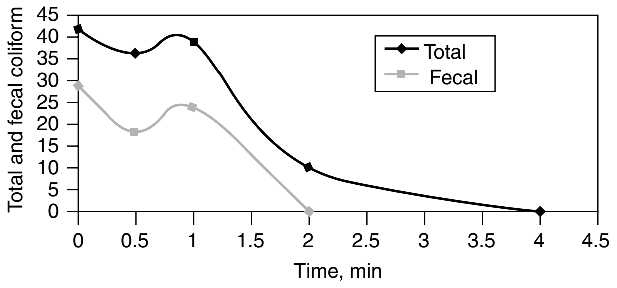

Figure 4. Variation of total and fecal coliform content in treated effluent within the first 5 minutes (initial trials).

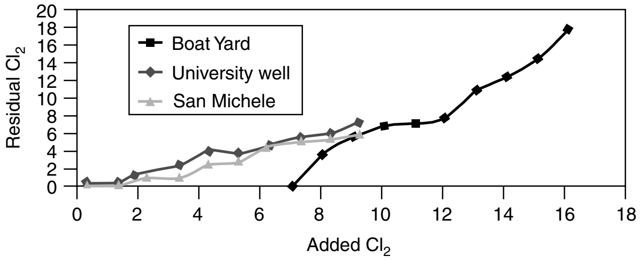

Figure 5. Chlorine demand of the source water.

The following example was used in comparing the cost of the UV treatment and chlorination using bleaching powder:

Water Source: Bolgoda Lake at San Michele location
Selected point of consumption: University canteen
Number of hours used per day: 16
Average flow rate: 300 L/h

— Annual consumption of water: 1,752,000 liters

UV treatment		
Cost of installation of the UV system	SLR 32344.00	US$ 359.38
Assumed lifetime of the unit	5 years	—
Price of a UV bulb	SLR 1200.00	US$ 13.33
Power of a UV bulb for 300 L/h unit	8 watts	—
Lifetime of a UV bulb	8000 hours operation	—
⇒ Number of bulbs required for 5 years	4	—
Cost of bulb per year	SLR 960.00 per annum	US$ 10.60
Annual cost of power for UV unit	SLR 280.00 per annum	US$ 3.11
At a discount rate of 15% per annum,	—	—
capital cost of UV unit as an annuity	SLR 9660.00 per annum	US$ 107.33
⇒ Total Annual Cost of UV unit	**SLR 10,900.00 per annum**	**US$ 121.11 per annum**
Chlorination using bleaching powder		
Required chlorine dosage at break point	2.5 mg/L	—
Required amount of chlorine per year	4.38 kg per annum	—
Percentage of chlorine in bleaching powder used	Approx. 8.9%	—
Required amount of bleaching powder,	44.88 kg per annum	—
	—	—
Total amount of bleaching powder required allowing 10% wastage	50 kg per annum	—
Cost of bleaching powder @Rs. 80 per kg	SLR 4000.00 per annum	US$ 44.44
Assumed annual O&M cost	SLR 12,000.00 per annum	US$ 133.33
⇒ Total Annual Cost of Chlorination	**SLR 16,000.00 per annum**	US$ 177.77

This example showed that the UV radiation equipment is more economical for this application than using bleaching powder for disinfection, considering the local conditions.

CONCLUSION

The case study showed that ultraviolet radiation preceded by activated carbon filtration was a very effective method of disinfecting water from surface as well as groundwater. Thus, it is a very useful method of disinfection when dual water supplies are used, and the treated public water supplies are supplemented by well or surface water, which does not require conventional treatment. The activated carbon unit reduces the color, turbidity, and dissolved organic substances that interfere with disinfection by ultraviolet radiation. However, if the water contains high amounts of the above substances, the filter unit will need frequent replacement. Therefore, it is most suitable for use with well water, rather than surface water. UV disinfection itself is more suitable for well water disinfection, as the disinfection effect of UV radiation on spore forming bacteria such as *Giardia lamblia* is not yet well established.

In comparing the cost of disinfection using UV radiation and chlorination, even though the UV equipment needs a rather high capital investment, the total annual cost of the UV system is lower than that of disinfection using bleaching powder. Considering the ease of operation and ability to have the unit on-line, it is a very attractive option for applications where a large number of users are expected to use water during short periods of time, such as in canteens and hostels.

However, care must be taken to maintain the system and to make sure that the UV lamp is turned on when the water is being used for consumption.

Acknowledgments

The case study was carried out by Messers H.G.C.K. Haththotuwa, S. P. Ranasinghe, K. Amarasinghe, and N.P. Liyanage, undergraduates of the Department of Civil Engineering, University of Moratuwa, under the supervision of the author during 1999, 2000, and 2001.

DRINKING WATER QUALITY STANDARDS (DWQS)-UNITED STATES

Babs A. Makinde-Odusola
Public Utilities
Riverside, California

In 1974, the U.S. Congress, through the Safe Drinking Water Act (SDWA), created the first-ever mandatory national program to protect consumers from harmful contaminants in drinking water. There have been several amendments to the Act—the most recent in 1996. The SDWA requires the U.S. Environmental Protection Agency (EPA) to set national drinking water quality standards (DWQS). The EPA has set primary and secondary DWQS for chemical, physical, radiological, and microbiological contaminants listed in Tables 1 and 2. More Americans are now served by water systems without health risk violations since the EPA (2) began tracking violations around 1980.

INTRODUCTION

Public Water Systems (PWS) are required to comply with the SDWA. A PWS, by definition, provides water to at least 15 connections or 25 persons for at least 60 days out of the year Public Water Supply—United States. PWS provide domestic water to about 275 million Americans (3); about 42 million people, or 16% (4) depend on private sources, such as house wells. EPA does not regulate the quality of water in private wells, but many state and local governments have regulations to protect users of private wells.

Media coverage of waterborne disease outbreaks, such as the 1993 outbreak of cryptosporidiosis in Milwaukee, and popular culture movies, such as "A Civil Action" and "Erin Brockovich" increased public interest in the health risks of contaminated water. At least 50 people died and more than 400,000 people suffered from gastrointestinal illness during the 1993 incident in Milwaukee (7). Many consumers resorted to drinking bottled water. Bottled water is regulated by the U.S. Food and Drug Administration, and is required to meet DWQS. Some consumers rely on "Point of Use" or "Point of Entry" devices to improve the quality of domestic water.

EPA considers costs and health benefits when setting DWQS (see Fig. 1). The annual costs of operating U.S. PWS exceed $3.5 billion (5). The EPA (6) estimated that it would cost about $31 billion (Table 3) over a 20-year period to comply with existing and proposed SDWA regulations. The SDWA requires PWS to have the technical, financial, and managerial capability to provide safe drinking water (2). There are many programs to assist PWS in complying with DWQS, such as the drinking water State Revolving Funds that has a budget authority of $9.6 billion for the fiscal period 1994–2003 [http://www.epa.gov/OW/regs/intro.html].

The SDWA includes a multiple-barrier protection framework against pollution—source water protection, treatment, distribution system integrity, and public information. PWS conduct Source Water Assessments to reduce the potential for contamination (Well Head Protection). The Underground Injection Control (UIC) program of the SDWA and other Federal environmental laws, such as the Clean Water Act (CWA), are important for source water protection (1). U.S. EPA is using source water protection [WELLHEAD PROTECTION], and water safety and security to leverage the linkages between the CWA and SDWA. The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (SDWA Section 1433(a)) requires certain CWS to conduct Vulnerability Assessments (VAs), and prepare/revise Emergency Response Plans (ERPs) to protect the security ["quality"] of drinking water. Under the CWA, U.S.

DRINKING WATER QUALITY STANDARDS (DWQS)-UNITED STATES

Babs A. Makinde-Odusola
Public Utilities
Riverside, California

In 1974, the U.S. Congress, through the Safe Drinking Water Act (SDWA), created the first-ever mandatory national program to protect consumers from harmful contaminants in drinking water. There have been several amendments to the Act—the most recent in 1996. The SDWA requires the U.S. Environmental Protection Agency (EPA) to set national drinking water quality standards (DWQS). The EPA has set primary and secondary DWQS for chemical, physical, radiological, and microbiological contaminants listed in Tables 1 and 2. More Americans are now served by water systems without health risk violations since the EPA (2) began tracking violations around 1980.

INTRODUCTION

Public Water Systems (PWS) are required to comply with the SDWA. A PWS, by definition, provides water to at least 15 connections or 25 persons for at least 60 days out of the year Public Water Supply—United States. PWS provide domestic water to about 275 million Americans (3); about 42 million people, or 16% (4) depend on private sources, such as house wells. EPA does not regulate the quality of water in private wells, but many state and local governments have regulations to protect users of private wells.

Media coverage of waterborne disease outbreaks, such as the 1993 outbreak of cryptosporidiosis in Milwaukee, and popular culture movies, such as “A Civil Action” and “Erin Brockovich” increased public interest in the health risks of contaminated water. At least 50 people died and more than 400,000 people suffered from gastrointestinal illness during the 1993 incident in Milwaukee (7). Many consumers resorted to drinking bottled water. Bottled water is regulated by the U.S. Food and Drug Administration, and is required to meet DWQS. Some consumers rely on “Point of Use” or “Point of Entry” devices to improve the quality of domestic water.

EPA considers costs and health benefits when setting DWQS (see Fig. 1). The annual costs of operating U.S. PWS exceed $3.5 billion (5). The EPA (6) estimated that it would cost about $31 billion (Table 3) over a 20-year period to comply with existing and proposed SDWA regulations. The SDWA requires PWS to have the technical, financial, and managerial capability to provide safe drinking water (2). There are many programs to assist PWS in complying with DWQS, such as the drinking water State Revolving Funds that has a budget authority of $9.6 billion for the fiscal period 1994–2003 [http://www.epa.gov/OW/regs/intro.html].

The SDWA includes a multiple-barrier protection framework against pollution—source water protection, treatment, distribution system integrity, and public information. PWS conduct Source Water Assessments to reduce the potential for contamination (Well Head Protection). The Underground Injection Control (UIC) program of the SDWA and other Federal environmental laws, such as the Clean Water Act (CWA), are important for source water protection (1). U.S. EPA is using source water protection [WELLHEAD PROTECTION], and water safety and security to leverage the linkages between the CWA and SDWA. The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (SDWA Section 1433(a)) requires certain CWS to conduct Vulnerability Assessments (VAs), and prepare/revise Emergency Response Plans (ERPs) to protect the security [“quality”] of drinking water. Under the CWA, U.S.

Figure 1. Key components to developing and monitoring drinking water standards.

EPA established the Human Health Water quality criteria [http://epa.gov.waterscience/humanhealth/15table-fs.htm], which though not DWQS are numeric values that protect human health from the harmful effects of pollutants in ambient water based solely on science without considering socio-economic impacts. DWQS standards are often regarded as "Applicable or Relevant and Appropriate Requirements" (ARARs) in cleanup decisions affecting polluted water. Water conservation programs may reduce the need to use poorer quality sources for drinking water.

DEFINITIONS

Many terms are used to describe the numerical and/or narrative qualities of drinking water. Such terms include regulations, standards, goals, levels, limits, advisories, etc. (8). Terms used by the EPA (9,10) in published drinking water regulations include

Maximum Contaminant Level Goal (MCLG): The level of a contaminant in drinking water below which there is no known or expected risk to health. MCLGs allow a margin of safety and are nonenforceable public health goals. Table 1 is a list of the MCLGs.

Maximum Contaminant Level (MCL): The highest level of a contaminant that is allowed in drinking water. EPA sets the MCL as close to the MCLG as feasible, using the best available treatment technology (BAT) and considering cost. MCLs are enforceable standards and are listed in Table 1.

Maximum Residual Disinfectant Level Goal (MRDLG): The level of a drinking water disinfectant below which there is no known or expected risk to health (Table 1). MRDLGs do not reflect the benefits of using disinfectants to control microbial contaminants.

Maximum Residual Disinfectant Level (MRDL): The highest level of a disinfectant allowed in drinking water (Table 1).

Secondary MCLs or "SMCLs" are established for nuisance chemicals only as guidelines for aesthetic considerations, such as taste, color, and odor and are not considered to present a risk to human health at the SMCL. SMCLs (Table 2) are unenforceable at the federal level. Some states enforce SMCLs at the state level (1).

Treatment Technique (TT): A required process to reduce the level of a contaminant in drinking water. EPA

[1] There are many footnotes, not reproduced here.

[2] Including fecal coliform and *E. coli*

[3] Proposed radon rule: MCLG = 0, MCL = 300 pCi/L; Alternate MCL = 4,000 pCi/L + an approved Multimedia Mitigation Program.

Log on to URL of source for full details.

Primacy states may have more stringent standards.

Adapted from: http://www.epa.gov/safewater/mcl.html specifies a TT only if it is not "economically or technologically feasible" to ascertain the concentration of a contaminant (2,8).

Action Level: "The concentration of a contaminant which, if exceeded, triggers treatment or other requirements which a water system must follow. For lead or copper, it is the level which, if exceeded in more than 10% of the homes tested, triggers treatment (9).

Alternative Maximum Contaminant Level (AMCL): Unique to radon in drinking water, it is the level of radon in drinking water that would not increase the level of radon in indoor air beyond the natural level of radon in outdoor air RADON IN WATER.

Health Risk Reduction and Cost Analysis (HRRCA): The goal of the HRRCA is to provide a neutral and factual analysis of the incremental costs, benefits, and other impacts of controlling contaminant levels in drinking water based on system size.

Best available technology (BAT): The field-proven feasible treatment technique for removing contaminants from drinking water below the MCL. Historically, the EPA has based feasibility on technologies appropriate for large PWS, but the 1996 SDWA requires EPA to specify compliance technologies that can be feasibly implemented by small water systems.

Health Advisories [http://www.epa.gov/ost/drinking/standards] describe the levels of a contaminant at which adverse health effects would not be anticipated for different durations of exposure (10).

Some states have additional standards. The Office of Environmental Health Hazard Assessment (OEHHA) within the California EPA sets a Public Health Goal (PHG) based exclusively on health risk assessment. A PHG [http://www.oehha.org/water/phg/allphgs.html] is set at the level at which no known or anticipated adverse effect on health will occur with an adequate margin of safety; considering possible synergistic effects resulting from exposure to two or more contaminants; and the existence of groups in the population that are more susceptible to adverse effects of the contaminant. PHG is nonregulatory, but another state agency, the California Department of Health Services (DHS), is required to use the PHG as the basis for setting MCL.

Action Level (AL): In California, an AL is a health-based advisory level for a contaminant for which an MCL has not been adopted. DHS sets an AL when one of the following occurs: (1) a chemical is found in an actual or proposed drinking water source; or (2) a chemical is in proximity to a drinking water source, and guidance is needed, should it reach the source. DHS set the AL at 4 μg/L for perchlorate, the main active explosive ingredient in rocket fuel [http://www.dhs.ca.gov/ps/ddwem/chemicals/AL/actionlevels.htm].

Table 2. Secondary Maximum Contaminant Levels

Parameter	SMCL	Noticeable Effects Above the Secondary MCL
Aluminum	0.05 to 0.2 mg/L*	Colored water
Chloride	250 mg/L	Salty taste
Color	15 color units	Visible tint
Copper	1.0 mg/L	Metallic taste; blue-green staining
Corrosivity	Non-corrosive	Metallic taste; corroded pipes/fixtures staining
Fluoride	2.0 mg/L	Tooth discoloration
Foaming agents (MBAS)	0.5 mg/L	Frothy, cloudy; bitter taste; odor
Iron	0.3 mg/L	Rusty color; sediment; metallic taste; reddish or orange staining
Manganese	0.05 mg/L	Black to brown color; black staining; bitter metallic taste
Odor	3 TON	"Rotten-egg," musty or chemical smell
pH	6.5–8.5	Low pH: bitter metallic taste; corrosion high pH: slippery feel; soda taste; deposits
Silver	0.1 mg/L	Skin discoloration; graying of the white part of the eye
Sulfate	250 mg/L	Salty taste
TDS	500 mg/L	Hardness; deposits; colored water; staining; salty taste
Zinc	5 mg/L	Metallic taste
Bolero[1,2]	0.001 mg/L	Odor is detected at a lower concentration than its taste
MtBE[1]	0.005 mg/L	–

Notes: MtBE: Methyl tertiary-butyl ether
TON: Threshold Odor Number
TDS: Total Dissolved Solids
[1] California SMCL
[2] Also known as Thiobencarb
Adapted from: http://www.epa.gov/safewater/consumer/2ndstandards.html
http://www.dhs.ca.gov/ps/ddwem/chemicals/MCL/secondarymcls.htm
*MCL for Aluminum in California is 1 mg/L

HISTORY OF U.S. DWQS AND SDWA

Clean drinking water used to mean clear, palatable, nonodorous water. It was not until the early 1900s that DWQS other than for general clarity existed (2), even though the first U.S. community water system (CWS) began in 1799 (8). By 1900, many of the more than 3000 CWSs then contributed to major disease outbreaks because they "provided an efficient vehicle for the delivery of pathogenic bacteria" (8).

Federal authority to regulate drinking water began with the Interstate Quarantine Act of 1893 (1). In 1914, the U.S. Public Health Services (USPHS) set bacteriological DWQS for water systems that provided drinking water to interstate carriers such as ships and trains, as directed by the Act. Those standards were commonly referred to as "Treasury Standards" (1). In 1915, the federal government committed to reviewing DWQS on a regular basis (8). USPHS revised and expanded the standards in 1925, 1946, and 1962 (1). All 50 states adopted the USPHS

Table 3. 20-Year Regulatory Need (in Millions of January 1999 Dollars)

Regulations	Current Need	Future Need	Total Need
Existing SDWA regulations	–	–	–
Surface Water Treatment Rule[1]	$14,492.1	$4,873.3	$19,365.4
Total Coliform Rule[1]	$358.1	$112.8	$470.9
Nitrate/Nitrite Standard[1]	$197.1	$31.9	$229.0
Lead and Copper Rule	$1,039.6	$186.5	$1,226.2
Total Trihalomethanes Standard	$39.1	$60.6	$99.7
Other Regulations[2]	$430.8	$85.4	$516.2
Subtotal National Need	$16,556.9	$5,350.4	$21,907.4
Costs Associated with Proposed and Recently Promulgated Regulations (Taken From EPA Economic Analyses)[3]	–	$9,324.3	$9,324.3
Total National Needs	$16,556.9	$14,674.8	$31,231.7

Note: Numbers may not total due to rounding.

[1] Regulations for contaminants that cause acute health effects.

[2] Includes regulated VOCs, SOCs, IOCs, and Radionuclides

[3] Includes regulations for contaminants that cause acute and/or chronic health effects. In the Economic Analyses, the compliance costs for some regulations are given as a range. In calculating the $9.3 billion need, the survey used EPA's lead option, unless one was not available in which case the survey used the more conservative estimate.

Source: U.S. EPA. Drinking Water Infrastructure Needs Survey: 2nd Report to Congress. Office of Water, Washington, D.C. EPA 816-R-01-004, February 2001. http://www.epa.gov/safewater/dwsrf.html

standards with minor modifications either as regulations or as guidelines even though the federal government did not mandate them (11).

In the late 1960s, several studies found that many man-made chemicals from sources, such as intensive agriculture and manufacturing plants, were contaminating water supplies. One of the environmental laws passed to protect public health is the SDWA in 1974. The 1974 SDWA required EPA to establish legally enforceable DWQS for all PWS in the United States and a surveillance system for PWS. The 1974 law also included a schedule and procedures for developing new drinking water standards, which are to be reviewed at least every 3 years. In 1975, the EPA promulgated interim regulations based on the 1962 USPHS standards, with some additional health-effects information (1). The SDWA was amended and/or reauthorized in 1977, 1979, 1980, 1986, 1988, and 1996 (2).

The SDWA amendments of 1986 declared that the interim standards promulgated in 1975 are final and required EPA to regulate 83 contaminants within 3 years after enactment (2). EPA was required to regulate an additional 25 contaminants every 3 years and to designate the best available treatment technology (BAT) for each regulated contaminant. EPA was directed to require all PWS to disinfect. Filtration was mandated for surface water systems.

The SDWA Amendments of 1996 [http://www.epa.gov/safewater/sdwa/sdwa.html] modified the regulatory schedule and included new sections such as criteria and procedures for variance, operator certification requirements, and provisions for capacity development (1). The EPA published guidelines for certifying and recertifying operators of PWS [http://www.epa.gov/safewater/opcert/plan.html].

STANDARDS SETTING

EPA promulgates two types of drinking water regulations—the National Primary Drinking Water Regulations (NPDWRs) and the National Secondary Drinking Water Regulations (NSDWRs). NPDWRs address health risks/effects that may be acute or chronic and include enforceable maximum limits for drinking water contaminants (MCL) and disinfectants. A NPDWR also includes BAT, monitoring, reporting, recordkeeping provisions, and Regulatory Impact Analyses (Fig. 1). NSDWRs address drinking water aesthetics such as taste and odor that render drinking water unpalatable or undesirable to use. NSDWRs (SMCL) are not enforceable at the federal level. Regulating aesthetic standards deters consumers from seeking more pleasant but less safe sources of water (12). In California, the SMCL for methyl tertiary-butyl ether (MtBE) (5 μg/L) is lower than its MCL (13 μg/L).

The EPA (13) usually follows these steps when setting DWQS (Fig. 1): Determine whether to regulate a contaminant based on peer-reviewed science; set an MCLG DRINKING WATER QUALITY—STANDARDS AND CRITERIA, DRINKING WATER QUALITY—STANDARDS, REGULATIONS AND GOALS; propose an MCL or treatment technique (TT); finalize by, setting an enforceable MCL or TT; and authorize states to grant variances for PWS that serve up to 3300 people based on affordability criteria. Stakeholders can participate in the process.

The EPA selects from the Contaminant Candidate List (CCL) that contains the names of unregulated contaminants. The EPA is to revise the CCL [http://www.epa.gov/safewater/ccl/ccl_fr.pdf], every 5 years. The EPA has developed and maintains a publicly available database known as the National Contaminant Occurrence Database (NCOD), which contains information on regulated and unregulated contaminants that can be found in drinking water [http://www.epa.gov/ncod/].

COMPLIANCE AND SUPERVISION

The EPA administers the SDWA through primacy states. The SDWA allows the EPA Administrator to treat

Tribes, District of Columbia, Guam, Puerto Rico, the Northern Mariana Islands, the Virgin Islands, American Samoa, and the Trust Territory of the Pacific Islands as states for purposes of primacy. Primacy states usually adopt EPA DWQS, but some states set standards that are more stringent than those of the EPA. Nothing precludes a state from establishing DWQS for any water constituent not regulated by the EPA. The EPA, the states, the PWS, and the public cooperatively implement the SDWA.

The EPA provides grants to primacy states to assist states in developing and implementing drinking water programs and provides oversight in enforcing the standards. The EPA (2) has granted primacy to all states but Wyoming. None of the tribal governments has yet been granted primacy. The EPA has primary enforcement authority in states without primacy. States must adopt newly promulgated EPA regulations to maintain primacy status.

PWS are required to collect and analyze water samples at designated intervals and locations. Water samples must be analyzed in approved laboratories and the results reported to the state, which determines compliance. The three main types of violations (2) are

- MCL violation: occurs when contaminant level in treated water exceeds the MCL.
- TT violation: occurs when a PWS fails to treat water as prescribed by the EPA.
- Monitoring and reporting violation: occurs when a PWS either fails to test its water for certain contaminants or fails to report test results in a timely fashion.

An MCL or TT violation indicates a potential health risk. The EPA (2) estimated that in 1994, 89% of the population was served by CWS with neither MCL nor TT violations. The EPA plans to achieve a 95% level by 2005 (2). PWS in violation must notify the public. The EPA maintains a Federal database of violations known as Safe Drinking Water Information (SDWIS) [http://www.epa.gov/enviro/html/water.html#SDWIS].

The EPA, some water-related national associations, and more than 200 surface water utilities throughout the United States established a voluntary cooperative effort known as the Partnership for Safe Water [http://www.awwa.org/partner/partner2.htm?]. Utility members of the Partnership implement preventive programs to increase safety where legislation or regulation does not exist. The preventive measures are based around optimizing treatment plant performance and thus increasing protection against microbial contamination in the drinking water supply. PWS must provide their customers with "Consumer Confidence Reports" (CCR) CONSUMER CONFIDENCE REPORTS.

FUTURE TREND

In the 1980s and 1990s, the EPA set DWQS using the "Risk Assessment/Risk Management" (RA/RM) paradigm based on targeted mandates that prioritize and manage environmental risks, pollutant by pollutant and medium by medium. The proposed radon rule allowed the EPA to address health risk reduction within a multimedia framework. The EPA Science Advisory Board (14) proposed a conceptual framework for integrated environmental decision-making to "guide the Agency in the continuing evolution of environmental decision-making."

VALVES

Zacharia Michael Lahlou
Technical Assistance
Consultant

Valves direct, start, stop, mix, or regulate the flow, pressure, or temperature of a fluid. Valves range from simple water faucets to control valves equipped with microprocessors. Many different valve types exist; however, the most common types include gate, plug, ball, butterfly, check, pressure relief, and globe valves.

WHAT ARE THE VALVE FUNCTIONS?

Valve functions vary based on the position of the closure element in the valve. The closure position can be adjusted manually or automatically. Valves usually fall into one of three classes:

1. shut-off valves block the flow or allow it to pass;
2. anti-reversal valves allow flow to travel in one direction; and
3. throttling valves regulate flow at a point between fully open to fully closed.

However, specific valve-body designs may fit into one, two, or all three classifications.

WHAT ARE THE BASIC VALVES?

Manual Valves (See Figure 1)

Manual valves require manual operation, such as a hand wheel or lever, which are primarily used to stop and start flow (shut-off valves), although some designs can be used for basic throttling. A manual valve operator is any device that requires the presence of a human being to operate the valve, as well as to determine the proper action (open, closed, or a throttling position). Manual valves are also used to divert or combine flow through a three- or four-way design configuration. Four types of manual valves exist:

1. rotating valves, such as plug, ball, and butterfly valves;
2. stopper valves, such as globe and piston valves;
3. sliding valves, such as gate and piston valves; and
4. flexible valves, such as pinch and diaphragm valves.

Check Valves (See Figure 2)

Check valves are automatic valves that open with forward flow and close against reverse flow. Check valves, also known as non-return valves, prevent return or reverse flow and maintain pressure. Check valves do not require an outside power supply or a signal to operate. In fact, a check valve's operation depends upon the direction in which the water is flowing. A pump or a pressure drop may determine water flow. If the flow stops or if pressure conditions change so that flow begins to move backward, the check valve's closure element moves with the reverse

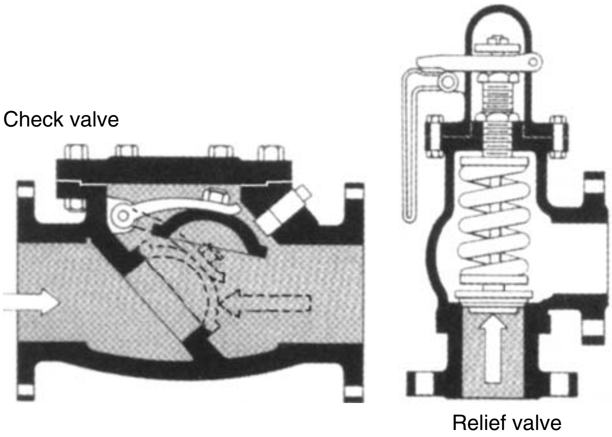

Figure 2. Check valves.

flow until it is seated, preventing any backward flow. There are different types of check valves, but they all have the same operating principle. Check valves include lift-check valves, swing-check valves, tilting-disk valves, split-disk valves, and diaphragm-check valves.

Pressure Relief Valves

A pressure-relief valve is used to protect against overpressurization of the system. When excess line pressure is detected, the pressure-relief valve automatically opens and relieves the excess pressure. A pressure-relief valve is installed where excess pressure constitutes safety concerns, such as pipes or equipment bursting. Following the depressurization of the water line to safe or normal limits, the pressure-relief valve automatically closes again to allow for normal system operation.

Control Valves (See Figure 3)

Control valves, also known as automatic control valves, are used to regulate flow anywhere from fully open to fully closed. Control valves are a fast growing segment of the valve industry because of the quickening pace of water-industry automation. Control valves are almost always equipped with some sort of actuator or actuation system (See definition under Manual Operators and Actuators below.) Manually operated valves and pressure regulators can stand alone in a throttling application, while a control valve cannot. Hence the difference: a control valve is a throttling valve, but not all throttling valves are control valves.

MANUAL OPERATORS AND ACTUATORS

With most valves, some mechanical device or external system must be devised to open or close the valve or to change the position of the valve. Manual operators, actuators, and actuation systems are those mechanisms that are installed on valves to allow this action to take place. Automatic valve control requires an actuator, which is defined as any device mounted on a valve that, in a response to a signal, automatically moves the valve to the required position using an outside power source.

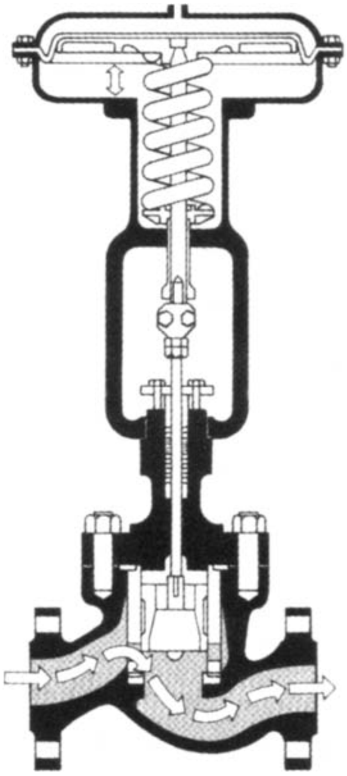

Figure 3. Control valves.

WHAT ARE COMMON VALVE PROBLEMS?

Pressure drop or pressure differential, which is the difference between the upstream and downstream pressures, makes water flow move through a valve. If the piping size is identical both upstream and downstream from the valve and the velocity is consistent, the valve will use frictional losses to reduce the fluid pressure and create flow. Because the pressure drop that a valve generates absorbs energy through frictional losses, an ideal pressure drop allows the full flow to pass through the valve's body without excessive velocity, absorbing less energy.

However, some systems may need to take a larger pressure drop through the valve. A high-pressure drop through a valve creates a number of problems, such as cavitation, flashing, choked flow, high noise levels, and vibration. Such problems present a number of immediate consequences: erosion or cavitation damage to the body and trim, malfunction or poor performance of the valve itself, attached instruments will not remain calibrated, piping fatigue, or hearing damage to nearby workers. In these instances, valves in high-pressure-drop applications require expensive trims, more frequent maintenance, large spare-part inventories, and piping supports. Such measures drive up maintenance and engineering costs.

Although users typically concentrate on the immediate consequences of high-pressure drops, the greatest threat a high-pressure drop presents is lost system efficiency. Usually, a pump adds pressure and, thus, energy to the system. As the system absorbs more energy, including the energy that valves with high-pressure drops lose, it must use larger pumps. Consequently, if the system is designed with few valves with high-pressure drops, the system is more efficient and able to use smaller pumps.

Cavitation

Cavitation happens when low-pressure bubbles suddenly form and then collapse within a small area of the valve within microseconds. Minor cavitation damage may be considered normal for some applications, which can be dealt with during routine maintenance. If unnoticed or unattended, severe cavitation damage can limit the life expectancy of the valve. It can also create excessive leakage, distort flow characteristics, or cause the eventual failure of the valve body and piping. In some severe high-pressure drop applications, cavitation can destroy valve parts within minutes.

One of three basic actions can control or eliminate cavitation. Operators can:

- modify the system;
- make certain internal body parts out of hard or hardened materials; or
- install special devices in the valve that are designed to keep cavitation away from valve surfaces or prevent the formation of the cavitation itself.

Flashing

When the downstream pressure is equal to or less than the vapor pressure, the vapor bubbles generated stay intact and do not collapse. This phenomenon is known as flashing. When flashing occurs, the fluid downstream is a mixture of vapor and liquid moving at a very high velocity, which results in erosion in the valve and in the downstream piping.

Unfortunately, eliminating flashing completely involves modifying the system itself, in particular the downstream pressure or the vapor pressure. However, not all systems are easily modified and this may not be an option. When flashing occurs, no solution can be designed into the valve, except possibly using hardened trim materials.

Choked Flow

The presence of vapor bubbles that cavitation or flashing cause significantly increase the specific volume of the fluid. This increase rises at a faster rate than the increase that the pressure differential generates. If upstream pressure remains constant, decreasing the downstream pressure will not increase the flow rate. Choked flow must be considered when sizing a valve.

HIGH VELOCITIES

Large pressure differentials create high velocities through a valve and in downstream piping. This in return creates turbulence and vibration if the velocities are not lowered. Lower velocities will reduce problems associated with flashing and erosion.

WATER HAMMER EFFECTS

A valve that is opened too quickly or slammed shut when the closure element is suddenly sucked into the seat (“bathtub stopper effect”) as the valve nears shutoff may cause water-hammer effect. Although water hammer generates considerable noise, the real damage occurs through mechanical failure. Water hammer can burst or damage piping supports and connections. In valves, water hammer can create severe shock through trim, gasket, or packing failure.

With valves, the best defense against water hammer is to prevent any sudden pressure changes to the system. For example, one solution may involve slowing the closure of the valve itself. Adding some type of surge protection to the piping system can also reduce water hammer.

WHAT ARE THE OPERATION AND MAINTENANCE REQUIREMENTS?

To avoid mechanical failure, design a practical valve maintenance program, which can result in cost savings for the water system. A job that appears to be mammoth becomes less daunting if the operator implements a systematic maintenance schedule. Operation and maintenance procedures for various types of valves are included in the manufacturer’s operation manuals and in the appropriate product standards. Valve records are essential for planning, operating, and verifying the system’s integrity. The valve record should contain information about valve condition, testing, and maintenance required.

WHAT ABOUT SAFETY/TERRORISM?

Recent events have understandably heightened concern that water supplies may be vulnerable to terrorist attacks—biological, chemical, and structural. Relief from this concern can come via knowledge, planning, and preparedness. It is crucial now to regularly inspect the location, accessibility, and operation of all the valves in the distribution system. This inspection will reveal the condition of the valve box and chamber.

It also is imperative to update the location of the valves on the map. E. H. Wachs Companies for example, offer “Valvecard” software that allows water utilities to manage their valve distribution system from a desktop computer. The software can be used to create valve inventory databases that require a secure user-friendly system to input, store, and analyze valve data or to collect valve information directly from each valve in a system. The software also can be used to operate and exercise valves in the system and record this information or monitor the system and keep it operational at all times. It can perform queries regarding valve properties, location, activities, and conditions as well as interface with Geographic Information Systems and map files.

After having complete and accurate information about all the valves in the system, the utility manager can run through a large number of “what if” scenarios to determine where a contaminant is likely to move and how valves or other utility operations can control its movement. To do this, the utility needs a calibrated, extendedperiod simulation model. There are a few types of software on the market for water distribution modeling and engineering that allow system managers to view scenarios graphically. Some of this software, such as WaterCad by Haestad Methods, can give a clear picture of what is occurring or will occur in the system in response to any operational measures that management proposes.

U.S. Environmental Protection Agency and the American Water Works Association in collaboration with Sandia National Laboratories continue to develop a risk- and consequence-based vulnerability assessment technique to improve the safety and security of water supply and distribution systems against emerging physical, chemical, and biological threats.

HAVE YOU READ ALL OUR TECH BRIEFS?

Tech Briefs, drinking water treatment and supply fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) publication *On Tap* for more than six years.

A package of *Tech Briefs* is now available as a product. A three-ring binder holds all the current *Tech Briefs* in print. New selections can easily be added to the package as they become available. To order this product, call the NDWC at the numbers listed at the bottom of this ad and ask for item #DWPKPE71. **The item is free.**

Additional copies of the *Tech Brief* fact sheets are also free; however, postal charges maybe added.

REMOVAL OF PATHOGENIC BACTERIA, VIRUSES, AND PROTOZOA

Kwok-Keung Au
Greeley and Hansen LLC
Chicago, Illinois

INTRODUCTION

Pathogenic bacteria, viruses, and protozoa can be removed from potable water by various processes. These removal processes can be categorized into three groups: (1) *initial*, (2) *principal*, and (3) *alternative/supplemental*. *Initial removal processes* are used to remove microbial pathogens before they enter or as they enter a treatment plant. The main objective of these processes is to reduce the particulate loadings, including microbial loadings, to the subsequent treatment processes of a treatment plant. Examples of initial removal processes are roughing filters, microstrainers, off-stream storage, bank filtration, and presedimentation with coagulation. *Principal removal processes* are those most frequently used to remove the majority of the microbes in the water being treated. These processes are sedimentation, flotation, and high-rate granular media filtration. They are often used in conjunction with coagulation and flocculation. *Alternative/supplemental removal processes* are used either as (1) alternatives to principal removal processes or (2) supplemental processes to enhance drinking water quality. These processes include slow sand filtration, precoat filtration, membrane filtration, bag filtration, and cartridge filtration.

The performance of removal processes is often quantified in terms of the log removal of pathogens, which is defined as log C_0/C, where C_0 and C are the pathogen concentrations in the water entering and leaving a process, respectively. A 1-log removal is equivalent to 90% removal, and a 2-log removal is equivalent to 99% removal. Drinking water regulations in the United States typically target log removals of pathogens. However, the performance of a removal process can also be quantified by the turbidity level in the outlet flow of the process or the removal of turbidity by the process. Turbidity is a measure of water clarity. A low turbidity level in the water leaving a treatment process is considered an indication that the process effectively removes pathogens.

INITIAL REMOVAL PROCESSES

Roughing Filters

Roughing filters are coarse granular media filters used to remove large particles from high turbidity waters prior to downstream processes. Although the term filter is used, roughing filters act more as a series of sedimentation boxes filled with media of decreasing size in the direction of flow. The media effectively reduce the settling distance of particles to the order of a few millimeters. The direction of flow through a roughing filter can be either horizontal or vertical. Typical roughing filter media are gravel, rock, crushed coconut, or other locally available materials.

According to a pilot study (1), a roughing filter can achieve average log removals of 0.28 for total bacteria and 0.20 for algal cells. It was also found that the removal of clay particles is improved when the filter has been ripened with algae. Another pilot study indicates a log removal of 0.64 to 0.96 for fecal coliforms, depending on filtration rate (2).

Roughing filters are often used in developing countries to serve as an initial process for slow sand filtration. Important design parameters for roughing filters are hydraulic filtration rate, filter depth (for vertical filters) or length (for horizontal filters), and media size. A review of design variables for roughing filters is available (2).

Microstrainers

Microstrainers are filtration units that use a thin medium, usually fabrics woven of stainless steel or polyester wires. The mesh sizes of microstrainer fabrics are less than 100 μm and typically from 15 to 45 μm. Microstrainers can be used to remove fine suspended particles and algal cells from surface waters. They are very effective for certain types of green algae, diatoms, and cyanophyta. A major application of microstrainers in potable water treatment is as an initial removal process for downstream membrane processes. They reduce particle loading to the membrane processes and also protect the membranes from debris.

The removal efficiencies of algae by microstrainers can vary from 0.22 to 0.52 logs, depending on the type of algae present (3). Large protozoa such as *Balantidium coli* cysts (whose diameter is about 60 μm) can also be removed by microstrainers. However, due to their small size, the removal of bacteria and viruses by microstrainers is usually insignificant.

Off-Stream Storage

Off-stream storage refers to reservoirs or basins whose locations in the treatment flow path are between the raw water source and treatment processes of a water treatment plant. Off-stream storage can improve microbial water quality through a combination of mechanisms. The major mechanisms are settling and die-off of pathogens and equalization of water quality spikes. The critical factors for the performance of off-stream storage are the storage's hydraulic residence time, flow patterns within the storage, and water temperature. Control of algal growth within the storage is important because algae can cause taste and odor problems in water. It is also very critical to avoid fecal contamination from animals and runoff from surrounding areas. Otherwise, the storage may actually deteriorate the quality of the water leaving it.

Settling is the primary mechanism by which pathogens are removed by off-stream storage. The longer the hydraulic residence time of off-site storage, the greater the amount of settling that takes place in it. The removal of coliform bacteria in off-stream reservoirs with hydraulic residence times greater than 40 days is from 0.7 to 2 logs (4). A 1.5 log reduction of enteroviruses was reported for an off-stream reservoir with a hydraulic residence time of about 100 days (5). In two studies, reductions of 1.4 to 2.0 logs for *Cryptosporidium*, 2.3 to 2.6 logs for *Giardia*, 2.2 logs for *Escherichia coli*, and 1.7 logs for fecal streptococci were found for storage reservoirs with residence times of 24 weeks or greater (6),(7). These results indicate that, for settling to be an effective method of removing microbes in off-stream storage, a long residence time and, therefore, a large land area are required.

Although not a removal process, the die-off of pathogens within off-site storage can improve microbial water quality. The die-off of pathogens is a kinetic process and may be considered a first-order reaction (8). Based on bench scale studies, the die-off rate constants found for *Cryptosporidium* are 0.01/day at 5 °C and 0.024/day at 15 °C (9). These are equivalent to a 0.5 log reduction in 50 days at 5 °C and in 21 days at 15 °C, indicating the significance of temperature in the die-off process.

Off-stream storage can also reduce the peak values of pathogen concentration spikes through the management of the source water pumping schedule. The peak levels of microbial contaminants are often associated with the turbidity spikes that follow rainfalls. By not using source water from the watercourse during these peaks and using the stored water instead, pathogen spikes of microbial contaminants can be avoided.

Bank Filtration

Bank filtration is a process by which surface water from a watercourse infiltrates into a groundwater aquifer and is later brought to ground level by well pumps. As the water passes through the ground, the aquifer acts as a natural filter and reduces the concentration of viable pathogens by two major mechanisms: deposition of the pathogens on porous aquifer materials and die-off of pathogens due to the long residence time within the aquifer. This process is also termed riverbank infiltration. It has been widely used as a water treatment process in European countries and, in the past few years, has received increased interest in the United States.

In a full-scale bank filtration study, no *Giardia* or *Cryptosporidium* were detected in wells, even though they were frequently detected in river water, and total coliform bacteria were never detected in wells (10). In a study of three different infiltration sites, the removals of bacteriophage were 3.1 logs and 4.0 logs when water passed through 2 m and 4 m of very fine dune sand, respectively (11).

Bank filtration can be highly effective in removing microbial pathogens. Aquifers suitable for bank filtration are composed of unconsolidated, granular, fine-grained materials and have open, interconnected pores that allow groundwater to flow (12). Other important factors affecting the treatment efficiency of bank filtration are the time of travel from the watercourse to the well (thus, the residence time of the water in the aquifer), the quality of the source surface water (e.g., turbidity), and the water temperature. USEPA proposes a treatment credit for *Cryptosporidium* of either 0.5 or 1.0 logs for bank filtration systems that meet some specific criteria. These criteria include aquifer compositions, distance from the pumping wells to surface water, and turbidity level in the well effluent (12).

Presedimentation with Coagulation

Presedimentation is used to remove gravel, sand, and other relatively large suspended materials from source water prior to principal treatment processes. It is often used for source waters that have highly variable raw water quality to reduce occasionally high solid loadings on the principal treatment processes. Microbial pathogens can be removed by this process if they are attached to or trapped inside larger particles. Adding coagulants can enhance the removal of pathogens by presedimentation.

According to a full-scale study of four presedimentation basins using surface loading rates of from 0.3 to 1.6 gpm/ft^2 and polymer and ferric sulfate as coagulants, the removal of *Bacillus subtilis* averaged 1.1 logs (12). The results of a full-scale study of inclined-plate presedimentation basins using a surface loading rate of 0.52 gpm/ft^2 and alum and polymer as coagulants indicated that the median removal of total aerobic spores and *Giardia* were 0.5 logs and 1.5 logs, respectively (12).

PRINCIPAL REMOVAL PROCESSES

Sedimentation

Sedimentation is a solid–liquid separation process that removes particles and pathogens from water by providing conditions that will cause them to settle under the force of gravity. The hydraulic loading per unit of surface area, hydraulic detention time, inlet/outlet conditions, and internal flow patterns are considered important design parameters for sedimentation basins, but the most important factor in removing microbial pathogens from sedimentation basins is the use of coagulation and flocculation processes upstream of the basins.

Due to their small size and low mass density, individual microbes have a very low settling velocity. In the absence of proper coagulation and flocculation, sedimentation does not achieve significant removals of microbial pathogens. Coagulation involves adding coagulants that either have or can form positively electrically charged species to neutralize negatively charged microbial particles. Because microbial particles are of like electrical charges, they repel each other. Neutralizing these charges facilitates contact between particles. When two or more particles come in contact, they form larger particles that settle more readily. The coagulant can also form precipitates or floc particles that attach to the naturally occurring particles in the water and form larger, heavier agglomerates. The flocculation process establishes conditions that increase the number of opportunities for particles and agglomerates to contact one another and result in large particles that have sufficient settling velocities to be removed in the sedimentation basins that follow.

To achieve good removal of pathogens by sedimentation, the type and dose of coagulant and the coagulation chemistry must be optimized. Also important in coagulation are rapid, thorough mixing, and gentle, relatively slow mixing and sufficient contact time in the flocculation process.

Based on pilot studies, it was reported that sedimentation achieved an average removal of 0.2 logs for *Cryptosporidium* under suboptimal coagulation conditions and the removal increased to 1.3 logs under optimal coagulation conditions (13). This indicates the importance of coagulation, as mentioned above.

Based on full-scale observations at treatment plants in various countries, sedimentation preceded by coagulation and flocculation achieved average removals of 0.14 to 0.59 logs for viruses, 0.17 to 0.89 logs for bacteria (total coliforms or fecal streptococci), and 0 to 1.22 logs for algae (14).

Flotation

Unlike sedimentation which removes materials whose mass densities are greater than that of water, flotation removes materials whose mass densities are less than that of water. In potable water treatment, the flotation of materials is induced and is termed dissolved air flotation (DAF). In DAF, dissolved air is injected into the process stream under high pressure. Then, the process stream is exposed to atmosphere pressure, and the dissolved air forms air bubbles. The bubbles form around and attach to particles in the process stream. This causes particle/air bubble agglomerates to have a mass density that is less than that of water and, thus, to float to the surface of the liquid where they are skimmed off. DAF is most applicable to waters with heavy algal blooms or waters with low turbidity, low alkalinity, and high color. These waters are difficult to treat using sedimentation because the coagulant floc particles produced typically have a low settling velocity.

The performance of DAF for *Cryptosporidium* oocyst removal depended on the pH, coagulant dose, flocculation time, and the ratio of the air-saturated water stream to process stream. According to several full-scale studies, DAF removes 1.4 to 2.0 logs of the algae *Aphanizomenon* and *Microcystis* (3). Study also shows that DAF achieved between 2 and 2.6 logs removal of *Cryptosporidium* oocysts, whereas conventional sedimentation resulted only in 0.6 to 0.8 log removals (15). Based on bench-scale testing, it was reported that DAF averaged 0.5 logs higher removal of *Cryptosporidium* than sedimentation (16).

High Rate Granular Filtration

High-rate granular filtration is the most widely used potable water treatment process for removing pathogens. This process is described separately in GRANULAR BED AND PRECOAT FILTRATION.

ALTERNATIVE/SUPPLEMENTAL REMOVAL PROCESSES

Slow Sand Filtration

Slow sand filtration is described separately in GRANULAR BED AND PRECOAT FILTRATION.

Precoat Filtration

Precoat filtration is described separately in GRANULAR BED AND PRECOAT FILTRATION.

Membrane Filtration

Membrane filtration is a separation process in which a thin, semipermeable membrane is used to remove contaminants from water. A differential hydraulic pressure across the membrane causes the water to pass through it. This differential pressure can be created by applying a higher pressure on one side of the membrane than the other and pushing the water through the membrane or by applying a negative pressure on one side and pulling the water through.

The most commonly used membrane processes in drinking water treatment are microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO). They differ from each other by their pore sizes. MF membranes have the largest pore size (of the order of 0.1 μm), followed by UF membranes (of the order of 0.01 μm) and NF membranes (of the order of 0.001 μm). RO membranes have the smallest pore size of the order of 0.0001 μm.

The pore size of the membrane is the key factor in determining which contaminants are removed by the membrane. Contaminants large than the membrane's pore size are retained and removed by the membrane. The pore size of the membrane also affects the operating hydraulic of the membrane process. Membranes that have smaller pore sizes require higher differential hydraulic pressures. The operating pressure of MF and UF is similar and from 30 to 50 kPa. It increases to 500 to 1000 kPa for NF and to 1000 to 5000 kPa for RO.

The sizes of protozoa and most bacteria are of the order of a micron or larger and can therefore be removed very effectively by MF. Removal of bacteria may sometimes be poor, if bacteria grow in the membrane system. Viruses have sizes from 0.01 to 0.1 μm and are likely to pass through MF membranes, unless coagulation pretreatment is provided. According to a pilot study using three MF membranes with pore sizes from 0.08 to 0.22 μm, log removals of greater than 4.6 to greater than 7.0 for *Giardia* and greater than 4.2 to greater than 6.9 for *Cryptosporidium* were achieved (17). Removals of MS2 bacteriophage were, however, less than 1 log. This was expected due to the small size of MS2, which is 0.025 μm. In a pilot study using MF with coagulation pretreatment, virus removals were more than 7 logs, even though the tested virus has a size of 23 nm and the membrane pore size is 100 nm (0.1 μm) (18).

In addition to bacteria and protozoa, UF can remove some viruses. In a study using UF membranes with pore sizes of 0.01 to 0.05 μm, neither *Giardia* nor *Cryptosporidium* were detected in the filtered water (17). The log removals were greater than 4.7 to greater than 7.0 for *Giardia* and greater than 4.4 to greater than 7.0 for *Cryptosporidium*. The membrane having the smallest pore size achieved MS2 bacteriophage removals of 6 logs and greater.

Because of their high costs, NF and RO are seldom used to remove microbial pathogens alone. NF is primarily used for softening because it can remove divalent, hardness-causing cations such as Ca^{++} and Mg^{++} and for removals of disinfection by-product precursors (dissolved organic carbon compounds). RO is primarily used for desalination because it can remove monovalent, salinity-causing ions such as Na^{+} and Cl^{-}. However, the ability of NF and RO to remove pathogens enhances their cost-effectiveness when they are used for these other treatment objectives.

During a bench-scale study using five different RO membranes, virus reductions of 2.7 logs to greater than 6.5 logs were achieved (19). A pilot study was conducted to investigate the efficiency of sequential membrane systems, using two different NF membranes with two different MF membranes as pretreatment (20). The removal of *Bacillus subtilis* endospores, a surrogate for *Cryptosporidium* oocysts and *Giardia* systs, varied from 8.0 to 11.0 logs.

Detailed descriptions of their design and operation are available in the literature (21). Maintenance of membrane integrity was very critical to process efficiency. The loss of membrane integrity (e.g., fiber breakage) certainly permits passage of pathogens into finished water.

Bag Filters and Cartridge Filters

A differential pressure is used to push the water through both bag filters and cartridge filters. Bag filters use nonrigid, fabric filter media bags housed in a pressure vessel. Water flows from inside the bags to outside the bags. Cartridge filters are quite the opposite. They use a rigid or semirigid, fabric filter media housed in a pressure vessel, and water flows from outside the cartridges to the inside of the cartridges.

These types of filters are often used for small systems and for point-of-use filtration applications. They can also be applied as an additional filtration process following the principle filtration processes such as high-rate granular filtration to improve water quality. High turbidity and algae cells can easily clog bag and cartridge filters, so they are appropriate only for high quality water. Addition of disinfectant prior to the filters should also be considered to minimize biofilm growth within filter media.

The typical pore size range for bag and cartridge filters is from 0.2 to about 10 μm. This is usually small enough to remove protozoa such as *Cryptosporidium* oocysts and *Giardia* cysts. Submicron-sized microbes, such as viruses and most bacteria, can pass through these filters. As water passes through a bag or cartridge filter, particles accumulated within the filter material increase the hydraulic pressure drop through the filter. When this pressure drop increases to a level that it is impractical for further operation, the bag or cartridge is replaced with a clean one.

Microbial removal by bag and cartridge filters can vary significantly. A range of 0.5 to 3.6 logs *Cryptosporidium* removal has been reported for bag and cartridge filters (12). Interestingly, there was not a correlation between nominal pore size and removal because the nominal pore size of a bag or cartridge filter medium, as reported by the manufacturer, represents only an average size. A pore size distribution exists, which means that some pores are of sizes greater than the nominal size and the pore size distribution values vary from one filter medium to another.

Mexican Institute of Water
Technology
Cuernavaca, Morelos, Mexico

HISTORY OF WATER METERS

A water meter is a device for measuring and registering the amount of water that passes through a pipe or other outlet, usually for billing purposes. Water meters have various synonyms, used in different cities, countries, or circumstances. Some of these equivalent terms are volume counter, flow-gauging device, water totalizator, flowmeter, and accumulator.

The physical device used to measure the water consumed in a house or industry, or the water extracted from a well or similar supply source, is relatively simple compared to other quotidian instruments. It gauges and adds up the water volumes as they flow in the intake pipe (flow rate is the volume during a certain time span).

In cities when consumers must pay their water bills according to the volumes used, meters must be massively installed, so the logistics to assure their timely reading, quality, precision, repair, replacement, and several other aspects require thorough technical assessment and planning. Many cities of the world depend on them nowadays, although they are relatively modern (no more than 150 years) and are having a rapid evolution. Let us review a little of this evolution.

Humans have always liked to count and measure things ("Man is the measure of all things," Protagoras). Our troglodyte father counted his trophies, wives, possessions, or days passed with his fingers. Later, some other measuring units and quantifying devices were invented, although counting a shapeless and moving liquid was not so easy for some centuries.

Some indirect and ancient ancestors of our modern water meters were the water clocks or "clepsydra" (from Greek "water thieves") used since about 325 B.C., which were stone vessels with sloping sides that allowed water to drip at a nearly constant rate from a small hole near the bottom. Afterward, more sophisticated and artistic water clocks were used (as the huge Su-Sung water clock from China). These in a sense had the inverse purpose of water meters nowadays: first, it was measuring time from a known volume of water; now we want to measure a variable flow of liquid during a known span of time.

Flow, or water volume, must always be referred to a time unit and we must express it as liters per minute, m^3 per month, cubic kilometers per year, etc.

Time is measured with a calendar and/or a wristwatch. Volume can be counted (or estimated by calculus and assumptions) in many ways. One method is using a bucket or container of known dimensions; another procedure is measuring its velocity of travel in a pipe of known cross section (flow = velocity × area).

Most modern water-meters act on the principle of counting the number of turns made by a small reaction turbine moved by the water as it flows through it. This is the basis of Sir William Siemens' invention, who patented his water meter ('fluid meter') in April 1852 (1). Until that time, water metering was not possible; several attempts had been made to devise a suitable device, but all had failed. W. Siemens also invented meters for other applications (bathometer for the depth of the sea, electric pyrometer, etc.).

Ironically, England, where meters were invented, remains until now one of the few countries where almost no houses have water meters installed. This gives an idea of the complexity and expense of installing and reading them, particularly when they are not really indispensable (the United Kingdom has a relatively good quantity of rain and water to waste, but it is not the same in other countries).

Nowadays, water meters, instead of mechanical transmission of movements and signals (as in old clock gearing), send magnetic, electric, or digital pulses which can be stored (remote dial counter or display, data-logger, etc.).

Besides volume, there are multiple water parameters requiring measurement or pondering, for instance, temperature, color, chlorine or salt content, velocity, pressure, and environmental value. Each feature is useful for a given purpose. In leak detection, or billing consumption, and general management of a water utility, water volumes (referred to specific time spans) are key topics.

WATER SUPPLY MANAGEMENT AND CHARGING PRACTICES

Urban utilities use and need water meters as tools for the proper management of a valuable resource, which is water. Numerous water meter types exist that differ in design, material, size, precision, operating principle, reading display, purpose, and site where installed (Fig. 1 shows a brief sample of them). Before entering in any technical detail about how meters work, it is important to review why meters are required. This will give insight into the convenient meter type for a given task.

Water meters can be used either to measure the volumes supplied by the utility through different sources and aqueducts (macrometering), or to know the volumes consumed by clients (micrometering). There usually are differences among the volumes supplied and those consumed. Logically in this comparison, supply should be greater than real consumption, and their difference represents water losses, which must be studied to keep them within reasonable limits.

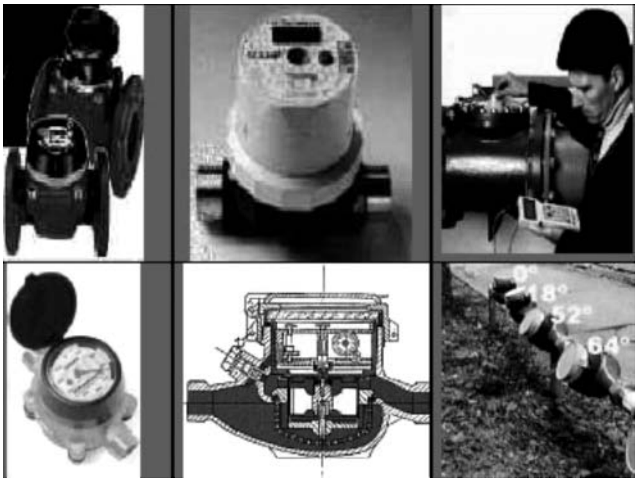

Figure 1. A variety of meters, installation and reading styles.

Metering is an important element to attain *water conservation* (*efficient water use*) in places where water availability is below potential demand. In fast growing cities with limited water resources, household water metering is primarily seen as an approach to control consumption (demand management). It avoids unrestricted use, so water supply and water demand can be balanced. Metering also leads the water undertaker into efficient use of other resources (money, energy, infrastructure, etc.) and good service. In some cases, "nonmetering" options can attain equivalent conservation results, but they must be evaluated carefully before any decision is made.

To be effective, water metering must be linked to appropriate tariffs and prices, together with ways to enforce them, for example, applying surcharges to consumers using more water than the average citizen or cancelling service to people who do not pay their water bills. This is particularly true when water conservation is a prime goal. The role of tariffs is to give a fair chance to everyone to use a reasonable quantity of water and to recover the operating and investment costs of the service. Tariff fixing is quite difficult and subjective when social fairness to consumers, historical privileges, and provisions for the future are involved.

Figure 2 illustrates different rate structure styles in a sample of 827 U.S. water utilities during 1996 (2). The most convenient style for conservation purposes is the "*increasing block rate*," where the price per each cubic meter is higher as total volume consumed grows.

REASONS AND PRIORITIES FOR HOUSEHOLD METERING

Water metering may have different approaches and purposes. Its most frequent bases are either slowing the growth of water demands via volumetric charges to consumers or improving the water utility's revenue through a fair pricing system. There may be other objectives, and any metering project obeys a combination of several of them.

Metering is not an exclusive way to obtain appropriate financial resources; other ways to get payments from consumers can be set up. Nevertheless, for *"consumptive" or "Western" mentalities*, billing water consumed through metering is a clear and fair charging system. The drawbacks are that meter installation, upkeep, and reading demand good organization and represent significant costs, particularly when massive radical changes are required in existing practices. It is relatively cheap when metering is done systematically in all new constructions and regular improvements in equipment and procedures take place.

The reasons and priorities to improve or adopt household metering may vary with place and time. For example in poor arid countries with fast growing urban populations, the priorities, in decreasing importance, may be:

1. Water conservation. Compel people to consume less water through volumetric charges. The water saved may allow extending the system, improving service standards, or protecting the environment.
2. Cost recovery and financial soundness of the water company. Appropriate revenue for all expenses (water supply, sewerage, pluvial drainage, or other services) and provision for future investments.
3. Individual household equity. Avoid discriminatory practices associated with fixed rate tariffs, and charge according to volume used.
4. Unaccounted for water reduction (*clandestine connections and leakages*) through better information on consumption.
5. Peak demand abatement. Cut down nonindispensable uses, or even provide the possibility of seasonal or hourly tariffs.
6. Social equity. Favor poor consumers, who use less water, with lower tariffs or through subsidies.
7. Better data about demand and variations to improve operation and planning of the water system.

Figure 3. Facets invovled in water meter planning.

Deciding the convenience of metering for a previously unmetered place, or upgrading it where it exists partially, requires careful evaluation of a broad spectrum of elements, ranging from local economy and politics to the family budget. It also involves family habits, health, institutional organization, and water service standards. Figure 3 represents the different elements that must be taken in account. Water metering planning requires a clear and careful bond of all technical, administrative, legal, and social aspects involved.

PRECISION TESTS FOR METERS

Various types of flow meters have mobile parts subject to wear, alteration, and clogging with debris or scaling (incrustation), so it is necessary to make periodic tests or replacements to assure their accuracy and proper performance. They could also have manufacturing defects or disarrangement during transport.

New and recently acquired meters usually are randomly tested at the utility's laboratory, on a testing bench, against the accepted standard (for example ISO 4064-1). Later, once installed, at intervals of some years, when

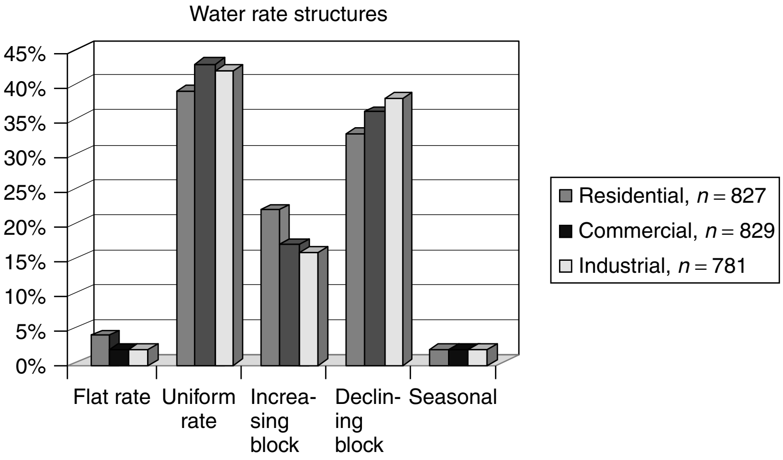

Figure 2. Water rate styles in various USA water utilities (year 1996).

a client complains about excessive charges, or there is a report of underregistration, the apparatus can be dismounted and taken to the lab to test its performance and to be repaired, although it is preferable to perform field tests (*in situ*, *without dismounting the house meter*) with a portable meter test kit. There is commercial equipment that provides everything needed to test domestic water meters accurately, contained in an easy-to-handle case. For more elaborate field assessment as in the case of intermittent service, where the main pipe could be empty, the utility may send a vehicle with all required elements for the test.

Water meters, like most gauging devices, even when new, are not always exact and reliable. Most meters do not perform well at very low flows, and at high flows, they also have errors. They have an appropriate working range where precision is high; out of it, errors increase exponentially. Meters of "*class D*" solve the underregistration presented by other types of meters when used in houses with frequently low inflow rates, for instance, those dwellings having a general storage tank with an admitting float ball-valve. These meters may be about 10% more expensive than "*class C*," but their impact on revenue (water sales) may be worth it. Even though they are more precise, they still cannot detect very low flows, for example, a leak through a dripping tap. Meters of "*class C*" are not precise for flows below 25 L/hour, and "*class D*" below 11 L/hour.

Meters by themselves, as any hydraulic fitting in a pipe, generate additional head losses and are obstacles that reduce the flow rate. It is important to know their potential effect because these losses may be reflected in additional pumping and energy costs for the undertaker in supplying appropriate pressure to some neighborhoods. Obviously meters that produce the lowest head losses are preferable. Figure 4 presents a typical precision graph and a head loss curve.

METER SELECTION AND SIZING

Many issues must be taken into account for the proper selection and sizing of a meter. The previous graph illustrates the need to select an apparatus yielding satisfactory precision without too much head loss. This evidently must be judged and compromised against purchasing and installation costs. Other factors to consider are house characteristics where meters will be installed; especial protection required against weather, vandalism, and tampering; or particular provisions for reading. When selecting a meter, it is necessary to assess the probable consumers demand (average flow, maximum flow), diameter and materials of the existing pipe, impact of water quality (corrosion, presence of sand or other suspended solids, scaling, dissolved air, temperature), effects of soil and environmental

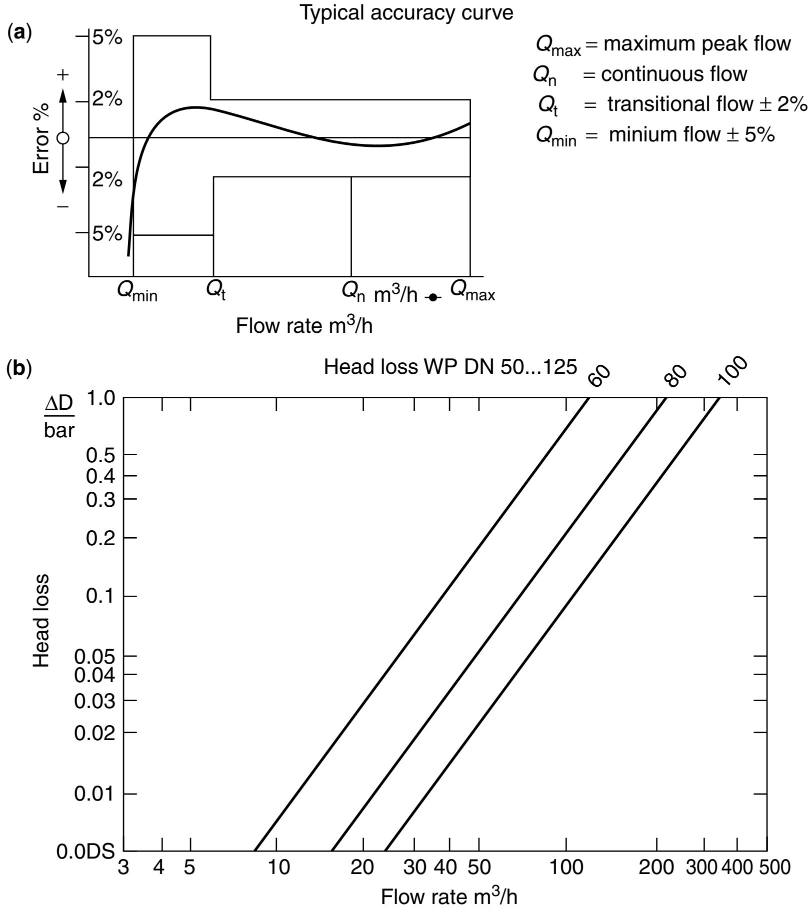

Figure 4. Examples of precision and pressure loss graphs for water meters.

aggression (temperatures, humidity, snow), tariff system and frequency for reading, inspection or replacement routines, risks of transport or from installation and bad practices (wrong position, inverted flow, tampering).

Still other issues affecting decisions are convenient stock for replacements (number of meters, models and their spare parts to be kept in reserve); available budget (acquisition, certification, storage, transport, installation, inspection, tests, visits, contracts and invoices to the consumer), financing sources, and legal and contractual adjustments (bylaws and codes to be modified or completed, inspections and enforcement required, renewal of contracts to customers).

Modern technology allows remote readings via radio, cable, or telephone, when the meter has the appropriate provisions for this, apart from the traditional direct display of its readings.

The installation of a macrometer (as for the study of a DMA, district-metering area) may require attaching some graphing or electronic recording device (data-logger) to it to monitor flow rates during different time spans.

In a consumer line with a rather big diameter, it is possible to save some money, sacrificing a little precision, by installing a “proportional meter.” This is placing a parallel detour (bypass) line with a smaller meter on it. Sometimes is possible to place “batteries of meters,” by means of parallel pipes with different meter diameters on each one.

Multirate meters and water charges through variable tariffs according to the time of day are quite feasible with modern electronics, although may be still expensive. Probably, in the next years, costs will drop and several cities will be using them (power companies in many parts of the world already use meters for electricity with such capability).

It is always important to select the appropriate meter in accord with consumer characteristics and their expected consumption patterns. The utility must have specific guidelines for different types of industries, commerce, service facilities, public offices housing, etc.

Meters can have a provision to restrict flow or pressure. Besides the billing effect of the meter in discouraging waste and high consumption, these adjustable restrictors associated with the counter, may lower peak demand during critical hours of the day. They can also reduce risks of leakage inside the house, or give equal chances to deliver fair and similar amounts of water to consumers in neighborhoods or streets too steep or long (with great differences in potential water pressure).

There can be approaches where nonpermanent installation of meters (random or temporary metering) or communal meters can be useful and economical. In old neighborhoods and in apartment buildings, the supply pipe is common to various dwellings, where installing individual meters, as well as periodic reading, may be extremely expensive and difficult.

TECHNICAL ASPECTS OF METERS

Flow meters work using basic physical and hydraulic principles of mass conservation or continuity, energy conservation (head losses due to flow and velocity energy converted to position energy), momentum, or inertia.

There is no space to describe the operating characteristics of the various measuring systems and instruments available and used nowadays. Figure 5 lists some of them (more details can be found in chapter 4 of Ref. 3).

Meters can be of various kinds, for example, volumetric, propeller, and remote sensing. All have different precision

Type of flow meter	Type of measurement
Venturi tube	Volumetric
Flow mazzle	Volumetric
Orifice plate	Volumetric
Magnetic	Velocity
Nutating disk	Volumetric
Oscillating piston	Volumetric
Bellows gas	Volumetric
Label impeller	Volumetric

Slide sense rotary Retracting vane rotary	Volumetric Volumetric
Helical gear	Volumetric
Turbine	Volumetric
Vortex shedding	Velocity
Vortex procession	Velocity

Type of flow meter	Type of measurement
Fluidic oscillating	Velocity
TOF ultrasonic	Velocity
Doppler ultrasonic Thermo-anemometer	Velocity Velocity (mass)
Calorimetric	Velocity (mass)
Corrolis mass	Mass flow
Relameter	Velocity

Figure 5. Physics operating principles of some meters.

and manufacturing standards, distinct installation and operating costs, and, of course, will render distinct benefits to the water company.

METERING DENSITIES, COSTS, AND IMPACTS

The following figures will give a rough idea of the costs, *per meter installed and working*, for the main concepts of a metering scheme: census, planning, and preliminary work \$2 US; device purchase \$30 US; installation \$15 US; operating costs (meter reading, billing, error correction, tests, etc.) as additional cost compared to fixed tariff system \$0.25 US/year, and meter reposition (in average every 15 years) \$38 US/15 years.

The most important impact of water counters is in reducing consumption, compared to a situation where meters do not exist. Several references report consumption reductions ranging from 5% to 54% when water price increases and there is a volumetric system. This is known as "*price elasticity of demand*". Figure 6 is an example, taken from a report by the World Bank, illustrating the consumption behavior (cubic meters per month per connection) in Brazilian utilities according to the percentage of meter coverage in each city (4). Reductions are on the water supply side and also on the volume of waste production and the required size of sewerage and treatment infrastructure.

"Universal metering" (all houses and industries in the city have a counter) is adequate only for rich cities, where the possibility of uncontrolled demand may occur randomly from any consumer. It is easy to finance when a meter is always installed in every new construction. Its cost can be recovered as part of the connection fee.

"Voluntary metering," "random metering," "selective metering," temporary metering, or neighborhood or hydrometric district control are ways to avoid expensive universal metering. These, if well planned, can lead to better budgetary results for the institution and to nearly the same water conservation results as universal metering.

Figure 6. Impact of metering coverage on water consumption.

METER READING AND INFORMATION PROCESSING

Medium to big cities have thousands of meters to be read and accounts to be monthly billed and followed. This represents a basic regular task, requiring managerial ability from the water utility. Its success depends on good quality and reliability of the information handled and perfect synchronization among different departments and people.

Here, any gain to save time or money during reading and billing is desirable, and this is why new techniques are being tested and adopted continuously. Some utilities use contact rods to enter digital readings directly into a computer, instead of traditional visual reading and writing. Others use, reading through radio reception on a van circulating through the city streets. Reading through modems (telephone) is practiced as well.

In cities where traditional meters still exist, one important engineering task is optimizing the reading routes to save distance and time. These routes should be frequently reviewed and enhanced according to new customer contracts and technical improvements in metering and reading.

MUNICIPAL WATERSHEDS

Timothy J. Downs
Clark University
Worcester, Massachusetts

INTRODUCTION

The Sustainable Development Summit in Rio de Janeiro in 1992 showed clearly that building and running more sustainable human settlements is one of the core challenges (1). Developed countries are characterized by having the majority of their population in urban settings, concentrations of relatively large numbers of people in a relatively small physical area. Transitional countries show a demographic shift from rural to urban settlement. In 2001, more than 54% of the world's 6 billion people lived in municipal centers (towns and cities); some countries have more than 90% (2). Developing and transitional countries often have megacities—Mexico City, Cairo, Sao Paulo, Jakarta, Bangkok—that completely dominate the watersheds they occupy. This form of municipal watershed lies at the least sustainable end of the scale because satisfying voracious demand is a priority, and water-producing zones of the watershed become either consumed by urban sprawl or cannot influence water policy.

In a humid environment, as a society moves from a preindustrial economy to an industrial economy, its watersheds experience three main stages of development (3): (1) few encroachments on water resources; more than enough water for everyone; water is free; (2) transitional infrastructure, including dams for energy and irrigation and interbasin transfers between water-rich and water-scarce watersheds; and (3) maximum streamflow regulation achieved, and aquifers are at maximum sustainable yield, so further development is both expensive and threatens to be unsustainable. Unfortunately, in the case of several megacity watersheds, a fourth stage of overexploitation by intensifying exploitive infrastructure and interbasin transfers is testing the functional viability of municipal watersheds.

TYPES OF MUNICIPAL WATERSHEDS

Megacities lie at one end of the municipal watershed scale (e.g., Mexico City); watersheds that have relatively equal-sized, similar economies and evenly distributed small towns form the other (e.g., Nashua River Watershed, Massachusetts, USA). In between, are watersheds that have a few large towns, a city or two, and several small towns; they have differing economies, needs, and priorities (Fig. 1).

As we move along the scale, the probability of achieving more integrated, sustainable watershed management declines primarily because of the rising conflicts of interest, increasingly significant cultural differences between municipalities, and growing pressure to overexploit natural resources that degrade the watershed ecosystem. In its most dramatic form, a megacity will also draw water resources from neighboring or external watersheds (e.g., Mexico City, Los Angeles), thereby becoming a regional 'sink' that has very significant ecological, sociopolitical, economic, and cultural impacts.

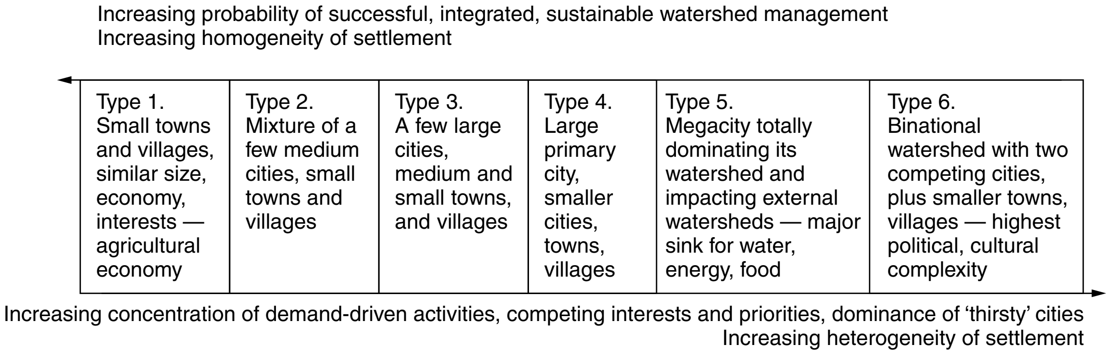
IMPACTS OF MUNICIPAL CENTERS ON WATERSHEDS

Water Quantity Impacts

Figure 2 shows a schematic of a typical municipal water cycle, which may also be considered to represent a composite of the water supply and wastewater sanitation infrastructure for all towns and cities of a municipal watershed. Humans perturb the stocks and flows of water in the watershed through withdrawals for water supply (4):

1. domestic (in-house and out-of-house);
2. industrial (e.g., factories, power stations), commercial (e.g., shops and hotels), and institutional (e.g., hospitals, schools);
3. agricultural (e.g., farms, crops, livestock);
4. public—for example, parks, fire fighting, sewer flushing;
5. Losses—distribution losses, consumer wastage, metering errors, and/or unrecorded consumption.

Domestic, industrial, and public demand tend to dominate municipal watersheds; agricultural demand dominates rural watersheds.



Type 1.	Type 2.	Type 3.	Type 4.	Type 5.	Type 6.
Small towns and villages, similar size, economy, interests — agricultural economy	Mixture of a few medium cities, small towns and villages	A few large cities, medium and small towns, and villages	Large primary city, smaller cities, towns, villages	Megacity totally dominating its watershed and impacting external watersheds — major sink for water, energy, food	Binational watershed with two competing cities, plus smaller towns, villages — highest political, cultural complexity

Figure 1. A simple typology of municipal watersheds.

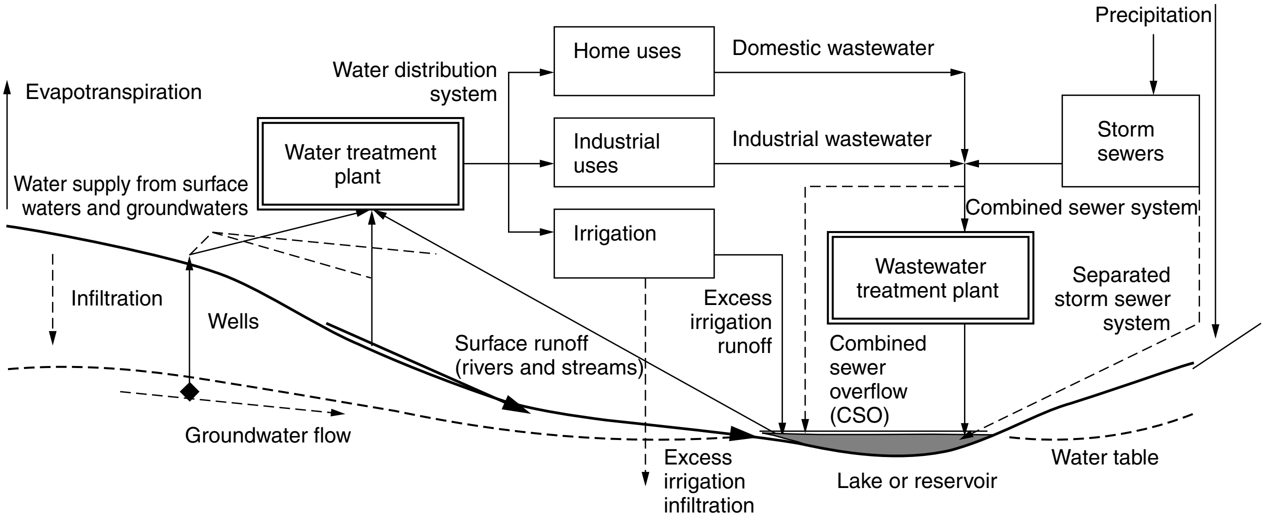


Figure 2. The water supply and wastewater sanitation cycle of a municipal center. The cycle also serves as a composite for the infrastructure serving a municipal watershed.

The estimation of water demand involves (4)

1. plotting the watershed population trend for the past 10–20 years and estimating the proportion likely to be due to immigration and that due to natural increase (births minus deaths);
2. dividing the supply area into different socioeconomic classes of domestic use and estimating the typical domestic consumption per capita in each class;
3. seeking values of future immigration and natural increase for the different classes of housing;
4. estimating distribution pipe loss rates, consumer wastage, and unsatisfied demand;
5. estimating the growth in industrial, commercial, and service demands (a function of population growth);
6. estimating growth in agricultural demand, hydroelectric demand, and public and ecosystem maintenance demand.

Water Quality Impacts

If the water supply–wastewater sanitation cycle is incomplete (usually the case in developing and transitional countries) and wastewater is untreated, it returns to the environment and pollutes receiving waters. The pollution by municipal wastewater also contaminates sediment and soil, air and biota; the distribution of contaminants is a function of their physicochemical properties and the biophysicochemical properties and processes of the environment. Even in a 'closed cycle' like (Fig. 2), municipal wastewater comprises stormwater runoff, combined sewer overflow (CSOs), and effluent from wastewater treatment plants (WWTPs), as well as industrial point source discharges. The location of the pollution sources, their magnitude, composition, frequency, and duration, plus the surface and groundwater hydrology of the receiving areas, will determine the impact. Specifically, it determines whether or not the assimilative capacity has been exceeded, causing pollutant accumulation. The temporal and spatial scales of impacts vary (after 2): (1) local scale for less than a day—acute toxic impacts, sediment resuspension, coarse material sedimentation; (2) subwatershed scale for days to weeks—BOD and DO changes, algal blooms; (3) watershed scale for months to decades—accumulation of pollutants in fish and sediments, cultural eutrophication, composition of aquatic species changes. As well as pollution potential, large municipal centers may affect microclimate by altering the energy regime, air quality, and circulation (2). Urban heat islands increase evaporation, whereas impervious surfaces reduce infiltration and increase runoff.

In developed countries, because of stricter laws, urban wastewater impacts mainly the recreational use of lakes and rivers, may contaminate shellfish, but rarely pollutes water supplies. Pathogens enter surface receiving waters from untreated CSOs, WWTP effluent, and stormwater runoff, posing risks to bathers, and leaking septic tanks can contaminate surface water and groundwater. In stark contrast, in developing countries, a polluted water supply, poor sanitation, and poor drainage cause a range of devastating impacts on public health (5,6): Vector-borne diseases like malaria and dengue fever (the former has an estimated annual global mortality of 1–2 million, morbidity 200 million, and more than 2 billion at risk); water-based diseases such as schistosomiasis (bilharziasis) and dracunculiasis (guinea worm); water-washed disease such as trachoma and scabia; and waterborne diseases such as cholera, bacillary dysentery, amebic dysentery, and typhoid (estimated annual mortality 4 million, morbidity more than 1.5 billion, 2 billion at risk).

In a municipal watershed, unregulated human activities produce a combination of ecological stressors: habitat destruction, flow modification, thermal pollution, invasive species, and toxic pollution from wastewater and solid waste. When these stressors act together, the possibility exists that degradation becomes synergistic, where one stressor magnifies the impacts of others. Clearly, from (Fig. 1), the municipal watershed ecosystems (including human populations) most at risk from such large-scale impacts are types 4, 5, and 6 because of the potential number, frequency, duration, and magnitude of stressors associated with large cities and megacities.

INTEGRATED MUNICIPAL WATERSHED MANAGEMENT (IMWM)—NEEDS

Municipal watershed management becomes *integrated* when actions on the local municipal scale are carried out in the context of connections with other settlements and the wider watershed. The integration can happen across dimensions described in terms of different kinds of capital. Scoones (7) identifies five categories of capital assets that sustain human livelihoods:

1. natural capital—land, water, wildlife, biodiversity—integration across types of natural resources because all are interrelated in the watershed ecosystem;
2. social capital—groups, networks, laws, regulations, institutions of people—integration across social groups (multistakeholder planning and management), and networking between communities, between government agencies, and between water users and government regulators;
3. human capital—skills, knowledge, healthy people—the integration of different disciplines, professions, interests, and abilities;
4. physical capital—basic infrastructure that supports shelter, transportation, energy, water supply and sanitation, health care, education, communications—the most obvious form of watershed integration, connecting water sources, supply and sanitation infrastructure serving different users;
5. financial capital—income, savings, credit—pooling of financial assets for investment in watershed management goals, including service charges, pollution taxes, and appropriate subsidies.

The last two are the most familiar; the first three require changes in thought, feeling, and action and are beginning to take place. It is notable that in the relatively few cases of 'successful' IMWM, integration has occurred, at some level or other, across each capital dimension. The goal of integrated water management has been described as: "the sustainable, coordinated management of water resources within a region, with the objectives of controlling and conserving water, minimizing adverse effects and achieving specified and agreed water management and social objectives" (8). The cycle of (Fig. 2) is made more sustainable as follows:

- optimizing the design of the engineered cycle to exploit sources responsibly and more sustainably and to minimize wastage, pipe leaks, unaccounted for losses, cross-contamination of supply and sanitation lines, and pollution of the receiving environment;
- reuse of wastewater for nondrinking uses (and drinking water if state-of-the-art tertiary treatment is economical, for example, in Windhoek, Namibia);
- water conservation measures by substituting more water efficient technologies (less water use), cleaner technologies (less wastewater production), and demand management through metering, pricing, and regulation.

Water Supply Enhancement

The World Health Organization (WHO) and the World Bank's basic water requirement for meeting survival needs is 20–40 liters/person/day (2). Many municipalities, especially in type 4, 5, 6 watersheds (Fig. 1), continue to develop new water supply projects and intra- and interbasin water transfer schemes to try to meet growing demand. New approaches emphasize conservation practices to regulate withdrawals (e.g., at or less than replacement levels for aquifers), enhance aquifer recharge, and exploit the economies of scale of conjunctive use of several water sources (2). Dual water supply systems—one for potable water, one for other uses—may be economical in areas of water scarcity, though retrofitting old water cycles is costly. Many new devices save water, like low-volume flushing toilets, shower heads, sprinklers, and washing machines. Considerable saving may be had from recycling rainwater or graywater (less polluted or partially treated wastewater). In a typical municipality, 20% of water use may be industrial, so improving process efficiency and reuse is an attractive option, especially for cooling waters that are polluted thermally. For dirty wastewaters, pretreatment options include ultrafiltration, activated carbon filtration, or reverse osmosis (2). Design of the treatment process depends on the effluent water quality, the required reuse quality, and the flow volume. Agricultural uses, though less important in a municipal watershed, may still account for 25%. Most water is used for crop irrigation and for cleaning dairy sheds (manure flushing), so reuse of graywater and rainwater is attractive. New hydroponic (soil-less) agriculture treats and recycles the water medium, using simple filtration (sand filters or biofilters) and ultraviolet disinfection (2). Xeriscaping—the planting of low water use plants for landscaping —is gaining popularity.

Wastewater Sanitation Enhancement

Development practitioners consider that 'environmental sanitation' encompasses wastewater, stormwater, and solid waste collection, handling, treatment and disposal, as well as personal, domestic, and communal hygiene practice. WHO considers that 'improved' sanitation consists of connection to sewers or septic tanks, pour-flush latrines, pit latrines and ventilated improved pit latrines; 'not-improved' devices include manually serviced bucket latrines and open latrines. The adoption of sanitation practices is heavily influenced by hygiene education and cultural norms. Black industrial wastewaters can undergo cheap pretreatment using unit processes like simple bioreactors (e.g., upflow anaerobic sludge bed technology) (2). The primary goal of wastewater treatment is to reduce total suspended solids (TSS), biochemical oxygen demand (BOD), chemical oxygen demand (COD), ammonia, and pathogens. Separation of wastewater streams at the source allows treating graywaters by simple primary filtration and settling processes (e.g., wetlands, sand filters) and then reuse; blackwaters are treated by primary (screening and settling) and secondary (aeration, bioreactors) unit processes (9). Urine may be collected, stored, and used as fertilizer; feces can be stored in a composting tank for later use as compost (10). In some places, biogas from biowaste decomposition is used for energy. Any agricultural reuse of wastewater and its sludge residue (biosolids) after treatment is carefully regulated so that food crops are not contaminated. Sludge processing can be costly, but the material can be used as a fertilizer.

Flood Protection and Drainage

By connecting land use/land cover planning with water flow management, the twin goals of flood defense and

Table 1. Key Aspects of Integrated Municipal Watershed Planning and Management

Information for Problem Definition[a]	Typical Priority Problems	Implementation Steps[b]
• Characterization of water resource capacities • Characterization of water quality • Inventory of aquatic life in the surface waters • Estimation of impacts of polluted water on humans and other species • Inventory of pollution sources (stormwater, CSOs, municipal, agricultural, and industrial point and nonpoint sources) • Inventory of existing water supply and sanitation infrastructure (treatment plant types, capacities) • Inventory of industrial and commercial wastewater discharges to municipal sewers • Land use/land cover inventory • Inventory of sensitive habitats • Soil contamination maps • Flood plain maps for various return periods • Groundwater hydrology and sustainable yield • Population data on numbers, growth, consumption	• Degraded habitats • Degraded water quality • Fisheries management • Supply deficits • Sanitation deficits • Leaky supply systems • User wastage	• Identify who the stakeholders are and their interests • Establish goals that are attainable, endorsed by stakeholders, and economically responsible • Develop a strategic plan on the appropriate (problem-determined) scale (local, subwatershed, watershed) • Develop the funding mechanism • Lobby politicians to gain support • Involve politicians in promoting the plan • Revise institutional roles and responsibilities to support the plan • Implement the plan • Monitor performance (postaudit)

[a] After (11).

[b] After (2).

habitat maintenance can be addressed. The former relies on educating people not to build in the floodplain, nonstructural measures such as laws and regulations, and structural measures such as reservoirs, levees, and revegetation. The considerable impervious surfaces in a municipal watershed reduce groundwater infiltration and increase rates of polluted runoff during precipitation. Stormwater management consists of three types (2):

1. policies and source controls—education, laws, regulations, including land-use zoning;
2. best management practices (BMPs) and community-level BMPs for the site—for example, rooftop detentions, ponding to increase infiltration, reducing slopes;
3. watershed-wide efforts—habitat conservation (especially wetlands), reducing soil erosion.

It has been shown that the total impervious area (TIA) of a watershed—a good development indicator—correlates with the biological integrity (BI—abundance and diversity of aquatic species) of streams (2): high BI—low TIA (<5–10%); moderate BI—moderate TIA (5–10% < TIA <35–45%); and low BI—high TIA (>35–45%). Stream restoration employs BMPs to provide sufficient, not excessive flows, and to mitigate pollution. In many cities of the developing world, periurban areas contribute highly polluted stormwater because of open sewers, open garbage dumps, and soil erosion from degraded slopes.

IMWM—Planning and Implementation

Not surprisingly, planning on a watershed scale requires a systems approach: (1) problem definition (needs and priorities); (2) description of alternative solutions; (3) evaluation of alternatives and selection of preferred option; (4) implementation of the preferred option; and (5) maintenance and monitoring of performance. Table 1 provides an overview of some key operational aspects.

CASE STUDY

The Nashua River Watershed (Fig. 3) and the Blackstone River Watershed are neighboring examples of municipal watersheds in New England, United States. Their management approaches illustrate many of the challenges for IMWM, and useful lessons can be drawn. Both rivers have similar industrial histories that caused severe pollution, equal areas (540 square miles), and both set out to clean up their rivers at the same time in 1969. Later, they set similar goals of meeting the 1972

Figure 3. Nashua River Watershed, a type 2 municipal watershed. Its integrated management has benefited from strong community leadership and a focus on water quality (12) (permission of Nashua River Watershed Association).

(and 1977 amendments) Clean Water Act standards of being ‘fishable and swimmable’ (Class B). Neither river has yet met this goal, originally set by the U.S. Environmental Protection Agency for *all* rivers in the country by 1983. But noticeable improvements in water quality have taken considerably longer in the Blackstone River than in the Nashua River. Why? Mailloux (13) found that Nashua’s watershed management has been more successful compared to Blackstone’s because of the strong community leadership that lobbied politicians and secured funding for paid positions in the Nashua River Watershed Association (NRWA). This community-based organization formed a cohesive, focused, highly motivated environmental movement devoted explicitly to improving water quality and able to take advantage of information resources and legislation. NRWA also formed strategic partnerships with industrial interests and government, significantly strengthening the social capital of their watershed. This process was aided by the relative homogeneity of the watershed settlements and constituent economies (type 2, (Fig. 1)). Blackstone did not enjoy the same homogeneity (type 3), complicated by bistate administration (Massachusetts and Rhode Island), and did not strengthen its social capital cohesively. Nor did it focus on the core issue of stemming water pollution; it was concerned primarily with recreational use and aesthetics.

CLOSING REMARKS

Municipal watersheds are complex socioecological systems that have many conflicting needs, interests, and priorities for the sustainable development of natural watershed resources: water, air, soil, energy, food, forests, and biodiversity. Without a watershed approach to stewardship, human needs sharply conflict with the needs of other species. With the rise of urbanization worldwide, municipal watersheds of different types are becoming geopolitically dominant in the landscape, placing strong demands on their water supply and wastewater sanitation systems and on their rural agricultural counterparts to produce food for them and often transfer water to them. In most developing countries, the problems are acute; few municipal watersheds have adequate systems; many have almost no sanitation. Unless major changes in policies and practices occur—those emphasizing integrated approaches, supply/sanitation optimization, cleaner production and efficiency—ever more settlements and habitats will be at risk from water stress, either from insufficient water quantity, degraded water quality, or both. Municipal watershed stewardship challenges our ingenuity and our political will, our core values, and the capacity of our institutions to respond. It is important, as always, to learn what works, and why, and draw on experience worldwide. Although the magnitudes of watershed problems differ from country to country, the underlying sociocultural obstacles to sustainable solutions are remarkably similar.

PUBLIC WATER SUPPLY WORLD

Mario O. Buenfil-Rodriguez
National University of Mexico &
Mexican Institute of Water
Technology
Cuernavaca, Morelos, Mexico

VALUE OF A WATER SUPPLY

A good, dependable water supply promotes health, productivity, beauty, arts, safety, recreation, and most of the desirable goals of life and society. Probably, the first ancient human settlements simply occurred in places granted by nature with fruits, animals, and other food, and with enough and easily reachable water. People used to move or travel when conditions changed (*drought, flooding, climate change*) or simply because they wanted to explore new horizons. Later, the discovery of agriculture made sedentary groups larger, and towns grew. Water had a prime role in the possibility of producing food and having a stable place to live. Production and living depended on reliable, good quality water, requiring as little effort as possible in its conveyance, storage, and use. The best water sources were, and still are, regular rains, the stable flow of a river, or the constant level of a lake.

Growing Complexity

Meeting one or more of the previous conditions for accessible water is not always possible or easy. Evidently, when towns grow, new residents need to set up a bit farther away from the river or community storage than already existing houses. This creates, for the newer inhabitants, more toil to fetch the water, the need to have a donkey or a cart, expending time and effort carrying, or investing in pipes to convey the water to their place, and possibly to pay continuously for energy (*pumps*) to raise water to higher spots.

Moreover, the best sites for cities and water were occupied since ancient times, so new settlements, forced by the overwhelming human growth of the last two centuries, are occurring in places without the appeal and qualities of those first towns and cities. Unfit locations are often aggravated by deteriorated water quality due to wastewater and debris discharged by upstream housing, industries, and agriculture.

HEALTH, FAIRNESS, AND ECONOMIES OF SCALE

In cities of high housing densities, ***public water supply*** started as a measure to improve hygiene and health, as well as a need for fairness among citizens, to give them an equal chance to have water and to pay similar amounts via taxes or equivalent. It is also much cheaper and less chaotic to have collective solutions than individual ones.

A public water service can concentrate and pay specialized personnel, devoted full time to these highly technical matters of searching, treating, transporting, raising, distributing, maintaining, and charging for water service.

Water service in most cities of the world is provided by governmental institutions (*either national. regional. municipal*), but in many other locations is operated by private utilities. There also exist mixtures of private and governmental (*public*) responsibilities. Nowadays, there is a tendency, often promoted by lending institutions, to give up (*"privatize"*) governmental services that have too many conflicts and poor quality.

In this article, the term "***public water supply***" refers to the water service provided by some official concessionaire (*independently if is private or government*) that attends to the needs of various clients in a city. For its character and to benefit from economies of scale, it is regularly a "monopoly" within the same city or region. This means that usually no competitors, doing similar tasks, are allowed within a location.

SUPPLY DIFFERENCES AND STYLES IN THE WORLD

Developed countries generally have better natural water resources than poor "developing" (*alias "third world"*) nations. Certainly the ease and abundance of water resources explains many of the differences in material progress among nations. Besides, public water supply quality in "first-world" countries is better, reflected in the continuity, quantity, quality, pressure of water, and the readiness to attend to consumer complaints or requests.

Such reliable and quality service in rich countries doesn't mean that their service is superior or more "efficient" than that offered in poorer and drier countries. Often it is just the opposite because cities that lack water use more ingenuity, toil, and productivity to do much more with fewer resources (*smaller in water availability, energy usage, investments*), covering larger populations, and have radically different, or even nil, water fees.

Service in rich cities typically leaves little care and worry to the individual household, except to pay its taxes or water fees. But as governments are poorer, institutions are weaker, or water scarcity is severer, situations change. There can be various combinations and styles among tasks and investments left to the individual homeowner and among duties performed by the public water utility or through other intermediate providers. There usually are more responsibilities and "choices" posed on the tenant as situations are more stringent. Table 1 presents some examples of a water supply system's components (*infrastructure, equipment*) often left as obligations (*duties*) of each homeowner or group of them.

Sometimes the government or the public privatized service can be in charge, or help, in some individual solutions such as cistern cleaning, rainwater harvesting, toilet retrofitting, and leak repair inside houses, to save water and be able to meet the water demand.

COMPONENTS AND EVOLUTION OF A WATER SYSTEM

All humans need or desire water to cover the following purposes in decreasing priority level or intensity: drinking,

Figure 1. Communal rainwater sotrage.

Table 1. Components of a Water Supply System

Source
Rain catchment and storage at community level (Fig. 1)
Rain catchment at domestic level (*rain harvesting*) (Figs. 2 and 3)
Hand pump well
Wells (*sakia, noria, shallow wells*)
Distribution and pressure
Individual transport (Fig. 4)
Open channel or aqueduct (Fig. 5)
Public standpost
Home connections (*built by the homeowner, built by the public facility, built by a concessionaire*), with valves or meter or without them (Fig. 6)
Electric or manual pumps to raise water to places where needed (*2nd floor, etc.*)
tankers (*buy complementary water from private distributors*). (Fig. 7)
Storage
Public regulation and storage tank
On the roof container (*tinaco*)
In-ground individual cisterns
In-floor collective container (*for a group of houses*)
Water quality
Chlorination
Filters
Boiling (*gas or wood consumption*)
Buying bottled water for drinking
Water saving
Meters and fees
Low consumption toilets, water saving showerheads, etc.
Rota cuts, intermittent service (*regular rationing*)
Very low water pressure (*just enough to reach the water intake, the house connection to the main at street level*)
Laws and regulations to install water saving devices
Reuse of gray water (*sullage*)

bathing, clothes washing, cooking, gardening, pet care, housekeeping, recreation, manufacturing a product, etc. Priorities and quantities vary with cultural, natural resources, and technological differences among regions.

Around the world, cultural preferences and technology are varying rapidly in these decades, and sometimes their fast evolution is confusing many people in thinking that natural resources also evolve at our will (*a mistake which is creating serious risks and damages to other species*). Additionally, there is a strong tendency toward similar (*globalization*) aspirations for comfort and life standards in most communities, although these are not always possible to meet due to economic constraints. The world would be much better if the environmental aspects of each region are considered carefully before embarking on seeking such water system standardization.

Not very far off in time, even nowadays in rich countries, nobody thought about (*"needed"*) water faucets or showers inside their dwellings. The components of a water supply system could then consist of

Figure 2. Rural domestic rain collection.

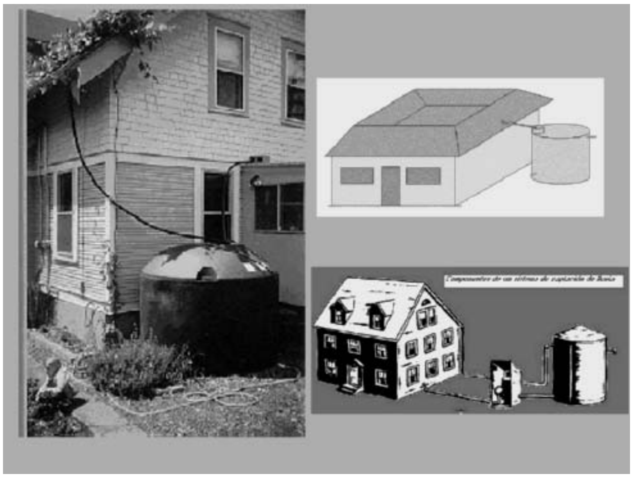

Figure 3. Urban domestic rain catchment.

Figure 4. Water transport.

Figure 5. Ancient acueduct.

Figure 6. House connections in dry tank.

Figure 7. Tanker supplying water.

- source (*storage for rain water, river intake, or shallow well*)
- gravity conduction or simple transport (*channel, simple aqueduct, buckets, animal cart, or pipes*)
- delivery at limited sites (*public fountains, stand posts*)

When water quality is not totally satisfactory or the quantity available from the source is insufficient during some seasons of the year or during some period of the day, a more "advanced" (*complex*) system is required (see Fig. 8) that has additional components:

- dam or long-term storage
- filter or chlorination
- short-term storage or regulatory tanks

Many public water supply systems in the world nowadays operate on a simple scheme, similar to those just mentioned. But as "progress" has advanced, pollution has increased, and people's expectations and habits have been transformed; the complexity of the systems has also enlarged. In such a case, some additional components can be (Fig. 9):

- regional or international agreements to use and share water
- deep wells
- long conduits
- pumping stations,
- metering and gauging stations
- leak detection equipment
- valves of different kinds
- dual distribution systems (*different water qualities on each*)
- house connections, consumption meters
- reading and billing mechanisms.

Much damage was done earlier by considering the water supply network isolated from the drainage or sewerage solution. Both must be understood as a unique, integrated, system. In this case, additional elements are

- sewerage network
- wastewater treatment plants
- reuse networks
- efficient water use and conservation programs
- legislation to prevent certain water uses and pollution of sources

It should also be realized that present ***technological progress*** has made different kinds of resources more intermingled and **interdependent**. Then, "public water supply" doesn't depend exclusively on water availability, but also on energy supply (*for pumping, treatment plants*), human resources (*requirements of trained personnel*), manufacturers and materials available in the region (*pipes, machinery*), and the political and legal framework (*standards, laws, institutions*).

PRESENT CONFLICTS AND NEEDS

Water supply and the possibility of having water and sanitation in our own houses, or at least very close to them, more than any law, invention, or medical advance is what

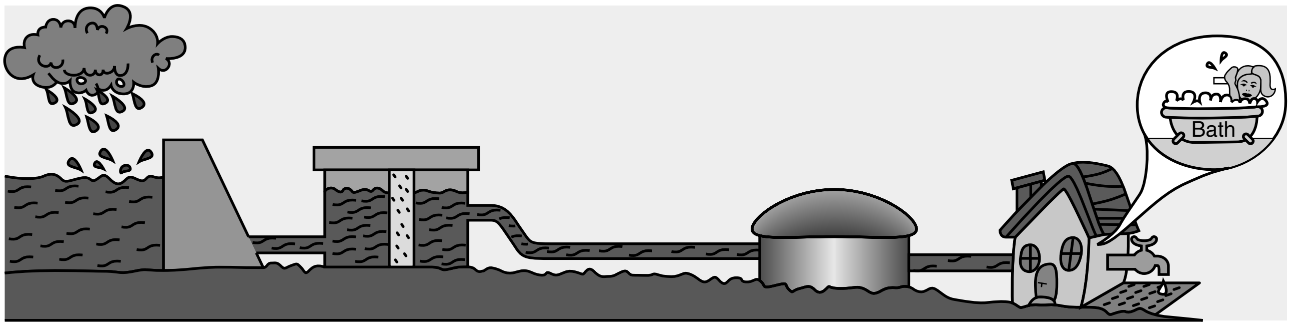

Figure 8. Elementary water supply and disposal system.

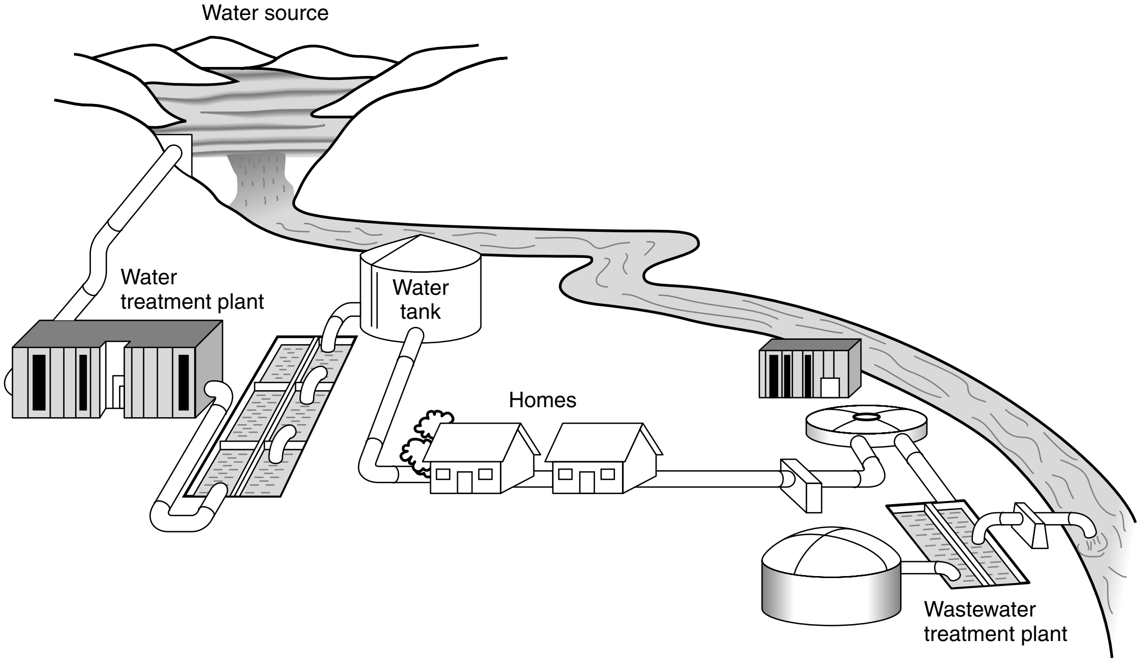

Figure 9. Increasing complexity for supply and disposal system.

has allowed extensive increments in comfort, health, and production and has accelerated the growth of cities. On the other hand, it is shocking that this main force, which made cities swell and consolidate in the past, is now causing the decline of security and comfort in many cities and regions. Past growth, mainly in Europe and well-gifted countries, was slower than that now occurring in poor regions. A slower pace gave the chance for trial and error, without so much risk as today, and also allowed time to mature and integrate useful capital (*material goods, infrastructure, knowledge, and educated people*).

The enormous global human population increase during the last decades, which will still continue during the next 40 years, has occurred almost entirely in the third world (*developing*) countries, ironically, where water scarcity is more evident, as shown by various studies of prestigious international organizations. These poorer countries, where 80% of humanity lives now, and where almost 90% will be in five decades (1–5), are facing “modernity” and high demands for welfare from their people, combined with mighty stresses on natural resources and without much time to think and try the best ways.

Risk or deterioration of those benefits provided by a water supply (*see value of a water supply*), comes from continuous and unrestricted demographic internal urban growth, aggravated by high immigration toward cities due to lack of employment, land, or water for irrigation in rural communities. Expectancies and water demands from these growing populations are difficult to meet without causing damage to other societies (*further in space or time*) or to the natural environment, particularly when the technologies and style of solutions proposed are still those used in the past (*no treatment of wastewater, intensive energy use for pumping, etc*).

The appeal of economies of scale, mentioned earlier, work in the opposite direction when cities are too big and complex (*smaller is better*). One example is Mexico City, where the *benefit/cost ratio* of augmenting the water supply is lower than in other cities of that country.

Some frequent and worrying signs of unsustainable water supply systems are

1. Water scarcity, caused when demands are greater than accessible volumes. Availability must consider the seasonal and regional variations of usable water.
2. Unrecoverable yearly drawdowns in aquifers.
3. Polluted rivers and lakes.
4. Lakes with decreasing water level, going dry or nearly extinguished.
5. Rivers not discharging any more into the ocean, due to deviations and use of their flows.
6. Deforestation threatening water recharge areas, creating erosion and flooding (*flow mode difficult to control*), and causing microclimate changes (*hotter spots*) that increase people's water demands.
7. Rubbish and contamination that menace aquifers and recharge areas.
8. Urban settlements and paving on zones of aquifer recharge or of high risk.
9. Untreated supplied water and free discharge of wastewater.
10. Supply services on rotation (*irregular*) and uncertainty of amounts provided.
11. Huge amounts of water lost through leaks, due to bad quality or status of water networks (*piping quality or poor operation and maintenance*).
12. Incorrect valuation of water. Fictitious or highly subsidized tariffs give the wrong message to the public (*hidden expenditure rob other services, regions, and/or the future*).
13. Institutional weaknesses as procrastination against nonpayment and clandestine connections.

WATER SERVICE BASIC DATA AND INDICATORS

To decide the size of the pipes and other items (*pumping stations, storage tanks, valves, etc*) of a public water network, it is essential to know first some characteristics of consumers' demands and of the supply sources. Studying the demand and ways to manage it, in case it surpasses the supply capabilities, is the prime step for any design. It is also important to know where and how is the existing infrastructure.

There are some typical key indicators used by most water utilities and recommended by international aid organizations (1,2,6). Indicators, parameters, or data describing the characteristics and status of a given water supply system can be grouped in various ways; one example is Table 2.

Tables 3, 4, and 5 list some indicators for three of the previous groups mentioned in Table 2.

This article cannot extend to a detailed discussion of these water service indicators or mention their representative values or ranks in some countries (*they can vary substantially. See reading list for more details*). Only two of them, coverage and demand, will be commented on briefly:

Table 2. Groups of Indicators of a Water Supply System

Coverage

Coverage is the ratio of people served to the whole population in a location. It varies widely among countries. Developed nations have values of 100% or near it; in very poor countries, it may be as low as 10 or 20% (*Cambodia, Haiti, Mozambique, etc.*). Moreover, broad differences exist between urban and rural areas in many countries. Certain cities that have apparently satisfactory infrastructure coverage present serious deficiencies due to droughts or useless networks that imply continuous rationing of the supply.

Demand (average water requirement)

Demand represents the volume that needs to be withdrawn from the water sources to satisfy all uses and inhabitants in a city. Usually, it is expressed as a per capita daily volume (*liters/person-day*). It has some similarity to "unit consumption" but is not necessarily the same, especially when the sources are insufficient to meet people's desire for water. The "demand" is a broader concept which includes other water uses, besides domestic. Some "uses" that never should be forgotten when reviewing or designing a supply network are the leaks and other UFW (*unaccounted for water*) that inevitably have to be fed to the system, to be lost so a certain water quantity really reaches individual houses. Figure 10 compares some values in developed countries for unit consumption at household level. Figure 11 shows some typical values in demand variation among seasons, and (Fig. 12) represents distribution of water volumes in a typical Canadian dwelling.

The design, improvement, or revision of a water supply network is relatively easy using modern hydraulic simulation programs. The real labor and complication is in defining, finding, measuring, and gathering the appropriate and correct data to make those calculations and in defining reasonable specifications and standards for

the system. Many textbooks and computer software forget to mention these difficulties. Basic data and indicators are not merely technical aspects, but are rather social, environmental, political and economic, and should be carefully tracked and understood by any person involved in a water supply project.

TEN KEY TRENDS THAT WILL SHAPE THE FUTURE OF THE WORLD WATER INDUSTRY

Steve Maxwell
TechKNOWLEDGEy Strategic Group
Boulder, Colorado

As we move into the new millennium, economic observers, social critics, and stock watchers are turning their attention toward the challenges and issues that, surround the country's continuing supply of clean drinking water. Water issues are now routinely addressed on the front pages of the national press—*USA Today* recently featured a full pull-out section dealing with the issues of clean drinking water; water scarcity issues were featured in a recent cover article in the *Harper's Magazine*. Water is increasingly described in such terms as "the key commodity of the twenty-first century." Like oil in the twentieth century, the substance will determine the course of human development and economic progress, over which conflicts or even wars may arise.

Some observers have perhaps waxed a bit melodramatic; however, it *is* clear that these sorts of challenges and problems are not imaginary; nor are they somewhere in the far distant future. Water *quantity* issues have long impacted politics and economic development in the western United States, and now water *quality* issues are increasingly critical in the East. Debates over water rights are the source of intensifying conflict between countries or between regions within countries. The human health challenges and vast economic issue of poor drinking water in many less developed countries represent one of the world's most pressing problems; a recent United Nations report estimated that as many as 10 million people a year die from unsanitary drinking water and associated waterborne diseases.

RISING WATER PRICES

Water is still very cheap; the price of water is not yet even really a significant driver of change in the industry. Prices will continue to rise, particularly in countries like the United States where past government policies—and the failure to account fully for the true *economic* cost of water usage—have kept prices artificially low. As prices increase, decisions relating to water usage will begin to take on greater significance in the overall economy. Focus will begin to intensify on more efficient water usage and demand management techniques, and new treatment technologies and supply sources such as desalination and water recycling will begin to gain market share.

STRONGER ENFORCEMENT OF REGULATIONS

Regulatory attention and water quality enforcement levels will remain strong in the United States, both in terms of drinking water quality and wastewater discharges. Although public concern and congressional attention to broader environmental issues have waned in recent years, the topic of drinking water quality continues to move to the forefront of the public agenda. Regulation of drinking water standards will also be strengthened in most other regions of the world. The water industry will clearly continue to be driven and buffeted by regulatory forces; however, products and services that offer cost savings, revenue enhancements, improved productivity, or reduction of capital expenditures, will enjoy stronger market growth than those that offer just regulatory compliance services.

BROADER REGULATORY FOCUS

Regulation and enforcement has been shifting slightly toward nonpoint sources of runoff and water pollution. Early enforcement attention was focused on the more obvious and more concentrated "point" sources of pollution; admirable progress has been made in correcting these—typically industrial—problems, and recent focus has shifted more to nonpoint source pollution. This (mostly agriculture-related) problem has seen substantial improvement in recent years as well. Biological wetlands treatment systems for animal waste management and pesticide and herbicide runoff are one example of new technologies being perfected to treat agricultural waste problems. Both point and nonpoint sources, as well as storm-water and general "wet weather" management, are likely to receive continuing regulatory attention and scrutiny in the coming decades.

INCREASING PRIVATIZATION

Industrial outsourcing and municipal privatization will remain key trends in the business. The contract operation business has been growing as much as 25% per year, and many private firms continue to diversify into this business despite the fact that, to date, profitability has been elusive. The potential for large-scale water privatization is typically cited as the main driver behind the recent onslaught of foreign acquirers—a belief that the United States is the last large market where water supply is still largely under public ownership and operation.

To date, privatization has been driven by broad political predilections to minimize the scope of government or by the widely held assumption that focused and private for-profit companies can operate more efficiently than public organizations. Many of the institutional and tax barriers to more complete privatization have melted away. To operators and employees of publicly held water and wastewater plants, privatization pressures over the last few years have sent a clear message—"shape up or ship out." However, public agencies and municipalities *have* responded to both the threat and to the root causes of this incipient pressure to privatize. These forces to economize are leading to municipal "optimization" as an alternative to privatization. Optimization may involve cost-cutting and improvements in efficiency from initiatives such as benchmarking, automation of operations, staff reductions, and improved information and analysis to facilitate better decision-making. From a broader social point of view, if the simple threat of privatization ultimately improves the efficiency of municipal facilities, then the same economic and productivity goals will have been achieved. Privatization will undoubtedly continue to grow, but it seems unlikely that it will reach the levels of 80% or 90% of total municipal systems, as has been predicted in the past.

GREATER WATER REUSE

There is an inexorable trend toward broader water reuse and recycling systems as a key means of addressing water shortages. Reuse is not a new idea, and using technologies readily available today, wastewater can easily be cleaned to levels where it can be recycled back into primary usage. This general idea, however, has not yet gained widespread social acceptance; put simply, most people don't want to think about using—and particularly drinking—their own wastewater. We have all been conditioned to think of water as something that we take out of the environment, use, and then discharge back into a vaguely understood natural system. Most observers believe that the *direct* reuse of wastewater for human *drinking* is not likely to be a widespread reality in the foreseeable future. There is still the (clearly disproven but emotionally more appealing) assumption that wastewater is somehow cleaner if it momentarily flows down the Potomac River (or any other less than pristine natural waterway) a few miles, or if it is briefly discharged into and then pumped out of a "natural" underground aquifer. This type of *indirect* use of wastewater for drinking is clearly acceptable and widespread, but *direct* reuse of our own wastewater is still a bit of a stretch for most Americans.

However, the boundaries between "water" and "wastewater" are already beginning to fade. For example, on some major rivers in the United states, water is used and reused up to 20 times as it travels to the sea—the discharge water from one wastewater treatment plant comprises the raw water intake for a primary drinking water plant a few miles downstream. As a result of 30 years under the requirements of the Clean Water Act, discharged streams from wastewater treatment plants are often cleaner than the rivers and streams they flow into; in other words, treated wastewater is actually helping to clean up our rivers.

What many observers have failed to clearly recognize—and what suggests that there may be real business opportunities here in the near future—is the obvious fact that very little of our water is used for drinking. Compared to the roughly 1200 gallons of water per person per day that it currently takes to power the U.S. economy, each person drinks only about a gallon a day. This leaves 1199 gallons per person per day, a substantial portion of which could be recovered through reuse, without anyone ever having to drink "recycled" wastewater. The bottom line is that even if only small incremental gains could be made in terms of nonpotable water reuse, water availability concerns could be substantially impacted. Over the longer term, society will move beyond the "linear" thinking of today and develop a more "circular" philosophy of water usage.

MORE AND BETTER INFORMATION

As the Internet revolution races on, the effects of better and more rapid information are being felt in the water industry. For example, the introduction of the Consumer Confidence Report will undoubtedly spur broader awareness of water quality issues across the American public, in turn driving demand for better monitoring and treatment technologies to improve the quality of our drinking water. Real-time watershed monitoring technologies and telemetry systems are becoming more commonplace and will help improve the quality and lower treatment costs in public water systems. Automatic meter reading, and more accurate remote systems for monitoring water usage will in turn make us more aware and attentive to the issues of our often sloppy usage.

CONTINUING INDUSTRY CONSOLIDATION

The era of consolidation is not over in this industry. Despite all of the attention paid to Veolia, Suez, RWE and other consolidators during the past few years, the water business is still rather fragmented compared to many industries, and business leaders continue to promote loudly the opportunities for "another U.S. Filter." The large transactions have hit the front pages, but dozens and dozens of smaller and less visible deals are also constantly ongoing. This massive rearrangement—and a distinct shift toward foreign ownership of the water industry—will determine the water industry's future competitive landscape. The very occent announcements of major divestitures by both veolia and suez demonstrate that changing ownership will continue to be a major factor.

NEW TECHNOLOGY

The advance of modern technology is often held out by optimists as the answer to all of our environmental and natural resource challenges. Whether or not this will be true is open to debate, but there is no doubt that new technology will play a key role in the improved management and extension of our water resources. Key examples include the broader usage of reverse osmosis/membrane systems to desalinize seawater for human usage, the trend toward replacing chlorine and other water treatment chemicals by advanced oxidation and other emerging physical and mechanical technologies, water-saving drip irrigation systems for more efficient agriculture, a wide spectrum of recycling systems and technologies, and new packaging and transportation systems for moving freshwater from regions of abundance to regions of scarcity.

CONSERVATION AND MORE EFFICIENT USAGE

Almost all of the trends mentioned before underscore the questionable efficiency and economics of today's water system and infrastructure. Some simple steps in more efficient usage can go a long way toward solving water shortages. For example, even the most modern water transmission infrastructure systems often incur leakage of as much as 10 to 20%—losses which can be fixed relatively easily. Water conservation ideas are only just beginning to take advantage of the “low-hanging fruit”; a recent rebate plan in New York City to promote the use of low-flow toilets purportedly resulted in saving 90 million gallons a day (although many users find “low-flow” toilets to be a bit of a misnomer, as they simply have to be flushed more times)! As water prices rise, there will be increasing financial incentives for industrial companies to retool their manufacturing systems to use less water, or to reuse water more efficiently—and dollars get everyone’s attention. And different types of applications can use different kinds of water—urban planners have pointed to the fallacy of spending billions of dollars annually to clean *all* of our water supply to drinking standards when, as mentioned, only a tiny fraction is actually used for drinking. More sophisticated systems and infrastructure in the future (such as dual potable and nonpotable piping in the home) may allow us to be more efficient in our management and use of limited water resources.

MORE INNOVATIVE POLICIES AND REVOLUTIONARY APPROACHES TO WATER USE

From a broader social and economic perspective, we will see many changes in infrastructural approaches and broader water management policies. For example, water “carriage”—analogous to the wheeling of electricity in the power utility business, where one utility may use another’s infrastructure for delivering water—is being experimented with in England. One historical trend that is likely to begin to reverse in the future is the construction of large-scale dams for power and irrigation purposes; the broader social and economic impact of large-scale dams is being gradually reevaluated, and it is conceivable that in the future we could see some of the big dams coming down. Water and hydropower utilities are beginning to come together in certain regions, realizing that water management issues are the driving forces behind each. In short, the entire way we think about and use water will be markedly different just a couple of generations from now.

CONCLUSION

As the saying goes, “it is very difficult to make predictions, especially about the future.” The water industry has confounded many observers in the past and continues to perplex many today; for example, if the demands are so great and the opportunities so huge, why aren’t more water companies currently performing better in the stock market? No doubt, the business will continue to be a tough one to define, segment, and understand, and it will probably take some more unexpected turns in the future. One thing, however, is clear, and distinguishes this industry from almost all others—water is an essential prerequisite of life. A continuing and dependable source of clean water is a critical necessity for our standard of living and our modern industrial economy. *And we are not going to find a substitute for water*. For well-managed organizations—both private and public—and for the thoughtful and prudent investor, the fundamentals of the water industry suggest the potential for strong growth and consistent profitability far into the new millennium.

ZEBRA MUSSEL CONTROL WITHOUT CHEMICALS

Charles H. Sanderson
T. C. Molden
Magnatech Corporation
Fort Wayne, Indiana

Since the introduction and spread of the zebra mussels *(Dreissena polymorpha)* in the mid-1980s, industry and municipal water users of North America have been plagued by the mussel shells, which have clogged water intakes, costing vast amounts of downtime and loss of production (1).

The U.S. Coast Guard has since named the zebra mussel the number one threat to American waterways as well as a threat to fish and other aquatic species. The possible effects on numerous communities is also of great concern (2). In 1994, the Great Lakes Environmental Research Laboratory stated that the barnacle-like zebra mussel poses a multibillion dollar threat to industrial and public drinking water supplies and may become a costly nuisance to shippers, boaters, commercial fishermen, anglers, and beach-goers as well—far more costly in human terms than all previous Great Lakes invaders combined (3).

The life cycle of the *Dreissena polymorpha* begins at the egg stage, advances to the veliger, postveliger, juvenile-settling stage, and then to a full sized adult. In the settling stage, mussels colonize very rapidly in areas where calcium and algae are plentiful. A water velocity of 6 feet per second, with high concentration of algae and calcium, is an ideal location for the zebra mussel to settle and develop its shell consisting of 93% calcium (4). The mussel ideally settles in an intake pipe where the food source is constantly supplied by the moving water.

The adult life span is 3–5 years, and it reproduces year round, averaging 35,000 eggs per year (5). Zebra mussels look like small clams, and they have yellowish and/or brownish “D”–shaped shells, usually of alternating dark and light bands of color (thus the name “zebra”) (Fig. 1).

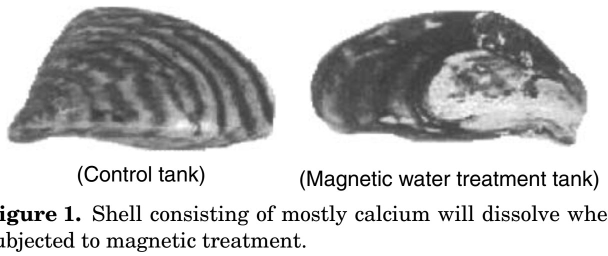

Figure 1. Shell consisting of mostly calcium will dissolve when subjected to magnetic treatment.

Zebra mussels can grow as large as 2 inches, but most are under one inch long, usually grow in clusters containing numerous individuals, and are generally found in shallow (6 to 30 feet deep) water. The zebra mussel is the ONLY freshwater mollusk that firmly attaches itself to solid objects, including rocks, boat hulls, and internal walls of pipes.

Methods to control the zebra mussel became top priority in many municipalities and industries that use water from the Great Lakes. In desperation, chemicals (mostly chlorine) became the quick fix; however, the toxic discharge back into the fresh water lakes increased the fish kill and killed other wildlife species. The U.S. Army Corps of Engineers sought other (nonchemical) means to control the spread of the mussel threat and set up workshops in which academic and industry professionals were invited participate.

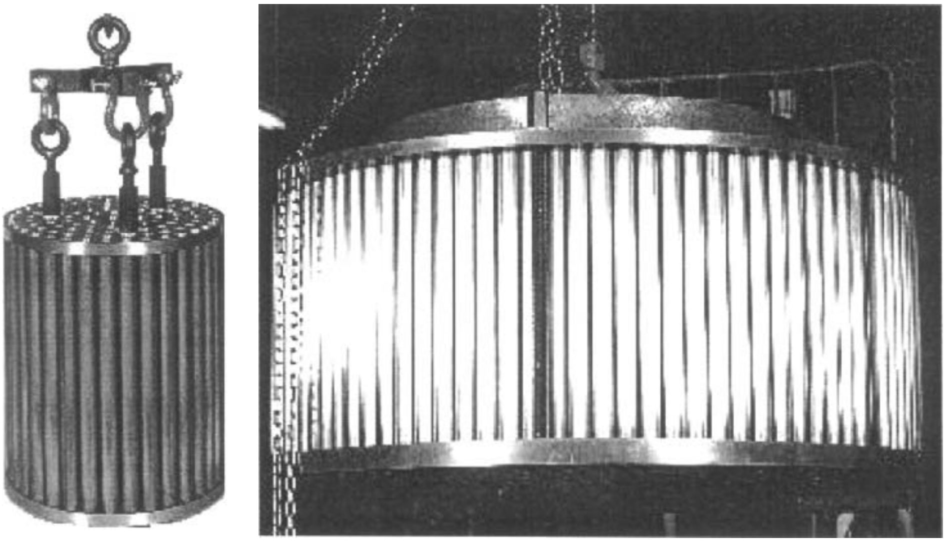
The National Research Council listed several technologies more friendly to the environment than chlorine and other chemical biocides. Among those identified were *filtration systems, thermal techniques, electric pulse and pulse plasma techniques, ultraviolet treatment, acoustic systems, magnetic fields, deoxygenation*, and *antifouling coatings*.

Under the heading of magnetic fields, the Council stated, "Water to be treated is passed through a magnetic field of specified flux that is generated by ferromagnetic or electromagnetic devices. The biological and chemical effects of magnetic systems are not well understood, but it is thought that the organic and inorganic constituents of living organisms in the water are altered by the magnetic field" (6).

Magnetic conditioners up to capacities of 12,000 G.P.M. and pipe 60" in diameter (Fig. 2) treatment has been used successfully to control hard water scale ($CaCO_3$) in boilers, cooling towers, and other heat transfer systems for many years. The need for chemicals to control hardness and scale can be eliminated or greatly reduced and can provide energy savings (7). The mussel shell has a high calcium content (formed from the hard water intake), so a 2-year study began in 1993 to determine what effects, if any, magnetic fields would have on the zebra mussel. The results were very encouraging, as shown in (Fig. 3).

Dr. Graham O. Davies, president of the Water Board of Long Beach, Indiana, graciously offered the use of his facilities for the study and obtained the approval of the EPA for the installation of the magnetic unit and test equipment (Fig. 4). The Bardygula-Nonn study (8) used a flow-through magnetic water treatment device. Based on the results, it was suggested that magnetic water treatment might be a means of controlling zebra mussel populations to prevent macrofouling (Fig. 3). Besides the shell deterioration, the magnetic water treatment appeared to have other negative impacts on zebra mussels, including ciliary damage, byssal thread destruction, valve growth reduction, and increased mortality of juveniles.

A 4 year study started in 1995 at Purdue University (9) had three objectives: (1) to determine if the results of



(20" dia. – 2,000 g.p.m.) ***Magnetic Perma-core™*** (60" dia. – 12,000 g.p.m.)

Figure 2. Magnetic assembly for inline treatment.

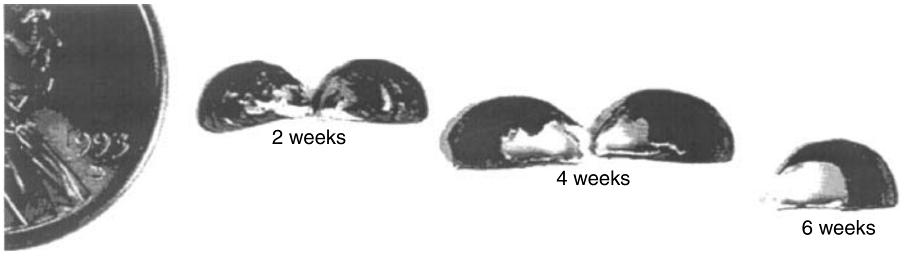


Figure 3. Zebra mussels exposed to magnetic water treatment- no chemicals were used.

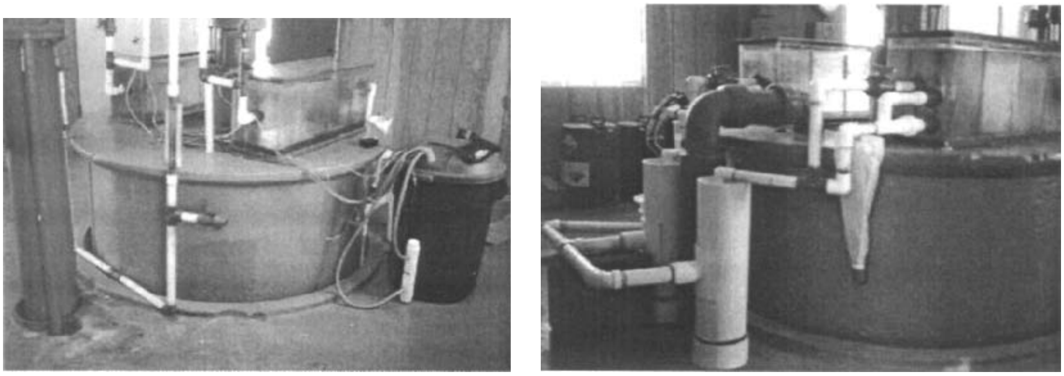

(Long beach facilities showing control tank (left) and magnetically treated water tank (right) with nutrient feeding tank)

(back view of the tanks with plankton nets filtering discharge water)

Figure 4. Research arrangement for side by side evaluation for mussels placed in the control tank vs. magnetic treated water.

the previous study could be reproduced in a controlled laboratory set-up, (2) to examine the effects of magnetic water treatment on adult zebra mussels in an industrial application, and (3) to examine the influence of magnetic water treatment on settling of veligers in an industrial application.

In the laboratory at Purdue, 65 of the 123 mussels from the control tank (those not used for dissection or elemental analyses) were alive at the end of the experiment, leaving 58 dead (Fig. 5). In the experimental tank, 33 of the 123 mussels were alive at the end of the experiment and 90 died during the course of the study (Table 1). The differential mortality levels observed from each tank were significantly different ($X_2 = 17.4 \text{ m df} = \text{in}, p < .005$). Therefore, significantly more zebra mussels died in the tank of magnetically treated water than in the tank of untreated water. This suggests that the magnetic treatment of water does have adverse effects on zebra mussels, under laboratory conditions, and increases the mortality rate. This coincides with the previous Bardygula-Nonn study.

INDUSTRIAL FIELD STUDIES ON ADULT MUSSELS

Mussels treated for 30 days had significantly lower wet-tissue weights than control mussels ($F = 8.10$, $p < .005$). Glycogen levels of the treated mussels were 17.6% lower compared with control mussels, a difference that was significant ($t = 2.23, \text{df} = 118, p = .028$). Treated mussels had a greater increase in shell length during the 30-day trial than control mussels. The difference was significant at ($t = 3.16, \text{df} = 118, p = .002$). No differences were observed between the control and treatment circuits for water quality or environmental parameters during the 30-day trial.

There was no significant increase in shell length of treated mussels during the 60-day trial compared with control mussels (as seen in the 30-day trial). Glycogen analyses were not done for these samples. The results of the Purdue study suggest that magnetic water treatment can reduce settlement of zebra mussels in an industrial setting and that the mortality of zebra mussels is increased when they are exposed to magnetically treated water. A combination of reduced chemicals such as chlorine and a magnetic unit may sometimes be required. Interestingly, the head chemist at an industrial field site reduced their first year's chemical use by 50%, then by 75%, and presently no chemicals at all are being used in the magnetically treated supply line (Fig. 6). The parallel control line remains at the 100% chemical-feed rate (9).

Table 1. Survival of Zebra Mussels Over the Course of the Laboratory Study

	Control Tank	Experimental Tank
Alive at end	65	33[a]
Died during	58	90
TOTALS	123	123

[a] $X_2 = 17.4$, $p < .005$; therefore, there is a significant difference between tanks in the survival of the mussels.

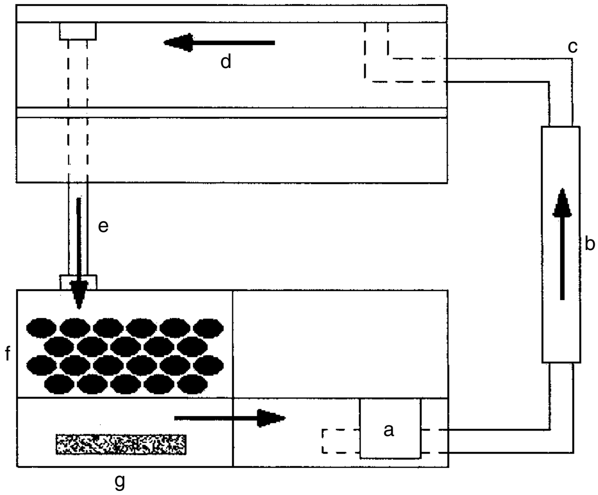

Figure 5. Diagram depicting setup of aquaria (control & treatment): (**a**) submersible pump, (**b**) magnetic treatment (treatment) or "dummy" unit without magnet (control), (**c**) water return line, (**d**) mussel bed, (**e**) overflow feed line, (**f**) biological filter media, and (**g**) aerator unit (air stone).

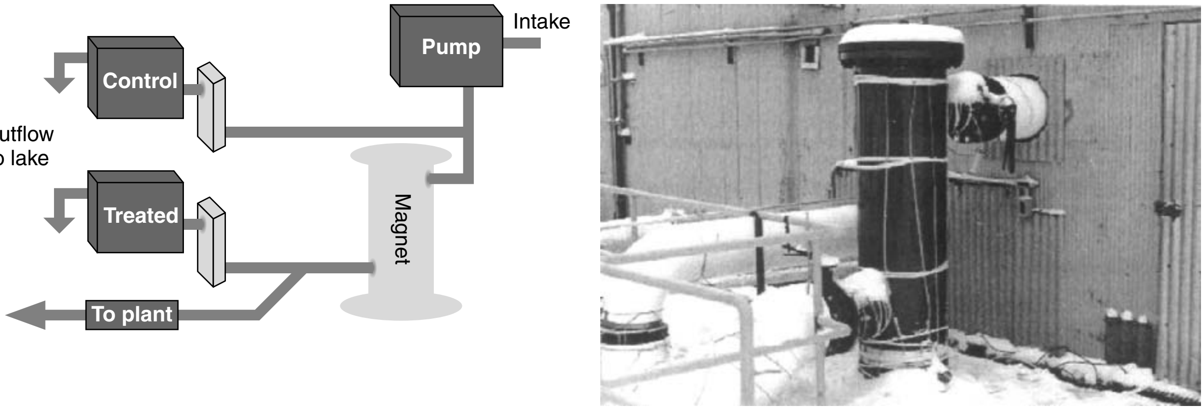

Figure 6. Diagram of industrial setup. Industrial magnetic water treatment system installed at a manufacturing plant on a parallel feed line with a flow rate of 1600 gallons per minute.

INDUSTRIAL FIELD STUDIES ON VELIGER SETTLING

A 53% reduction in settlement was observed in the treatment sampler compared with the control sampler. Chi-square analysis of settlement data revealed that the reduction was significant ($p > .001$). No significant differences were observed in recorded water quality parameters between the two sampling boxes. The results of this study suggest that magnetic water treatment can reduce settlement of veligers in an industrial water intake.

RESEARCH CONCLUSIONS

At this time, it is not clear how magnetically treated water could cause the greater mortality observed in the experimental tank compared with the control tank. Perhaps the changes, which occur when water is magnetically treated, serve as a stressor or influence cell membrane functions. It is known that magnetic water treatment causes the electrons of calcium ions to move, temporarily, into different orbitals (10). Perhaps this change in the ions can influence the zebra mussel's calcium uptake or metabolism. Calcium is especially important in shell formation, cell membrane function, muscular contraction, and ciliary contraction in zebra mussels. Therefore, if magnetism were affecting free calcium ions in the water, it would have potentially wide ranging effects on the zebra mussel's metabolic functions, which could generally explain an increase in mortality.

Ongoing research has shown that, by inserting probes at each of the alternating reversing magnetic pole sites and using active filters to eliminate any common noise (0.40 Hz) at the outputs, not only is a voltage induced in the conductor (water) but also a frequency. The frequency is a complex waveform whose fundamental frequency is <30 Hz. This falls into the extremely low frequency (ELF) spectrum of electromagnetic energy. More research is being done today on this aspect of the technology (9).

The biological effects of ELF radiation are well documented (11). ELF radiation lowers the energy barrier of cellular ion transport between the high-dielectric aqueous phase and low-dielectric lipid-containing barriers. This will influence the ion influx and efflux for the biological systems. The bonding interactions of ions with cellular membranes and tissue, which will consequently influence normal cellular functions, are also affected by ELF radiation. ELF, it has been shown, affects ion binding to cellular-membrane macromolecules, influences transmembrane ion transport, and alters membrane-signaling events. Ryan has suggested that ELF might affect the mussel's ability to assimilate calcium from water and also remove calcium from the shells and bodies of the zebra mussels. Proper containment of zebra mussel is necessary to prevent further spread of this nuisance non-indigenous species throughout the United States fresh water rivers and lakes (Fig. 7). Besides the distribution through connecting water ways, the mussel can survive a 3,000 mile trip by boat and trailer if the boat is not adequately cleaned after being pulled from a contaminated lake.

PACKAGE PLANTS

National Drinking Water
Clearinghouse

Small water treatment systems often find it difficult to comply with the U.S. Environmental Protection Agency (EPA) regulations. Small communities often face financial problems in purchasing and maintaining conventional treatment systems. Their problem is further complicated if they do not have the services of a full-time, trained operator. The Surface Water Treatment Rule (SWTR) requirements have greatly increased interest in the possible use of package plants in many areas of the country. Package plants can also be applied to treat contaminants such as iron and manganese in groundwater via oxidation and filtration.

PACKAGE PLANTS: ALTERNATIVE TO CONVENTIONAL TREATMENT

What is a Package Plant?

Package technology offers an alternative to in-ground conventional treatment technology. They are not altogether different from other treatment processes although several package plant models contain innovative treatment elements, such as adsorptive clarifiers. The primary distinction, however, between package plants and custom-designed plants is that package plants are treatment units assembled in a factory, skid mounted, and transported to the site.

These units are most widely used to treat surface water supplies for removal of turbidity, color, and coliform organisms with filtration processes. However, many other treatment technologies are available to small systems as package plants. These technologies or a combination of them can be incorporated into a package plant to provide comprehensive water treatment, including:

- disinfection (chlorination, ozonation, ultraviolet radiation),
- filtration (bag and cartridge filters, membrane filtration including reverse osmosis or ultra filtration, slow sand filtration, pressure filtration, diatomaceous earth filtration),
- aeration,

- ion exchange,
- adsorption (using powdered activated carbon or granular activated carbon), and
- softening.

How to Select a Package Plant

Package plant systems are most appropriate for plant sizes that treat from 25,000 to 6,000,000 gallons per day (GPD) (94.6 to 22,710 cubic meters per day). Influent water quality is the most important consideration in determining the suitability of a package plant application. Complete influent water quality records need to be examined to establish turbidity levels, seasonal temperature fluctuations, and color level expectations. Both high turbidity and color may require coagulant dosages beyond many package plants design specifications. Pilot tests (tests that evaluate treatment processes and operations on a small scale to obtain performance criteria) may be necessary to select a package plant for more innovative designs using high flow rates and shorter detention time unit processes. Package treatment equipment manufacturers often perform these tests.

System Description and Design Considerations

Package plants can differ widely with regard to design criteria, and operating and maintenance considerations.

Package Plant Advantages

Package plants arrive on site virtually ready to operate and built to minimize the day-to-day attention required to operate the equipment.

Other major advantages of package plants are compact size, cost effectiveness, relative ease of operation, and design for unattended operation.

The main advantages of a packaged factory-finished system are savings in engineering, design and installation costs, and operation and maintenance. These features make package plants attractive to communities that must operate on a tight budget.

Package plants can effectively remove turbidity and bacteria from surface water of fairly consistent quality, provided that they are run by competent operators and are properly maintained. Package plants also can be designed to remove dissolved substances from the raw water, including color-causing substances and trihalomethane precursors (which are organic materials in source water that can react with chlorine to form disinfection by-products).

Package Plant Limitations

Highly variable influent water quality requires a high level of operational skill and attention, and that tends to negate the package plant advantages of low cost and automation.

Despite the relatively large number of package plants in use, many states are reluctant to endorse them completely.

The requirements of the Safe Drinking Water Act and its amendments might challenge package capability. Challenges include the possible inability of package plants to treat multiple types of contaminants.

Many communities are currently using package plants to treat water supplies, but little data has been collected to demonstrate long-term performance and operations of these systems. State agencies responsible for reviewing plans for the installation of package systems must review each potential plan on a case-by-case basis, with only their own experience to judge the potential for success or failure. Presently, there is no national verification process for package plants.

Types of Package Plant Filtration Systems

Conventional Package Plant. Conventional package plants are manufactured by several firms to a variety of specifications. As their name indicates, they contain the conventional processes of coagulation, flocculation, sedimentation, and filtration. Typical design standards for these units are:

- 20 to 30 minute flocculation detention time,
- 2 hour sedimentation detention time, and
- rapid sand filters rated at 2 gallons per minute (gpm) per square foot (1.34 liter/second/square meter).

Tube-Type Clarifier Package Plant. Tube-type clarifier package plants use tube settlers to reduce settling detention time (the average length of time water remains in the tank or chamber).

A flow diagram of a tube-type clarifier package plant is illustrated in (Fig. 1). This type of plant has two versions with different capacity ranges; one version can treat from 10 to 100 gpm (0.63 to 6.3 liters/second), and the other, equipped with dual units, can treat from 200 to 1,400 gpm (12.6 to 88.3 liters/second).

In these package systems, the disinfectant, primary coagulant, and polymer coagulant aid are added before the influent enters the flash mixer; then the water enters the flocculation chamber where mechanical mixers gently agitate the water for 10 to 20 minutes depending on the flow.

The flocculated water then enters the tube settlers, which consist of many 1 inch (2.5 centimeters [cm]) deep, 39 inches (99 cm) long split hexagonal shaped passageways. The large surface area of the many 1 inch (2.5 cm) deep tube settlers achieves an effective clarification overflow rate of less than 150 GPD/square foot (6.1 cubic meters/day/square meters). Adequate clarification is attained with less than 15 minute detention times.

The clarifier water then enters a gravity flow mixed-media filter (a filter with a coarse-to-fine gradation of filter media or several types of filter media). A constant filtration rate is maintained by a low-head filter effluent pump discharging through a float-operated, level control valve. After a preset headloss is reached, backwashing of the filter is initiated automatically. (Headloss is pressure or energy loss as a result of turbulence caused by the velocity of water flowing and the roughness of the channel walls.) A manual backwash cycle can be initiated any time (if desired). Settled sludge from the tube settlers is flushed during the backwashing cycle. Combining backwashing and tube settler flushing simplifies operations and reduces operator skill requirements.

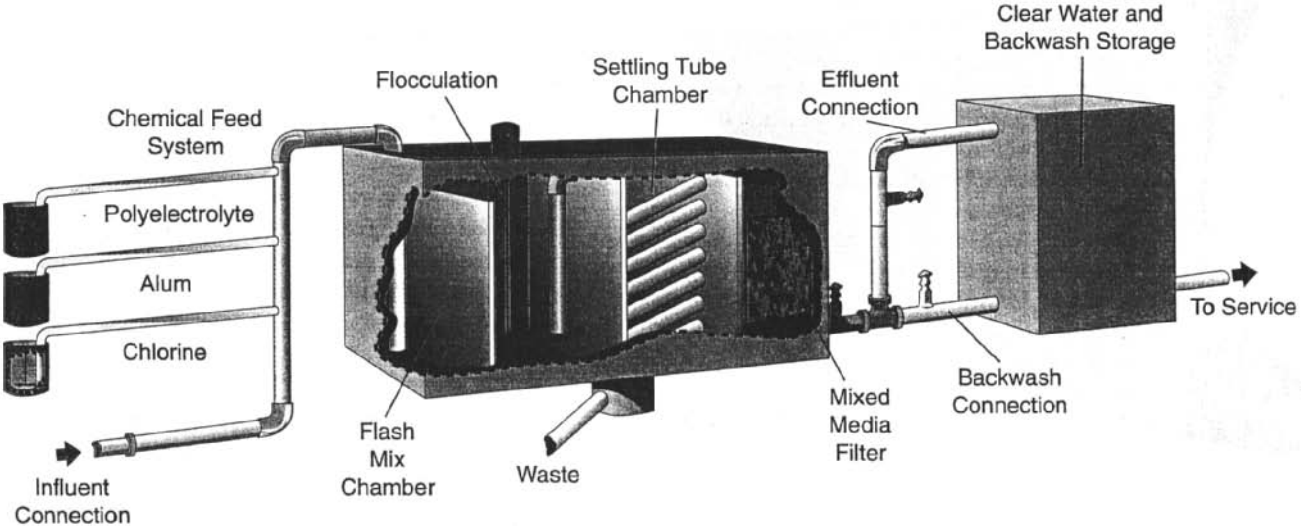

Figure 1. Tube-type clarifier package plant. *Source*: U.S. Environmental Protection Agency, 1989.

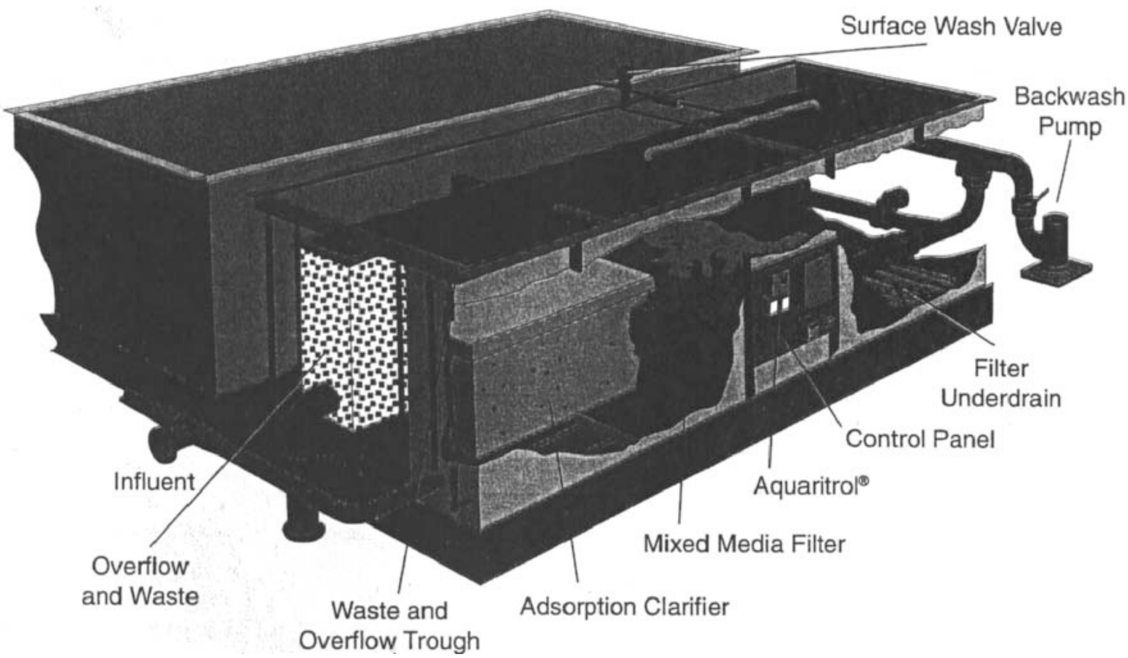

Figure 2. Adsorption clarifier package plant. *Source*: U.S. Environmental Protection Agency, 1989.

Adsorption Clarifier Package Plant. Adsorption clarifier package plants use an upflow filter with low density plastic bead media (called the adsorption clarifier) to replace the flocculation and sedimentation basin, thereby combining these two steps into one. A mixed media filter completes the treatment. Figure 2 shows a typical example.

While passing through the adsorption media, the coagulant and water are mixed, contact flocculated, and clarified. The mixing intensity, as measured by the mean velocity or gradient, ranges from 150 to 300 feet per second. Flocculation is accomplished through turbulence as water passes through the adsorption media. In addition, flocculation is enhanced by contact between the flocculated materials and the floccoated media. Turbidity is reduced through adsorption of the coagulated and flocculated solids onto the adsorption media and the previously adsorbed materials. The adsorption clarifier can achieve 95 percent or greater removal at 10 gpm/square foot (6.8 liters/second/square meter). This highly efficient clarification method results in extremely compact designs.

Adsorption clarifiers are cleaned by a combination of air scouring followed by water flushing. The air scouring starts the cleaning process for the plastic media used in the clarifier. Adsorption clarifier cleaning is initiated more frequently than filter backwashing because more solids are removed by the clarifier. The clarifier cleaning process is automatically initiated either by a timer or a pressure switch that continuously monitors headloss across the adsorption media.

The air introduced under the adsorption media causes a vigorous scrubbing action. The scrubbing action dislodges solids, which are washed away by the flow of the incoming water. Flushing is generally timed to occur between every fourth and eighth hour. Complete cleaning of the adsorption media is not desired because performance is enhanced by some residual solids.

Operation and Maintenance

Package plant operation is simplified by automated features such as effluent turbidimeters connected to chemical feed controls and other operating parameters, such as backwashing. Chemical feed controls are especially important for plants without full-time operators or with variable influent characteristics. Maintenance requirements are well documented in manuals. However, the operator needs to be well acquainted with water treatment principles and the plant manual, and should have attended a comprehensive training session.

The effluent turbidimeters and fail-safe controls are built into many plants to ensure that the finished water does not exceed set turbidity levels. Automated chemical feed systems are especially appropriate for plants without full-time operators or with highly variable influent characteristics.

Typical plant operator and maintenance manuals contain operating principles, methods of establishing proper chemical dosages, operating instructions, and trouble shooting guides.

Periodic visits by the manufacturer to make adjustments to the plant and inspect the equipment operation and performance are recommended. The first visit should be no more than six months after initial operation; the next should follow in another six months. Subsequently, annual visits should be sufficient.

Operators are the critical factor in overall success of any package plant, particularly in situations where raw water quality varies. When the automation fails, the operator needs to turn off the automatic controls/instrumentation and operate the plant manually.

Where Can I Find More Information?

Information in this fact sheet was obtained primarily from two sources:

(1) *Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities*, EPA/625/4-89/023; and
(2) “Package Plants for Small Systems: A Field Study” by Susan Campbell, Benjamin W. Lykins Jr., James Goodrich, Dallas Post, and Trudie Lay. *AWWA Journal*, Nov. 1995 pages 39–47.

Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities can be ordered free from the U.S. Environmental Protection Agency Office of Research and Development at (513) 569-7562.

The National Drinking Water Clearinghouse (NDWC) offers this document also, but at a cost to help recover photocopying expenses. *Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities*, a 209-page book, costs $30.05. To order, call the NDWC at (800) 624-8301 or (304) 293-4191 and request item #DWBKDM04. NDWC products also may be ordered via e-mail at ndwc_orders@ndwc.wvu.edu. Postal charges are added to orders.

Also, the NDWC's Registry of Equipment Suppliers of Treatment Technologies for Small Systems (RESULTS) is a public reference database that contains information about technologies in use at small water systems around the country. For further information, call the NDWC at one of the above numbers.

Additional free copies of Tech Brief fact sheets are available at the above numbers or you may download Tech Briefs from our Web site at http://www.ndwc.wvu.edu.

ANAEROBIC SEWAGE TREATMENT

Lucas Seghezzo
Grietje Zeeman
Gatze Lettinga
Wageningen University and
Research Center
Wageningen, The Netherlands

WHAT IS SEWAGE?

Sewage is the wastewater generated by a community, namely: a) domestic wastewater, from bathrooms, toilets, kitchens, etc., b) raw or treated industrial wastewater discharged in the sewerage system, and sometimes c) rainwater and urban runoff (1). Domestic wastewater is the main component of sewage, and it is often taken as a synonym. Sand and coarse material (paper, bottles, etc.) are not considered part of sewage. They are transported by sewage but handled as solid waste when they arrive at a treatment facility. The sewage flow rate and composition vary considerably from place to place, depending on economic aspects, social behavior, type and number of industries in the area, climatic conditions, water consumption, type of sewers, etc. The main pollutants in sewage are suspended solids, soluble organic compounds, and fecal pathogenic micro-organisms. In addition, a variety of chemicals, like heavy metals, trace elements, detergents, solvents, pesticides, and other unusual compounds like pharmaceuticals, antibiotics, and hormones can also be detected in sewage. With urban runoff come potentially toxic compounds like oil from cars and pesticides that may reach the treatment plant and, eventually, a water body.

WHY SHOULD WE TREAT SEWAGE?

Direct discharge of raw or poorly treated sewage into the environment is one of the main sources of pollution on a global scale (2). Improved sanitation would have a significant impact on people's lives in terms of safety, privacy, convenience, and dignity (3). Sanitation is also a good starting point for addressing long-term poverty issues and reducing child mortality, because children are more susceptible to suffer from inadequate water supply and sanitation services. The lack of water, sanitation, and hygiene for all was dubbed as "... one of the biggest scandals of the last 50 years" (4). Simple, affordable, and efficient sewage treatment systems are urgently needed, especially in developing countries, where most of the conventional technologies currently in use in industrialized nations are too expensive and complex (5). Sustainable sewage treatment technologies will help to preserve water ecosystems and their biodiversity, indispensable for the provision of clean water, flood control, and other vital services.

Today, several technological options are available for sewage treatment, ranging from traditional waste stabilization ponds (WSP) to conventional aerobic systems (like trickling filters or activated sludge), from anaerobic reactors to integrated systems in which a variety of biological processes can be applied. Anaerobic processes are attracting the attention of sanitary engineers and decision-makers more and more, especially the upflow anaerobic sludge bed (or blanket) (UASB) reactor developed in the early 1970s by Lettinga and co-workers (6). Anaerobic sewage treatment in UASB reactors is an absolute success in tropical countries like India and Brazil, but it is also finding its way in other regions, even in subtropical and more temperate countries. Recent studies showed that it can be successfully applied at temperatures as low as 15 °C for a variety of different types of sewage (7–9). The lack of sewage treatment is not at all a technological or economic problem but a political one. In fact, governments, even from developing countries, have been spending billions of dollars per year on water and sanitation, usually to build expensive, centralized sewers and sewage treatment facilities for a few privileged citizens instead of low-cost appropriate sanitation systems for the needy majority.

THE PROCESS OF ANAEROBIC DIGESTION

Anaerobic bacteria, belonging to the domain Archaea, are the most ancient forms of life on earth. They evolved about 3.7 billion years ago in an oxygen-free atmosphere and fed from the nutrients in the aqueous environment around them. When, because of the action of cyanobacteria and algae, the atmosphere became dangerously full of oxygen, anaerobic bacteria were relegated to niches where anaerobic conditions could still be found. Anaerobic bacteria thrive today in the bottom of marshes, swamps, and wetlands, and in the stomach of ruminants, insects, and humans, where they degrade organic matter and produce biogas, a mixture of methane and carbon dioxide with a small percentage of hydrogen sulfide and traces of other gases.

The anaerobic (bio)degradation of complex, particulate organic material has been described as a multistep process of series and parallel reactions catalyzed by several groups of bacteria (10,11). Seven subprocesses are now recognized during anaerobic digestion: (1) hydrolysis of complex, particulate organic materials (proteins, carbohydrates, and lipids); (2) fermentation of amino acids and sugars; (3) anaerobic oxidation of long-chain fatty acids and alcohols; (4) anaerobic oxidation of intermediary products such as short-chain fatty acids (except acetate); (5) acetate production from carbon dioxide and hydrogen (homoacetogenesis); (6) conversion of acetate to methane (aceticlastic methanogenesis); and (7) methane production by reduction of carbon dioxide by hydrogen.

Hydrolysis was found to be the rate-limiting step in the degradation of wastewaters like sewage, high in volatile suspended solids (12). Hydrolysis rate in anaerobic systems is normally described as a first-order process with respect to the concentration of degradable particulate organic matter (13). Preliminary conversion mechanisms such as cell death and lysis are the first steps in the process of transforming viable micro-organisms to available substrate and can also be included in a kinetic model of the anaerobic digestion of aerobic sludges. However, these processes have been found not to be rate-limiting (14). Even if cell death and lysis were an important factor in the overall kinetics of anaerobic degradation, these processes are not applicable in the case of treatment of raw domestic sewage, and therefore hydrolysis may be considered as the only possible rate-limiting step in this case (15).

Some factors affecting the rate and extent of the anaerobic degradation of organic matter are temperature, pH, particle deposition, internal mixing in the reactor, and presence of toxic compounds. Further details on the effect of these factors is beyond the scope of this work and can be found in Heertjes and van der Meer (16), Rittmann and Baskin (17), Bouwer (18), Bohle (19), and van Haandel and Lettinga (1), among others.

ANAEROBIC SEWAGE TREATMENT

Anaerobic processes have been used to treat domestic and industrial wastewater for more than a century (20,21). The septic tank is the oldest and most widely used example. The striking success of the UASB reactor (Fig. 1) made anaerobic systems come back to the forefront, and they are now used for the treatment of several types of wastewater.

The UASB concept is based on the establishment of a dense sludge bed in the bottom of the reactor, in which all biological processes take place. This sludge bed is formed by accumulation of incoming suspended solids and by bacterial growth. In upflow anaerobic systems, and under certain conditions, it was also observed that bacteria could naturally aggregate in flocs and granules (22). These dense aggregates have good settling properties and are not susceptible to washout from the system under normal reactor conditions. Retention of granular or flocculent active sludge within the UASB reactor enables good treatment performance at high organic loading rates. Natural turbulence caused by the influent flow and the biogas production provides good wastewater biomass contact in UASB systems. Several configurations can be imagined for a wastewater treatment plant including a UASB reactor. In any case, a sand trap, screens for coarse material, and drying beds for the sludge must

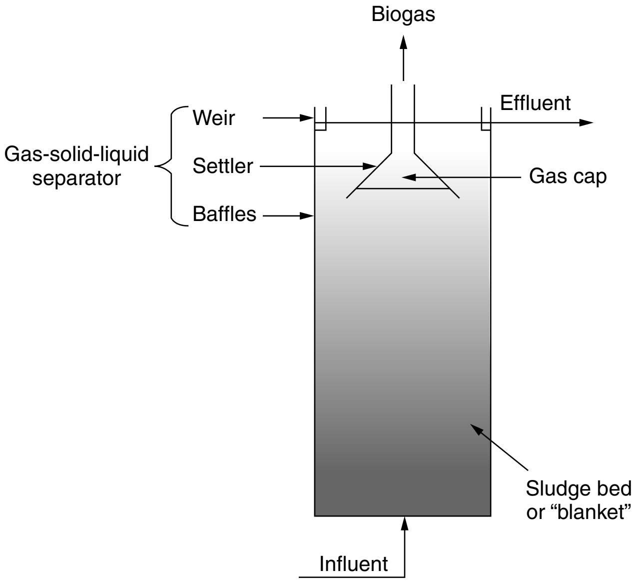

Figure 1. Basic scheme of a UASB reactor for sewage treatment.

exist. The UASB reactor may replace the primary settler, the anaerobic sludge digester, the aerobic step, and the secondary settler of conventional aerobic treatment plants like activated sludge or trickling filters.

UASB-based anaerobic treatment systems are recognized to be highly efficient, simple to construct and operate, and flexible to be applied on either a very large or a very small scale. UASB reactors have low space requirements and consume negligible amounts of energy, if any. Moreover, energy is produced during the process in the form of methane. The production of sludge is very low in comparison with aerobic methods, because of the slow growth rates of anaerobic bacteria. Besides, the sludge is well stabilized for final disposal, and it can be preserved for considerable periods of time without a significant reduction of its activity, allowing its use for the startup of new reactors. The process requires no additional nutrients, and an adequate and stable pH can be maintained without the addition of any chemicals. Anaerobic systems are well suitable for campaign industries because the adapted anaerobic sludge can be stored unfed within the reactor for entire seasons. The use of anaerobic systems can lead to a high degree of self-sufficiency.

Some disadvantages of anaerobic sewage treatment have been put forward, like low pathogen and nutrient removal. In fact, pathogens are only partially removed, except helminth eggs, which are effectively captured in the sludge bed. The removal of nutrients is also not complete and a post-treatment is generally required if the nutrients cannot be reused for agriculture or aquaculture within a reasonable distance from the treatment plant. The startup of anaerobic reactors usually takes longer compared with aerobic processes, unless good inoculum is available to speed up this stage. Hydrogen sulfide is produced during the anaerobic process, especially when high concentrations of sulfate exist in the influent. A proper handling of the biogas is then required to avoid bad smell. A significant proportion of the total amount of methane produced by the reactor is actually dissolved in the effluent. Its recovery may be required to minimize smell nuisances and methane emissions to the atmosphere. Substantial improvements have been made in tackling most of these alleged disadvantages (23).

Anaerobic treatment was considered economically more attractive and conceptually more holistic than aerobic treatment (24). The costs of aeration and sludge handling, the two largest costs associated with aerobic sewage treatment, would be reduced dramatically because no oxygen is needed in the process and the production of sludge is much smaller than in aerobic treatment (17). Moreover, the sludge (biomass) produced in aerobic processes has to be stabilized before it can be safely disposed of, which adds to the complexity of aerobic treatment plants. Anaerobic treatment can make a substantial contribution to the protection of the environment and the preservation of natural resources as part of a sustainable and appropriate wastewater treatment system for developing countries.

EXAMPLES OF SEWAGE TREATMENT IN ANAEROBIC REACTORS

UASB Reactors

The full-scale application of UASB reactors to domestic wastewater has been a success in tropical areas with sewage temperature above 25 °C (25). Studies in this field started many years ago in Cali, Colombia, where UASB reactors were found to be cheaper than facultative ponds and oxidation ditches, especially when capital costs were included (26). The efficiency of UASB reactors for sewage treatment was found to be similar in tropical and subtropical regions (sewage temperatures around 18–23 °C) using the same design parameters (9). The application of UASB reactors to sewage treatment under even lower temperature conditions has been studied in the Netherlands since 1976 (27,28). Promising results were obtained in Jordan, with UASB reactors treating strong raw sewage at a temperature of 18 °C in winter and 25 °C in summer (8). Encouraging results have also been obtained in the Mediterranean area (29). Although substantial experience on the design and operation of UASB reactors for sewage treatment has been gathered lately, most of the results have not been published (30). Under specific conditions, the use of two-stage anaerobic reactors (8,31–33), additional heated sludge digesters (7), or chemically enhanced primary sedimentation (34) have been proposed to further improve the performance of anaerobic systems.

Other Technologies

Technologies other than the UASB, like the anaerobic filter (35), traditional anaerobic digesters currently in use in China, the anaerobic attached film expanded bed (AAFEB) system (36), plug-flow reactors, and modified anaerobic baffled reactors (37), among others, have also been used for the anaerobic treatment of sewage.

Post-Treatment

Anaerobic sewage treatment systems generally fail to comply with COD discharge standards, as established by Council Directive 91/271/EEC on Urban Waste Water Treatment, dictated by the European Union Council of Ministers (38) (125 mgCOD/L), or the guideline proposed by the World Health Organization (39) for unrestricted irrigation (less than 1000 fecal coliform per 100 mL and less than 1 helminth egg per L). Therefore, a post-treatment step is mandatory in most cases to remove remnant COD, fecal coliform (as an indicator of pathogenic micro-organisms), helminth eggs, and even nitrogen and phosphorus when direct reuse is not feasible. WSP are among the most efficient and cost-effective post-treatment methods available (40). Other post-treatment methods are the biorotor system, or rotating biological contactor (41), integrated duckweed and stabilization pond system (42), trickling filters (43), and activated sludge (44), among others. See the review presented by Tawfik (41).

On-Site Systems

Application of modified UASB reactors for single households in isolated locations, like farms and recreational facilities not connected to the centralized sewerage system, was studied under different temperature conditions in the Netherlands (45) and Indonesia (46). These systems were called UASB septic tanks, because they shared features of both methods. Sludge gradually accumulates in the reactor, as in septic tanks, but they are operated in upflow mode, as UASB reactors. The design is almost as simple as that of conventional septic tanks, but the treatment efficiency is much higher (47). Suggestions for improving the treatment efficiency in these systems include the use of two- or three-stage UASB reactors and the adoption of post-treatment methods, like small aerobic lagoons (46). The UASB process was also applied to treat sewage from small-size communities in Brazil (48). The potential of anaerobic technology in so-called DESAR (Decentralized Sanitation And Reuse) schemes is huge, and more efforts should be directed to test these systems in the field (23).

WHAT IS THE FUTURE OF ANAEROBIC SEWAGE TREATMENT?

Anaerobic reactors should be more widely applied in tropical countries as the main pretreatment step for sewage. Conditions for anaerobic digestion are so good under these conditions that the application of any other system to treat the organic pollution in sewage is highly questionable on technical, environmental, economic, and social grounds. The application of UASB reactors for sewage treatment could be safely expanded to subtropical regions, and clear indications exist that even in temperate regions its use should not be discarded altogether. Anaerobic systems should also be used in DESAR schemes where the preservation of water, nutrients, and energy is indispensable. Anaerobic systems can significantly contribute to the achievement of more sustainable sanitation in most developing countries, and their potential should be recognized and explored by universities, private companies, and governments.

PERSISTENCE OF PATHOGENS IN WATER

ABID M. NASSER

Tel-Aviv, Israel

WATERBORNE PATHOGENS SIGNIFICANT TO HEALTH

Natural water sources become contaminated with pathogenic micro-organisms by the discharge of inadequately treated wastewater. Four major pathogen groups can be found in wastewater: over 100 types of enteric viruses, 7 types of pathogenic bacteria, 10 types of protozoan parasites, and 6 types of helminthes of health significance to humans and animals. The concentration of pathogenic micro-organisms in wastewater is affected mainly by the amount of precipitation, the season of the year, and the socioeconomic status of the community. For most pathogenic micro-organisms, the methods of detection are expensive, time-consuming, and difficult to perform. Therefore, data on the prevalence of pathogenic micro-organisms in wastewater effluents and natural water sources is limited to types for which a detection technique was developed. The recently developed molecular biology-based techniques enhanced our capability in detecting human pathogenic micro-organisms in water sources.

The viruses that are detected most often in polluted water are enteroviruses, because of the availability of tissue culture for virus cultivation and enumeration. In wastewater, researchers reported on the presence of 1000 pfu/L enteroviruses (1). Discharge of inadequately treated wastewater may result in the viral contamination of natural water sources. Enteric viruses have been detected in rivers, lakes, and even in groundwater. Using reverse transcription-PCR (RT-PCR), it was reported that 24 out of 48 well water samples (50%) were found positive for enteric viruses, including enteroviruses, rotaviruses, hepatitis A virus, adenoviruses, and noroviruses, and 10 out of 12 river water samples (83%) were found positive for viruses by RT-PCR (2).

Giardia cysts and *Cryptosporidium* Oocysts were detected in 100% raw wastewater samples at a concentration of 10^3 cysts/L and 5×10^2 oocysts/L, respectively (3). Most conventional wastewater treatment processes result in the reduction of parasites in the treated effluent; however, the remaining low numbers may pose a health risk. *Cryptosporidium* was detected in 50% of effluent samples of oxidation ponds. Mayer and Plamer (4) reported 99.9% removal for *Giardia* and 99% for *Cryptosporidium* by biological treatment of wastewater. *Cryptosporidium* and *Giardia* were removed by 90% and 99%, respectively, by activated sludge treatment. Despite difficulties in detecting procedures, the number of Cryptosporidium oocysts detected ranges from 0.005 to 252.7 oocysts/L of surface waters in different countries of the world. In a study conducted in Japan, it was found that oocysts of *Cryptosporidium* increased in numbers from late summer to early autumn, and the maximum number of oocysts detected in three rivers was 3.3 to 5 oocysts/L (5). The reported frequencies of occurrence of contamination of surface water with *Giardia* and *Cryptosporidium* are from 60–96% in the United States and from 20–64% in Canada. Their levels in surface waters were found to be very low, ranging from 0.5 to 5,000 oocysts in 100 liters of water. Analysis of 139 surface water samples in Finland revealed the presence of *Giardia spp.* in 19 (13.7%), *Cryptosporidium* oocysts in 14 (10.1%), and Noroviruses in 13 (9.4%) of the samples (6). The pathogens were isolated less frequently during the winter than during the summer months. Based on risk analysis, it has been proposed that the action levels to prevent outbreaks with these protozoa should occur when concentration in 100 liters water sampled are >5 *Giardia* cysts and 10 to 30 oocysts of *Cryptosporidium* (7).

PERSISTENCE OF PATHOGENS IN WATER

Most of the persistence data for micro-organisms was generated in laboratory experiments. Micro-organisms are seeded into water of certain quality and incubated at test temperature. The concentration of micro-organisms in the suspension is measured as a function of time. To investigate the effect of environmental factors under field conditions on the survival of micro-organisms, investigators have used environmental chambers. The chambers are of small volume that contain the micro-organisms in the matrix, but allow limited exchange with the surrounding environment by means of permeable membrane. Using sentinel chambers, Keswick and Gerba (8) reported the survival of micro-organisms ranked in increasing order were *E.coli*, fecal streptococcus, f2 bacteriophages, SA-11 rotavirus, echovirus 1, coxsackievirus B3, and poliovirus 1. Enteric viruses and bacteria were reported to survive longer in groundwater than in surface water, which was attributed to a number of factors, including lower temperatures, protection from sunlight, and limited microbial antagonisms.

Temperature is the most important factor that influences pathogenic micro-organisms persistence in the natural water and in the environmental setting in general (9). Inactivation rates increase with temperature, and temperature can therefore be a useful predictor of pathogen die-off in the environment (10). Moisture content and loss of moisture are also related to pathogen survival (10). In general, the survival of many micro-organisms is prolonged at lower temperatures, whereas at elevated temperatures, inactivation or die-off is fairly rapid. It is important to examine more than one stressor because, under natural environmental settings, multiple factors may influence the persistence of pathogens. A study was conducted in our laboratory to examine the impact of temperature, salinity, and organic material load on the persistence of *E.coli*, Coxsackievirus A9, and *Cryptosporidium* parvum. At 30 °C, the fastest die-off was observed for Cox A9 virus, where die-off of 5 orders of magnitude was recorded regardless of the water quality. At 15 °C, Cox A9 persistence was similar to that of *Cryptosporidium*, and no change was observed in the concentration of both organisms after 30 days incubation. Whereas a die-off of 5 orders of magnitude was recorded for *E.coli*. The die-off of *E.coli* was faster than that of the other tested micro-organisms regardless of the water quality In a previous study, we compared the persistence of *E.coli*, F+coliphages, poliovirus 1, and hepatitis A virus in phosphate buffered saline (PBS), groundwater, and raw wastewater. In this study, it was determined that micro-organism type and temperature are the most important factors influencing the persistence of micro-organisms in natural waters. Indigenous F+ bacteriophages persisted longest followed by Poliovirus 1, HAV, and the bacterial indicator *E.coli*. The enhanced inactivation of viruses at higher temperatures may be attributed to greater microbial activity in the natural waters. The microbial activity of *P.aeroginosa* has been shown to accelerate the die-off of enteric viruses and other pathogenic micro-organisms. At lower temperatures, where the microbial activity is low, *Cryptosporidium* oocysts' concentration was reduced by only one order of magnitude after 160 days of incubation. Microbial activity has been shown to enhance the die-off of HAV in wastewater, and the time needed for the inactivation of 90% of the virus at 25 °C was 8.3 days as compared with 15.1 days in autoclaved waste (11).

Short-wave ultraviolet (UV) components of sunlight are lethal to enteric pathogens. UV is used for disinfection in water and wastewater treatment processes. The site of the UV damage is the nucleic acid, where the damage inhibits the multiplication capability of the micro-organisms. UV damage may be reduced by the DNA repair mechanisms present in some cells. In marine water, the inactivation rate of *Cryptosporidium* oocysts, poliovirus 1, *Giardia* cysts, and salmonella increased when exposed to natural sunlight, with oocysts exhibiting the highest persistence Sattar et al. (12) demonstrated a detrimental effect on oocyst survival of exposure to sunlight and UV light.

Most of the data generated for the prevalence of the protozoan parasites *Cryptosporidium* and *Giardia* in natural water sources is based on microscopic determination of their presence and viability. As the concentration of the parasites in natural water is low, there were no attempts reported to correlate the viability and the infectious state of naturally occurring parasites in natural waters. Although laboratory experiments have shown that the protozoan parasites may persist for longer periods of time in natural waters, their infectivity potential should be determined in order to more accurately assess the health risk posed by these parasites in natural waters.

PREDICTING THE PERSISTENCE OF PATHOGENS IN WATER

Data on the persistence of pathogens in water generated in laboratory and field experiments can be used to establish models to predict the time needed to inactivate pathogens under various natural sittings. The die-off of sensitive micro-organisms can be described by linear regression equation

$$Y = b + aX$$

where Y represents the response, b represents the y-axis intercept, X represents the independent variable (time), and a is the slope. The value of the slope a is influenced by factors affecting the persistence of pathogens in water. For example, at 15 °C, the slopes recorded for *E.coli*, Coxsackievirus A9, and *Cryptosporidium* in stream water were -0.14, -0.06, and -0.01, respectively. At 30 °C, the die-off slopes for *E.coli* and *Cryptosporidium* did not change; however, that of coxsackie A9 increased to -0.14. The effect of part of the environmental variables on the survival of micro-organisms was found to be significant. The effect of temperature on the persistence of pathogenic micro-organisms was found significant in numerous studies (9). Therefore, the effect of temperature can be predicted by the linear regression equation. On the other hand, water quality effect was not found to be significant. Furthermore, the interaction of water quality with temperature was not found to be significant. The effect of micro-organism type on the persistence in water is significant, and also the interaction of micro-organism type and temperature was found to be significant (9). It is possible to classify micro-organisms into three groups according to their capacity to persist in waters and, consequently, use a multiple linear regression equation in which a slope value for each independent variable will be assigned (10).

CONCLUSIONS

1. Pathogenic micro-organisms may be introduced to natural water sources and may be present at concentrations that may pose health risks.
2. At low temperatures, viruses and protozoa parasites may persist for prolonged periods of time in natural water sources, which will enable their transmission to people consuming the contaminated waters.
3. Most studies in which the persistence of fecal coliforms was compared with those of pathogenic viruses and protozoan parasites revealed that the bacterial indicator is more sensitive than the pathogens and, therefore, it dose not accurately represent the health risks posed by these pathogens in natural waters.

WELL HEAD PROTECTION

Babalola Makinde-Odusola
Public Utilities
Riverside, California

Groundwater, especially karst aquifers (1) or groundwater under the direct influence (2) of surface water, is vulnerable to contamination from possible contaminating activities (PCAs) (3) related to land use. A wellhead protection (WHP) plan (WHPP) essentially includes the integrated proactive management practice(s) that protect the quality of groundwater that is a source of drinking water. WHP is part of an integrated (from source to consumer's tap) multibarrier system to reduce risks to public health from drinking water. WHP fits into the World Health Organization's (WHO's) Water Safety Plan that recommends the use of hazard analysis and critical control points (HACCPs) as a risk management tool in drinking water operations (4). In the United States, many public water systems (PWSs) are required to conduct source water assessment (SWA) (3,5–7). For PWSs that source from groundwater, a WHPP can be part of their SWA program (SWAP). A PWS must develop its WHPP in accordance with guidelines established by regulatory agencies (1–3).

An important step in WHP is the delineation of one or more WHP zones (WHPZs) to form a WHP area (WHPA) that includes surface and subsurface zone(s) that reasonably contribute water to the well(s) that are being protected from potential source(s) of contamination. Methods and criteria for delineating protection zones range from simple geometric shapes to complex numerical groundwater models based on the specified time of travel (TOT) of contaminant (1,8–11). The most appropriate criterion and method for delineating the WHP zones are selected after careful assessment of many factors, including regulatory acceptance, susceptibility of the aquifer(s) to contamination, available hydrogeological data, computational and technical resources, and the hydrogeologic setting of the aquifer. "Derived/estimated" protection zones must be adjusted to meet the required minimal distances mandated by regulations. Delineation of a WHPA by itself does not protect groundwater quality. Delineation must be followed with the implementation of appropriate management strategies to prevent groundwater contamination and periodic evaluation of their effectiveness. Using a computer-based geographical information system (GIS) to map the protection zones is recommended (12). Cooperation among appropriate jurisdictional agencies and stakeholders is beneficial and may increase the effectiveness of the WHPP.

INTRODUCTION

Groundwater is vulnerable to contamination from many PCAs such as leaching effluents from septic and underground storage tanks (USTs) or leaching pesticides and/or fertilizers. Emerging major concerns are xenobiotics (13) and organic wastewater compounds (14) in effluents from wastewater treatment plants and/or confined animal feeding operations (CAFOs) that may impair the beneficial use and/or environmental value of the groundwater. Xenobiotics include pharmaceuticals, hormones, and other compounds found in medicines and other personal care products. The U.S. Environmental Protection Agency (EPA) reported that over 200 different chemicals have been detected in groundwater in 38 states (15).

The goal of WHP is to manage PCAs to reduce, or preferably prevent, potential impairment of groundwater to assure public health. The U.S. EPA (16) estimated that, between 1971 and 1996, contaminated source waters (surface and groundwater) were the cause of 86% of waterborne disease outbreaks within the United States. The protection of surface water may often be linked to the protection of groundwater and vice versa. The failure of a pumping station from a lightning strike led to an outbreak of cryptosporidiosis in Brushy Creek, Texas, following the accidental discharge of raw sewage into a creek 2 mi upstream of the 120- and 200-ft deep municipal wells (17).

The U.S. EPA (16) observed that deep wells are not immune from biological contamination. Lawson et al. (18) reported an outbreak of gastroenteritis caused by Norwalk virus in water produced from a 600-ft deep well. In the aftermath of the Walkerton incident, Health Canada (19) identified WHP as one of the protective measures that should be implemented and maintained "if source water is subject to human fecal contamination or if human enteric viruses have been responsible for past waterborne outbreaks." The U.S. EPA (16) proposed the Groundwater Rule (GWR) to address risks of consuming waterborne pathogens in groundwater.

Many states require source water assessment before permitting new drinking water sources (such as wells) for PWSs (3). For proposed PWS wells, WHP begins with the proper siting and construction of well(s) in accordance with good sanitary practices and recommended well design standards (20). A successful WHPP protects public health and avoids the expense of treating polluted water or drilling replacement wells (7). There are additional benefits from implementing WHP (21–23). The U.S. EPA identified over 90 measures as possibilities for measuring success of source water contamination prevention at the national level (24).

The United Kingdom Margate Act (11) of 1902 and Brighton Act of 1924 are examples of earlier efforts directed toward the protection of groundwater produced from wells used for drinking. The Margate Act empowered a water authority to control drains, cesspools, and so on over an area of 1500 yards from any well (11). In 1986, the U.S. Congress introduced a Wellhead Protection Program (WHPP) as part of the Amendments to the Safe Drinking Water Act (SDWA) (25). A wellhead protection area (WHPA) as defined by that Act as "the surface and subsurface area surrounding a water well or well field, supplying a public water system through which contaminants are reasonably likely to move toward and reach such well or well field." The U.S. EPA (16) sometimes refers to a WHPA as "groundwater protection area." The California Department of Pesticide Regulation (DPR) defines a groundwater protection area (GWPA) as "an area of land that is vulnerable to the movement of pesticides to ground water according to either leaching or runoff processes" (26).

Amendments to the SDWA in 1996 required states to establish source water assessment programs (SWAPs) (6). Sourcewater protection is the generic term for describing management activities to protect the quality of water used for drinking water irrespective of the nature of the source: surface water, groundwater, or groundwater under the influence of surface water. Source water protection is the leading first barrier of the multibarrier approach to protecting the quality of drinking water delivered to consumers. Other elements of the multibarrier protection framework against pollution are source water treatment (including disinfection), distribution system integrity (including cross-connection control programs), and public information. The Minnesota Department of Health (7) differentiates between "source water assessment" plan and a "wellhead protection plan" as two different documents, with separate and distinct purposes. A PWS that sources from groundwater can use the completed SWA plan in developing a WHPP (7).

DEVELOPING A WHPP FOR A PWS

Many countries have developed regulations governing the practice of WHP (2,9–11). In the United States, the SDWA mandated states to develop WHP programs that must include some specified elements (9,22). The U.S. EPA must approve state WHP programs before implementation. As of 2004, the U.S. EPA has approved WHP programs for all states except Virginia (27). WHP programs developed by states provide regulatory guidance to PWSs on how to develop appropriate WHP plans (3,7).

Typical steps for developing a WHP plan include the following: (1) defining the statement and purpose of the WHP; (2) defining the members, roles, and duties of the team; (3) delineating the WHP zones; (4) inventorying the PCAs; (5) assessing the vulnerability; (6) developing management programs; (7) developing contingency plans for alternative water supplies; and (8) developing an optional source water protection program (9,22,28). Those steps are mainly sequential, but some steps can also be iterative.

Many PWSs have developed WHP plans, some of which included stakeholder participation. Some examples are available on the Internet (29,30). The U.S. EPA (31,32) maintains a directory of useful tools for developing a WHPP. Witten et al. (28) identified some financing strategies for wellhead protection.

DELINEATION CRITERIA AND METHODS

An important step is the delineation of one or more protection zones to which WHP management measures would be tailored. Five major criteria that may be used singly or in combination to delineate a protection zone are distance, drawdown, time of travel (TOT), assimilative capacity, and flow boundaries (8,9). Factors that determine the preferred delineation criterion/criteria include local regulatory requirements, number of wells involved, complexity of aquifer(s), spatial extent, and available resources and professional skills. The delineation methods can be deterministic or stochastic. Kunstmann and Kinzelbach (33) describe stochastic methods for delineating a WHPA.

The distance criterion is the simplest and least expensive. It is based on a fixed perimeter radius around the well professionally "judged" adequate to provide reasonable protection. The drawdown criterion is based on the zone of influence (ZOI) where groundwater level declines due to pumping from the well. The TOT criterion requires the delineation of isochrones (i.e., contours of equal time) representing the duration it takes for water to reach a well or a contaminant to reach a well in concentration exceeding a target level. The assimilative capacity criterion permits reduction in the spatial extent of the zone of contribution (ZOC) of the WHPA when contaminants can be attenuated to concentrations lower than the target level before reaching the well through biogeochemical processes such as dilution, dispersion, sorption, or biodegradation. The flow boundary criterion uses physical and hydrogeologic features that control groundwater flow to define the spatial extent, that is, the ZOC of the WHPA.

The U.S. EPA (9) categorized the methods for delineating into four major groups of increasing complexity: geometric, simple analytic (SA), hydrogeologic mapping (HM), and computer modeling (CM). Geometric methods involve the use of a predetermined fixed radius or simplified shapes that have been precalculated for a range of pumping and aquifer conditions. Examples are the arbitrary fixed radius (AFR), calculated fixed radius (CFR), and modified CFR.

AFR involves drawing a circle of defined distance around the well on a base map. The defined distance (radius) is based on professional judgment and regulatory acceptance. CFR is similar to the AFR but the radius is calculated based on the volume of cylinder with pore volume equal to the volume of water pumped during the specified period.

SA methods use appropriate analytical solutions to groundwater flow, such as the uniform flow equation, and known aquifer characteristics to derive protection zones. HM involves the use of a combination of hydrological, geological, and geochemical data and geologic mapping techniques to delineate the area contributing water to the well(s). HM methods are appropriate in settings where geologic features greatly influence groundwater flow such as in karst aquifers (15,34). CM methods numerically simulate groundwater flow and contaminant transport to calculate rate and direction of flow, travel times, and so on. The model developed may be used to compare the system's response to proposed management options (15).

The U.S. EPA (9) lists the advantages and disadvantages of each delineation method. The number of person-hours required to delineate a WHPA per well range from 1–5 for AFR to 10–200+ for numerical modeling (8). Figures illustrating the delineation methods are in given in Reference 9. Some states prefer specific methods for delineating WHPAs for special wells. California (13) prefers detailed hydrogeologic analyses when delineating WHPAs for nonvertical wells (e.g., horizontal wells). California (13) prefers using the delineation method that utilizes the most available detailed information. A combination of methods can be used to delineate one or more zones. For example, the innermost zone to the well may be based on a fairly simple geometry while the outermost protection zone may be delineated using complex numerical models.

WHP ZONES

A WHPA consists of one or more WHPZs, to which appropriate management measures can be tailored. The innermost WHPZ is usually delineated to protect against biological contaminants and to protect the integrity of the well. Some outermost zones regarded as buffer zones may be optional. In California (3), the suggested approach is to define four zones and an optional buffer zone. The required zones in California are (Fig. 1):

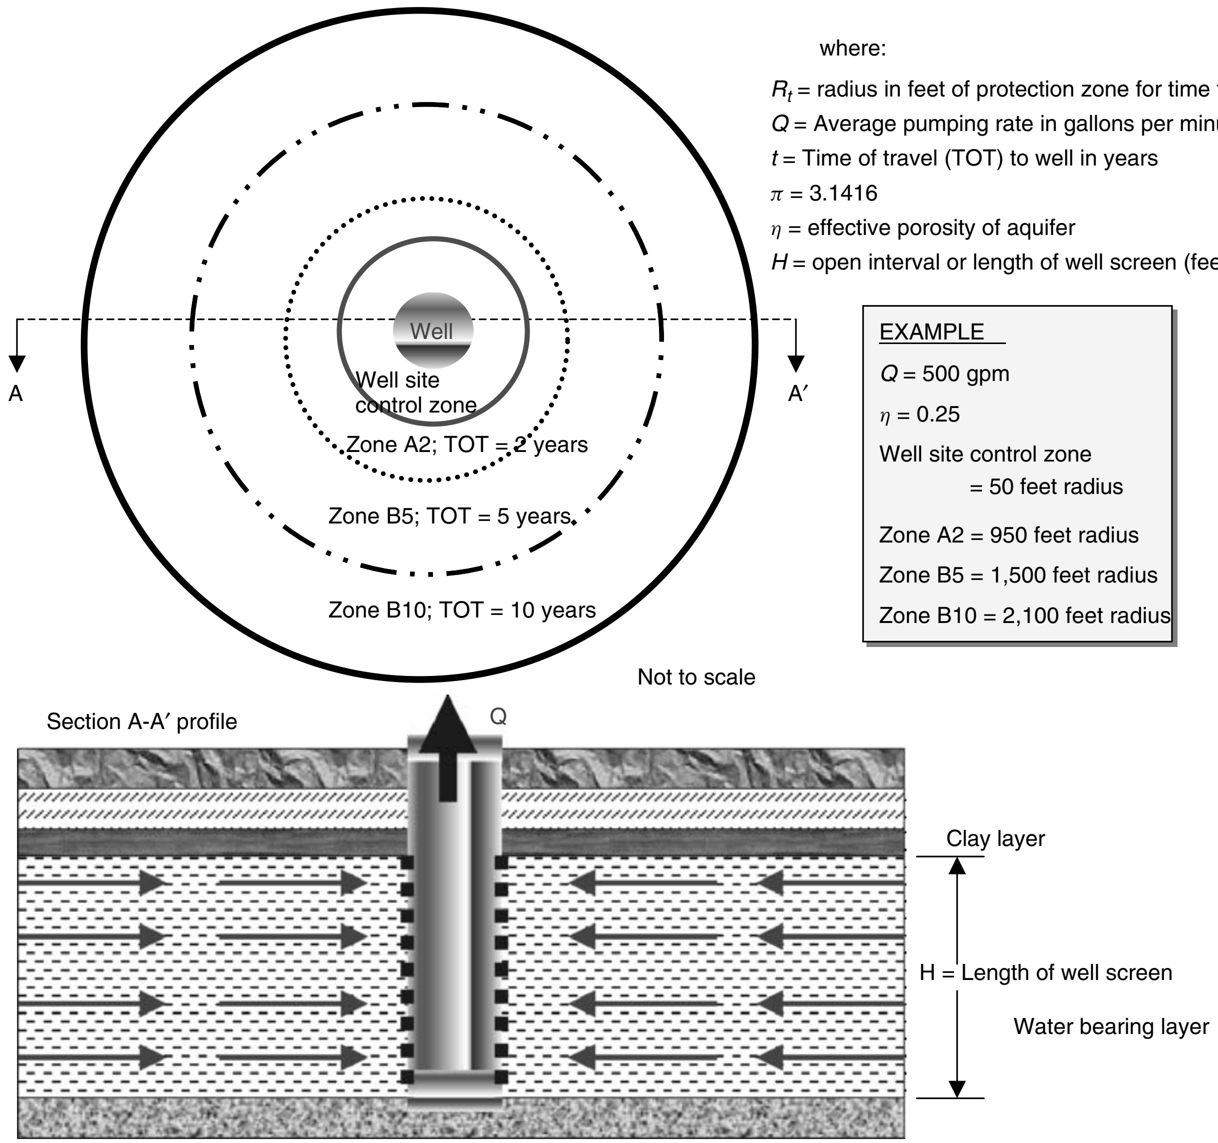
Well Site Control Zone (WSCZ). The closest zone to the wellhead is the area immediately surrounding the well. The WSCZ is managed to prevent seepage of contaminants, vandalism, or tampering. The recommended minimum radius is 50 ft.

Zone A2 or the Microbial/Direct Chemical Contamination Zone. This is the surface area above the aquifer that contributes water to well(s) within a 2-yr TOT. This zone was established to comply with the requirement of the proposed Groundwater Rule (8) based on research that bacteria and viruses are not likely to survive beyond 2 yr in soil and groundwater. Recommended minimum radii

$$R_t = \sqrt{(70,267Qt/\eta\pi H)}$$

where:

R_t = radius in feet of protection zone for time t
Q = Average pumping rate in gallons per minute (gpm)
t = Time of travel (TOT) to well in years
π = 3.1416
η = effective porosity of aquifer
H = open interval or length of well screen (feet)



EXAMPLE
Q = 500 gpm
η = 0.25
Well site control zone
= 50 feet radius
Zone A2 = 950 feet radius
Zone B5 = 1,500 feet radius
Zone B10 = 2,100 feet radius

Figure 1. Wellhead protection zones delineated by calculated fixed radius (CFR) method.

are 600 ft and 900 ft for porous aquifer (PA) and fractured rock aquifer (FRA), respectively.

Zone B5. This chemical contamination zone is that surface area above the aquifer between the 2- and 5-yr TOT. This zone provides additional response time to manage a chemical spill. Recommended minimum radii are 1000 ft and 1500 ft for PA and FRA, respectively.

Zone B10. This chemical contamination zone is that surface area above the aquifer between the 5- and 10-yr TOT. This zone allows for some natural attenuation of contamination and development of mitigation measures. Recommended minimum radii are 1500 ft and 2250 ft for PA and FRA, respectively.

Buffer Zone (Optional). This zone is generally beyond Zone B10. The zone offers a higher level of protection and may be extended to include the entire recharge area, especially where there are potential sources of significant contamination such as landfills or other hazardous materials.

The delineated zones can be refined in shape and/or size based on professional judgment and/or local knowledge of some site-specific hydrogeology. In California, the final assessment map must be based on a USGS quadrangle 7.5-minute series topographic map (3).

INVENTORY OF PCAS

The purpose is to identify all possible contaminating activities (PCAs) by location within the WHPA. Typical resources used in developing the inventory of PCAs include land use maps, business license records, hazardous waste databases, and the Internet (35,36). A field reconnaissance can identify other potential sources of contamination.

The comprehensive inventorying of PCAs can be in phases with initial focus on sources that could pose the greatest risk. The inventory should include past and present sources of contamination and might require geophysical investigations for inactive sources such as abandoned wells and waste disposal sites. The information gathered should include the type of source, potential contaminants from each source, and location of source. The information gathered must be updated periodically. Many PWSs use global positioning systems (GPSs) to locate PCAs and GIS system to map the locations. The Groundwater Foundation (37) has developed a primer on using such technologies to develop an inventory of PCAs.

VULNERABILITY ASSESSMENT (VA) OR SUSCEPTIBILITY ASSESSMENT

The U.S. EPA (38) defines groundwater "vulnerability" as "the relative ease with which a contaminant introduced into the environment can migrate to an aquifer under a given set of management practices, contaminant properties, and aquifer hydrogeologic characteristics." Groundwater vulnerability can be specific (specified contaminant) or intrinsic (any contamination in general) and must consider long-term effects (39). The purpose of VA in WHP planning is to evaluate and rank the risks of the identified PCAs that pose the most significant threats to groundwater quality within the WHPA. VA under WHP should not be confused with the VA required under the U.S. Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (PL 107–188). The Bioterrorism Act addresses the vulnerability of the entire water system (not just source waters) to intentional acts (e.g., terrorism) intended to substantially disrupt the ability of the system to provide a safe and reliable supply of drinking water. The U.S. EPA (16) proposed a groundwater rule that requires hydrogeologic assessments to identify wells sensitive to fecal contamination.

There are many methods for evaluating and mapping groundwater vulnerability to contamination ranging from a simple process to detailed numerical modeling of fate and transport of chemicals of concern (9,26,39–42). VA must factor the type and proximity of the PCA and site-specific hydrogeological information such as the presence of karst formations and any physical barrier that may affect the fate and transport of the PCA (3). DRASTIC [Depth to water table, net Recharge, Aquifer media, Soil media, Topography (slope), Impact to vadose zone, and hydraulic Conductivity of the aquifer] is a widely used method for evaluating relative vulnerability to groundwater contamination (9,41). Many VA models have technical limitations. Focazio et al. (40) illustrated the use of scientifically reliable tools for groundwater VA.

MANAGEMENT MEASURES (MMS)

Among the factors that influence the choice of MMs are availability of alternate sources of water, types of contaminants, hydrogeologic setting, and community and regulatory acceptance. MMs must be tailored to be most appropriate for each WHPZ. Land uses in the zone closest to the well are usually managed to avoid all possible risks, including those from bacteria, viruses, and chemical spills (2).

WHP MMs may be regulatory or nonregulatory. Nonregulatory MMs include public education to increase community awareness of the WHPP, economic incentives, land acquisition (43), and conservation easements. Regulatory MMs include local ordinances and zoning/land use planning. Additional examples of MMs are provided by the U.S. EPA (8,9,15). It is preferable that a WHP plan, that includes land use controls, use scientifically and legally defensible criteria to delineate the protection zones (40). Where feasible, installation of groundwater quality monitoring well(s) between the significant potential sources of contamination and the wellhead and periodic sampling could provide an early warning detection system.

CONTINGENCY PLANNING

A contingency plan (CP) should be developed to deal with emergency threats to groundwater quality and natural disasters such as floods. It is advisable to coordinate with the local emergency planning committee. The following elements are typically included in the CP: basic water system information, WHPA boundaries, a list of potential contaminant sources and locations, short-term and long-term water supply options, water rationing plans, and emergency response plans (ERPs). The development of a CP can be coordinated with other efforts such as that of the ERP required under the Bioterrorism Act. The U.S. EPA (44) maintains a list of ERP guidance documents and planning tools.

CONCLUSION

Wellhead protection planning is now one of the major programs within the SDWA related to protecting the quality of groundwater. The other programs are groundwater rule, sole source aquifer, source water assessment, underground injection control (UIC), source water petition, and comprehensive groundwater protection grants. The U.S. EPA is strengthening the linkages between the Clean Water Act (CWA) and the SDWA. The U.S. EPA is coordinating the source water protection program in each state with federal and state underground storage tank programs using GIS to map underground storage tank sites within source protection zones of drinking water sources.

Wellhead protection zones and plans should be periodically reviewed and updated. Regular sanitary surveys and vulnerability assessments could reveal operational deficiencies especially after special events such as floods. Curriero et al. (45) found that over half of the waterborne disease outbreaks in the United States in the past 50 years were preceded by heavy rainfall. Outbreaks due to groundwater contamination, which accounted for approximately 36% of all outbreaks, were more associated with extreme precipitation occurring within a 3-month lag preceding the outbreaks (45).

CHEMICAL DRINKING WATER STANDARDS, PAST, PRESENT, AND FUTURE

Patrick Sullivan
Franklin Agardy
Forensic Management Association
San Mateo, California

Water resources in the United States have already been shown to contain the chemical byproducts of water treatment and disinfection, industrial chemicals (both organic an inorganic), human drugs (prescription and nonprescription), veterinary and human antibiotics, pharmaceuticals (e.g., from the clinical treatment of cancer using chemotherapy drugs), sex and steroidal hormones, antioxidants, detergents and detergent metabolites, fire retardants, plasticizers, polycyclic aromatic hydrocarbons, petroleum products, and a wide range of pesticides that are either regulated, anticipated to be regulated, or unregulated. As any given water resource will contain a mixture of individual chemical compounds, scientists, engineers, and environmental policy professionals need to ask the question, can existing drinking water standards, that are based on individual chemical-specific water quality criteria, be shown to protect the public health? In attempting to answer this question, we hope to put into context the validity of chemical drinking water standards in a world where the boundaries between water and wastewater are becoming increasingly blurred.

CHEMICAL POLLUTANTS OF THE PAST

Prior to the 1940s and the mass production of synthetic organic chemicals, the vast majority of industries produced chemicals that were dominated by inorganic compounds or biodegradable organic compounds, for example, canneries, dairies and feedlots, distilleries, fertilizers, foundries (iron and steel), metal plating, mining and smelting, pulp and paper, paint products, meat packing, tanneries, textiles, and timber products. In addition, a growing number of petroleum-based compounds were also being produced and used in coal-derived chemicals manufacturing, manufactured gas production, petroleum refining, and wood treating. As a result, common water pollutants included inorganic acids (chloride and sulfate), arsenic, copper, cadmium, chromium, cyanide, lead, nickel, nitrate, and zinc as well as phenols and a wide spectrum of petroleum hydrocarbons.

Some of these common pollutants were contained in the 1925 standards for drinking water (1). The 1925 standards state that, with respect to chemical and physical characteristics, for water to be suitable for drinking and culinary purposes, it should be free from toxic salts and should not contain an excessive amount of soluble mineral substances or any chemicals employed in treatment. In addition, when any of the following compounds exceed their standards, the water should be rejected for use:

Constituent	Concentration (mg/L)
Copper	0.2
Iron	0.3
Lead	0.1
Magnesium	100
Zinc	5.0
Chloride	250
Sulphate	250
Total Solids	1,000

By 1946 (2), grounds for rejection of the water supply was expanded and based on the following standards:

Constituent	Concentration (mg/L)
Arsenic	0.05
Chromium (6+)	0.05
Lead	0.1
Fluoride	1.5
Selenium	0.5

whereas the following chemical substances should preferably not occur in excess of the following standards:

Constituent	Concentration (mg/L)
Copper	3.0
Iron	0.3
Magnesium	125
Zinc	15
Chloride	250
Sulphate	250
Phenolic	0.001

Phenolic compounds (commonly associated with wastes produced by manufactured gas production, wood treating, and synthetic chemical manufacturing) were the first organic chemicals added to the drinking water standards. However, by the 1950s, the high-volume use of the synthetic organic surfactant, alkyl benzene sulfonate, in detergents and the widespread distribution of highly toxic halogenated pesticides, shown to be responsible for fish kills around the United States, resulted in the addition of more organic compounds to the 1962 water quality standards.

Based on the 1962 (3) standards, grounds for rejection of the water supply should occur when the following standards are exceeded:

Constituent	Concentration (mg/L)
Arsenic	0.01
Barium	1.0
Cadmium	0.01
Chromium (6+)	0.05
Cyanide	0.2
Lead	0.05
Selenium	0.01
Silver	0.05
Fluoride	0.6–1.7 (based on air temperature)
Copper	1.0

whereas the following chemical substances should not occur in excess of the following standards:

Constituent	Concentration (mg/L)
Alkyl Benzene Sulfonate	0.5
Carbon Chloroform Extract	0.2[1]
Phenols	0.001
Iron	0.3
Manganese	0.05
Zinc	5.0
Cyanide	0.01
Nitrate	45
Chloride	250
Sulphate	250
Total Dissolved Solids	500

As a result of the continued and extensive use of halogenated and nonhalogenated hydrocarbons since the 1940s and the recognition of halogenated disinfection byproducts in treated drinking water, the current drinking water standards now include 27 inorganic criteria and 63 organic criteria. The current National Primary Drinking Water Standards for chemicals are:

Contaminant	Maximum Contaminant Level(MCL) (Micrograms per liter)[2]
Inorganic Compounds	
Antimony	6.0
Arsenic	50.0
Barium	2000.0
Beryllium	4.0
Bromate	10.0
Cadmium	5.0
Chlorine gas (as Cl_2)	4000.0
Chlorine dioxide (as ClO_2)	800.0
Chlorite	1000.0
Chromium (total)	100.0
Copper	1300.0
Cyanide	200.0
Fluoride	4000.0
Lead	15.0
Mercury	2.0
Nitrate	10000.0
Nitrite	1000.0
Selenium	50.0
Thallium	2.0
Organic Compounds	
Acrylamide	1000.0
Alachlor	2.0
Atrazine	3.0
Benzene	5.0
Benzo(a)pyrene	0.2
Carbofuran	40.0
Carbon tetrachloride	5.0
Chloramines (as Cl_2)	4000.0
Chlordane	2.0
Chlorobenzene	100.0

2,4-D	70.0
Dalapon	200.0
DBCP	0.2
O-Dichlorobenzene	600.0
p-Dichlorobenzene	75.0
1,2-Dichloroethane	5.0
1,1-Dichloroethylene	7.0
cis-1,2-Dichloroethylene	70.0
trans-1,2-Dichloroethylene	100.0
Dichloromethane	5.0
1,2-Dichloropropane	5.0
Di(2-ethylhexyl)adipate	400.0
Di(2-ethylhexyl)phthalate	6.0
Dinoseb	7.0
Dioxin	0.00003
Diaquat	20.0
Endothall	100.0
Endrin	2.0
Epichlorohydrin	20000.0
Ethylbenzene	700.0
Ethylene dibromide	0.05
Glyphosate	700.0
Haloacetic acids (HAA5)[3]	60.0
Heptachlor	0.4
Heptachlor epoxide	0.2
Hexachlorobenzene	1.0
Hexachlorocyclopentadiene	50.0
Lindane	0.2
Methoxychlor	40.0
Oxamyl(Vydate)	200.0
Polychlorinated biphenyls	0.5
Pentachlorophenol	1.0
Picloram	500.0
Simazine	4.0
Styrene	100.0
Tetrachloroethylene	5.0
Toluene	1000.0
Total Trihalomethanes (TTHM)[4]	100.0
Toxaphene	0.003
2,4,5-TP (Silvex)	50.0
1,2,4-Trichlorobenzene	70.0
1,1,1-Trichloroethane	200.0
1,1,2-Trichloroethane	5.0
Trichloroethylene	5.0
Vinyl chloride	2.0
Xylenes (total)	10000.0

[1] Measures extractable organic residues (i.e., pesticides).

[2] The maximum level of a contaminant in drinking water at which no known or anticipated adverse effect on the health effect of persons would occur, and which allows for an adequate margin of safety.

[3] The HAA5 compounds are dibromoacetic acid, dichloroacetic acid, monobromacetic acid, monochloroacetic acid, and trichloroacetic acid.

[4] The TTHM compounds are bromodichloromethane, bromoform, chloroform, and dibromochloromethane.

The National Secondary Drinking Water standards are nonenforceable guidelines regulating contaminants that may cause cosmetic effects or aesthetic effects in drinking water. The United States Environmental Protection Agency (USEPA) recommends secondary standards for water systems but does not require systems to comply. However, individual states may choose to adopt them as enforceable standards.

Contaminant	Secondary Standard (Micrograms per liter)
Aluminum	0.05
Chloride	250
Iron	0.3
Manganese	0.05
Silver	0.1
Sulfate	250
Total Dissolved Solids	500
Zinc	5.0

All of these pollutants are associated with industrial and chemical use practices evolving over the last 100 years.

CHEMICAL POLLUTANTS OF THE PRESENT AND FUTURE

The National Research Council estimates that there are approximately 72,000 organic chemicals in commerce within the United States, with nearly 2000 new chemicals being added each year (4). Given this number of chemicals, it would seem impossible that the USEPA can identify every chemical that poses a hazard to the public health. In fact, it is impossible. For example, under the Toxic Substances Control Act that was established in 1979, the USEPA has conducted an assessment program to determine which new chemicals present an unreasonable risk to human health or the environment. Since 1979, the USEPA has only reviewed some 32,000 new chemical substances. With so many chemicals left to evaluate, the USEPA chose to exclude all chemicals that are produced in amounts less than 10,000 pounds per year as well as all polymers from further consideration. The remaining 15,000 chemical subset has been identified as being the broad focus of the USEPAs existing chemical testing and assessment program with the primary focus being on the 3000 high-production-volume chemicals that are produced/imported at levels above 1 million pounds per year (4).

Once toxicity data are collected from animal studies, the USEPA must still identify those chemicals that should be regulated in drinking water. As of 1998, USEPA had completed their evaluation of approximately 400 compounds for potential regulation in drinking water. Of these top 400, a list of 50 chemicals were selected for consideration as future drinking water standards. The 50 chemicals that make up the 1998 Drinking Water Contaminant Candidate List are:

Acetochlor
Alachlor ESA (and acetanilide degradation products)
Aldrin
Aluminum
Boron

Bromobenzene
DCPA nonacid degradate
DCPA diacid degradate
DDE
Diazinon
1,1-dichloroethane
1,1-dichloropropene
1,2-diphenylhydrazine
1,3-dichloropropane
1,3-dichloropropene
2,2-dichloropropane
2,4-dichlorophenol
Dieldrin
2,4-dinitrophenol
2,4-dinitrotoluene
2,6-dinitrotoluene
Disulfoton
Diuron
DPTC (s-ethyl-dipropylthiocarbanate)
Fonofos
Hexachlorobtadiene
p-isopropyltoluene (p-cymene)
Linuron
Manganese
Methyl bromide
Methyl-t-butyl ether (MTBE)
2-Methyl-phenol (o-cresol)
Metolachlor
Metrobuzin
Molinate
Naphthalene
Nitrobenzene
Organotins
Perchlorate
Prometon
RDX
Sodium
Sulfate
1,1,2,2-tetrachloroethane
Terbacil
Terbufos
Triazines (and degradation products)
2,4,6-trichlorophenol
1,2,4-trimethylbenzene
Vanadium

A minimum of 5 compounds must be selected for regulation under the primary drinking water standards. The 2003 revised Drinking Water Contaminant Candidate List is now composed of the following 42 chemicals:

1,1,2,2-tetrachloroethane
1,2,4-trimethylbenzene
1,1-dichloroethane
1,1-dichloropropene
1,2-diphenylhydrazine
1,3-dichloropropane
1,3-dichloropropene
2,4,6-trichlorophenol
2,2-dichloropropane
2,4-dichlorophenol
2,4-dinitrophenol
2,4-dinitrotoluene
2,6-dinitrotoluene
2-methyl-Phenol (o-cresol)
Acetochlor
Alachlor ESA and other acetanilide pesticide degradation products
Aluminum
Boron
Bromobenzene
DCPA monoacid degradate
DCPA diacid degradate
DDE
Diazinon
Disulfoton
Diuron
EPTC (s-ethyl-dipropylthiocarbamate)
Fonofos
p-Isopropyltoluene (p-cymene)
Linuron
Methyl bromide
Methyl-t-butyl ether (MTBE)
Metolachlor
Molinate
Nitrobenzene
Organotins
Perchlorate
Prometon
RDX
Terbacil
Terbufos
Triazines and degradation products
Vanadium

As this list becomes more focused, a major problem still remains. Approximately seven years after the first Drinking Water Contaminant Candidate List was proposed, no new chemicals have been added, which is a disturbing result as well as a disturbing trend. From a scientific and practical point of view, the USEPA never has had the time or resources to comprehensively evaluate and regulate the entire list of 72,000 chemicals. However, to limit selection to a minimum of five chemicals is just absurd. It is extremely difficult to accept the premise that of all the chemicals used in this country there are only five additional chemicals need be added to the Candidate

List every few years that are a hazard to human health. Consequently, many hazardous chemicals that should be regulated on the basis of their potential toxicity to humans will go unregulated, and when these unregulated chemicals occur in drinking water, there will be no requirement to warn the consumer[5]. Furthermore, based on the USEPAs performance to-date and their pace of evaluating and regulating chemicals in drinking water, we might all be dead by the time the USEPA ponders the fate of its initial list of 50 chemicals. Such delays are inherent in current federal policy. For example, the Toxic Substances Control Act requires the USEPA demonstrate that a chemical is dangerous before it can take any action against that chemical (i.e., regulate that chemical). It is because of this type of policy that the presence of unregulated chemicals in our drinking water poses one of the greatest threats to America's public health. The current Drinking Water Contaminant Candidate List does not even consider a wide range of chemicals that are present in home care products (e.g., phthalates and nonylphenols) or drugs and pharmaceuticals (e.g., Ibuprofen, Clofibrate [cholesterol treatment], Estrogen, Bleomycin [cancer treatment]) that have already been identified in our water resources.

The fact that there are 1) whole new classes of chemicals that are not even evaluated by the USEPA as a potential threat to drinking water, 2) chemical mixtures in drinking water that are not regulated, and 3) approximately 2000 new chemicals produced and/or used in the United States each year, drinking water standards cannot be demonstrated to actually protect the public health.

Given this condition, it is our recommendation that water provided by either public- or privately-operated water utilities not solely rely on federal or state drinking water standards to protect their consumers. Water utilities should treat their raw water resource with the appropriate water treatment technologies (e.g., granulated activated carbon, ion exchange, reverse osmosis, advanced oxidation) to remove all potentially harmful inorganic and organic pollutants from their final product.

Based on our interviews with both public- and privately-operated water utilities, the cost to apply advanced water treatment technologies to remove the maximum amount of either inorganic or organic compounds would only require a 20% increase in the water utility customer's water bill. Given this level of available treatment, the only technical issue that remains is how to monitor for pollutant removal. Treatment efficiency can be determined by producing a chemical fingerprint of the raw water and the treated product, which can be accomplished by using standard liquid and gas chromatography methods, Raman spectroscopy methods, or the use of new ion diffusion spectroscopy.

Protection of our drinking water resources will become increasing difficult because (5) the boundaries between water and wastewater are already beginning to fade. Therefore, the only real future defense against the consumption of polluted drinking water is to abandon our reliance on water quality standards and implement appropriate water treatment technologies to minimize pollutants in our drinking water.

INDUSTRIAL WATER

MAGNETIC WATER CONDITIONING

Ingrid Ritchie
Indiana University-Purdue University
Indianapolis, Indiana

INTRODUCTION

Hard water contains minerals such as calcium, magnesium, and other hard ions that can form scale on a variety of surfaces that come into contact with the water, especially when it is heated. Magnetic water conditioning is a nonchemical technology that can prevent the formation of scale in hard water.

There are two basic categories of magnetic water conditioning devices: nonpermanent magnetic units (electromagnetic and electrostatic units) (Fig. 1) and permanent magnet units (Fig. 2). Electromagnetic units generate a magnetic field through the use of electromagnets, in which an electric current passes through a wire. Electrostatic units also use electricity to impose an electric field on the water flow, which attracts or repels ions in the water and generates a magnetic field.

Permanent magnetic units, the focus here, utilize permanent magnets rather than electricity to generate the magnetic field. Most permanent magnetic units utilize standard two-pole magnets, but one manufacturer utilizes a unique multiple, reversing pole magnet (Fig. 2) (1). The magnetic field exerts a force on ions as they pass through the field, which changes the crystallization behavior of the ions and promotes bulk solution precipitation rather than the formation of an adherent scale. Unwanted particulates can be removed by filtration, water/solids separation, blowdown, bleed-off, or draining.

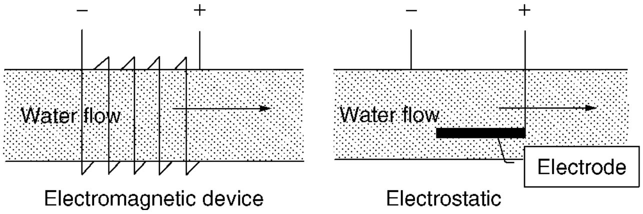

Figure 1. Diagram of classes of nonpermanent magnetic devices. (From Reference 1.)

Permanent magnetic units and electromagnetic units can be located so they are invasive (the magnet is located in line with the water flow) or noninvasive (the magnet is located so it is external to the water flow) as shown in Fig. 3. In-line systems are shielded magnets that are installed inside a section of pipe (see also Fig. 2). External units clamp onto the pipe through which the water flows.

THE PROBLEM OF HARD WATER AND SCALE

Hardness in water is due primarily to calcium and magnesium carbonates and bicarbonates (carbonate hardness that can be temporarily removed by heating) and calcium sulfate, calcium chloride, magnesium sulfate, and magnesium chloride (noncarbonated or permanent hardness that cannot be removed by heating). The sum of carbonate and noncarbonated hardness is total hardness, expressed as calcium carbonate. The World Health Organization (3) classifies hardness (in mg/L) as $CaCO_3$ as: 0–60, soft; 60–120, moderately hard; 121–180, hard; more than 180, very hard. Hard water, depending on the alkalinity, pH, temperature, and other factors, is responsible for the buildup of scale. Excessive hardness has a number of adverse effects in home, commercial, and industrial applications.

Hard water poses a significant problem in industrial boilers, cooling towers, and other heat transfer equipment. When hard water is heated, bicarbonates precipitate as carbonates and adhere to the pipe or vessel. In boiler and hot water tanks, the scale resulting from hardness reduces the thermal efficiency of heat transfer devices and eventually causes a restriction of the flow of water in piping systems. As a consequence, there is an increase in the system pressure that is required to move the water through a scale-restricted piping system. Both of these

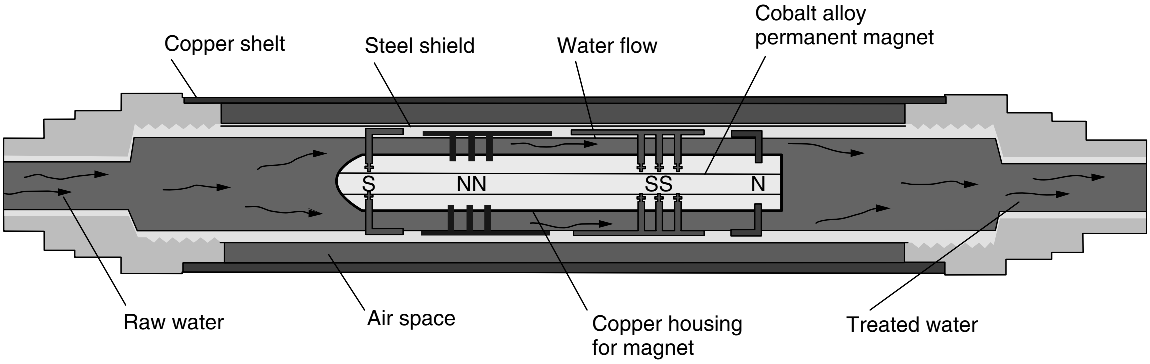

Figure 2. Diagram of a multipole permanent magnetic device. (From Reference 2. Available at: http://www.superiorwatercond.com/Products/our_superior_technology.html. Used with permission.)

problems increase the energy costs and maintenance costs of using and maintaining affected equipment. Table 1 provides example increases in energy consumption as a function of scale thickness.

The total cost of scaling in heat exchanger applications is estimated to be over $32 billion for the United States, Japan, German, the United Kingdom, Australia, and New Zealand combined, and over $14 billion in the United States alone (4).

In addition to increasing energy costs, hard water impairs the performance of detergents, which leads to dingy clothing and deterioration of fabrics and unsatisfactory cleaning of dishes and utensils in home, commercial, and industrial applications. Hard water results in spotting in car washes. Coffee makers, steamers, dishwashers, ice-makers, and other similar restaurant equipment are easily clogged by hard water and scale reduces the energy efficiency of these devices. In agricultural applications, hardness can reduce the efficiency of misting nozzles and irrigation systems.

APPLICATIONS OF PERMANENT MAGNETIC WATER CONDITIONING UNITS

According to the U.S. Department of Energy Technology Alert on nonchemical technologies for scale and hardness control, magnetic water conditioning "can be used as a replacement for most water-softening equipment," including lime or lime-soda softeners, ion exchange, and reverse osmosis (1). Magnetic water conditioning technology can also be used as a preconditioner to allow conventional devices to work more efficiently and last longer. The American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) identifies magnetic technology as a nonchemical treatment method that "has been used for scale control in boiler water, cooling water, and other process applications" (5).

There are many benefits of this "green" technology over traditional technologies. The elimination or reduction of chemicals translates into dollar savings (which can reach thousands of dollars each year in some applications) when the costs of chemicals, labor, and equipment needed for chemical scale control are considered. Potential adverse health and environmental effects from the use of these chemicals are also eliminated or significantly reduced. Another advantage over chemical softening and ion exchange is that permanent magnetic water conditioning does not increase sodium concentrations in water and, thus, is a better option in those instances where sodium ions pose a health or other concern.

Periodic descaling of heat exchange equipment can be nearly eliminated, which, in turn, translates into savings because there is less downtime (as a consequence of scale formation), and the chemicals and labor needed for descaling are eliminated or significantly reduced. A related benefit is that heat exchanger tubes and related equipment failures caused by scale buildup are reduced, thus extending equipment life. In each of the applications in the section above on the problem of hard water and scale, permanent magnetic water conditioners can prevent the formation of scale and reduce existing scale. Because the technology keeps solids in solution, solids separation is needed in those applications where the process cannot tolerate particulate matter.

Even though applications are worldwide, magnetic water conditioning can be considered to be an emerging technology, whose future applications are likely to have significant impacts in colloidal chemistry and other fields. Any environmental, health, or industrial problem that is caused by hardness deposits could, in theory, be aided by magnetic treatment. A few examples to illustrate the diverse applications follow.

- In a dental study, patients who irrigated their teeth with an irrigator fitted with a magnetic device had 44% greater reduction ($p < 0.0005$) in calculus volume and a 42% greater reduction in calculus area ($p < 0.0001$) when compared to a control group that irrigated with conventional irrigation (without a magnetic device) (6).
- The Indianapolis 500 Brickyard Crossing Golf Course has realized a 71% reduction in the use of wetting agents and fertilizers and a related cost savings of 62% after the installation of the magnetic unit. The payback time for the magnetic unit at this facility, which does not pay for its water, is about 4.5 years based only on the wetting agent and fertilizer usage. The facility reports other benefits, including improved distribution and penetration of water, which substantially eliminates both wet and dry areas (7).
- In a case study, the DOE compared the costs and benefits of traditional lime softening and alternative permanent magnetic treatment for a recirculating boiler water system with a flow of 1000 gal/min at a hypothetical facility using extremely hard water (350 mg/L as CaCO3) (1). The magnetic technology had a simple payback of less than one year and

> produced an annual cost savings of over $200,000 per year over traditional lime softening. The DOE estimated a life-cycle savings of $2.77 million for the magnetic technology. Benefits assigned to the magnetic technology included energy savings and pollution reduction.

Permanent magnetic water conditioners are available in many sizes, ranging from small residential units (1 gal/min) to very large commercial and industrial units. The cost of magnetic water conditioning varies, depending on the amount of water to be treated. The costs are lower or in the same range as conventional water treatment systems; however, since the process is a physical rather than chemical process, there are no chemicals to buy and no on-going maintenance costs, which produces energy, labor, equipment, and chemical cost savings.

Magnetic technology, like other technologies, must be installed and used correctly. It is not appropriate in all applications. Additional guidelines developed by various manufacturers (1) include:

- *Installation*. Magnetic technology must be sized and installed correctly.
- *Water Quality*. Magnetic technology is not appropriate for soft water and some manufacturers report upper limits for hardness. Iron, which can cause fouling of the magnet, and silica, which can form scale with or without calcium, must be within specified limits.
- *Applications in Boilers and Heat Exchange Equipment*. Additional precautions must be taken with respect to alkalinity (to prevent corrosion), hydrogen sulfide (to prevent corrosion), and cycles of concentration.
- *Electrical Interference*. Magnetic units must be installed at an appropriate distance (at least 48 in.) from three-phase systems to avoid electrical interference, which causes magnetic lines of force to stray.

SCIENTIFIC SUPPORT FOR THE TECHNOLOGY

Historically, references to magnetic water conditioning date to the late 1800s, when lodestones (a naturally occurring permanent magnet) and naturally occurring magnetic mineral formations were used to decrease the formation of scale in cooking and laundry applications. From this modest beginning, magnetic water conditioning technologies have been and are being used throughout the world in a variety of applications to control scale. The acceptance of magnetic water conditioning, however, has not been universal, and there has been resistance to the technology in the United States, particularly by the water softening industry. Historically, the scientific literature has produced studies both positive and negative to magnetic water conditioning, and skeptics have centered their arguments against the technology largely on the lack of a consensus regarding the mechanism of action and lack of reproducibility in scientific studies. However, the more recent literature is increasingly supportive of the technology. Troup and Richardson (8) summarize earlier studies (pre-1978) for preventing scale formation and Baker and Judd (9) provide an informative review up to the mid-1990s. A few additional studies are noteworthy.

Barrett and Parsons (10) replicated the work of Higashitani and co-workers and found that magnetic treatment affects calcium carbonate formation under quiescent conditions, and the effect is reproducible. Both authors also determined that magnetic treatment produces a memory effect when the water is stored. Barrett and Parsons hypothesize that the formation of calcium carbonate is affected by the suppression of nucleation and acceleration in crystal growth.

Bogatin and others (11) propose that magnetic treatment of irrigation water increases the number of crystallization centers and the change of the free gas content, and that irrigation with magnetically treated water is the most effective for soils with high soda content. Other important parameters for effective treatment include flow rate through the apparatus, hardness, and pH.

Cho and co-workers (4) provide definitive evidence that physical water treatment (using a permanent magnet, solenoid coil, and high voltage electrode devices) is effective for the mitigation of fouling in cooling tower applications. (Fouling is contamination of a surface on which a liquid is boiling, that is, scale formation.) In this pivotal study, the authors demonstrated that multipole permanent magnets (with alternating fields) produced a significant reduction of 84% in fouling resistance compared to no treatment, and that a permanent magnet without alternating fields was not effective in reducing fouling. The authors also determined that previous studies showing no effect may have been limited because the treatment devices were not configured in an optimum way, giving support to manufacturers' instructions to install and operate the devices according to directions. The study proposed bulk precipitation as the mechanism of action. The magnetic field (or electric field, depending on the device) precipitates mineral ions in the water solution and forms clusters (i.e., colloidal particles of submicron size) in solution. As the temperature of the solution inside the heat transfer equipment increases, the solubility of the mineral ions decreases and the clusters grow in size and produce soft sludge coatings on the heat transfer surface rather than hard scale.

CONCLUSION

Permanent magnetic water conditioning technology is a physical process for reducing scale formation. It is a "green" technology that does not use chemicals or electricity to produce its effect. Because the magnetic unit does not have moving parts, it lasts for many years with very little, if any, maintenance.

These advantages enable permanent magnetic water conditioning to save energy, reduce the use of chemicals that treat and soften water, reduce the disposal of wastes from water treatment units such as water softeners, and conserve water. All of these benefits improve the environment and the health of our communities and reduce the costs of preventing and removing scale.

WATER IMPACTS FROM CONSTRUCTION SITES

JAMES A. JACOBS
Environmental
Bio-Systems, Inc.
Mill Valley, California

Surface water and, to a lesser degree, groundwater are impacted by runoff from construction sites, parking lots, roadways, and other nonpoint sources. Soil particles and dissolved constituents in runoff reduce the beneficial uses of water and have become a major regulatory challenge. Erosion rates at construction sites may be 10 to 20 times greater than for undisturbed lands (1). Construction sites, including environmental remediation activities and redevelopment, might contain a variety of natural and manmade contaminants that might exceed regulatory levels. Sediment runoff from nonpoint sources is primarily the result of wind and water erosion. Construction sites are locations where special erosion control measures may be needed to prevent storm water runoff and sediment buildup in nearby waterways and groundwater recharge areas (1,2).

To put this challenge into perspective, approximately 1.7 to 1.9 billion m^3 (1.4 to 1.5 million acre-feet) of the storage areas of reservoirs and lakes are permanently filled each year with sediment. The U.S. government annually spends over \$500 million each year to remove the sediment from harbors, rivers, and other waterways, primarily through the oversight of the U.S. Army Corps of Engineers. It has been estimated that erosion-related pollutants cost the United States about \$3.2 billion to \$13 billion each year (3). Since 1990 when the report was written, the challenge from nonpoint source pollution is better understood and studied. Over the years, the methods have been designed for effective sediment and erosion control to significantly reduce pollution and sediment volume from construction sites and other nonpoint sources. A good summary of the erosion control at construction sites and various engineered solutions are found in Fifield (1,2).

The objective of sediment and erosion control is to reduce the water-quality impacts from nonpoint sources, and many of the regulations and statutory requirements that attempt to ensure that construction projects are performed in a way that minimizes potential impact to the environment. The U.S. Congress has passed several laws to protect the environment from nonpoint sources, including construction sites. These laws include the National Environmental Policy Act, the Clean Water Act, the Coastal Zone Management Act, the Safe Drinking Water Act, the National Wild and Scenic Rivers Act, the Endangered Species Act, the Resource Conservation and Recovery Act, and the Federal Insecticide, Fungicide and Rodenticide Act. In addition to these federal acts, various state and local laws or guidelines have also been enacted.

Erosion occurs when raindrops, moving water, or wind transports soil particles. Both wind and water are transport agents for soil particles. Wind erosion is normally a problem in semiarid and arid regions where ground vegetation may be limited. Controlling wind erosion at construction sites is common and is frequently managed by spraying water to keep the dust and soil particles from becoming airborne. Silt fences consist of vertical plastic sheeting or other materials that catch and retain soil particles from leaving construction sites.

Water erosion at construction sites is common in humid regions where rainfall events are frequent. According to Fifield (2), six types of water erosion exist: Splash erosion is the dislodging of soil particles by raindrop impacts; sheet-flow erosion is the uniform removal of the saturated soil particles conveyed in storm runoff; rill erosion is a long, narrow depression or soil incision caused by increased topographic relief and higher runoff velocities; gully erosion is the deep and wide depression or incision caused by concentrated storm runoff flows; stream bank erosion is the removal of soil by a natural drainage pattern such as toe cutting and bank sloughing; and shoreline erosion is the removal of soil by high-energy wave action, which results in sloughing and mass wasting of shoreline cliff faces. Water-related erosion on construction sites is usually the result of raindrop impacts and sheet flows, although specific conditions at construction sites can contribute to water erosion near rivers or beaches.

One way to minimize water impacts at construction sites is to use sediment containment systems. Sediment containment systems create conditions for deposition of soil particles that are in suspension. Two types of sediment containment units exist: retention and detention systems. Retention systems tend to be large and, for individual construction sites, may be difficult for lack of space. Properly designed sediment retention systems provide the necessary volume for containment of all the incoming storm water runoff, including both the water and sediment portions. Within the sediment storage area, a properly designed retention system will have the capacity to allow for the sedimentation of the suspended soil particles. Finally, the sediment retention system will be designed to discharge the storm water at a controlled rate. Evaporation and seepage must be calculated to allow for the retention system to drain before the next incoming storm water surge. Retaining all storm waters from a construction site is generally not feasible because of space and time constraints.

Instead of trying to retain all storm water, a well-designed sediment detention system captures only a specific size of particles while being able to drain the large volume of storm water passing through. To be effective at reducing the suspended soil particles, detention containment systems must hold the storm water only long enough for the deposition of the suspended soil particles to occur (2).

Surface water runoff from construction sites, parking lots, roadways, and other nonpoint sources can enter groundwater through recharge areas. Turbidity, naturally occurring heavy metals as well as pesticides, hydrocarbons, and other organic contaminants, can be major sources of nonpoint pollution into surface waters during construction, which entails disturbing existing ground cover, trees, rocks, and soil. The total suspended solids (TSS) are the total amount of sediment in the water. The dissolved portion of solids in water is called total dissolved solids (TDS). In addition to high TSS and TDS, a large volume of sediments in surface water includes changes in water chemistry, such as too much salt, iron, lead, copper, and zinc or other metals. Along with the sediment, an influx of chemicals poisonous to fish and other aquatic life can occur. Other effects include the destruction of fish breeding grounds, the flattening of streambed channels, and the increased potential of surface flooding as river and lake storage capacity is reduced because of sediment buildup. Other wastes from construction include wash water from concrete mixers, paints and wash water from painting equipment, and wastes from cleaning of vehicles and equipment.

The solution to erosion and sediment control issues is site-specific erosion plans and sediment and waste containment systems. Site-specific sediment control systems in the past have used commonly available materials (plantings, rocks, sand bags, and straw-bales). More recently, engineered systems with synthetic materials have been tested and proven in the field. Surface and groundwater impacts from nonpoint source pollution, especially at construction sites, can be minimized and managed effectively.

INDUSTRIAL COOLING WATER—BIOFOULING

T.R. Bott
University of Birmingham
Birmingham, United Kingdom

The accumulation of living matter in cooling water systems may be the result of the activity of microorganisms such as bacteria, algae, and fungi, or the growth of macroorganisms that include mussels, barnacles, hydroids, and serpulid worms and plant material such as water weeds. The extent of the deposition of both micro- and macroorganisms, depends very much on the origin of the water employed in the cooling water circuit. In general, the water is taken from a natural source, which contains the organisms and nutrients to sustain life and growth. Some sources, such as borehole water, are relatively free of organic material, but in “open” cooling water circuits, it rapidly becomes contaminated from contact with the atmosphere. Water from other sources, including freshwater rivers, canals or lakes, estuarine or seawater, is already heavily contaminated before it is taken into an industrial system.

The presence of living matter on surfaces, particularly heat transfer surfaces, may promote fouling by mechanisms, including particle deposition, scale formation, and corrosion. In general, this is due to the metabolic activity of the living matter that creates localized changes in the properties of the water, particularly pH.

To maintain efficient operation of a cooling water system, it is necessary to combat the detrimental effects of the accumulation of unwanted deposits. It is particularly important with respect to heat transfer surfaces because the deposit represents a resistance to heat flow across the surface, thereby seriously reducing the capability of the system to operate according to the design requirements. Generally, the principal difficulties in cooling water circuits arise from the presence of microorganisms, because it is possible to reduce the gross effects of macroorganisms generally, by filtration at the cooling water intake.

SURFACES AND BIOLOGICAL FOULING

For both micro- and macroorganisms, although there are some exceptions, settlement on a surface is an essential element in biological activity. The advantages of residing on a surface include a continuous supply of nutrients, removal of waste products by the movement of the water, and some measure of protection from predators. Furthermore, it has been suggested (1) that for bacteria, the surface provides an enhanced protection from changes in the surrounding environment, compared to those microorganisms that are “free swimming” (planktonic) in the water. The changes that organisms might experience include variations in water pH, changes in nutrient concentration, and in some systems, the inorganic salt concentration. Changes in water velocity, in turn, affect the shear forces acting on the biofilm and hence the tendency for removal. It has been suggested that the colonization of a surface by bacteria depends on an adsorbed conditioning layer made up of macromolecules that are in plentiful supply in water from natural sources due to the breakdown of living matter. It is considered that the bacteria form a chemical bond with this layer of macromolecules. The movement of water in relation to the atmosphere in cooling towers and spray ponds usually means that the water becomes saturated with oxygen, conducive to the growth of organisms that depend on oxygen for survival, for example, aerobic bacteria.

Bacteria

Mozes and Rouchet (2) suggested that three zones are present in a biofilm consisting of bacteria:

1. the layer of cells in direct contact with the surface
2. the bulk biofilm
3. the layer of cells residing at the interface between the bulk biofilm and the water phase

Conditions are likely to be different for each of these groups of cells. The activity of the microorganisms will vary, depending on the mass transfer of nutrients, including oxygen for aerobic species, to and through the biofilm, and similarly for the removal of waste products of metabolism. If the biofilm is relatively thick, it is more than likely that the nutrient concentration will become zero either at the solid surface or somewhere in the bulk biofilm. Under these conditions, it is possible for the cells to die with potential consequences for the integrity of the biofilm.

Mass transfer depends on a concentration driving force, the extent of the turbulence at the water/biofilm interface, and the openness of the biofilm structure that either restricts or facilitates nutrient transport. The turbulence at the biofilm surface is very dependent on the water velocity across the surface.

Heat exchanger surfaces are particularly suitable for bacterial growth, because of these desirable benefits and also because the surface temperature is usually conducive to growth. In natural conditions, bacteria colonize stones and rocks, but in cooling water circuits, they use the metal surfaces in contact with water. Metal surfaces give rise to metal ions that could interfere with adhesion of the biofilm to the surface (3). Some metallic ions, for example, copper ions, may act as a biocide. As the colonies of bacteria grow on a surface, extracellular products (usually polysaccharides) are formed and accumulate around the clusters of cells to give a complex matrix of cells and these extracellular polymers. Apart from keeping the structure together, it is understood that the function of extracellular material is first and foremost to protect the cells. Protection may be afforded against predators or noxious substances in the water that might adversely affect the cells or kill them. It is also believed that the extensive growth of polysaccharides, when nutrients are in ample supply, is a method of storing nutrient material against a time when the supply is reduced or eliminated, so that survival is ensured. The spaces within the matrix are filled with water that represents 90–95% of the mass of the biofilm. Work by Stoodley et al. (4) demonstrated that water flows in the duct-like voids in a biofilm and facilitates the availability of nutrients for the cells in the matrix and the removal of waste products. The structure of the biofilm, therefore, has implications for the mass transfer of nutrients from the bulk water to the individual organisms in the biofilm, particularly those remote from the bulk water flow. The structure of the biofilm is very much a function of the conditions under which it was formed, particularly the magnitude of the water velocity across the cells that colonized the surface. Higher velocities tend to produce more compact structures. The use of nutrients by the cells reduces the local nutrient concentration in the vicinity of the biofilm, thereby enhancing the concentration driving force for mass transfer between the bulk water and the biofilm. It is possible that the cells close to the solid surface may be starved of nutrients that may cause changes in metabolism or even cell death.

OPERATING CONDITIONS AND BACTERIAL BIOFILM FORMATION

Because of the versatility of bacteria and the favorable conditions for growth in heat exchangers, bacterial biofilms on heat transfer surfaces represent a serious problem in cooling water circuits. The principal difficulties are the reduction of heat transfer efficiency and the increased energy required to pump the water through the system for a given bulk water flow rate necessary to achieve the desired heat removal. Substantial increases in operating costs may be the result.

The development of a biofilm generally follows the accepted pattern for most fouling phenonema, as shown by the idealized curve in Fig. 1. For a short interval of the order of a few days, there is little evidence of any biofilm accumulation. This is when the adsorption of macro organic molecules takes place and the surface becomes "conditioned," allowing microorganisms to colonize the surface. Once the surface has been colonized and providing sufficient nutrients are available, there is relatively rapid growth of the biofilm. After a period of accelerated growth, the rate of growth reduces to a point where the biofilm thickness remains reasonably constant, although variations in thickness about a mean are likely due to sloughing of lumps of the biofilm from the surface. It is generally understood that sloughing is due to the effects of the shear forces at the water/biofilm interface induced by the water velocity. As the biofilm develops and becomes thicker, its structure becomes less robust and more susceptible to the effect of fluid shear. As a result, there is a balance between growth and removal of the biofilm.

Figure 1 provides an indication of the general shape of the biofilm growth curve, but the shape of individual curves varies depending on the prevailing conditions. For instance, higher velocities are likely to produce thinner but robust biofilms, compared with biofilms formed under low velocities that have a more open structure. Biofilms formed at a temperature near the optimum for maximum growth for the prevailing species are thicker than those formed at a lower or higher temperature. Higher availability of nutrients encourages growth. As for all living material, the presence of trace elements is vital for healthy growth. All these influences change with the seasons, including the cooling water velocity which is likely to be lower in the winter months when the lower temperature of the water reduces the demand for cooling water for a given cooling requirement.

The topography of the surface on which the biofilm develops is also a factor. In general terms, rough surfaces favor biofilm accumulation, whereas smooth surfaces are less hospitable to biofilm growth. Bacteria carry a surface charge, so that its value in relation to the electric charge on the surface also influences the rate of colonization.

Suspended particulate solids in the water flow can also affect the development of biofilms. Reduced biofilm accumulation can be anticipated due to the scouring action of particles, although the nature and size of the particles themselves also exert an influence. Sand particles can remove biofilms very effectively, but at the same time, erosion of the metal surface could become a serious problem. On the other hand, softer clay particles may become part of the deposit structure and, under those circumstances, may reduce the robustness of the biofilm matrix.

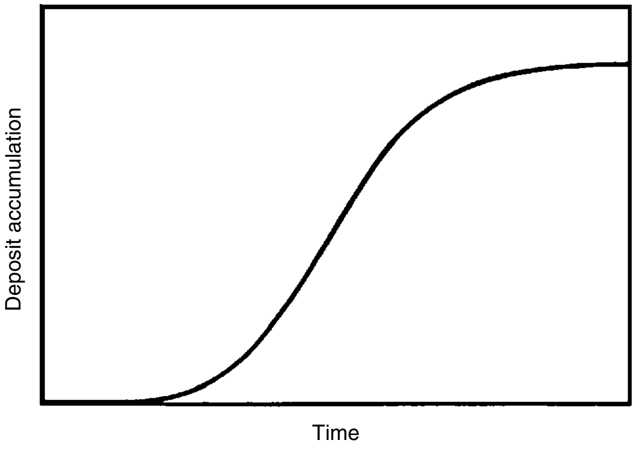

Figure 1. Idealized fouling curve.

Most bacteria flourish in an environment where the water pH is near 7. Variations affect the growth of biofilms, although most microorganisms can tolerate small changes in pH.

Algae

Algae require sunlight, carbon dioxide, and inorganic chemicals as their primary source of nutrients and energy for metabolism. Their natural habitat is attachment to rocks and stones in aqueous environments, or they may be "free floating" in lakes or reservoirs. Algae are larger than bacteria and exist as single entities or as filamentous colonies in an aqueous environment or attached to solid surfaces. In cooling water systems, they may be found where areas resemble those in nature that have access to sunlight, such as cooling tower basins, spray ponds, and serpentine coolers where the water, exposed to the atmosphere, flows over banks of horizontally mounted tubes. The formation of algal biofilms is initiated by the adsorption of water-soluble organic material, such as glycoproteins, and colonization by bacteria. Diatoms, unicells that have a symmetrical silica outer surface, are often early algal colonizers.

Algae themselves are not generally a problem in the enclosed parts of a cooling water circuit such as heat exchangers and pipelines, because of the lack of sunlight. The problem of algae growth in other parts of the system, however, is the production of organic debris that may give rise to blockage or be a source of nutrients for other microorganisms, such as bacteria that accumulate on heat transfer surfaces and in piping.

Fungi

Fungi require a fixed organic source of carbon. Their rigid cell wall limits them to being saprophytic on organic substrates or parasites living on higher forms of life, for example, so-called "athletes' foot" in humans. They lack chlorophyll, so that they cannot use photosynthesis in their metabolism.

In relation to cooling water systems, the nuisance value of fungi is not unlike that of algae. In sofar as they require a consumable substrate, they are to be found, for instance, on the wooden structures of older cooling towers. The attack of fungi on wooden structures involves enzymes (produced by the fungi cells) that open up the cellulose structure and make the structure liable to attack by other forms of microbial life. The presence of large quantities of living and dead material on the weakened wooden structure is likely to make it collapse. Modern cooling towers generally contain polymer packing that is resistant to fungal attack. The principal problem that fungi pose in cooling water circuits is the breakdown products and debris that arise from fungal growth. Operating problems may develop due to deposition on heat transfer surfaces and in pipelines, and by providing nutrients for microbial activity, particularly bacteria, as discussed earlier.

MACROFOULING OF SURFACES

Macrofouling is largely associated with sea or estuarine water involving the growth of macroinvertebrates. The fouling is usually confined to water intakes and culverts. Whitehouse et al. (5) summarized the conditions that support macrofouling of surfaces, including the continuous flow of seawater to provide oxygen and nutrients and reduced competition from algae and predators. Colonization of surfaces may be facilitated by bacterial biofilms (slime layers) already on the surface. The spectrum of species in the water varies with location and season.

Mussels

The growth of mussels is very much dependent on the season. Higher temperatures of summer facilitate growth, but at the lower winter temperatures, growth is restricted. Rapid growth, however, can occur at temperatures above about 10 °C. Following fertilization and a free swimming larval stage, metamorphosis occurs to produce a “spat.” Settlement onto a surface then occurs to provide a permanent adult site, where rapid growth can take place under suitable conditions. Settlement can be strongly affected by the water velocity across the surface; low velocities favor deposition and attachment. It is not practical to filter the water prior to the settlement process to remove the “spats,” because the small mesh size required would give rise to rapid “blinding” of the filter.

Barnacles

Barnacles are more of a problem in tropical regions than in more temperate zones. Planktonic larvae progress toward metamorphosis into small barnacles that can settle on surfaces under a higher water velocity than that for mussels. Blockage of filter screens is a common problem. Larvae can be carried forward into heat exchangers, where, if the velocity is relatively low, they may settle and develop to cause problems of blockage, pressure loss, and reduced heat transfer efficiency.

Hydroids

Hydroids are surface colonizers that facilitate the attachment of mussels. They are primitive creatures living in colonies of numerous microscopic units. There is a free swimming stage in development. The outer walls of hydroids are not calcified like barnacles and mussels, so their fouling potential is not great. Large accumulations, however, can severely restrict water flow.

Serpulid Worms

Calcareous tubes built by serpulid worms can cause fouling problems. Encrustations in pumps and valves can cause malfunction.

Other Organisms

There are many living organisms contained in estuarine and seawater that have not been listed but can cause severe operating problems in cooling water systems. The examples cited illustrate the general problems of macrobiofouling.

CONTROL OF BIOFILMS

It is essential to control biofilm growth in cooling water circuits particularly in heat exchangers, to maintain cooling efficiency and thus optimize costs. The two basic methods are chemical and physical.

Chemical Control

Chemicals, particularly chemical biocides that kill bacteria, have been used for many years. The action of the additive has essentially three phases:

1. adsorption onto the cell wall
2. penetration into the cell wall
3. chemical combination of the biocidal chemical and essential cell structures or components that directly affects cell metabolism or the integrity of the cell structure itself.

Chlorine has been the preferred biocide for many years on account of its availability and relatively low cost. Free chlorine reacts with water in the following way:

$$Cl_2 + H_2O \longrightarrow HOCl + HCl$$

and

$$HOCl \longrightarrow H^+ + OCl^-$$

Because it is a strong oxidizer, chlorine reacts with organic material in water. Many of these compounds are cancer forming, and chlorine can enter the food chain. It has, therefore an environmental risk, so its use is declining and in some places, it is not possible to discharge water that contains chlorine or its derivatives back into the environment from which it came without treatment. Other oxidizing biocides include hydrogen peroxide, ozone, and chlorine dioxide. The advantage of hydrogen peroxide and ozone is that they break down to water and oxygen.

There are many other chemical biocides available for the control of biofilm formation. In recent years, so-called “environmentally friendly” biocides have been developed that have a short life in aqueous solution and break down to innocuous by-products or nutrients for microorganisms that effectively disposes of these additives. Other chemicals that are used to control biofilm growth are biostats. These compounds reduce the activity of microorganisms, so that their influence is limited. Biostats may be included with appropriate biocides in proprietary mixtures for microbial control.

Physical Control

The use of physical techniques to control biofouling is not as widespread as the use of chemical additives. The principal reason for this is that chemicals are carried to all parts of the system, whereas this is not so for physical methods of control. Furthermore, the geometry of the cooling water system, particularly the heat exchangers, does not lend itself easily to the use of physical techniques.

One technique that has been successful in controlling biofouling in power station condensers is the so-called Tapproge system that involves circulating sponge rubber balls with the cooling water through the tubes of the condensers. The technology is suitable because the large number of tubes in a condenser are uniform in diameter. The balls are slightly larger in diameter than the internal diameter of the tubes, so that as the balls are forced through the tubes by the water flow, they are "squeezed" and wipe the inside surface of the tubes. The technique involves collecting balls, rejecting worn balls, and reinjecting acceptable balls. The effectiveness of the system depends on the availability of sufficient balls and the probability that balls pass through each tube reasonably frequently. Under ideal conditions, it has been estimated that each tube should receive 12 balls per hour (6). A potential drawback of the system is that balls may get stuck in the tubes or at a tube entrance on the tube plate, thereby causing a reduction in effective heat transfer area and an increase in pressure drop.

Potential future physical methods for biofouling control have recently been discussed (7). The use of ultrasound, the inclusion of wire-wound or spring-like inserts in tubes, and the circulation of robust polymer fibers are under development. The two former techniques depend, to some extent at least, on heat exchanger geometry and on increasing the removal forces acting on the biofilm generated by increased turbulence in the flowing water. The inclusion of polymer fibers in the flowing water, on the other hand, is more akin to the use of chemicals because the fibers are transported to all parts of the system by the water. The removal action is assumed to be from contact between the fibers and the deposit.

Ultraviolet light has been used to control biofilm growth, but the technique has severe drawbacks in cooling water systems. To be effective, the UV light source has to "see" the biofilm or the planktonic organisms in the circulating water. It is impossible, therefore, to control biofilm growth on heat transfer surfaces. It is possible, however, to pass the cooling water through a UV light unit that destroys organisms in the water. The problem that arises is that unless the kill is 100%, the remaining microorganisms can become colonizers of heat exchanger surfaces that are untouched and therefore are free to develop unwanted biofilms.

Treatment to modify the quality of surfaces likely to become fouled is a method of biofouling control. Electropolishing of stainless steel reduces fouling (8). The use of coatings to change the hydrophilicity of the surface has also been successfully used. Ion implantation has been effective in fouling control (9). The additional capital costs. imposed by these techniques and maintenance of the integrity of the treated surface are reasons why they are not used extensively in industry.

A more extensive discussion of cooling water and biofouling is to be found in (10).

INDUSTRIAL COOLING WATER—CORROSION

T.R. Bott
University of Birmingham
Birmingham, United Kingdom

Corrosion is often a problem when metals are in contact with an aqueous environment. It may be defined as the deterioration and loss of metal due to some form of chemical attack. In general, it results from impurities in the water, which need only to be in trace quantities to initiate corrosion. Trace impurities can include gases dissolved from the atmosphere, particularly oxygen and carbon dioxide, that play important roles in the corrosion process. Small amounts of mineral salts in water can also become involved in corrosion reactions. Where the metal makes up an essential component of a structure, such as a bridge or equipment forming part of an industrial process, for example, a cooling water circuit, constant vigilance is required to maintain the integrity of the structure and the equipment involved. Corrosion is a complex phenomenon dependent on chemical and physical conditions within the particular system.

In general, corrosion is associated with iron and steel, although under certain circumstances, other metals and alloys may attacked. However, to illustrate the mechanisms of corrosion, reactions involving iron will be used.

The reddish-brown deposit that is generally evident when iron corrodes is the iron compound ferric hydroxide, usually mixed with ferrous oxide. It is produced by a sequence of electrochemical reactions in which a difference in electric potential develops between two different metals or between different areas on the same metal. The difference in potential enables electrons to flow from the positive to the negative regions which, is an electric current. Thus, there is a movement of electrons which affects the chemical nature of the surface, where they originate or the area to which the migrate, by localized electrochemical reactions. The mechanism is often referred to as "galvanic action." These centers of electrochemical activity, usually termed the "galvanic cell," have an anode and a cathode. Metal dissolution takes place at the anode. The overall corrosion process is facilitated by dissolved salts, usually inorganic, in the water, because they affect the electrical conductivity of the water. Water that has a high salt concentration is more conductive than water of a relatively low salt content. The basic migrations are shown in Fig. 1.

At the anode, electrons are released from the metal enabling it to dissolve in the water in ionic form.

$$\mathrm{Fe} \longrightarrow \mathrm{Fe}^{2+} + 2\mathrm{e} \tag{1}$$

where e represents an electron.

Electron flow through the metal constitutes an electric current. At the cathode, it is possible for electrons to take part in electrochemical reduction reactions.
Examples are

$$2\mathrm{H}^+ + 2\mathrm{e} \longrightarrow \mathrm{H}_2 \uparrow \tag{2}$$

The H ion arises from the disassociation of water molecules which occurs to a small extent in water.

$$\mathrm{H_2O} \longrightarrow \mathrm{H}^+ + \mathrm{OH}^- \tag{3}$$

$$2\mathrm{H_2O} + 2\mathrm{e} \longrightarrow \mathrm{H}_2 \uparrow + 2\mathrm{OH}^- \tag{4}$$

$$\mathrm{O}_2 + 2\mathrm{H_2O} + 4\mathrm{e} \longrightarrow 4\mathrm{OH}^- \tag{5}$$

As the combination of hydrogen ions takes place to form hydrogen gas, the depletion of hydrogen ions causes Equation 3 to move to the right, thereby releasing further OH^- ions. The result is a significant increase in alkalinity, represented by the increased concentration of OH^- ions. The presence of Fe and OH^- ions can give rise to chemical reactions and hence relatively insoluble deposits such as ferrous hydroxide:

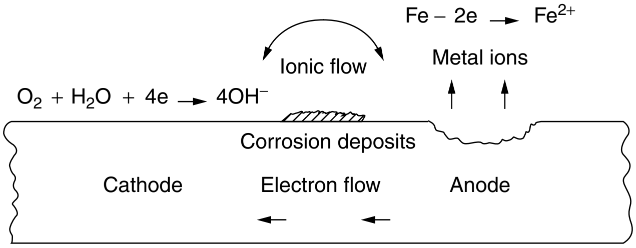

Figure 1. Electrochemical corrosion.

$$\mathrm{Fe}^{2+} + 2\mathrm{OH}^- \longrightarrow \mathrm{Fe(OH)_2} \downarrow \tag{6}$$

Ferrous hydroxide itself can further react to give ferric hydroxide:

$$4\mathrm{Fe(OH)_2} + \mathrm{O_2} + 2\mathrm{H_2O} \longrightarrow 4\mathrm{Fe(OH)_3} \downarrow \tag{7}$$

Ferric hydroxide can react further:

$$2\mathrm{Fe(OH)_3} \longrightarrow \mathrm{Fe_2O_3} + \mathrm{H_2O} \tag{8}$$

Thus a mixture of corrosion products can be formed, and within the deposits, there may be inclusion of solids from the water, such as suspended particles comprised of clay, sand, and other mineral matter, along with microbial cells.

The character of the deposit can affect the continued rate of corrosion. For instance, if the deposit is porous, corrosion can continue. On the other hand, a dense impervious structure prevents ionic migration and thereby protects the underlying metal from further corrosion. The "oxide layer," as it is called, is often relied upon to provide protection and may be deliberately laid down for corrosion control.

Equations 2 to 5 demonstrate that hydrogen gas or hydroxyl ions are produced at the cathode, as a result of corrosion. If hydrogen and hydroxyl ions remain in the vicinity of the cathode, they represent a barrier that interferes with the diffusion of oxygen gas or hydrogen ions to the cathode that would enable further chemical reactions to take place. The barrier therefore acts as a natural corrosion inhibitor. The overall process is termed "polarization."

This barrier, however, cannot be relied on as an effective method of corrosion control because it is easily disturbed. In most situations, the water is flowing and the "flushing" that is created removes the hydroxyl ions and the hydrogen bubbles from the surface. Furthermore, because the water is likely to contain dissolved carbonates and carbon dioxide in ionic form that can produce hydrogen ions, the pH of the water is reduced. The chemical reactions involved are

$$\mathrm{H_2O} + \mathrm{CO_2} + \mathrm{CaCO_3} \longrightarrow \mathrm{Ca(HCO_3)_2} \tag{9}$$

$$\mathrm{Ca(HCO3)_2} \longrightarrow \mathrm{Ca}^{2+} + 2\mathrm{HCO}^{3-} \tag{10}$$

and

$$\mathrm{H_2O} + \mathrm{CO_2} \longrightarrow \mathrm{H_2CO_3} \tag{11}$$

$$\mathrm{H_2CO_3} \longrightarrow \mathrm{H}^+ + \mathrm{HCO_3}^- \tag{12}$$

The increased concentration of H^+ ions allows reactions with the OH^- in the barrier to form water, thereby in effect removing the barrier.

The discussion so far, has centered on the corrosion of iron, but other metals immersed in water can corrode and produce a measurable potential. The alkaline earth and alkali metals hold their outer shell of electrons rather loosely and have a greater potential difference than iron. On the other hand, so called "noble" metals such as gold produce very few electrons and therefore have relatively low potential. Those metals displaying lower potential, it could be assumed, corrode less extensively and less easily than those of higher potential.

The discussion has emphasized the importance of H^+ ions in the corrosion process. The pH of an aqueous solution is the negative $\log_{10}$ of the molar concentration of H^+ ions. The range of pH values is 0–14. Low pH (<7) signifies an "acidic" condition, whereas high pH (>7) represents alkaline conditions. The effect of pH on metals is dictated by the behavior of the metal oxide. If, for instance, a metal oxide is soluble under acidic conditions, the metal will exhibit a high corrosion rate under these conditions. Alternatively, if the metal oxide is soluble under alkaline conditions, $\text{pH} > 7$, the metal will corrode in contact with water. Some metals have oxides that are soluble in both acid and alkaline conditions. Zinc, tin, and aluminum fall into this group and are usually referred to as amphoteric metals. Metals that are insoluble at any pH are called "noble," as already indicated.

Iron corrosion displays what might be considered inconsistent behavior. At low pH up to about 4, acidic conditions, the behavior is similar to that of an acid soluble metal. Between a pH of around 4 and up to about 11, the pH of the water has relatively little effect on the corrosion rate because oxygen depolarization is considered the principal influence on the corrosion process. Further increase in pH values reduces corrosion even further, the minimum is at a pH of around 12. At higher pH values, iron displays amphoteric behavior and corrosion again increases.

In industrial operations, notably cooling water applications, there are generally influences from the processing environment, in which the water is being used, for instance, the use of a biocide to control biofouling. Chlorine has been the preferred biocide to control microbial growth in cooling water systems for many years on account of its availability and effectiveness, but it can influence the corrosion of the cooling water system. Chlorine is soluble in water and reacts with it to give hypochlorous acid.

The chemical equation is

$$Cl_2 + H_2O \longrightarrow \underset{\text{Hypochlorous acid}}{HOCl} + \underset{\text{Hydrochloric acid}}{HCl} \tag{13}$$

The acids ionize to give H^+ ions that reduce the pH and hence increase the potential for corrosion. The associated equations are

$$HOCl \longrightarrow H^+ + OCl^- \tag{14}$$

and

$$HCl \longrightarrow H^+ + Cl^- \tag{15}$$

Unwanted chemicals in the system may cause corrosion. For instance, ammonia may be introduced into cooling water from leaks of process fluids in the coolers of a chemical works. Ammonia can be highly corrosive to copper. The chemical reaction involved is

$$2Cu + 2H_2O + O_2 + 8NH_3 \longrightarrow 2Cu(NH_3)_4{}^{2+} + 4OH^- \tag{16}$$

The cuprammonium ion $Cu(NH_3)_4{}^{2+}$ is very soluble, and it can cause rapid deterioration of copper components in a system.

A common problem in cooling water systems is the accumulation of micro- and macroorganisms on surfaces, particularly on heat transfer surfaces. The metabolism of these organisms can give rise to modified local conditions that are often acidic, and thereby produce local corrosive conditions under the microbial deposit. If the attack on the metal is sustained, this can give rise to a corrosive condition known as "pitting."

Some microbial growth can produce unique corrosion conditions. A microbial species known as *Desulfovibrio desulfuricans,* a sulfate reducing bacterium, gives rise to the production of hydrogen sulfide from the sulfates commonly found in water used for cooling purposes. Hydrogen sulfide dissolved in water lowers the pH and hence initiates corrosion. Hydrogen sulfide in solution in contact with iron or steel produces iron sulfide. The iron sulfide that is cathodic with respect to iron promotes galvanic corrosion.

Other Combinations of Conditions That Can Lead to Corrosion

When two dissimilar metals are in contact and are immersed in a salt solution, as described earlier, a potential difference can develop. This potential difference provides the opportunity for corrosion to occur, and this corrosion can be severe. The basic conditions for the interaction of two dissimilar metals are illustrated in Fig. 2.

Metal X has a lower electrode potential than metal Y. Ions migrate into the conducting water, and electrons flow across the junction of the two metals. Metal X is corroded at Z.

Immersion of the bimetallic couple in conducting water indicates only that corrosion is possible, but the rate of corrosion is governed by other external influences. The rate of corrosion, for instance, increases in proportion to the ratio of cathode to anode area. Generally, corrosion is also affected by other influences. Corrosion is the result of chemical reactions, so increased temperature accelerates corrosion. The velocity of the water across the corroding metal can exert an effect on the corrosion rate because it affects the resistance to the mass transfer of chemical components across the laminar sublayer.

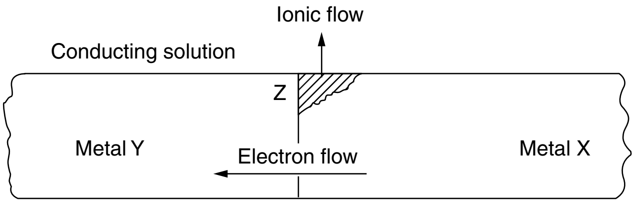

Figure 2. Corrosion at the junction of two dissimilar metals.

The metallurgy of the metal or alloy undergoing corrosion can also affect the extent of corrosion. Surface flaws such as scratches can become anodic to the rest of the metal. Anodic sites may also be established where there is stress within the metal at grain boundaries. Such a condition is often referred to as "stress cracking." So-called "caustic embrittlement" is considered a version of "stress cracking," and may result from the production of high concentrations of sodium hydroxide in the water in contact with the metal. Inclusion of metal particles that are not homogeneous with the principal metal in the system can also create a corrosion cell. For instance, brass is prone to this form of corrosion. Brass is an alloy of zinc and copper, if the zinc is removed from the surface of the metal, a porous copper layer remains that can establish corrosion cells. The process is usually referred to "dezincification." A combination of a corrosive environment and repeated working may result in early failure called "corrosion fatigue cracking." The fatigue is brought about by the repeated application of stress, such as in the tubes of a shell and tube heat exchanger that vibrate in response to operating conditions. If the protective oxide layer on the surface of the metal, discussed earlier, is subject to impingement of solid particles, or even bubbles traveling at high velocity in the water flow, the protective layer may be removed or not even formed, thereby allowing corrosion to occur.

CORROSION CONTROL

There are two principal ways in which corrosion of metal components can be eliminated or, at least, reduced by additives in circulating water. They include corrosion inhibitors and "controlled scaling." In general terms, the protection is achieved by positioning an electrical barrier on the metal that is under threat of corrosion, so that the electrical circuit is broken and the electron flow restricted. As indicated earlier, some systems have "natural" resistance to corrosion through the development of an impervious oxide layer on the metal surface that acts as an effective electrical barrier.

Corrosion, as described earlier, involves anodic and cathodic reactions. Chemicals that arrest or restrict these reactions halt or reduce corrosion. The terms anodic and cathodic inhibitors are used to classify the chemicals that are used for this purpose. Anodic inhibitors prevent or restrict electron flow (see Fig. 1), whereas cathodic inhibitors form a barrier at the cathode, restricting hydrogen and oxygen transport to the cathode surface. These are some chemical additives and their disadvantages:

Anodic Inhibitors	
Chromates	Generally not used now due to their toxicity
Nitrites	Nutrient for aquatic plant life
Silicates	Slow acting
Tannins	Nutrient for biological activity
Benzoates	Unreliable except perhaps for aluminum
Orthophosphates	Nutrient for aquatic plant life

Cathodic Inhibitors	
Zinc salts	Unlikely to be environmentally acceptable
Polyphosphates	Sludge forming and nutrient for aquatic plant life
Polyphosphonates/ molybdates	Require O_2 for effective protection; expensive.

So called "filming amines" that cover the entire surface of a metal liable to corrosion are used, particularly in the presence of steam condensate. An alternative is to apply an electrical current to the metal that is susceptible to corrosion to reverse the reactions described by Equations 2, 4, and 5, applying Le Chatelier's principle.

A more comprehensive discussion of corrosion in industrial cooling water can be found in Bott (1).

INDUSTRIAL COOLING WATER—SCALE FORMATION

T.R. Bott
University of Birmingham
Birmingham, United Kingdom

Any source of naturally occurring water used of industrial cooling has been in contact with the earth, soil, and rock formations. As a result, soluble inorganic salts have been taken into solution that can give rise to "scaling" in industrial equipment. The phenomenon is apparent in domestic kettles that have been used to boil so-called "hard water." A whitish-brown deposit forms on the areas within the kettle that are subject to the highest temperatures, for example, the heating element in electric kettles. In cooling water circuits that usually employ water from natural sources such as rivers or lakes, deposition of inorganic salts, or "scaling" as it is often called, can represent a serious problem. The presence of these salts usually results in operating problems. The accumulation of deposits on heat transfer surfaces can lead to severe loss in cooling efficiency if not effectively controlled.

In general, there are two categories of salt present in water that is natural in origin, "normal" and "inverse solubility" salts. As the temperature of the water is increased, the solubility of the normal salt also increases, for example, sodium chloride. As the temperature of an inverse solubility salt solution is increased, the solubility of the salt decreases, and, if the solubility limit is exceeded, the salt begins to precipitate. Inverse solubility salts, for example, calcium carbonate, are usually sparingly soluble, whereas normal solubility salts have relatively high solubility. It will be seen from Table 1 that many common mineral salts display the properties of inverse solubility salts. They are often referred to as "hardness salts."

Table 1. Common Inverse Solubility Salts

Calcium	carbonate hydroxide phosphate silicate sulfate
Lithium	carbonate sulfate
Magnesium	hydroxide silicate

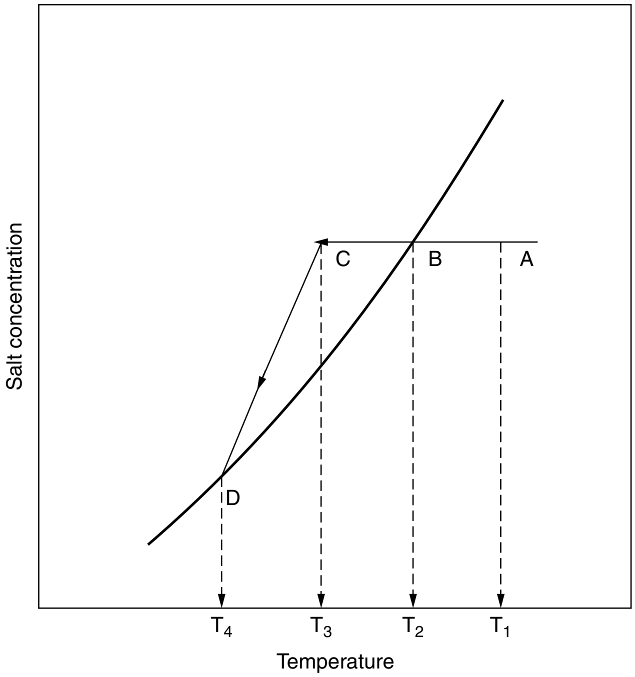

Figure 1. Cooling a normal solubility salt solution.

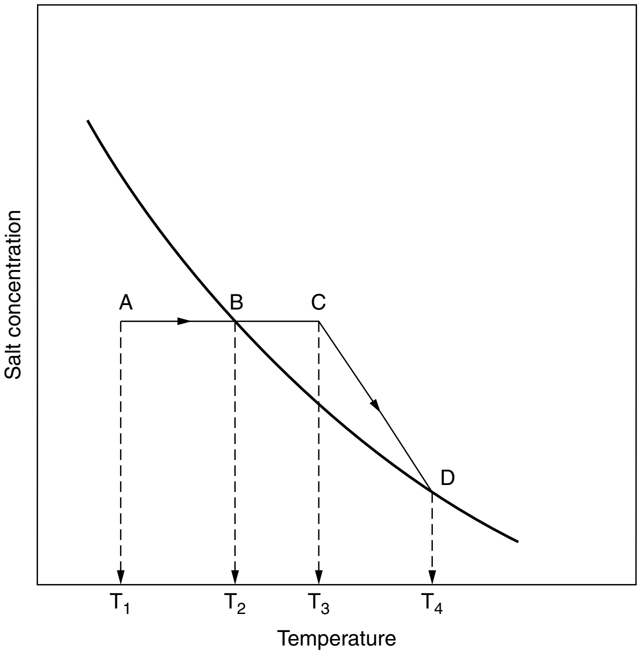

Figure 2. Heating an inverse solubility salt solution.

Whenever the temperature distribution changes in a water system containing dissolved salts, such as in an industrial cooling water system, the temperature sensitive solubility can affect successful operation. Deposition of inverse solubility salts is often one of the causes of operating problems in cooling water circuits, particularly on heat exchanger surfaces. The potential for scaling in industrial equipment is usually very high.

A solution that is in equilibrium with a soluble solid phase is said to be "saturated." The concentration in the water is the maximum that is possible at the given temperature. It is possible, however, under certain conditions, that as a saturated solution of an inverse solubility salt is raised slightly in temperature, precipitation is retarded, and the solution is said to be "supersaturated." Supersaturation can also occur with normal solubility salts. If the temperature of a saturated solution of a normal solubility salt is lowered slightly, a supersaturated solution may be produced.

Supersaturation is a necessary prerequisite for crystallization from a salt solution to occur. Its importance is illustrated in Figs. 1 and 2.

The curves in both figures represent the variation of saturated concentration with temperature. For a normal solubility salt, if the unsaturated solution represented by 'A' at temperature T_1 in Fig. 1. is cooled, that existing concentration will represent saturated conditions at the lower temperature T_2 at 'B'. Further cooling down to T_3 produces supersaturated conditions at 'C'. Supersaturation is represented by the temperature difference T_2-T_3, sometimes referred to as the "maximum allowable undercooling." 'C' represents a metastable condition; any disturbance such as the introduction of particles or crystals results in precipitation. If cooling (and precipitation) is continued, eventually a new equilibrium is reached at 'D' on the solubility curve, where saturation occurs at temperature T_4. Crystallization can occur either in the bulk or at the cold surface, through which heat is being withdrawn from the solution. The latter gives rise directly to deposit formation (scaling), and the crystallites produced in the solution may move toward the surface, under the influence of the hydrodynamics of the system, to be incorporated into the deposit on the surface.

The sequence of events, when an inverse solubility salt solution is heated is illustrated in Fig. 2. As the solution represented by 'A' is heated, it moves toward the saturation point 'B' on the solubility curve. As the temperature is further increased, point 'C' is reached where there is a degree of supersaturation and metastable conditions exist. The supersaturation is T_3-T_4. As the temperature is further increased, accompanied by a disturbance of the metastable condition, precipitation occurs, and the concentration of the salt in solution decreases till point 'D' is reached, representing equilibrium saturation conditions at temperature T_4. In a cooling water system, this could represent an operational problem in the coolers. In cooling operations, the highest temperature in contact with the coolant water is at the heat exchanger surface/water interface. Under these conditions, deposit formation, or "scaling," on the heat transfer surface can be expected. Furthermore, disturbance of the metastable supersaturation in the bulk water gives rise to crystallites that are likely, under the prevailing hydrodynamic conditions, to migrate toward the heat transfer surface with the further possibility of incorporation into the developing deposit.

In summary, the complex sequence of steps leading to scale formation is as follows: temperature changes that lead to supersaturation; disturbance of the metastable conditions, usually caused by solid particles, for instance, crystallites formed elsewhere in the system or particles of corrosion material that initiate the formation of crystallites, and ultimately crystals, either in the bulk water or at the heat transfer surface. Local hydrodynamic and temperature conditions affect the location of crystal and deposit formation.

Under constant heat flux, the presence of scale, a resistance to heat transfer, changes the temperature distribution across the heat transfer surface. These changes may affect the deposit structure and hence its strength, by reorienting the crystal lattice, with implications for the control of deposit accumulation. The degree of supersaturation may also be affected.

The previous discussion emphasizes that the key to scaling is the degree of supersaturation that is present, and it is likely that this will be different in different parts of the system. The following is a brief resume of the conditions that could lead to supersaturation; more detail is to be found in Bott (1).

Evaporation of water vapor from a solution, increases the salt concentration that could lead to supersaturation. The principal points in a system where this can occur is a cooling tower or a spray pond. It is here that the cooling water temperature is reduced for reuse by removing heat due to the latent heat required to vaporize some of the water. The "buildup" of dissolved salts is controlled by "blowdown," the removal of water containing relatively high concentrations of dissolved solids, to be replaced by "makeup" water that has the lower concentrations of the source water.

Mixing of different waters containing a common ion may lead to precipitation, the so-called "common ion effect" and attendant supersaturation. For instance, mixing a $Ca\ Cl_2$ solution with a solution of $Na_2\ CO_3$ may cause $Ca\ CO_3$ to precipitate if supersaturation occurs as a result.

Mixing of saturated or nearly saturated solutions may result in supersaturation and consequent precipitation.

Carbon dioxide, from the atmosphere dissolves in water in a cooling tower or spray pond. The chemical equilibria are

$$H_2O + CO_2 \longrightarrow H_2CO_3$$
$$H_2CO_3 \longrightarrow H^+ + HCO_3{}^-$$

The bicarbonate ion can further ionize:

$$HCO_3{}^- \longrightarrow H^+ + CO_3{}^{2-}$$

If the water is already saturated with dissolved $CaCO_3$ the additional $CO_3{}^{2-}$ ions can produce supersaturation of $CaCO_3$, and crystallization of $CaCO_3$ is possible. Hydrogen ions are involved in the reactions, so the solution pH will also affect the extent of supersaturation (2).

Crystallization

Before crystallization can occur that might lead to scale formation, it is necessary to "seed" the solution to initiate the process; usually this is accomplished by minute particles. The process is generally referred to as "heterogeneous crystallization." The particulate solids may be foreign bodies, such as pieces of scale broken off the deposit upstream, corrosion products, or crystallites that have been spontaneously formed in solution. Suitable nucleation sites may also be present on surfaces such as heat exchanger surfaces within a cooling water system. It is possible that this process is responsible for the initial deposition that provides a structure onto which further crystallization can occur or into which crystallites and larger crystals can be accommodated. Spontaneous crystallization occurs without the need for seeding. The mechanism is not well understood, but it is considered that it is related to random clustering of molecules in suitable juxtaposition to allow a tiny crystal to form. Spontaneous crystallization, however, is unlikely to occur in industrial cooling water systems because of the almost universal presence of particulate matter that will initiate scaling before spontaneous crystallization can occur.

Depending on the prevailing conditions, it is possible for a robust crystal structure to be formed on solid surfaces, particularly on heat transfer surfaces, where the necessary supersaturation is present. The structure may be weakened, making removal easier, by the presence of impurities, such as particles, in the structure.

The factors and conditions that affect scaling may be summarized as follows (1):

System Variables

Total dissolved solids concentration

Concentration of particular species

Alkalinity/acidity defined as free alkali (e.g., $CaCO_3$) and free acid (e.g., H_2SO_4) expressed as mg/L.

pH

Temperature

Plant Factors

Residence time

Evaporation, that is, concentration effects

Changes in heat load that affect the temperature distribution across the heat transfer surface, thereby changing the surface/water interface temperature

Water velocity

The general design of the equipment may affect the deposition process.

SCALING CONTROL

The conditions and factors listed that affect the scaling process are generally inherent in any cooling water system and its associated processes. In most scaling problems, therefore, the operating conditions cannot be modified. Even in a medium-sized plant, due to the large volumes of water in the cooling water system, the amount of $CaCO_3$ present, even in small concentrations, will be large and may amount to several tonnes; this has to be kept in solution by suitable water treatment.

Due to the complex chemistry of cooling water containing dissolved salts, it is difficult to assess whether or not the water will be scale forming or corrosive. As a result "indexes" were proposed to provide guidance. If the pH of water saturated with $CaCO_3$ by contact with the solid salt is denoted pH_s and pH is the measured pH of the water in the system, Langelier (3) proposed that $(pH - pH_s)$ could be used as an index to indicate whether the water would produce scale or be corrosive. If the Langelier index $(pH-pH_s)$ is negative $(pH_s > pH)$, it is assumed that the water would be corrosive. If on the other hand, the index is positive $(pH > pH_s)$ the water is saturated in $CaCO_3$, and scale formation is a distinct possibility.

Ryznar (4) suggested an improved index, $(2pH_s-pH)$. If the index is above 7, it is likely that the water would be corrosive. An index of 6 or lower suggests the possibility of scale formation.

Although these indexes have been used for many years in connection with water treatment in cooling circuits, there is some evidence that they are not altogether reliable because they are based on $CaCO_3$. Such a procedure ignores the complex water chemistry of associated cooling water systems and plant operating conditions.

Acid Treatment

The indexes discussed above suggest that a method of scale control could be the addition of acid, for example, sulphuric acid, to reduce the pH. There is a distinct risk, however, that severe corrosion may occur as a result of the acid treatment, so that in general, more sophisticated techniques are employed.

Water Softening (Removal of Hardness Salts)

Lime softening, ion exchange, and the use of membranes are potential methods for the control of scaling in industrial cooling water systems, but because of the large volumes of water to be treated, only lime treatment is used to any extent from this group of techniques. The more sophisticated techniques of ion exchange are far too expensive, except in closed cooling water circuits. Pretreatment with lime involves precipitation of carbonate hardness by hydrated lime, as calcium carbonate and magnesium hydroxide. An alternative is to pretreat with soda ash (Na_2CO_3) that precipitates other calcium salts in solution in addition to the carbonate. Soluble by-products in the form of sodium salts remain in solution.

Threshold Treatment (Sequestration)

When some chemicals are added to cooling water, even in relatively small quantities, they prevent the precipitation of alkaline salts and other scaling compounds, particularly calcium ions and manganese salts. Sometimes the result of the treatment is the production of sludge rather than scale that adheres to the heat transfer surface. The sludge can be removed from the system by suitable flushing. Phosphorous compounds are often used as sequestering agents. Table 2 provides some information on phosphorous compounds and their advantages and disadvantages for use with cooling water.

Crystal Modification

In the discussion of crystallization, it was stated that impurities included in the scale can reduce the cohesiveness of the crystal structure. It is possible, therefore, to effect scale control by adding so-called "scale modifiers" to cooling water. The action of these chemical additives does not prevent precipitation, as does threshold treatment, but simply reduces the opportunity for strong crystalline structures to form on heat transfer surfaces. The weaker structure of the scale makes it more susceptible to removal forces produced by the water velocity at the water/solid interface. Naturally occurring organic compounds, such as lignin or tannin, have been used for this purpose, but synthetic chemicals such as polycarboxylic acids are now more widely used as crystal modifiers. Polymaleic acid, for instance, produces a soft deposit with precipitating calcium carbonate that is easily removed.

Dispersants

It is possible to add a dispersing agent to the cooling water to keep the individual crystallites apart as they form in the water, and so reduce the opportunity of forming coherent crystal structure. Surface active agents on solid surfaces, such as heat transfer surfaces, may also hold the crystallites away from the surfaces, and so restrict scale formation. Dispersants that have been used for

Table 2. Organophosphorous Compounds Used as Sequestering Agents[a]

Compound Type	Advantages	Disadvantages
Polyphosphates	Hydrolysis to orthophosphate which reacts with calcium to form a sludge	Nutrient for microorganisms
Phosphonates	Effective against both alkaline and nonalkaline scaling conditions	If supersaturation levels are allowed to rise, uncontrolled precipitation may occur
Phosphate esters	Wide range available; biodegradable	Less effective than phosphonates
Phosphoncarboxylic	Similar to phosphonates	Some rise in supersaturation may be tolerated without attendant precipitation

this purpose include organophosphorous compounds and polyelectrolytes.

General

Treatment programs for scale prevention are likely to include a range of chemical additives so that a number of techniques are working in parallel to control scale formation and also for corrosion control and biofouling mitigation.

Figure 3 is a diagram published some years ago that demonstrates how chemical additives may be used to control scaling and corrosion for different Ryznar indexes (5).

ECONOMICS OF INDUSTRIAL WATER DEMANDS

Steven J. Renzetti
Brock University
St. Catharines, Ontario,
Canada

This article examines what is known regarding the economic characteristics of industrial water use. Understanding the economic dimension of industrial water use is important for several reasons. First, in some countries, industrial water use is already an important part of total water use. Furthermore, in a number of countries, the proportion of total water use accounted for by industry is rising rapidly. Second, much of industrial water use results in significant alterations in water quality. Third, industrial water use differs from water use in other sectors because many firms recycle water and because many firms may choose their source of water supply.

INTRODUCTION

Manufacturing firms, mines and power generating plants typically withdraw water from the natural environment for three main reasons. First, water is applied in a production process. This includes cleaning and moving intermediate inputs as well as inclusion in final output (the production of beer). Second, water is used to cool

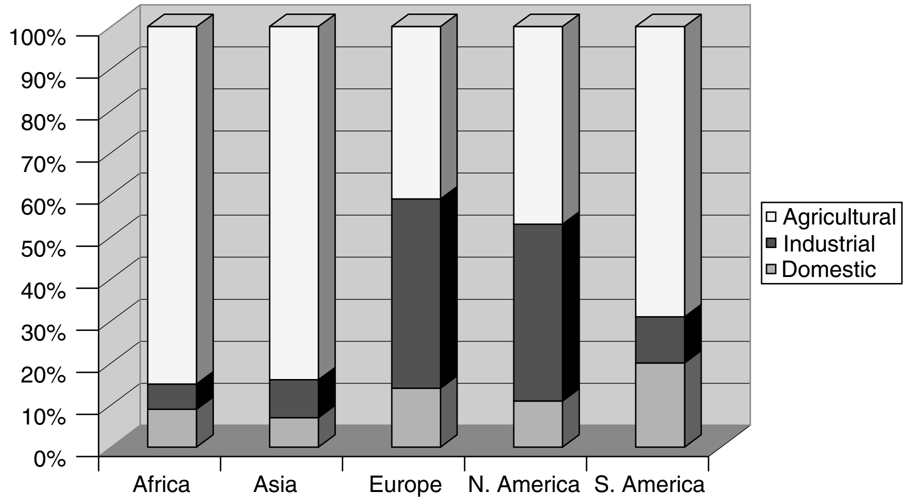

Figure 1. Sectoral shares in water use (1990) (1).

intermediate inputs (the production of petroleum-based fuels) or to produce steam (thermal electric generating plants). Third, water is used for a variety of miscellaneous purposes such as plant cleaning and personal sanitation.

The share of national water use accounted for by industrial water use (including water use in electrical power production) ranges from less than 5% in a number of low-income countries to more than 70% in a number of northern, high-income countries (1) (Fig. 1). Furthermore, in a number of countries experiencing rapid economic development and industrialization such as China, Indonesia and India, industrial water use's share is rising quite rapidly (2).

The next section of this article outlines briefly the economic theory that supports modeling industrial water use. The third section reviews the body of empirical industrial water demand models and the results that flow from this set of work. The last section concludes and provides suggestions for future research. Any brief survey must be selective in its coverage. A number of topics that are related to industrial water use are not discussed here. These include water-based commercial transportation, industrial wastewater discharges, and the valuation of industrial water use. These topics are covered in other articles found in this *Encyclopedia*. In addition, readers interested in a more detailed treatment of the issues surrounding the economic features of industrial water use may refer to Young and Gray (3), Stone and Whittington (4), Gibbons (5), and Renzetti (6,7).

The Economic Theory of Industrial Input Demands

Until recently, it was commonplace to assume that the amount of water required to produce a given quantity of output was fixed (8). In addition, aside from minor variations from differences in technology and the age of capital stocks, it was assumed that the ratio of water use to output was not sensitive to changes in the price of water or the prices of other inputs. In contrast, economists who believe that profit-maximizing firms' use of any input is sensitive to its own price, the prices of inputs, and the price of output have criticized this perspective. To see this, suppose that a firm's technology is represented by a production function $y = f(x_1, \ldots x_N)$ that shows that maximal amount of output (y) that can be produced from input quantities ($x_1, \ldots x_N$). Assuming that the firm faces a price of output (p) and prices of inputs ($w_1, \ldots w_N$) and that the firm seeks to choose output and input quantities to maximize its profits, then the firm's problem may be cast as the following:

$$\max_{\{y,x_i\}} p \cdot y - \sum_i w_i \cdot x_i, \quad i = 1 \ldots N$$

Carrying out this optimization yields the firm's profit-maximizing output supply and input demand equations (Ref. 7, chap. 4; 9):

$$\begin{aligned} y &= g(p, w_1, \ldots w_N), \\ x_i &= h(p, w_1, \ldots w_N), \quad i = 1 \ldots N \end{aligned}$$

It is clear from this presentation that the demand for any input (including intake water) is a function of its own price, all other input prices, the price of output, and the firm's technology. Only in exceptional circumstances should it be expected that the ratio of water intake to output be invariant to prices. Economic theory predicts that both increases in the price of output and decreases in the price of intake water will increase the demand for water. The impact of changes in other input prices on the demand for water will depend on whether those inputs are substitutes or complements to intake water in the firm's production process. Economists typically report these types of relationships as an "elasticity." For example, the own-price elasticity of intake water demand is the change in the quantity of water intake used by the firm in response to a small change in the price of intake water (both changes are expressed in percentages). The strengths of all of these relationships (that is, the magnitude of the elasticities) is a matter for empirical investigation.

EMPIRICAL MODELS AND RESULTS

The main purposes for estimating or calibrating empirical models of industrial water use are to understand water's role in production processes; to examine the relationship between intake water, internal water recirculation, and other inputs; and to measure the sensitivity of water demands to prices. These models may be used to forecast water demands as well as predict the sensitivity of industrial water uses to policy measures aimed at promoting water conservation. There are two main obstacles standing in the way of this type of industrial water demand research. The first is the fact that much of industrial water intake is self-supplied rather than being supplied by a municipal or regional water utility. The result of this is that many industrial water users face either no price for their intake water or only an administrative price that bears little resemblance to the value of water. The second obstacle stems from the lack of data on industrial water intake, recirculation and discharge. Few countries regularly collect and report these data (9).

Despite these challenges, a number of researchers have considered the structure of industrial water demands. The modern literature concerned with industrial water demands begins with a major research effort undertaken by analysts at Resources for the Future (10–12). These studies are noteworthy for their careful application of economic principles and measurement techniques and combining of econometric and engineering methods to represent firms' water use patterns. Since that time, researchers have employed econometric and programming models to examine industrial water demands. Both of these approaches are discussed briefly here.

Initial econometric efforts use ordinary least squares to fit linear equations to plant-level data (13,14). The data included observations on the price of water, the quantity of intake water, and the level and type of output. Both authors report elasticities whose values vary by industrial sector and use of water. De Rooy finds that price and output elasticity estimates vary according to the use of the intake water: −0.894 and 1.212 (cooling); −0.354 and 1.359 (process); −0.590 and 1.243 (steam generation).

An important issue in these and subsequent studies concerns the specification of the price of intake water. For publicly supplied firms, industrial water prices are typically a combination of a connection fee and a complex rate schedule (9). When price is a function of quantity, this creates the possibility of introducing a simultaneity bias into the estimated demand equation. Ziegler and Bell (15) and Renzetti (16) address this issue by estimating demand equations using an instrumental variable technique.

An even more serious challenge arises from industrial water users who are self-supplied. In this case, there may be no external price for intake water. Self-supplied firms incur several types of cost for their water use. First, the firm incurs internal costs resulting from pumping, treatment prior to use (chlorination, descaling, etc.), and on-site storage. Second, the firm may face external costs arising from fees and charges set by government. Third, the firm may incur internal costs for water disposal such as treatment, removal of effluents, pumping, and on-site storage. It is very likely that information regarding the first and third sources of cost will not be publicly available and firms may not even collect this information themselves. This means that it is difficult to specify and measure the cost of an incremental increase in water intake. Grebenstein and Field (17) address this challenge by relying on water utility prices to proxy self-supplied firms' water costs, whereas Renzetti (16) relies on plant-level observations on water utility prices, government water charges, and internal water use costs to construct a proxy for the price of water.

A number of authors (16–19) have used a system of equations approach to estimate the industrial demand for water. This increases the efficiency of estimation and allows the authors to examine the relationship between water and other inputs. Each of the authors assumes that the technology of the manufacturing sector may be represented by a cost function that includes the prices of capital, labor, energy, materials, and water as well as the level of output, as explanatory variables. A system of input demands is then derived from the cost function and estimated. Babin, Willis, and Allen find that the own-price elasticity of intake water ranges from 0.0 to −0.66 and an estimate of −0.66 for all sectors combined. Water's relationship to other inputs also varies across sectors. Water is a substitute for capital in some sectors and is a complement in others. Renzetti (16) finds that water intake's price elasticities range from −0.153 to −0.589, depending on the sector. Water recirculation is seen as a substitute for intake for all industries. Industries that are heavy water users (paper and wood products, chemicals, petroleum, food and beverage) also are the most sensitive to price changes.

More recently, Dupont and Renzetti (20) take a different approach in examining industrial water demands. The authors incorporate water recirculation and technological change in their estimation model and examine the impact of water use regulations on water demands. Because self-supplied firms in Canada must obtain a permit before withdrawing water, the authors consider whether firms are free to choose the optimal quantity of intake water (as is assumed in deriving input demand equations). Two alternative models are estimated: one assuming that water intake is a variable input and the other assuming that water intake is fixed. Specification tests support the choice of modeling water as a variable input. Water intake is found as a substitute for energy, labor, capital, and water recirculation. The relationship between water intake and recirculation is stronger when water use is process-related rather than related to cooling and steam production. Technological change has been biased in the direction of increased water intake and decreased water recirculation.

An alternative to using econometric methods to model water demands is to use linear programming techniques. Linear programming is a technique that is employed to find optimal solutions to problems when the objective function is linear and constraints are expressed as linear inequalities. For example, the objective function may measure a firm's revenues, and the constraints may reflect production processes that relate combinations of input quantities to levels of output. The solutions to linear programming problems have several interesting features that differentiate them from the estimated econometric demand models discussed before. For example, input demand equations derived from linear programming models are typically piecewise, continuous and linear. Discontinuities in the demand equation correspond to the adoption of new production processes (such as the installation of a cooling tower that permits recirculation and reuse of cooling water). Simulations conducted by Calloway, Schwartz, and Thompson (21) demonstrate the significance of this feature. Their results indicate that for intake water prices anywhere below 3.2¢ (1971 US$) per 1000 gallons, a plant producing ammonia employs a water intensive 'once-through' cooling system. At 3.2¢ per 1000 gallons, however, the plant switches to recycling its cooling water, this reduces water intake by 95%, and further price increases do little to encourage further water conservation.

Thompson and Young (22), Singleton, Calloway, and Thompson (23), and Kindler and Russell (24) are representative of this approach. Thompson and Young (22), for example, use engineering data and linear programming techniques to examine water use in thermal power generating stations. They find that there are a number of options for conserving water intake and these options become financially feasible at differing water prices. In addition, the authors find that the power plants can be encouraged to reduce water intake through policy measures such as heat discharge taxes.

Firms that use water in their production processes must find some way to dispose of that water. Water quality regulations typically impose limits on the quantity and/or concentration of effluents that can be discharged. Some analysts argue that water quality regulations have been a driving force in compelling firms to reduce their emissions (25,26). Empirical evidence also suggests that economic forces are relevant. A number of authors (12,16,27) have examined the sensitivity of firms' water discharge decisions to economic factors such as sewage prices, discharge fees, and fines. For example, Renzetti (16) finds that, for the Canadian manufacturing sector as a whole, the price elasticity of water discharge is −0.9752.

The discussion thus far has concentrated on water use in the manufacturing sector. A limited number of studies have considered commercial and institutional water use. The limited amount of work done in this area suggests that this sector's water use is sensitive to water prices and the firm's level of output. Schneider and Whitlatch (28) estimate a series of demand equations to calculate price and income elasticities for several user groups, including commercial, industrial, government, and education. The account-specific price elasticities (following the order of user groups set out before) are −0.918, −0.438, −0.781 and −0.956. Given the diversity of water users in these sectors, generalizations regarding the nature of their water use is quite difficult.

Water use in the mining and electricity power production sectors also has received relatively little attention, maybe because mining water use in most countries is a small share of total estimated withdrawals (it is approximately 1% in the United States and Canada; (26). Despite mining's small share in total withdrawals, water use by mines can be important regionally if they are located in areas where water is scarce such as the American Southwest or the western provinces of China. Mining water use can also be important because of the water contamination that frequently results from mining operations. More attention has been paid to water use in electricity production. The primary concern here, however, has been in establishing the value of water in this use, as opposed to estimating water's role in this technology (29). Young and Gray (3), Gibbons (5), and Renzetti (7) survey the methods used to estimate the value of water use in electricity production.

CONCLUSIONS AND DIRECTIONS FOR FUTURE RESEARCH

Industrial water use is important for several reasons: in a number of countries, it makes up a significant part of total water use; firms derive significant benefit from its use, it has the potential for causing substantial alterations in water quality, and it often involves decisions by the firm regarding the degree of internal recirculation to undertake. For these reasons, a number of researchers have sought to understand the economic character of industrial water use. The available empirical evidence indicates quite clearly that decision-making with respect to water does not differ significantly from that for other inputs. Thus, industrial water use is sensitive to its own price, the price of output, and other input prices. Future directions for research will include efforts to combine econometric and engineering process models of industrial water use. These approaches are quite complementary: process models are very detailed and satisfy materials balance constraints, and econometric models are based on a range of technologies and market prices. Another area that remains understudied is the set of factors that influence firms' decisions regarding whether (or how much) to recirculate water.

ELECTRIC GENERATING PLANTS—EFFECTS OF CONTAMINANTS

Robin J. Reash
American Electric Power, Water & Ecological Resource Services
Columbus, Ohio

INTRODUCTION

Environmental pollution incidents concerning electric generating facilities have often been widely publicized. Some examples of these include choking air emissions, catastrophic coal ash spills, temporary releases of radioactivity, and contamination of groundwater. In some cases, a direct threat to human health was the cause for concern. In the movie "Erin Brokovich," an activist (played by actress Julia Roberts) draws public attention to the contamination of groundwater by potentially toxic trace metals that have leached through a power plant ash disposal facility. Most of these spectacular pollution events, however, occurred before full, widespread implementation of major environmental statutes (e.g., Clean Air Act, Safe Drinking Water Act, Resource Conservation and Recovery Act, Clean Water Act), enacted by the U.S. Congress during the period 1970–1980. These statutes provide minimum (baseline) environmental protection requirements for the release of pollutants to air, water, and land. Although most states have implemented the requirements of these statutes for several years, concerns regarding pollution released from electric generating facilities still remain in some locations.

This article concerns contaminants released or discharged to the water environment by electric generating facilities. The focus of this article will be on contaminants originating from the combustion and use of fossil fuels. Releases from nuclear-powered facilities will not be considered, largely because the only significant contaminant released by these stations is heated water. The pathway by which power plant contaminants affect aquatic ecosystems may be either direct or indirect. Some pollutants emitted to the air by coal combustion facilities, for example, have the potential to degrade surface waters or affect human health. A general historical review of power plant environmental impacts and environmental control will be discussed, followed by an assessment of sources and effects of pollutants in the water environment.

Historical Review of Power Plant Generation and Contamination

In general, the historical pattern of environmental effects caused by electric generating facilities mirrors the extent and magnitude of fossil fuel (largely coal) combustion. More precisely, the efficiency and extent of pollution control technology in the mining, transport, and combustion of coal and coal-derived materials has been a significant determinant concerning the release of contaminants. The extraction and combustion of coal has a legacy of environmental degradation to air, land, and water. Ecological and human health effects from fossil fuel combustion, which occurred through the first half of the twentieth century, played a significant role in the public's demand for a cleaner environment. Most of these perturbations occurred in the coal-bearing Appalachian region, which is not to say that significant environmental degradation during the first 50–70 years of the twentieth century was limited to fossil fuel combustion; numerous other environmental problems (e.g., discharge of raw sewage, indiscriminant use of persistent pesticides, urban air pollution) affected many industrialized countries during this period. In short, the congressional adoption of the major environmental statutes during the 1970s was driven, at least in part, by the desire to mitigate the environmentally harmful effects of coal mining, transport, combustion, and waste disposal.

As a result of the oil embargo instituted by OPEC countries against the United States during the early to mid-1970s, a national policy of reducing United States dependency on foreign oil was instituted, which resulted in the unprecedented construction of coal-fired (and nuclear-powered) electric generating stations during the mid-to-late 1970s. An increased demand for coal began as the construction of more proposed coal-burning facilities was approved by government regulators. As greater and greater amounts of coal were burned, the magnitude of pollutants emitted (and waste disposed of) began to reach peak levels. During this period, several environmental concerns became widely publicized: acid rain, thermal pollution, particulate matter, acid mine drainage, groundwater contamination, and others. Ultimately, new federal laws and regulations were successful at reducing or mitigating the harmful effects of power plant contaminants.

During the past 30 years, the quality of ambient air and water has improved considerably. This success has resulted largely because of two factors: the adoption of more stringent ambient standards and the requirement to meet best available technology controls for each industry sector. The investment of pollution control technologies and process modifications made by the power industry has not been insignificant. New coal combustion facilities must meet "new source standards" for environmental controls. A new era of "clean coal" technologies is now being implemented. In 2002, combustion of coal (and coal-derived fuels) represented approximately 53% of the U.S. electricity demand (1). This high percentage is likely to remain for some time, as the domestic coal reserve is anticipated to last for about 200 years, considerably longer than reserves for oil and natural gas (2).

It is important to note that the process of coal combustion does not "create" new pollutants. Rather, the extraction and combustion of coal changes the forms, mobility, and environmental compartmentalization of natural constituents in coal. Coal mining mobilizes constituents that normally would be secured in geological strata. When coal is combusted, the natural constituents in this fuel (trace metal, radionuclide, and organic compounds) are transformed into volatile forms (air emissions) or concentrated in ash (solid waste) because of chemical reactions caused by high combustion temperatures.

Air Emission Contaminants

In terms of total mass of pollutants released to the environment, power plant air emissions far outweigh the amount of pollutants released to land and water. Table 1 indicates the types of contaminants released to the air during coal combustion and potential adverse effects on human health and terrestrial/aquatic receptors. Depending on site- and region-specific fate and transport processes, many contaminants emitted by fossil fuel combustion can eventually transfer to the aqueous (water) medium; contaminants such as mercury and selenium do have the potential to be bioaccumulated in surface water

Table 1. Typical Contaminants Released to the Air During Fossil-Fuel Combustion, and Potential Human Health and Environmental Effects

Contaminant Class	Representative Contaminants	Potential Human Health and Environmental Effects
Gases	CO, SO_2, SO_3, NO_2, O_3	Respiratory irritants; atmospheric warming; acidic wet deposition; eutrophication of surface waters; increased ozone and haze
Trace elements	As, Ba, Cd, Cr, Pb, Hg, Ni, Se, Tl	Respiratory irritants; bioaccumulation in crops; bioaccumulation in terrestrial and aquatic food webs
Radionuclides	Isotopes of U, Th, Ra	Radiation exposure via inhalation, dermal, or ingestion exposure routes
Carbonyl compounds	Formaldehyde, acetaldehyde	Respiratory irritants
Aromatic hydrocarbons	Dioxins, phenol	Potential carcinogenic effects; respiratory irritants; food chain bioaccumulation
Acids	Hydrofluoric acid, hydrochloric acid, sulfuric acid	Respiratory irritants
Fine particulates	Sulfur particulates	Respiratory irritants; eye and throat irritants

systems. Other power plant contaminants emitted by coal-fired power plants return to the soil or are sequestered in biomass (trees, grasses, crops). The potential of these sequestered contaminants to elicit adverse effects in the water environment is typically small or negligible.

In 1998, U.S. EPA issued a report to Congress on the levels, and associated health risks, of hazardous air pollutants (HAPs) emitted by utilities using fossil fuel combustion (3). A total of 67 pollutants were assessed by the agency. The report indicated that, for most toxic contaminants emitted to the air, the inhalation (respiratory) route of exposure was most important. Emissions of mercury from coal-fired utilities was the HAP of greatest potential health concern, because mercury is highly persistent and can bioaccumulate to potential harmful levels in foodstuffs (mostly fish and shellfish). Three HAPs were identified that pose potential health concerns, although considerable uncertainties remain: dioxins, arsenic, and nickel. Dioxin, like mercury, has the potential to accumulate in crops or food web compartments. The mass of dioxin emitted from power plants, however, is very small compared with other HAPs. U.S. EPA concluded that, for the majority of generating facilities studied, the cancer risk from inhalation exposure is estimated to be less than 1 in one million (1×10^{-6}).

Damage to aquatic ecosystems from the atmospheric drift and fallout (deposition) from industrial point sources has been well documented in certain geographic areas. Pervasive ecological damage (caused by deposition of several trace metals and resulting bioaccumulation) was documented in several lakes downwind of the Sudbury, Ontario smelter (4). Fossil-fueled power plants emit approximately 45 tons of mercury each year in the continental United States (5). The transport and fate of mercury emitted from coal-fired facilities is complex, however, and is driven largely by chemical speciation of mercury and local meterological conditions. Some studies have shown a close association between mercury emissions from a power plant and levels observed in proximate environmental compartments [e.g., (6)], whereas others have not [e.g., (7)].

Solid Waste and Water Contaminants

Although some contaminants emitted to air during fossil fuel combustion have the potential to deposit on surface water watersheds to levels that could cause adverse ecological effects, contaminants released from dry ash and aqueous (wet) ash disposal facilities have a greater potential to enter aquatic ecosystems because of the much greater proximity to surface waters and groundwater. Table 2 indicates the contaminants that are typically released to groundwater and/or surface waters as a result of solid and aqueous disposal of coal combustion byproducts.

Coal combustion results in voluminous amounts of ash, which must be disposed. Two types of ash predominate: fly ash and bottom ash. Fly ash (which represents about 80% of the total coal combustion waste) is composed of fine-grained particles that have a variable morphology and consist primarily of an amorphous glassy material. The elemental composition of fly ash is highly variable and directly related to compositional variations in the parent coals and to the operational characteristics of individual power plants. Some elements are concentrated (enriched) on fly ash particle surfaces. Some trace metals are particularly enriched on fly ash particles. Suloway et al. (8) reported that arsenic, selenium, antimony, and lead typically have concentrations in ash that are 2–10 times the concentration in parent coal samples. Depending on factors such as pH, some trace metals may desorb from the ash particles and become soluble in ash ponds (treatment facilities used to precipitate metals, salts, and other constituents prior to discharge). Fly ash leachates may be toxic to aquatic receptors, depending on the concentration and bioavailable fraction.

Table 2. Typical Coal Combustion Byproduct Contaminants Released to Groundwater and/or Surface Waters from Solid and Aqueous Disposal Facilities

Coal Combustion Byproduct Disposal Method	Typical Contaminants	Potential Groundwater/Surface Water Effects
Solid waste- dry fly ash disposal	Trace metals	Leachate may contaminate aquifer if impermeable liner has not been installed. Collected leachate may be discharged to surface waters
Solid waste—FGD Sludge Disposal	Salts (sulfate, chloride, calcium); some trace metals	Leachate may contaminate aquifer if impermeable liner has not been installed. Collected leachate may be discharged to surface waters
Fly ash and bottom ash—aqueous disposal	Trace metals; particulates; extreme pH	Direct toxicity to aquatic life if toxic (bioavailable) form predominates. Suspended particulates may precipitate on stream substrate or lake bottom. Proximal sediments may be toxic to aquatic life. Bioaccumulative metals may cause indirect food web effects (effects on top predators or aquatic-dependent wildlife)

Bottom ash is composed of heavier, agglomerated ash particles that are too dense to be carried in the flue gas. Bottom ash is typically gray to black in color, is quite angular, and has a porous surface structure. Normally, bottom ash is less enriched in trace metals and salts compared with fly ash.

Another type of power plant combustion byproduct that may affect surface waters or groundwater is flue gas desulfurization (FGD) material. FGD systems are installed at power plants to provide enhanced removal of sulfur compounds from flue gas, a process that involves the capture of sulfur gases with sorbents. Limestone (calcium carbonate), lime (calcium oxide), and ammonia are the most widely used sorbents. FGD wastes are typically enriched with various calcium and sulfur-based salts. If released from disposal facilities, these constituents can alter surface water ionic strength and, subsequently, cause ionic imbalances in aquatic life.

Contamination of groundwater is a concern if the affected aquifer is a source of drinking water. If ash disposal facilities are not placed on impermeable geological formations (e.g., clay) or not adequately enclosed with a synthetic liner, leachate materials (salts and/or trace metals) can infiltrate into nearby aquifers [e.g., (9, 10)].

EFFECTS OF CONTAMINANTS—WASTEWATER DISCHARGES

Cooling Water Contaminants

For power plants that use once-through cooling (ambient water withdrawn for heat transfer in the condenser pipes), a few contaminants may be added to the heated water at concentrations that may affect nearby aquatic life. On a periodic basis, condenser pipes are flushed with a strong oxidant (typically chlorine or bromine) to reduce biofouling buildup on the pipes. Biocides may also be used to directly kill small mollusks or other larger fouling organisms. Adverse effects to aquatic life have been demonstrated when chlorine is used for biofouling control [e.g., (11)]. In addition, synergistic effects have been observed when aquatic life is exposed to both chlorinated water and heated water, simultaneously.

Condenser pipes experience chemical corrosion over time. Thus, metals may slough off these pipes and, depending on the available dilution, can be present in potentially toxic amounts. Wright and Zamuda (12) measured elevated levels of particulate and dissolved copper downstream of a once-through cooled power plant in Maryland. These levels were clearly above ambient concentrations.

Chemicals may be deliberately injected into the condenser system to help prevent alloy metal corrosion. These chemicals can be toxic to aquatic life if the dosing regime is not adequately regulated.

Coal Ash Byproduct Contaminants

Some useful reviews of the chemical composition, toxicity, and environmental hazards of power plant ash have been published (13–15). The extensive review by Rowe et al. (15), in particular, provides excellent coverage of the chemical characteristics of coal combustion wastes and the range of documented toxicological and ecological effects caused by contaminants in these wastes. As the chemical characteristics of coal ash differ considerably because of the blend of coals burned, generalizations regarding the environmental hazards of coal ash wastes are only speculative. Site-specific assessments of final coal ash discharges (concentration, dissolved and particulate phases, mitigating characteristics) are needed to make definitive predictions of potential toxicity. Often, basic characteristics of the receiving waters (dilution capacity, buffering capacity, suspended solids concentrations) dictate whether *in situ* adverse effects actually occur.

Numerous studies have been conducted documenting the adverse effects of wet ash discharges. Table 3 summarizes the range of observed adverse effects caused by coal ash wastewater discharges, grouped by type of ecological aberration. See Rowe et al. (15) for a more comprehensive review of adverse effects from the discharge of coal ash combustion wastes to surface waters.

Table 3. Types of Adverse Ecological Effects Caused by Coal Ash Wastewater Discharges, with Selected Literature Examples

Ecological Effect	Selected Examples and Reference Citations
Direct toxicity of seepage/wastewater	Acidic, iron-enriched ash pond seepage caused direct mortality to fish (16)
Simplification/modification of invertebrate or fish community	Structural and functional modifications to stream invertebrates (17, 18)
	Tolerant invertebrates and fish species downstream of fly ash pond discharge (19, 20)
Sediment toxicity/metal accumulation	Elevated levels of metals in sediments influenced by fly ash pond discharge (21, 22)
Trace metal bioaccumulation	All food web compartments with elevated concentrations of some trace metals (21, 22)
	Elevated levels in specific fish tissues (23)
Physiological/biochemical/hematological aberrations	Several assays in affected fish significantly different compared to reference fish (24, 25)
Reproductive toxicity	Top predator fish in power plant cooling lakes (receiving coal ash inputs) showed reproductive toxicity due to selenium (26, 27)

REGULATORY CONTROLS—WASTEWATER DISCHARGES

Power plant wastewaters are currently regulated under technology-based national categorical effluent standards. These standards were promulgated in the Effluent Guidelines and Standards for the Steam Electric Power Generating Point Source Category in 40 CFR 423.12 in 1982 and 1983. These limitations include monthly and daily maximum limitations for pH, total suspended solids, oil and grease, and free chlorine (all regulated outfalls); maximum limitations for copper and chromium for boiler chemical cleaning wastes; and maximum chromium and zinc limitations for cooling tower blowdown. For all outfalls, no detectable amounts of PCBs are allowed. Most power generating facilities are able to comply with these categorical standards, as adequate treatment facilities can be designed well in advance of plant operation.

More problematic for power plant wastewater discharges, in terms of compliance, is the requirement to meet water quality-based effluent limitations (WQBELs). These limitations are based on numeric, not-to-exceed water quality criteria that often differ among states. Water quality criteria are estimates of pollutant-specific concentrations that would not cause adverse effects to aquatic life or humans (based on contact recreation or consumption of fish). In contrast to the fixed, categorical effluent limitations, WQBELs can change with time because water quality criteria change (often becoming lower in concentration, or more stringent). In many instances, power plant facilities have installed costly treatment systems to remove constituents (typically trace metals) in order to meet certain WQBELs.

Like other source categories, power plant wastewaters are subject to complying with whole effluent toxicity criteria and/or limitations. Whole effluent toxicity criteria are meant to protect against unacceptable toxicity in the aggregate wastewater discharge. Typically, discharges are assayed using standardized laboratory testing procedures. If effluent toxicity is high, a facility may be required to identify the causative toxicant and remove (or mitigate) the source of the pollutant.

SUMMARY

As an energy source, the combustion of fossil fuels has been a principal factor in the rapid industrialization of many countries during the twentieth century. The legacy of environmental degradation caused by coal combustion is well documented, from coal extraction activities (mining) to release of contaminants into the atmosphere. The adoption and promulgation of several major environmental statutes, however, has lessened the overall environmental impacts of coal combustion. New coal-fired power plants use coal that has low levels of sulfur, mercury, and other environmentally important constituents. The electric utility industry has made prudent investments in cost-effective pollution control technologies. The pressures to implement new, less polluting technologies will drive the industry to balance use of this abundant energy source with cost-effective environmental controls.

ENERGY DISSIPATION

T. R. Bott
University of Birmingham
Birmingham, United Kingdom

Many process industries, such as oil refining or chemical manufacture, need to cool products or intermediate streams that may be either liquids or gases, before storage or further processing. To conserve heat and hence costs, it is usual to transfer as much heat energy as possible from an outgoing "hot" stream to an incoming cold stream or intermediate. However as the temperature of the "hot" stream is reduced, there comes a point where it is no longer economical or feasible to reduce the temperature of the stream to be cooled by further interchange of heat. As the temperature of the "hot" stream approaches the temperature of the incoming stream, the temperature driving force for heat transfer is reduced so that a relatively large heat transfer area is required to complete the cooling process. In general, naturally occurring water has a relatively low temperature and because there is so much of it in the world—in seas, lakes, rivers, canals, and boreholes—water is used as a universal cooling medium. The increasing world shortage of water, however, requires effective water management to conserve supplies and to protect the environment.

Apart from process industries, cooling is essential for efficient use of fuel for power generation. In the power industry, steam is usually made by combusting fossil fuel, biomass, or flammable waste, such as domestic refuse. The steam produced is used to power turbines, which drive electricity generators. It is possible to arrange for the exhaust steam from the turbines to be discharged at atmospheric pressure, but if the exhaust steam is condensed, the pressure drop across the turbine is increased so that additional energy from the steam can be converted into electrical energy. Heat removal from the steam that reduces the steam pressure is usually achieved in water cooled condensers, adding significantly to the overall efficiency of the power station in converting the chemical energy stored in the fuel to electrical energy.

The use of water for cooling purposes has several advantages. It is generally plentiful, although in some arid parts of the world it is not available in adequate quantities. Under these circumstances, air cooling is likely to be preferred. Water has a relatively high heat capacity and a relatively wide operating temperature range. It is easily transported around a cooling circuit by pumping. It is reusable, provided that its temperature, after use as a coolant, can be reduced and it is suitably treated to prevent operational problems that would otherwise occur.

COOLING WATER SYSTEMS

Three cooling water systems are used in industry: enclosed recirculating, open recirculating, and "once through" systems.

Enclosed Recirculating Systems

In the enclosed recirculating system, the water is totally enclosed and isolated from the atmosphere. In operation, the water takes heat from the process stream or condensing steam in a suitable heat exchanger and is then pumped through air blown coolers. Usually the tubes in these coolers are finned on the air side to improve the heat transfer from the water to the air stream. The air passes through the cooler by natural draft or is forced through by a suitable fan. The air may be drawn through the heat exchanger by a fan mounted on top of the exchanger, in which case it is known as an "induced draft" cooler. Alternatively, a fan mounted below the cooler is called a "forced draft" system. Provided that the water is suitably treated to avoid deposition and corrosion problems and the water quality is monitored frequently, the enclosed system can operate for long periods of time with a minimum of attention. The system is not common, however, at least in temperate zones, because of the additional capital cost involved, largely due to the fact that the heat is removed from the water as sensible heat. It is more usual to remove the heat gained by the cooling water by evaporating some of the water to the atmosphere in an open recirculating system. The removal of latent heat necessary to vaporize the water lowers the water temperature.

Open Recirculating Systems

It is possible to effect the necessary evaporation in a "spray pond." Here, water is sprayed into the atmosphere out of nozzles mounted on horizontal pipes. The pipes themselves are mounted in a concrete "pond." The evaporating droplets of water fall back into the pond for reuse in the recirculating system. The desired cooling can be achieved by adjusting the spray conditions.

In an open recirculating system, however, it is more usual to employ a cooling tower to evaporate some of the recirculating water, as illustrated in Fig. 1. In this technique, the water falls over suitable packing contained in the cooling tower. For many years, the packing in cooling towers consisted of a large number of wooden slats over which the water trickled as a film. The purpose of the packing was to maximize the contact area between the airflow and the water film. The use of wood was far from ideal because the damp wood and the favorable temperature conditions led to the growth of fungi on the packing and this, as well as the increased weight, tended to weaken the integrity of the wooden structure. Failure of the wooden structure was not uncommon in the past. In recent times, plastic materials that resist fungal growth have been used to fabricate packing. The use of these materials, molded to shape, has allowed more sophisticated designs of packing to be introduced, which maximize evaporation of water in the tower under given operating conditions.

It is usual to maintain the airflow by natural convection, as illustrated in Fig. 1. It is possible, however, to have special designs where the airflow is driven by a motorized fan, as described for the enclosed cooling system to create induced or forced circulation.

In the cooling tower, water is lost from the system by evaporation and what is known as "windage," as illustrated in Fig. 2. The windage is made up of droplets of water that leave the top of the tower and are often seen as a plume downwind from the tower. Water loss also occurs from any leakage from the system and from "drift loss" in the region of the cooling tower basin. The water used in open recirculating systems is usually taken from natural sources such as lakes, rivers, or canals and therefore contains dissolved solids in addition to biologically active material, such as microorganisms.

As water is removed from the system by evaporation, the concentration of the dissolved solids increases. Therefore, it is necessary to discard some of the recirculating water, usually back to the source, and replace it with "makeup" water from the source, which has a lower concentration of dissolved solids. The deliberate discharge of water is usually referred to as "blowdown." It may be continuous or intermittent, depending on the rate of buildup of dissolved solids. The "makeup" water (M) has to replace that lost from the system by all mechanisms and from Fig. 2,

$$M = E + W + L \tag{1}$$

A concentration factor n may be defined by

$$n = \frac{\text{Dissolved solids concentration in the blowdown water}}{\text{Dissolved solids concentration in the makeup water}} \tag{2}$$

In general n is in the range of 3–5, but it depends on the operating conditions in the cooling tower.

Blowdown B may be calculated ignoring windage and leakage water losses which are usually small compared with the evaporation, so that

$$B = \frac{E}{(n-1)} \tag{3}$$

Once Through System

In the once through system, water is taken from the source, passed through the system, and discharged back to the source without cooling. The technique reduces the capital cost of the installation, but there may be environmental problems associated with the temperature of the discharge water in relation to the temperature of the water source, a problem which is usually referred to as "thermal pollution." Local regulations may restrict the allowable thermal pollution of the natural source

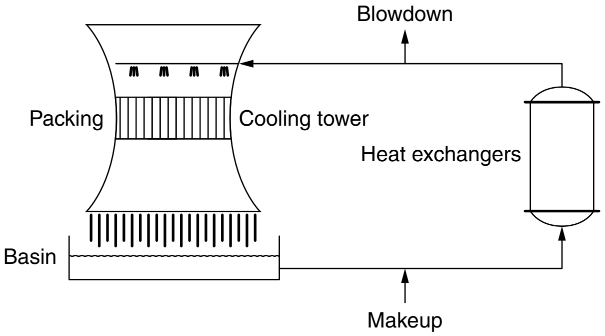

Figure 1. Recirculating cooling water system with cooling tower.

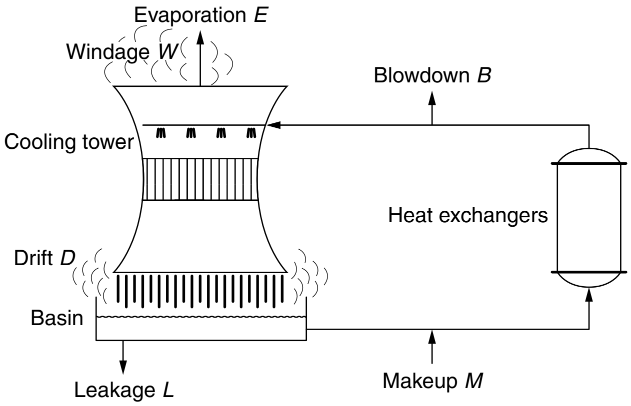

Figure 2. Water loss from a cooling tower circuit.

on account of its possible effect on the ecology of the water source.

Water Treatment

The origin of the water from a natural source in cooling water systems means that it can give rise to operating problems, generally associated with the heat transfer surfaces. Fouling may result from particulate deposition, microbial growth, or corrosion. These phenomena, the factors which influence them, and the methods available for control, are described elsewhere in this encyclopedia. Fouling is often controlled by chemical additives. Of general concern in open recirculating systems employing cooling towers or spray ponds is the presence of *Legionella* bacterium in the circulating water. Unless adequate precautions are taken, the bacterium may be present in the plume of water droplets, which leaves the top of the cooling tower or in the droplets above a spray pond. As a result, personnel who happen to be downwind of the tower or spray pond are susceptible to infection from the contaminated water. It is imperative for health and safety, quite apart from other considerations, to monitor the quality of the water within the system frequently and regularly.

CONCLUDING REMARKS

It is likely that the use of water for energy dissipation will continue in the future, but with greater emphasis on environmental protection and health and safety. It will increasingly be subject to regulation. To comply with the demands of legislators, the costs of operating the system are likely to be substantial. Effective management is necessary to keep the costs to a minimum.

WATER USE IN ENERGY PRODUCTION

Herbert Inhaber
Risk Concepts
Las Vegas, Nevada

The United States uses far more water to produce energy and electricity than any other sector. A slight reduction in water use in the electricity sector would far outweigh other modes of saving—toilets using less water, low-flow shower heads,—in the household sector.

Most attention here will be devoted to thermoelectric and hydroelectric plants. Thermoelectric plants can be divided into fossil fuel—coal, oil, and natural gas—and nuclear. These constitute almost all the electricity producers in this country.

However, this may not always be the case in the future. Some government reports and projections have said that renewables—solar, wind, geothermal, ocean thermal—will be used more in coming years. The so-called Kyoto Protocol (unratified at this time) anticipates a decrease of thermoelectric plants (due to their emissions of carbon dioxide, a greenhouse gas) and increased use of renewables. For example, in Denmark now about 10% of its electricity is supplied by windpower.

Water use is usually defined and measured in terms of withdrawal or consumption. The former is what is taken, and the latter is that which is used up. Water withdrawal in energy production is much greater than consumption. In hydroelectric plants, far more water is used than in any other energy source. However, the amount of water consumed—that is, not available for further use—is a small fraction of the water used and is attributable to evaporation from lakes behind hydro dams. Energy consumption for thermoelectric plants is of the order of 2% of water used.

Some of the water used to produce energy becomes contaminated with pollutants. This aspect of energy production is not discussed in this article; it is treated in detail in other articles in this publication.

Units

Units in the discussion of energy water use are both English and metric. The graphs here use metric units. Where the original form is English, metric units follow in parentheses, using the conversion factor $1\ \mathrm{m}^3 = 275$ gallons.

OVERALL WATER USE IN ENERGY PRODUCTION

More water is used for energy production than in any other sector in the United States, according to the Geological Survey (1). Of the 402,000 million gallons ($1460 \times 10^6\ \mathrm{m}^3$) per day of withdrawals, 189,000 million (690×10^6), or 47%, was used in thermoelectric plants. Irrigation was second at 134,000 million gallons ($490 \times 10^6\ \mathrm{m}^3$) per day.

During 2000, total U.S. net generation of electricity was $3{,}800 \times 10^9$ kWh (2). Of this, coal generated 1,967 (in the same units), or about 52%. This was followed by 754 from nuclear (20%), 612 from gas (15%), 273 from hydro (7%), 109 from petroleum (3%), and 84 from renewables (2%). Total fossil fuel electricity production was 2,688 billion kWh.

Of the renewables in the first six months of 2001, 0.37% of total production was from geothermal, 1.7% from biomass, 0.19% from wind, and 0.018% from solar (2).

CONVENTIONAL ENERGY SYSTEMS

Thermoelectric Water Use and Consumption

Most water withdrawn for thermoelectric power production is used for condenser and reactor cooling. Consumption of water was much less, at about 3,700 million gallons ($13.5 \times 10^6\ \mathrm{m}^3$) per day, about 2% of the total amount of water withdrawn.

What is the rate of water withdrawal for the four types of thermoelectric plants noted before? Official data are divided into fossil fuel and nuclear (3). It is not clear how geothermal data are handled, but this forms only a small proportion of total electricity production. Fossil fuels have a total withdrawal of 135,000 million gallons ($490 \times 10^6\ \mathrm{m}^3$) per day and consumption of about

2,800 (10×10^6 m^3) in the same units. For nuclear, the corresponding values are 54,500 (198×10^6 m^3) and 900 (3.3×10^6 m^3).

It would be of interest to determine (1) water use per unit of energy generated for each of the three fossil fuels—coal, gas, petroleum—compared to nuclear, (2) how the values varied within each type of energy, and (3) the relationship of water use to thermal efficiency of each type, but the data are not available in the official document.

However, the data above show that fossil fuels have a withdrawal of 67 m^3 per megawatt-hour (MWh) and consumption of 1.4 in the same units. For nuclear, the corresponding values are 97 and 1.6, respectively. The results are shown in Fig. 1. Hydroelectric values, to be discussed later, are also included.

Figure 1 uses a logarithmic scale because of the large amount of water use per unit of energy output for hydroelectricity. Values for water use in nuclear power are higher than for fossil fuels, primarily because of the lower thermal efficiency of the former. However, water consumption for both nuclear and fossil fuels are about the same. The ratio of consumption to water use for hydro, while not specified in official data, is much less than the approximately 2% for thermoelectric plants.

Two major documents dealing with water use in energy production in recent years, other than the Geological Survey document, are Gleick (4) and a German official publication (5). The values shown in the German document for thermoelectric plants using noncirculating water use (6), 160–220 m^3 per MWh, are somewhat higher than those in Fig. 1. Cooling water losses, or consumption, usually stay below 2% of water use, again in accordance with Fig. 1. The document also refers to small water requirements, in addition, of the order of 0.1 m^3 per MWh, for topping up the steam cycle, cooling the ashes, and operating certain types of flue-gas purification equipment (spray absorption, wet processes).

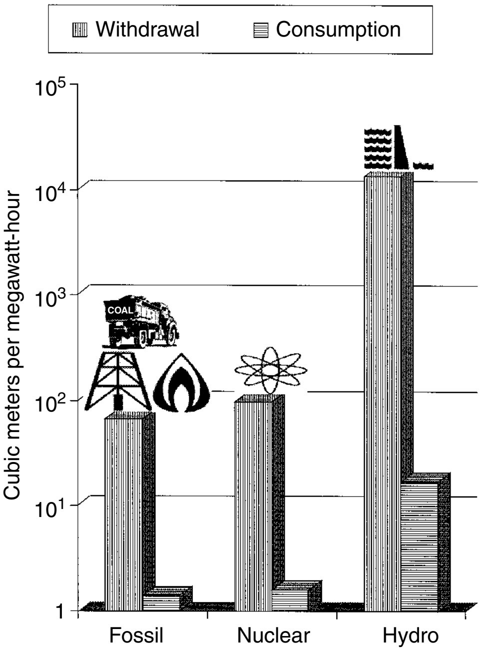

Figure 1. Water withdrawal and consumption rates for fossil fuels, nuclear and hydroelectricity, in cubic meters per MWh of electricity generated.

Reference 7 shows “consumptive water use” (taken to mean consumption as opposed to withdrawal) for the three main fossil fuels plus nuclear in m^3 per 10^{12} joules (thermal). Reference 7 considers many aspects of the fuel cycle, in addition to the generation phase, for each of the four major electricity sectors, that is, an attempt is made to estimate water requirements for the entire fuel cycle. This is in contrast to the Geological Survey and German documents, which concentrate on the generation phase. However, no indication is given in Ref. 7 about which of the components of water use for each technology is in widespread use.

For example, under nuclear, nuclear fuel reprocessing is shown as requiring about 50 m^3 of consumption per 10^{12} joules (thermal), the largest, by a factor of 2.5, of any of the nuclear components. But this aspect of nuclear technology is not in use in the United States.

Similarly, for the oil cycle, six possibilities are shown for enhanced oil recovery. The highest, micellar polymer, has the largest water consumption of any of the components for the four major technologies listed in the table. But it is not stated how common this technology is.

A later table (8) in Ref. 4 shows the average water consumption per megawatt-year for just the generating phase of the four major electricity sources. Results are then on the same basis as that of the official data. The values for fossil fuels with once-through cooling are comparable to those of Fig. 1, so they will not be repeated here. The results for coal and oil-fired generation are shown for both once-through cooling and cooling towers, although most fossil-fuel generation in the United States uses the former cooling method. Cooling towers consume about twice the amount of water of once-through cooling. The results in Ref. 8 for coal, oil, and gas are similar, so averaging over the three fossil fuels in Fig. 1 is reasonable.

Nuclear Power Water Use

Reference 3 states that nuclear plants use and consume somewhat higher amounts of water per MWh produced than fossil fuel plants. However, there are some proposed models of nuclear plants that will use and consume less. For example, the so-called MHTGR (modular high temperature gas reactor), due to its greater thermal efficiency, should require both less water use and consumption than other types of nuclear plants (9). At present, the MHTGR is not deployed in the United States.

In Ref. 8, only cooling towers are shown for nuclear generation, although most nuclear plants, like fossil-fuel plants, use once-through cooling. This produces a consumption value of about twice the official data, and tends to make nuclear look more water-consuming than is the case.

Hydroelectricity Water Use

Hydroelectricity produced about 6% of all U.S. electricity in the first 8 months of 2001. The proportion varies slightly from year to year, depending on rainfall, runoff, and other factors. In some countries, such as Canada and Norway, the proportion is much higher. Hydro is clearly a renewable system, but it is included in this section because it is conventional and widely used.

Water use for hydroelectric purposes is by far the largest of all U. S. energy sources, at 3,160,000 million gallons ($11{,}500 \times 10^6$ m^3) per day. This is about 2.6 times the total of the total annual runoff of the lower 48 states (10). This refers only to the withdrawal of water, the amount that passes through lakes and hydro dams.

Water is consumed, or evaporates, from the lakes behind dams. One set of estimates is from Ref. 11. The range of values for California dams is enormous, a factor of about 5,000 between the most water-conserving dams (measured in water consumption per MWh) and the most profligate. The variation will depend on such factors as the size of the lake, dam height and type, contours of the land, and outdoor temperatures.

For the United States, the average value is about three times that of the California average (12). The results are shown in Fig. 1. Average water consumption, per MWh, for hydro plants is about one-quarter the total withdrawal of fossil-fuel plants. If the most water-consuming dam had been used as a maximum for hydro, its value would have been greater than the entire water use for fossil and nuclear.

In 1995, 310×10^9 kWh of hydroelectricity were produced. This required 3,160,000 million gallons ($11{,}500 \times 10^6$ m^3) per day of withdrawals. So about 10 gallons (0.036 m^3) day, or 3700 gallons (13 m^3) per year, is required per kWh. The national average cost per kWh (enough to light a 100-watt light bulb for 10 hours) is about 8¢; so this implies that about 450 gallons (about 1.6 m^3) of water are required to produce about 1¢ of hydroelectricity value.

NONCONVENTIONAL ENERGY WATER USE

The key point in estimating water use and consumption by renewable energy systems was stated by the California Energy Commission (13): "In determining whether a particular fuel is 'clean' or not, consideration must be given to environmental impacts across the entire fuel cycle of the type of generation proposed (e.g., including fuel production, transportation, refinement, and generation)."

Renewable energy made up about 2% of all electricity production in the United States in the first 8 months of 2001. This fraction has changed only slightly in recent years. It has been widely claimed that this fraction will increase substantially in coming decades. Whether these claims are true can be verified only by the passage of time. Their present total water use is extremely small. All values presented here are only approximations. As more data are gathered, it is likely that many, if not all, of the values in this section will change. The German study (14) discusses the water implications of renewable energy sources, but nonquantitatively. It does make clear, however, that the entire fuel and energy cycle should be considered, not merely one aspect. This is also the implication of Reference 7.

Material Requirements for Energy Systems

To compare renewables with conventional energy systems in a consistent manner, the ratio of water use, both indirect and direct, per unit of energy or electricity output is required. The place to start is materials requirements for energy systems. The results of one calculation are shown in Fig. 2 (15).

Materials requirements for renewables, per unit of energy output, tend to be much higher than those for conventional energy systems. The main exception is hydro, but most of the requirements there are rock and earth, which require little water use. Solar and windpower generally are very dilute per unit volume compared to fossil and nuclear fuels. Thus considerably more collecting apparatus, again per unit energy output, is required. In turn, the collecting apparatus requires considerable material (and associated labor).

Water Use for Materials in Energy Industries

The next step is to estimate the water use for each of the materials shown in Fig. 2. For steel, the German study noted before estimates 5 m^3 per metric ton (16). This is in accordance with other estimates. On the other hand, "mini-mills generate up to 80 m^3 (of water use) per metric ton of steel product" (17). The value of 5, used here, may be different in non-Western countries. It is estimated that China requires 23–56 m^3 per ton (18).

For aluminum, one estimate is 1.5 tons of water (19) per ton of product. Another detailed look at the aluminum

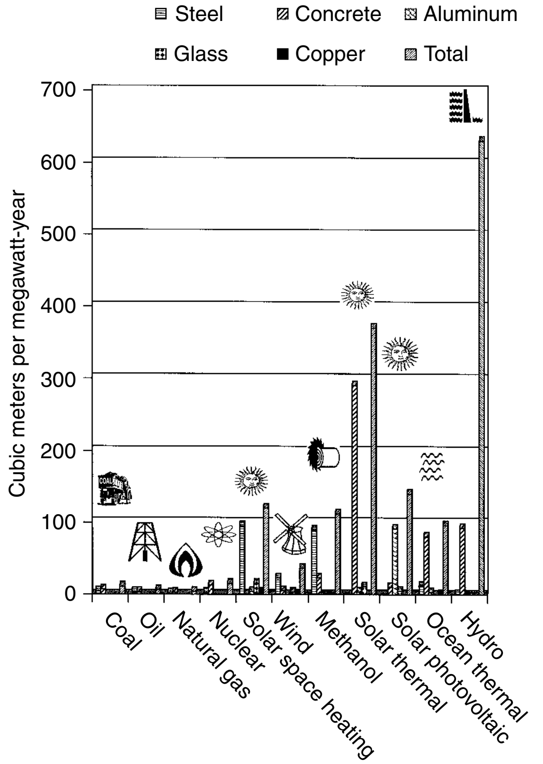

Figure 2. Material requirements for energy systems, per megawatt-year net output. Fuel—coal, oil, gas, and nuclear fuel—is not included.

industry suggests 5 m^3 of process water per metric ton of alumina and 1.88 m^3 of alumina per metric ton of aluminum. This then implies 2.6 m^3 of water per ton of aluminum, and this value is used here (20).

For copper, although water is undoubtedly used in its production, it proved difficult to obtain reliable data. For glass, "The average water consumption in a glass works should be less than 1 m^3/t of glass produced" (21). For cement, about 1–1.6 m^3 of water per metric ton of cement is required, depending on whether the dry or wet process is used (22). Concrete is one part cement to 6–8 parts other materials, so water use is adjusted accordingly.

Noted that values for water in materials production are likely use, not consumption. The data sources do not always make the distinction. The results for water use are as follows in m^3 per metric ton: steel, 5; aluminum, 2.6; copper, not available; glass, 1; cement, 1–1.6; and concrete, 0.1–0.25.

Indirect Water Use for Energy Systems

The indirect water use attributable to the materials used in all energy systems may be estimated by multiplying the values for specific materials in the preceding paragraph by the materials used per unit of energy output in Fig. 2. No values could be found for copper, so it is not included in the calculations. Its inclusion would change results only slightly. Minima and maxima of the results are shown as the bottom two components in the columns of Fig. 3.

Because of the wide differences between both components and the total of each column, the results are shown on a logarithmic scale. In each column, the lowest entry is for the minimum of indirect water use. The next highest entry is for the maximum of this component. Hydro has the highest amount of material use in Fig. 2, but almost all is rock and earth, assumed to have negligible water requirements. For coal-, oil-, and gas-fired, nuclear and hydro plants, values for direct water use are taken from Fig. 1. These are the next highest components of each column. Some technologies, such as solar photovoltaic, have negligible direct water use, so this component for their columns is blank. For solar thermal plants, an estimate of direct water consumption, as opposed to use, is available (23). It is assumed here that the ratio of water use to consumption for thermoelectric plants, approximately 50, also applies to this technology. Solar space heating, although included in Fig. 2, is excluded here because its output is thermal, not electrical.

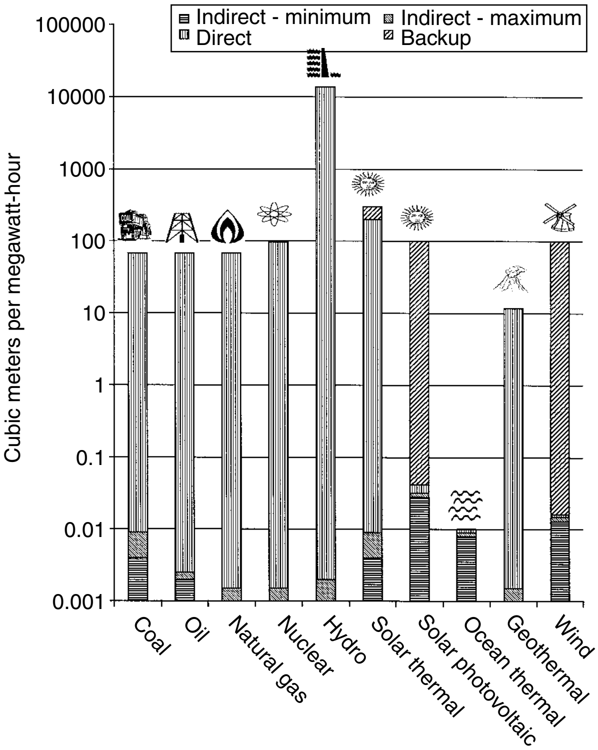

Figure 3. Water use per kWh output for conventional and renewable systems.

For geothermal, only values of consumption, not use, are available (23). Three values, for plants in the United States and New Zealand, have data, and the average was taken. It is likely that water use is higher than consumption for geothermal. One source states (24), "A geothermal plant produces much more wastewater than a coal-fired or atomic power plant," although no data on the proportion seem available. Backup water use, to be discussed in the next section, is shown for three energy systems.

Backup Energy and Electricity

Many articles dealing with renewable energy systems (other than geothermal and biomass) acknowledge the need for backup when the sun does not shine and the wind does not blow (25–29). The assumption is that consumers want reliable power, at least as reliable as present conventional systems. Given the fact that utilities are deluged with complaints after a power outage due to weather or other reasons, this is a reasonable assumption.

As a specific example of backup needed, consider Solar Two, one of the world's largest solar thermal plants. "During one stretch in the summer of 1998, the plant operated for 32 of 39 days", according to a U.S. Department of Energy Website dubbed "success stories" (30). Although this was only a demonstration project, in real life, consumers would be concerned about no power for 7 out of 39 days. Its average energy production was about 20% of its rating; fossil-fuel and nuclear plants routinely operate at 80% or more.

What proportion of backup is necessary? Estimates vary, depending on a host of factors: the variation of sunlight and wind, how much reliability is expected of renewable sources, whether the source is to be for peak power demands, and so on. Sørensen (31) notes that the "fuel-based supply system [for renewables] ... is a tenth of average load," that is, about 10% of conventional—fossil fuel, nuclear, and hydro in national proportions—electricity sources will be assumed as backup. Systems like geothermal, ocean thermal, and biomass require no backup because they produce energy continuously.

This proportion will change from one part of the country to another. For example, the proportion of hydro in the Pacific Northwest is higher than that in other parts. This would tend to make water use and consumption for backup higher there than elsewhere, on the basis of Fig. 1.

Backup would not apply to such renewable sources as biomass and geothermal, which produce power about as reliably as conventional energy systems. Using the values of Fig. 1 and the proportions of electricity production from fossil fuels, nuclear and hydro from earlier, an average national kWh of electricity would require 1.0 m^3 of water withdrawal and 0.0025 of consumption. Even though hydro is only about 7% of national electricity production, it generates about 95% of electricity water withdrawal and about half of water consumption. If an average backup of 10% is assumed, this implies 0.1 m^3 of withdrawal and 0.00025 of consumption per kWh of underlying energy attributable to backup.

SUMMARY

Most attention in water use and consumption has been focused on fossil-fuel and nuclear plants, though renewable energy systems, both present and in the future, can use considerable water when the entire energy cycle is considered. Hydro is classified as a renewable energy source by the Energy Information Administration and many other authors. It uses about 100 times the water and about ten times the consumption of thermoelectric plants, per MWh generated. Thermoelectric and hydro plants produce about 98% of all U.S. electricity. But hydro requires about 95% of all electricity water use and about half of electricity water consumption.

A number of conclusions can be drawn from Fig. 3. First, it clearly is important to take all aspects of the fuel or energy cycle into account when estimating water use and consumption. Second, hydro clearly has the highest water use (and consumption) of any major present or future energy electricity source. Third, although the material requirements estimated in Fig. 1 are useful, they affect overall results only slightly. Fourth, although Ref. 4 suggests that water use by most renewable energy sources will be negligible, Fig. 3 shows that this is not the case. Hydro and solar thermal rank the highest. Fifth, ranges of data are not shown in this figure except for water use associated with materials requirements, but remember that values in most cases are approximate and vary considerably. Sixth, ocean thermal (OT) apparently has the lowest water use of any of the technologies considered. OT uses considerable water in operation, but all of it is saline. Seventh, backup requirements make a considerable difference in water use for some renewable energy systems. Eighth, geothermal ranked second lowest of the systems, but its water use is probably underestimated in the graph, for the reasons explained in the caption.

In summary, to make rational decisions about which systems use more or less water, the entire fuel or energy cycle must be taken into account. Figure 3 shows the results of such calculations.

EVALUATION OF TOXIC PROPERTIES OF INDUSTRIAL EFFLUENTS BY ON-LINE RESPIROMETRY

Petros Samaras
Technological Educational
Institute of West Macedonia
Kozani, Greece

Industrial effluents often contain chemical compounds that have potential toxic properties which upon co-treatment with municipal wastewaters may affect the operation of a wastewater treatment plant. Respiration measurements, corresponding to the estimation of oxygen uptake rate (OUR) of living microorganisms, may be used to evaluate the toxic properties of industrial wastewaters, estimate their biological treatability, and predict the impact on the performance of a wastewatewater treatment plant. Several commercial on-line respirometric biosensors have been developed for monitoring various parameters such as carbon/nitrogen biological removal, anaerobic digestion, and activated sludge settling; these systems have common characteristics such as a simple measurement principle, low amount of chemicals required during their use, and the absence of a sample pretreatment step. On-line biosensors may be used as early warning tools in treatment plants, to protect plant operation and to increase efficiency, contributing to the development of toxicity management plans, especially in plants treating industrial wastes.

INTRODUCTION

The activated sludge process is considered today the most effective method for the biological treatment of wastewaters. The activated sludge process is based on the development of a heterogeneous microbial community in an aeration basin, which allows the system to be flexible with regard to considerable fluctuation in the influent wastewater composition. The activity and the concentration of the microorganism populations are crucial for the effective operation of the system, and the presence of certain toxic substances in increased concentrations in the influents may result in the reduction of microorganism activity. The effect of toxic substances on the more sensitive nitrifying bacteria is especially important, as these bacteria have a very low reproduction and growth rate (1,2). Toxic throughput is one of the major causes of the failure of biological treatment plants and results in noncompliance with discharge permit limits.

The operation of wastewater treatments plants has become an essential issue in European Union countries. According to Directive 91/271/EEC, all wastewaters in the territories of the European Union have to be collected and treated by appropriate methods prior to their discharge into a water receiver. In addition, municipalities with more than 15,000 inhabitants should have constructed and operated a wastewater treatment plant by the year 2000, whereas municipalities of more than 2000 inhabitants should have a secondary wastewater treatment plant by the end of 2005 to be able to discharge their wastewaters to a freshwater receiver. Furthermore, industrial wastewaters should be subjected to the same provisions as municipal wastewaters. In practice, industrial wastewaters are often discharged to a domestic collecting system and are fed to a municipal wastewater treatment plant for co-treatment. Thus, several municipal wastewater plants are receiving industrial wastewaters, which are often partially treated or even untreated; as a result, failure of the operation of municipal wastewater treatment plants is often attributed to the presence of certain compounds of industrial origin whose properties are potentially toxic to activated sludge microorganisms. Therefore, continuous monitoring of the potential toxic properties of influents is very important, prior to their introduction into the biodegradation process, to improve effluent quality, reduce operating cost, and increase reliability.

Conventional chemical analysis methods alone have been found inadequate for evaluating the toxic properties of wastewaters and for ensuring that the influents will not have significant effects on the receiving sewage works. Industrial wastewaters are characterized as complex mixtures of varying concentration of pollutants that may affect system performance. However, inhibitory metals and specific organic compounds may be detected in an industrial wastewater, but these data alone do not prove that the growth of bacteria and protozoa comprising the activated sludge biomass of the aeration basin will be suppressed. In addition, analytical chemical scans are very expensive and time-consuming and provide circumstantial evidence of the inhibitory nature of the waste. Furthermore, the toxicity of multicomponent mixtures to activated sludge microorganisms may differ from an additive response because synergistic or antagonistic interactions between mixture components may make the mixture more toxic than predicted by summing the effects of each individual toxicant (3). Consequently, an alternative method is necessary to evaluate the impact of industrial wastewaters on the performance of a domestic activated sludge treatment plant, based on assessing the toxicity of influents in a wastewater treatment plant.

TOXICITY ASSESSMENT OF INDUSTRIAL WASTEWATERS

Several biotests have been developed for evaluating wastewater toxicity to determine the toxic level of compounds to aquatic organisms. Test organisms that have been incorporated in bioassays include plants, invertebrates, fish, and microorganisms (4). Species that are widely used for determining the ecotoxic quality of freshwaters include (5,6): brook trout (*Salvelinus fontinalis*), Coho salmon (*Oncorhyncus kisutch*), bluegill (*Lepomis macrochirus*), channel catfish (*Ictalurus punctatus*), and invertebrates such as crayfish (*Pacifastacus leniusculus*) and Cladocera (*Daphnia magna, Daphnia pulex, Ceriodaphnia* spp.). In addition, marine species have been used for examining the ecological condition of seawater, including red algae (*Champia parvula*) and mysid shrimp (*Mysidopsis bahia*).

However, most of these bioassays are time-consuming and require scientifically skilled personnel and specific equipment. Moreover, the use of higher organisms, such as a fish, as a test species may be ethically undesirable. As a result, the development of an early warning system for monitoring the toxicity of influents is necessary. The last years of research has been directed to examinating of appropriate toxicity tests that are rapid, easy to operate, and inexpensive. Bacterial screening tests using microorganisms have been studied for their ability to assess the toxicity of wastewaters based on various principles such as microbial transformations, determination of microbial enzymes, and measurement of luminescent activity or respiration rate (5,7).

Most of the bacterial screening tests, such as the Microtox®, ToxAlert®, and the Mutatox® tests, which are used to detect cytotoxic and genotoxic agents, respectively, measure bioluminescence (8–10). The basic technology of these tests is using luminescent bacteria, specifically the strain *Vibrio fischeri*, to measure the toxicity of environmental samples. When properly grown, luminescent bacteria produce light as a byproduct of their cellular respiration. Cell respiration is fundamental to cellular metabolism and all life processes. Bacterial bioluminescence is tied directly to cell respiration, and any inhibition of cellular activity (toxicity) results in a decreased rate of respiration and a corresponding decrease in the rate of luminescence. The more toxic the sample, the greater the percentage of light lost from the test suspension of luminescent bacteria. Bacterial bioluminescence has proven a convenient measure of cellular metabolism and consequently, comprises a reliable sensor for measuring the presence of toxic chemicals in aquatic samples and for determining the toxicity of single compounds, mixtures of compounds, and industrial wastes (11). The particular strain was originally chosen for acute and chronic tests because it displayed high sensitivity to a broad range of chemicals.

The Microtox® acute test has been successfully used for a variety of environmental applications:

- wastewater treatment plant influent and effluent testing,
- toxicity reduction evaluations (TREs) and toxicity identification evaluations (TIEs), and
- assessment of soil contaminated with metals and energetic compounds.

However, the relevance of the information obtained by these bioassays is not considered essential for operating a municipal wastewater treatment plant, and continuous monitoring of the toxicity of industrial wastewaters is not achieved by such methods. Toxicity detected by *Vibrio fischeri* cannot always be associated with a biochemical cause that will exert the same activity reduction on the biomass culture in an activated sludge process (12). In general, toxicity assessment by Mictotox® may result in overestimating the acute toxicity effect on the biomass operating in a plant (13).

The key determinant in the response of a wastewater treatment plant is microbiological behavior. Thus, a proper estimate of the effect of toxic influents on an activated sludge unit should incorporate a system that closely mimics the conditions in the target plant because the response of a bacterial culture to a change in environmental conditions is highly dependent on the culture's physiological state, that is, it is determined by its growth history. Therefore, alternative techniques for on-line detection of toxicity relying on respirometric techniques, using activated sludge as the biological material, are considered the most suitable. Devices based on these techniques are easily operated, need minimum maintenance, and give fast and relevant responses (14–16). Respirometry was recognized many years ago as a key parameter for process control because it is a direct measure of the viability and activity of biological organisms. Therefore, respirometry plays an important role in detecting toxicity and in process control of wastewater treatment plants.

TOXICITY ASSESSMENT OF INDUSTRIAL EFFLUENTS BY RESPIROMETRIC TECHNIQUES

Respirometry is the measurement of oxygen uptake rates (OUR) of living biomass, such as activated sludge microorganisms, and can be used as an indicator of microbial activity in an aerobic biomass. On-line respirometry thus provides dynamic measurements of biological activity as well as a measure of the organic strength of a wastewater, which in turn gives an indication of the effective capacity of the system when sampled throughout the system.

Activated sludge is a flocculent mixture of microorganisms, mainly bacteria, which degrade multiple substrates to grow. The active organisms in the biomass of an activated sludge facility are contained in the solid phase and depend for growth on the carbohydrates, proteins, nucleic acids, and lipids contained in the influent to the plant. The organisms require dissolved oxygen to oxidize the organic food in wastewater and to provide organic carbon to synthesize the compounds necessary for reproduction. This oxygen consumption is referred to as respiration. Respiration is intimately linked to the growth of the activated sludge and to biodegradation.

In activated sludge heterotrophic bacteria which consume organic carbon, the carbon taken up is divided between that which is broken down in respiration and that which is built up into macromolecules for growth. The relationship between respiration, growth, and total carbon uptake (which equals biodegradation) is shown in Fig. 1.

By measuring the respiration rate (A), it is possible to calculate the amount of organic carbon (B) that is being used to provide energy. (A) can therefore be used to predict (B). Respiration rate (A) can also be used to predict the energy used in growth. It can be assumed that there is a proportional relationship between this energy and the amount of carbon being used for growth (C). (A) can therefore be used to predict (C). (B) + (C) equals the total carbon uptake, which equals the rate of biodegradation. Respiration rate (A) predicts (B) and (C), so it can be used to predict the rate of biodegradation. The situation in nitrifiers is simpler because the oxygen uptake rate provides a direct measure of ammonia biodegradation. These two mechanisms show the central role of the respiration rate (or more strictly, oxygen uptake rate, OUR) in the aerobic breakdown process.

In heterotrophic bacteria, toxic compounds in wastewater can inhibit either growth or respiration. Because of the tight linkages among respiration, growth, and biodegradation, it is obvious that if growth is inhibited, the requirement for energy decreases, and the respiration rate is reduced. Less carbon is required for respiration, so the rate of carbon uptake or biodegradation decreases. At the same time, the amount of carbon that is incorporated in growth is reduced. This also leads to reduced biodegradation. Conversely, if the toxic compound inhibits respiration, the amount of carbon for respiration is reduced, leading to reduced biodegradation. A decreased supply of energy from respiration results in a reduced growth rate and hence a lowered rate of carbon uptake or biodegradation. From this it can be seen that wherever the toxicity acts, there is inhibition of both the respiration rate and the rate of biodegradation. Nitrifiers are particularly prone to inhibition by toxic substances. Inhibition of either growth or the energy yielding oxidation reactions results in a decrease in both oxygen uptake rate and rate of uptake biodegradation of ammonia. The oxidative processes of respiration and nitrification that underlie the breakdown and removal of organic carbon and ammonia may be measured by respirometry, using specific biosensors.

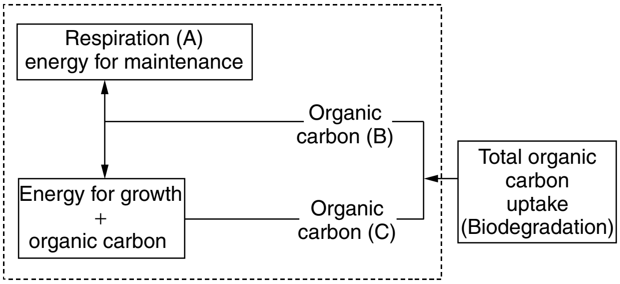

Figure 1. Relationship between respiration, growth, and biodegradation in heterotrophic bacteria.

Eight different types of respirometers have been developed, and in general they may be distinguished according to two criteria (17): (1) the phase where oxygen concentration is measured (liquid or gas) and (2) the method of liquid/gas introduction (flowing or static). Most respirometric methods are based on measuring the oxygen content in the liquid phase by using a dissolved oxygen (DO) probe. Static gas respirometers may be operated with a static or a flowing liquid phase. The static gas–static liquid respirometer is operated by withdrawing a sample of activated sludge from the aeration tank of a treatment plant, transferring it into a small reactor vessel, and then monitoring the decline of DO concentration by the time following a short aerated phase. The use of static gas–liquid respirometers is restricted due to potential problems from oxygen limitation. This type of respirometer, however, has the benefits of simple construction and measurement principle (18–20).

Flowing gas–static liquid respirometers, on the contrary, are continuously aerated and have the advantage that higher sludge concentrations can be used because there is a continuous input of oxygen, though oxygen limitation is unlikely (21). In this case, the oxygen transfer coefficient and the saturation DO concentration have to be known to calculate the respiration rate. Static gas–flowing liquid respirometers measure the DO concentration at both the inlet and the outlet of a closed respiration chamber (22). Aerated sludge is pumped continuously through the respiration chamber. The oxygen uptake rate is calculated by making an oxygen mass balance over the respiration chamber using the input and output DO concentration and the residence time in the vessel.

Several commercial biosensors have been presented for determining the toxicity of industrial effluents and assessing activated sludge plant performance, such as the Rodtox (Fig. 2a), the Stiptox (Fig. 2b), and the Manotherm. The Rodtox consists of a temperature controlled reactor vessel, which is filled with about 10 liters of activated sludge continuously aerated and stirred, while the dissolved oxygen concentration is monitored (21). Injection of a biodegradable calibration liquid in the reactor leads to a peak in the dissolved oxygen concentration. The total surface and the maximum height of the peak are proportional to the amount of BOD added, and the maximum slope of the respirogram is a measure of the activity of the activated sludge. The BOD of an unknown sample (short-term BOD, $\mathrm{BOD_{st}}$) is obtained by comparing the respirogram of the sample with that of the calibration liquid (23). Toxicity can be detected by comparing the peak of the calibration liquid before and after the addition of the sample. Stiptox is a toxicity analyzer with immobilized turbulent-bed biology where the microbes grow on the

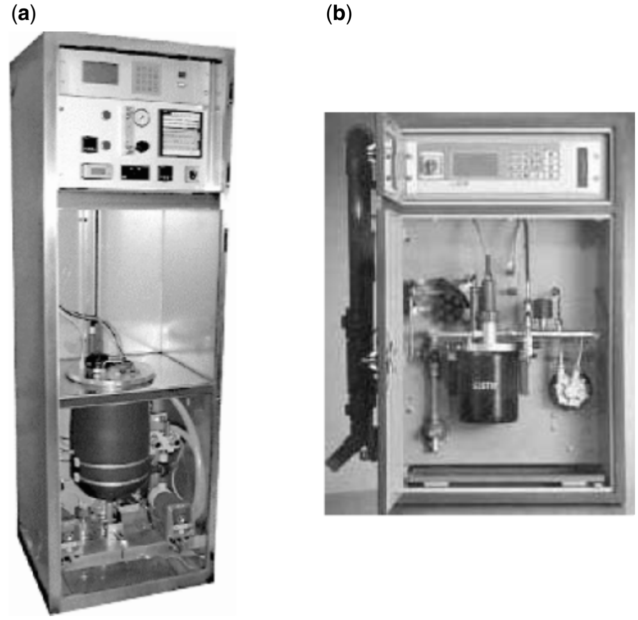

Figure 2. Commercial on-line toxicity biosensors: (**a**) Rodtox; (**b**) Stiptox.

inner surface of small hollow cylinders (24). Like the activated sludge of a treatment plant, the microbial population in the bioreactor is adapted to the conditions of the wastewater. As long as the wastewater is not toxic to the adapted biology, the organisms in the bioreactor take up dissolved oxygen. A toxic impact inhibits the respiration of the organisms, causing an increase in the dissolved oxygen level.

An alternative biosensor incorporating bacterial cells that can be used for rapid ecotoxicity analysis has been developed by Evans et al. (25). The amperometric biosensor device was called Cellsense and used ferricyanide, a soluble electron mediator, to divert electrons from the respiratory system of the immobilized bacteria to a suitable poised carbon electrode. The resulting current was, thus, a measure of bacterial respiratory activity, and the perturbation by pollutants could be detected within minutes as a change in the magnitude of the current.

In addition to carbonaceous removal, respirometric measurements are useful for monitoring nitrifying sludge activity and biological nitrogen removal. The interest in the nitrification capacity of activated sludge results from the higher sensitivity of nitrifiers to toxic compounds compared with heterotrophs (1). However, the main problem in measuring nitrifying capacity is separation of the nitrification oxygen uptake from the oxygen uptake for carbon substrate oxidation and endogenous metabolism. In general, batch experiments using activated sludge in the endogenous state may be used to determine nitrifying activity. In static gas–static liquid respirometers, the increase in OUR due to nitrification may be observed just after the addition of a certain amount of NH_4^+ (26). Respirometric methods consisting of pulse substrate additions to activated sludge cannot be used for estimating nitrification activity, as fresh substrate for both carbon oxidation and nitrification is continuously provided by the fresh wastewater entering the plant. Thus, selective nitrification inhibitors should be added; in this case, the experimental procedures consist of two subsequent phases. Initially, the total OUR of the sludge is measured, a nitrification inhibitor is added to the sludge, and OUR is measured again. The actual nitrification rate is then estimated by the difference between the two OUR values (20). Furthermore, respirometric experiments have been used to identify and quantify nitrogen nutrient deficiency in activated sludge processes (27). These methods may be applied to evaluate potential nitrogen nutrient deficiency and to estimate the amount of nitrogen required to remedy a nutrient deficiency in the sludge.

Respirometers have been used for detecting influent toxicity in wastewater treatment plants, using nitrifying bacteria as the indicating organisms, by the addition of specific nitrifying inhibitors (19,28). Nevertheless, specific techniques have been reported based on the implementation of bacteria from nitrifying enriched cultures containing no or little heterotrophic bacteria, where the addition of nitrification inhibitors is not necessary (19,28).

CASE STUDY: EXAMINATION OF INDUSTRIAL EFFLUENTS BY A RESPIROGRAPHIC BIOSENSOR

To evaluate the effect of industrial discharges on the performance of a municipal wastewater treatment plant, a biosensor (Rodtox, Kelma, NV) was installed in the industrial area of Thessaloniki, Greece. Several production plants are included in the Greater Industrial Area such as metal processing units, food industries, chemical-agrochemical, and pharmaceutical companies. Effluents from each process are partially treated on site and are discharged into a common pipe. Currently, industrial wastewaters are further treated in an industrial wastewater treatment plant; in the near future, industrial effluents will be fed to the Thessaloniki municipal wastewater treatment plant. The inhibition of the activity of activated sludge microorganisms due to the addition of industrial discharges to the respirometric biosensor, was estimated from the corresponding respirometric curves (21).

During the measuring period, activated sludge from the Thessaloniki municipal wastewater treatment plant was used as the biological material in the respirometric sensor. Activated sludge properties were considered as remaining almost similar during the monitoring time, as the wastewater treatment plant was fed by domestic wastewaters and its operation was maintained at constant conditions. In addition, the influence of the properties of activated sludge on the inhibitory results were periodically examined using calibration substances of known toxicity (solution of $ZnCl_2$), and slight differences were observed in the respirometric response. Similar results regarding the effect of the activated sludge origin have been already reported, underlying the insignificant influence of activated sludge on inhibition data (11).

Characteristic values measured in industrial wastewater samples are presented in Table 1. As shown in this

Table 1. Characteristic Values of Wastewaters from the Thessaloniki Industrial Area, mg/L

Parameter	Min	Max	Average
pH	7.1	8.3	7.6
BOD_5	71	2640	553
COD	155	4027	975
Ammonium nitrogen	2	317	62
Kjeldahl nitrogen	9	526	90
Total phosphorous	2	8	5
Suspended solids	148	376	249

table, industrial wastewaters in general were more polluted than municipal wastewaters; organic compounds reached up to 1000 mg/L COD. As a result, continuous monitoring of the toxicity of industrial discharges was very important to protect the co-treatment plant. Fluctuations in characteristic values could be attributed to seasonal variations, nontreated effluents, or effluents from processing units for which on-site wastewater treatment systems presented operating problems.

The short-term BOD of industrial wastewaters (BOD_{st}) and the corresponding inhibition of the respiration of activated sludge microorganisms during a 6-month period are shown in Figs. 3 and 4, respectively. High variation in both inhibition values and BOD_{st} was observed as a result of the complex nature of the samples. Short-term BOD values reached up to 3300 mg/L, and the corresponding inhibition values reached up to 98%, indicating that these wastewaters were toxic to the activated sludge microorganisms and could adversely affect the operation of the municipal treatment plant.

From the analysis of the relation between short-term BOD and inhibition of microorganism respiration during the particular period, it was concluded that the organic content of the industrial samples did not correlate directly with the toxicity of the samples. Samples of high toxicity, exceeding 35% inhibition, had BOD_{st} values ranging from low values up to 3000 mg/L. On the other hand, samples of low toxicity had a variation of organic loading from low levels up to levels exceeding 3000 mg/L. According to this observation, factors other than organic substances might affect the toxicity of the samples, such as inorganic compounds and especially metals and their speciation (29).

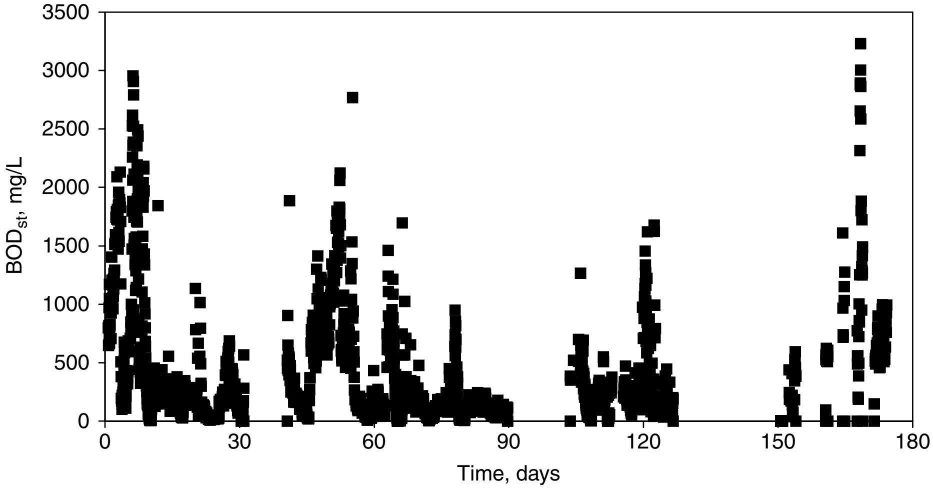

Figure 3. Short-term BOD values of industrial wastewaters, measured by an on-line toxicity meter.

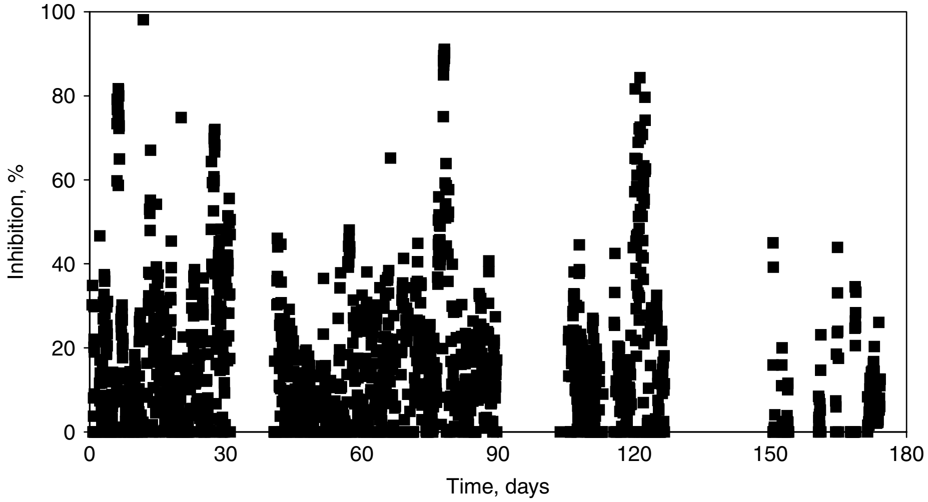

Figure 4. Inhibition of the respiration of active sludge microorganisms by the addition of industrial wastewaters.

Statistical analysis of the collected inhibition data was performed to obtain the daily toxicity distribution of industrial effluents; the characteristic values are shown in Table 2. In addition, the weekly frequency of toxicity values exceeding 35% inhibition is included in this table. As shown, the highest average toxicity values were observed on Saturday and Sunday, reaching about 18.5 and 20%, respectively. However, the maximum toxicity was observed on Tuesday evening. In addition, industrial effluents of high toxicity were supplied to the system on Thursdays and during weekends, corresponding to about 70% of the total number of values exceeding 35% inhibition. Furthermore, from the examination of the daily variation of inhibition values exceeding 35%, it was found that 63% of the peak inhibition values were observed during the night from 23:00 to 07:00. These results could be attributed to the reduced control of existing wastewater treatment systems in industrial plants, resulting in discharge of wastewater of low quality.

In conclusion, respirometry is an indispensable tool for assessing the biological treatability of industrial wastes separately and in combination with municipal wastewaters and for providing significant information about the impact of toxic effluents on the performance of a wastewater treatment plant. The benefit of on-line respirometric measurement is that it is a microcosm of the treatment facility and of what really affects process success. It shows the relative strength of the wastewater, how much treatment is needed, and the quality of the effluent produced.

Common characteristics of respirometric biosensors are the simple measurement principle, the low amount of chemicals required during their use, and the absence of a sample pretreatment step. Several biosensors have been developed to monitor various parameters such as biological removal of carbon and nitrogen, anaerobic digestion, and activated sludge settling characteristics that provide detailed information about important activated sludge processes. On-line respirometric biosensors may be used as early warning systems in influent toxic load detection, protecting the wastewater treatment plant from toxic shocks (30). Thus, their use in wastewater treatment plants supports the development of appropriate control strategies (31) to protect the efficient operation of a plant, to optimize system performance by better control of the treatment plant, and to improve effluent quality.

Table 2. Average Values and Daily Toxicity Variation of Industrial Discharges, %

Day	Min	Max	Average	Values Exceeding 35% Inhibition
Monday	0	79.7	13.7	10.7
Tuesday	0	98.1	7.7	0.9
Wednesday	0	64.4	8.4	2.8
Thursday	0	81.7	17.6	21.5
Friday	0	88.4	13.5	15.3
Saturday	0	91.1	18.5	23.9
Sunday	0	84.3	19.9	24.8

POLYCYCLIC AROMATIC HYDROCARBONS

Samuel C. Ashworth
Idaho National Engineering and
Environmental Laboratory
Idaho Falls, Idaho

Polycyclic aromatic hydrocarbons (PAHs) are a large group of organic compounds that have two or more fused aromatic rings. They have relatively low solubility in water and are highly lipophilic. The term polycyclic organic matter (POM) defines a broad class of compounds that generally includes all organic structures that have two or more fused aromatic rings. Polycyclic organic matter has been identified with as many as seven fused rings and, theoretically, millions of POM compounds could exist; however, only about 100 species have been identified and studied, and typically only a small fraction of them are regularly tested for as part of emissions measurement programs (1). Any effort to quantify emissions of POM relies on the group of compounds or analytes targeted by the test method employed. The EPA has defined these eight major categories of compounds in the class known as POM (2).

- polycyclic aromatic hydrocarbons (PAHs);
- aromatic hydrocarbons that contain nitrogen in a heterocyclic ring;
- aromatic hydrocarbons that contain a carbon–nitrogen double bond (C=NH);
- aromatic hydrocarbons that contain a one-ring carbonyl divalent group (C=O), also known as quinones; contain two-ring carbonyl divalent groups;
- carbonyl arenes that contain hydroxy groups and possibly alkoxy or acyloxy groups;
- oxa arenes are aromatic hydrocarbons that contain an oxygen atom in a heterocyclic ring; thia arenes are aromatic hydrocarbons that contain a sulfur atom in a heterocyclic ring; and
- some polyhalo compounds, such as polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs), may be considered POM although they do not have two or more fused aromatic rings.

PAHs, the focus of this article, include naphthalene, phenanthrene, anthracene, fluoranthene, acenaphthalene, chrysene, benz[*a*]anthracene, cyclopenta[*cd*]pyrene, benzopyrenes, indeno(1,2,3-cd)pyrene, benzo(ghi)perylene, coronene, and some alkyl derivatives of these compounds. The structural representations of some of these PAHs are presented in this section (Fig. 1).

There are other naming divisions used also. If two or more benzene rings share pairs of carbon atoms resulting in fused aromatic rings, they have been known as polycyclic aromatic hydrocarbons (PAHs) and polynuclear aromatic compounds (PNAs). The PNA classification is more general and includes heterocyclic aromatic compounds (as discussed above in the EPA definitions). The rings constituting PAHs contain only carbon (3). PAH nomenclature is based on 35 IUPAC-prescribed compounds and naming sequences described in detail elsewhere (3).

Most POM compounds are solids that have high melting and boiling points and are extremely insoluble in water. The PAHs are primarily planar, nonpolar compounds whose melting points are considerably higher than 212 °F (100 °C). Phenanthrene, whose melting point is 214 °F (101 °C) and benzo(c)phenanthrene, whose melting point is 154 °F (68 °C) are two exceptions. The molecular weights,

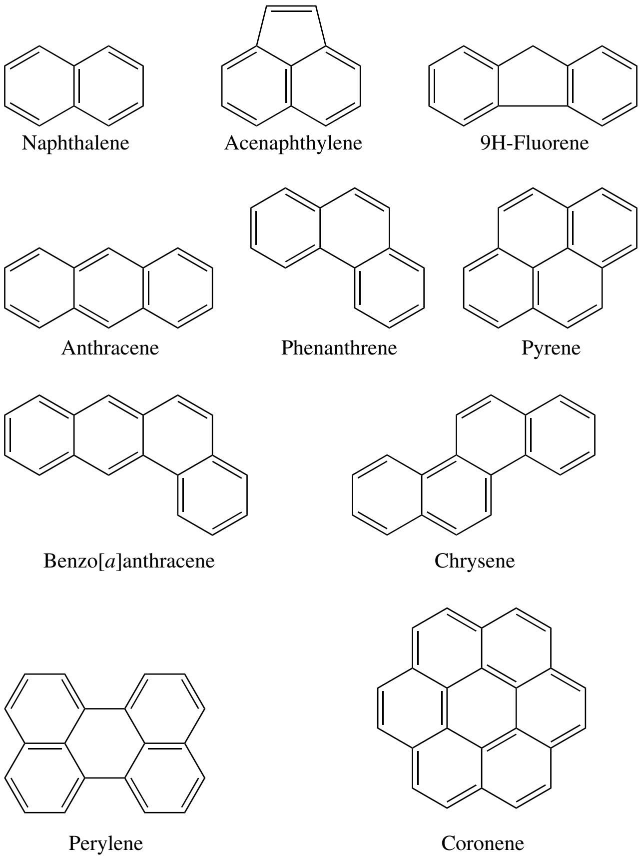

Figure 1. PAH structural representations.

melting points, and boiling points of selected PAH species are listed in Table 1.

The vapor pressures of POM compounds vary depending on the ring size and the molecular weight of each species. The standard vapor pressures of pure PAH compounds vary from 6.8×10^{-4} mmHg for phenanthrene to 1.5×10^{-12} mmHg for coronene (4). Table 1 includes vapor pressures at 25 °C for selected PAHs. Ultraviolet absorption spectra are available for many POM compounds. Most polycyclic aromatic hydrocarbons absorb light at wavelengths found in sunlight (>300 nm) and are believed to be photochemically reactive by direct excitation.

The chemistry of POMs is quite complex and differs from one compound to another. Most of the information available in the literature concerns polycyclic aromatic hydrocarbons. Generally, PAHs are more reactive than benzene, and reactivities toward methyl radicals tend to increase with greater conjugation. Conjugated rings are structures that have double bonds alternating with single bonds. Conjugated compounds are generally more stable, but they are more reactive toward free radical addition (6). For example, in comparison to benzene, naphthalene and benz(a)anthracene, which have greater conjugation, react with methyl radicals 22 and 468 times faster, respectively.

PAHs undergo electrophilic substitution reactions quite readily. An electrophilic reagent attaches to the ring to form an intermediate carbonium ion; to restore the stable aromatic system, the carbonium ion then gives up a proton. Oxidation and reduction reactions occur to the stage where a substituted benzene ring is formed. Rates of electrophilic, nucleophilic, and free radical substitution reactions are typically greater for PAHs than for benzene.

Environmental factors also influence the reactivity of PAHs. Temperature, light, oxygen, ozone, other chemical agents, catalysts, and the surface areas of particulates onto which the PAHs are adsorbed may play a key role in the chemical reactivity of PAHs.

The principal formation mechanism for POM occurs as part of the combustion process in many different types of sources. A secondary formation mechanism, primarily represented by naphthalene production and use categories, is volatilization of lightweight POM compounds. However, the combustion mechanism is much more significant in overall POM formation, and it also much more complex.

Most PAHs that have low vapor pressure in the air are adsorbed on particles. Dissolved in water or adsorbed on particulate matter, PAHs can undergo photodecomposition when exposed to ultraviolet light from solar radiation. In the atmosphere, PAHs can react with pollutants such as ozone, nitrogen oxides, and sulfur dioxide, yielding diones, nitro- and dinitro-PAHs, and sulfonic acids, respectively.

Table 1. Physical Constants of PAHs[a]

PAH	Mol. wt.	Solubility (μg/L)	Vap. Pressure at 25 °C (mmHg)	Log K_{ow} (Log K_{oc})	Henry's Law Constant,[b] atm-L/mole	MP °C	BP °C
Naphthalene	128.2	12,500 to 34,000	1.8×10^{-2}	3.37	4.5	80.5	218
Acenaphthylene	152.2	3420	10^{-3}–10^{-4}	4.07 (3.40)	0.24	96.2	279
Fluorene	166.2	800	1.64×10^{-5}	4.18 (3.86)	0.074	116	295
Anthracene	178.2	59	2.4×10^{-4}	4.5 (4.15)	1.8×10^{-3}	217	340
Phenanthrene	178.2	435	6.8×10^{-4}	4.46 (4.15)	—	100	340
Pyrene	202.1	133	6.9×10^{-7}	4.88 (4.58)	0.013	153	360
Benz[*a*]anthracene	228.3	11.0	1.1×10^{-7}	5.63 (5.30)	1.2×10^{-3}	160	435
Chrysene	228.3	1.9	5.3×10^{-9}[b]	5.63 (5.30)	6.7×10^{-4}	252	448
Perylene	252.3	2.4	—	6.21	—	274	500
Coronene	300.3	0.14	1.5×10^{-11}	7.36	1×10^{-6}	438	525

[a] Reference 5.

[b] Polycyclic aromatic hydrocarbons (PAHs) database in alphabetical order, http://chrom.tutms.tut.ac.jp/JINNO/DATABASE/00alphabet.html.

PAHs may also be degraded by some microorganisms in the soil (7,8).

PAHs are formed mainly as a result of pyrolytic processes, especially incomplete combustion of organic materials during industrial and other human activities, such as coal and crude oil processing, natural gas combustion, including heating, combustion of refuse, vehicle traffic, cooking and tobacco smoking, as well as in natural processes such as carbonization. There are several hundred PAHs; the best known is benzo[*a*]pyrene (BaP). In addition, a number of heterocyclic aromatic compounds (e.g., carbazole and acridine), as well as nitro-PAHs, can be generated by incomplete combustion (7).

Examination of a number of drinking-water supplies for six PAHs (fluoranthene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, BaP, benzo[*ghi*]perylene, and indeno[1,2,3-*cd*]pyrene) indicated that the collective concentrations generally did not exceed 0.1 μg/L. The concentrations of these six PAHs were between 0.001 and 0.01 μg/L in 90% of the samples and higher than 0.11 μg/L in 1%. Concentrations of BaP in drinking water range to 0.024 μg/L (9).

PAH compound treatment depends upon the end user requirements. Some of the criteria are provided in Table 2. From a treatment perspective, it is only practical to target the objective at the criterion or detection limit (DL), whichever is smaller. In some instances, the practical quantitation limit (PQL) would be the target. Some of the standards shown in Table 2 require values below the PQL (e.g., for benzo [*a*] anthracene $0.013 < 0.044 < 0.13$).

Napthalene and other PAHs by extension are classified as aromatic compounds because they exhibit some of the properties of benzene. Napthalene has the required structure of an aromatic compound (6). It contains six-membered rings, and the atomic orbitals show that the structure can provide π clouds that contain six electrons, as shown in Fig. 2. As illustrated, ten carbons lie at the corners of two fused hexagons. Each carbon is attached to three other atoms by σ bonds. The bonds result from the overlap of trigonal sp^2 orbitals, so all carbon and hydrogen atoms lie in a single plane that has π electron clouds above and below forming a shape like fused toroids by the overlap of p orbitals (6).

Table 2. PAH Detection Limits and Criteria

PAH	Detection Limits[a] DL, μg/L	Detection Limits[a] PQL,[b] μg/L	Drinking Water, μg/L	Surface Water, μg/L
Naphthalene	1.8	18		
Acenapthylene	2.3	23	1200[c]	2700[c]

PAH compounds, like other aromatic compounds, are resonance hybrids or resonance structures. The following Kekulé diagram illustrates the resonance equilibria (Fig. 3). Unlike benzene, all carbon–carbon bonds are not the same length. However, from a general approach, naphthalene and other PAH compounds are expected to have many of the typical aromatic properties, especially those relating to the π bond and resonance.

Two of the reactions discussed in Morrison and Boyd, (6) including oxidation (Fig. 4) and reduction (Fig. 5), reduce the bond order in PAHs. These can be helpful for researchers and designers in determining some of the potential reactions and treatment in water and possibly solid media. It is also speculated that PAH compounds can be treated via high-energy chemistry (e.g., UV/H_2O_2) to reduce toxicity. This may be assisted by using surfactants because, as previously discussed, PAHs are not very soluble in water and prefer a solid phase. This is discussed after the classical naphthalene reactions.

The first reaction reduces the bond order. The product may or may not be toxic, but the use of chromium is excluded, because it is a listed toxic metal. The second reaction has been commercialized in a different form known as the aqueous electron. However, due to the energetic sodium metal, this is not used for aqueous liquids (10).

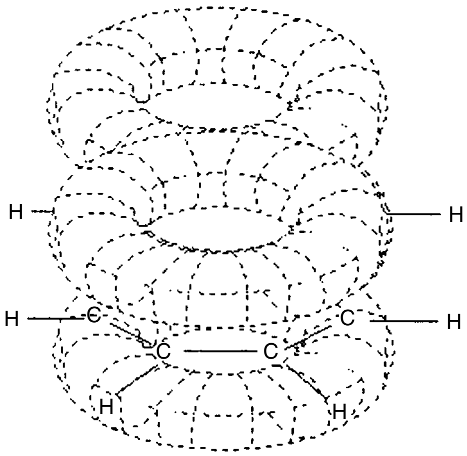

Figure 2. Napthalene π clouds.

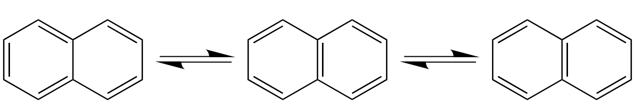

Figure 3. Napthalene Kekulé diagram.

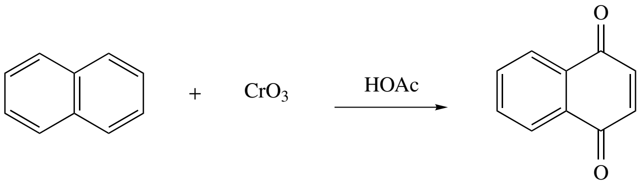

Figure 4. Oxidation using chromate.

A possible reaction path for naphthalene is shown in Fig. 6. This shows that naphthalene produces an aldehyde-ring compound that would be expected to undergo further additions thereby destroying the ring structures and likely forming complex aldehydes.

However, PAHs are sparingly soluble, so only the small amount in the aqueous phase would be removed, and the equilibrium would shift from the solid, if present, to maintain the solubility until there is no appreciable PAH left. It may be possible to use a surfactant to promote solubility and enhance this reaction. This requires evaluation because there are UV interferences, including phosphates, hydroxyl scavengers, and precipitates, all common in waters, that can impact the feasibility of this technology. The section on organic treatment discusses some of these technologies (11).

Because of low volatility, PAH compounds are not generally good candidates for removal by air stripping. The stripping factor (11) shows that quite large quantities of air are required:

$$\frac{G}{L} = \frac{R}{H} \tag{1}$$

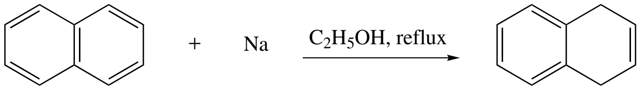

Figure 5. Reduction by sodium in alcohol.

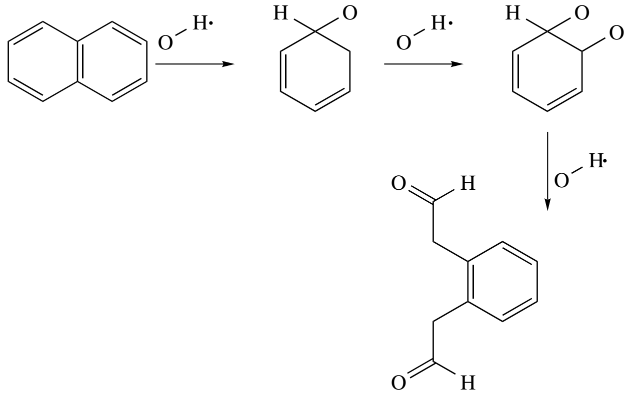

[2-(2-Oxo-ethyl)-pheny]-acetaldehyde

Figure 6. Possible reaction mechanism using UV/H_2O_2.

Using the highest H for Napthalene in the above and a break-even $R = 1$,

$$\frac{G}{L} = \frac{1}{4.5\ \text{atm} - \text{L/mole}}{}^{*}0.0823\ \text{L} - \text{atm/mole/K}^{*}298\ \text{K} = 5.45$$

Assuming a flow of 10 kg/min, the air rate would need to be 54.5 kg/min or 42 standard m^3/ min. This is feasible, but it represents excessive air requirements and becomes unrealistic for the other PAH compounds shown in Table 1.

Frequently, estimates of the air, water, and solid phase concentrations are desired. Assuming that the components of the phases are in equilibrium, the fugacities are equal (12).

$$f_{i,\text{gas}} = f_{i,\text{liquid}} = f_{i,\text{solid}} \tag{2}$$

Therefore, the gas and solid fugacities can be equated with the liquid fugacity. The result for a closed system (e.g., a closed vessel at atmospheric pressure) is

$$x_L = \frac{x}{K_D S + HV + L} \tag{3}$$

$$x_S = \frac{xK_D}{K_D S + HV + L} \tag{4}$$

$$x_V = \frac{xH}{K_D S + HV + L} \tag{5}$$

To illustrate the hydrophobic tendencies and also explain the meaning of K_{ow} in Table 1, the above values are calculated for fluorine. K_D is found from K_{oc} and f_{oc} (13):

$$K_D = K_{\text{oc}}{}^{*}f_{\text{oc}} \tag{6}$$

The octanol–water partition coefficient is a measure of the distribution of an organic compound between water and octanol. It is a general measure of a compound's hydrophobic tendencies. High values indicate hydrophobicity; low values indicate hydrophilic tendencies and hence higher solubility, for example, in alcohol.

K_{oc} can be found by a relation of the sort:

$$\ln K_{\text{oc}} = a \ln K_{\text{ow}} + b \tag{7}$$

However, the value listed for fluorine is log (K_{oc}) = 3.86 so that $K_{\text{oc}} = 7,240$ L/g. Assuming that the organic fraction of the solid is 1% ($f_{\text{oc}} = 0.01$), the solid phase has 10 g, the liquid phase and gas phases are 1 L each, and adding $x = 10$ mg,

$$K_D = K_{\text{oc}} f_{\text{oc}} = 72.4$$

$$x_L = \frac{10\ \text{mg}}{72.4\ \text{L/g}^{*}10\ \text{g} + 0.074\ \text{L} - \text{atm/mole/}\,(0.0823\ \text{L} - \text{atm/mole K}^{*}298\ \text{K})^{*}1\ \text{L}^{*}0.082 + 1\ \text{L}}$$

$$x_L = 0.0138\ \text{mg/L}$$

$$x_S = \frac{10\ \text{mg} \times 72.4\ \text{L/g}}{725} = 1\ \text{mg/g}$$

$$x_V = \frac{10\ \text{mg} \times 0.00302}{725\ \text{L}} = 4.17 \times 10^{-5}\ \text{mg/L}$$

This estimate demonstrates conclusively that PAH compounds are distributed preferentially on solids containing organics. In addition, the solids do not necessarily need to contain organics. However, the presence of the organic fraction ensures high distribution on the solid phase.

If there is no solid, then the fluorine will split into the water phase and a separate PAH phase consisting of nearly pure fluorine,

$$10\text{ mg} = 0.8(\text{mg/L}) \times L(L) + x\text{mg}$$

or $x = 9.2$ mg in a separate phase with a distinct vapor pressure of 1.64×10^{-5} mmHg. Therefore, the presence of a solid has a very large effect on the distribution between the phases and must be considered in treatment strategies.

Granular activated carbon (GAC) is an excellent technology for removing PAH compounds from water due to its demonstrated isotherms. Freundlich adsorption isotherms available for PAH compounds show that K's vary from 115 for acenapthalene to 376 for anthracene (14). The article in this Encyclopedia on organic treatment (11) provides examples of removing benzene that has a poor Freundlich isotherm, $K = 1.0$, $1/n = 1.6$. Removal of PAH compounds using GAC would require far less carbon than that for benzene and be much more efficient.

High-energy chemistry processes for bond reduction and detoxification of PAHs are potentially feasible processes. High-energy chemistry is defined as

$$E > \kappa T \tag{8}$$

This energy is not supplied in the form of heat but through the impact either of an electron, ion, atom, molecule, or photon or by application of electric, magnetic or other fields (15). PAHs are expected to be less refractory (i.e., more reactive toward free radicals) than benzene. As previously discussed, the main problem for these processes is low solubility. However, some of them (e.g., Fenton's reagent) do not depend on light transmittance and can be readily implemented (11).

NOMENCLATURE

a	Constant
b	Constant
E	Energy ML^2/t^2
f	Fugacity Pa
f_{oc}	Fractional organic carbon in solid
G	Gas rate in stripping M/t/L^2
H	Henry's law constant
K	Freudlich isotherm coefficient (capacity constant) mg/g*(L/mg)$^{1/n}$
K_D	Distribution coefficient, L/M
K_{oc}	Organic-carbon distribution coefficient, L/M
K_{ow}	Octanol–water distribution coefficient, L/M
L	Liquid phase or liquid rate in stripping, M/t/L^2
$1/n$	Freundlich bonding constant
R	Stripping factor
S	Solid phase
x	Concentration, M/L^3
V	Vapor phase

HYDROCARBON TREATMENT TECHNIQUES

SAMUEL C. ASHWORTH
Idaho National Engineering &
Environmental Laboratory
Idaho Falls, Idaho

There are various criteria concerning hydrocarbons for water needs. Some water users have little concern for dissolved hydrocarbons (e.g., agriculture), and some have strict standards (e.g., drinking water). In general the presence of organic compounds, including hydrocarbons, in water can lead to a buildup of biofilms. Biofilms can be problematic in many situations including drinking water, cooling water, recirculating water, and water used for various other industrial processes. During biofilm formation, the first substances on the surface are not bacteria but trace organics (1). Almost immediately after the clean pipe surface comes into contact with water, an organic layer deposits on the water/solid interface (2). These organics form a conditioning layer that neutralizes excessive surface charge and surface free energy that may prevent a bacteria cell from approaching near enough to initiate attachment. In addition, the adsorbed organic molecules often serve as a nutrient source for bacteria.

Though there are many criteria, the thrust of this article is on the treatment, including the removal and destruction of hydrocarbons for whatever purpose. It is assumed in this article that the hydrocarbons are dissolved in water, so that technologies such as incineration or decantation will not apply. The focus will be on water-phase separation and destruction. No economic evaluation is considered. In reality, the trade-offs would need to be considered, for example, waste disposal costs, electrical cost, and materials.

BACKGROUND

In general, water from natural sources will lead to poor cooling performance unless adequate steps are taken to remove hydrocarbon contaminants (3). The extent of the problem, however, will depend on the quality of the raw makeup water. The deposits that occur on heat exchanger surfaces are complex and are likely to include particulate matter, crystalline salts, corrosion products, and biofilms. It is necessary to counteract this problem of deposition onto surfaces to maintain heat exchanger effectiveness.

The shape and structural arrangement of a biofilm growing in a flowing fluid will influence the mass transfer characteristics of the biofilm system as well as the drag force exerted on individual biofilm structures (4). If the biofilm is a highly compliant material, the shape will vary through the growth cycle of the biofilm and also due to variations in fluid shear stress (5). Fluctuations in biofilm shape will also affect the hydrodynamic drag that in turn will influence the detachment rate and pressure losses in a flowing system. In addition, it is thought that biofilm viscoelasticity may explain the large pressure drops observed in biofilm fouled pipes (6).

There are also regulatory standards for certain waters (e.g., drinking water and water discharged to aquifers and bodies of water). Some of these that might apply include the Safe Drinking Water Act (42 U.S.C. 300f et seq.), Clean Water Act (33 U.S.C. 1251 et seq.), Resource Conservation and Recovery Act (42 U.S.C. 6901 et seq.), and a host of others. Many of them provide standards for organic compounds including hydrocarbons in effluents and source waters.

The above are a few reasons for removing organic compounds but there are others, including the pharmaceutical and semiconductor industries that have specific needs and criteria in this regard.

TREATMENT

Separation

Separation is the process of removing a compound from one phase to another (e.g., activated carbon adsorption). One of the simplest methods for separating volatile hydrocarbons and other organic compounds from water is air stripping. An example is benzene, a ring molecule shown in Fig. 1.

A typical stripper is a packed system using Raschig rings or other packing that provides high surface area, as shown in Fig. 2.

Descending water containing dissolved benzene enters the top of the column and is distributed to flow through the packing. The air enters at the bottom contacts the descending water, and the benzene transfers from the water to the air, an interphase mass transfer operation. The clean water is used for the purposes required, and the air is ejected to the atmosphere, regulations permitting, or treated accordingly (e.g., vapor-phase activated carbon).

The driving force for mass transfer is the gradient from the water to the air. At the interface, it is normally assumed that the interfacial water concentration and the air partial pressure are in equilibrium. If the amount of dissolved organic in the water is small enough (water mole fraction not appreciably different from 1.0), equilibrium is expressed using Henry's law (7). Henry's law is a special case of the following relation for gas–liquid

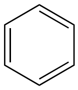

Figure 1. Benzene molecule.

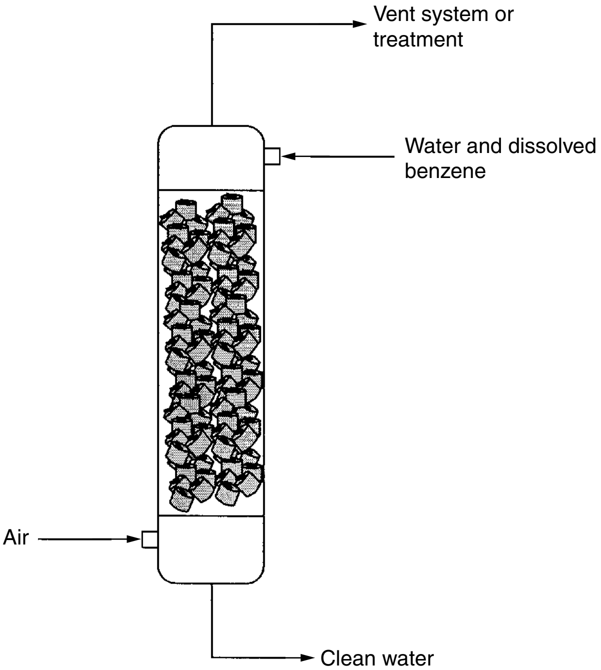

Figure 2. Packed-bed air stripper.

thermodynamic equilibrium[a]:

$$y_i \phi_i P_T = x_i P^{vap} \gamma_i$$

$$p_i = \frac{P^{vap} \gamma_i}{\phi_i} x_i = H x_i$$

Or the partial pressure of i equals Henry's constant times the liquid mole fraction of i where H (Henry's constant) is constant for small mole fractions in the liquid phase. The rate of mass transfer is based on using Henry's constant. For a dissolved gas, there are two resistances, gas-phase and liquid-phase. The mass transfer (F) flux is

$$F = K_L(C_B - C^*) = K_G(p^* - p_B)$$

The C^* and p^* above are virtual properties; C^* is the concentration in equilibrium with the bulk pressure if there were a liquid present. Similarly, p^* is the partial pressure that would be in equilibrium with the bulk liquid. Figure 3 illustrates these relations. Because C^* is not known, p_B/H is substituted for it. Similarly, C_BH is substituted for p^*. This is the easiest form as all that needs to be known are the bulk liquid concentration and bulk partial pressure.

The mass transfer based on individual coefficients is (see Fig. 4)

$$F = k_G(p_i - p_B) = k_L(C_B - C_i)$$

By combining these and using Henry's Law, the following is determined for the overall mass transfer coefficients either one can be used:

$$K_L = \frac{1}{\dfrac{1}{Hk_G} + \dfrac{1}{k_L}}$$

$$K_G = \frac{1}{\dfrac{1}{k_G} + \dfrac{H}{k_L}}$$

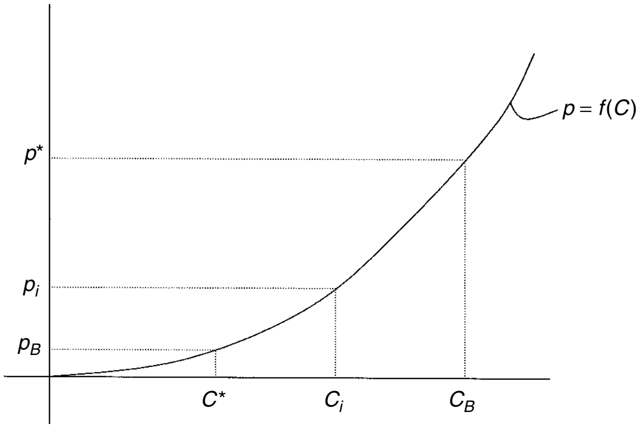

Figure 3. Stripper concentration and partial pressure relations.

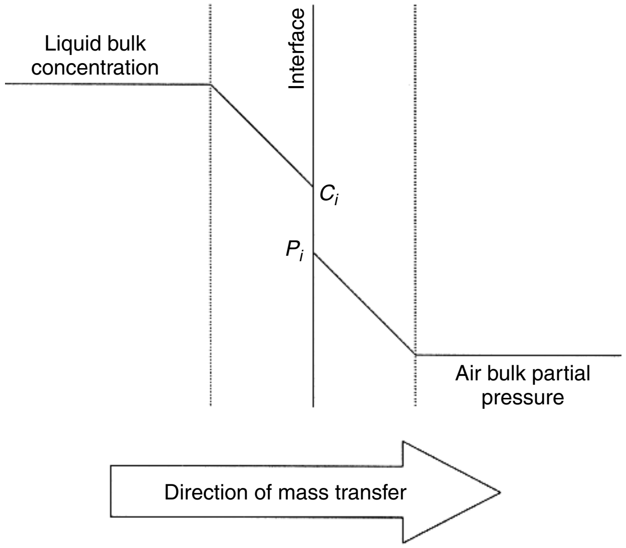

Figure 4. Interphase mass transfer.

There are many references that cover this thoroughly (8,9,11) but if Henry's Law applies, the height of a stripping column is

$$h = HTU * NTU$$

$$HTU = \frac{L}{K_L a}$$

$$NTU = \frac{R}{R-1} * \ln \frac{C_i/C_o * (R-1) + 1}{R}$$

$$R = \frac{HG}{L}$$

Using benzene as an example with an MCL of 5 μg/L, the height will be determined to achieve this starting with 50 μg/L and the data in Table 1. This would take a stripper approximately 5 m high (15–20 ft) to meet the MCL for benzene.

The R parameter is called the stripping factor and must be greater than one ($R > 1$) for stripping to be feasible. As observed by its definition, a small H can be somewhat overcome by a large G/L. The trend is such that volatile materials are easy to strip, whereas the semivolatiles and large organic compounds that have low vapor pressures are difficult to strip.

Adsorption

The use of activated carbon for organic removal from a water source or effluent is another very common and useful separation process. There are two types in use, granular and powdered. Only the granular type is discussed here; the powdered type is covered in other sources (10). Normally, the system is designed so that water flows into the top of the column and exits the bottom, as shown in Fig. 5.

Some methods for multicomponent adsorption are available. One is the multicomponent Langmuir that doesn't always give good predictions (11). There has also been some work on multicomponent systems (2). Some

[a] a Actually, $H_i \equiv \lim_{x_i \to 0} \dfrac{f_i^L}{x_i}$

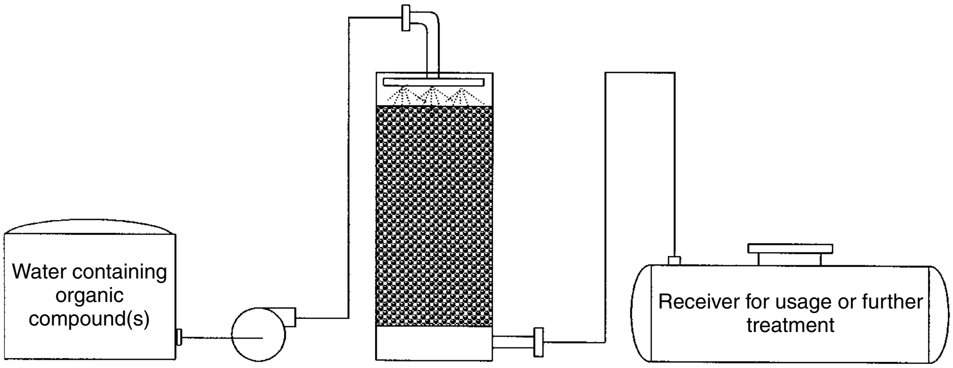

Figure 5. GAC system.

Table 1. Data for Air Stripping Benzene

Given Data	Values
C_i, μg/L	50
C_o, μg/L	5
G, $m^3/m^2/h$	1000
H, atm L/mg	5.52E−05
H, Dimensionless	1.80E−01
K_{L_a}, hr^{-1}	10^a
L, $m^3/m^2/h$	20
Flow, gpm	10
Calculated	
R	9.00
HTU, m	2
NTU	2.47
h, m	4.94
A, m^2	0.11
D, m	0.38

[a] This was an assumed value. Note that K_La is a combined, overall liquid mass transfer coefficient where a is the surface area to volume ratio of the packing and is usually measured or estimated as a single quantity. It is found similar to the K_G and K_L and there are correlations for it in many references, e.g., 8–10.

computer software is available for sizing but is limited to 8–10 components. Vendors also have programs and rule of thumb methods available. Freundlich isotherms for many of the compounds are readily available, and hence, this method is used for single organic compounds. The Freundlich isotherms are sometimes used for scoping multicomponent systems. However, the Freundlich method is not amenable to multicomponent systems. Therefore, it is assumed that they are additive, each compound adsorbs independently of the others without competition. Column dynamic testing of the actual liquid is preferred for multicomponent systems.

The Freundlich isotherm is explained by

$$q_e = KC_e^{1/n}$$

The additive type of method assumes that the organic compounds adsorb in layers; the strongest bonding molecules profile toward the top of the equilibrium zone, and the less strongly bonded toward the bottom (K is related to capacity, and $1/n$ is related to bonding strength). This is shown ideally in Fig. 6. It shows that the organic compounds that have the highest affinity for GAC profile toward the top of the column and those of low affinity profile toward the bottom. Hence, breakthrough of benzene would occur first if in a multicomponent system.

The procedure is to determine the amount of GAC for a component individually via the method of Snoeyink (Pontius 1990) (11) and determine the amount of GAC required. Using benzene again at 50 μg/L (it does not have a very favorable isotherm),

$$q_{e,Benzene} = 1 * 0.05^{1.6} = 0.0083 \text{ mg/g}$$

The amount of water per GAC, according to Snoeyink is,

$$Y = \frac{q_e}{C_i - C_o} * \rho_{\text{GAC}} = \frac{0.0083 \text{ mg/g}}{0.05\text{–}0.005 \text{ mg/L}} * 500 \text{ g/L}$$
$$= 92 \text{ gal/galGAC}$$

The amount of GAC is then the volume to be treated/Y. For 1000 gallons this is

$$\text{GAC} = \frac{1000}{92} = 11 \text{ gal}$$

or 11 gallons of GAC per 1000 gallons treated.

To avoid immediate breakthrough, the bed length must be greater than the mass transfer zone (MTZ). The MTZ is calculated from column dynamic tests as

$$\text{MTZ} = L\frac{t_s - t_b}{t_s}$$

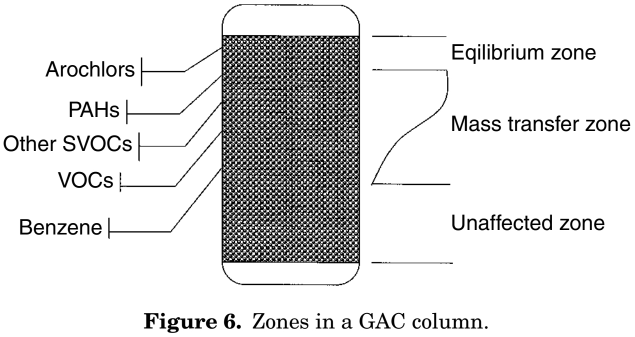

Figure 6. Zones in a GAC column.

The most important GAC adsorber design parameter is contact time, most commonly described by its empty bed contact time (EBCT) (11), V/Q. The empty bed contact time (EBCT) is an important design parameter in GAC column design. The range for 47 plants was 3–34 minutes, and the median was 10 minutes (Pontius 1990)(11). Longer contact times are normally used for highly concentrated solutions, so this design uses the value of 5 minutes. Based on this, the minimum column volume is

$$V_{\text{column}} = EBCT * Q = 5 \text{ min} * 10 \text{ gpm} = 50 \text{ gal}$$

A typical hydraulic loading is 3–4 gpm/ft^2. Using 10 gpm, the area is 2.5 ft^2. The height is

$$h = \frac{50 \text{ gal} * \text{ft}^3/7.48 \text{ gal}}{2.5 \text{ ft}^2} = 2.67 \text{ ft}$$

Destruction

The final technologies discussed for removing organic compounds from water are destruction/reaction techniques based on high-energy chemistry. High-energy chemistry is defined as

$$\text{E} > \kappa\text{T}$$

So-called advanced oxidation technology is a subset of high-energy chemistry that uses free radicals to oxidize the target compound. All of these processes work by generating free radicals followed by attack on the target's bonds by the free radicals. All of these processes are commercially available. However, some of them have certain restrictions on their use (e.g., nitrates, liquid only,). The following are some of the processes comprising advanced oxidation.

The UV/H_2O_2 process consists of a chemical reactor (batch or flow-through) that uses UV light to produce free-radical hydroxyls (Fig. 7)

$$\text{H}_2\text{O}_2 + h\nu \rightarrow \text{OH}\cdot$$

The free radicals extract electrons from the target and create a free radical target product. The ensuing mechanism is a chain reaction eventually degrading the target to CO_2 and H_2O and other simple, less regulated compounds. The overall reaction can usually be modeled by first-order kinetics. The design relation used for this type of reactor is the EE/o, the electrical energy per volume per order of magnitude (in kwh/1000 gal/order). This relationship provides all of the information required to determine efficiency (i.e., once known, any efficiency can be obtained by adjusting the power).

There are several similar systems that produce free-radical hydroxyls, including

- UV/ozone
- ozone/peroxide
- Fentons' reagent
- UV-vis/Peroxide

It has been speculated that UV is required for some compounds like polychlorinated biphenyls (PCBs), to activate the bonds, and OH^- is required to react with the activated bonds (i.e., synergism) (13).

For some compounds (e.g., NDMA), direct irradiation of organic pollutants by high-intensity UV light provides a significant destructive pathway. The target compounds degrade after absorbing UV light. The target must strongly absorb UV.

The hydrated electron is a very strong reducing agent that can react with halogenated alkanes and alkenes. The hydrated electron interacts with the chlorine–carbon bonding electrons and provide energy to break the bond and demineralize the target. There are several commercially available processes involving reduction via aqueous electrons. The aqueous electron is produced by several mechanisms including nuclear and high-energy processes, photochemistry, and chemical. Some processes require transferring high-energy electrons through thin films of water because the free path or linear energy transfer (LET) is small for electrons (high voltage process).

The baseline process is a UV-catalyzed process. The chemical added that is shown is a proprietary catalyst. The catalyst interacts with UV light shown by the energy arrow that produces the aqueous electron (e^-_{aq}). An example of this production reaction is

$$\text{Fe(CN)}_6^{-4} + h\nu \rightarrow \text{Fe(CN)}_6^{-3} + e^-_{\text{aq}}$$

The aqueous electron then interacts with the chlorine–carbon bond producing chloride ion and a free radical chlorinated aromatic:

$$e^-_{\text{aq}} + \text{C}_{12}\text{H}_5\text{Cl}_5 \rightarrow \text{C}_{12}\text{H}_5\text{Cl}_4^- + \text{Cl}^-$$

The free radical goes on to extract electrons from another molecule, and a chain reaction usually occurs. The rate constants for reductions are normally quite large. This process is particularly well suited to compounds not amenable to advanced oxidations, for example, CCl_4. The UV-induced process is commercially available (e.g., Calgon Advanced Oxidation Technologies).

Supercritical water oxidation, sometimes known as hydrothermal waste processing, uses the solvating traits of water in its supercritical state to destroy liquid organic wastes. As water is heated beyond its critical temperature (374.1 °C) and critical pressure (250 Mpa-s, about 3219 psi), the density of the water drops dramatically (typical operating densities are 0.15–0.2 g/cm^3). These changes in density and hydrogen bonding make organics highly soluble, and inorganic substances become nearly insoluble. The organic material is dissolved in an oxygen-rich environment where conversion occurs rapidly due to the high temperature of the process. Under such high pressure and temperature, organic materials are rapidly decomposed by oxidation at removal efficiencies of 99.9999% or greater.

Ultrasound can induce unusual high-energy chemistry through the process of acoustic cavitation, the formation, growth, and implosive collapse of bubbles in a liquid. Cavitation can occur in both clouds of collapsing bubbles (multi-bubble cavitation) or with high symmetry for isolated bubble (single-bubble cavitation, SBC). Multi-bubble cavitational collapse produces localized, transient hot spots with intense local heating (approx > 5000 K), high pressures (>2000 atm), and short lifetimes (sub-microsecond) in an otherwise cold liquid. From hydrodynamic modeling of this cavitational collapse, it has been estimated that both the heating and cooling rates are in excess of 1010 K/s. Acoustic cavitation is a unique means of creating high-energy chemistry, easily and inexpensively. Aqueous sonochemistry produces, supercritical water conditions on a microscopic scale. In this regime of temperature and pressure, the sonochemistry of water is an extreme limiting case of supercritical phenomena and is closely related to hydrothermal oxidation. For example, the ultrasonic irradiation of water produces a variety of extraordinarily reactive species (including OH^-, H^+, and HO_2^-) that can decompose many organic compounds.

The last design example is treating benzene-contaminated water to the same degree as the previous two examples using UV/H_2O_2. Figure 7 illustrates a schematic batch test reactor. Benzene has an EE/o = 2–5 kWh/1000 US gal/order (14). Therefore, the dosage of UV required in a flow-through system at 10 gal/min is (using 5 for the worse case) and the industry design relation (14):

$$\begin{aligned}&\text{Power(kWatt)}\\&= \frac{5\ \text{kWh} * 10\ \text{gal/min/order} * \log_{10}(50/5) * 60\ \text{min/hr}}{1000}\\&= 3\ \text{kW}\end{aligned}$$

So a UV lamp of 3 kW is sufficient to meet the requirement. Of course, if the flow rate were 100 gpm, it would require 30 kW, and so on. There will be economic trade-offs, electrical power costs, and chemical costs.

It is highly useful at this point to consider reaction kinetics and reactor design as there are some unusual features for this type of reactor. For a batch system, as shown in Fig. 8, the material balance and first-order reaction are

$$\frac{dC}{dt} = -kC$$

$$\ln\left(\frac{C_i}{C_o}\right) = kt$$

The first-order reaction coefficient is inversely proportional to the EE/o:

$$k = \frac{\ln 2 * P(kW)}{V * \text{EE/o} * \log 2}$$

The power for a batch reactor is then the same used for the industry design equation (14):

$$P(kW) = \frac{\ln(C_i/C_o) * V * \text{EE/o} * \log 2}{\ln 2 * t}$$

In a plug flow reactor (see Fig. 8), a material balance on a differential volume element yields:

$$QC - Q(C + dC) - kCdV = V\frac{dC}{dt}$$

At steady-state,

$$\ln\frac{C_i}{C_o} = k\frac{V}{Q}$$

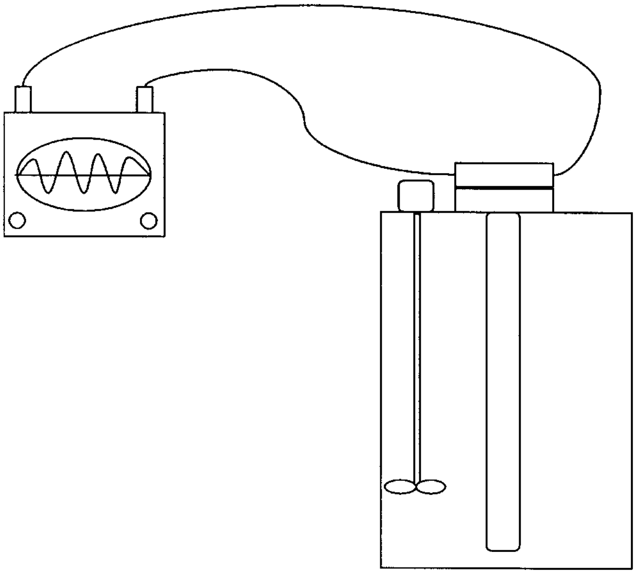

Figure 7. Batch reactor with lamp and agitator.

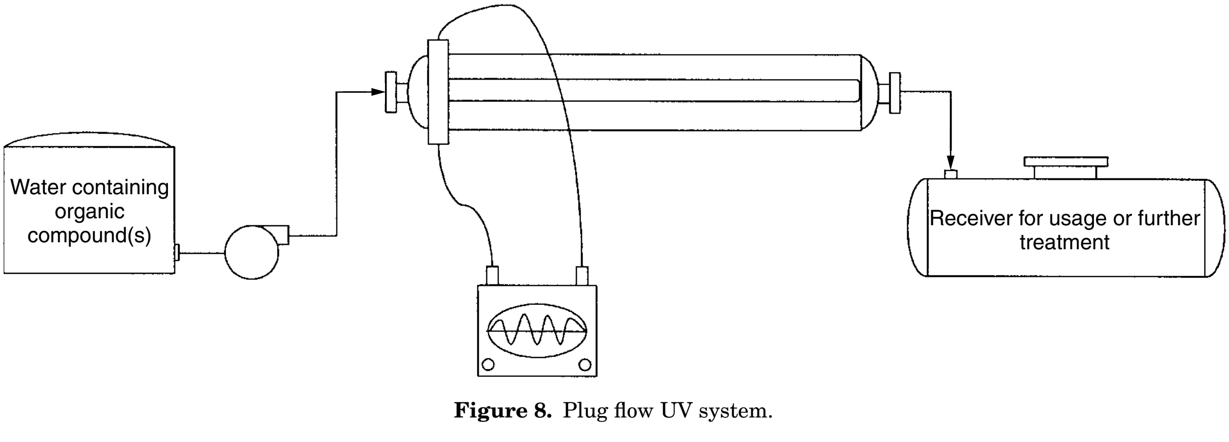

Figure 8. Plug flow UV system.

The power, based on this k, is then the industry design equation (14).

$$\mathrm{P(kW)} = \frac{\mathrm{EE/o} * \log 2 * Q * \ln(C_i/C_o)}{\ln 2}$$

For a continuously stirred reactor (CSTR), the steady-state material balance yields

$$\frac{C_i}{C_o} = \frac{kV}{Q} + 1$$

This does not yield the industry design equation. The answer to this seemingly paradoxical result is that the plug flow design applies, regardless of the reactor type for flow-through reactors. This is so because the reaction must be in the vicinity of the lamp surface; a solute in a CSTR must, at some time in its residence history, approach the lamp sufficiently close. This is one reason that flow-through reactors require appropriate design to obtain turbulence.

Nomenclature

A	Cross sectional area
C_B	Bulk liquid concentration
C_e	Equilibrium concentration
C_i	Inlet concentration
C_o	Outlet concentration
$C*$	Fictitious concentration in vapor phase
D	Diameter
EE/o	Electrical energy/1000 gallons/order
F	Mass transfer flux
G	Gas mass velocity
H	Henry's Law constant
$h\nu$	Photon energy
HTU	Height of a transfer unit
k	1st order reaction coefficient
K	Freundlich constant (related to capacity)
K_G	Overall mass transfer coefficient based on gas
K_L	Overall mass transfer coefficient based on liquid
k_G	Gas phase mass transfer coefficient
k_L	Liquid phase mass transfer coefficient
K_{L_a}	Overall liquid phase mass transfer coefficient
L	Liquid mass velocity, length of column
NTU	Number of transfer units
$1/n$	Freundlich exponent (related to bonding strength)
P	Power
P_T	Total pressure
p_B	Bulk gas partial pressure
p_i	Partial pressure at interface
P^{vap}	Pure component vapor pressure
$p*$	Fictitious pressure in liquid phase
q_e	Quantity adsorbate/adsorbent
Q	Liquid flow rate
R	Stripping factor
t_b	Breakthrough time
t_s	Saturation time (influent = effluent)
V	Volume
x_i	Liquid phase mole fraction
y_i	Gas phase mole fraction
γ_i	Activity coefficient
κ	Boltzmann's constant
ϕ_i	Fugacity coefficient

USE OF ANAEROBIC-AEROBIC TREATMENT SYSTEMS FOR MAIZE PROCESSING PLANTS

María-del-carmen Durán-de-bazúa
UNAM, National Autonomous
University of Mexico
University City, México

After the discovery of the American continent by the Spaniards in the fifteenth century, corn (*Zea mays*), an indigenous plant from Mexico, spread all over the world and became a staple food for many human groups. However, the traditional ways of eating the many products derived from this cereal in Mexico, inherited from the Mayan, Aztec, and other Mexican indigenous groups, were not disseminated until the last 20 years. Due to globalization, one of these maize products, "tortillas," is now an extremely popular food that can be found in most countries of the world. "Tortillas" are a sort of unleavened bread in circular form that, due to a mild flavor, can be combined with vegetables, meats, pulses, etc. They are the bread equivalent to "chapattis" for the people from India and "falafel" for the people of the Middle East (Fig. 1).

The traditional production of "tortillas" involves a Precolumbian technique, known as "*nixtamalization*," derived from the Aztec words *nextli* = lime ashes and *tamalli* = cooked corn dough. This ancient process, almost as old as corn domestication and cultivation, is a time- water- and energy-consuming technique (Fig. 2). Modernization of the traditional process to produce cornmeal instead of dough to lengthen its shelf life as well as some other changes for mass production have been introduced in the last 50 years. However, these changes affect the sensory characteristics of "tortillas," mainly "rollability," "sturdibility," and softness, so it has been a common practice among large-scale producers to introduce some chemical additives to make the new "supermarket tortillas" desirable from the sensory point of view. Unfortunately, from the nutritional point of view, it has not yet been proved that these additives do not affect the health of consumers. Some innovative processes that maintain these desirable nutritional and sensory characteristics, and at the same time, reduce energy and water consumption, and most importantly, processing time, have also been developed and started to be used (2–5). However, the traditional plants (more than 100,000 small-scale and 25 large-scale in Mexico) are still in operation, so methods to treat and stabilize the wastewater generated in the traditional process (so-called "nixtamal" mills that process around 0.5 to 4 metric tons maize per day) or in its industrial modifications (so-called precooked cornmeal or masa-harina factories that process from 100–1,000 metric tons maize per day) and contain appreciable amounts of soluble and insoluble organic matter (Table 1) have also been developed. These methods are based on anaerobic and aerobic systems, and the interesting issue is that by-products from the treatment can be further used, giving added value to these treatment processes.

The biological processes developed were screened out after testing at laboratory level. These processes are commonly used in biological wastewater treatment, such as activated sludge, aerated lagoons, facultative lagoons, low and high rate anaerobic reactors, etc. (7). Figure 3 shows the method developed for treating the wastewater from maize alkaline processing to produce "tortillas," particularly for those factories that process considerable amounts of corn. After primary settling to recover broken maize pieces and peelings, the anaerobic process is carried out to transform most of the biodegradable dissolved matter in the wastewater into methane-rich biogas. This is followed by the aerobic process that polishes the treatment, removes the traces of sulfide and other undesirable compounds in treated water, and converts the remaining biodegradable matter into protein-rich biomass. A tertiary treatment using activated carbon or any organic adsorbent will render recyclable water for the process. The water absorbed by corn is added as makeup freshwater to the overall process. The recycling of the by-products generated is shown in Fig. 3. The amount of methane from biogas obtained from the anaerobic treatment of the wastewaters is 9.6–16.8 m^3 per metric ton of maize processed (considering 5 m^3 of wastewater produced per metric ton maize at a conversion of 80% of the dissolved biodegradable matter into biogas). If this gas contains roughly 80% methane, the yield of this energy-rich gas is 7.7–13.48 m^3 methane per metric ton of maize processed. This methane-rich biogas may be washed and compressed to be used as a secondary source of energy during the lime-cooking of corn grains (nixtamalization). The amount of biomass and suspended solids obtained may be processed by extrusion to form pellets or flakes for fish feedstuff, considering the mass balances from the aerobic and anaerobic processes is of 23 kg SS and 10.6 kg biomass per metric ton of maize cooked. These biomass and suspended solids pellets or flakes proved comparable

to that for commercial feedlots for carp and other edible fish (8).

The reactors most suitable for this type of carbonaceous wastewater are those that develop active biofilms, particularly because the biomass formed tends to show more cohesion and separates more easily from the liquid phase by sedimentation. For the anaerobic step, packed bed anaerobic reactors or upflow anaerobic sludge blanket reactors are those that render the highest conversion into methane-rich biogas at the lowest hydraulic residence times between 24 and 48 hours. For the aerobic step, rotating biological reactors are excellent for transforming the soluble remaining biodegradable dissolved and colloidal organics into an easily settleable aerobic biomass. The energy consumption for the rotational speed needed is very low, and the area occupied by the reactors is also very small. Figure 4 shows the system to be used in cornmeal factories. Both systems, the anaerobic and the aerobic, are compact and easy to operate. The saving in water and energy consumption, wastewater disposal costs, and the sale of biomass for fish protein-rich feedlots make the treatment and recovery process economically feasible. The

turnover rate is 1.5 years, that is, the money invested in the wastewater treatment plant together with the accessories to recover biogas and biomass and to reuse them is recovered in 18 months.

Due to the size of nixtamal mills, it is not so economical to install an anaerobic-aerobic process for treating their wastewaters (between 2.5 to 20 m^3). An aerobic system is then used for these small establishments (Fig. 5). The solid material collected from the filter press can be fed directly to small farm animals and, although the protein cannot be directly assimilated by the animals, it does not damage them. In this case, partially treated wastewater is sent to the municipal sewer system. Finally, it should be mentioned that this combined anaerobic-aerobic process may be applicable to wastewater from other food industry sectors, particularly to those that contain carbonaceous substances. When proteinaceous wastewater is to be degraded, the wastewater may be anaerobically treated, but the gases must be washed to remove the sulfur compounds separated from protein matrices before using the biogas as a combustion or fuel source. Hydrogen sulfide is extremely corrosive and toxic, but once dissolved in water, may be used by aerobic organisms to be reconverted into biomass protein.

Worldwide environmental problems are becoming more and more acute. It is known that many specific industrial wastewater streams with large flows contain toxic metals in concentrations up to 500 mg/L, which have to be removed prior to water recycling, indirect discharge into a sewage system, or direct discharge into surface waters. Some examples are (1) rinse water in metal working enterprises, containing Cu, Ni, Zn, Sn, Cd, Pd, Ag, Al, Au, Cr, Mo, etc.; (2) rinse water in the semiconductor industry, containing Cu, Sn, Pb, Sb; (3) wastewater from the copper industry, containing As, Se; (4) other types of water in which the presence of toxic metals causes problems; (5) drinking water from ground water contaminated with As; and (6) mine water contaminated with different toxic metals (e.g., U, Ra, As).

When discharged directly into rivers, polluted wastewater poses a great risk to the aquatic ecosystem, and discharge into a sewage system negatively affects biosludge activity and leads to contamination of the sludge to be disposed of. As a result of the standards specified in the Water Resources Act, which was amended in 1986, industry takes precautions against these risks by treating dangerous components in a partial stream before mixing with other types of wastewater. So, research was focused, among others, on the development of highly selective bonding agents (often denoted as BA) with fast reaction kinetics for removing heavy metal ions (Fig. 1a). The latter may lead to better use of the capacity of bonding agents, resulting in smaller units and low residual concentrations of toxic metals in treated water streams, to comply with individual standards for water reuse or discharge—sorption kinetics constitutes another article in this *Encyclopedia of Water*.

In addition to zeolites (1,2), other typical materials extensively used are apatites (3,4) and various iron sorbents (5,6). These BA materials are broadly classified in three classes: carbon sorbents (active carbons, activated carbon fibers, molecular carbon sieves, fullerenes, heterofullerenes, nanomaterials), mineral sorbents (silica gel, activated alumina, oxides of metals, hydroxides of metals, zeolites, clay minerals, inorganic nanomaterials) and others (synthetic polymers, composite sorbents, mixed sorbents, etc.).

A review paper on bonding agents recently presented to a conference (7) also mentioned new types such as mesoporous materials and chelating resins and their potential applications to metal bonding from aqueous solutions. It also presented the equilibrium sorption capacity for metal ions of certain sorbents and stated that the functionalized silica materials have shown higher uptake capacity than that of other materials found in the literature. An inherent disadvantage of these materials is their low loading capacities and relatively small metal ion binding constants.

To circumvent these limitations, promising heavy metal sorbents have been prepared by coupling chelating ligands (e.g., thiol, amine, or crown ether functions) to support matrices consisting of inorganic oxides (e.g., silica, alumina, or clay) or organic polymers (e.g., polystyrene, cellulose, or polymethyl-methacrylate). Such functionalized materials have relatively high metal ion loading capacities and strong binding affinities for selected metal ions. This performance can be attributed to the presence of the surface-bound ligands, which can be specifically tuned to accommodate the selective sorption of targeted metal ions. Although superior in performance to conventional ion exchangers, functionalized matrices remain relatively inefficient because only a fraction of the immobilized ligands is accessible for metal complexation. The discovery of mesoporous metal oxide molecular sieves (by Mobil researchers) and organoceramic sorbents has given rise to new prospects for sorbent and catalyst design (7).

The knowledge of the governing chemical state of the metal ion to be removed is a prerequisite, so that any new development is based on a solid scientific

Worldwide environmental problems are becoming more and more acute. It is known that many specific industrial wastewater streams with large flows contain toxic metals in concentrations up to 500 mg/L, which have to be removed prior to water recycling, indirect discharge into a sewage system, or direct discharge into surface waters. Some examples are (1) rinse water in metal working enterprises, containing Cu, Ni, Zn, Sn, Cd, Pd, Ag, Al, Au, Cr, Mo, etc.; (2) rinse water in the semiconductor industry, containing Cu, Sn, Pb, Sb; (3) wastewater from the copper industry, containing As, Se; (4) other types of water in which the presence of toxic metals causes problems; (5) drinking water from ground water contaminated with As; and (6) mine water contaminated with different toxic metals (e.g., U, Ra, As).

When discharged directly into rivers, polluted wastewater poses a great risk to the aquatic ecosystem, and discharge into a sewage system negatively affects biosludge activity and leads to contamination of the sludge to be disposed of. As a result of the standards specified in the Water Resources Act, which was amended in 1986, industry takes precautions against these risks by treating dangerous components in a partial stream before mixing with other types of wastewater. So, research was focused, among others, on the development of highly selective bonding agents (often denoted as BA) with fast reaction kinetics for removing heavy metal ions (Fig. 1a). The latter may lead to better use of the capacity of bonding agents, resulting in smaller units and low residual concentrations of toxic metals in treated water streams, to comply with individual standards for water reuse or discharge—sorption kinetics constitutes another article in this *Encyclopedia of Water*.

In addition to zeolites (1,2), other typical materials extensively used are apatites (3,4) and various iron sorbents (5,6). These BA materials are broadly classified in three classes: carbon sorbents (active carbons, activated carbon fibers, molecular carbon sieves, fullerenes, heterofullerenes, nanomaterials), mineral sorbents (silica gel, activated alumina, oxides of metals, hydroxides of metals, zeolites, clay minerals, inorganic nanomaterials) and others (synthetic polymers, composite sorbents, mixed sorbents, etc.).

A review paper on bonding agents recently presented to a conference (7) also mentioned new types such as mesoporous materials and chelating resins and their potential applications to metal bonding from aqueous solutions. It also presented the equilibrium sorption capacity for metal ions of certain sorbents and stated that the functionalized silica materials have shown higher uptake capacity than that of other materials found in the literature. An inherent disadvantage of these materials is their low loading capacities and relatively small metal ion binding constants.

To circumvent these limitations, promising heavy metal sorbents have been prepared by coupling chelating ligands (e.g., thiol, amine, or crown ether functions) to support matrices consisting of inorganic oxides (e.g., silica, alumina, or clay) or organic polymers (e.g., polystyrene, cellulose, or polymethyl-methacrylate). Such functionalized materials have relatively high metal ion loading capacities and strong binding affinities for selected metal ions. This performance can be attributed to the presence of the surface-bound ligands, which can be specifically tuned to accommodate the selective sorption of targeted metal ions. Although superior in performance to conventional ion exchangers, functionalized matrices remain relatively inefficient because only a fraction of the immobilized ligands is accessible for metal complexation. The discovery of mesoporous metal oxide molecular sieves (by Mobil researchers) and organoceramic sorbents has given rise to new prospects for sorbent and catalyst design (7).

The knowledge of the governing chemical state of the metal ion to be removed is a prerequisite, so that any new development is based on a solid scientific

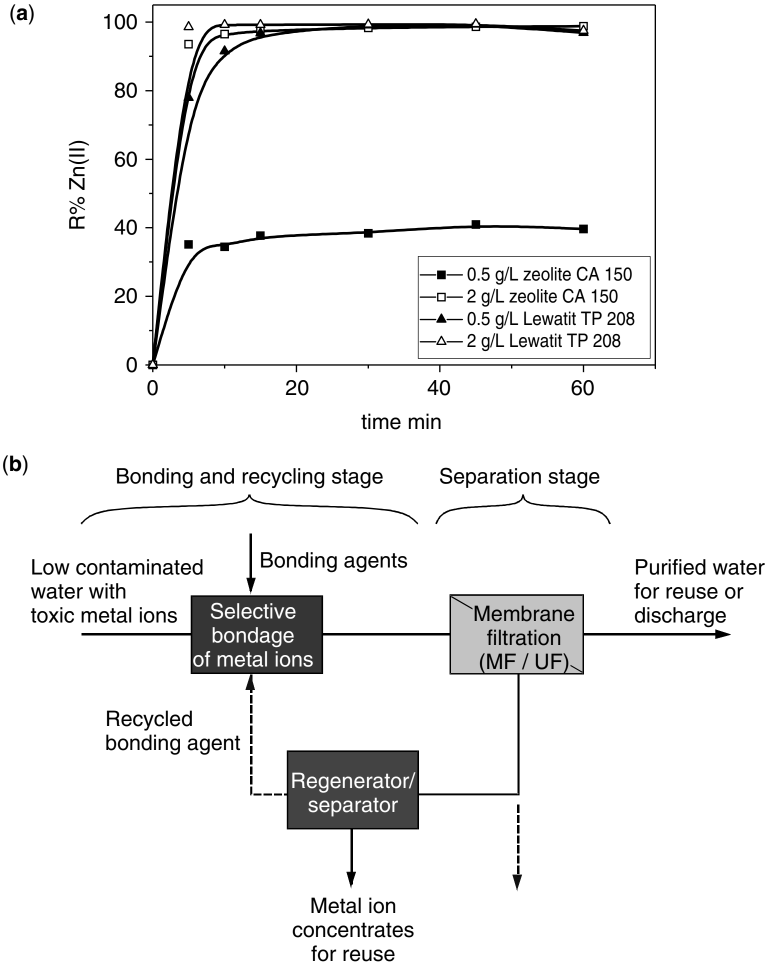

Figure 1. (**a**) Removal of zinc (50 mg/L, pH 6) by an ion exchange resin and zeolites for comparison (unpublished data). (**b**) Membrane separation of bonding agent/metal complexes for wastewater (METASEP project). Reprinted with gratitude from Reference 10.

foundation (8). The impact of chemical speciation is important in any process, including adsorption, ion exchange, or precipitation. These often act together, and the dominance of one specific is often hard to distinguish without careful chemical measurements and advanced analytical techniques. Identifying the bonding mechanism of metals on the agent/sorbent used is significant because, for example, the mechanism could dictate the mobilities of the species in their existing environment.

A new treatment process aimed at water and metal reuse was developed for the selective separation of heavy metals from wastewater to reduce costs and mitigate the environmental impact of wastewater pollutants (9). One of the variants, divided into three stages (shown as Fig. 1b), was the separation of BA-metal complexes by cross-flow microfiltration/ultrafiltration from wastewater that has metal concentrations less than 50 mg/L. This project was a contribution to the key action of European Union "Waste water treatment and re-use," in the 5th Framework programme.

The use of iron-based bonding materials, such as goethite and akaganėite, was successful because they are inexpensive, easily synthesized, suitable for both cation and anion sorption, and present low risks of adding a further pollutant to the system. Typical results are presented in Fig. 2; the sorbents had high surface area and defined pore size distribution. The synthesis of these materials involved hydrolyzing aqueous solutions of ferric salts followed by membrane purification and freeze drying (6). Sorption, in general, depends on the solution pH and its ionic strength. These macroscopic observations were used to differentiate between the kind of adsorption, physical or chemisorption (13). Other additional indications were obtained by examining the influence of temperature during equilibrium experiments and/or calculating (from the van't Hoff equation) the change of the respective enthalpy.

The stability of a suitable bonding agent should be evaluated in a real process, for chemical and physical stability as well as losses in the proposed flowsheet. The selected industrial effluents in the aforementioned research project (e.g., METASEP) are presented in Table 1.

An effective mode of a sorption process is based on a fixed-bed contactor configuration (14). The sorption bed has to be porous to allow the liquid to flow through with minimum resistance but allow the maximum mass transfer into the particles—see also the article on Sorptive filtration in this *Encyclopedia*. Another possibility for this solid/liquid separation stage of loaded ultrafine material, as adsorbents and ion exchangers are, constitutes flocculation, as examined for goethite (Fig. 3a). The dynamics of flocculation were studied by a technique based on measuring the fluctuations of transmitted light in flowing dispersions.

An alternative for metals removal is *in situ* production, for instance, of ferric hydroxide (see Fig. 3b), which could be also conducted by electrocoagulation. Specifically, adsorbing colloid flotation is the process that involves removing a solute from an aqueous solution by adsorption on, coprecipitation with, or even occlusion in a carrier floc, often produced from ferric or aluminum salts by hydrolysis and solution pH modification. The aggregate, including the metals, is usually then floated after the addition of a suitable surfactant or collector (11).

The combination of flotation following sorption downstream (termed sorptive flotation) for metal cation removal by ion exchange materials, as the synthetic zeolites (of MAP type), gave promise for an improved metal separation process (16). A disadvantage of this is the application of surfactants, as flotation collectors; this represents an enormous demand, as flotation also applied in mineral processing, is currently met by numerous chemicals, mainly petroleum-based, hence, substances that are usually toxic to the environment and nonbiodegradable. For this reason, the successful application of biosurfactants was investigated (17).

Regeneration of bonding agents is, of course, a prerequisite often overlooked. The following two modes for different BA regeneration were envisaged: (1) The conventional, by changing the pH value; after separating it from the treated effluent, the loaded sorbent was mixed with a solution containing a strong acid (or alkal in the case of oxyanions) to shift the fixation equilibrium, to recover the metal in the acidic solution, and to produce a regenerated agent, where the protons have replaced the metal cations and could be recycled. (2) Electrodialysis with bipolar membranes for uncharged water-soluble bonding agents and modified electrodialysis for powdered agents (see Fig. 4). The loaded sorbent was fed into an electrodialysis reactor where, due to the electric field, the metals were separated from the material. The metal cations migrated in the electric field and crossed a cation-exchange membrane to enter into an other compartment, where they reacted with hydroxyl ions generated by a second bipolar membrane or by a cathode. The regenerated materials were recovered on one side, and a hydroxide sludge was recovered on the other side (18).

Elsewhere (19), another multistage process was proposed for removing aqueous cadmium consisting of, among others, elution at high concentrations of the sorbed metal ion from the biomass (the BA used here), recycling sorbent and eluant, wherever possible, and recovering cadmium electrochemically by a rotating cathode cell, in the form of metal powder as the end product. The flow diagram is shown with three cycles/routes for the combined process (investigated under an EU-funded research programme, too); the second-middle cycle represented flotation separation of the metal-loaded biomass. Biosorption, the uptake of heavy metals by dead biomass, has gained credibility during recent years, as it offers a technically feasible and economical approach. Several biological materials were investigated for heavy metals removal, including bacteria, yeasts, algae, and fungi.

Concluding, the "*polluter pays*" principle ensures nowadays that companies have to pay the costs of environmental damage, or at least in part. Therefore, from their point of view, an economical and effective solution is required by developing techniques for improved treatment. On the other hand, many of the metal ions (cations or oxyanions) that are target compounds in effluents could be further concentrated for recycling; incineration of toxic sludge should be avoided, as this entails transferring pollution from one state to another. The strategy is to reuse water and metals, so "end-of-the-pipe" solutions will no longer be necessary. Attempts have been made to develop a more specific water treatment technique to provide industrial process water as close as possible to the source, applying quality assurance and efficiency control techniques for operational management. An innovative and cost-effective approach minimizes environmental impact from wastewater and prevents potential damage to health.

The examination of membrane processes started mostly as a search for effective product separation that is crucial to economical operation in process industries. Certain types of materials are inherently difficult to separate, and their processing has become of increased importance in recent years, especially due to the growth of the biotechnological industry (1) This new technology using synthetic membranes for process separations has developed rapidly. Industrial membrane processes are classified according to the size range of materials, which they are to separate, and the driving force used in separation. The most common pressure-driven process is microfiltration (often denoted as MF) (2). This technique separate a size range of 10–0.1 μm; typical examples of materials separated are small particles, large colloids, and microbial cells.

Conventional processes for treating wastewater, precipitation, precipitation/reduction, ion exchange/sorption bed filtration, etc., often have disadvantages such as high use of treatment chemicals; large quantities of sludge produced that has to be treated and disposed of; inadequate selectivity; slow kinetics of the metals and their oxyanions and therefore, large water treatment units and high investment costs are required; low capacity of ion exchangers and sorbents; the residual metal concentration in the treated water streams can be high and water reuse or discharge is problematic; fouling and scaling problems, very low membrane permeability, and low water yield (up to 75%) are problems often encountered in conventional membrane processes; treatment processes are periodic and not continuous, followed by a regeneration step in which regeneration chemicals and rinsing water are employed, ultimately generating a new quantity of wastewater; treatment of wastewater streams with large volume flow and high concentrations is mostly not cost-effective. So, combinations of treatment processes are usually applied in practice.

Such a combination could, for instance, have as the first step the use of a suitable bonding agent followed by another separation technique downstream as a membrane process (3); see also the article on Bonding of toxic metal ions in this *Encyclopedia of Water*. Metal ion recovery by membrane technologies from aqueous waste streams was reviewed by several vendors in the field (4). At a lower particle size range than that for microfiltration, as aforementioned, other membrane processes are applied. Some examples of these applications involve, among others, ultrafiltration (UF) of fruit juices using tubular configuration polymeric and ceramic membranes (5) and reverse osmosis in treating sugar beet press water (6). Different polymeric membranes from commercial companies were tested for wine clarification (7), and the ceramic membranes were compared with polymeric ones for removing of natural organic matter from drinking water sources (8).

Ceramics are good materials for producing membrane filtration tubes (9). The advantages of ceramic membranes compared to polymer membranes include resistance to high temperatures up to 280 °C (in specially developed modules and systems up to approximately 700 °C); good corrosion resistance: resistance to organic solvents and a wide pH range; suitability for cleaning and steam sterilization; high mechanical strength: the possibility to back pulse, resulting in efficient removal of the dirt layer and the possibility of treating fluids with high viscosity; chemical inertness: a wide range of application possible in the chemical industry; long operational life; and high membrane flux from a composite structure. The disadvantages of ceramic membranes compared to polymeric membranes are brittleness and so they must be handled with care; the surface area/volume ratio is low so systems have larger dimensions; and the investment in ceramic membranes is high.

Microfiltration constitutes a physical barrier to solid particles (as bonding agents), but has limitations because of increased fouling at high concentrations. Conventionally, cross-flow processes are applied, where high shear rates on the membrane surface are created to prevent fouling of membranes. The corresponding high energy consumption led to the development of so-called low-energy systems (10), which are characterized by immersed membranes operated by vacuum or hydrostatic pressure. Fouling is often controlled by air blowing from below the membranes, creating shear forces near the membrane surface. The energy consumption of these systems is considerably lower than that of cross-flow systems, yet still significant (11). Furthermore, flux is also low, especially at higher concentrations of suspended solids in the reactor. Immersed membranes have been used for a variety of applications, mainly biological wastewater treatment and drinking water production (12).

New MF/UF membrane modules were developed (13) with emphasis on crossflow or submerged operation, optimized hydrodynamics (in contrast to commercial hollow fiber or spiral-wound modules) to work at higher bonding agent (BA) concentration in water, high fluxes in real process water, low fouling tendency, easy cleaning suited for backwashing, and low production costs. Both

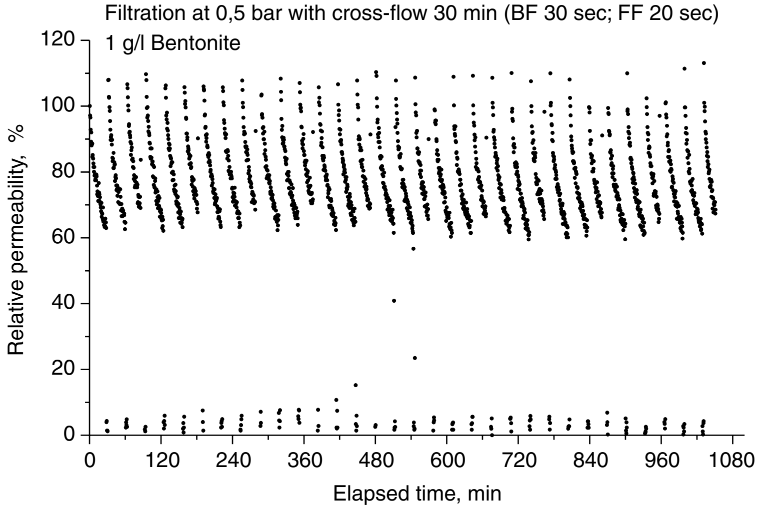

Figure 3. Filtration of bentonite suspension with PP membrane module in back-flush mode.

polypropylene (PP) as well as polyethersulphone (PES) based membranes were developed (see Fig. 1). PP fibers have a symmetrical wall, low flux and are inexpensive. PES capillaries have an asymmetrical wall, and higher flux, but are more expensive. Because of this trade-off, both membranes are of much interest in research. These PP fibers were used in common longitudinal membrane modules, as shown in Fig. 1a–d with bench-scale modules. Figure 1c shows a cross-flow module with PES multichannel, flat sheet membranes.

The PES capillary membranes were used for the transversal flow membrane module (TFM). Previous studies showed that within TFM modules, membranes tend to break because of the high stress at the potting-membrane interface. Much improved capillary membranes were developed. They possess three times the tensile strength at break (13). This was the result of adding a component to the extrusion mixture that resulted in a tighter sponge in the support layer. Figure 1d, left, shows the TFM module consisting of 10 active layers of 8 membranes next to each other in a grid.

The process scheme of the bench-scale plant used is presented in Fig. 2, based on feed-and-bleed processing; automatic back-flush was incorporated. Experiments with bentonite and the PP membrane modules in longitudinal outside mode showed that relative permeability decreased,

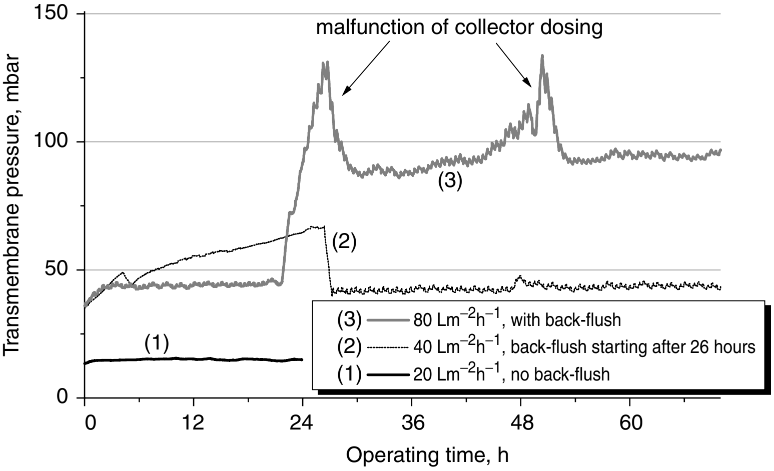

Figure 4. Transmembrane pressure as a function of time for the hybrid process at various operating modes, under the following conditions: $c(\text{zeolites}) = 8$ g/L, $c(\text{CTABr}) = 20$ mg/g, $u_g = 0.33$ cm/s, back-flushing (if applied) every 30 min for 10 s.

when the transmembrane pressure was increased. Somewhat surprising, but very promising was that the back-flush mode has been very effective. At least during 22 hours, permeability was constant (Fig. 3). When selecting membranes for efficiency and rejection of substances, permeability and pore size or molecular weight cutoff were examined as important criteria (14).

Today, there is a tendency for combined and more compact processes as, for example, membrane bioreactors (15). Membrane fouling was also said to be the main limitation to the faster development of the latter. A newly developed type that has the further advantage of energy saving is the submerged membrane bioreactor.

A large number of techniques have been used to limit membrane fouling, such as cross-flow liquid velocity, the use of baffles, back-flushing, transmembrane pressure (TMP) pulsing, and air sparging (16). Depending on the membrane process, the function of air can be different: a gas back-flush detaches and carries away deposited particles, the formation of a particle or concentration polarization may be prevented or limited, and even a compound may be transferred by gas to a liquid phase.

Air bubbling, under appropriate conditions, could also be used as the transport for flotation, which is another efficient separation method applied in water treatment (17). The aim of this innovative idea was integrating both processes in the same tank, taking advantage of dispersed-air flotation combined with microfiltration by submerged membranes. For this, ceramic flat-sheet membrane modules with multichannel geometry were tested; the pore size was 0.3 μm, pure water flux 3000 $\text{L m}^{-2}\ \text{h}^{-1}\ \text{bar}^{-1}$, the material of permeate collector polystyrene, and sealing material epoxy. The membrane distance was 20 mm, geometry 100 × 100 and area 0.054 m^2 (Fig. 1d, right). The hybrid cell was tested on-site at the Assarel-Medet open pit copper mine effluent, near Panagyurishte, Bulgaria (18). The flotation separation techniques employed and investigated were based on three different mechanisms: (1) ion flotation using xanthates, (2) precipitate flotation generating copper hydroxide, and (3) sorptive flotation using zeolites as sorbent material—see also the article on Flotation in this *Encyclopedia*.

A parallel economic study showed that the capital investment for the hybrid unit would be of the order of 0.92 M€. The operating cost of the plant is about 1.42 M€ per year. Comparison with separate systems (MF following flotation) showed that the hybrid system has a lower capital cost and lower operating costs. The former also requires larger membranes.

The advantageous influence of flotation may be apparent from Fig. 4. Membranes were operated at constant flux in all experiments. For an initial zeolite concentration of 8 g/L the membranes could be operated at 20 $\text{L/m}^2\text{h}$ without back-flushing. Resulting transmembrane pressure was as low as 15 mbar. However, to achieve stable membrane performance at higher fluxes, back-flushing was necessary. A cycle of 10 s back-flushing every 30 min was sufficient, resulting in TMP of 45 and 90 mbar (the mean of two cycles between backwashing) for imposed fluxes of 40 and 80 $\text{L/m}^2\text{h}$, respectively. The relatively long time between back-flushing resulted in a permeate loss of less than 5% due to backwashing (19).

In Fig. 4, it can also be seen that the increase in transmembrane pressure when operating the membranes at 40 $\text{L/m}^2\text{h}$ without back-flushing was fully reversible. Switching the operating mode of a membrane, that had been operated in continuous permeate withdrawal for 24 hours, to back-flushing resulted after less than 1 hour in the same transmembrane pressure as a membrane, which had been operated with back-flushing from the beginning. This proves that the loss in membrane performance was attributed to an easily removable cake layer, which was also visually observed. The resistance-in-series model (20) may be used in this case, which describes filtration resistance as the fraction of TMP to flux; the resistance of the cake layer can be evaluated according to

$$J = \frac{\text{TMP}}{\eta(R_\text{M} + R_\text{C})} 3.6 \times 10^8, \tag{1}$$

where J is permeate flux, R_M is membrane resistance, R_C is the resistance of the cake layer or, in general, fouling resistance; and η the viscosity of water to be filtered. Cake resistance is of the same magnitude as membrane resistance and thus, quite low, which can be attributed to a highly permeable cake layer that zeolites form. These results could be also considered in terms of the concept of "critical flux" (the flux up to which the relation between flux and TMP is linear), which is currently often applied to microfiltration processes (21). Although this concept does not imply back-flushes, from a process point of view, it can also be concluded that the membranes in our process were operated in the subcritical flux region. In all investigations, the air supply was determined by that required for flotation. No additional aeration of the membranes was carried out. This has to be considered when relating membrane performance to conventional immersed membrane systems because the superficial air velocity used in the hybrid cell was about 10 times lower than that usually applied in these systems.

Concluding, one of the main objectives of environmental technology today is to design and implement processes to clean effluents from industrial production; recycling valuable materials and microfiltration has certainly a definite role having presented very promising results. Product recovery and waste recycling have been addressed by providing novel integrated processes for reusing water and the possibility of metal recycling, aiming to meet regulatory requirements with environmental benefits, not merely by reducing risks.

WATER TREATMENT IN SPENT NUCLEAR FUEL STORAGE

Samuel C. Ashworth
Idaho National Engineering and
Environmental Laboratory
Idaho Falls, Idaho

Many facilities are changing their storage to dry mode, but in 1996, there were 100,000 tons of Zircaloy-clad spent nuclear fuel (SNF) in wet storage (1). Much of this fuel is stored in extended mode, beyond the period of time originally planned. Thus, this extended storage can create problems.

A typical spent nuclear fuel pool storage system is shown in Fig. 1. The main functions of water storage pools are to contain the fuel and any radionuclides that leak and to remove heat generated by radionuclide decay. Water is withdrawn from pools via overflow sumps and pumped through a filter to remove solids including microorganisms. The water is treated by ion exchange

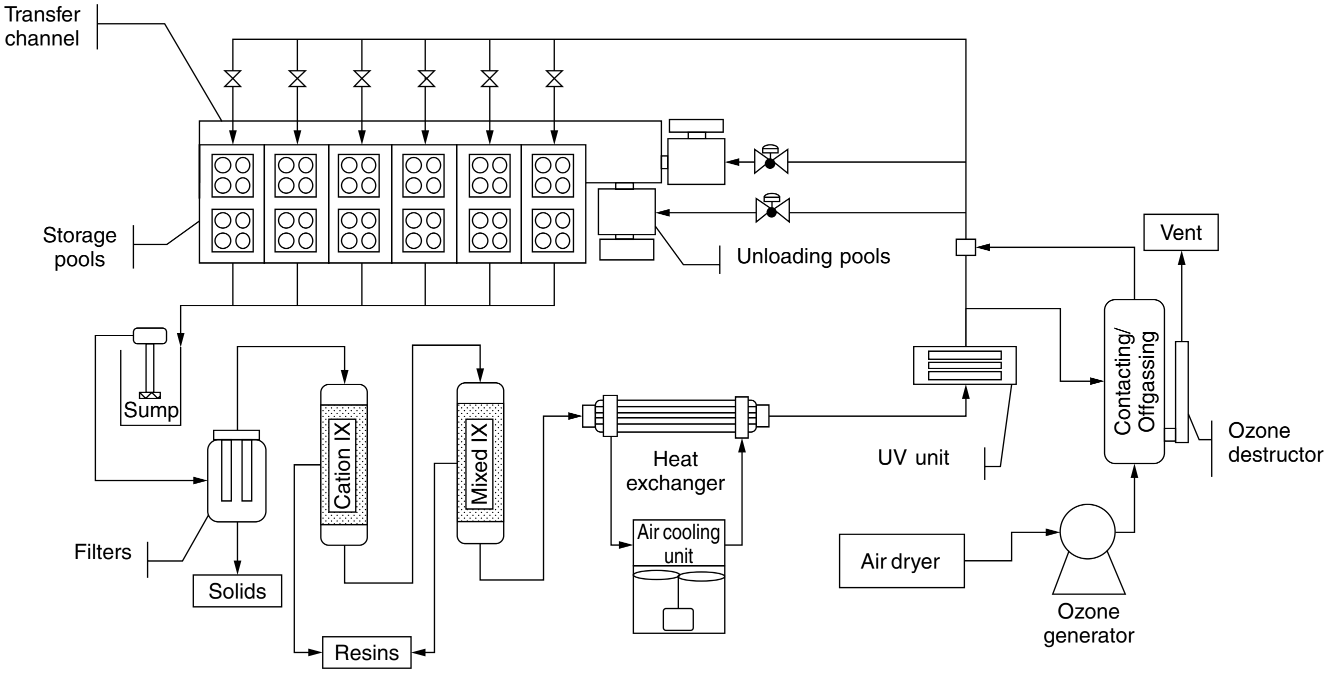

Figure 1. Typical spent fuel storage schematic.

to remove radionuclides and other dissolved substances. Heat exchangers remove the decay heat that the spent fuel transfers to the water. Some systems have ultraviolet (UV) light systems that kill microorganisms. An ozonator is also shown in Fig. 1, even though many systems do not have this. The supply makeup water normally has very low conductivity ($\kappa \leq 1$ μS/cm), so there is very little ion exchange capacity used up unless the fuel is in very bad shape and is leaking. There is also a need to provide basin chemistry/corrosion control to minimize corrosion of SNF, parts, and equipment. The following are typical limits imposed to minimize corrosion: $5.0 < \text{pH} < 8.0$, exclusion of heavy metals or their salts including Cu, Pb, Sn, Hg, Ni, and Co, keeping $\text{Cl}^- < 10$ ppm, and limiting conductivity <10 μmho/cm (μS/cm). There may be a potential for microbiologically induced corrosion (MIC) in storage pools, so it is important to control microorganisms. This article focuses on microbiological control that presents the biggest challenge facing pool storage systems. The corrosion of fuel element cladding must be minimized to ensure containment of radionuclides and worker protection. The general outline is a discussion of mechanisms, rationale for treatment, and treatment methods for storage pools.

MICROBIOLOGICAL MECHANISMS

Some of the variables that affect the growth of microorganisms include food/nutrient availability, temperature, pH, biocide concentrations, radiation, makeup water microorganism concentration, and predation. There are practical limitations to the types of activities that can be used to control microorganisms, for example, restricting the use of biocides or pH out of the range of water chemistry requirements.

The first substances on a surface during biofilm formation are trace organics (2). Almost immediately after the clean pipe surface comes into contact with water, an organic layer deposits on the water/solid interface (3). These organics form a conditioning layer that neutralizes excessive surface charge and surface free energy that may prevent a bacterial cell from approaching near enough to initiate attachment. In addition, the absorbed organic molecules often serve as a nutrient source for bacteria.

Some planktonic (free-floating) bacteria approach the pipe or equipment wall and become entrained within the boundary layer. Some of these cells strike and adsorb to the surface for some finite time and then desorb. This initial attachment is based on electrostatic attraction and physical forces. Some of the reversibly adsorbed cells begin forming structures that may permanently bond the cell to the surface. These cells become irreversibly adsorbed. Figure 2 provides a schematic of this stage of biofilm development.

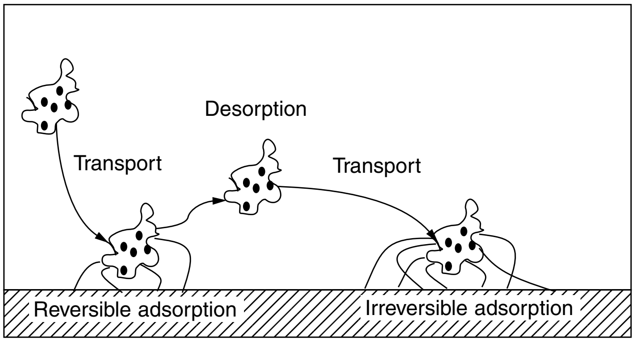

Figure 2. Biofilm development.

Biofilm bacteria excrete extracellular, polymeric substances that contain the biofilm and attach it to a wall. These polymer strands trap scarce nutrients and protect bacteria from biocides. Attachment is mediated by extracellular polymers that extend outward from the bacterial cell wall (3). The polymeric material, or glycocalyx, consists of charged and neutral polysaccharide groups that facilitate attachment and also act as an ion-exchange system for trapping and concentrating trace nutrients from the overlying water. As nutrients accumulate, the pioneer cells proceed to reproduce. The daughter cells then produce their own glycocalyx, greatly increasing the volume of ion-exchange surface. A viable colony of bacteria is thereby established (4).

A biofilm-covered surface is gelatinous and slippery because the glycocalyx matrix holds water (75–95%) (5). The glycocalyx net also absorbs other types of microbial cells through physical restraint and electrostatic interaction. These secondary colonizers metabolize wastes from the primary colonizers and produce their own waste that other cells then use in turn. Bacteria and other microorganisms develop cooperative colonies within the biofilm. An anaerobic biofilm may develop underneath the aerobic layer. The biofilm thickness will reach equilibrium as flowing water detaches cells extending out into turbulent flow.

Different species live in the films, helping each other to exploit food supplies and to resist biocides through synergistic interactions. Some species use toxic wastes produced by another species as food. By pooling their biochemical resources to build a colony, several species of bacteria, each with different enzymes, can break down food supplies that no single species could digest alone. The biofilms are permeated at all levels by a network of channels through which water, bacterial wastes, nutrients, enzymes, metabolites, and oxygen travel. Gradients of chemicals and ions between microzones provide the power to shunt substances around the biofilm (6).

A biofilm can spread at its own rate by ordinary cell division, and it also periodically releases new pioneer cells to colonize downstream sections of piping and equipment. As the film grows to a thickness that allows it to extend through the boundary layer into zones of greater velocity, some cells are sloughed off. These later pioneer cells more easily adsorb than their upstream predecessors because the parent film releases wastes into the stream that may serve as either the initial organic coating for uncolonized pipe sections downstream or as nutrient substances for other cell types (4).

The development of a mature biofilm may take several hours to several weeks, depending on the system (3). *Pseudomonas aeruginosa* is a common pioneering bacteria and is used frequently in biofilm research. In one experiment, researchers found that *Pseudomonas* cells adhere to stainless steel, even to electropolished surfaces, within 30 seconds of exposure (7). The association of bacteria with a surface and the development of a biofilm can be viewed as a survival mechanism. Bacteria benefit by acquiring nutrients and protection from biocides.

Potable water systems, especially high-purity water systems, are nutrient-limited environments, but even nutrient concentrations too low to measure are sufficient to permit microbial growth and reproduction. Bacteria and other organisms capable of growth in nutrient-limited environments are called oligotrophs. Bacteria have evolved the means to find and attach to surfaces to increase the chances of encountering nutrients.

In a study on the attachment of *Pseudomonas* to stainless steel surfaces (8), researchers put cells in a blender to remove the flagella. They found that the rate of cell attachment decreased at least 90% when flagella were removed.

Many organisms faced with the starvation conditions encountered in purified water systems respond by altering their cell wall structure to increase their affinity for surfaces. By altering the protein and lipid composition of the outer membrane, the charge and hydrophobicity can be changed. The cell wall becomes hydrophobic. Once in the boundary layer, they are attracted to a pipe surface (4).

Recent research has dispelled some earlier assumptions about bacteria and biofilms. In the past, microbiologists assumed that biofilms contained disorderly clumps of bacteria located in no particular structure or pattern. In most cases, the base of the biofilm is a bed of dense, opaque slime 5 to 10 μm thick. It is a sticky mix of polysaccharides, other polymeric substances, and water, all produced by the bacteria. Water currents that flow in channels between the colonies carry nutrients and waste (9).

Past researchers assumed that biofilm bacteria behaved much like solitary, free-floating microorganisms. Biofilm bacteria have exactly the same genetic makeup as their free-roving relatives, but their biochemistry is very different because they activate a different set of genes. The instant the bacteria dock to glass, they switch on certain genes involved in the synthesis of alginate (an unusually sticky form of slime), switching them off again once the bacteria are engulfed in alginate. It is now estimated that as many as 30 to 40% of the proteins in bacterial cell walls differ between sessile and planktonic bacteria. Some of the targets for biocides are not there any more, so the bacteria become difficult to kill.

Researchers are studying the chemicals (called sigma factors) which signal bacteria to change their biochemistry to life in a biofilm (9). If they can discover a reverse sigma factor which would change biofilm bacteria into planktonic free-floaters, it might be possible to dissolve biofilms by sending the equivalent of an evacuation signal (6).

The surface material has little or no effect on biofilm development. Stainless steel is just as susceptible as plastic pipe. Piping material to which microorganisms cannot adhere has yet to be discovered. Studies have shown that microbes adhere to stainless steel, Teflon, PVC, and PVDF (Kynar) nearly equally (4). Incorporating an antimicrobial additive into plastic to delay or reduce the attachment of biofilm is possible (10). However, the chemicals used are not normally safe for drinking water supplies. Some ion exchange resins have been silver-coated to prevent microbial growth. However, silver-tolerant bacterial populations can develop (11). There are no practical examples of toxic surface coatings for drinking water piping.

One major factor influencing biofilm development in purified-water systems is surface area. Industrial water systems, unlike most natural environments (lakes and rivers), offer a tremendous amount of surface area for attachment. RO membranes, ion exchange resins, storage tanks, cartridge filters, and piping systems all provide surfaces suitable for bacterial attachment and growth (3).

Although smoother surfaces delay the initial buildup of attached bacteria, smoothness does not significantly affect the total amount of biofilm that attaches to a surface. No surfaces have been found that are exempt from biofouling (12). Surface structure influences the rate of fouling, but only initially during the first few hours of exposure. In general, smooth surfaces foul at a slower initial rate than rough ones, but biofilm formation after a period of days is inevitable.

High water flow rates may alter biofilm growth but do not prevent the attachment of bacteria to pipe surfaces. Work by Mittelman (3), Patterson (13), and Meltzer (12) supports this conclusion. High flow does not prevent bacterial attachment or remove an existing biofilm for the following reasons:

- Low flow in the boundary layer. The velocity is zero at the wall of a pipe or other surface. Near the wall, a boundary layer exists that is controlled by viscous effects, whereas outside the boundary layer, the flow is not determined by viscous effects. Within this boundary layer, for both laminar and turbulent flow, particles and microorganisms can transport and attach to surfaces. Regardless of the water velocity, the velocity profiles are such that it flows most slowly in the layers adjacent to pipe surfaces. The laminar sublayer thickness was calculated (14) for various flow velocities and for five pipe sizes. The shear forces within the laminar sublayer are much less than the forces produced in biofilm attachment.
- Strong adhesion by exopolymers. In water systems where high-velocity flow is continuous, the bacteria that accumulate in a biofilm tend to be filamentous varieties (such as *Pseudomonas*) especially suited for attachment by filaments.
- Although high flow velocity does not prevent the attachment of bacteria to pipe surfaces, it does have the following effects on the biofilm structure:
  - Denser biofilm. At higher flow rates, a denser, somewhat more tenacious biofilm is formed (3).
  - Limited biofilm thickness. The maximum thickness of a biofilm can be considered the thickness of the laminar sublayer (see Table 1).
  - Limited nutrients. Like other living creatures, bacteria require certain nutrients for growth and reproduction. Limiting these nutrients limits, bacterial growth, but nutrient levels in high-purity systems are unequivocally sufficient to permit microbial growth and reproduction to a troublesome extent (15). Table 1 lists some sources of nutrients in purified water systems.

Bacteria can get some of their nutrients from the pipe and fittings in a water system (11). Most plastics are not biodegradable, but pipe cements and plasticizers that leach from epoxy resins, PVC pipe, and polyamide pipe can be organic carbon sources for bacteria. Cellulose-based RO membranes can also be a nutrient source. That is why RO feedwater needs chlorination. Bacteria can also obtain trace metal nutrients from stainless steel and other metal components.

Table 1. Nutrients for Bacterial Growth Found in Pure Water Systems[a]

Nutrient	Sources
Organic carbon	Humic and fulvic acids (source water), pipe plasticizers and solvents, fiberglass-reinforced plastics (FRPs), pump and gauge lubricants, microbial by-products, personnel, airborne dust
Nitrogen	Humic and fulvic acids (source water), nitrates and nitrites (source water), microbial by-products, airborne dust
Phosphorus	Phosphates (source water), microbial by-products, airborne dust
Sulfur	Sulfates (source waters), sulfuric acid (RO pretreatment), membrane surfactants, airborne dust
Trace metals and salts	Source waters, process piping, fiberglass-reinforced plastics (FRPs), stainless steel system components, RO pretreatment, chemicals, personnel, airborne dust

[a] Reference 3.

Currently available technology cannot reduce nutrient levels completely; so total control of bacteria is not achievable by simply controlling nutrients. Similarly, very small quantities of oxygen will adequately support bacterial growth, even if the bacteria do not revert to anaerobic respiration, which most bacteria can do. Therefore, a thriving bacterial population can exist, even in high-purity water systems (14). Nutrient-limiting environments can actually promote the attachment of bacteria to surfaces because that is where the trace organics accumulate and extracellular polymers in a biofilm capture trace nutrients. Although bacteria cannot be completely starved out, nutrient-poor reverse osmosis water will support less biofilm than regular tap water supplies.

Water samples collect only planktonic or free-floating bacteria. Free-floating bacteria in animal drinking water are either sloughed off the biofilm or pass through from the incoming water supply. If a plate count test is low, one should not assume that bacteria are not present in the watering system. More than 99% of the bacteria in water systems are in biofilms attached to pipe and equipment surfaces. A mature biofilm may not slough off many cells into the drinking water if the integrity has not been disrupted (e.g., by recent flushing or sanitization). However, it is still there.

TREATMENT RATIONALE

Some of the main reasons to control microorganisms include: water clarity/turbidity, heat transfer surfaces and other equipment problems, and microbiologically induced corrosion.

Water Clarity/Turbidity

Very clear water is required to see the bottom of a pool (≈10 m). Therefore, both algal and sedimentary, particles must be removed so that required clarity can be maintained. Turbidity refers to how clear the water is. The greater the amount of total suspended solids (TSS) in the water, the murkier it appears, and the higher the measured turbidity. Algal turbidity varies seasonally and with depth in a complex manner in response to physical, chemical, and biological changes. Figure 3 shows the effect of algae concentration on turbidity. A comparison with sediments is shown in Fig. 4. Turbidity is reported in nephelometric units (NTUs) referring to the type of instrument (turbidimeter or nephelometer) used for estimating light scattering from suspended particulate material. The nephelometer, also called a turbidimeter, has a photocell set at 90° to the direction of the light beam to estimate scattered rather than absorbed light. This measurement generally provides a very good correlation with the concentration of particles in the water that affect clarity.

Another inexpensive device is called a turbidity tube. It involves looking down a tube at a black and white disk (Secchi disk) and recording the depth of water that makes the disk disappear. Secchi disk depth, then, is a measure of water clarity. There have not been many efforts to correlate distance clarity and turbidity. However, a rough correlation is provided in Fig. 5. Turbidity units (NTU and JTU) are interchangeable units. They differ only in that their name reflects the device used to measure turbidity. One JTU is equivalent to 1 ppm of silica.

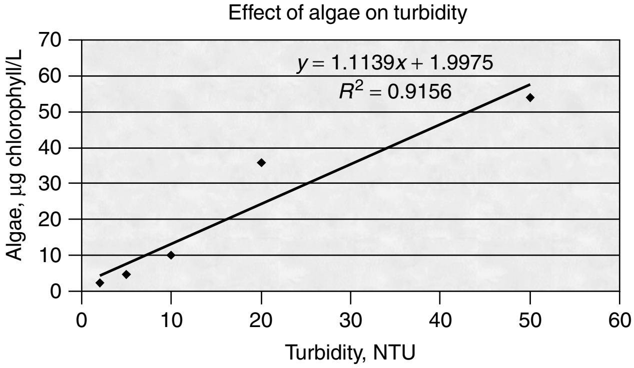

Figure 3. Turbidity vs. algae.

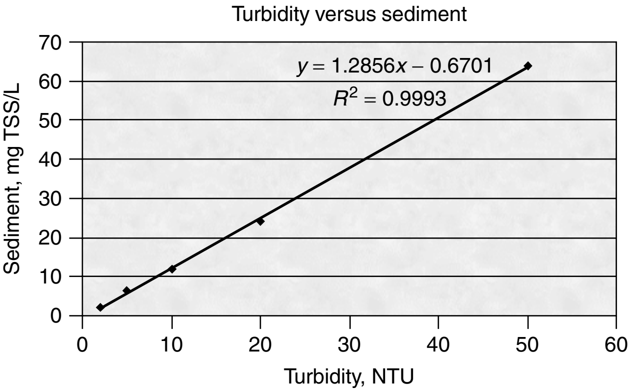

Figure 4. Turbidity vs. sediment.

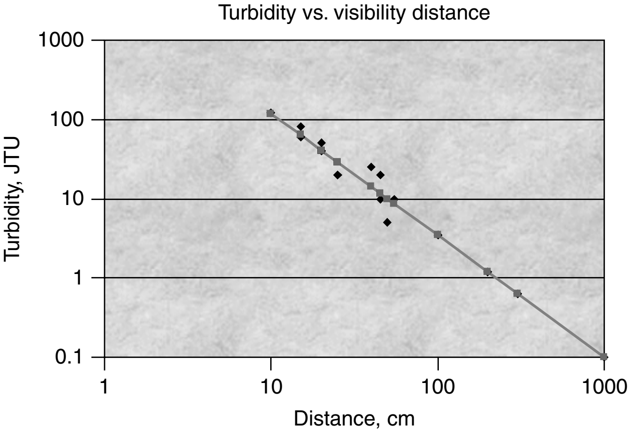

Figure 5. Turbidity vs. distance.

Heat Transfer/Equipment Problems

The waterside heat transfer systems of a treatment loop heat exchanger are susceptible to a biofilm that can reduce the overall heat transfer coefficient and hence efficiency. Microorganisms can cause biofilms to coat piping, valves, pumps, and other equipment. Further, biofilms can occur on ion exchange resins, filters, in-basin structures, and spent nuclear fuel. Minimizing microorganisms and biofilms to help prevent this is highly desirable. In general, water from natural sources leads to poor cooling performance unless adequate steps are taken (16). The extent of the problem, however, depends on the quality of the raw makeup water. Deposits on heat exchanger surfaces are complex, and are likely to include particulate matter, crystalline salts, corrosion products, and biofilms. It is necessary to counteract this problem of deposition onto surfaces to maintain heat exchanger effectiveness.

When using natural waters, the presence of microorganisms is probably the predominant cause of poor heat transfer efficiency. The conditions on the waterside of a cooler are usually conducive to the growth of microorganisms, notably bacteria, because of suitable temperature conditions and the availability of nutrients. The colonization of a heat transfer surface and the subsequent growth of a biofilm may, under favorable conditions, lead to a deposit 1 mm thick or more, unless preventive action is taken. This layer represents resistance to heat transfer: it acts as an insulating layer. The biofilm may also act as a trap for particulate matter and corrosion products. In addition, the biofilm may encourage corrosion of the underlying metal due to biological activity, thereby adding to operating and maintenance costs.

The shape and structural arrangement of a biofilm growing in a flowing fluid influences the mass transfer characteristics of the biofilm system as well as the drag force exerted on individual biofilm structures (17). If the biofilm is highly compliant, the shape varies through the growth cycle of the biofilm and also due to variations in fluid shear stress (18). Changes in biofilm shape affect its porosity and density, therefore affecting the transfer of solutes into and through the biofilm. Fluctuations in biofilm shape also affect the hydrodynamic drag that in turn influences the detachment rate and pressure losses in a flowing system. In addition, it is thought that biofilm viscoelasticity may explain the large pressure drops observed in biofilm-fouled pipes (19). However, very few studies have been conducted on the material properties of intact biofilms, in part, due to the technical difficulty of such testing. The small dimensions and pliability of biofilms makes sample handling extremely difficult, and removal of the biofilm from the substratum radically changes the integrity of the sample.

Boundary layers have a large role in biofilm formation, so some discussion concerning them is instructive for the purposes of this section. In fluid mechanics, Prandtl (20) called the region where the viscous forces cannot be ignored the boundary layer. Prandtl arbitrarily suggested that it be considered the region where the x component of the velocity is less that 99% of the free-stream velocity. This is an arbitrary division that does not correspond to any physically measurable boundary but corresponds to an arbitrary mathematical definition. However, it is a very useful concept, clarified numerous unexplained phenomena, and provides a much better intellectual basis for discussing complicated flows (21).

An analogous concept exists for heat and mass transfer. The momentum boundary layer represents the flow regions dominated by viscous forces, and the thermal boundary layer represents a region dominated by conduction. Analogously, the mass boundary layer represents a region dominated by diffusion. The dimensionless numbers corresponding to them are the Reynolds (*Re*), Prandtl (*Pr*), and the Schmidt (*Sc*) numbers, respectively. Figure 6 shows laminar boundary layers and profiles for momentum, heat, and mass. In general, these will not be the same. The flat plate, boundary layer thickness for momentum, heat, and mass are given elsewhere as are the complicated profiles near the wall in turbulent flow (22).

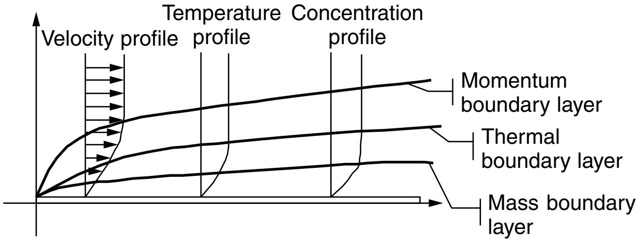

Figure 6. Laminar boundary layers.

The following provides an alternate, more practical correlation for determining the laminar, flat plate momentum boundary thickness (21):

$$\delta_{\mathrm{m}} \approx 5\sqrt{\frac{\nu\, x}{\nu_{\infty}}}. \tag{1}$$

Turbulent boundary layers differ in that there are several zones, including a laminar sublayer, a buffer zone, and a turbulent core. As the distance along a flat plate increases, a transition region develops followed by turbulence, as shown in Fig. 7. Estimating the turbulent boundary layer thickness can be done from (21)

$$\delta_{\mathrm{m}} = 0.37x\left[\frac{\nu}{\nu_{\infty}x}\right]^{1/5}. \tag{2}$$

The laminar sublayer is quite thin but represents the largest resistance to transport in the flow. However, the resistance is much less for turbulent than for laminar flow because the laminar sublayer is so thin and gradients are much steeper.

Microbiologically Induced Corrosion

Microbial cells on a metal surface can cause microbiologically influenced corrosion (MIC) or biocorrosion. The forms of corrosion caused by bacteria are not unique. Biocorrosion results in pitting, crevice corrosion, selective dealloying, stress corrosion cracking, and underdeposit corrosion. The basic corrosion equations for the corrosion cell shown in Fig. 8 are

$$\mathrm{M} \longrightarrow \mathrm{M}^{2+} + 2e^{-} \tag{3}$$

$$\mathrm{H_2O} + \tfrac{1}{2}\mathrm{O_2} + 2e^{-} \longrightarrow 2\mathrm{OH}^{-} \tag{4}$$

Nonuniform (patchy) colonies of biofilm result in the formation of differential aeration cells where areas under respiring colonies are depleted of oxygen relative to surrounding noncolonized areas. Having different oxygen concentrations at two locations on a metal creates a difference in electrical potential and consequently corrosion currents. Under aerobic conditions, the areas under the respiring colonies become anodic, and the surrounding areas become cathodic.

Oxygen depletion at the surface of stainless steel can destroy the protective passive film. Stainless steels rely

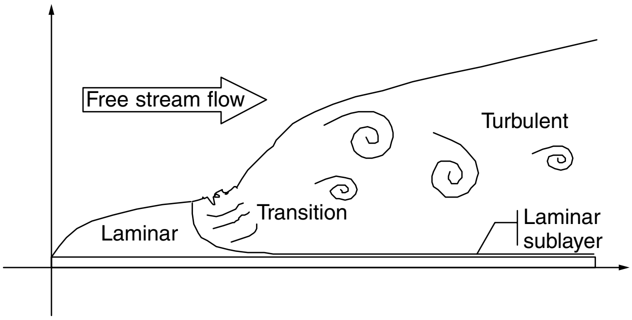

Figure 7. Turbulent boundary layer.

on a stable oxide film to provide corrosion resistance. Corrosion occurs when the oxide film is damaged or oxygen is kept from the metal surface by microorganisms in a biofilm. Oxygen depletion at the surface also provides a condition for anaerobic organisms such as sulfate-reducing bacteria (SRB) to grow. This group of bacteria is one of the most frequent causes for biocorrosion. They reduce sulfate to hydrogen sulfide that reacts with metals to produce metal sulfides as corrosion products. Aerobic bacteria near the outer surface of the biofilm consume oxygen and create a suitable habitat for the sulfate-reducing bacteria at the metal surface. SRBs can grow in water trapped in stagnant areas, such as dead legs of piping. Symptoms of SRB-influenced corrosion are hydrogen sulfide odor, blackening of waters, and black deposits. The black deposit is primarily iron sulfide (5). One method of limiting SRB activity is to reduce the concentration of their essential nutrients: phosphorus, nitrogen, and sulfate. Thus, purified (RO or DI) waters would have fewer problems with SRBs. Also, Any practices that minimize biofilm thickness (flushing, sanitizing, eliminating dead-end crevices) minimize the anaerobic areas in a biofilm that SRB need (5).

Bacteria can produce aggressive metabolites, such as organic or inorganic acids. For example, *Thiobacillus thiooxidans* produces sulfuric acid and *Clostridium aceticum* produces acetic acid. Acids produced by bacteria accelerate corrosion by dissolving oxides (the passive film) from the metal surface and accelerating the cathodic reaction rate. Many microorganisms produce hydrogen gas as a product of carbohydrate fermentation. Hydrogen gas can diffuse into metals and cause hydrogen embrittlement. Iron-oxidizing bacteria, such as *Gallionella, Sphaerotilus, Leptothrix,* and *Crenothrix,* are aerobic and filamentous bacteria that oxidize iron from a soluble ferrous (Fe^{+2}) form to an insoluble ferric (Fe^{+3}) form. The dissolved ferrous iron could be from either the incoming water supply or the metal surface. The ferric iron these bacteria produce can attract chloride ions and produce ferric chloride deposits that can attack austenitic stainless steel. The deposits of iron bacteria on austenitic stainless steel are typically brown or red-brown mounds.

TREATMENT METHODS

Once the microorganisms have attached, they can withstand normal disinfection processes. Biofilm bacteria display high resistance to biocides (23). Research demonstrates that biofilm associated bacteria may be 150–3000 times more resistant to free chlorine and 2–100 times more resistant to monochloramine than free-floating bacteria. Research (24) suggests that *Pseudomonas* has a clever way of eluding its attackers. It secretes a sticky slime that builds up on the pipe interior. A germicide flushed through the water distribution system kills free-floating microbes, but it is less effective against bacteria embedded in the slimy biofilm.

When bacteria are in a film, they are very resistant to biocides. They often produce more exopolymers after biocide treatment to protect themselves. To destroy the cell responsible for forming a biofilm, the disinfectant must first react with the surrounding polysaccharide network. The cells themselves are not actually more resistant; rather they have surrounded themselves with a protective

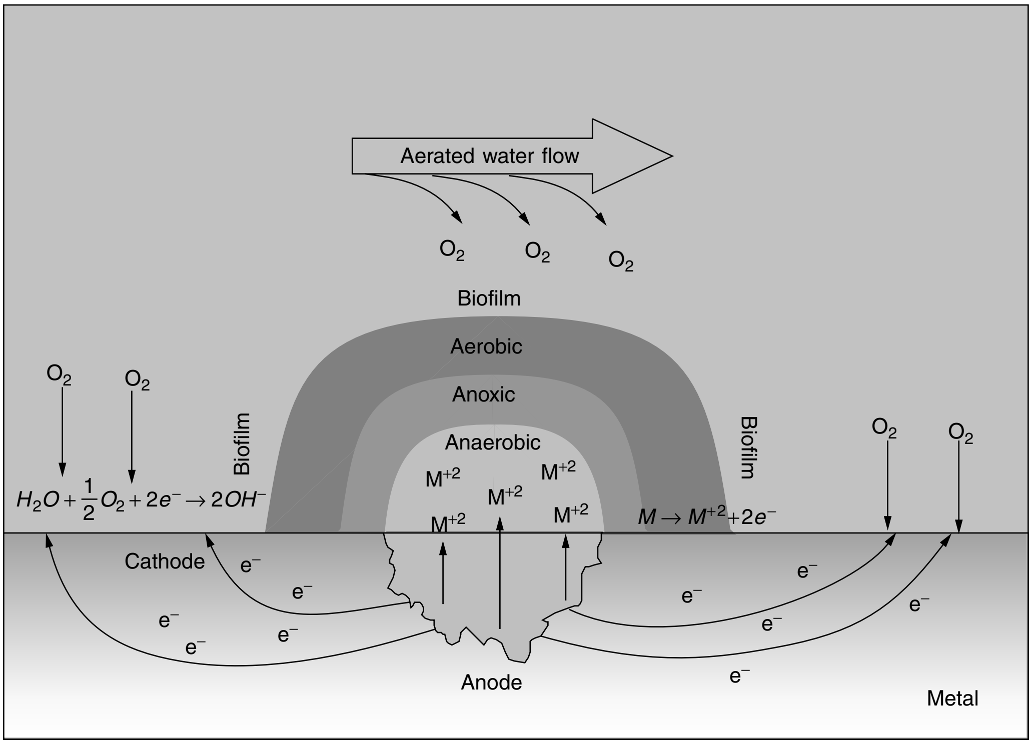

Figure 8. Biofilm corrosion mechanism.

film. The disinfectant's oxidizing power is used up before it can reach the cell.

When cells are attached to a pipe wall, delivery of the disinfectant is limited by the rate of diffusion of the compound across the boundary layer and through the film. It takes a higher concentration in a longer contact time for the disinfectant to reach the bacteria cells in a biofilm compared to free-floating organisms. Trace organics concentrate on surfaces. Extracellular polymers further concentrate trace nutrients from bulk water. Secondary colonizers use waste products from their neighbors. By pooling their biochemical resources, several species of bacteria, each that has different enzymes, can break down food supplies that no single species could digest alone.

Traditional disinfectant testing has been done using single-species free-floating laboratory cultures. The CT constant (concentration × time) for a disinfectant required to kill a particular bacteria should not be extrapolated to bacteria in biofilms. This explains how bacterial counts can be measured, even when water contains low levels of chlorine. Typical chlorine levels in tap water are from 0.5–2.0 ppm. This amount of chlorine kills free-floating bacteria but may not be enough to kill biofilm bacteria. Chunks of sloughed off biofilm can contain viable bacteria which show up in plate counts. This is a particular problem with *Pseudomonas* that is a great slime producer, and so is more chlorine resistant.

The development of biocide resistance is not understood, but recent studies have used a variety of model systems to determine how and why biofilms are so resistant to antimicrobial agents (25). As the importance of biofilms in water treatment has increased, much energy has been directed toward the study of the effects of antimicrobial agents on these surface-attached communities. Biofilm resistance mechanisms include physical or chemical diffusion barriers to antimicrobial penetration into the biofilm, slow growth of the biofilm owing to nutrient limitation, activation of the general stress response, and the emergence of a biofilm-specific phenotype.

Biofilms can be removed and/or destroyed by chemical and physical treatments. Chemical biocides can be divided into two major groups: oxidizing and nonoxidizing. Any chemical that may result in residuals, attack ion exchange resins, or cause corrosion must not be used to control microorganisms. Physical treatments include mechanical scrubbing and hot water. An article by Mittelman (26) has the most comprehensive information on treatment of biofouling in purified water systems. Table 2 provides typical dosage levels and contact times for various biocides.

Table 2. Typical Biocide Dosage Levels[a]

Biocide	Dosage Level, mg/L	Contact Time, h
Chlorine	50–100	1–2
Ozone	10–50[b]	<1
Chlorine dioxide	50–100	1–2
Hydrogen peroxide	10% (v/v)	2–3
Iodine	100–200	1–2
Quaternary ammonium compounds	300–1,000	2–3
Formaldehyde	1–2% (v/v)	2–3
Anionic and nonionic surfactants	300–500	3–4

[a] Reference 26.

[b] Ozone dosage is 10–50 mg/L, but the residual levels in water were 1–2 mg/L.

The effectiveness of oxidizing biocides in purified water systems based on an equal milligram-per-liter dosage decreases in the following order:

$$\text{Ozone } (O_3) > \text{chlorine dioxide } (ClO_2) > \text{chlorine } (Cl_2) > \text{iodine } (I_2) > \text{hydrogen peroxide } (H_2O_2).$$

Chlorine is probably the most effective and least expensive of all oxidizing and nonoxidizing biocides (26). The level of activity of chlorine against attached biofilms is particularly high; planktonic and biofilm bacteria are killed, and chlorine also reacts with and destroys the polysaccharide web and its attachments to the surface. By destroying extracellular polymers, chlorine breaks up the physical integrity of a biofilm. Characklis (27) recommends improving a chlorine treatment program by taking specific additional measures.

In addition to their biocidal activity, quaternary ammonium compounds are effective surfactants/detergents, which may be an important factor in their use for biofilm inactivation and removal from surfaces. Rinseability can be a problem because removal from a purified water system often requires exhaustive rinsing. Formaldehyde has been applied to pharmaceutical-grade systems. It is relatively noncorrosive to stainless steel. Its effectiveness against biofilms is questionable, and it is a toxic carcinogen. Anionic and nonionic surface-active agents (surfactant or detergent compounds) have limited biocidal activity against the bacteria in purified water systems. Applications may be found for these detergents in conjunction with other biocides to improve biofilms and other particulate removal.

Pharmaceutical water-for-injection systems use recirculating hot water loops (hotter than 80 °C) to kill bacteria. When these systems are used continuously, planktonic bacteria are killed, and biofilm development is reduced (26). Biofilms are even found in hot water (80 °C). Periodic hot water sanitization can also be used to destroy bacteria in a biofilm, but this requires a temperature of 95 °C for a period in excess of 100 minutes (28).

Heavy biofilms cannot be removed from storage tank walls by chemicals alone; mechanical scrubbing or scraping, high-pressure spraying, or a combination is also required. Mechanical removal of biofilm from distribution systems is impractical (26).

Unlike antibiotics used to fight bacteria associated with human, animal, and plant diseases, bacteria do not develop the same type of resistance to industrial biocides. The difference between antibiotics and industrial biocides is that an antibiotic may have a small number of target sites on or in a bacterial cell, but all oxidizing biocides have a multitude of potential target sites. It is thought that chlorine, for example, has more than a hundred potential target sites on or in microorganisms. It is virtually impossible for microorganisms to develop general resistance to such compounds (26). However, bacteria in a biofilm can resist biocides because they are shielded in slime.

Bacteria associated with biofilms are much more difficult to kill and remove from surfaces than planktonic organisms. Numerous investigators and plant operators have observed a rapid resumption of biofouling immediately following chlorine treatment (27). Incomplete removal of the biofilm allows it to return quickly to its equilibrium state, causing a rebound in total plate counts following sanitization. Initially, the bulk water bacteria count in one study dropped to zero after sanitization, but this was followed by a gradual increase in numbers to levels at or below pretreatment levels. In this example, regrowth started after 2 days and was back up to equilibrium levels after 20 days. Biofilms can also recover based on various mechanisms (27).

As an oxidizer, ozone is approximately twice as powerful as chlorine at the same concentrations. Like chlorine dioxide, ozone must be generated on-site because of its high reactivity and relative instability. Systems must be designed of appropriate ozone-resistant materials. Ozone is usually dosed continuously at 1–2 mg/L. Success in employing higher dosages noncontinuously has been limited, possibly because of the limited solubility of ozone in purified water; it is difficult to produce high concentrations of ozone in solution (26). Although chlorine is not as powerful as ozone when you compare 1–2 mg/L of each, chlorine can be used in higher sanitizing concentrations with equal disinfecting strength.

Ozone is soluble in water only up to the partial pressure above it; therefore, the concentration of ozone in the generator gas stream becomes very important. According to Henry's law, the efficiency of absorbing a specific gas into an aqueous phase is based on the partial pressure of that particular gas in the total gas flow. Therefore, the higher the partial pressure of ozone in the generator gas stream, the more complete is the concentration of ozone in the water. Table 3 shows the theoretical residuals of ozone that can be achieved in water, based on an ozone gas partial pressure of 1.0 atmosphere and Henry's law constants given in Perry (29). As would be expected, ozone solubility decreases as water temperature increases. Also as a consequence of Henry's law, the solubility of ozone increases as the partial pressure of ozone in the gas stream increases. In practical applications, ozone does not have sufficient contact time to achieve equilibrium conditions, resulting in solubility levels lower than those shown in Table 3. Figure 9 shows a multiple chamber diffusion contact system. The ozonated water stream is led along a pipe located at the bottom of each contact tank. The pipe is perforated by small holes to allow fine bubbles to escape and diffuse into solution.

Table 3. Maximum Ozone Solubility at p_{O_3} = 1.0 Atmosphere

T, °F	H, Atmosphere/x	Solubility, mg/L (ppm)
32	1940	1374.57
41	2180	1223.24
50	2480	1075.27
59	2880	925.93
68	3760	709.22
77	4570	583.52
86	5980	445.93

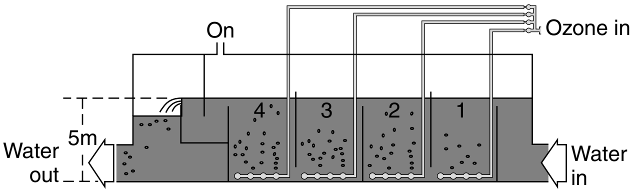

Figure 9. Diffusion contact chambers.

The latest ozone engineering principle involves using a self-contained ozone contacting/off-gassing system. This system means that the large contact tanks found in older system designs are no longer required. This results in significant capital savings on a new pool or retrofit (typically 50 to 75%). This system replaces the traditional contact tank design with a compact self-contained contacting system that is 98% efficient. Instead of a 20,000–30,000 gallon contact tank for a 100,000-gallon pool, the new system uses a powered contacting/mixing/off-gas unit.

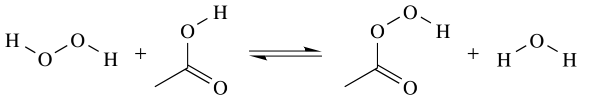
Ozone is an oxidative and reactive gas that is harmful to humans above certain concentrations. Ozone gas is heavier than air; therefore, any undissolved ozone must be removed from the system and disposed of correctly. Several methods are available for ozone destruction, the simplest is by ozone adsorption and reaction with granulated activated carbon (GAC). Activated carbon adsorption is extensively used for small applications where air is the ozonator feed gas. This is an adsorption process whereby the reaction consumes the carbon medium. The material used is elemental carbon which has been steam activated to provide a large internal surface area. Carbon is a strong reducing agent; therefore, upon contact with ozone gas, the carbon is oxidized to carbon monoxide and carbon dioxide, resulting in destruction of the ozone molecule. This reaction degrades or powderizes the GAC; therefore, it has a finite life. To this end, the ozone consumes the carbon by slow-rate combustion. Due to the consumption of carbon, the medium must be replaced regularly. When the carbon is saturated with water and washed with sprays, the reaction becomes partially catalytic and requires a larger volume of GAC. For ozone installations where oxygen is used as the feed gas, carbon adsorption destructors must not be used, due to the dangers of combustion. The other method is heat treatment that degrades the ozone rapidly to oxygen.

Hydrogen peroxide is frequently used as a biocide in microelectronic-grade purified water systems because it produces no by-products and rapidly degrades to water and oxygen. A 10% by volume solution in purified water is effective in killing planktonic bacteria, but more studies are needed on the effectiveness against attached biofilms (26). The use of hydrogen peroxide, though not expected to be as effective as ozone, would be very simple to implement.

Peracetic acid, a derivative of hydrogen peroxide, displays a very wide bandwidth of attack against microbes. Research has shown that peracetic acid will be used to an ever-increasing degree in the field of human medicine due to its bacterial, fungicidal, sporicidal, and antiviral action. Because of the wide spectrum of attack, peracetic acid is very suitable as a wide bandwidth disinfectant for ion exchange resins (results of work done by Degussa Technical Applications Department in conjunction with Chemiewerk Homburg). Using a 0.2% peracetic acid solution (in water, with a reaction time of 1 hour), a slime concentration of 104–105/ mL, including mold, was reduced to almost zero. The short rinsing time after using peracetic acid is important (typically about 45 minutes or 10–15BV). In addition to the excellent disinfection action, peracetic acid (according to experiments) has a minimal effect on the ion exchange properties of cation or anion resins.

Peracetic acid (peroxyacetic acid), $C_2H_4O_3$, the peroxide of acetic acid, is a disinfectant that has the desirable properties of hydrogen peroxide: broad-spectrum activity against microorganisms, lack of harmful decomposition products, and infinite water solubility.

Peracetic acid forms in an equilibrium reaction where hydrogen peroxide and acetic acid react:



(5)

Peracetic acid also has greater lipid solubility and is free from deactivation by catalase and peroxidase enzymes. However, it is corrosive, and degradation products may have to be rinsed from the surface of disinfected materials. Peracetic acid is a more powerful antimicrobial agent than hydrogen peroxide and most other disinfectants (30–32). It has advantages for disinfection and sterilization not found in any other agent. Against spores of *Bacillus thermoacidurans,* it was reportedly the most active of 23 germicides (33); against a range of bacteria it is lethal at 6–250 ppm, toward yeasts at 25–83 ppm, fungi at 50–500 ppm, bacterial spores at 100–500 ppm, and viruses at 15–2,000 ppm (34). The values obtained are determined by the medium employed and the time necessary for inactivation.

Table 4 gives a comparison of peracetic acid and two other disinfectants against food-poisoning bacteria (35). Peracetic acid retains its activity better than many disinfectants at refrigeration temperatures and is more effective at lower pH values (31). Aqueous solutions are comprised of the acid in combination with hydrogen peroxide, acetic acid, sulfuric acid, water, and a stabilizing agent. All of these ingredients are necessary to keep it stable in storage; the concentration of the hydrogen peroxide in some formulations may considerably exceed that of the peracetic acid. Peracetic acid vapor, like that of hydrogen peroxide, is active against bacterial spores and has been found most effective at 80% relative humidity, it has little activity at 20% relative humidity.

Table 4. Comparison of Disinfectants Against Food-Poisoning Bacteria[a,b]

Organism	Peracetic Acid	Active Chlorine	Benzalkonium Chloride
	At 20 °C		
Listeria monocytogenes	45	100	200
Staphylococcus aureus ATCC 6538	90	860	500
Enterococcus faecium DSM 2918	45	300	250
	At 5 °C		
Listeria monocytogenes	90	860	500
Staphylococcus aureus ATCC 6538	90	1,100	750
Enterococcus faecium DSM 2918	90	450	500

[a] Lethality in 5 min.
[b] Concentrations of disinfectants given in ppm.

Peracetic acid has been accepted worldwide in the food processing and beverage industries as an ideal for clean-in-place systems (36); it does not require rinsing where the breakdown product, acetic acid, is not objectionable in high dilution. Peracetic acid is more toxic than hydrogen peroxide and is a weak carcinogen but can be used with safety when diluted. Like all peroxides, it is a powerful oxidizer and should be handled with proper safety precautions. It is more corrosive to metals and plastics than hydrogen peroxide (36).

UV energy is found in the electromagnetic spectrum between visible light and X rays and can best be described as invisible radiation. The energy employed for UV water treatment is further categorized into two primary levels measured as wavelengths—254 nm and 185 nm, where nm = 1/1000 of a micron. For disinfection and ozone destruction, the 254-nm wavelength is used. All living organisms contain DNA (deoxyribonucleic acid). DNA provides the mechanism for all functions needed to sustain life.

UV light disinfection systems emit UV light that penetrates the outer cell membrane of microorganisms, passes through the cell body, reaches the DNA, and alters the genetic material. The microorganism is thereby destroyed nonchemically and cannot reproduce.

Ultraviolet processing involves using radiation from the ultraviolet region of the electromagnetic spectrum for disinfection (37). Typically, the wavelength for UV processing ranges from 100 to 400 nm, as shown in Fig. 10. This range may be further subdivided into UVA (315 to 400 nm) normally responsible for changes in human skin that lead to tanning; UVB (280 to 315 nm) that can cause skin burning and eventually lead to skin cancer; UVC (200 to 280 nm), called the germicidal range, because it effectively inactivates bacteria and viruses, and the vacuum UV range (100 to 200 nm) that can be absorbed by almost all substances and thus can be transmitted only in a vacuum.

The germicidal properties of UV irradiation are mainly due to DNA mutations induced through absorption of UV light by DNA molecules. This mechanism of inactivation

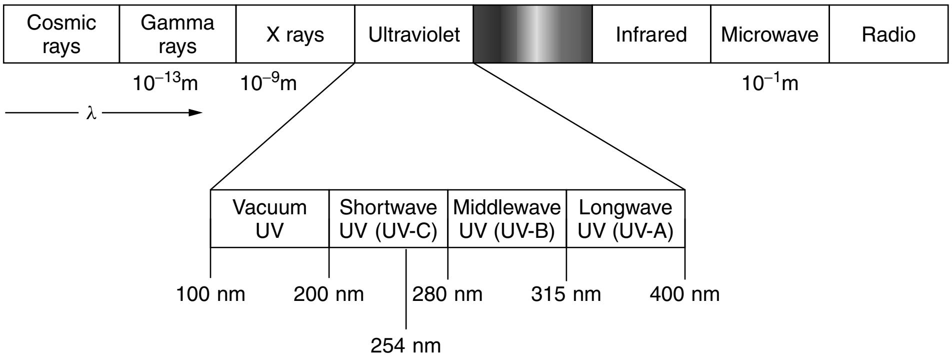


Figure 10. UV light spectrum.

results in a sigmoidal curve of microbial population reduction. To achieve microbial inactivation, the UV radiant exposure must be at least 400 J/m^2 in all parts of the product. Critical factors include the transmissivity of the product; the geometric configuration of the reactor; the power, wavelength and physical arrangement of the UV source(s); the product flow profile; and the radiation path length. UV may be used in combination with other alternative processing technologies, including powerful oxidizing agents such as ozone and hydrogen peroxide. Applications include disinfection of water supplies and food contact surfaces. Recently, interest has increased in using UV to reduce microbial counts in juices.

The shape of the curve for microbial inactivation by UV light is sigmoidal. Figure 11 is an idealized depiction of a sigmoidal curve. The initial plateau is due to an injury phase of the microorganism in response to UV exposure. After the initial plateau, the maximum amount of injury has been surpassed; thus, minimal additional UV exposure would be lethal for microorganisms, and survivor numbers rapidly decline. The end of the curve has a tailing phase due to UV resistance of the microorganisms and to experimental components, such as suspended solids, that may block the UV irradiation.

Much of the prior literature has focused on UV disinfection of water supplies. The literature is insufficient to develop comprehensive microbial inactivation reaction kinetics data or models. There are, however, studies relative to the UV radiant exposure required to obtain a four-log reduction of various microorganisms. These data suggest that the log reduction is related to the UV radiant exposure. The curve has a linear section with a shoulder and tailing effects (38). All organisms tested were reduced by four-log cycles when UV radiant exposure was less than 400 J/m^{237}. In some bacterial cells, photoreactivation, a repair mechanism that is enhanced by visible light in the blue spectral range, may occur. Photoreactivated cells show greater resistance to UV radiation than nonreactivated cells.

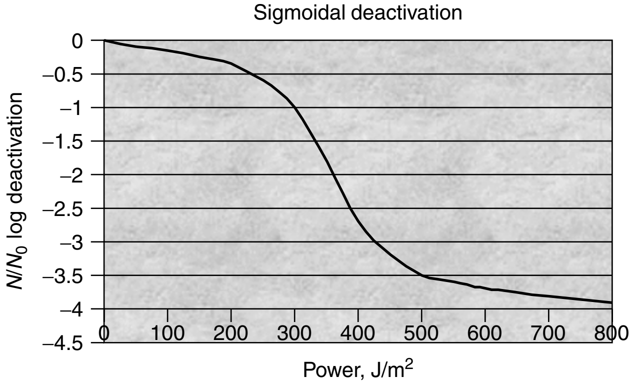

Figure 11. Idealized microorganism deactivation.

The germicidal properties of ultraviolet irradiation are due to DNA absorption of the UV light, causing cross-linking between neighboring pyrimidine nucleoside bases (thymine and cytosine) in the same DNA strand (39). Due to the mutated base, formation of hydrogen bonds to purine bases on the opposite strand is impaired. DNA transcription and replication is thereby blocked, compromising cellular functions and eventually leading to cell death. The amount of cross-linking is proportional to the amount of UV exposure. The level of mutations that can be reversed depends on the UV repair system in the target microorganism. Once the threshold of cross-linking is exceeded, the number of cross-links is beyond repair, and cell death occurs (39). This phenomenon is reflected in the shape of the inactivation curve described before. The cross-linking threshold corresponds to the point of rapid decline after the initial plateau phase on the sigmoidal survival plot of UV exposure.

To disinfect water, it is essential that all parts (each volume element) of the product receive UV radiant exposure of at least 400 J/m^2 (at 254 nm) to reduce human pathogens and viruses by at least four-log cycles (40). Thus, the homogeneity of the flow pattern and the radiation field may have critical effects on disinfection. An additional critical factor is the transmissivity of the material being disinfected. If the material is highly transparent to UV light, disinfection may be more effective; turbid materials attenuate and scatter UV radiation, resulting in less microbial inactivation. The thickness of the radiation path through a material is also important because attenuation increases with the length of passage; thus, the geometric configuration of process systems is critical. Another critical factor to consider is the UV wavelength used because it affects microbial inactivation.

The growth of organisms increases as temperature increases. The effect of temperature on the reaction rate of a biological process is usually expressed in the following form (41):

$$r_T = r_{20}\theta^{(T-20)} \tag{6}$$

This is similar to the Arrhenius equation used in chemistry; an approximate doubling of reaction rate for each 10 °C temperature rise. The range is limited because there is little biological activity in ice or boiling water. Figure 12 illustrates this and shows that a decrease from 80 to 60 °F has a significant impact on the growth rate. The growth rate can be reduced, but the temperature changes that are practical in pools do not kill the organisms.

Increasing temperature also increases the kill rate (decreases kill time). The effect of temperature on the kill rate of microorganisms is well represented by a form of the Van't Hoff–Arrhenius relationship (41). In terms of the kill time (t in the equation) required for a given percentage kill, the relationship is

$$\ln\frac{t_1}{t_2} = \frac{E(T_2 - T_1)}{RT_1T_2} \tag{7}$$

Using $T_2 = 20\,^\circ\mathrm{C}$ and chlorine at pH = 7.0, the effects of temperature on kill rate are illustrated in Fig. 13. Figure 13 shows that kill time can be significantly reduced by modest increases in temperature.

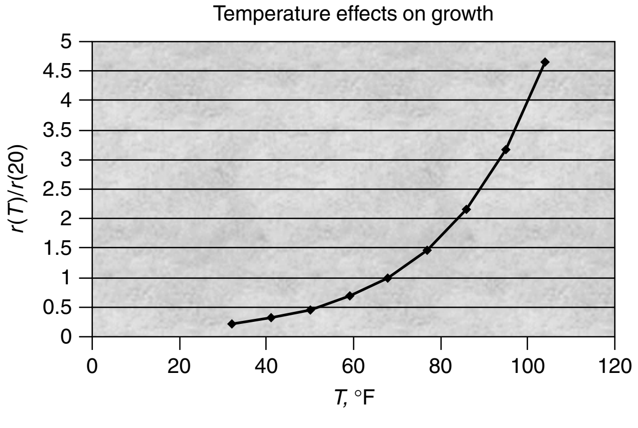

Figure 12. Temperature effects on biological growth.

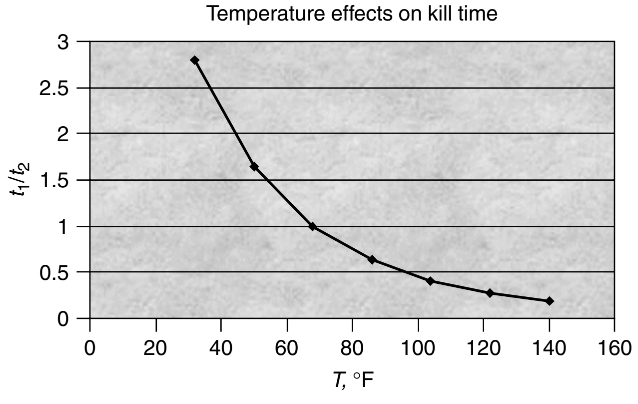

Figure 13. Temperature effects on kill time.

The reduction of light may reduce the growth rate of some microorganisms. Microbes may be classified according to their energy and carbon requirements (42). Growth from light is expected for some organisms as a result of photosynthesis. For example, algae use carbon dioxide in photosynthetic activity to produce new cells, oxygen, and water.

The criteria for chemical addition and other microbiological control for a typical nuclear fuel storage pool include

- minimal corrosion
- no damage occurs to other parts and/or systems
- no residual remains that can adsorb onto ion exchange resins
- personnel safety.

This severely limits the treatment chemicals that can be used, for example, chlorine cannot be used. Although there may be beneficial affects from controlling and/or manipulating light and temperature, the focus is on treatment to remove microorganisms and keep them minimized. Also, as previously discussed, the chemicals focus on those that will not leave residuals or cause corrosion. Therefore, the focus is on ozone, peracetic acid, and hydrogen peroxide. The International Atomic Energy Agency has studied this in some detail (1). They provided a list of potential methods for removing microorganisms from spent fuel pools that should be considered in a final study or evaluation. Ion exchange columns must be bypassed when ozone is at a high concentration in the water because ozone attacks and degrades the resins (43). It is believed that ozone is effective in long residence times and for sustained residuals. This expectation is partly based on experience from vendors using ozone in biofilm-fouled swimming pools (44).

The use of chemical agents must be demonstrated for personnel safety. The maximum possible dissolved ozone in the pools that transfers to the atmosphere would be related to Henry's law. At 86 °F, $H = 5980$ atmospheres/mole fraction, and the residual is 1 mg/L. The mole fraction (x) is then,

$$x = \frac{1\ \mathrm{mg}}{L} \times \frac{L}{1,000\ \mathrm{g}} \times \frac{18\ \mathrm{g}}{\mathrm{mole}} \times \frac{\mathrm{mole}}{48\ \mathrm{g}} \times \frac{\mathrm{g}}{10^3\ \mathrm{mg}} = 4\times10^{-7}$$

The partial pressure (maximum) in equilibrium with the pool surface is based on Henry's law constant (H) in Table 3:

$$\begin{aligned} p_i &= Hx = 5980 \times 4 \times 10^{-7} \\ &= 2 \times 10^{-3}\ \text{atmospheres (2,000 ppm)} \end{aligned}$$

The STEL/Ceiling/TWA is 0.1 ppm, so this is significantly higher. A material balance is used to determine the effective vapor phase concentration. Figure 14, material balance shows the ozone transferring from the water surface into the ventilation air. The material balance is thus:

$$Q_{\mathrm{ozone}} = (Q_{\mathrm{vent}} + Q_{\mathrm{ozone}})\, y_{\mathrm{ozone}} \tag{8}$$

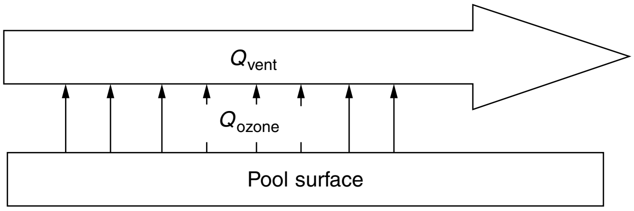

Figure 14. Material balance [SCA1][nlh2]diagram.

A dissolved gas has two resistances, gas-phase and liquid-phase. The mass transfer (F) flux is

$$F = K_L(C_B - C^*) = K_G(p^* - p_B) \tag{9}$$

The flux is also equal to the individual driving forces as

$$F = k_G(p_I - p_B) = k_L(C_B - C_I) \tag{10}$$

By combining these and using Henry's law, the following are determined for the overall mass transfer coefficients, and either one can be used:

$$K_L = \frac{1}{\dfrac{1}{Hk_G} + \dfrac{1}{k_L}} \tag{11}$$

$$K_G = \frac{1}{\dfrac{1}{k_G} + \dfrac{H}{k_L}} \tag{12}$$

According to Thibodeaux (45), the gas-phase and liquid-phase coefficients for water and CO_2 are 3000 cm/h and 20 cm/h, respectively. The ozone value can be directly used as 20 because the molecular weight falls in the range for direct substitution. However, the value of the gas-phase coefficient is determined from the ratio of the cube roots of molecular weights (46):

$$k_{G-O_3} = k_{G-H_2O}\left(\frac{18}{48}\right)^{1/3} = 2163$$

The overall coefficient is then

$$K_L = \frac{1}{\dfrac{1}{5,980 \times 2,163} + \dfrac{1}{20}} = 20$$

Thus it is seen that the transfer is totally controlled by the liquid phase. The material balance then becomes

$$\frac{p_B}{P_T}\frac{M_{O_3}}{M_{\text{air}}} = \frac{K_L A\left(C_B - \left(\frac{p_B}{H}\right)\right)}{K_L A\left(C_B - \left(\frac{p_B}{H}\right)\right) + Q_{\text{vent}}} \tag{13}$$

For small p_B, this can be simply solved as

$$p_B = \frac{K_L A C_B}{K_L A C_B + Q_{\text{vent}}}\frac{M_{\text{air}}}{M_{O_3}}P_T \tag{14}$$

The estimated partial pressure of ozone was based on the values in Table 3. The NIOSH time weighted average (TWA) is 0.1 ppm. The estimated concentration is 1.27 ppm that exceeds the limit. Therefore, the liquid concentration would need to be controlled at less than 0.1 mg/L to ensure personnel protection. However, an ozone system that intermittently supplies high-concentration ozone was effective in preventing biofilm formation using a 1-mg/L ozone dose for 10 minutes (47). Asea Brown Boveri (ABB) carried out tests with ozone as a biocide on the water of a small industrial cooling tower in Switzerland (48). The test results showed that ozone is an excellent biocide. In 1988, an ozonation plant was installed at the side stream cooling water system of a heating power station in Germany (49). The operation showed that ozone works well at 0.1 mg/L for 2–3 hours contacting time per day. Ozone destroys and reacts with pollutants in the air. If this is considered, the ozone concentration in air in pool areas will be much lower than the worse case calculation (Table 5).

The concentration above the pools using the 10-minute treatment is then

$$C_{10\,\text{min}} = 1.27 \times \frac{10\,\text{min}}{24\text{ h} \times 60\text{ min/h}} = 0.00882$$

This result is well below the TWA of 0.1 ppm.

NOMENCLATURE

A	Area
C	Concentration
C_I	Concentration at interface
C_B	Concentration in bulk solution
C^*	Fictitious concentration in bulk gas
CT	Concentration × time
E	Activation energy, J/g mole
F	Mass transfer flux
H	Henry's law constant
k_G	Local gas mass transfer coefficient
k_L	Local liquid mass transfer coefficient
K_G	Overall mass transfer coefficient, based on gas
K_L	Overall mass transfer coefficient, based on liquid
M	Molecular weight
p	Partial pressure, atmospheres
p_I	Partial pressure at interface, atmospheres

Table 5. Calculation of Ozone Above Pools

Parameter	Value
M_{O_3}, g/mole	48.00
M_{air}, g/mole	29.00
P_T, atm	0.87
Q_{vent}, scfm	28,100
Q_{vent}, g/h	6.2E+07
C_B, mg/L	1.00
K_L, cm/h	20.00
K_L, m/h	0.20
A, m^2	648.14
$F \times A$, g/h	129.63
Calculated p, atm	1.10E−06
Calculated O_3, ppm	1.27

p_{B}	Partial pressure in bulk, atmospheres
p^*	Fictitious pressure in bulk liquid
P_{T}	Total pressure, atmospheres
Q	Gas mass flow rate
R	Gas constant
Re	Reynolds number
r_{T}	Reaction rate at $T\,^{\circ}$C
r_{20}	Reaction rate at $20\,^{\circ}$C
T	Temperature
t	Time
v	Velocity
x	Mole fraction
y	Vapor mass fraction
δ	Boundary layer thickness
κ	Conductivity
ν	Kinematic viscosity
θ	Temperature-activity coefficient

INDUSTRIAL MINE USE: MINE WASTE

Constantin Von Der Heyden
School of Geography and the
Environment
Oxford, United Kingdom

INTRODUCTION

Intensive industrial development and particularly the production of effluents from mining operations has led to worldwide concern for environmental and health impacts following decades of contaminated effluent discharge into natural waterways (1). Developing economies often depend heavily on extractive or primary industry, and many third-world governments face the difficult task of reconciling economic development with environmental and social protection. Concern arising from the discharge of polluted effluent from the mining industry was recorded as early as 1556 (2), and the legacy of unsustainable development is clearly chronicled in sediments worldwide (3–6). as the discharge of mining and industrial effluents has led to a substantial increase in riverine, estuarine, and marine sediment metal concentrations (7–9).

Several types of acid and toxic effluents are produced by mining and metallurgical processes during operations and following site decommission (Table 1). These effluents include tailings excess decant (rainwater or process water running off tailings impoundments), process acid streams, and mine drainage waters. Drainage from tailings impoundments is often circumneutral in pH and contains low concentrations (<20 mg/L) of total dissolved metals (10). Process acid stream effluents originate from the use or generation of acids during metallurgical processes and can contain very high levels of dissolved solids and toxic metals. Mine drainage waters are commonly of three main types: (1) saline formation waters; (2) acidic, heavy-metal- and sulfate-containing waters formed during biologically mediated and abiotic oxidation of sulfides (so-called acid mine drainage or AMD); and (3) alkaline, hydrogen-sulfide-containing, heavy-metal-poor waters resulting from buffering reactions (usually carbonate) and sulfate reduction within AMD (11,12). AMD surfaces as discharge from adits and abandoned workings of sulfidic mines or as drainage from sulfide-rich overburden material or spoil heaps (13).

ACID MINE DRAINAGE GENERATION

Acidity generation due to sulfide oxidation occurs by two processes: proton acidity and metal acidity. The former occurs during the oxidation of sulfides, and the latter is from the hydrolysis of metal species in solution (15). Each is discussed here in more detail.

Iron pyrite, the most common mineral leading to AMD, reacts with oxygen and water according to the following reaction (16):

$$2FeS_2 + 7O_2 + 2H_2O \leftrightarrow 2Fe^{2+} + 4SO_4{}^{2-} + 4H^+ \qquad (1)$$

This reaction often occurs in underground workings or deep within spoil heaps and overburden, resulting in the removal of oxygen and the discharge of an anaerobic effluent. Accordingly, oxygen is a limiting substrate within the deeper workings or lower levels of the spoil heap where anaerobic conditions prevail throughout the year. Younger (17) differentiates the production of AMD from flooded workings into "juvenile" and "vestigial" acidity: the former is the dissolution of weathering salts formed on sulfides when the water table within the workings rises following cessation of dewatering activities; the latter is the continuing oxidation of sulfides in the seasonally flooded zone of the workings as the water table rises and drops within the annual hydrologic cycle.

Table 1. Typical Mine Drainage Composition[a]

	Coal Mines	Cu–Pb–Zn Mixed Sulfide Mines	EPA Statutory Limits
pH	2.6–6.3	2.0–7.9 mg/L	6–9
Al	1–58		
Cu		0.005–76	0.05
Fe	1–473	8.5–3200	3.5
Mn	1–130	0.4	2
Pb		0.02	0.2
Zn		0.04–1600	0.2–0.5

[a] Reference 14.

On contact with the atmosphere, which often commences only at the site of effluent discharge from flooded workings or spoil heaps, the oxidation of ferrous to ferric iron and the precipitation of ferric oxyhydroxides generates further acidity:

$$Fe^{2+} + O_2 + 4H^+ \leftrightarrow Fe^{3+} + 2H_2O \qquad (2)$$

$$Fe^{3+} + 3H_2O \leftrightarrow Fe(OH)_3 + 3H^+ \qquad (3)$$

As noted, Equations 1 and 2 are dependent on an aerobic environment. However, once ferric iron has been formed, Fe^{3+} acts as the oxidizing agent and the oxidation of pyrite can proceed in an anaerobic environment:

$$FeS_2 + 14Fe^{3+} + 8H_2O \leftrightarrow 15Fe^{2+} + 2SO_4{}^{2-} + 16H^+ \qquad (4)$$

The reaction kinetics in Equations 1 and 3 are significantly higher than those of Equation 2, and accordingly the oxidation of ferrous iron is the rate-limiting step in this series (11). However, numerous iron oxidizing bacteria can markedly increase the oxidation of ferrous to ferric iron. Of these, *Thiobacillus ferrooxidans* and *Leptospirilium ferrooxidans* are likely to be the most important organisms, increasing the rate of reaction by six orders of magnitude (10^6) (11). These organisms function optimally below pH 3, thus requiring a degree of pyrite oxidation and ferric hydrolysis to lower the solution pH to optimal levels (18). Johnson and Hallberg (19) and Hallberg and Johnson (20) show that a host of other organisms known as moderate acidophils, which include sulfur-oxidizing bacteria and archaea, heterotrophic microorganisms, and some lower eukaryotic life-forms, function optimally at pH 3–5.5 and may be involved in the initial sulfide oxidation and proton acidity generation.

Other members of the pyrite family, such as arsenopyrite (FeAsS) and chalcopyrite ($CuFeS_2$), also generate proton acidity upon oxidation, releasing As or Cu into solution in addition to Fe. Monosulfide minerals, such as chalcocite (Cu_2S), sphalerite (ZnS), and galena (PbS), are also often encountered in sulfidic deposits. Although the oxidation of these minerals does not generate proton acidity (see Equation 5), subsequent hydrolysis of the metal ions generates metal acidity as in Equation 3:

$$ZnS + 2O_2 \leftrightarrow Zn^{2+} + SO_4{}^{2-} \qquad (5)$$

TYPES OF MINE EFFLUENT REMEDIATION FACILITIES

Mine effluent discharge is almost always a point source, so mine-water problems may be addressed by isolating the contaminant source and either treating the discharge *in situ* (i.e., within the working or the spoil heap by suppressing the reactions releasing contaminants) or by active or passive water treatment following discharge. Innovative *in situ* treatment techniques such as galvanic suppression, application of bactericides, and introduction of neutralizing or reducing agents are receiving increasing attention and represent real potential. However, such techniques have not yet achieved widespread application and require further applied and fundamental research on both field and laboratory scales.

Active or conventional treatment processes for effluent remediation usually involve expensive technology and infrastructure and high process costs. Kuyucak (10) lists some of the common active, physicochemical processes:

1. active neutralization systems
2. ion exchange materials, such as resins and zeolites (21)
3. membrane processes, such as reverse osmosis, ultrafiltration/microfiltration
4. solvent extraction
5. electrochemical treatment (22)
6. bioremediation through controlled sulfate reduction (23,24)

Passive treatment technology, which as the name implies has significantly lower capital and maintenance costs, commonly includes (13)

1. aerobic, surface-flow wetlands (reed beds)
2. subsurface flow systems, such as reducing and alkalinity producing systems—RAPS (25,26)
3. combination wetlands, such as compost wetlands (27)
4. anoxic and oxic limestone drains (28,29)
5. biosorbents (30–32)

Active neutralization facilities are still most widely used to treat mine waters but vary greatly in the degree of sophistication, depending on the geography and local specifications of the site, the nature of the effluent, and various other environmental, technical, and financial constraints. As such, the facilities can range from the simple addition of neutralizing agents to the effluent stream, to complex chemical plants consisting of reactors, clarifiers, and sludge dewatering technology. Lime as CaO or $Ca(OH)_2$ is the most common neutralizing agent used for treating low pH effluent, owing to the widespread availability, low cost, and high reactivity of the material. However, lime neutralization results in poor quality effluent and the need to dispose of large volumes of sludge; accordingly, certain situations require using other neutralizing reagents, such as $Mg(OH)_2$, Na_2S, NH_3, Na(OH) and $CaCO_3$ (10).

The current state-of-the-art active lime neutralization process is called the high density sludge process (HDS), where more than one reactor is used to perform the neutralization, and a mixture of sludge, recycled from the clarifier, and lime is used as the neutralizing agent in the first reactor (Fig. 1). Polymers are added to improve flocculation, and a clarifier is used to enhance solid/liquid separation, decreasing the volume and increasing the stability of the disposal sludge.

PROCESS IN MINE EFFLUENT REMEDIATION

The activity of hydrogen ions in solution (the pH of the solution) is the key determinant in the composition of mine waters and of their toxicity (16). Metal mineral solubility

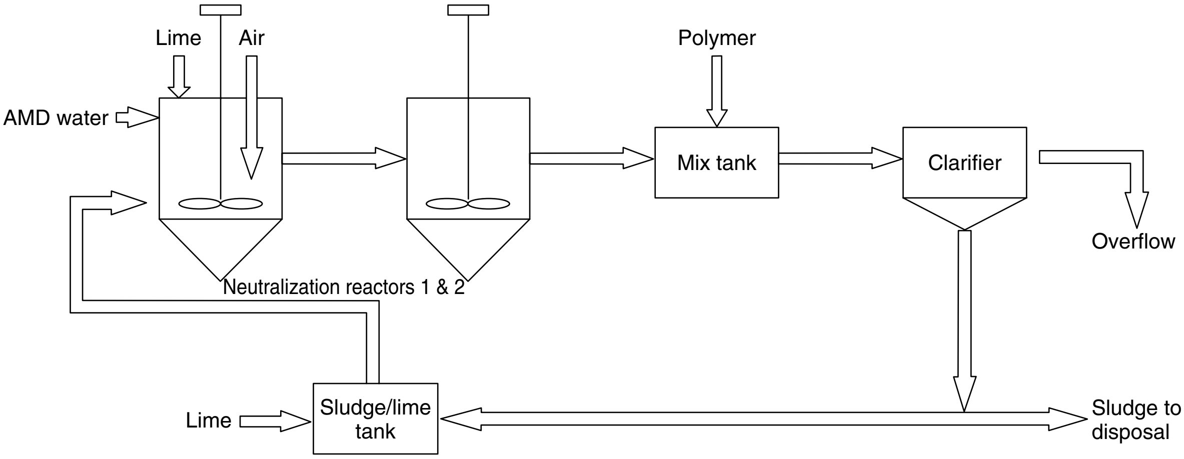

Figure 1. The high density sludge process (10).

increases markedly at low pH, and the precipitation of the dissolved metal cation as an insoluble species is low. Moreover, adsorption, which is often a primary process of metal removal from anthopogenically polluted systems (7,9), is also often strongly pH dependent (33). Adsorption approaches zero as the pH decreases below the adsorption edge of the metal, which for common metals such as Cu, Co, Ni, Pb, and Zn is around pH 4–5 (34). Anions, for example SO_4, demonstrate the converse; a pH decrease leads to greater anion adsorption (34,35). The free aquo ion is the most bioavailable, so the pH of the solution also affects its toxicity, directly through pH-mediated effects on organisms and indirectly as a result of its effect on the concentration of anions (e.g., oxyanions of Cr and As) and toxic metals such as Cu, Pb, and Zn (36–38). As such, correcting the pH is the most important and first consideration in mine effluent remediation (13).

Assuming that effluent pH has been regulated within an acceptable range (pH 5–9), Hammer (39) and Dunbabin and Bowmer (40) list the most common chemical and biological processes by which mine effluent quality is improved:

1. oxidation and hydrolysis
2. reduction reactions
3. adsorption of pollutant complexes to organic and inorganic surfaces
4. uptake of pollutants by plants
5. physical filtering of suspended solids by plants and substrate
6. Neutralization and precipitation by the formation of ammonium (NH_4^+) and carbon dioxide (CO_2)

Oxidation and Hydrolysis

The change in valence state following oxidation of certain metals can dramatically influence their solubility: oxidation of Fe^{2+} and Mn^{2+}, both highly soluble in the reduced state, to Fe^{3+} and Mn^{4+} results in rapid metal precipitation as oxide and (oxy)hydroxides.

The complexation of metal cations with hydroxide ions results in the formation of insoluble metal hydroxide (Equation 6), oxide, and oxyhydroxide precipitates (33,41). Hydrolysis and oxidative hydrolysis are the most common processes of metal precipitate formation in aerobic surface waters (13,42). However, hydroxide precipitation decreases the pH of the water due to the production of hydrogen ions: the metal acidity discussed above (Equation 6). As such, oxidation of effluent with high metal concentrations [e.g., Wheal Jane, see (43)] can rapidly lower the pH of the water and hence affect the mobility and solubility of other metals (15,44).

$$M^{2+(or)3+} + H_2O \leftrightarrow M(OH)_{2(or)3} \downarrow +2(or)3H^+ \quad (6)$$

Reduction Reactions

Reduction processes are used in active bioreactors and in RAPS, and numerous researchers identify bacterially mediated sulfate reduction as the most effective way to decrease sulfate and heavy metal concentrations in contaminated mine drainage (23,45,46). The reduction of sulfate and the production of hydrogen sulfide lead to an increase in alkalinity and the precipitation of insoluble metal sulfides (Equations 7 and 8):

$$SO_4 + C_xH_yO_z \leftrightarrow H_2S + wHCO_3 \quad (7)$$

$$M^{2+} + H_2S \leftrightarrow MS \downarrow +2H^+ \quad (8)$$

Adsorption by Organic and Inorganic Surfaces

Adsorption and surface complexation commonly occurs on sediments, suspended or colloidal matter, and plant surfaces (47). Within contaminated drainage, transport of pollutants is often facilitated by adsorption on a variety of suspended and colloidal solid surfaces. Colloidal aggregate formation and settling and the settling of suspended solids are common processes whereby such contaminants are incorporated into sediments.

Adsorption is highly pH-dependent (33,41), for example, SO_4 adsorption onto $Fe(OH)_3$ approaches 100% below pH 3, whereas metal cations dominate the adsorption surface above pH 4.5 (34). The most important and widely studied adsorption surfaces in mine effluent impacted systems are (oxy)hydroxide precipitates of iron and manganese (35,48–51). The order of metal affinity for MnO_2 binding sites is $Co > Ni \geq Zn > Cu$ (52), and that for FeOOH sites is $Pb > Zn \geq Co \geq Ni > Cu$ (34).

Metals are also complexed with a range of organic material such as algae, bacterial cells, detritus, and organic coatings on mineral surfaces (40,47,53,54). The organic adsorption affinity of metals decreases in the order $Cu = Fe \gg Zn \gg Mn$ (55,56). Adsorption and surface complexation are rapid processes producing pollutant attenuation from the water column but are transitory due to marked pH dependency (33,41). Ions immobilized as surface complexes are rapidly released during changes in effluent pH conditions.

The Effect of Aquatic Vegetation

The uptake and accumulation of metals in plant biomass has been extensively studied under laboratory conditions (57–59). Dunbabin and Bowmer (40) investigated the partitioning of metals within emergent hydrophytes and found that the majority of metals were stored in the roots and rhizomes. Floating wetland plants have been shown to hyperaccumulate Cu and Fe up to 78 times their concentration in wastewater (57). However, direct uptake and accumulation of metals within plant biomass usually constitutes a minor component of the overall removal processes (14,60–62).

In addition to metal uptake, wetland plants attenuate metal contaminants through a number of further mechanisms:

- Plants release oxygen through their roots, creating a zone of aerobic conditions in the substrate (14,40). The oxidizing conditions within the substrate increase metal oxidation with insoluble precipitate formation [commonly Fe (oxy)hydroxide plaques]. These precipitates provide a further surface for trace metal adsorption (63).
- Bacterial biofilms forming on root surfaces are strong adsorbents of trace metals (63).
- The turnover of aquatic vegetation is the dominant source of simple carbohydrates, which are the main substrate for sulfate-reducing bacteria and other fermentative organisms important in the production of sulfides, ammonium, carbon dioxide, and alkalinity (14,40,64,65).
- The humic substances of organic decay play an important role in aquatic contaminant chemistry through the adsorption of metals and subsequent transport as colloidal complexes or incorporation into the sediment as settled solids.

The Role of Microbial Processes

Microbial activity is integral to many of the processes described above. The importance of the microbiology of mine effluent remediation has recently been recognized, as evidenced by numerous studies in this discipline (66–69). Nordstrom (70) provides a good review of the state of knowledge and the gaps in the present understanding of the microbiology of acid mine waters. The processes that use or depend on, microbial action have been described above. Hence, listed here are the most common examples of microbial involvement in processes of mine effluent remediation:

- oxidation of Mn (71,72)
- oxidation and hydrolysis of Fe (73,74)
- oxidation of sulfides (11)
- sulfate reduction
- products of organic decay (CO_2, NH_4^+, and organic acids)
- surfaces for adsorption

SUGARCANE INDUSTRY WASTEWATERS TREATMENT

María-del-Carmen
Durán-de-Bazúa
UNAM, National Autonomous
University of Mexico
México D.F., México

Sugar (sucrose) is a sweet, crystalline, white or colorless substance, derived from the juice of several plants. World sugar production amounts approximately to 120 million tonnes, of which two-thirds come from sugarcane and one third from sugarbeet. Sugarcane is a perennial grass that grows between the tropics (30° latitude north and 30° latitude south) in more than 100 countries. It is the most efficient earth grass plant for storing solar energy as biomass and reaches field yields up to 150 ton/ha. A variety of products are obtained from this versatile plant (Fig. 1). Many studies on sugarcane are published in journals and books. Sugarcane processing to produce sugar represents one of the oldest "industries" in modern times. In America, the first sugarcane processing plants were located in the New Spain territories as well as in the Caribbean islands since the sixteenth century. In Mexico, for example, the first sugarcane mill was established in Veracruz on the Gulf of Mexico in 1525 (1,2).

The power for sugarcane mills originally came from water sources (rivers) and from cane bagasse burning. Considering that up to the first half of the twentieth century, industry was a synonym for smoke, wastewater, and wastes in general, the sugarcane industry was no exception. Therefore, considering modern sustainability concepts, the more than 2000 sugar processing plants still operate around the world with relatively poor technologies from an environmentally friendly point of view. Figure 2 shows a schematic diagram of a sugarcane factory, including the wastes generated.

Roughly, one metric tonne of sugarcane renders the following products:

350	kg wet bagasse	35%
100	kg sugar	10%
60	kg straw and leaves	6%
40	kg final syrup, molasses	4%
40	kg cachasses	4%
100	kg cane heads	10%
310	kg evaporated water	31%
1000	kg sugarcane	100%

After sugar, the by-product with more added value is the final syrup, known as molasses. Molasses is a

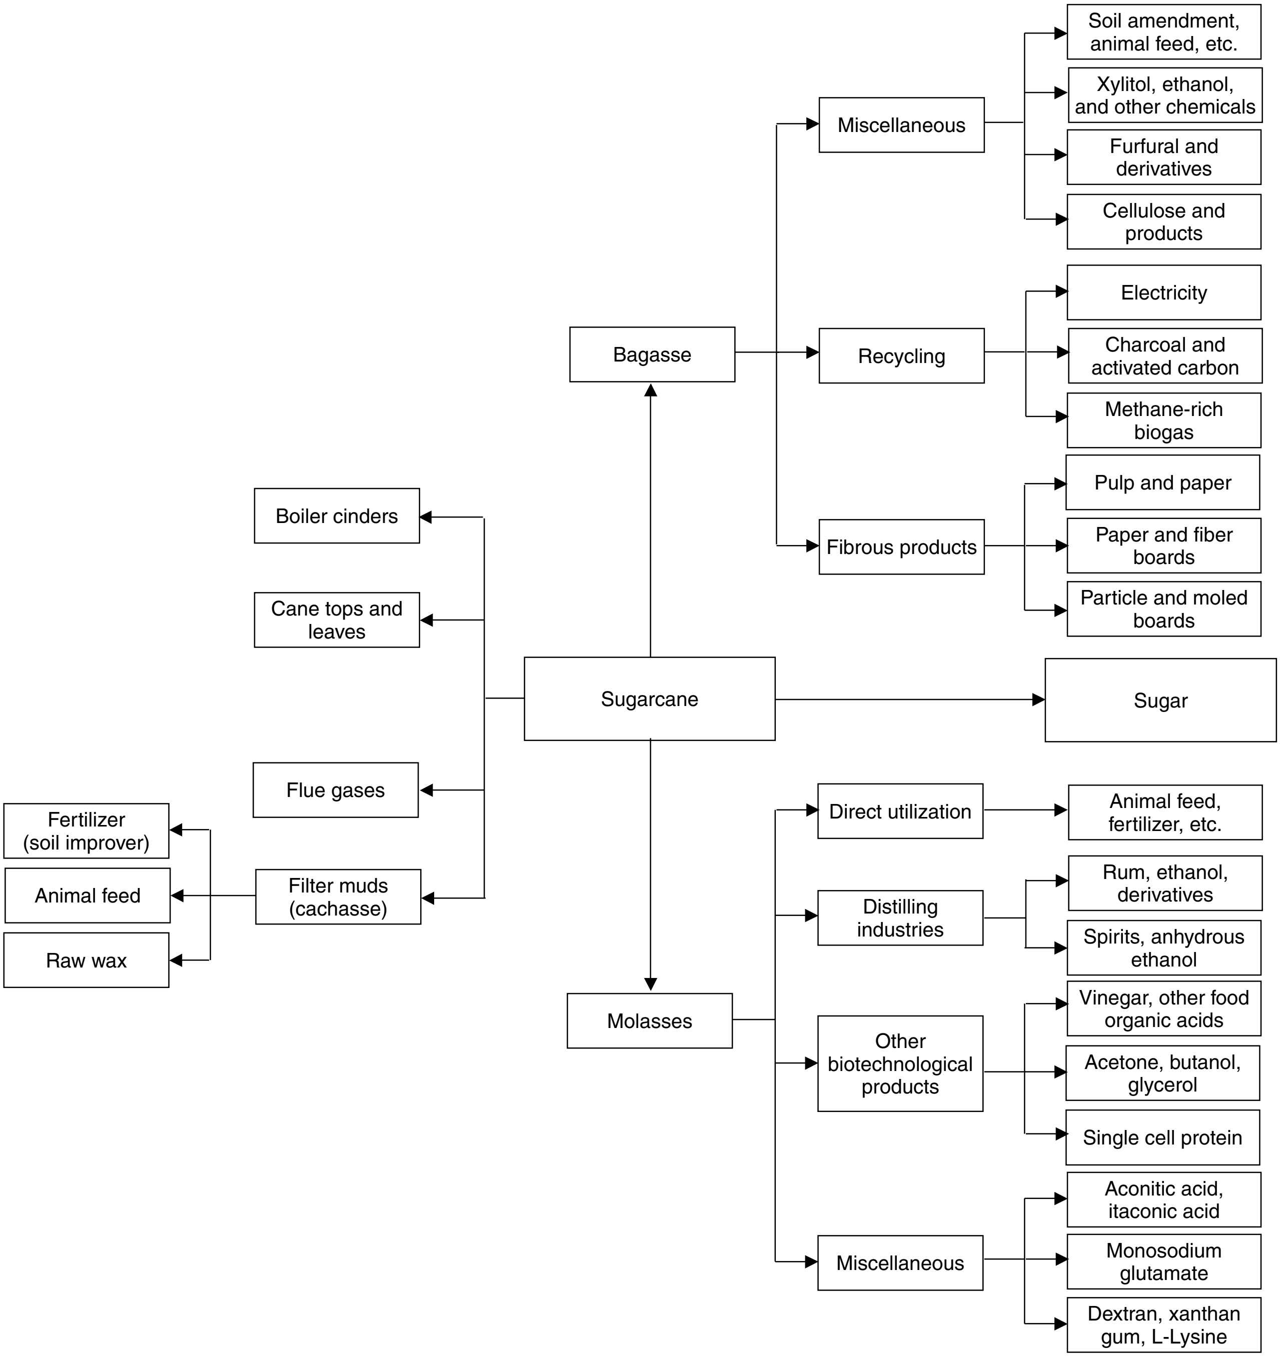

Figure 1. Versatile sugarcane use.

very inexpensive carbon source for many biotechnological products, including vaccines and antibiotics (Table 1). Of course, fermented and distilled beverages, such as rum, are more widely known biotechnological products.

In Figs. 3 and 4, diagrams for sugar and ethyl alcohol production are presented. In Fig. 3, the example is the production of raw sugar. The two other most popular sugar commercial products are the so-called plantation white sugar or mill white sugar (in Mexico, it is known as "standard" sugar) and refined sugar. Literature presents block diagrams for the production of these different types of sugar (1). Wastewaters are the most conspicuous wastes, and many processes have been devised to reduce their polluting impact and to gain some added value from treating them (5). Tables 2 and 3 show the average composition of some of these wastewaters, and Table 4 presents the regulatory limits that Mexico established in the 1990s for this agro-based industry.

It is clear from Table 3 that liquid effluents from a distillery in the sugarcane mill have a very important impact on the overall composition of its wastewaters. Also, to comply with the regulations for both sugar production and distilled products, namely ethanol (ethyl alcohol), a removal efficiency of more than 95 and

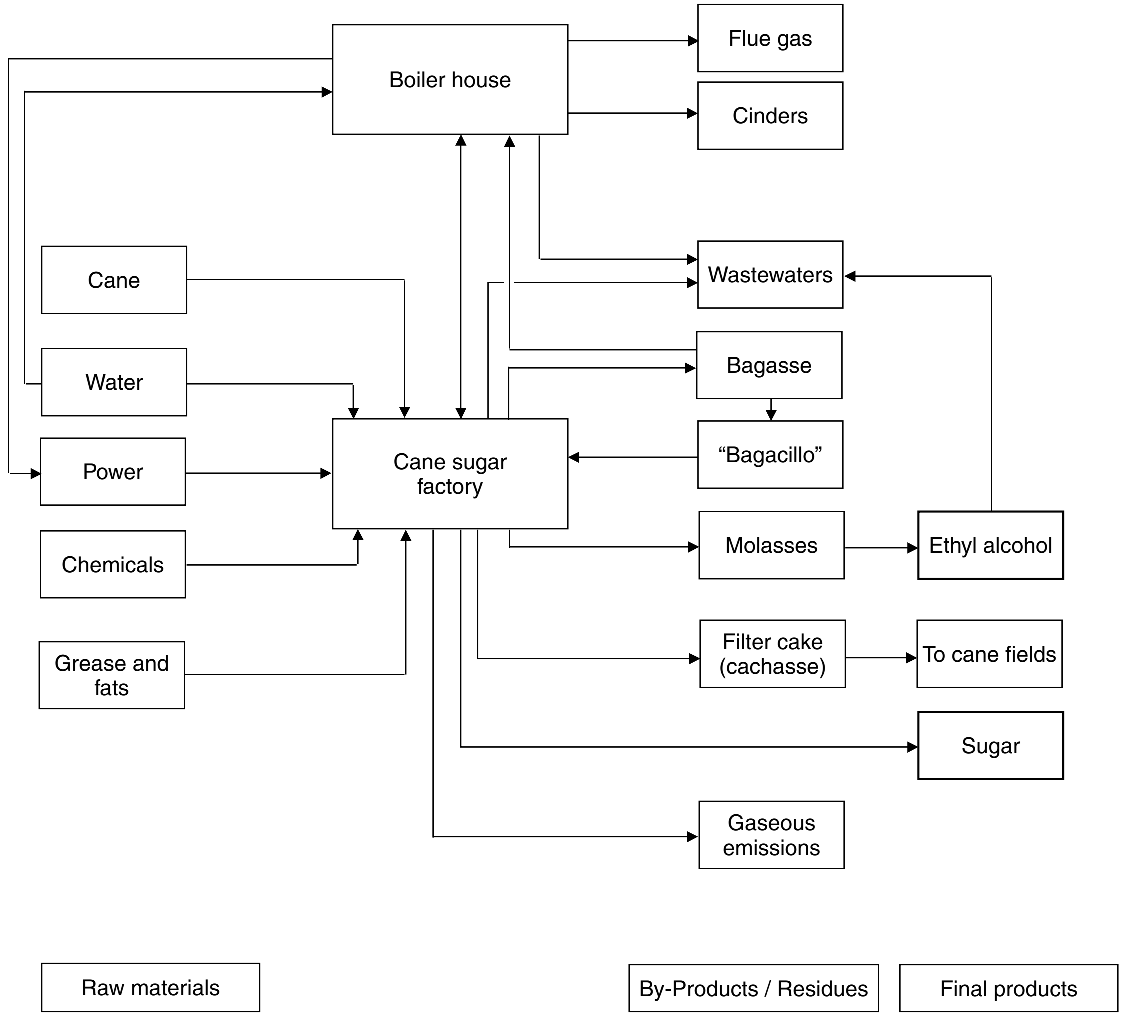

Figure 2. Raw materials, products, and by-products of the sugarcane industry.

99.8% must be reached for general wastewaters and vinasses, respectively. Most of these vinasses, to date, are discharged to receiving bodies (soil, surface water sources) without any treatment or with a partial depuration because of the notion that these wastewaters improve soil. However, this is true only when soils are very poor. For good agricultural soils, they have a negative effect (9–11).

To reduce costs, biological systems are preferred to physicochemical processes. For that reason, in general, anaerobic systems are chosen for treating those process streams that contain biodegradable compounds because methane-rich biogas can be a plus from the bioconversion. To improve the biotreatment and reuse the water in the process, aerobic polishing and sometimes a physicochemical treatment are added. From the aerobic treatment, the biomass produced can be used in feedlots, particularly for fish (12). Leftover treated water can be used for irrigating cane fields. In tropical countries, it is very common to "cultivate" river shrimp (*Cammarus montezumae*), known in Mexico as "*acociles*" (from the Nahuatl or Aztec language, atl = water, cuitzilli = bent, that bends in the water). Then, an interesting biological cycle is rendered. Aerobic biomass together with carotenoproteins from cephalothorax and exoskeleton from river shrimp (the unedible portion), are pelleted for fish feedlots, and the unedible residues from fish are ground and used for shrimp cultivation. Figure 3 shows a complete nature-like cycle process instead of the typical man-made linear polluting processes (Fig. 2).

When wastewaters contain mainly high concentrations of inorganic compound and they are highly soluble, as

Table 1. Molasses Composition[a]

Parameter	% weight	Parameter	% weight
Water	20	K_2O	3.5

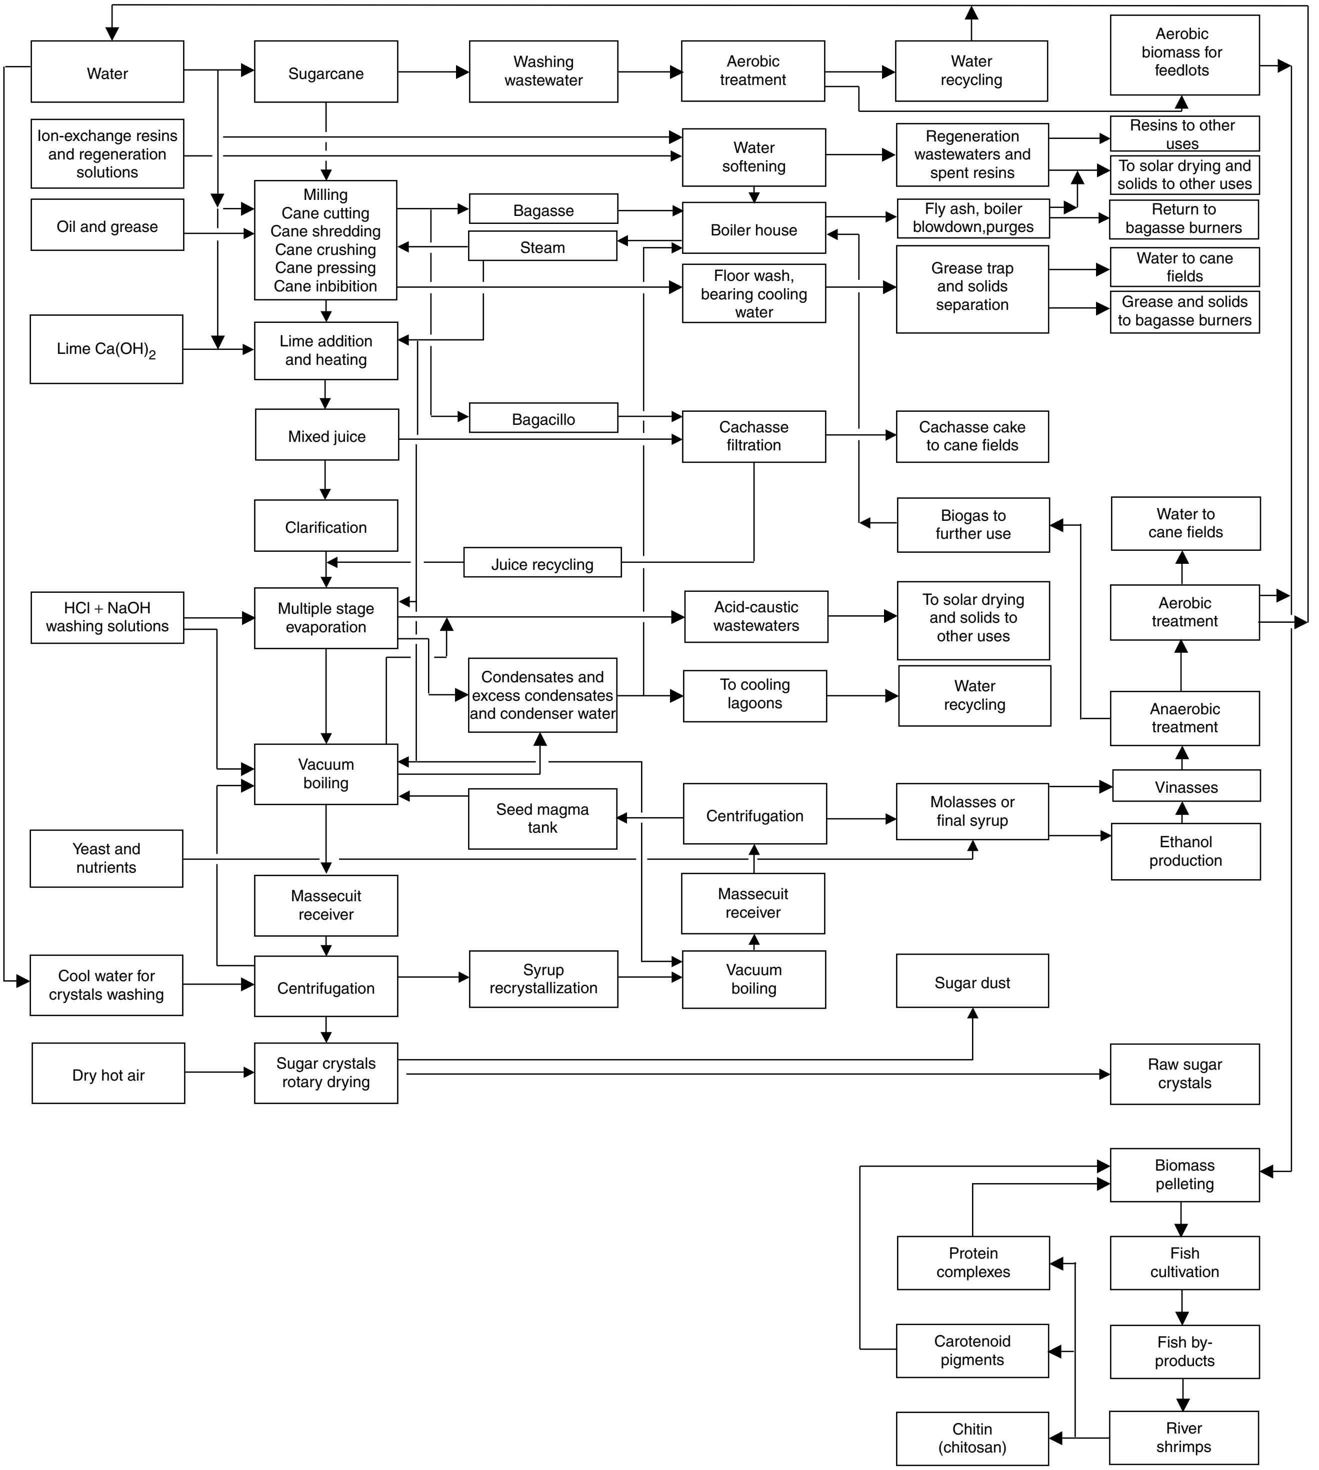

Figure 3. Example of water use, wastewater generation, and treatment proposals for raw sugar.

happens with boilers purges and acid-caustic solutions used to clean heat transfer surfaces in evaporators and vacuum boiler pans, the most suitable process is to eliminate water by evaporation (preferably solar evaporation, taking advantage of climatic conditions in tropical areas). The resulting impure salts, collected as dry solids, may be recycled by the companies that sell the caustic and acid products used as raw materials in the sugarcane mill, reducing the environmental impact of both enterprises (2).

Figures 5 and 6 present schemes of an aerobic plant for treating wastewaters generated in a plantation sugar production plant (14). This plant wastewater treatment system had a different approach. The wastewater

composition is similar to those of other countries that do not contain vinasses (Table 2), so once the suspended matter is eliminated in a primary settler, an aerobic reactor is adequate for removing most of the dissolved biodegradable pollutants. Here, the feasibility of using an anaerobic reactor to "digest" the aerobic biomass when it is not used for feedlots is shown (13). This reactor gives the added value of methane-rich biogas production, once the gas is stripped in a column using the treated water to dissolve H_2S leaving the methane-rich gas free of this corrosive compound and "enriching" the treated wastewater in sulfur compounds before sending it to cane fields as irrigation water.

Table 3. Average Vinasse Compositions[a]

Parameter		Parameter	
pH	4.8–4.9	Total volatile solids, g/L	76–83
Biochemical oxygen demand, mg/L	90,000	Total fixed solids, g/L	21–23

ESTIMATED USE OF WATER IN THE UNITED STATES IN 1990 INDUSTRIAL WATER USE

U.S. Geological Survey

Industrial water use includes water for such purposes as processing, washing, and cooling in facilities that manufacture products. Major water-using industries include, but are not limited to, steel, chemical and allied products, paper and allied products, and petroleum refining.

Many States have developed permit programs that require reporting of industrial withdrawals and return flows. Estimates for 1990 are improved over those of previous years because of the availability of more comprehensive inventories of industrial facilities and more complete water-use records. Information on deliveries from public suppliers to industrial users were estimated from a variety of methods if not available directly from public suppliers. Consumptive-use estimates generally were based on coefficients ranging from 3 to 80 percent (depending on the type of industry) of withdrawals and deliveries.

Industrial water use (freshwater withdrawals, public-supply deliveries, saline water withdrawals) during 1990 was an estimated 19,300 Mgal/d of self-supplied

freshwater, 5,190 Mgal/d of public-supplied freshwater, and an additional 3,270 Mgal/d of saline water. (See Table 1: water-resources regions and Table 2: States.) Industrial freshwater use during 1990 was 13 percent less than during 1985 and represents 7 percent of total freshwater use for all offstream categories. Surface water was the source for about 82 percent of self-supplied industrial withdrawals; ground water, 18 percent; and reclaimed wastewater, only a fraction of 1 percent. Public-supplied deliveries to industries accounted for 13 percent of public-supply withdrawals.

The source and disposition of water for industrial purposes are shown in the pie charts below (or as a GIF file or PostScript file (94 Kb)). The consumptive use of freshwater for industrial purposes during 1990 was 3,330 Mgal/d, or 14 percent of freshwater withdrawals and deliveries; saline consumptive use was 913 Mgal/d, or about 28 percent of saline water withdrawals.

In 1990, the Great Lakes and Mid Atlantic water-resources regions had the largest withdrawals for industrial purposes as shown in figure 20 (GIF file), or (PostScript file (620 Kb)). Indiana, Louisiana, Texas, Pennsylvania, and Michigan reported the largest state withdrawals for industries as shown in figure 21 (GIF file) or (PostScript file (508 Kb)). Indiana, Louisiana, Pennsylvania, and Michigan reported the largest freshwater use (figure 22 (GIF file)), or (PostScript file (508 Kb)), and Maryland and Texas reported the largest quantities of reclaimed wastewater used by industries.

WASTE WATER TREATMENT

AERATION

Arnim R.H. Hertle
GHD Pty Ltd
Wembley, Washington
Australia

OVERVIEW

The aeration of wastewater and byproducts is a key process in the operation of most modern wastewater treatment plants (WWTP), which is reflected in the energy consumption of a WWTP's aeration system, which can be up to 70% of the WWTP's total energy consumption.

As most wastewater treatment plants and many sludge treatment plants include aerobic biological processes, the transfer of oxygen into the wastewater (or sludge) is a key operation.

As a result of the large quantities of CO_2 produced in the course of the aerobic degradation of organic matter, the pH in such a reactor can be significantly lower than that of its feed. These CO_2-related effects can be amplified when nitrification occurs or when the liquor's alkalinity is low. This drop in pH can lead to decreased performance of the plant as well as to impacts such as concrete and metal corrosion if not managed properly. The second key function of an aeration system is therefore to remove CO_2 from the reactor (1).

One of the important functions that an aeration system has to provide is mixing to prevent settling of the biomass in the reactors and optimize the contact of wastewater with the biomass.

TERMS AND DEFINITIONS

The following terms and definitions will be used herein:

1. α (alpha) factor is the ratio of the apparent volumetric mass transfer coefficient kL in wastewater to that in clean water. α is normally <1.
2. Oxygen transfer rate (OTR) is the mass of oxygen dissolved by a given aeration system in a given volume of water under given water temperature, barometric pressure, and operating conditions [initial dissolved oxygen (DO) concentration, gas flow rate, power input] per unit time.
3. Standard oxygen transfer rate (SOTR) is the OTR in clean water at 20°C, whose initial DO concentration is zero in all parts of the waterbody, and is at 101.3 kPa barometric pressure.
4. Oxygen transfer efficiency (OTE) is the fraction of oxygen in an injected gas stream that is transferred into water at given initial DO, gas flow rate, water temperature, and barometric pressure.
5. Standard oxygen transfer efficiency (SOTE) is the OTE in clean water at 20°C, whose initial DO concentration is zero in all parts of the waterbody, and is at 101.3 kPa barometric pressure. The oxygen transfer efficiency per meter submergence for a given aeration system under given ambient and operating conditions is relatively constant for installation depths in the technically most important range around 4 to 5 meters. It is, therefore, often quoted in percent per meter submergence to allow the user of this information to calculate the OTE or SOTE case-by-case for the respective aerator installation depths rather than providing a long list of values for different submergences.
6. Aeration efficiency (AE) is the OTR divided by the total power input for the aeration system, measured as either brake power or wire power.
7. Standard aeration efficiency (SAE) is the AE based on the SOTR.

Further explanations and definitions of further parameters and terms used to characterize aeration systems and their design are provided in Refs. 2 and 3.

AERATION SYSTEMS

Numerous aeration mechanisms are used in wastewater treatment plants; each has its particular advantages. The oxygen transfer from air (or pure oxygen where it is applied) into liquor can take place only through a common surface of the two media; so the common goal of all aeration mechanisms is to make as much active surface area available as possible. A classification of the technical systems used for aeration purposes can be based on the mechanical equipment that is used. Alternatively, the systems can be classified on the basis of where the oxygen transfer mainly takes place, which indicates how the design calculations are carried out. Aeration systems are therefore differentiated into

- — surface aeration and
- — submerged aeration.

SURFACE AERATION

Natural Aeration

The specific characteristic of natural aeration is that no energy is directly applied and/or no mechanical equipment is directly involved in the oxygen transfer. Examples are

- — the oxygen transfer through the water surface of a facultative wastewater treatment pond;
- — the aeration of wastewater in a trickling filter where natural draft is relied on to move the air through the filter when it is brought into contact with the wastewater; or
- — postaeration of secondary effluent in a cascading system before it is discharged into the receiving waters.

The first two types of systems are typically designed on the basis of specific loads of biochemical or chemical oxygen demand (BOD or COD) and/or nitrogen (e.g., in kg BOD/(ha · d)) without explicitly designing the aeration process per se. Depending on the system, the contribution of algae to the oxygen balance in a pond may also be considered in the design calculation. These systems are not discussed here.

The secondary effluent can be postaerated by natural aeration in a cascade, although other systems such as fine bubble diffused air aeration can also be applied. The key design parameter of a cascade postaeration system is its height and the shape of the cascade, for example, a weir or steps. The required height is calculated based on the oxygen deficit ratio, the ratio of the difference between the saturation concentration and the actual oxygen content to the difference of the saturation concentration and the target effluent concentration. As the saturation concentration decreases with increasing water temperature, these systems typically have to be designed for the highest temperature when the deficit ratio and hence the required cascade height is greatest.

Mechanical Surface Aeration

An aeration system is referred to as mechanical surface aeration system when air is entrained in the liquor at the surface by moving mechanical equipment. These systems are usually operated with uncompressed ambient air. Low- and high-speed aeration turbines, rotating brush aerators, and aspirating mixer aerators are probably the most commonly used types of mechanical surface aerators.

Aeration turbines and brush aerators work on the principle of lifting some liquid up and accelerating and dispersing it in the air above the liquid surface, which achieves oxygen transfer mainly through the large total surface area of the small liquor droplets in the air and, to a lesser extent, through the turbulent surface of the liquor in the tank and air entrainment when the accelerated liquid falls back down and hits the liquor surface.

Aspirating mixers are high-speed mixers with a hollow inclined or vertical shaft. They use the vacuum created by the rapid motion of the liquid at the mixer tip to suck ambient air through the hollow mixer shaft into the zone of rapid liquid movement at the mixer tip and in the mixer's jet stream. The high shear forces in this area result in mixing the two streams.

Application of Mechanical Aeration Systems

Mechanical surface aeration systems are typically preferred if one or more of the following criteria are met:

- Shallow reactor. Diffused air aeration systems are inefficient here; their efficiency is a function of depth, whereas the efficiency of mechanical aeration systems is almost unaffected by depth. Note that, although this criterion of shallowness is often met in lagoons and mechanical aerators are, therefore, often used in lagoons, it would be wrong to deduce a genuine requirement to aerate lagoons with mechanical aerators because diffused air aeration systems are available that are specifically designed for lagoons.
- Very deep reactor. Fine bubble diffused air aeration is not preferred in such installations because of their reduced CO_2-removal efficiency. Instead, systems that have a lower oxygen transfer efficiency such as coarse bubble diffused air aeration or mechanical aeration are preferred for deep tanks (see below).
- Reactor and process configuration lend itself for it. A typical example is oxidation ditches. These reactor/process layouts typically benefit from the combined aerating and mixing action of mechanical, rotating-brush surface aerators, whereas diffused air aeration systems would require additional horizontal mixers to provide sufficient velocity of mixed liquor circulation.
- Simplicity is imperative. The installation of mechanical aeration systems comprises less components and is significantly simpler than that of diffused air aeration systems that have associated benefits regarding maintenance, for example, that all equipment can be easily accessed from the surface.
- Medium unsuitable for fine bubble diffused air aeration. A typical example would be the aeration of sludge, where fine bubble diffused air aeration loses its efficiency advantage due to effects of the medium, most of all bubble coalescence. Systems that produce coarser bubbles, such as coarse bubble diffused air aeration or mechanical aeration, lose their respective disadvantage, and other benefits, such as simplicity, become the driver for equipment selection. Other examples would be wastewaters that have a high tendency to scale up or foul the diffusers or one that is aggressive to the rubber or other compounds used in the diffusers, all of which can render their use impracticable and be a driver toward mechanical aeration.

The biggest drawback of mechanical aeration compared with fine bubble diffused air aeration is its lower AE in medium deep tanks of around 4 m depth and deeper. In particular, in medium and large municipal installations, this difference in AE often outweighs the advantages of mechanical aeration in capital and maintenance costs and leads to lower life cycle costs for diffused air aeration. Typical AE for mechanical aeration systems is in the range of 1.3–2 kg O_2/kWh. Note that fine bubble diffused air aeration systems may end up in the 2 kg O_2/kWh range as well after a few years of operation, which can lead to process problems. Mechanical aeration systems, in contrast, will stay on their initial AE level, and the oxygen input is at a point source; thus a tapered DO profile can be achieved that can enhance nitrogen removal.

SUBMERGED AERATION SYSTEMS

Submerged aeration systems can be differentiated into

- mechanical submerged aeration systems and
- diffused air aeration systems.

Mechanical Submerged Aeration Systems

A mechanical submerged aeration system entrains ambient air or compressed air in the liquor by moving mechanical equipment at a point close to the tank floor. The concept is to increase the contact time between air and liquor, and hence the oxygen transfer, by letting the air bubbles travel through the liquor and to attempt to produce fine bubbles via agitation. Mechanical submerged aeration systems comprise floor-mounted aspirating or sparger (when operated with compressed air) mixers and ejector pumps.

Aspirating and sparging mixers are high-speed, submerged mixers that introduce air at or below the rotor where it is dispersed and mixed with the liquid, as shown in Fig. 1. In the aspirating mode, the working principle is as described before for aspirating mixers for surface aeration. However, in some cases, the oxygen demand requires a supply of compressed air (sparger mixer). Figure 2 shows an installation of a submerged aspirating mixer.

Ejector pumps use a venturi nozzle on the pump's discharge to entrain ambient air or compressed air into a jet of pumped liquid. They work with the vacuum created by the acceleration of the liquid in the nozzle, which sucks air into this highly turbulent zone where the two streams are mixed.

Diffused Air Aeration

Diffused air aeration is a system where air (or pure oxygen) is compressed and then diffused into small bubbles by a passive component.

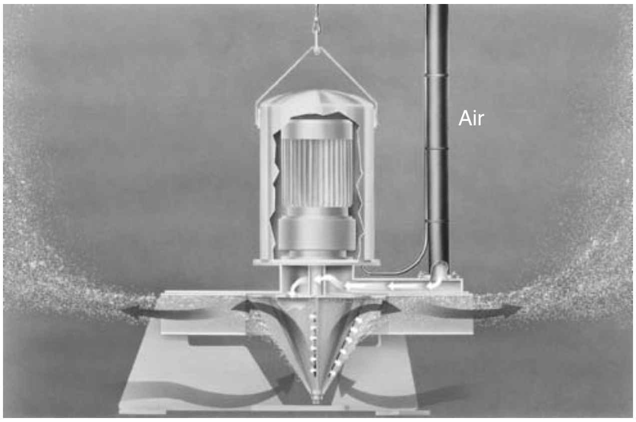

Figure 1. Working principle of a submerged aerating mixer.

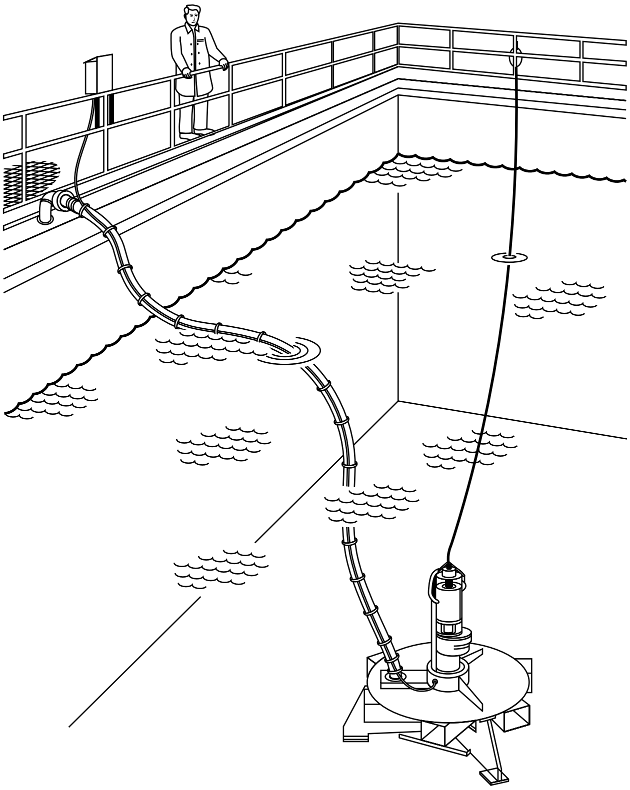

Figure 2. Installation of a submerged aspirating mixer.

Medium or coarse bubble diffusers are being used for applications requiring mixing, in deep tanks, or for the aeration of sludge. They have relatively large openings for the air to pass through. Rubber membranes and rigid porous materials are rarely used for these diffuser types, which include static mixer type arrangements, compressed air jets, perforated pipes, and orifices. Some examples of coarse bubble diffusers are shown in Fig. 3.

Fine bubble systems are used for wastewater aeration applications. Compressed air is passed through floor-mounted, finely slotted rubber membranes or rigid porous diffuser bodies to form small bubbles that rise through the mixed liquor to the surface. An example of a rubber

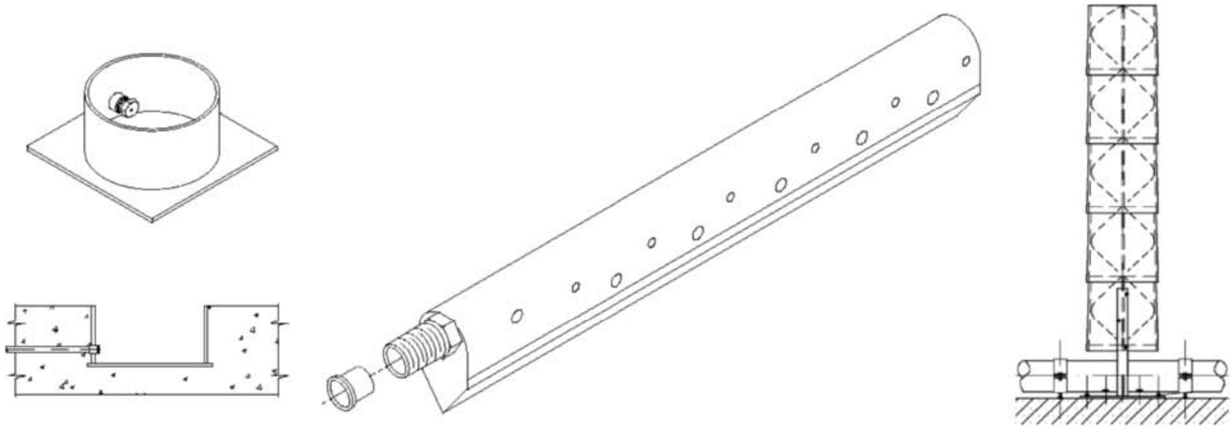

Figure 3. Coarse bubble diffuser types.

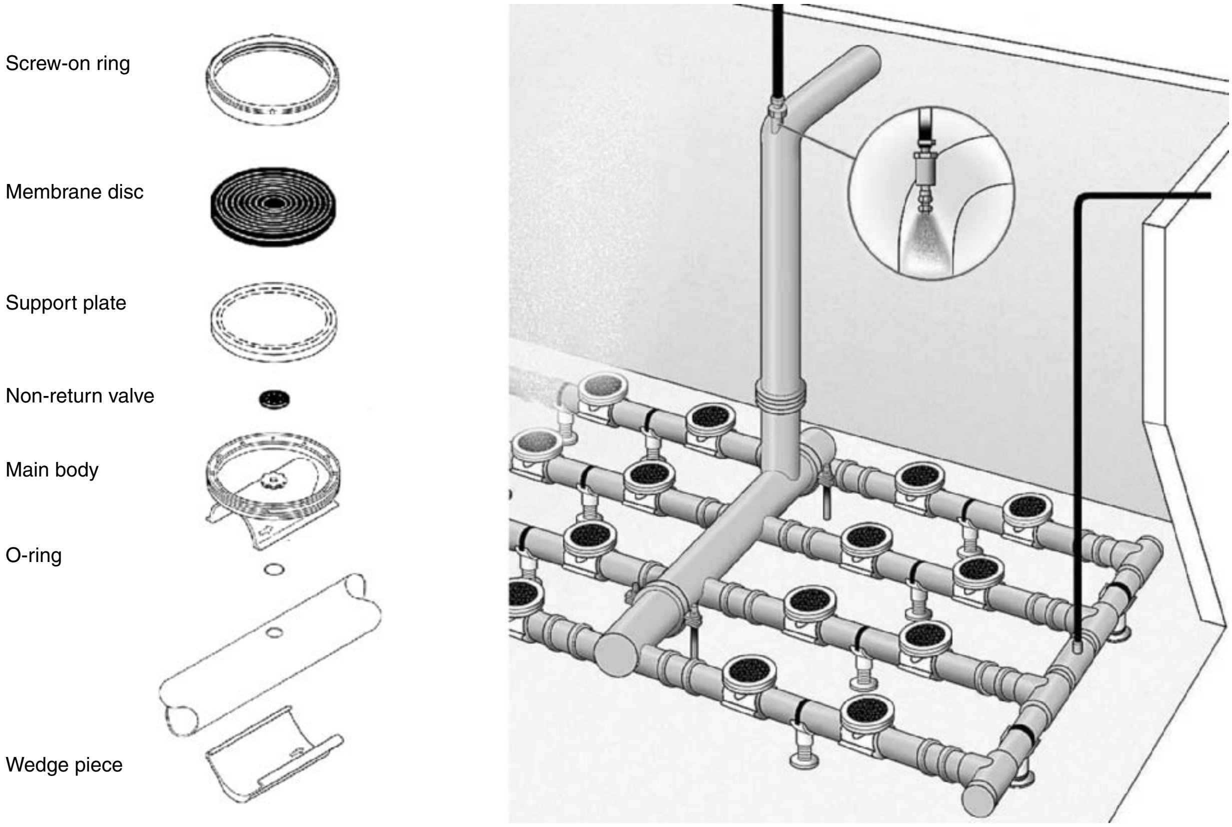

Figure 4. Typical membrane fine bubble diffuser details and installation.

membrane fine bubble diffuser for a fine bubble diffuser installation is shown in Fig. 4.

The mechanical and process design of fine bubble diffused air aeration systems can be quite involved. A dedicated section, therefore, expands on these systems.

FINE BUBBLE DIFFUSED AIR AERATION SYSTEMS

Arnim R.H. Hertle
GHD Pty Ltd
Wembley, Washington,
Australia

DIFFUSER TYPES

Fine bubble diffusers are typically used for aerating activated sludge tanks in municipal wastewater treatment plants because medium or coarse bubble diffusers are not economical in medium depth tanks, which are prevalent in municipal applications.

Two types of fine bubble diffusers are available on the market:

- — rigid porous diffusers; and
- — elastic/rubber membrane diffusers.

A general comparison of rigid porous and rubber membrane diffuser systems is given in Table 1.

Rigid Porous Fine Bubble Diffusers

The first rigid porous diffusers were made of sintered ceramics such as sintered alumina; many diffusers are still made of this material. Its biggest advantage lies in its chemical inertness. Ceramic diffusers can be refired, for example, in a brick kiln, or acid cleaned to remove scaling and fouling and bring their permeability/head loss back to nearly new condition (1). Practical experience indicates that they need to be refired every 5 to 10 years and that this can be done only two to three times. However, refiring may not often be practical once tank downtime or total cost, including replacement of lost (broken) diffusers, is accounted for.

Alternative materials used to manufacture rigid porous diffusers include sintered HDPE granulate and round quartz sand in a phenol–resin matrix. These diffusers cannot be cleaned thermally because the temperatures

Table 1. Comparison of Rubber Membrane and Rigid Porous Diffusers

	Rubber Membrane Diffusers	Rigid Porous Diffusers
Continuous operation	Well suited	Well suited
Intermittent operation	Reasonably suited	Not suited
Turndown ratio	Large	Moderate
High water hardness	Scaling may lead to short membrane replacement intervals	Carbonate scaling can be controlled with in-line acid dosing
High water temperature	Not suited	Depending on diffuser material
High oil and grease concentrations	EPDM: not suited Silicone: well suited	Well suited
In-line cleaning	Bumping	Acid gas injection
Typical head loss	Higher	Lower
Typical oxygen transfer efficiency	Higher	Lower
Typical asset life	Replace membrane after 3 to 5 years Replacement of membrane brings diffuser back to new condition	Refire or acid clean after 5–10 years Refiring or acid cleaning can bring diffuser back to nearly new condition

in a kiln would destroy them. However, they can be acid cleaned and, due to the more regular and smoother geometry of the particles from which they are made, high-pressure hosing may have a greater effect than on diffusers made from genuine ceramic. The use of a resin matrix also makes it possible to include fouling inhibitors (bactericides) in the matrix and thus reduce bacterial growth on the diffuser and in its pores.

Rigid porous diffusers are manufactured in many shapes and types such as domes, cylinders, circular disks, and plates (noncircular disk). The method of mounting the actual porous diffuser element to the pipework is important in selecting a diffuser to provide flexibility for replacement, which is critical for converting a rigid porous diffuser system to a membrane diffuser system and vice versa, if required. Further, some suppliers offer features such as a nonreturn valve or a pressure sample port that can be integrated into the diffuser carrier. A nonreturn valve prevents intrusion of larger quantities of mixed liquor into the diffuser and the pipework, if the airflow should drop below the required minimum or should cease. A pressure sample port in the diffuser carrier in combination with a pressure probe in the header pipe and a static pressure measurement allows a determination of the dynamic wet pressure of the diffuser to judge whether a cleaning cycle is required.

The lifetime of rigid porous diffusers is determined mainly by

- the lifetime of the bond between the diffuser body particles (disintegration);
- reduction of the pore diameter by scaling (e.g., $CaCO_3$ precipitation);
- reduction of the pore diameter by fouling (intrusion/growth of bacteria); and
- blockage of pores due to dust and other particles in the air.

Due to blockage of its pores, the head loss of a rigid porous diffuser can only increase over its lifetime. At the same time, its oxygen transfer efficiency (OTE) may increase as the pores, and hence the air bubbles, produced become smaller, leading to reduced required air throughput. If they occur, these two effects may offset each other to some degree and may thus expand the useful life of the diffusers. There will, however, be a point where the aeration blowers cannot deliver sufficient quantities of air at the required, increased pressure any longer, and the wastewater treatment process becomes underaerated (oxygen deficient).

Rubber Membrane Fine Bubble Diffusers

Rubber membrane diffusers are made of a finely slotted rubber membrane mounted on a carrier, typically made of plastic. Most rubber membranes are made of EPDM because of its favorable physical properties and acceptable chemical resistance at a low price. However, the drawback of EPDM in wastewater applications is that its plasticizers are washed out over time by oils, grease, and solvents, which are always present in small quantities in wastewater and in compressed air, which in turn causes the membrane to become stiff over time and lose its ability to contract fully and close its pores when the air is cut off. The speed at which this process progresses is a function of various parameters; one of them is the oil and grease content of the wastewater. EPDM membranes are, therefore, unsuitable for wastewaters that have a high concentration of these constituents.

Alternative membrane materials that overcome some of the shortfalls and diffuser membranes are also available now in materials such as silicone rubber and polyurethane rubber. These materials are resistant to oil and grease in wastewater because they do not contain plasticizers.

Note that the resistance to oil and grease is not the only material characteristic where the various rubber types differ. Table 2 shows a number of physical parameters that demonstrate how different these materials are and that, for example, EPDM and silicone are not uniquely specified substances but can be produced to match different physical and chemical requirements. It can also be seen that EPDM varieties have higher tear resistance than the alternative materials; however, once a tear has formed, it will grow longer more easily than in the other materials.

An important aspect that is not captured in Table 2 is how the membranes perform over time ("aging"). EPDM membranes become stiffer, whereas silicone membranes tend to become softer. If not replaced before these effects become noticeable and with other effects,

Table 2. Examples of Diffuser Membrane Materials[a]

Material	EPDM (1)	EPDM (2)	Silicone (1)	Silicone (2)	Polyurethane
Plasticizer content, %	12	18	0	0	0
Tear resistance, MPa[a]	13	14.4	10	10.5	11
Ultimate elongation, %[a]	700	580	650	680	700
Tear strength, N/mm[b]	11.4	10.5	40	44.5	23

[a] DIN-53504.

[b] Various testing standards.

e.g., scaling, left aside, this different aging process may lead to slightly finer bubbles and an associated increase in OTE for EPDM membranes and slightly larger bubbles and an associated decrease in OTE for silicone membranes.

Due to the different properties and aging patterns of rubber membrane diffusers, compared with rigid porous diffusers, maintenance and cleaning are also different. A wash down with water is a typical means at water pressures often quite low to avoid damaging the membranes. Acid injection is rarely used to clean membranes. Rubber membrane diffusers can be "bumped" to remove scale, which is done by sharply increasing the airflow and then dropping back to a low (or nil) flow. By doing so, deposits on the diffuser surface break and loosen when the rubber membrane expands and are washed away.

The most common shapes of rubber membrane diffusers are circular discs, tubes of circular and noncircular cross section (e.g., cylindrical diffuser elements of a round cross section), and plates (noncircular disk).

Most diffuser types comprise a carrier and a separate membrane mounted on the carrier. Tube types have the diffuser membrane all around the carrier; the flat disk and plate types have a membrane sheet that is attached to the upper side of the carrier. Apart from these three main types of diffusers less frequently used designs also exist, such as diffuser tubes without an internal carrier where the membrane tubes are fixed to a support grid to hold them in place.

The most important difference between rigid porous diffusers and membrane diffusers is that membrane diffusers have built-in backflow prevention properties, which results from the elastic rubber membrane totally contracting when the air is cut off and thereby closing its pores.

Note that the membrane lifts off the carrier when pressurized and returns to its initial position and lies tightly on the carrier when the air is cut off. Further, all diffuser assemblies are designed so that the membrane closes the air entry ports in the carrier when it is resting, which is facilitated by the static head of the liquor above the diffuser. In addition to these nonreturn mechanisms, some disk diffusers include a nonreturn flap in the air entry port of the carrier. These properties make it possible to cut off the air supply to submerged diffusers without flooding the diffusers or the piping, which is a characteristic that is vital for diffused air aeration systems in sequencing batch reactors or in plants that have large diurnal load fluctuations, where diffusers have to be cut off at certain times.

The lifetime of rubber membrane diffusers is determined mainly by

- — operating temperature (higher temperatures, e.g., in tropical regions or in industrial applications, lead to a shorter lifetime);
- — the lifetime/residence time of the membrane plasticizer (leading to decreased membrane elasticity and increased head loss);
- — other aging effects on the rubber, such as UV radiation or oxidation;
- — chemically or biochemically induced hydrolysis of the rubber;
- — loss of pores self-closing properties from scaling (e.g., $CaCO_3$ precipitation) due to reduced elasticity and/or deposits in the pores;
- — reduction of the pore diameter by scaling (e.g., $CaCO_3$ precipitation);
- — reduction of the pore diameter by fouling (intrusion/growth of bacteria); and
- — blockage of pores due to dust and other particles in the air.

Over its lifetime, the head loss of an EPDM rubber membrane diffuser typically first drops when the membrane elongates slightly as a result of the expansion–contraction cycles experienced during operation. Once the head loss has reached its minimum, it can only increase from there on as a result of the above impacts. The OTE of rigid porous diffusers, may increase and lead to reduced air throughput requirements. The increased head loss can reach a point where the aeration blowers cannot deliver sufficient quantities of air at the required pressure. The increased operating pressure of the (then stiffer) diffuser also includes an increased risk of membrane failure.

Mixed Diffuser Systems

It is possible to combine rigid porous diffusers and rubber membrane diffusers in one installation. By doing so, some of the wastewater treatment plant's diffuser installation can benefit from the long lifetime of rigid porous diffusers, and some can benefit from the large turndown ratio of rubber membrane diffusers, for example,

- — rigid porous diffusers in the main nitrification zone and rubber membrane diffusers in a bivalent zone ("swing zone") that can be operated anoxic in summer to maximize nitrogen removal and aerobic in winter to compensate for the lower nitrification rate at lower temperatures by providing more aerobic tank volume and hence longer aerobic sludge age.

- a modified Ludzack–Ettinger process arrangement that has rigid porous diffusers in the main nitrification zone and rubber membrane diffusers in the last aerated zone to minimize aeration there and thus oxygen recycling back into the anoxic zone.
- a plant that has strong diurnal or seasonal load fluctuations where rigid porous diffusers cover the base load and additional rubber membrane diffusers can be switched on to cover the additional oxygen demand during peak hours or peak season.

Such systems have been built and are being operated successfully, but many factors have to be considered. The diffuser types need to be suitable for the particular wastewater, and the grid and control system layout also needs to be adapted. For example, because the head loss for the two diffuser types varies differently when the diffusers are aging, one must be aware that unless the airflow to each subsystem is automatically controlled separately (e.g., air supply valve modulating based on a DO reading) in each tank, the adjustment of the flow split between the two subsystems is a recurrent additional task for plant operators. Other factors are increased piping costs and increased spares storage.

DESIGN CONSIDERATIONS FOR DIFFUSED AIR AERATION SYSTEMS

Oxygen Transfer Efficiency

Aeration systems, in general, and diffused air aeration systems, in particular, are often compared on the basis of their SOTE, which is measured in a laboratory and refers to standardized conditions. Both the testing procedures and the reference conditions are set out in standards, such as the ASCE standard (3), which is probably, internationally, the most frequently used standard for this application.

The SOTE of diffused air aeration systems is a function of the average bubble diameter produced by the diffuser as well as of other parameters that are discussed further below. The dependence on bubble size is demonstrated by the following typical values for the SOTE, quoted in % oxygen transferred per meter of diffuser submergence:

- for coarse bubble systems: 2–3%/m;
- for medium bubble systems: 4–5%/m; and
- for fine bubble systems: 5.5–6.5%/m.

The SOTE can vary among suppliers and materials, and, even for a given diffuser system, it is still widely variable, depending on factors such as

- Specific air throughput per meter of diffuser length or square meter diffuser area: The SOTE decreases with increasing specific air throughput because the average diameter of the bubbles produced increases, which leads to a decreasing surface area to volume ratio for the gas bubbles.
- Floor coverage, the ratio of installed diffuser surface area to tank floor area: The SOTE increases with higher floor coverage and more even diffuser distribution, which is due to the decreased formation of “rolling” motion patterns in the liquor, which are typically observed in line aeration systems, where the liquor is accelerated upward by the rising bubbles from the aeration line (airlift pump principle) and flows back downward in the unaerated areas. These patterns lead to shortened detention time of the bubbles in the water and hence a decreased SOTE.
- strong currents in the basin due to mixers that may coalesce fine bubbles but may also add a horizontal flow component that increases the bubble detention time. The effect on the SOTE can, therefore, be detrimental as well as positive.
- tank depth: The effect of deep tanks on the design of aeration systems is quite complex and is discussed separately later.

Head Loss

Diffused air aeration systems require low head loss to be efficient. However, because the head loss is also a function of bubble size, a balance between head loss and oxygen transfer efficiency must be maintained to provide optimal aeration efficiency.

The increase in head loss from coarse to medium and fine bubble diffusers is usually compensated for by the associated increase in oxygen transfer efficiencies. The overall power requirements and, thus, operating costs in typical municipal wastewater applications are, therefore, typically lower for fine bubble diffusers than for coarser systems. When fine bubble diffusers start to clog, bubble size decreases, and oxygen transfer efficiency and head loss increase. In practice, these two effects may compensate for each other initially; in particular, for rigid porous diffusers, this effect is well documented (4). However, there is a point where the increased head loss cannot be compensated for any longer and the overall efficiency drops or where the blowers cannot any longer deliver the required quantities of air at the increased head.

Other impacts on the head loss of a diffuser are the material from which it is made, its condition (new/old, fouled, scaled, etc.), and the specific air throughput.

Deep Tanks

A tank is generally considered “deep” when its depth is 6 meters or more. The aeration of wastewater in deep tanks requires the designer to account for some physicochemical effects that come into play only in deep tanks (5).

The alpha factor (α) is basically not affected, but the SOTE is affected by

- the higher average static pressure and related higher solubility of oxygen, as can be deduced from Henry’s law (it increases the SOTE).
- the lower average oxygen content (partial pressure) in the bubble because its detention time in the liquor

is longer and hence more oxygen can be transferred from the bubble into the liquor, leading to a higher degree of oxygen depletion in the bubble. This effect decreases the SOTE.

- A potentially lower average bubble size due to higher total mass transfer from the bubble into the liquor because the solubility of air in water increases with pressure and the quantity of oxygen transferred per m^3 of air injected is also increased. This effect can be positive as well as detrimental. If the diffuser would produce relatively large bubbles, it helps to increase the bubble detention time and hence the SOTE. However, if the diffuser already produces small bubbles, the bubble surface becomes "stiffer," and mass transfer may be slower due to a slower surface renewal rate.

Overall, the effect is typically a lower SOTE per meter of diffuser submergence (%/m or $g/(Nm^3 \cdot m)$) compared with shallower tanks at the same specific air throughput and floor coverage. This effect can be compensated for to a certain extent by increasing the number of diffusers to increase floor coverage and decrease specific air throughput; however, this leads to increased capital and maintenance costs.

Published SOTE data typically refer to tank depth of around 3.5 to 5 meters, which is higher than the average SOTE for a deep tank. Care has to be taken when extrapolating from such data; preferably it should be avoided, and the supplier be contacted.

Normal aeration tanks show a pH drop of around 0.3 units depending on initial alkalinity/buffer capacity and the degree of nitrification and denitrification, which will be aggravated in deep tanks due to the increased solubility of CO_2 and reduced aeration air volumes, which in turn reduces the CO_2 stripping capacity of the system. A highly efficient diffuser system is not recommended for a deep tank because the more efficient the system is, the less air is required, and the more CO_2 builds up in the aerated liquor. Deep tanks are, therefore, often aerated by medium or coarse bubble diffusers or mechanical aeration systems because of their lower SOTE and associated higher air throughputs.

Fouling, Scaling, and Clogging of Diffusers

Fouling, scaling, and clogging can affect the performance of diffusers quite significantly. Fouling is mainly a function of how well a biofilm can be established on the diffuser surface. Some systems claim potential advantages of their diffuser system (ability to clean or inhibition of biofilm growth). Fouling and scaling should always be taken into account in the performance of rubber membrane and rigid porous diffused air aeration systems.

Fouling of rigid porous diffusers can be removed in-line by acid cleaning; an acidic gas such as HCl is dosed into the aeration air. However, in particular, in low alkalinity wastewaters, care has to be taken to avoid negative effects on the process due to impacts on the pH. For rubber membrane diffusers, diffusers are normally bumped to remove biofilms that may have formed. High-pressure water cleaning is an effective means of off-line biofilm removal from all diffuser types; ceramic diffusers offer the additional option of refiring.

The two main reasons for diffuser scaling are water hardness and chemical precipitation. The risk and severity of scale formation is easier to assess than fouling. Scaling from water hardness can be removed via acid cleaning and bumping; high-pressure water jetting, however, may not be effective. Scaling from phosphorus precipitation or other precipitation reactions may not lend itself as easily to acid cleaning or refiring but should, in most cases, still be removable to a sufficient extent by diffuser bumping.

Clogging is caused mainly by particles in the compressed air. These particles typically do not dissolve in acids nor can they be quantitatively removed by refiring. Clogging is, therefore, an irreversible process for rigid porous diffusers. Although diffuser bumping would probably push some of these particles through a rubber membrane diffuser, a good practice is to minimize dust and oil in the compressed air by installing appropriate filters.

The need for a cleaning cycle can be determined by measuring the head loss over a diffuser element, which can be done in-line. Measurement of the delivery pressure in the supply air header can also give an indication if temperature effects are considered and the delivery pressures are compared at similar air throughputs.

Note that the "bumping capability" of rubber membrane diffusers decreases when the membrane loses elasticity. Therefore, the effectiveness of bumping to remove fouling, scaling, or clogging decreases over time. Also, the more bumping treatment occurs, the more likely the diffuser is to fail.

Life Cycle Costs

Aeration systems, in general, are a prime example for an asset whose ongoing operating and maintenance costs exceed investment costs. A thorough life cycle cost analysis is critical to decide on the type of aeration system and supplier.

The major component of the operating costs of all aeration systems is the cost of electrical power. For flexible membrane diffuser systems, membrane replacement is a key contribution to life cycle costs. The factors affecting cost are

- the SOTE at the given floor coverage and typical air throughput;
- total replacement costs for membranes, including equipment and labor for installation;
- bankable guarantees on membrane lifetime;
- for existing systems: Effect of the head loss at typical air throughput on blower power consumption and hence on AE.

Other Design Aspects

In applications that have low process oxygen demands (for example, the last aerated section in a MLE process), the air quantities required to supply oxygen may become so small that satisfactory mixing cannot be achieved by the aeration system alone. In these instances, checking the calculated air demands with the air throughputs required for mixing is recommended. Aeration rates of

0.6 to 0.9 m^3/h per m^3 tank volume are suggested (6) for a diffused air aeration system where the diffusers are evenly distributed across the tank floor. For line aeration systems that have a spiral roll liquid motion, the suggested aeration rates are higher at 1.2 to 1.8 m^3/h per m^3 tank volume.

Where diffusers have to be selected for an existing wastewater treatment plant, consideration should be given to conducting on-site trials to determine the alpha factor. If a rubber membrane system is being considered, tests should be conducted to determine the performance of various membrane materials over time.

CONCLUSIONS

Fine bubble diffused air aeration is successfully used on many wastewater treatment plants, regardless of their size. It can provide significant advantages over other aeration systems in energy efficiency. Two main types of diffused air aeration systems are known, rigid porous systems and membrane systems. Of these, the latter offer, by far, better turndown properties. However, rigid porous systems are used more often again due to the longer lifetime of the diffuser element and the lower life cycle cost often associated with that.

Notwithstanding the common use of fine bubble diffused air aeration systems, their successful use depends on choosing the right application and designing the aeration system properly. In some applications, for example, deep tanks or shallow tanks, alternative aeration systems are often to be preferred, as discussed earlier.

AIR STRIPPING

Jeff Kuo
Cerritos, California

Air stripping is a physical process that enhances volatilization of compounds from water by passing clean air through it. It is commonly used in treating groundwater contaminated with volatile organic compounds (VOCs) and in removing ammonia in wastewater.

An air stripping system creates air and water interfaces to enhance mass transfer of target compound(s) between the air and liquid phases. Several system configurations, including tray columns, spray systems, diffused aeration, and packed towers, are commercially available. Packed towers (also known as air strippers) are the most popular alternative for groundwater treatment.

A typical air stripper includes a liquid distribution system (e.g., a spray nozzle) at the top of the tower. It sprays influent water over the packing in the column. As the water trickles down, air enters the lower portion of the tower and is forced up through the column by a blower. Packing materials within the tower increase the surface area of the contaminated water that is exposed to air, thus maximizing the migration of VOCs from the liquid stream to the air stream. A sump at the bottom of the tower collects the decontaminated water. The exhaust from the top of the tower, which is commonly referred to as "off-gas," is either discharged to the atmosphere or directed to an off-gas treatment system.

The design of an air stripping system includes determining the diameter and height of the column, type and size of packing materials, air-to-water ratio, blower rating, and treatment of off-gas from the tower. The information needed for the design includes flow rates and quality of the influent water (contaminant concentrations, mineral content, pH, and temperature), quality of the influent air (temperature and contaminant concentrations), height restrictions on the tower; and restrictions on contaminant concentrations in the effluent water and air discharge from the tower.

Although air stripping is widely used to treat VOC-contaminated water, there are several limitations and concerns:

- Air stripping transfers only contaminants from water to air, and the contaminants are not destroyed. Consequently, treatment of the off-gas, which is laden with contaminants, is often necessary.
- Biological and inorganic fouling of packing may require pretreatment or periodic column cleaning.
- Air stripping is effective only for water contaminated by compounds of high vapor pressure and low solubility. Modifications of a conventional air stripping operation may be needed. The temperature of the influent liquid may need to be raised to increase the volatility of the target compound(s). For ammonia stripping, the pH of the water should be sufficiently high, in the range of 10.5 to 11.5, so that most of the ammonia is converted to a gas.
- The visual impacts associated with air strippers and the noise level of the air blower should also be considered. They are often viewed as nuisances when located in residential areas.

Removal efficiencies greater than 95% are typical for towers that have 4.6 to 6 meters (15 to 20 feet) of conventional packing and are removing compounds amenable to stripping, such as B/T/E/X, chloroethane, TCE, DCE, and PCE. When the height of the stripper may be a problem, alternatives such as installation of multiple columns in series, aeration tanks, or low-profile air strippers should be considered. Aeration tanks strip volatile compounds by bubbling air into a tank (diffused aeration) through which contaminated water flows, and their profiles are much lower. The low-profile stripper has a number of trays that are set almost horizontally. Water is cascaded over the trays to maximize air–water contact while minimizing vertical space. Equipment that can be added to the basic air stripper includes an air heater to improve removal efficiencies and automated control systems with sump level switches and safety features, such as differential pressure monitors, high sump level switches, and explosion-proof components.

LAND APPLICATIONS OF WASTEWATER IN ARID LANDS: THEORY AND CASE STUDIES

J.G. Mexal
D.S. Rodriguez
T. Sammis
G. Picchioni
W. Zachritz II
C. Erickson
Z. Samani
New Mexico State University
Las Cruces, New Mexico

Land application of wastewater is recommended by the Environmental Protection Agency as a method of recycling nutrients and organic matter while protecting freshwater resources (1). Wastewater has been applied to agronomic crops, rangelands, forests, and recreation areas, including parks and golf courses, and to disturbed lands such as mine spoils sites (2–5). Benefits from recycling wastewater include creating a supplemental irrigation source, thereby conserving drinking water, and reducing fertilizer costs because wastewater contains nitrogen and phosphorus (6). As wastewater moves through the soil profile, the soil and plants act as filters that trap and treat, through various mechanisms, waste particles and contaminants allowing the remaining water to drain through the soil profile (7,8). Wastewater provides an effective source of nutrients that vegetation roots can absorb and allow the plant to assimilate. The benefit of this system is both the effective remediation of wastes and the recycling of water, nutrients, and carbon via biomass production (4).

Previous studies have demonstrated the effectiveness of saline wastewater application to horticultural systems (9) and to agronomic crops such as cotton (*Gossypium hirsutum* L.), alfalfa (*Medicago sativa* L.), and cantaloupe (*Cucumis melo* L.) (10). Both studies have shown that plants take up and store salt ions in vegetative organs.

Conventional land application systems are accepted technology for many communities, but many communities lack the resources and infrastructure to support them. Any technology considered for implementation should have low capital input and low operating cost. The wastewater treatment system should also stimulate the local economy and be easy to maintain (11). Unfortunately, there is limited information to guide land managers in highly fragile arid and semiarid environments where wastewater may be the only source of supplemental irrigation.

A land application system design, as depicted in (Fig. 1), requires balancing the input of water required by plants against the amount of nitrogen that can be applied without adverse environmental impact (12,13). The wastewater application rate is governed by the total amount of nitrogen allowed to enter the groundwater. Typically, this is expressed as the amount of NO_3-N in the wastewater leached to the groundwater that cannot exceed 10 mg NO_3-N/L. Yearly water (Eq. 1) and nitrogen mass balance (Eq. 2) equations were used to develop the design criteria.

$$L_{w(p)} = \mathrm{PET} - P + W_p \tag{1}$$

where $L_{w(p)}$ = wastewater hydraulic loading rate (cm/mo);
PET = potential evapotranspiration rate (cm/mo);
P = precipitation rate (cm/mo);
W_p = design percolation rate (cm/mo);

$$L_{w(n)} = \frac{[C_p{}^*(\mathrm{P} - \mathrm{ET}) + (U^*4.4)]}{[(1 - \mathrm{f})^* C_n - C_p]} \tag{2}$$

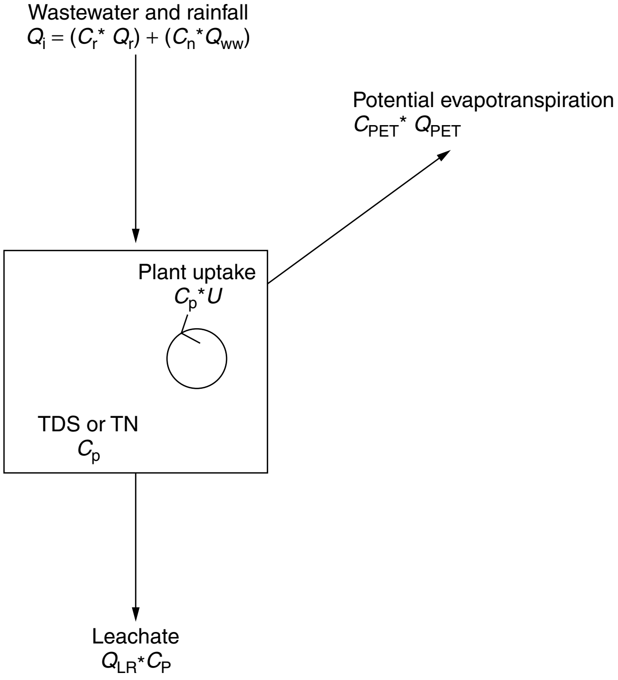

Figure 1. Mass flow diagram of the land application system with inputs, outputs, and process transformations where Q = flow; I = input; r = rainfall; ww = wastewater; LR = leachate; PET = potential evapotranspiration; C = Nitrogen concentration; r = rainfall; n = wastewater; p = percolating water; LR = leacheate; PET = potential evapotranspiration; U = Crop nitrogen uptake; TDS = Total dissolved solids; TN = Total nitrogen (12).

where $L_{w(n)}$ = allowable hydraulic loading rate (cm/yr);
ET = design PET rate (cm/yr);
P = design precipitation rate (cm/yr);
C_p = total nitrogen in percolating water (mg/L);
C_n = total nitrogen in applied wastewater (mg/L);
U = crop nitrogen uptake rate (kg/ha/yr); and
f = fraction of applied total nitrogen removed by denitrification and volatilization

Salt loading, soil salinity and its impact on plant survival and growth, must also be considered in plant selection. Salt loading is not incorporated into the design equations, but guidelines are provided in several sources (13,14). Most plants are intolerant to salt in the seedling stages than in more mature stages, so alternative sources of water may be required during the establishment period. When excess soluble salts accumulate in the rhizosphere, growth is reduced. Salt buildup can be controlled by applying additional irrigation water to leach salts below the root zone (15).

To use the limited amount and potentially saline wastewater, land managers must balance wastewater quality, crop water usage, nitrogen (fertilizer) requirements, and potential soil salinization. Crop coefficients can be calculated from local climate data to estimate evapotranspiration for particular crops from estimates of potential evapotranspiration (PET). Irrigation scheduling models have been developed for crop production in agronomic crops (16).

The following case studies explore the use of saline wastewater for pulpwood, nursery production, and wastewater treatment and disposal in arid regions (Table 1).

Ojinaga, Chihuahua, Mexico

Ojinaga, Chihuahua, Mexico is situated at the confluence of the Rio Grande and Rio Conchos on the U.S.–Mexican border (29.6°N 104.4°W). The climate of this part of the Chihuahuan Desert is arid; the annual rainfall is less than 250 mm, and approximately 75% of the rainfall occurs between June and October; annual potential evapotranspiration is 2450 mm. The maximum temperature is 50 °C, and the minimum temperature is −10 °C.

Municipal sewage is piped directly into an anaerobic lagoon, which acts as a settling pond for separating the solids from the waste stream and providing some reduction in waste strength. A 2-hectare (60,000 m^3) single-cell-anaerobic lagoon constructed in 1995 receives both industrial and municipal wastewater. Currently, one-half of the Ojinaga population is connected to the municipal wastewater system. According to Junta Municipal de Agua y Saneamiento (JMAS), the wastewater from Ojinaga is almost exclusively domestic. Industries in the area include a slaughterhouse and several cottage industries that contribute little in the way of metals or toxic organics. The contribution of the slaughterhouse wastewater is intermittent but high in organic waste. The influent is treated by a manual bar screen to remove large solids. Grit and materials that pass the bar screen are collected in the anaerobic cell by simple sedimentation with no active system for removing these materials. The single-stage anaerobic lagoon is designed to reduce biological oxygen demand (BOD), total suspended solids (TSS), and fecal coliform (FC) to some degree. Wastewater from this system flows to the land application unit for final treatment and disposal.

A pilot land application site (~1.1 ha total area) was established in April 1997 with black locust [*Robinia pseudoacacia* (L.)], clones of eucalyptus [*Eucalyptus camaldulensis* (Dehnh.)] and hybrid poplar [*Populus* (L.)]. Tree species selection was based on the criteria of drought tolerance, salt tolerance, and a short rotation cycle for wood fiber. Monitoring included wastewater effluent and groundwater quality characteristics, soils, and plant growth.

After 6 years, there was minimal overall impact on groundwater, no fecal coliform contamination or increase in NO_3-N, and about a 10% increase in salinity caused by high transpiration of the crop trees. The best tree species was *Eucalyptus* clone 4019. (Fig. 2). The growth rate exceeded the expected results and may allow harvesting on a 6-year rotation, which is 1 to 3 years faster than other studies with similar species. The advantages of commercial forestry include (1) providing a source of income and employment opportunities to the local economy, (2) improving abandoned saline agricultural lands, (3) maintaining irrigation district infrastructure, (4) diversifying the local economy, and (5) establishing an organization to produce wood fiber commercially. This endeavor could produce community-based jobs and have a positive cash flow for operation and maintenance. Ojinaga has been involved in master plan development for the past 3 years to develop a new treatment plant.

Table 1. Site Characteristics of Three Wastewater Use Studies

Parameter/Site	Ismailia, Egypt	Ojinaga, Mexico	Las Cruces, US
Soil type	Sand	Clay loam	Sand
Soil depth	10 m (to groundwater)	3 m (to groundwater)	3 m (to impervious layer)
Species	*Cupressus, Pinus*	*Populus, Eucalyptus*	*Larrea tridentata, Prosopis glandulosa*
Rotation	15–20 yr	6–7 yrs	n/a
Irrigation	Drip	Flood	Sprinkler
TDS	550	1950–2220	2500–3500
BOD	46	29–43	28
TKN	45	14–37	8–21

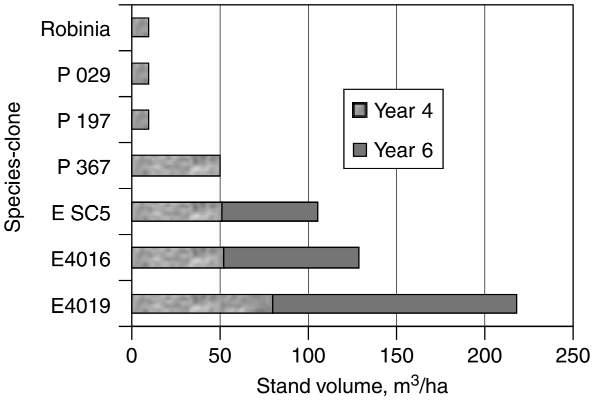

Figure 2. Ojinaga, Mexico, pulpwood stand volume 4 and 6 years after establishment.

Ismailia, Egypt

Ismailia, Egypt (30.60°N 32.29°E) built the Serrabium Wastewater Treatment Plant with Egypt and US AID support in 1995; it is operated by the Suez Canal Authority. The average mean temperature is 21.4 °C; monthly temperatures vary from 13.2 °C in January to 28.5 °C in July and August. Annual potential evapotranspiration rates are 2340 mm and annual precipitation is 25 mm. The treatment plant's designed capacity is 90,000 m^3/day, and the current flow is 80–85 thousand m^3/day. The amount of nitrogen in the wastewater is 45 mg/L, and groundwater depth is 10 m.

Pretreatment for the facility consists of three self-cleaning bar screens and two grit chambers. Flow is divided into two parallel treatment branches with three lagoons (aerated, facultative, and polishing lagoons) for each branch. The aerated lagoon has 20 aerators; 10 operate at any one time; the facultative lagoon has 10 aerators that are used only as needed to increase dissolved oxygen. The polishing lagoon is 3.5 m deep to facilitate the removal of fecal coliform bacteria and *Ascaris* eggs. The total detention time of the system is 11 days, designed to reduce BOD, TSS, *Ascaris* eggs, and fecal coliform bacteria.

The land application facility uses an area of 200 ha. The plants are drip irrigated with tertiary or secondary treated wastewater (90,000 m^3/day). The nursery at Serrabium Forest has a capacity to produce 100,000 seedlings/yr in polybags (12 × 15 cm) with a sand/clay/peat moss medium. Tree species produced are *Pinus pinea* (L.), *P. halepensis* (Mill.), *P. brutia* var. *eldarica* (Medv.), *Khaya senegalensis* (Desr.), *Cupressus arizonica* (Green), *C. sempervirens* (L.), *C. macrocarpa* (Hart.), *Morus alba* (L.), *Morus japonica* (Bail.), and *Cassia* sp. (L.). The wastewater is supplied to the site via an underground pipeline and is filtered through an in-line screen and then through several sand filters before it is delivered to the irrigation system.

There was no apparent soil layering or caliche development; however, root development appeared stunted in the upper 40 cm of the soil surface. Soils were saturated below the surface at the midpoint between trees indicating overapplication of wastewater and a potential risk of groundwater contamination. The stunted roots may have also resulted from the overirrigation of wastewater which may have contained some untreated dissolved organics which resulted in oxygen deficiency in the soil column.

Las Cruces, New Mexico, US

The study site located in Las Cruces, New Mexico, USA (32°18′ N, 106°55′ W) is semiarid the average rainfall is 220 mm, and approximately 50% of the annual rainfall occurs between July and September. The annual mean temperature is 15.8 °C, monthly temperatures vary from 5.5 °C in January to 26.6 °C in July. The potential evapotranspiration of the site is 1800 mm. The City of Las Cruces disposes of treated wastewater onto 36 ha of native Chihuahuan Desert vegetation including creosote bush *Larrea tridentata* (DC.) Cov. mesquite *Prosopis glandulosa* (Torr.) and annual and perennial forbs and grasses. The treatment plant designed capacity is 1500 m^3/day; current flows are 200 m^3/day applied to the 36-ha site.

The wastewater originates from tenants in an industrial park involved in dairy processing and metal wire fabrication. The total salinity (TDS) has reached as much as 4000 mg/L and is comprised mostly of sodium and chloride. (Fig. 3). The total nitrogen applied to the research application site in 2002 was 43.9 kg/ha. The wastewater

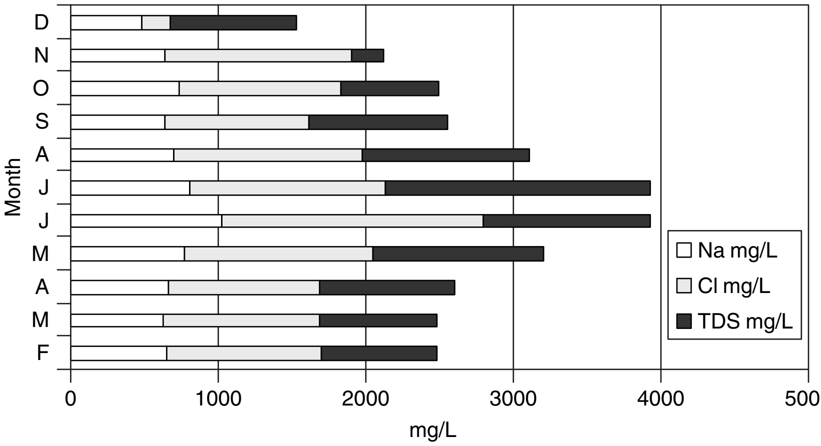

Figure 3. Las Cruces, NM, Effluent characteristics during first year of wastewater application.

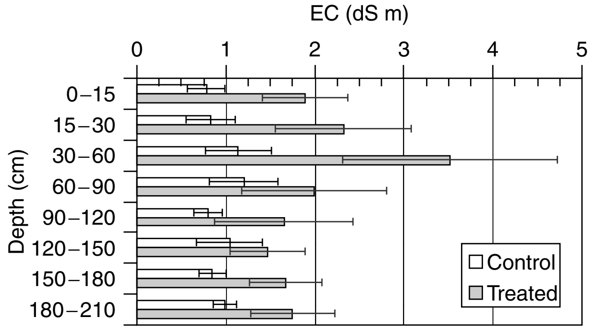

Figure 4. Electrical conductivity of soil vs. depth after 64 cm of wastewater application.

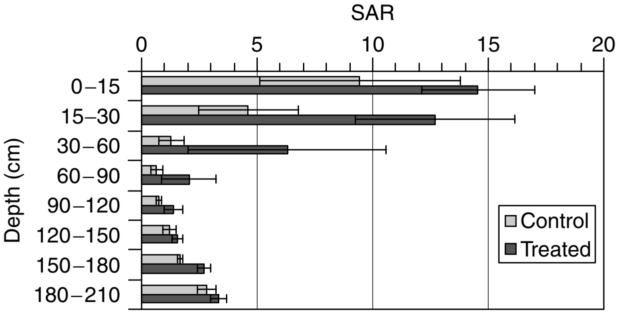

Figure 5. Sodicity measurements on soil after 64 cm of wastewater application.

is sent to a treatment train and then into aerated lagoons with a complete mix basin that has a fixed floor fine bubble diffuser system and a settling basin. The wastewater is then sent to a final holding pond before being land applied through a fixed head sprinkler system. After 64 cm of wastewater application during a growing season, there was an increase in soil salinity. Electrical conductivity (EC) peaked at 3.25 dS/m in the 30–60 cm sampling depth (Fig. 4). The sodium adsorption ratio (SAR) increased to a potential sodium hazard in the top 15 cm (Fig. 5). After 1 year, wastewater effectively deposited the salt ions in the top 60 cm; little or no salt accumulated in the lower depths. Further application will further deposit the salts beyond the root zone and limit growth reduction of the vegetation.

CONCLUSION

These wastewater land application case studies are located in arid regions that have minimal precipitation and high evapotranspiration. The applied water must be balanced against the needs of the plant and salt and nitrogen loading to ensure the development of a sustainable system. Therefore, the applied wastewater must meet the plant's water use needs. When seasonal plant demands are lower in the winter months, the wastewater must be applied at depths to prevent soil salinity increases in the rhizosphere. These interactions must be resolved through proper plant selection, site characteristic considerations, and water quality. The goals of the system in terms of the final product need to be incorporated into the process. These systems can be privately or publicly owned, but infrastructure and community support must be developed in advance and are essential to a project's success.

TECHNOLOGIES FOR ARSENIC REMOVAL FROM CONTAMINATED WATER SOURCES

I. Katsoyiannis
A. Zouboulis
Aristotle University of Thessaloniki
Thessaloniki, Greece

The majority of established arsenic removal technologies can be divided into three main categories, depending on the specific mechanism that is responsible for removing arsenic. These categories are usually referred as coagulation–precipitation, membrane, and sorption processes.

COAGULATION–PRECIPITATION PROCESSES

Three processes in this group have been developed for arsenic removal; aluminum or iron coagulation, lime softening, as well as a combination of iron and manganese removal with arsenic.

Coagulation Using Aluminum or Iron Salts

The coagulation/filtration process is considered a common water treatment technology, used to remove suspended, colloidal, and dissolved constituents from water sources or from wastewater. The coagulation process promotes the aggregation of suspended solids to form larger flocs, which can be subsequently separated/removed by sedimentation (settling) and/or filtration. Coagulation consists of three steps; coagulant addition and hydrolysis, particle destabilization, and interparticle collisions (floc growth). The first two steps, coagulant formation and particle destabilization, occur during initial rapid mixing, whereas the third step takes place during the following slow mixing, which enhances the flocculation of solids.

Aluminum (III) and iron (III) salts, such as aluminum sulfate (usually referred to as alum) or ferric chloride, are the most common coagulant reagents, used in water treatment (drinking or wastewater). Coagulation by aluminum or iron (III) salts, or a combination of them, such as the mixed sulfate salt, can also be used to remove dissolved inorganic contaminants such as arsenic from drinking water. The two primary mechanisms for removing dissolved inorganic contaminants are adsorption and occlusion. During adsorption, the dissolved contaminant attaches to the surface of a particle or precipitate. Occlusion occurs when the dissolved contaminant is adsorbed to a particle and then entrapped, as the particles continue to agglomerate. Several factors affect the efficiency of the coagulation process: coagulant dosage, pH, turbidity, natural organic matter, the presence of other anions or cations in the solution to be treated, the zeta potential of the system, and the temperature.

Most of the studies of arsenic removal have focused on As(V) treatment because As(V) can be removed more effectively than As(III) due to its speciation in aqueous solutions (i.e., the formation of dissociated/charged species). Furthermore, As(III) can be rather easily oxidized to As(V) by using a strong oxidant, such as chlorine. Ferric and alum salts are almost equally effective in removing arsenic on a molar basis, but when compared on a weight basis, ferric salts proved more effective than aluminum salts. These results occur because the iron hydroxides produced by the hydrolysis of ferric salts are less soluble than the respective aluminum hydroxides over a wide pH range. As(V) removal proved pH-independent in the pH range from 5.5–8.5, when coagulation took place from the addition of iron salts. When aluminum salts were used, arsenic removal decreased above pH 7. As(V) removal was independent of the initial arsenic concentration in the range of interest for drinking water treatment, and it correlated directly with coagulant dosage (1–3).

Lime Softening

Lime softening is commonly used for removing hardness from water. Hardness is due primarily to dissolved calcium and magnesium species. The addition of lime provides the necessary hydroxide ions, which increase the pH of water, resulting in calcium and magnesium removal by the formation of insoluble $CaCO_3$ and $Mg(OH)_2$ precipitates. Lime softening has also been applied successfully to remove heavy metals, radionuclides, dissolved organics, and viruses by adsorption and occlusion within the calcium carbonate and magnesium hydroxide produced. The typical lime softening treatment process train includes initial rapid mixing of lime, followed by flocculation of solids and separation by sedimentation (settling). These three steps are usually combined in one single unit, called a solids-contact softener. Filtration is usually used for subsequent treatment of the supernatant. Lime or a lime–soda mixture is used for softening, whereas the selection between them depends primarily on the specific type of hardness.

Relatively few studies have been conducted to evaluate the removal of arsenic during lime softening, indicating that arsenic removal is strongly pH-dependent. Removal of both As(III) and As(V) species is relatively small at pH values lower than 10. However, at a pH over 10.5, As(V) removal can reach almost 100%, whereas the removal of As(III) is about 75%. The presence of orthophosphates, as well as of carbonates, could limit the removal of arsenates by $Mg(OH)_2$ precipitates. If manganese is also present in the source water, some additional arsenic removal could be achieved through sorption onto the $Mn(OH)_2$ precipitate, although the formation of $Mn_3(AsO_4)_2$ solid was not considered a major mechanism. The initial arsenate concentration does not seem to affect the efficiency of the method in the range from 5–75 μg/L (2,3).

Combined Removal of Arsenic by Iron and Manganese

A number of processes, which are used to remove soluble iron and manganese cations from contaminated groundwater, involve oxidizing these ions, transforming them to the respective insoluble hydroxides, which can be further separated by sedimentation or filtration. Either iron or manganese ions can be oxidized by using a strong chemical reagent (oxidant), such as chlorine (4). Another way to oxidize iron and manganese cations is by biological

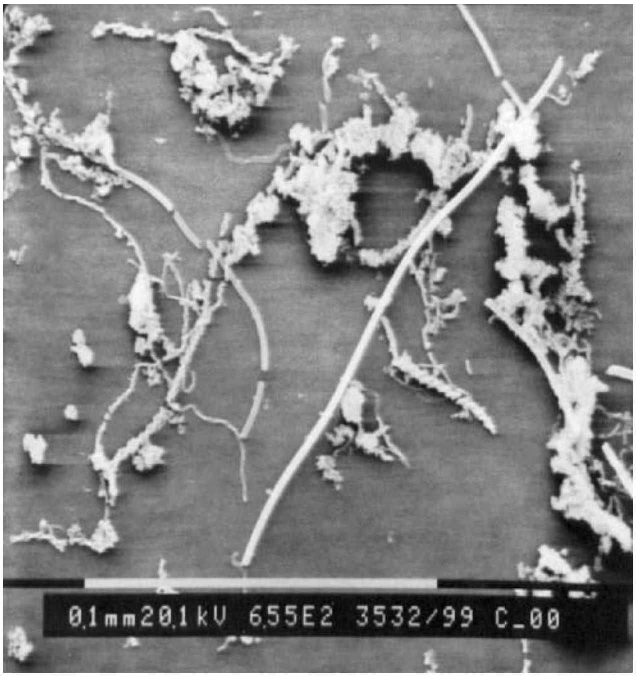

Figure 1. Common iron oxidizing bacteria of the *Gallionella* and *Leptothrix* genera.

oxidation, using so-called “iron oxidizing bacteria”; these facultative bacteria are indigenous to most groundwater (Fig. 1). Biological oxidation involves only preliminary aeration of groundwater to allow bacterial growth and then, the bacteria effectively oxidize iron and manganese to their insoluble hydroxides (5).

In both oxidation cases (chemical and biological), arsenic in the water can be subsequently sorbed onto the iron and manganese hydroxides formed (6). The following major steps have been suggested during iron and manganese oxidation, when used for simultaneous removal of arsenic:

(1) Indigenous “iron oxidizing bacteria” are colonized and immobilized on appropriate inert surfaces (filter media), such as granular sand or polymer beads, forming biofilm deposits and provoking the oxidation of soluble iron and manganese cations that form the respective insoluble precipitates.
(2) The precipitates are subsequently separated from the water by filtration.
(3) Arsenic attaches mainly to the iron hydroxides removed and to manganese oxides by adsorption and/or coprecipitation.

In this method, the initial concentration of iron seems to be critical because the efficiency of arsenic removal is increased by increasing the iron concentration (7). The initial concentration of arsenic does not affect the effectiveness of the method. During the application of biological oxidation for removing iron and manganese, the linear velocity does not affect arsenic removal up to 20–22 m/h (8). A typical biological iron removal (pilot-scale) plant is presented in Fig. 2.

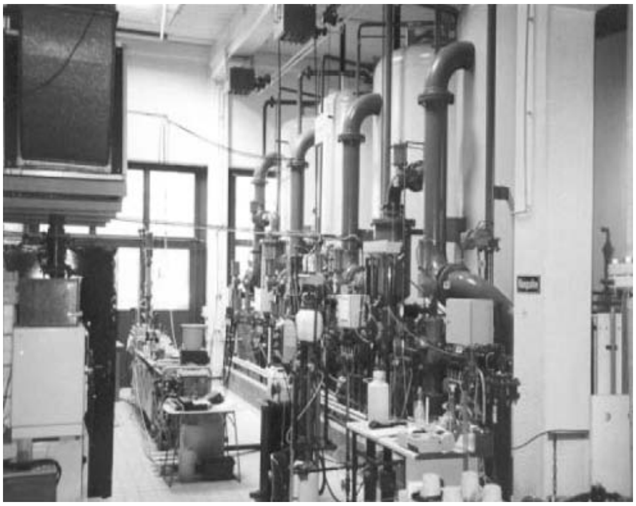

Figure 2. Pilot plant unit, which was used for the biological oxidation and removal of iron and manganese (Umweltbundesamt, Institute for Hygiene of Water, Soil and Air, Berlin, Germany).

MEMBRANE PROCESSES

Two types of membrane processes remove arsenic efficiently from water sources: reverse osmosis and electrodialysis.

Reverse Osmosis

Two types of reverse osmosis units are used for arsenic removal: nanofiltration and hyperfiltration (Fig. 3).

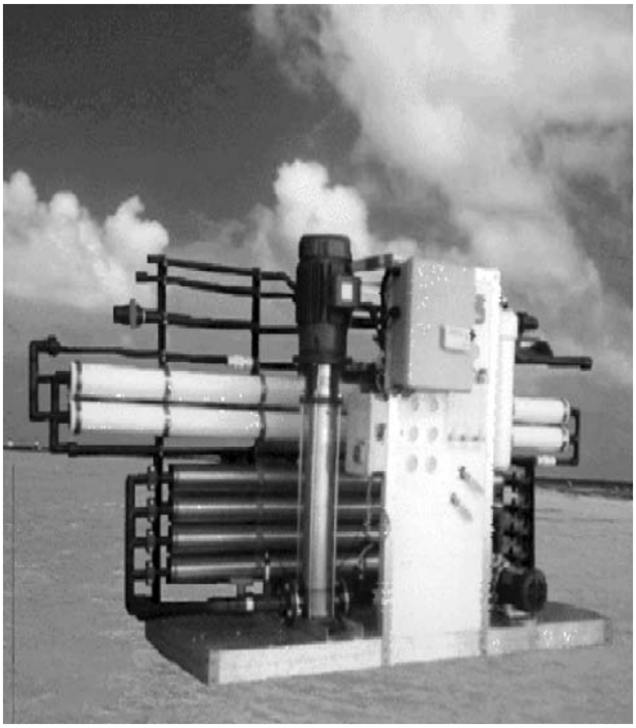

Figure 3. Typical commercial reverse osmosis unit used for drinking water treatment.

Nanofiltration is a relatively lower pressure reverse osmosis process that removes primarily the larger dissolved solids, compared to hyperfiltration. Nanofiltration is also known as a membranous softener because it removes divalent calcium and magnesium cations from water, which cause water hardness. Nanofiltration can also remove sulfates, as well as monovalent dissolved solids, such as chlorides and sodium.

Conversely, hyperfiltration operates at higher pressures, resulting in greater removal of all dissolved solids. A typical example of hyperfiltration is seawater desalination.

Nanofiltration and hyperfiltration are both effective for removing As(V), and the respective efficiencies are up to 95%, but when As(III) is present, a preoxidation step is usually required because As(III) removal efficiencies reportedly reach only 80%. The chemical reagents used to oxidize As(III), such as chlorine, are rather harmful to membranes, which is a major disadvantage of this oxidation method. Furthermore, reverse osmosis rejects/removes simultaneously large amounts of water, the desired product, which is another consideration for drinking water treatment applications (3).

Electrodialysis

Electrodialysis is another type of membrane process, using the passage of direct electric current through the aqueous solution to be treated and appropriate electrodes. Although the main applications of this method are to treat brackish waters, it can be also used for drinking water treatment. Dissolved solids exist as cations (positively charged, such as calcium and magnesium) and anions (negatively charged, such as sulfates and arsenic), so the cations can be moved toward the negatively charged electrode, and the anions to the positively charged electrode. The respective cell is divided into chambers, using specific ion exchange membranes that allow the selective passage of only cations or anions.

The problems in reverse osmosis also exist for electrodialysis. Strong oxidizing agents are usually harmful to the membranes. Large amounts of water are also rejected, eliminating the efficiency of the method. However, there has been little research on arsenic removal by electrodialysis (3).

ADSORPTION PROCESSES

Adsorption processes are another category of arsenic removal technologies; they are based on the adsorption of arsenic onto suitable adsorbing media. Two different technologies have been applied to remove arsenic, activated alumina and ion exchange.

Activated Alumina

Sorption onto activated alumina is considered mainly a physical (and to a lesser extent chemical) process, by which ions are removed from aqueous solutions by available adsorption sites on the surface of aluminum oxide. Activated alumina, usually prepared by dehydrating $Al(OH)_3$ at high temperatures, consists of amorphous and γ-aluminum oxide (Al_2O_3), usually placed in columns. Activated alumina removes arsenic in a number of cases. Although the process has not been yet fully characterized, it is believed that arsenic is adsorbed onto the surface of activated alumina mainly by electrostatic forces. A number of parameters affect the removal efficiency of this treatment method, such as arsenic oxidation state (i.e., tri- or pentavalent), the pH, the presence of other competitive anions, as well as the empty bed contact time (EBCT), which is the main operational/modeling parameter for column operation.

Similarly to the other previously presented treatment methods, As(V) can be removed more effectively than As(III), and the breakthrough point of 0.05 mg/L (the previous concentration limit for arsenic in drinking water) is reached after the treating 300 bed volumes (BV) for As(III), whereas for As(V) after 23,400 BV. The pH also affects the removal of arsenic significantly. Anions are better adsorbed below a pH of 8.2, which is the typical point-of zero charge for activated alumina. Below this value, the surface of activated alumina holds a positive charge, which can be balanced by adsorbing anions, such as arsenates. Several studies showed that As(V) removal is independent of pH in the range between 5.5 and 6. As(III) removal in that pH range is not equally efficient because As(III) is present as nonionic (molecular) arsenious acid (H_3AsO_3).

The presence of other competitive anions, such as phosphates and carbonates, can also affect the method's efficiency for arsenic removal because activated alumina has specific preferences for certain ions. Finally, the correlation between EBCT and arsenic removal is linear, and therefore, as EBCT is increased, the efficiency of arsenic removal is also increased (9,10).

Ion Exchange

Ion exchange is a physical/chemical process, by which ions held electrostatically on the surface of an appropriate solid phase can be exchanged with ions of similar charge from an aqueous solution. The solid phase is typically a synthetic ion exchange resin placed in columns and used preferably to remove particular contaminants of concern; certain natural products, such as zeolite, have been also used occasionally. Ion exchange is commonly used in drinking water treatment to remove hardness from water sources and also to remove nitrate, arsenate, chromate, and selenate anions from municipal water. Anion exchange resins are available in two main types, strong-base resin (SBA) and weak-base resin (WBA). Typically, SBA resins are used for arsenic removal because they tend to be more effective over a wider pH range than WBA resins.

Ion exchange does not remove As(III) because it occurs predominantly as uncharged species (H_3AsO_3) at the usual pH of most water sources. On the other hand, As(V) is negatively charged, and thus, it can be removed by appropriate ion exchange resins. When all the available sites on the resin have been exhausted, the bed can be regenerated by the passage of brine solution (chloride exchange).

The efficiency of the ion exchange process for arsenic removal is strongly affected by the presence of other competitive ions, such as total dissolved solids and sulfates. Other factors affecting the operating efficiency of the ion exchange process are the empty bed contact time, and the disposal of spent regenerant solutions (10).

Adsorptive Filtration Using Iron Oxide Coated Sand

This technology, relatively new in water treatment, is based on the adsorption of cationic metals and/or oxyanions onto the surface of iron oxide, and the particulate matter is simultaneously filtered from the water. Iron oxides form coatings on the surfaces of appropriate granular filter media placed in tanks or in columns, such as sand; subsequently, the modified material can act together as a filter and as an adsorber.

To remove oxyanions from contaminated water, the pH has to be adjusted below 7.2, which is the typical point-of-zero charge of iron oxides. Below this value, iron oxides are positively charged and can remove arsenic effectively. In this technology, As(V) is also treated more efficiently than As(III), because as discussed previously, As(III) is present as an uncharged species, up to pH 8. Above pH 8, As(III) starts to form anionic species, but iron oxides are also negatively charged at these high pH values; thus they cannot interact. Another crucial parameter for column operation is empty bed contact time. By increasing the respective contact time, arsenic removal is also increased. The initial arsenic concentration does not affect the efficiency of the method (11).

OXIDATION OF AS(III)

Arsenic can be removed from water by several technologies, but most of these techniques cannot remove As(III) effectively due to its speciation in water. Therefore, an oxidation step is usually required to transform As(III) into As(V). Oxygen is the preferred oxidant because using it avoids problems that other chemicals present, but the oxidation of arsenic by dissolved oxygen is very slow and therefore, cannot be effectively used. The most feasible oxidants today for arsenic removal are potassium permanganate and Fenton's reagent (a mixture of H_2O_2/Fe^{2+}). Chlorine or hypochlorites have also been used as oxidants of trivalent arsenic. Other techniques are UV irradiation and the use of ozone (9).

BIOCHEMICAL OXYGEN DEMAND

Michael A. Butkus
Joe D. Manous, Jr.
United States Military Academy
West Point, New York

BIOCHEMICAL OXYGEN DEMAND IN NATURAL AND ENGINEERED SYSTEMS

A vast number of organisms, primarily bacteria, survives and even thrives in an environment containing no oxygen. However, most living creatures with which we commonly interact are aerobic; they need oxygen to survive. Aerobic creatures include all of the higher life forms, such as fish, birds, mammals, and reptiles, as well as simpler species such as some bacteria and protozoa. The 4.7 billion year development of the earth and the evolution of species in response to this development have created many types of ecosystems; most support a balance between the demands of aerobic organisms for oxygen and the availability of oxygen. These "balanced ecosystems" are found in aquatic, terrestrial, and atmospheric biomes.

In a natural aquatic system, a large number of aerobic organisms exists. Interestingly, the higher life forms, fish, mammals, and shellfish, do not normally place a large oxygen demand on an aquatic system. Bacteria, and in particular those bacteria that decompose organic material, such as dead aquatic vegetation, for example, algae, can create a high oxygen demand due to the sheer number of organisms that reproduce in a short period of time. Aquatic bacteria that decompose organic material are endemic in the environment. Their populations are typically balanced by the natural system, and the available oxygen is generally sufficient; but human influences can upset this balance. The primary anthropogenic (human) sources of organic material in aquatic systems are sewage and other waste stream discharges. This increase in "food" can stimulate the growth of bacteria and can cause oxygen consumption at a rate greater than can be resupplied naturally. In addition to organic material, waste stream discharges along with overland runoff from agricultural fertilizers can increase the concentration of nutrients such as nitrogen and phosphorus in an aquatic system. This increased nutrient availability can stimulate the growth of aquatic vegetation, especially algae. When this vegetation dies, it serves as a source of organic material and stimulates aerobic bacterial growth and a corresponding oxygen demand. This process is called cultural eutrophication.

Certain chemical compounds (organic and inorganic) can also exert a demand for oxygen if the resulting combination of the chemical compound and oxygen forms a thermodynamically favorable spontaneous reaction. The *combined* biological and chemical requirement for oxygen in a waterbody is termed the biochemical oxygen demand (BOD). Material that makes up BOD can be either in dissolved or particulate (solid) form.

Whether BOD is considered a problem depends on two factors: the magnitude of the oxygen demand and the rate at which oxygen is resupplied to the water. The primary oxygen source in all natural waterbodies is the diffusion of molecular oxygen, O_2, from the atmosphere into water. This transfer of oxygen is limited by the solubility of oxygen in water (see Henry's law) and physical movement of oxygen molecules across the air–water boundary at the water surface.

MICROBIAL GROWTH

The life cycle for bacteria may only last a few days to weeks, but the growth rate can be rapid in response to the availability of some limiting factor. This rate of growth can be described, based on the growth factor that is in shortest supply, by using the empirical Monod model as follows:

$$\frac{dX}{dt} = \frac{\mu_m S X}{K_s + S} - k_d X \tag{1}$$

where X = concentration of biomass (mass/volume)
t = time
K_s = half saturation (limiting factor) constant (mass/volume)
k_d = endogenous decay (death) rate constant (time^{-1})
S = concentration of limiting factor (mass/volume)
μ_m = maximum growth rate of the organisms (time^{-1})

Limiting factors include an energy source (organic or inorganic), a carbon source to build new cell material, and nutrients.

MICROBIAL ENERGETICS

Microorganisms require a source of energy, a source of carbon, and nutrients to grow and reproduce. Microorganisms commonly obtain energy for metabolism via reduction—oxidation (redox) reactions. Redox reactions involve the transfer of an electron from a reduced compound to an oxidized compound. All complete redox reactions must contain a compound that becomes oxidized (loses an electron) and a compound that becomes reduced (gains an electron.) To gain energy, microorganisms oxidize a compound, which is called the "electron donor" because it loses an electron. The electron donor is also referred to as "food." Because electron transfer requires a complete electrical circuit, an electron acceptor is required to complete the transfer. The molecule that receives an electron is called the terminal electron acceptor (TEA).

Electron donors often consist of organic material found in sewage or natural systems, for example, dead aquatic vegetation. These highly reduced compounds contain more electrons and have a higher standard free energy than oxidized compounds that serve as TEAs (1). Inorganic compounds, such as ammonia and ferrous iron, can also serve as electron donors. The concentration of electron donor material in waste is sometimes referred to as the "strength" of the waste.

When oxygen is present in a particular system, it is commonly the preferred TEA over other oxidized compounds, such as nitrate and sulfate, because it is a stronger oxidizer. The chemical reduction half-reaction for molecular oxygen in aquatic systems can be summarized as follows:

$$2e^- + 2H^+ + \tfrac{1}{2}O_2 \longrightarrow H_2O \tag{2}$$

This "consumption" of 1/2 mole of O_2 for every two electrons transferred from an electron donor is the source of the oxygen demand exerted on a system and often the cause of oxygen depletion in waterbodies that contain sewage or other waste discharges. Organisms that use oxygen as a TEA are called aerobic.

MICROBIAL COMPOSITION

In addition to using oxygen as a TEA, microbes also use oxygen as a nutrient. In this case, oxygen is incorporated directly into the cell structure. The microbial cell structure is commonly modeled as follows: $C_5H_7O_2N$ (1). Thus, two moles of oxygen are consumed for every mole of cells produced.

Reaction Kinetics

In a natural or engineered system, there are typically numerous chemical and biological reactions that consume oxygen. Consequently, it is difficult to estimate oxygen demand based on stoichiometry or a biological assay. One method for estimating the quantity of oxygen-demanding material in a waste is to make a gross measurement of the quantity of oxygen consumed by the waste via chemical and biological reactions. For domestic sewage and many natural systems, the gross rate of oxygen consumption over time (sum of chemical and biological reactions) is commonly modeled as the following first-order reaction:

$$\frac{d(\text{DO})}{dt} = -k\text{DO} \tag{3}$$

where DO = dissolved oxygen concentration (mass/volume, e.g., mg/L)
t = time
k = reaction rate (oxygen consumption rate) constant (time^{-1})

For a closed system, Eq. 3 can be integrated from time 0 to t, which yields the following:

$$\mathrm{DO}(t) = \mathrm{DO}_0 e^{-kt} \quad (4)$$

where $\mathrm{DO}(t)$ = the dissolved oxygen concentration at a particular time (mass/volume)
DO_0 = the initial dissolved oxygen concentration (mass/volume)

This relationship is illustrated in Fig. 1, which indicates that there is an exponential decline in oxygen over time.

Similarly, the biochemical oxygen demand, BOD(t), at any time t can be defined as the quantity of oxygen *consumed* up to a given time (t) via chemical and biological reactions:

$$\mathrm{BOD}(t) = \mathrm{BOD}_{\mathrm{ult}}(1 - e^{-kt}) \quad (5)$$

where $\mathrm{BOD}_{\mathrm{ult}}$ = maximum or ultimate demand for oxygen that can be exerted under given conditions (mass/volume)

As illustrated in Fig. 2, BOD(t) increases exponentially over time until $\mathrm{BOD}_{\mathrm{ult}}$ is reached.

Many compounding factors influence BOD, but a significant environmental condition is the temperature of the system. Standard methods have been established for sampling and measuring BOD for comparison and analysis, but a temperature correction is typically required to correlate these laboratory results with field conditions. The correction is determined by using the relationship presented as Eq. 6 (see Ref. 2) and is applied to k (reaction rate constant). This correction is empirical and accounts for changes in both chemical and biological components of the reaction rate constant:

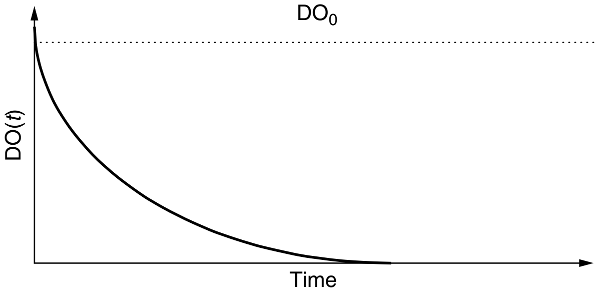

Figure 1. Change in dissolved oxygen with time.

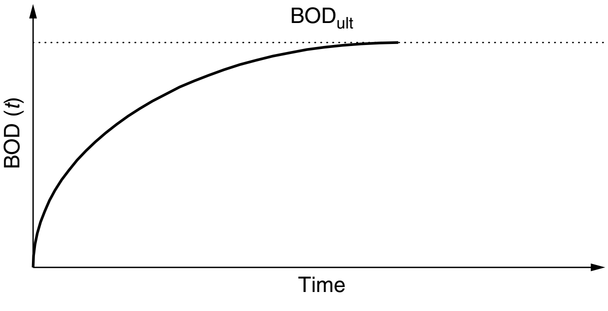

Figure 2. Exertion of BOD in a system.

$$k_{\mathrm{temp}} = k_{20}\theta^{(T-20)} \quad (6)$$

where k_{20} = reaction rate constant at 20 °C
T = temperature (°C)
$\theta = 1.135$ when $4\,^\circ\mathrm{C} \leq T \leq 20\,^\circ\mathrm{C}$ (3)

MEASUREMENT OF BOD

The BOD test is one method for quantifying the concentration of oxygen-demanding material in a waste. In this test, the quantity of oxygen consumed by the waste over a period of 5 days is measured. This measurement includes all viable oxygen-consuming chemical and biological reactions. The standard procedures for BOD measurement are detailed in *Standard Methods for the Examination of Water and Wastewater* (4). The basis of the Standard Methods procedure is measurement of the change in dissolved oxygen concentration in a standard size container after 5 days of incubation under a set of standard environmental conditions (i.e., sealed from the atmosphere, 20 °C, dark conditions). The resulting change in DO is related to the total biochemical oxygen demand of the waste. If the "strength" of the waste is high (high BOD), the standard sample may consume all available oxygen in the sealed sample before the end of the incubation period and yield inconclusive results. In such cases, the sample water is diluted with aerated water to ensure that a nonzero value of DO is measured at the end of the 5-day incubation. The BOD experiment is illustrated in Fig. 3. The water is aerated to saturate it with oxygen (see Henry's law for a discussion of saturation). A seed (freeze-dried microorganisms) can be added to ensure that sufficient microorganisms are present to consume the waste (electron donor). If used, a seed will place an additional oxygen demand on the sample, which must also be considered.

The samples are placed in an incubator at 20 °C for 5 days and are shielded from sunlight to minimize the influence of photosynthesis on the dissolved oxygen concentration. The following relationship is used to

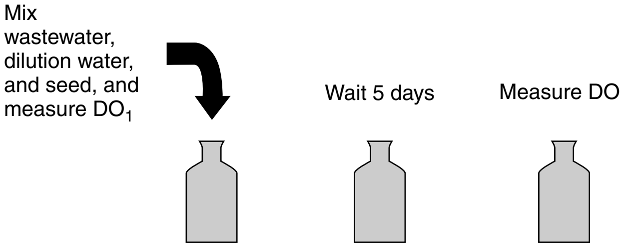

Figure 3. BOD experiment.

calculate the BOD (5) of a sample in which no seed is added:

$$\text{BOD} = \frac{(\text{DO}_1 - \text{DO}_2)}{P} \tag{7}$$

where

$$P = \frac{V_{\text{waste}}}{V_{\text{waste}} + V_{\text{dilution}}}$$

DO_1 = dissolved oxygen concentration of waste/dilution mixture immediately after preparation (mass/volume)
DO_2 = dissolved oxygen concentration of waste/dilution mixture immediately after a 5-day incubation (mass/volume)
V = volume

The BOD (4) is typically less than BOD_{ult} for most wastewaters. However, the BOD (4) is typically used for water quality standards and engineering designs. The total demand for oxygen (BOD_{ult}) by the water body can be determined from the BOD (5) measurement using Eq. 5 and t equal to 5 days.

CONTROL STRATEGIES

For centuries, rivers and lakes have been used as receptacles for human waste. These wastes are major sources of organic material, which can stimulate the growth of aerobic bacteria. In addition, waste streams can contain reduced chemical compounds that react with dissolved oxygen. Contrary to popular belief, the primary purpose of sewage treatment is not to rid the waste of harmful pathogens (though an important side benefit), but to ensure that the carbon and sometimes the nutrient contribution of the sewage to the receiving waterbody does not create a situation where lack of oxygen becomes limiting to aquatic life.

The most common Environmental Protection Agency (EPA) approved control strategy is removal of oxygen-demanding material from waste streams before the discharge enters a natural watercourse. Solid organic material is removed by settling processes (primary treatment), and dissolved organic material is removed through accelerated biological activity (secondary treatment). In secondary treatment, bacteria that are commonly present in domestic waste are provided with sufficient oxygen (a process called aeration) to consume dissolved organic material. In addition, as the organisms reproduce, additional dissolved organic material in the waste is converted into biomass, which is then separated (typically by gravity settling) from the water.

Following secondary treatment, various biological and chemical techniques can be employed (tertiary treatment) to remove additional "contaminants" such as nitrogen, phosphorous, and heavy metals. Primary and secondary treatment of municipal wastewater is required by law in the United States. The requirement for tertiary treatment is determined, case-by-case, based on a combination of total contaminant being discharged in the waste stream and the receiving waterbody's ability to assimilate the contaminant.

MOLECULAR BIOLOGY TOOLS FOR MONITORING BIODIVERSITY IN WASTEWATER TREATMENT PLANTS

INTRODUCTION

The group of organisms most directly associated with wastewater treatment is bacteria. They dominate all other groups, both in numbers and biomass, and lead to mineralization and elimination of organic and inorganic compounds (1). Therefore, it seems a natural progression to study the biodiversity and ecology of these organisms in relation to wastewater treatment.

In recent years, molecular methods have been used to study microbial community structure and function due to the revelation that the majority of microbes in the environment are unculturable on standard laboratory agars and conditions (2). It is thought that the percentage of culturable organisms is in the range of 1–10% of the total community; the figure for the number of bacteria described so far is thought to be approximately 1% (3). Taking this into consideration, the use of molecular methods has provided a far more objective and unbiased picture of the total community in wastewater systems.

The methods available can be used in various ways to provide separate pieces of information. Some are used to give a profile of the total community at the site, whereas others identify the organisms performing a specific function. Another set of methods focuses on fluorescent probing of specific whole cells. More recently, new technologies have emerged, which are substrate based, labeling organisms according to their catabolic potential.

COMMUNITY PROFILING METHODS

Community profiling methods produce rapid surveys, which provide us with a phylogenetic profile of the microbial population at a particular site. The speed of application and specificity of these techniques can be used to assess the community composition across space, through time, down pollution gradients, and under various treatments.

Methodologies that provide "molecular fingerprints" are most commonly based on polymerase chain reaction (PCR) amplification of 16S rRNA genes. The 16S rRNA gene is essential as it encodes for a subunit of the prokaryotic ribosome, and therefore is present in all prokaryotic life forms. The equivalent gene in all eukaryotes is the 18S rRNA gene. The gene contains variable regions, which allow identifying organisms down to various taxonomic levels. Fingerprinting studies can also be carried out by amplifying particular functional genes and subsequently analyzing the evolution and phylogeny of enzymes of particular interest.

Denaturing Gradient Gel Elecrophoresis

Denaturing gradient gel electrophoresis (DGGE) has been used successfully in many investigations of community structure. It is now one of the most widespread and well-established methods used in obtaining culture independent microbial profiles.

DGGE is based on analytical separation of DNA fragments of identical or near-identical length based on their sequence composition (4). Separation is based on the changing electrophoretic mobilities of DNA fragments migrating in a gel containing a linearly increasing gradient of DNA denaturants. Changes in fragment mobility are associated with partial melting of the dsDNA in discrete regions, the so-called melting domains. Each band shown on the gel represents a taxonomic unit in the environment, and the band intensity can be associated with the species' abundance within it. Once the gel has been visualized, it is also possible to cut out bands directly for sequencing.

The methodology derives from one used in the medical sciences (4) and was subsequently modified for microbial community analyses (5), where the procedure is performed on the total community nucleic acid. An example of a DGGE gel is shown in Fig. 1 (6). The communities shown were extracted from various points of a diesel-contaminated groundwater remediation system.

DGGE is an efficient and inexpensive method of analyzing a community structure and diversity. It also allows higher phylogenetic resolution than many other community analysis methods. Furthermore, one has an advantage in being able to excise bands for sequencing. The only drawback of the method is that only sample sets of up to 50 can be analyzed on one gel, as gel-to-gel comparisons can be difficult.

Length Heterogeneity PCR

More recently, other methods have become available, such as length heterogeneity PCR (LH-PCR); (7). LH-PCR works by exploiting the natural variation in length of the 16S rDNA gene due to group-specific "variable regions" of microbial community members (8). The PCR is carried out using one fluorescently labeled primer, and the amplicons lengths are then separated on a sequencer, where the resultant peaks, comparable with DGGE gel bands, represent various phylogenetic groups. An example of an LH-PCR output can be seen in Fig. 1, where peaks shown represent various phylogenetic groups in a community in a diesel-contaminated groundwater sample.

LH-PCR is reliable for determining the identity of organisms down to class/subclass level and allows processing large sample sets where samples are directly comparable due to an internal size standard run on the sequencer. One drawback of LH-PCR is that organisms can be effectively identified down only to class/subclass level and single peaks may represent multiple bacterial genera within the same taxonomic subclass (e.g., γ-*Proteobacteria*). LH-PCR is especially suitable for tracking known community members through time or during different treatments. In time, this method will become more reliable when the databases available for various environmental samples are improved.

Terminal Restriction Fragment Length Polymorphism (tRFLP)

tRFLP has been used as a reliable community profiling technique by sizing variable length restriction fragment digest patterns of amplified 16S rDNA (9). The method is similar to LH-PCR but involves an endonuclease restriction step and gives a higher phylogenetic resolution based on the specific sequence variance within the 16S rRNA gene.

tRFLP is reliable for determining the identity of organisms down to group level and, in parallel with LH-PCR, it allows processing large sample sets where samples are directly comparable; an example is shown in Fig. 1. The problem of identifying organisms below group level is somewhat mitigated by tRFLP. It must be emphasized that the choice of enzyme for digests to resolve bacterial taxonomic groups during tRFLP analyses is critical and requires some a priori knowledge of the bacterial groups in the samples for effective phylogenetic targeting.

THE USE OF MOLECULAR PROBES IN COMMUNITY ANALYSIS

Rather than providing a community fingerprint, these methodologies are used to probe for certain known community members. These methods require some a priori knowledge of the population or can be used to determine whether an organism is present. A molecular probe is applied, which hybridizes with the DNA or RNA of the specific organism. The probe can be applied *in situ* or *ex situ*. These methods are powerful tools, which avoid the possible biases of cloning and PCR amplification techniques, and can yield a more direct measure of the target groups of interest.

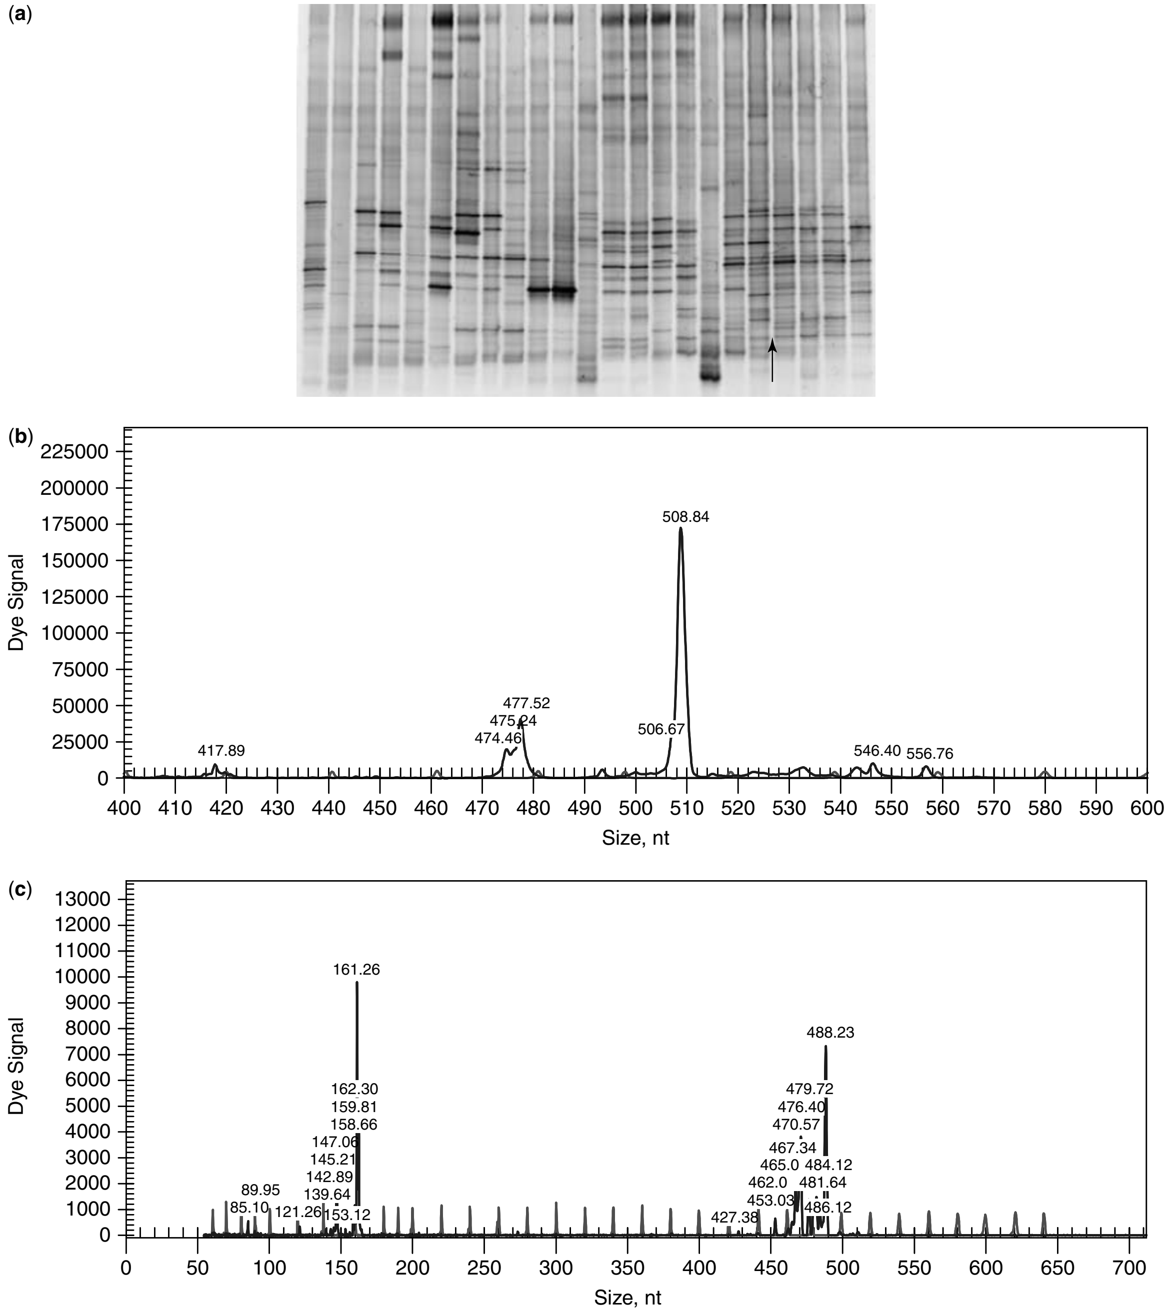

Figure 1. (**a**) DGGE profile showing samples taken from a groundwater diesel remediation system. (**b**) An example of an LH-PCR output. (**c**) An example of a tRFLP output. Both outputs correspond to lane 20 on the DGGE gel.

DNA Microarrays

A DNA microarray (a DNA microchip or DNA chip) is an orderly, high-density matrix of hundreds (or thousands) of individual longer cDNA probes or short oligonucleotides bound directly or indirectly to a solid surface (10). Unlike membrane hybridization, the chip is a high-density format that allows simultaneous hybridization of a labeled DNA or RNA target to a large set of probes, thus providing high throughput. Most applications have been in cell biology such as applied to drug discovery or to monitor gene expression patterns in pure culture, but more recently, the technology has been used successfully in environmental studies (11). Microarrays are a useful tool for high turnover screening of large numbers of samples. They are, however, rather expensive to construct.

Reverse Sample Genome Probing

Reverse sample genome probing (RSGP) uses the entire genome of a microorganism as a specific probe that allows detecting it in the environment. Whole genome probes have been used to detect *Mycobacterium, Mycoplasma, Chlamidia, Bacteroides, Pseudomonas, Sphingomonas*,

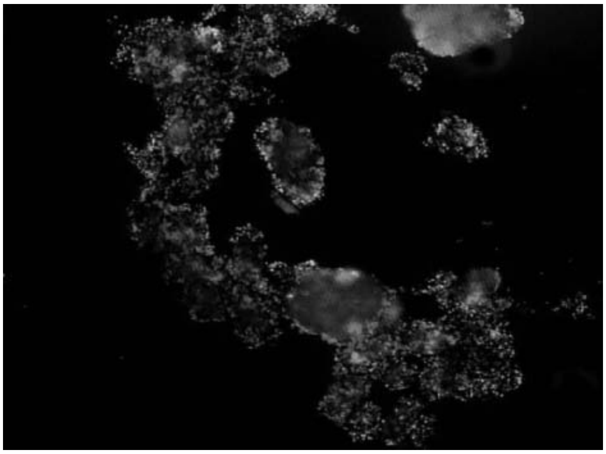

Figure 2. FISH probing of *Thauera* species in a wastewater treatment system. The *Thauera* specific probe is labeled in red. The species Eub358 is shown in green.

and *Campylobacter* species. A good example of the use of this method was looking for sulfate-reducing organisms in contaminated oil fields (12).

Fluorescent *In Situ* Hybridization of Whole Cells

Whole cell *in situ* hybridization with fluorescently labeled oligonucleotides in community analysis was first developed in the late 1980s (13). The procedure involves fixing the environmental sample to permeabilize the cells while maintaining their morphological integrity. The cells are then immersed in hybridization solution containing fluorescently labeled oligonucleotide. After washing to remove unbound probes, the sample is viewed by epifluorescence microscopy. Cells that show specific hybridization with the fluorochrome-labeled probe can be identified and enumerated, as shown in Fig. 2.

THE USE OF LABELED SUBSTRATES TO PROBE FOR ORGANISMS

In addition to community profiling methods and the use of specific oligonucleotide probes, substrate-based procedures have been developed that are culture independent and can be employed *in situ*. These methods, in particular, employ stable isotopes, such as ^{13}C, to determine exactly which organisms are involved in the breakdown of specific contaminants. These methods allow identification of the organisms involved in processing the contaminating compound and are some of the most sophisticated methods used in the field.

Polar Lipid-Derived Fatty Acid-Based SIP

^{13}C labeled substrate is pulsed into the microbial community in the environment and results in labeling polar lipid-derived fatty acids (PLFAs) from assimilating organisms. PLFAs are then extracted, separated, and analyzed for ^{13}C enrichment by isotope ratio mass spectrometry (IRMS). Because specific phylogenetic groups produce signature PLFA profiles, the stable isotope enrichment of certain PLFAs reveal which organisms were dominating the metabolism of the labeled substrate.

The first PLFA-SIP investigation was carried out by Boschker et al. (14), who identified the microorganisms responsible for oxidizing the greenhouse gas methane in a freshwater sediment.

DNA Stable Isotope Probing

More recently, nucleic acids have been used in SIP studies. These methods are more user-friendly because sequence information is so widely available, and nucleic acid extraction from environmental samples is easy.

Stable isotope labeled DNA can be isolated from mixed microbial communities based on the increase in buoyant density from isotopic enrichment. Density centrifugation in cesium chloride gradients was used to separate "heavy" for natural DNA, and 16S rDNA clone libraries constructed from heavy DNA were sequenced to obtain the identity of organisms assimilating the ^{13}C labeled substrate used in the study. This technique has been used to attribute methanol to use particular *Proteobacteria* in an oak forest soil (15).

RNA Stable Isotope Probing

Due to the fact that DNA synthesis is associated only with cell replication, the amounts of DNA synthesized in the duration of a ^{13}C pulse may be low in a natural environment with low cell replication. The use of RNA in SIP, however, offers the same sequence-based resolution but avoids the limitations of labeling due to its high turnover rate. The procedure is performed as DNA-SIP above, and reverse transcription of the heavy RNA to identify organisms is added. RNA-SIP has been applied to an operative industrial phenol-degrading wastewater treatment system to identify organisms responsible for metabolizing phenol (16). Figure 3 shows the fractionation of natural and heavy ^{13}C labeled RNA. The fractionation,

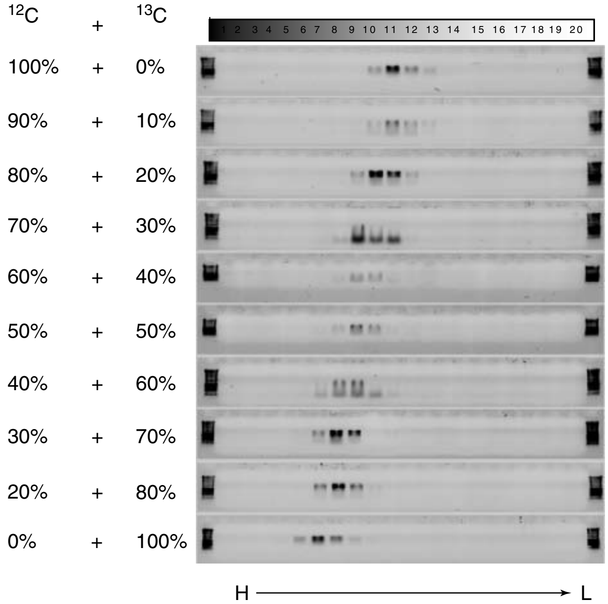

Figure 3. The appearance of natural (^{12}C) and heavy (^{13}C labeled) RNA shown in RNA-SIP. The top gradient fractions contain the natural weight RNA, and the heavy RNA becomes apparent as we move down the fractions (17).

extraction, and subsequent sequencing of the heavy RNA resulted in identifying the dominant phenol degrader in a wastewater system as a *Thauera* species.

Fluorescence *In Situ* Hybridization and Secondary Ion Mass Spectrometry

Recently, investigations in which individual cells or mixed aggregates of cells in methane-consuming communities were identified by fluorescence *in situ* hybridization and, subsequently, analyses for ^{13}C content by secondary ion mass spectrometry (18). The natural abundance of ^{13}C in methane is low, thus enabling the association of cells harboring depleted ^{13}C signatures with methane consumption.

All SIP techniques outlined before are sophisticated methods of associating an organism with a specific function, their catabolic potential. The one problem of SIP is that the labeled substrates are hard to obtain and may require custom synthesis, which is a rather costly process.

BIOSOLIDS

IZRAIL S. TUROVISKIY
Jacksonville, Florida

Wastewater treatment processes remove organics, inorganic materials, and contaminants in sludge. Biosolids are treated municipal wastewater sludge that can be beneficially used, especially as a soil amendment, in accordance with standards.

The Water Environment Federation (WEF) has adopted a policy of encouraging the use of the word ‘biosolids’ in place of sludge to promote public acceptance of reused materials. Land application of biosolids has been and continues to be successfully implemented by many countries. Many countries have rules and regulations associated with biosolids reuse and disposal. Almost all rules are based on reducing pathogens and pollutants. However, rules and regulations vary in different countries. Criteria and methods of obtaining results to determine the use of biosolids also vary.

The United States EPA Standards (US EPA, 1993,1995) for using sludge includes pathogen requirements, vector attraction reduction requirements, and pollutant ceiling concentrations. In accordance with them, two classes of requirements—Class “A” and Class “B” were accepted as rules. To achieve Class “A” (pathogen) requirements, either the density of fecal coliform bacteria in the sludge shall be less than 1000 most probable number (MPN) per gram of total solids, or the density of *Salmonella* sp. bacteria shall be less than 3 MPN per 4 grams of total solids. In addition, the sludge must contain less than one unit of plaque-forming virus and less than one helminth ova per 4 grams of total solids.

Class “B” sludge product must meet one of three alternative requirements. In the first of these, the geometric mean of the density of fecal coliform (expressed either by MPN or colony-forming units per gram of total solids) for seven samples must be less than 2,000,000. The geometric mean is the antilogarithm of the arithmetic average of the logarithms of seven samples. Alternatively, the sludge may be classified as Class “B” by being treated by a process to significantly reduce pathogens (PSRP) or by a process determined to be equivalent to PRSP by the permitting authority.

Class “A” sludge is prone to regrowth of pathogenic bacteria, such as *Salmonella* sp., after treatment because it lacks an adequate density of competitive organisms. Concerns for regrowth led to several additional requirements. First, pathogen reduction must be achieved prior to or at the same time that certain vector attraction reduction requirements are met. Second, pathogen density requirements must be met when the biosolids are used or disposed of, not when sludge is treated. Third, Class “A” biosolids applied to the land for vector attraction reduction must be applied within 8 hours after discharge from the pathogen treatment process.

Class “B” biosolids cannot be sold or given away in a bag or other container for land application. Biosolids, which meet Class “B,” can be applied to agricultural land, forests, public contract sites, or reclamation sites. Land application of Class “B” has restrictions for the harvesting of crops and turf, grazing of animals, and public access.

These restrictions are designed to provide time for the natural environment to reduce the pathogenic organisms in the biosolids. Food crops that touch the biosolids/soil mixture and are aboveground cannot be harvested for 14 months after application of biosolids to land. Root crops cannot be harvested for 20 to 38 months after biosolids application. In this case, the lowest time period applies if biosolids remains on the land surface for 4 months prior to incorporation into the soil, and the higher value applies when it does not. Class “A” and Class “B” biosolids have some vector attraction reduction requirements for land application.

The disposal alternatives are based on the treatment level provided. The most common methods for achieving Classes “A” or “B” biosolids include digestion, composting, thermal drying, and alkaline stabilization.

DIGESTION

Several sludge digestion technologies that consist of anaerobic and aerobic processes are widely used.

Anaerobic Digestion

Anaerobic digestion is a biological process of reducing volatile solids by microorganisms in the absence of oxygen; it reduces odor and pathogen content. Digesters are cylindrical reservoirs with conical bottoms; the upper section of the reservoir has a sealed cover with a device for collecting gas. One-stage and two-stage digesters are in use. In two-stage digesters, the first stage has covered heated reservoirs, and the second stage has open, unheated reservoirs.

Two types of anaerobic digestion processes are in use—mesophilic and thermophilic. Mesophilic processes function in the temperature range of 32–35 °C. The thermophilic process is operated at a higher temperature (50–55 °C) to reduce organic solids and pathogen content further. The process can use conventional standard rate and high-rate digesters with solid retention time from 30–60 days to 10–20 days. To produce Class “B” biosolids, digested sludge has to meet one of the following: reduce volatile solids by a minimum of 38%, or demonstrate that further anaerobic digesting of a portion of the sludge in a bench-scale lab unit for 40 additional days at a temperature between 30 and 37 °C will reduce the volatile solids by less than 17%.

The end products of anaerobic digestion are biosolids, gas, and water. The following gas composition can be expected: methane —60 to 75%; carbon dioxide —16 to 40%; nitrogen, hydrogen, and oxygen —0.4 to 6%. The average heat of combustion of this gas is 21 million joule/m^3. Depending on the chemical composition of the sludge, the liberation of gas varies from 5 to 20 m^3 per m^3 of sludge or 1 m^3 for every 1 kg of a disintegrated sludge’s organic content.

Anaerobic digestion requires energy in the form of heat and electricity. Supplying this energy can be expensive unless part of the energy required is received directly from using the gas. When less than 10–12 m^3 of gas is liberated per 1 m^3 of sludge, the resulting heat balance may be negative. If the gas obtained is in excess of 12 m^3 per 1 m^3 of sludge, it may be used in boilers, heating systems, and so on.

Methane is characterized by explosion hazard and may poison people, if the gas leaks. The volume of gasholders is determined in accordance with gas production and the demand schedule. The volume of gasholders is approximately equal to 2–4 hours of gas production.

Aerobic Digestion

Aerobic digestion is a process of oxidation of the organic part of sludge by microorganisms in special tanks in the presence of oxygen (air aeration of sludge). Aerobic digestion has been widely used in wastewater treatment plants (WWTP) for many years. The purpose of aerobic sludge digestion is to stabilize raw sludge and produce biosolids for further treatment and disposal. Equipment for aerobic digestion is simpler, with in design and operation than that for anaerobic digestion. The more useful sludge aerobic digestion processes are conducted in open structures of the aeration tank type. The duration of the volatile part of solids oxidation depends on the food/microorganism ratio, temperature, intensity and quantity of aeration, and also on wastewater composition and technological demand. This process is more useful for digesting and stabilizing thickened activated sludge.

The detention time to reduce volatile solids and stabilize a mixture of waste activated sludge and raw primary sludge may be 10–15 days at an operating temperature of 20 °C (68 °F). Traditionally, digesters have been designed for a detention time of 20–30 days. However, to meet Class "B" sludge regulations by aerobic digestion, Federal Regulations (40 CFR 257) require detention times of 40 and 60 days at temperatures of 20 °C and 15 °C (68 °F and 59 °F), respectively, and reduction of volatile solids by a minimum of 38%. Long aerobic digestion times require large tank volumes. To reduce tank volumes, the solids concentration can be increased by gravity, belt, or drum thickeners.

Aerobically digested biosolids should be settled for 1.5–5 hours in a sedimentation zone inside the aeration tank or settling in sedimentors. The supernatant BOD is about 100 mg/L, and the COD varies from 350 to 700 mg/L. The moisture content of the biosolids is 95–98% after sedimentation.

Oxidation of the organic part of sludge releases about 3.6 kcal of heat per gram of volatile suspended solids (VSS) in aerobic autoheating mesophilic digestion or autothermal thermophilic aerobic digestion. Temperature control is important in both processes. These processes use heat, created by biochemical oxidation of the organic substances by air introduced into the reactors. The processes are realized in hermetically sealed reactors. The heat balance has to take into account heat loss to surroundings, effluent gas, effluent sludge, and so on.

Autothermal thermophilic aerobic digestion (ATAD) systems for sludge stabilization and disinfection include two hermetically sealed reactors which can be operated with an existing anaerobic digester (prestage ATAD) or operated as conventional ATAD. By using the ATAD process for heat balance, activated sludge has to be thickened to 5% or more of dry solids using belt or rotary drum thickeners. Technological schemes include waste-activated sludge holding and buffer tanks, thickeners, pumps, heat exchangers, reactors, treated sludge holding tanks, and communications. Depending on the temperature and process duration, ATAD can be used to produce Class "B" or "A" biosolids. Class "A" biosolids should be heated to 55–60 °C and aerated for about 10 days. Class "B" aerobic and anaerobic digested biosolids may be converted to Class "A" by maintaining a temperature of at least 70 °C for a minimum of 30 minutes. This can be done by inserting hot air or gases directly into the digested biosolids or by using heat exchangers.

COMPOSTING

Composting of domestic waste and manure has been used for thousands of years. However, the production of compost from wastewater sludge of large-scale municipal wastewater treatment plants began in the 1960–1970s.

Composting can be performed as aerobic or anaerobic biothermal processes which release heat during the decomposition of organics. Aerobic biothermal processes release almost 30 times more heat than anaerobic processes. That is why aerobic processes are used more often. The composting process reduces the organic material in the sludge by approximately 25–30%. During composting, the heat generated by the decomposition of the organic portion of the sludge, reduces the moisture content of the sludge, stabilizes the sludge, and renders the residual harmless by transforming it into usable biosolids.

The heat generated by decomposition of 1.0 kg of organic material averages 20–21 million joules (Mjoule). This generated heat drives the biothermal process and moves the composting process from the mesophilic phase (25 to 40 °C) to the thermophilic phase (55 to 65 °C). Most pathogens are destroyed during the thermophilic phase.

The generated heat also facilitates the evaporation of moisture. Approximately 4.0 Mjoule of heat will evaporate 1.0 kg of moisture (taking into account heat losses and heating of the compost material). Thus, decomposition of 1.0 kg of organic material facilitates the removal of approximately 5.0 kg of moisture from the sludge (21 Mjoule/4 Mjoule/kg of water).

Before composting, it is necessary to dewater sludge. Dewatering reduces the volume of sludge, and it also decreases the amount of moisture to be evaporated by the composting process.

The aerobic process can be performed by using different systems—windrow, aerated static piles, or in-vessel. Sludge is composted together with bulking materials, such as saw dust, wood chips, peat, paper product waste, and ready compost, which provide the mixture with the necessary moisture, porosity, and carbon content.

For vector attraction reduction requirements and to achieve Class "B" biosolids during composting, the temperature has to be above 40 °C (104 °F) for a minimum of 14 days and average more than 45 °C for the same period. To obtain Class "A" compost, the US EPA requires that the temperature in the piles have to be at least 55 °C (131 °F) for 3 days.

Windrow piles or trenches are effective, but mixing and turning does not provide enough air, that is why anaerobic conditions (sometimes) take place in these devices, which generates odors. More often aerated static pile composting is used. Piles have been made by mixing dewatered sludge with wood chips or saw dust. Arrangements of dewatered sludge and amendments prior to mixing follow recycled wood chips (or saw dust) on the floor, dewatered sludge on the top, or when fresh, wood chips (or saw dust) or recycled compost. To prevent heat loss and protect against insects and rodents, piles are covered by ready compost.

In aerated static piles, perforated pipes mounted underneath the composting pile provide aeration. Pipes are covered with layers of sand, gravel, or bulking material and are connected to blowers.

Aerated static pile composting is an effective process. It is easy to operate and does not require high personnel qualification. Compost is a dry, disinfected, and stabilized product. However, the speed of the process depends on several factors, such as bulking materials; proportion of bulking materials to dewatered sludge; efficacy of mixing bulking materials with dewatered sludge; temperature, moisture, and porosity of the mixture; mass of the mixture being composted; quantity of air and duration of aeration; correction between C and N; quantity of recycling compost and bulking material, and toxicity to biological decomposition.

The moisture content of mixed sludge-bulking material has to be 60–67%. The quantity of air is 10–25 m^3/hour per ton of volatile solids. Increased air allows an increase in process speed, but excess air decreases the process speed and temperature. Aeration begins 5–10 days after starting the process and lasts 25–30 days for 8 hours every three days. The index of aeration is the concentration of CO_2. When the concentration of CO_2 increases to more than 7% of gas volume, inhibition of microorganisms and a decrease in temperature occur. At the beginning of the process, the carbon to nitrogen (C:N) ratio is 30:1–34:1 in a pile with saw dust and 25:1–27:1 in a pile with ground bark. Compost is cured for 1–3 months. In the United States, more than 200 composting facilities are in operation now, mostly aerated static piles. But windrow and in-vessel composting also takes place.

Windrow piles are turned with mobile equipment every 3–5 days until the temperature is maintained at 55–65 °C and composted for a period of 3 to 5 weeks, when cured and stored in piles for 1–2 months. The process is based on constructing a windrow from a mixture of dewatered sludge, bulking agent, and recycled compost that provides composting material of proper moisture content, porosity, and carbon source for microorganisms.

Composting processes such as windrow, static piles, aerated static piles, and different types of in-vessel (vertical towers, vessels, reactors, containers, and so on) are widely used in Europe, Japan, and other countries. In-vessel composting processes are accomplished inside enclosed containers that provide a completely controlled environment, temperature, aeration, and odor control. However, in-vessel systems are more complicated and expensive than windrow or aerated static piles and require qualified personnel.

THERMAL DRYING

Thermal drying is designed to disinfect and decrease the weight and volume of wastewater sludge. Thermal drying permits economical sludge transportation from treatment plants and subsequent use.

Thermal drying of sludge is conducted in drying systems consisting of a drying device (dryer) and auxiliary equipment, which includes furnaces with a fuel supply system, feeders, cyclones, scrubbers, blowing equipment, conveyors and bins, as well as monitoring and measuring instruments and automatic control equipment.

To reduce fuel required, sludge should be dewatered before thermal drying by using belt process, centrifuges, or plate presses. For thermal drying of sludge, use fluidized bed dryers, drum dryers, opposite jet dryers, dryers with peripheral discharge of the dried sludge, or Pelletech drying systems. In dryers, the drying temperature should reach 500–800 °C, and drying time is approximately 10–15 minutes.

The Pelletech dryer is a vertically oriented multistage unit that uses steam or thermal transfer fluid in a closed loop to achieve 90% or greater dry solids content in the product. This process minimizes formation of dust and oversized chunks. Pelletizing and drying involves heat and mass transfer, mixing, combustion, conveying, classification, and evaporation.

Thermal dryer sludge is a Class "A" biosolid when sludge achieves 75% dry solids concentration, if no unstabilized primary is present, and 90% of dry solids content, if unstabilized primary sludge is present, by direct or indirect contact with hot gases. Either the temperature of the sludge particles exceeds 80 °C (176 °F) or the wet bulk temperature of the gas in contact with the sludge as the sewage sludge leaves the dryer exceeds 80 °C (176 °F).

The thermal drying process exceeds Class "A" biosolids regulations and can be used for soil improvement without additional restrictions; the solids can be bagged or sold in bulk as fertilizer to landscape contractors or the general public.

ALKALINE STABILIZATION

To produce biosolids that meet pathogen and vector attraction reduction requirements, wastewater treatment plants often use alkaline stabilization. For sludge stabilization, which meets Class "A" or "B," quicklime or hydrated lime are used. Lime is added to sludge before or after dewatering. If quicklime is added to sludge, it initially reacts with water to form hydrated lime. This reaction is exothermic and releases approximately 15,300 cal/g mole (27,500 Btu/lb/mole). The reaction between quicklime and carbon dioxide is also exothermic, releasing approximately 43,300 cal/g mole (78,000 Btu/lb/mole). To achieve Class "A" pathogen reduction, the quantity of added lime is determined so that the pH of the sludge and lime mixture is raised to 12 or greater for 72 hours; the temperature of the sludge during this period must be higher than 52 °C for 12 hours or longer. In addition, air-dried resultant biosolids have to achieve greater than 50% solids content. This process is often called sludge pasteurization. The lime pasteurization process provides a higher level of pathogen reduction than lime stabilization and the result is biosolids that meets Class "A" requirements.

For vector attraction reduction that meets Class "B," the mixture of sludge and lime has to be raised to pH 12 for at least 2 hours and remain over pH 11.5 for an additional 22 hours, all without further alkali addition.

Disinfection of sludge with quicklime or hydrated lime is widely used in Europe to reduce odor, pathogens, and putrefaction of the sludge. Lime stabilization can be part of a sludge conditioning process prior to dewatering (prelime stabilization) or following a dewatering step (postlime stabilization). As a rule, lime is stored in silos and mixed with sludge by various types of mixers.

BIOSOLIDS USE

Biosolids are often used as an organic-mineral nitrogen-phosphorus-potassium fertilizer, soil amendment, or soil conditioning material. Biosolids may be used as a fertilizer on agricultural lands, forests, public contact sites, reclamation sites, rangeland, pastures, lawns or home gardens, or as Class "A" biosolids that are given away in a bag or other container for application to land. Biosolids contain necessary macro- and micronutrients for plant growth. Biosolids may be considered a lime fertilizer when the lime is used for sludge stabilization or pasteurization. The mineral part of biosolids is usually represented by combinations of calcium, silica, aluminum, and iron. Several types of micronutrients are present in biosolids, which increase the speed of many biochemical reactions during plant growth. Most micronutrients can be considered microfertilizers. For example, copper increases the harvest of wheat on marshy and sandy soils. Manganese contributes to increasing the harvest of beets, corn, and some other agricultural crops. A deficiency in iron and zinc in plant growth causes serious breaches in vital activities of plants, specifically related to fruit plants, grape, and cotton plants. Boron is very important for crops such as flax, sugar beets, cotton, feed legumes, peas, clover, alfalfa and several other fruits, berries, and vegetable crops. Micronutrients also contribute to assimilation of organics from the sludge by plants. However, the increased concentration of microelements exercises a negative influence on the growth and quality of plants.

According to the standards for biosolids use, it is necessary to reduce pathogens as mentioned above, but it is not enough. It is very important to determine the pollutants concentration in biosolids, which have to be less than limits and whether biosolids meet cumulative pollutant loading rates (kg/ha) and annual polluting loading rates to soil (kg/ha-year).

Several microelements are essential and some not essential for plants and animals, depending on their doses. Some of them are heavy metals that require some restrictions in use. Among them are arsenic, cadmium, chromium, copper, lead, mercury, molybdenum, nickel, selenium and zinc. Some chemicals, such as barium, beryllium, carbon disulfide, dioxins, and phenol, should be considered hazardous enough to be a potential threat to the health of people and wildlife. The United States currently regulates nine chemical pollutants, but the EPA has already considered regulating six more pollutants. There are special rules and regulations in several economically developed countries that restrict the content of heavy metals in biosolids used as fertilizers and also restrict doses of embedding biosolids in soils.

The requirements for heavy metal content in biosolids become less restrictive when using the soils for shrubs, flowers, for fast-growing trees, like willows, for development of low productive soils and their recuperation, for reinforcement of ravines and hillsides, and for planting trees and shrubs on former industrial waste sites.

If biosolids contain more pollutant concentrations than the requirements of standards, these biosolids should be buried in landfills or incinerated. To reduce expenditures for incineration, sludge organics should be used as fuel.

CONCLUSION

Biosolids are treated wastewater sludge that can be beneficially used as a soil amendment. When considering the use of biosolids, how and where biosolids may be used and how they should be prepared for use corresponding to the requirements of Standards should be determined.

Several processes for sludge treatment such as different methods of digestion, thermal, biothermal, or chemical treatment provide reduction of pathogens and vector attractions to achieve Class "A" or "B" biosolids. Aerobic and anaerobic digestion of sludge are widely used processes of sludge stabilization and produce biosolids that meet Class "B" sludge regulations. Autothermal thermophilic digestion systems operated in hermetically sealed reactors allow production of Class "A" biosolids.

Thermal drying, lime stabilization, and lime pasteurization are used to destroy pathogens, eliminate odor, reduce most of the water content and the volume of sludge, and lower transportation costs of biosolids. These processes are in use for Class "A" or "B" biosolids.

Composting is an effective way of stabilizing and reducing pathogens in sludge. Many utilities use wastewater sludge composting systems, such as windrow, aerated static piles, and in-vessel.

Composting delivers high quality product, which has macro-and micronutrients and can be used as a soil conditioning material, amendment, or fertilizer—either as Class "A" or "B."

Biosolids, after appropriate treatment, may be used as a fertilizer on agricultural lands, forests, public contact sites, reclamation sites, rangeland, pastures, lawns, or home gardens. It should be determined if Class "A" or Class "B" pathogen requirements can be reached and also if the sludge meets one of the vector attraction reduction criteria. After that, pollutant concentration and doses of embedding biosolids in soils should be determined.

Extensive use of dewatered and disinfected biosolids received from municipal wastewater treatment plants as fertilizers will contribute to the solution of the problem of their effective, economical, and ecologically acceptable removal and disposal.

INTEGRATED CAPACITY BUILDING NEEDS FOR WATER SUPPLY AND WASTEWATER SANITATION

Timothy J. Downs
Clark University
Worcester, Massachusetts

INTRODUCTION

Sustainable development is "development that meets the needs of the present without compromising the ability of future generations to meet their own needs" (1). This was the unifying theme of the 1992 Earth Summit in Rio de Janeiro that produced Agenda 21, Blueprint for Sustainable Development. To do most of what the new sustainable development paradigm challenges society to do requires us to strengthen our collective capacity to respond to those challenges and opportunities. "Capacity building is the sum of efforts needed to develop, enhance and utilize the skills of people and institutions to follow a path of sustainable development" (2). A UNDP program, Capacity 21 (2), seeks to build capacity to implement Agenda 21 (3). At the core of integrated watershed management (IWM) lies the engineered human water supply and wastewater sanitation cycle, operating within the hydrologic constraints of the surface watershed and aquifer system (Fig. 1). We must remember, however, that although water resources are the prima facie focus, water cycling depends on a functioning ecosystem comprising interactions of air, soil, climate, forests, and biodiversity.

It is evident from the simplified schematic diagram of the water cycle that this is a complex system that has many types of capacities needed to sustain the sociopolitical, economic, and technological networks it entails. In a typical settlement, there are diverse users of water/producers of wastewater. In a typical watershed, there are many such settlements of varying size and productive activity, comprising people living in water-producing zones (aquifer recharge zones, upland forest zones) and those who consume most water and produce most wastewater (cities and major farming/irrigation zones).

One common focus for societal capacity building is education and training, centered on strengthening human resources. Another common clientele for capacity building is government institutions. Howe (4) has identified key institutional water management requirements for a watershed scale: (1) coordinated management of surface water and groundwater resources, (2) coordinated management of both water quantity and water quality, (3) provision of incentives for greater economic and technical efficiencies in water use, and (4) protection of public values associated with water service (e.g., reliable, safe, clean, affordable supply). To achieve this, the water institutions must develop the following characteristics (after 1):

- the capacity to coordinate water plans with other agencies (e.g., urban planning, agriculture, public health, environment, industrial);
- the capacity to solve water problems creatively using a variety of options and approaches (e.g., laws, pricing, taxes, tradable supply and/or pollution permits, subsidies);
- the foresight to separate roles and responsibilities for water resource planning and management activities

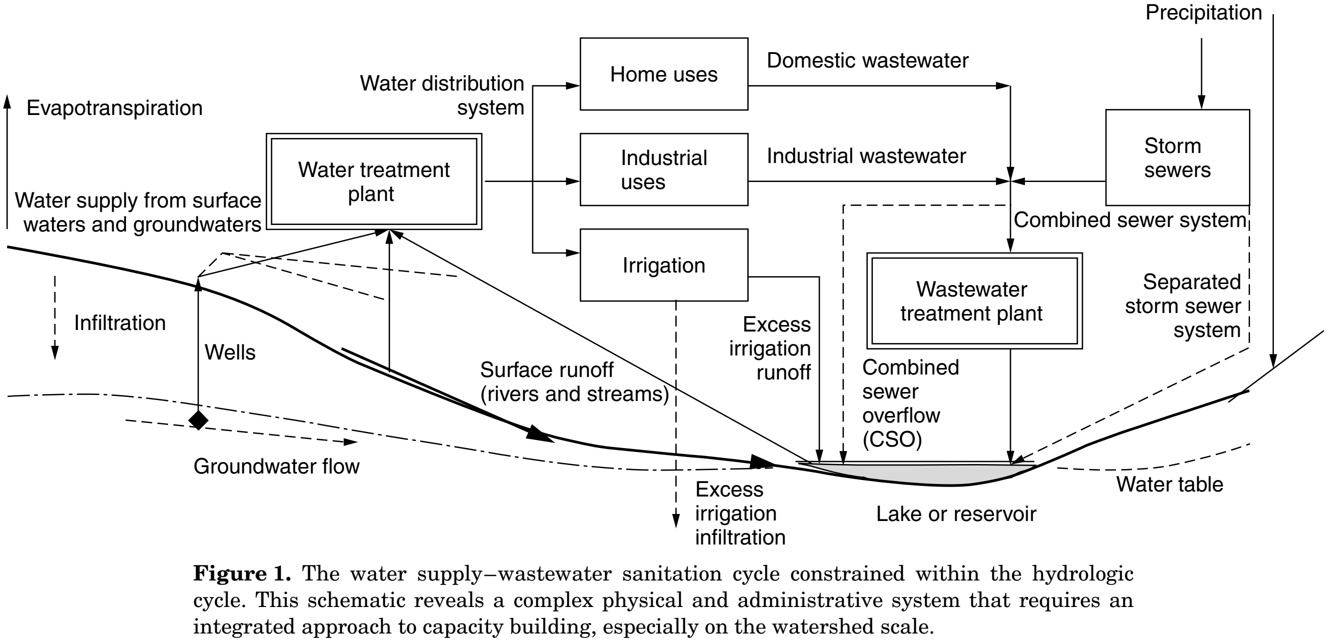

Figure 1. The water supply–wastewater sanitation cycle constrained within the hydrologic cycle. This schematic reveals a complex physical and administrative system that requires an integrated approach to capacity building, especially on the watershed scale.

from construction activities (i.e., avoid conflicts of interest);

- the multidisciplinary capacity to undertake multicriteria/multiobjective planning and evaluation of alternatives;
- devolve decision-making power to the lowest practical level—national, state/regional (provincial), local or municipal—consistent with the scale of the water issue;
- capacity and willingness to use appropriate participatory methods involving different stakeholders at different stages of a project (preplanning/conceptual, planning and design, implementation, maintenance, monitoring and evaluation);
- ability to reward innovation and adapt to changing conditions and priorities.

Wherever capacities are missing or weak, a process of integrated multiobjective, multidisciplinary capacity building is needed, a very common requirement worldwide.

Laws and regulations express societal norms and values and are crucial instruments that help us respond to the challenge of water sustainability. Designing and implementing such responsive legal instruments also reveals the need for an integrated capacity building approach. These legal instruments should (after 5)

- Encourage administration at the appropriate hydrologic scale: watershed, multiwatershed and/or aquifer system.
- Foster internalization of the values and ethics of sustainable resource development.
- Encourage integrated approaches to water supply and sanitation, ecology, and public health.
- Prevent water allocation/usage policy-making from fragmenting among agencies.
- Promote integrated appraisals, notably environmental, economic, and sociopolitical impacts assessment of alternative actions.
- Enforce reward and penalty incentives that encourage sustainability.

And to achieve this, de facto, they should also

- encourage integrated capacity strengthening of governmental institutions, NGOs, community associations, and businesses to transition into more sustainable policies and practices, and work collaboratively.

Current practices of natural resource management and current development policies do not exploit the codependency between coupled water sustainability topics such as (1) water quantity management (e.g., conservation, higher efficiency, and demand management through equitable pricing), (2) water quality management (e.g., standards demanded by diverse users and uses), and (3) aquifer recharge protection and upland forest conservation. This occurs mainly because there is no systematic way to do this that accommodates diverse stakeholder interests and concerns and bridges institutional barriers while strengthening the required social and technological assets (6). Existing methods—with very few notable exceptions—are largely ineffective and not adaptive to changing sociopolitical and geophysical conditions. A recent body of work called participatory integrated capacity building (PICB) addresses this challenge.

PARTICIPATORY INTEGRATED CAPACITY BUILDING

What is participatory integrated capacity building (PICB)? From 1998–2000, local working groups in collaboration with the Mexican National Water Commission (CNA), coordinated by Downs (7), developed a PICB approach to urban water planning and management. Following an analysis that compared relatively sustainable development projects worldwide during the past 10–15 years (those yielding a steady stream of benefits *after* external support was removed) with a much larger number of *un*sustainable projects, six broad synergistic categories of capacity building emerged as critical components for success: (1) strengthening political and financial commitment; (2) strengthening human resources, including education, training, and awareness-raising; (3) strengthening information resources for policy-making (e.g., monitoring and GIS tools for data integration); (4) strengthening policies, regulations, enforcement, and verification; (5) applying appropriate technology and basic infrastructure (e.g., for water and wastewater treatment); and (6) stimulating local enterprise development (i.e., support products and services that provide socioeconomic sustainability. Each one builds on those before it with positive feedback.

This six-story framework is made up of elements that are operational, that is, for which we can design an action plan (Table 1). Table 1 was synthesized from fieldwork, workshops, and literature, notably Alaerts et al. (8), UNDP (9), UNCED (10,11). Although Table 1 considers the needs of an urban area, the same six levels can be extended to determine the needs of periurban and rural areas of the watershed. This integrated approach can be applied on different scales and contexts of settlement, so it can, in theory, also be applied to networks of settlements that comprise a watershed as a whole.

Using Table 1 (or a rural, periurban, or watershed-scale version of it) as our diagnostic template, local working groups undertaking strategic planning can assess existing capacity, then prioritize elements using several criteria, including cultural acceptability, potential cost-effectiveness, and strategic importance to solving the priority problems that have been identified as objectives. In the case study (7), strategic planning was carried out to identify the capacity-building needs of three pilot cities: Mérida, Yucatán; Ciudad Juárez, Chihuahua; and Atizapán de Zaragoza in the State of México. The project was successful in developing strategic work plans that were used to leverage support for the ongoing implementation phase. The main lesson learned in the field was that horizontal multistakeholder processes worked well, even where the norm is nonproductive competition among social groups. The author also saw the need to strengthen sociopolitical support and seed

Table 1. PICB Elements for Sustainable Water Supply and Sanitation in an Urban Context[a]

#	Element Name	Description
		Level 1. Strengthen sociopolitical support and seed financial support
1.1	Sociopolitical support	Build local, state, and federal political support, and commitments of in-kind support (labor and materials).
1.2	Seed finance	Obtain seed funding then leverage other funds for capital projects
		Level 2. Strengthen education and awareness-raising
2.1	Water and sanitation education at the community and school levels	Awareness-raising of water and sanitation issues in the community and the community's rights, obligations, and roles. Education of children at kindergarten, primary, secondary, and preparatory school levels.
2.2	Promotion of a sustainable water and sanitation culture	Use of media instruments and campaigns (TV, radio, print, Web) to promote water savings, efficiency and sanitation goals, and fair pricing. Encourage recognition of water as an economic good and provider of ecological services.
2.3	Train the local trainer	Train local trainers for community, scholastic, and professional education to remove dependency on external experts and make training self-sufficient (links to 2.1 and 2.5).
2.4	Education at university level	Local/regional university education at undergraduate and postgraduate levels to form skilled young professionals and researchers who support water management.
2.5	Professional training	Training in specialist technical and administrative topics for public and private sector participants in water management.
		Level 3. Strengthen information and monitoring to inform policy
3.1	Integrated data collection, processing, and interpretation for informed decision making	Design integrated collection, processing, and interpretation of key water, public health and ecology data, implement it, and integrate information in a GIS format for easy access and decision support.
3.2	Analysis by certified laboratories	Build capacity of laboratories to provide quality-assured analysis of key indicators from 3.1 (links to 2.4, 2.5, 3.1). Instigate locally accessible certification via partnerships with U.S. or Canadian institutions.
3.3	Periodic sustainability diagnosis	Check progress of the sustainability/capacity-building process at intervals for decision-making. Links to 3.1, 4.1.
3.4	Make applied research more cost-effective using a regional applied research network	Facilitate and instigate improved communication and collaboration among researchers to eliminate duplication of effort. Identify, quantify, and prioritize risks. Develop interventions and communication programs with water/sanitation stakeholders.
3.5	Regional institutional network	Facilitate and instigate improved communication and collaboration among public and private institutions (e.g., public health, water, ecology, urban planning).
3.6	Multistakeholder forum for decision making	Facilitate and instigate improved communication and collaboration among representatives from the community, public sector, private sector, and academia to take joint decisions.
		Level 4. Strengthen policy making, regulations, and compliance
4.1	Pollution prevention and reduction policies	Statutory endorsement of sustainable pollution prevention/reduction goals by political leaders at regional, national, state, and local levels.
4.2	Responsive regulatory framework	Review and improve the water supply and sanitation regulatory framework at the municipal, state, and federal levels to make them responsive to municipal, state, and federal needs.
4.3	Regulatory compliance program	Design, develop, and implement a compliance program, including verification and incentives with emphasis on voluntary compliance.
4.4	Tariff and rights schemes	Review and improve the legal and judicial schemes used to assign pollution tariffs and rights. Implement schemes with user buy-in. Equitable supply pricing and allocation for basic needs.
		Level 5. Strengthen basic sanitation infrastructure
5.1	Sustainable water supply	Improved coverage and quality of safe drinking water supply, increasing user's willingness to pay and financial viability of service. Combine sustainable use of groundwater and surface water with demand management and wastewater reuse.
5.2	Wastewater handling/disposal	Best appropriate available technologies (BAATs) for domestic, industrial, and agricultural wastewaters. Includes a spectrum from small-scale rural 'ecological' sanitation to treatment plants with reuse of effluent and viable biosolids.
5.3	Pollution prevention and waste minimization	Design, develop, and implement pollution-prevention programs including pretreatment of industrial effluents, source reduction, and alternative process technologies.
5.4	Solid waste handling/disposal	BAATS for solid waste, including landfill and safe incineration with energy cogeneration.
5.5	Stormwater drainage	Effective evacuation of rainwater and flood prevention. Includes avoidance of stagnant water bodies that harbor disease vectors.

(*continued overleaf*)

Table 1. (*Continued*)

#	Element Name	Description
	Level 6. Strengthen local enterprise development for support products and services	
6.1	Utility company performance	Improve utility company's effectiveness and efficiency at the technical (e.g., leak detection, metering) and administrative levels (e.g., billing)
6.2	Water supply tariffs and rights scheme	Review and improve the legal and judicial schemes used to assign water supply and sanitation tariffs by capacity to pay and rights to water by use priority (direct links to 4.1, 5.3)
6.3	Water supply and sanitation service quality	Improve water supply and sanitation service quality (e.g., continuity, pressure and water quality), in turn boosting users' willingness to pay and economic sustainability
6.4	Develop local water supply and sanitation market	Stimulate local and external provision of products and services to support the water and sanitation sector. Emphasize local providers' participation.
6.5	Stimulate sector investment	Stimulate enterprise development. Provide regulatory and fiscal incentives.

[a] Reference 7.

financial support (Level 1 of Table 1) from the outset and not wait for work plans to be designed. A related issue was to remove any dependency on external, nonlocal support and so make success contingent *primarily* on community resources complemented by some federal support for the first phase of implementation that addressed priority actions.

It is worth noting that the sixth PICB level—enterprise development and the 'market'—recognizes water as an economic good that should be priced according to users' ability to pay. For subsistence communities, a full public subsidy is appropriate to cover basic needs. Overprivatization risks occur when water services are run purely for profit, and marginalized communities unable to pay incur crippling water debts (12). This has occurred in South Africa and touches a nerve in many other places where water is viewed as both a public good and a human right that should not be controlled by commercial interests. We also recognize that the issue of user willingness to pay for water services is cultural (habits of free water) and also one of poor service quality: Why should a person pay for water that is not clean and only comes intermittently? Experience in one pilot site for the PICB project—Ciudad Juárez, a water-scarce, rapidly growing city across the border from El Paso, Texas—demonstrates that even low-income users *are* willing to pay for a reliable, good quality water and sanitation service in a way that allows public utilities to break even on costs.

Significantly, the Ciudad Juárez case was one in which the community of water users was involved in planning and designing from the outset such that a strong sense of ownership of the water supply and sanitation infrastructure was developed. When special interests attempted to take control of the project, the community mobilized to prevent this, one of the few instances of successful public mitigation of corruption in Mexico. This lends credence to our hypothesis that PICB can weather political instabilities and corrupt power plays and also change the public's sense of power over its destiny, restoring faith in the public process and partnerships with responsible institutions. In this way, the three types of sustainability—economic, social, and environmental—are satisfied through a societal capacity building process.

The other caveat to the sixth (and most controversial) level is that PICB places emphasis on *local* providers of products and services such that local entrepreneurs have incentives and opportunities to compete fairly in the water market with external suppliers. External suppliers too often supply inappropriate technological solutions to developing countries where the capacity to operate and maintain the foreign plant is weak or nonexistent. Unfortunately, there are far too many cases, for example, of wastewater treatment plants and analytical laboratories that have been abandoned because of a lack of personnel trained to operate and maintain them (6,7).

OPERATIONAL CONSIDERATIONS

Operational sustainability is a function of integrated capacity building (7). Experience of this capacity building project (7) revealed the need to be clear and concise about the objectives and rationale behind what appears to be a very ambitious and complex process. Integrated watershed management—any environmental management problem—must pass through three key stages *before* any capacity building occurs (although when projects are done in a participatory way, one can argue that societal capacity is already being built). These preplanning stages are (1) a baseline survey of existing conditions and priority needs; (2) problem formulation based on the assessment—identification of priority watershed problems; and (3) project objectives, often policy questions that seek to design and implement 'sustainable solutions' to priority problems. Once preferred solutions/management options are chosen for each priority problem using a multicriteria method (e.g., environmental and social impacts assessment, ESIA), the integrated capacity required *to sustain* each solution is determined. The way PICB fits into typical watershed project stages is shown in Fig. 2.

A participatory, integrated approach to capacity building has one major strategic advantage. Solutions of priority environment–development problems share significant amounts of capacity building requirements. For example, marginalized communities often face coupled sets of problems: (1) unsafe water supply; (2) inadequate wastewater and solid waste sanitation; (3) inadequate water-related disease detection, prevention, and control; (4) grossly inefficient irrigation; and (5) no conservation/mitigation of soil erosion caused by surface runoff. By addressing them

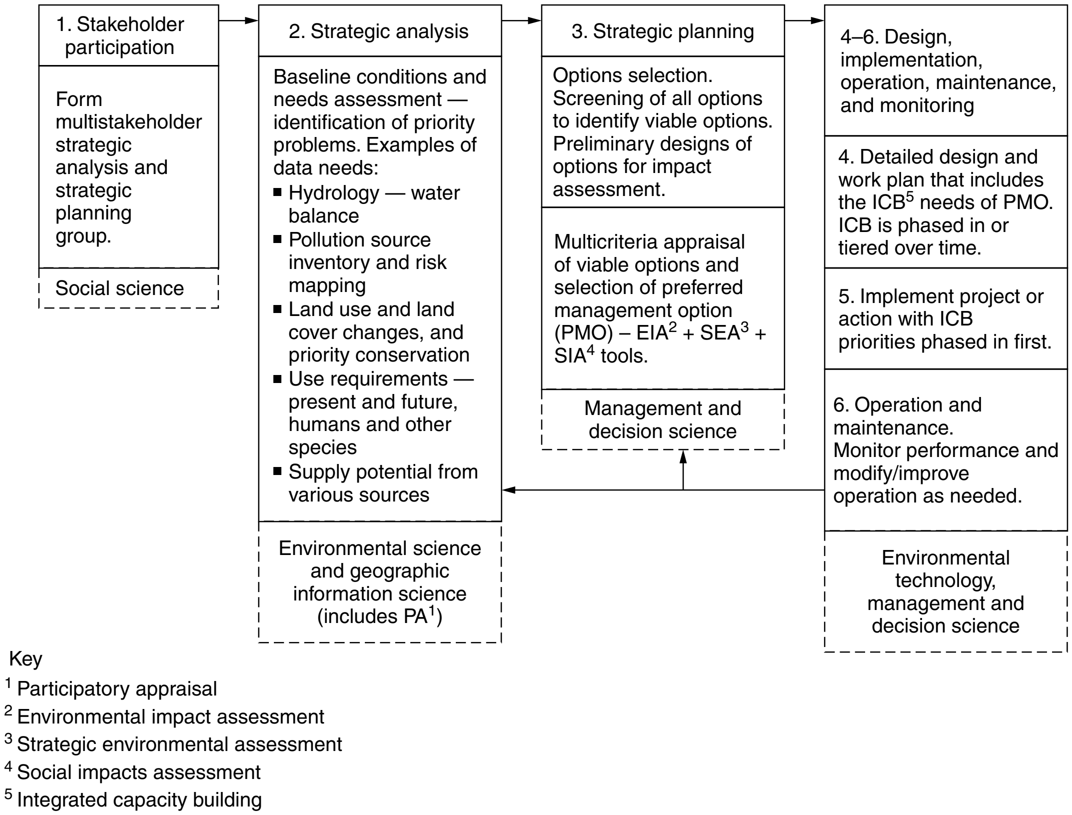

Figure 2. The key role of integrated capacity building (ICB) in sustainable watershed planning and management (6).

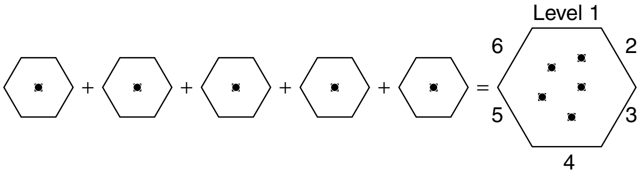

Figure 3. Strategic economies of scale emerge. Six levels of participatory integrated capacity building (PICB) support preferred solutions to five hypothetical priority problems. The integrated six levels are shown as hexagons, solutions as centered dots—the hexagons sustaining the dots. The final plan is shown as a large hexagon of integrated capacities sustaining the five coupled water-centered priority problems. The 'hexagonal' process of integrated capacity building is iterative, cyclical, continuous, just as the process of Fig. 2 is adaptive to new needs and priorities.

collectively, significant economies of scale emerge in the required societal capacity, as shown in Fig. 3.

MULTICAPITAL CONTEXT

Capacity building that supports sustainable development may also be viewed in the theoretical context of investments in, and returns on, strengthening different kinds of capital. Scoones (13) identifies five categories of capital assets that sustain human livelihoods:

1. *Natural Capital*: land, water, wildlife, biodiversity;
2. *Social Capital*: groups, networks, institutions of people;
3. *Human Capital*: skills, knowledge, healthy people;
4. *Physical Capital*: basic infrastructure that supports shelter, transportation, energy, water supply and sanitation, health care, education, and communications;
5. *Financial Capital*: income, savings, credit.

This means that to sustain water resources and watersheds requires the support of all five types of capital and further reinforces the concept that capacity building to strengthen this capital must be multifarious and integrated. Although the concept of capital is human-centered, it can be viewed in the context of ecosystem management, where humans are integral, supermodifying parts of the system. Watersheds are logical ecosystem delineations based on surface hydrology and topography.

Social capital is worthy of special note. Social capital is considered in institutional capacity building, but commonly, formal government agencies are addressed by donors. The central government in developing countries is often given funding from development agencies to build its capacity. Local nongovernmental organizations (NGOs) and community-based organizations (CBOs) typically have to rely on volunteer personnel and donations to function and build capacity. Universities still tend to build their own capacities through academic research grants, though some do partner with NGOs, CBOs, and local government to carry out projects that have clear practical goals. Empirical evidence points strongly to community-based natural resource management and participatory processes as keys to social sustainability. But how can this be done on the watershed scale required for ecological sustainability? The answer lies in strengthening the social capital of the watershed by forming collaborative networks of communities, principally CBOs, local NGOs, local (municipal) government, and local universities. When this is done, human capital and financial capital are also strengthened and become aligned with the mutual gains and common imperatives of watershed stewardship. For example, often in developing countries, marginalized rural agroforesters occupy the upper reaches of the watershed and become, de facto, ‘producers’ of water resources for downstream users because their actions affect zones of upland precipitation, groundwater recharge, and runoff. Both ‘producers’ and users share the common interest of watershed sustainability, and both must be involved in strategic planning. By networking and through capacity building coordinated by NGOs, marginalized communities can gain the social capital/political power they need to negotiate for mutual gains with influential user groups and government agencies. In Mexico, for example, the country has been divided into 26 watershed councils that administer water services to 100 million Mexicans. Unfortunately, the sustainability of this approach is called into question by the lack of participation by ‘producers’ and the clear domination of demand-driven policy-making by influential industrial and agricultural users. This is a useful example because it is a common equity issue in many countries that undermines watershed/ecosystem sustainability in three ways:

- conceptually, because equity issues are at the core of sustainable development;
- thermodynamically, because water-producing zones drive the water cycle; and
- practically, because without effective stakeholder participation, neither can diverse interests be reconciled, nor required integrated societal capacity be built.

CLOSING REMARKS

The concepts and practices of sustainable development, integrated watershed/ecosystem planning and management, equitable stakeholder participation, capital assets, and integrated capacity building are closely connected. The process may appear complex because of its multifaceted nature, but a strategic approach allows us to identify the most important issues, negotiate mutual gains for diverse stakeholder interests, and exploit the considerable economies of scale that emerge. Another advantage of integrated capacity building is that as well as mutual gains, the process delineates responsibilities, roles, and contributions as a collaborative socioecological enterprise.

WASTEWATER CHARACTERIZATION

Absar Ahmad Kazmi
Nishihara Environment
Technology, Inc.
Tokyo, Japan

An understanding of the nature of wastewater is fundamental to the design and operation of wastewater collection, treatment, and reuse facilities. Wastewater is characterized in terms of its physical, chemical, and biological composition. Greater emphasis is being placed on wastewater characterization because of its changing characteristics and the imposition of stricter limits on wastewater discharges that are used beneficially. Thorough characterization of wastewater in the design and optimization of biological treatment processes is increasingly important due to the advent of process modeling. Process modeling for activated sludge, as it is currently conceived, requires experimental assessment of kinetic and stoichiometric constants.

The principal physical properties and the chemical and biological constituents of wastewater and their significance are as follows.

PHYSICAL CHARACTERISTICS

Physical characteristics are those characteristics that respond to the senses of sight, touch, taste, and smell. The most important physical characteristic of wastewater is its total solids content, which is composed of floating matter, settleable matter, colloidal matter, and matter in solution. Other important physical characteristics include particle size distribution; turbidity; color; transmittance; temperature; conductivity; and density, specific gravity, and specific weight. Table 1 illustrates common physical characteristics, their analyses, and importance in wastewater treatment.

CHEMICAL CHARACTERISTICS

The chemical constituents of wastewater are typically classified as inorganic and organic. Inorganic chemical constituents of concern include nutrients, nonmetallic constituents, metals, and gases. Organic chemical constituents of concern are BOD, COD, and specific organic compounds.

Inorganic Chemical Characteristics

The sources of inorganic nonmetallic and metallic constituents in wastewater derive from background levels in the water supply, from the additions resulting from domestic use, from the addition of highly mineralized water from private wells and groundwater, and from industrial use. Because the concentration of various inorganic constituents can greatly affect the beneficial uses for the waters, the constituents in each wastewater must be considered separately. Table 2 illustrates the common inorganic chemical characteristics, their analyses, and importance in wastewater treatment.

Organic Chemical Characteristics

Organic compounds or organics are normally composed of combinations of carbon, hydrogen, and oxygen, together with nitrogen in some cases. Many organics are soluble in water. Most natural organics consist of decay products of organic solids, synthetic organics are usually the result of wastewater discharges or agricultural practices. The organic matter in wastewater typically consists of proteins (40–60%), carbohydrates (25–50%), and oils and fats (8–12%). Along with the proteins, carbohydrates, fats and oils, and urea, wastewater typically contains small quantities of a very large number of different synthetic molecules, whose structures range from simple to complex.

Organic constituents of interest in wastewater are classified as aggregate and individual. Aggregate organic constituents are comprised of a number of individual compounds that cannot be distinguished separately. Laboratory methods commonly used today to measure aggregate

Table 1. Common Analyses Used to Assess the Physical Constituents in Wastewater

Test[a]	Abbreviation/Definition	Use or Significance of Test Results
Total solids	TS	To assess the reuse potential of wastewater and to determine the most suitable type of operations and processes for treating it
Total volatile solids	TVS	
Total fixed solids	TFS	
Volatile suspended solids	VSS	
Fixed suspended solids	FSS	
Total dissolved solids	TDS (TS-TSS)	
Volatile dissolved solids	VDS	
Total fixed dissolved solids	FDS	
Settleable solids		To determine those solids that will settle by gravity in a specified time period
Particle size distribution	PSD	To assess the performance of treatment processes
Turbidity	NTU[b]	Used to assess the quality of treated wastewater
Color	Light brown, gray, black	To assess the condition of wastewater (fresh or septic)
Transmittance	% T	Used to assess the suitability of treated effluent for effluent disinfection
Odor	TON[c]	To determine if odors will be a problem
Temperature	°C or °F	Important in the design and operation of biological processes in treatment facilities
Density	ρ	
Conductivity	EC	Used to assess the suitability of treated effluent for agricultural applications

[a] Details of various tests may be found in Reference 1.

[b] NTU = nephelometric turbidity unit.

[c] TON = threshold odor number.

Table 2. Common Analyses Used to Assess the Inorganic Chemical Constituents in Wastewater

Test[a]	Abbreviation/Definition	Use or Significance of Test Results
Free ammonia	NH_3	Used as a measure of nutrients present and the degree of decomposition in the wastewater; the oxidized form can be taken as a measure
Organic nitrogen	Org N	
Total Kjeldahl nitrogen	TKN (Org N + NH_4^+)	
Nitrites	NO_2^-	
Nitrates	NO_3^-	
Total nitrogen	TN	
Inorganic phosphorus	Inorg P	
Total phosphorus	TP	
Organic phosphorus	Org P	
pH	$pH = -\log[H+]$	A measure of the acidity or basicity of an aqueous solution
Alkalinity	$HCO_3^- + CO_3^{2-} + OH^- - H^+$	A measure of the buffering capacity of wastewater
Chloride	Cl^-	To assess the suitability of wastewater for agricultural reuse
Sulfate	SO_4^{2-}	To assess the potential for the formation of odors and may impact the treatability of waste sludge
Metals	As, Cd, Ca, Cr, Co, Cu, Pb, Mg, Hg, Mo, Ni, Se, Na, Zn	To assess the suitability of wastewater for reuse and for toxicity effects in treatment. Trace amounts of metals are important in biological treatment
Specific inorganic elements and compounds		To assess the presence or absence of specific constituents
Various gases	O_2, CO_2, NH_3, H_2S, CH_4	To assess the presence or absence of specific gases

[a] For test details, see Reference 1.

Table 3. Common Analyses Used to Assess the Organic Chemical Constituents in Wastewater

Test[a]	Abbreviation/Definition	Use or Significance of Test Results
Five-day carbonaceous biochemical oxygen demand	$CBOD_5$	A measure of the amount of oxygen required to stabilize a waste biologically
Ultimate carbonaceous biochemical oxygen demand	UBOD (also BOD_U, BOD_L)	A measure of the amount of oxygen required to stabilize a waste biologically
Nitrogenous oxygen demand	NOD	A measure of the amount of oxygen required to oxidize biologically the nitrogen in the wastewater to nitrate
Chemical oxygen demand	COD	Often used as a substitute for the BOD test
Total organic carbon	TOC	Often used as a substitute for the BOD test
Specific organic compounds and classes of compounds	MBAS[b], CTAS[c]	To determine the presence of specific organic compounds and to assess whether special design measures are needed for removal

[a] For test details, see Reference 1.
[b] MBAS = Methylene blue active substances
[c] CTAS = cobalt thiocyanate active substances

organic matter (typically greater than 1 mg/L) in wastewater include BOD, COD, and TOC. Both aggregate and individual organic constituents are of great significance in the treatment, disposal, and treatment of wastewater. Table 3 illustrates common organic chemical constituents, their analyses, and importance in wastewater treatment.

BIOLOGICAL CHARACTERISTICS

The biological characteristics of wastewater are of fundamental importance in controlling diseases caused by pathogenic organisms of human origin and because of the extensive and fundamental role played by bacteria

Table 4. Common Analyses Used to Assess the Biological Constituents in Wastewater

Test[a]	Abbreviation/Definition	Use or Significance of Test Results
Coliform organisms	MPN (most probable number)	To assess the presence of pathogenic bacteria and the effectiveness of the disinfection process
Specific microorganisms	Bacteria, protozoa, helminths, viruses	To assess the presence of specific organisms in connection with plant operation and for reuse.
Toxicity	TU_a and TU_c,	Toxic unit acute, toxic unit chronic

[a] For test details, see Reference 1.

and other microorganisms in decomposing and stabilizing organic matter in nature and wastewater treatment plants. Most species of pathogens such as bacteria, viruses, and protozoa can survive in wastewater and maintain their infectious capabilities for a significant period of time. Table 4 illustrates common biological characteristics, their analyses, and importance in wastewater treatment.

CHEMICALLY ENHANCED PRIMARY TREATMENT OF WASTEWATER

Frédéric J.F. Chagnon
Donald R.F. Harleman
Massachusetts Institute of Technology
Cambridge, Massachusetts

Chemically enhanced primary treatment (CEPT) is a wastewater treatment process in which small doses of chemical compounds are added to wastewater in order to increase the operating efficiency of sedimentation basins. The chemicals cause the suspended particles to clump together via the processes of coagulation and flocculation. The particle aggregates, or flocs, settle faster and thus enhance the treatment efficiency, which is measured as the removal of solids, organic matter, and nutrients from the wastewater. The chemicals utilized in CEPT are the same ones commonly added in potable water treatment (e.g., metal salts and/or organic polymers).

CEPT allows the sedimentation basins to operate at twice the overflow rate (defined as the flow per unit area in the sedimentation basin) of conventional primary treatment, while maintaining higher removal rates of total suspended solids (TSS) and biochemical oxygen demand (BOD). (The increase in BOD removal by CEPT is usually larger than that of suspended solids because of the removal through precipitation of colloidal BOD.) The treatment infrastructure is thus smaller, which reduces capital costs. The capital costs of a CEPT plant are approximately 25% of the capital costs of a conventional secondary treatment plant of equal capacity, while the operational costs are one-half those of a conventional secondary treatment plant (1). Additionally, CEPT provides the opportunity for either reducing the size of subsequent biological treatment units, or increasing the capacity of existing conventional treatment plants.

Table 1. Comparison of Removal Efficiencies (1)

Treatment Method	TSS, %	BOD, %
Conventional primary treatment	55	35
Conventional primary + biological secondary treatment	90	85
Chemically enhanced primary treatment	85	55

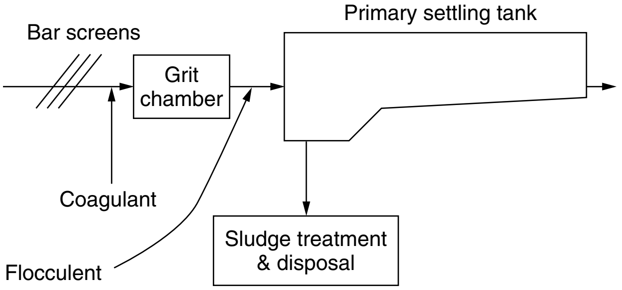

Figure 1. Schematic of conventional primary treatment and CEPT. (The addition of a flocculent in the form of organic polymers is optional.)

CEPT is almost as efficient as secondary treatment with respect to removal efficiencies (Table 1). CEPT may be implemented using a dedicated “CEPT tank” (i.e., a settling tank specially designed for CEPT) or by retrofitting a conventional primary treatment facility or stabilization ponds (2–5). The latter two incarnations of CEPT are relevant when upgrading overloaded existing systems (6).

A conventional primary treatment process consists of bar screens, a grit chamber, and a settling tank (Fig. 1). To upgrade a conventional primary treatment facility to a CEPT facility, all that is needed is the addition of a chemical coagulant (and optionally a flocculent). With CEPT’s high surface overflow rate, the sedimentation basins will not need to be large when compared to conventional primary sedimentation basins (7).

CEPT has been used for over one hundred years, yet it is not as commonly found as would be expected upon analysis of its performance. The misconception is that CEPT dramatically increased sludge production. However, CEPT is used today with a minimal coagulant dosage (10–50 mg/L), and the chemicals themselves make only a slight contribution to the total sludge production. The greatest portion of the increase of sludge production is due to the increased solids removal in the settling tank.

CEPT does not preclude secondary or tertiary treatment. It makes any subsequent treatment smaller and less costly due to the increased efficiency. CEPT is a relatively simple technology providing a low-cost and effective treatment, which is easily implemented over existing infrastructure (6,8,9). CEPT is also one of the least expensive wastewater treatment processes in which the effluent can be effectively disinfected.

GETTING OUR CLEAN WATER ACT TOGETHER

DAN WOLZ
City of Wyoming, Michigan
Wyoming, Michigan

Sometimes, having ideas or understanding ideas takes a long time. Maybe it is like fine wine. This idea was born in the current business climate of mission statements, defining the product, public perception, reality and principles and practices of Total Quality Management (TQM—which has reached the stage of maturity where an individual can now be a Certified Master TQMer). The idea: our industry's main product is clean water. No duh! (Not a TQM phrase.) This may not be a great revelation to anyone except maybe me. So what is my point? It is simply a question, "Why do we call them wastewater plants when the main product is clean water?" This could be rephrased to say "What cookie factory calls itself the flour, lard, baking soda, raisin, cinnamon, chocolate chip factory'?" This is the topic of this article.

As I began to think about this idea, I kept asking myself why we did not call the end product "clean water" right from the start. I can understand the use of the term "wastewater treatment plant" but not the shortened term "wastewater plant" now in common use. The subtle implication is that somehow "wastewater" is the product. It was starting to bother me. The message is inconsistent. There is something subliminally wrong with giving a negative connotation to something that does not deserve it. The well-worn axiom may fit here: If it walks like a duck and swims like a duck and quacks like a duck, it's a duck. I came to the conclusion it was time to call a duck "clean water." We spend a great deal of time and money trying to convince the dozens of students and the visiting public how well we clean it—just to call it "wastewater."

Before proceeding, I need to thank the author or authors of the word "wastewater" (you know, the word that is never recognized by your spell checker until you add it). Incidentally, if Virgil Langworthy, a Michigan resident and long-time water professional, is not the originator of the word, he can certainly be credited with being one of the early purveyors of it in the early 1960s. "The reason for the change" he said, "was the bad perception of the term 'sewage.'" And this was before TQM.

The word "wastewater" is far better than "sewerage" or "sewage" and was a great addition to our descriptive word quiver for our evolving industry language. These words have served us well over recent years, but the time has come to add and use the term "clean water" as the focus or our business. I must hasten to add that these traditional words should not be abandoned but further defined and applied when these new definitions warrant their use. "Wastewater" should now properly be redefined "as the used water leaving a household or industry and entering a sewer system." It could be also used as another way to describe plant influent but NOT what leaves a plant.

I read once that traditional Eskimo culture has more than 30 terms in its language to describe snow. The words were needed to describe the varying conditions of the harsh climate. We add more words to language to communicate concept, especially where we spend great amounts of time and study. One additional example would be the in computer industry. How many of us knew what "W.Y.S.I.W.Y.G." was in the early 1980s? (For those unfamiliar with that term, it was an acronym for "What you see is what you get," but it lost its periods and made its way into the dictionary as a genuine word.)

I decided to put action to my thoughts and began to use "clean water plant" in conversation with my co-workers and neighboring plants. Surprising resistance to the idea came from some of my brothers in drinking water plants who said things like "You are the 'dirty water people' and we are the 'clean water people'." The other comment was "if you use the term 'clean water' at a wastewater plant, the public will be confused." My response is simply to point out how frequently after a tour of the wastewater plant many people comment "I always wondered where my drinking water came from" when they leave. At that point, I feel like a total failure as a public educator. I do not think the public cares about our heterohydrophobic (fear of different kinds of water) distinctions, as long as they are receiving good service.

If there is confusion about the use of the term, it is because we in the clean water industry have failed to appropriate it and use it. The United States Congress gave us the "clean water" title 25 years ago with the passage of the Clean Water Act (CWA) which set discharge standards for WASTEWATER PLANTS since 1972. They then passed the Safe Drinking Water Act (SDWA) a few years later for DRINKING WATER PLANTS. What are we waiting for? Is not more than 25 years long enough to wait and see if the 800-pound gorilla (CWA) sitting in our living room is here to stay permanently? NEWS FLASH: He's *here to stay and while we were waiting, his whole family moved in and one of them, some say, is bigger and uGLIer (GLI is*

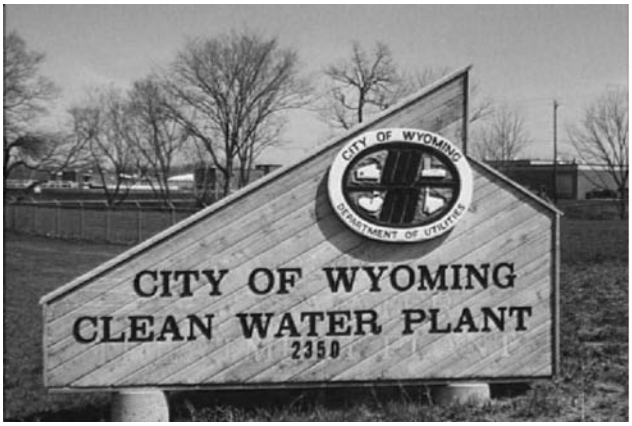

Figure 1. Sign at Wyoming waste water treatment plant.

an intentional reference to the Great Lakes Initiative). And they all want bananas!

Our society wants clean water, and it takes lots and lots of bananas to make it happen and keep it happening. We are giving society clean water now and we need to continue this good work, BUT make sure we acknowledge it is discharged from a Clean Water Plant. We all know bananas do not grow on trees (or is that money), and we do know how demanding gorillas can be. A word to the wise: feed the gorillas and suggest family planning.

In summary, I propose a global renaming of our "wastewater treatment plants" to "clean water plants." The drinking water plants are left with titles such as "safe drinking water plants," "drinking water plants," and/or "water filtration plants." I know of no drinking water plants that use the term "clean water" in their title. So, it is time to drive this idea out of the giant parking lot of ideas whose time has not yet come onto the freeway of ideas in everyday usage. I know the City of Wyoming, Michigan's Clean Water Plant is already on the freeway entry ramp hoping to see you at our clean water destination—the banana plantation (Fig. 1).

INADEQUATE TREATMENT OF WASTEWATER: A SOURCE OF COLIFORM BACTERIA IN RECEIVING SURFACE WATER BODIES IN DEVELOPING COUNTRIES—CASE STUDY: EASTERN CAPE PROVINCE OF SOUTH AFRICA

M.N.B. Momba
C. Mfenyana
University of Fort Hare
Alice, South Africa

INTRODUCTION

Sanitation, in its broadest meaning, refers to the formulation and application of measures designed to protect public health. It also covers the purification of wastewater and sewage before it is returned to the water cycle. Usually, wastewater treatment involves collecting the wastewater in a central, segregated location (the wastewater treatment plant) and subjecting the wastewater to various treatment processes (biological treatment and disinfection of the final effluent). The characteristics of these wastes, which are significant in pollution, are the suspended solids, oxygen demand of the organic matter (BOD), the coliform bacteria, and other pathogenic micro-organisms (1).

The presence of coliform bacteria in drinking water is the most common reason for the violation of the water standards. Coliform bacteria have a long history in water quality assessment, mainly because of their association with fecal pollution and relatively easy and rapid detection. Some members of the group are almost conclusively of fecal origion, whereas others may also multiply in suitable water environments (2,3). The South African General and Special Standards stipulate that treated sewage should comply with a standard of nil fecal coliforms/100 ml (Act 96 of May 18, 1984 No. 9225, Regulation 991). The efficiency of a wastewater treatment plant in removing harmful micro-organisms from the influent is therefore of utmost importance. Failure to remove such micro-organisms will result in harmful pathogens returning into the receiving surface water body. Being a major source of pathogens that are carried in water, monitoring sewage for pathogens has been demonstrated to be an excellent epidemiological tool for determining what diseases may be prevalent in the community at any one moment (4).

In the developing world, much of the population consumes untreated and nonpiped drinking water. Typically, people collect water from any available source and store it in a vessel or a container in the dwelling for domestic and potable use, often without treatment or protection from further contamination. It is therefore not surprising that an estimated 15–30% (5) of community gastrointestinal diseases in developing countries are attributed to unsafe drinking water, with studies indicating similar percentages (15–20%) of waterborne diarrheal diseases (6). These problems could be attributed to the unavailability of proper sanitation methods or when the existing methods are not functioning adequately (7). Severe problems with the microbial quality of water could be expected, especially in rural and informal settlements. In these areas, widespread scarcity, gradual destruction, and increased pollution of water sources exists. The situation is aggravated by the existence of many insufficient, poorly operated or maintained sanitation services (8). Fecal contamination of water supplies by untreated and/or inadequately treated sewage effluents entering rivers and dams that serve as the source of municipal water supplies create conditions for the rapid spread of pathogens, a problem encountered in both the developing and the developed parts of the world (9).

Although the Eastern Cape province of South Africa, where this study was conducted, is predominantly rural in composition, both rural and urban sectors can be found within the province. The Eastern Cape Province is one of South Africa's poorest provinces, where the official poverty rate in 1998 was at least 70%, and only a quarter of all households possessed an inside water tape (10). Although great strides have been made in effort to provide access to clean water, many small villages still lack safe water supplies (11), whereas large communities have water treatment plants, which fail to provide potable water of high quality to their consumers (12). The areas without water supplies use water directly from available and often contaminated sources without any treatment. In both cases, communities are therefore exposed to water-related diseases. This situation also pertains in most of the communities in the poor areas of developing countries.

The aim of this study was to evaluate the efficiency of the urban, semiurban, and the rural wastewater treatment plants for the removal of coliform bacteria in order to establish the relationship between the microbiological quality of the final effluent and that of the receiving water body, which may further influence infection and disease in the community. Our intention was to provide information that could assist water authorities in developing countries to address problems in the management of wastewater treatment plants in terms of microbiological standards of the effluent as set down by official guidelines, such as those in South Africa (13,14). Two of the four wastewater treatment plants used during the present survey, i.e., in Alice and Fort Beaufort, serve predominantly rural areas, whereas the other two wastewater treatment plants, i.e., East London and Dimbaza, serve urban and semiurban communities, respectively.

MATERIALS AND METHODS

Study Sites

Four wastewater treatment plants that serve the Buffalo City and Nkonkobe Municipal areas in the Eastern Cape Province of South Africa were used in the present study. The wastewater treatment plants are located in urban (East London–East Bank Reclamation Works), semiurban (Dimbaza), and rural areas (Alice and Fort Beaufort). The activated sludge system is the biological wastewater treatment used in all plants, followed by chlorination of the final effluent.

The final effluent from the East Bank Reclamation Works is discharged into the Indian Ocean between Nahoon and Eastern Beach at Bats Cave and into a pond for the irrigation of a nearby golf course. Supernatant liquor from the sedimentation tanks is channeled into a fish pond located within the plant premises. The Dimbaza wastewater treatment plant discharges its final effluent into a stream that empties into the Tembisa sewerage dams. The Alice wastewater treatment plant is situated on the banks of the Tyume River, which is also used as the receiving water body for the final effluent from the plant. The final effluent from Fort Beaufort Sewage Works is discharged into the Kat River. All these final effluents or receiving water bodies are often used by the communities for one or various purposes, which include domestic, agricultural, or recreational purposes.

Sample Collection

Wastewater samples were collected weekly from different stages (the raw influent, the aerobic zone, the clarifier, the final effluent, and the receiving water body) of the four plants between August and October 2003. For the microbiological quality analyses, sampling was done aseptically into sterile glass bottles. For the effluent samples, sodium thiosulphate (*ca* 17.5 mg/L) was added to bottles before autoclaving. The samples were then placed in ice bags and transported to the base laboratory at the University of Fort Hare for analyses within 2–4 h after collection.

Analyses of Wastewater and Receiving Water Body Samples

Free Chlorine Residual. The concentrations of free chlorine residual in the treated effluents were determined using a multiparameter ion-specific meter (Hanna BDH-laboratory).

Coliform Counts. The membrane filtration technique was considered, but the method proved to be too sensitive for the analyses of the samples. Consequently, the standard spread plate procedure was used during the study period. Three different selective media, namely Chromocult coliform agar (Merck), Fluorocult *E. coli* 0157: H7 agar (Merck), and Sorbitol–MacConkey agar (Mast Diagnostics) were used for the isolation of coliforms and other *Enterobacteriaceae* (Table 1). The agars were prepared according to the manufacturer's instruction. Water samples were analyzed for the above microorganisms using internationally accepted techniques (15). The enumeration of coliforms was based on the color of colonies corresponding to presumptive coliforms as indicated in Table 1.

Identification of Coliform Isolates. Bacterial colonies from the influent, final effluent, and the receiving water

Table 1. Summary of the Various Bacterial Colonies and Presumptive Coliform Strains Isolated from Different Culture Media

Culture Medium	Presumptive Bacterial Strain	Color of the Colony
Chromocult coliform agar	*Citrobacter freundii*	Salmon to red
	Escherichia coli	Blue to violet
	Salmonella enteritidis	Colorless
Fluorocult *E. coli* 0157:H7 agar	*Proteus Mirabilis*	Brown
	Enterobacter aerogenes	Yellow
	Escherichia coli 0157:H7	Colorless
	Salmonella typhimurium	Yellow with black center
Sorbitol–MacConkey agar	*Escherichia coli 0157:H7*	Colorless

body samples differing in size, shape, and color were randomly selected from different plates and transferred onto the same medium by streak plate technique and incubated at 37 °C for 24 h. These were further isolated on MacConkey agar (Biolab) by the same method and incubated at 37 °C for 24 h, thereafter they were further purified by the same method at least three times using nutrient agar biolab before gram staining was done. Oxidase tests were then conducted on those colonies that were gram negative. The 20E API kit was used for the oxidase-negative colonies and the strips were incubated at 37 °C for 24 h. The strips were then read and the final identification was secured using API LAB PLUS computer software (BioMérieux, Marcy l'Etoile, France).

RESULTS

Concentration of Free Available Chlorine (Residual) in the Final Effluents

The concentrations of the free chlorine residuals fluctuated in all the plants with the exception of the East London wastewater treatment plant (Table 2). Chlorine overdosing occurred during the first two months of the study period (August and September) in the Fort Beaufort plant and in September in the Dimbaza plant. A constant concentration of free chlorine residual was noted during the whole study period in the East London plant, whereas low concentrations of free chlorine residuals were noted in the final effluent of the Alice wastewater treatment plant (Table 2). Although the 1996 South African Guidelines do not specify any standard for the concentration of free chlorine residual in the treated effluent, this study considered those for domestic water supplies, which recommend ranges of 0.3–0.6 mg/l as ideal free chlorine residual concentration and 0.6–0.8 mg/l as good free chlorine residual concentration with insignificant risk of health effects (14). With the exception of the final East London treated effluents, none of the wastewater plant treated effluents complied with the above-mentioned recommended limits for domestic water supplies.

Table 2. Concentrations of Free Chlorine Residual in the Final Effluents from during the Study Period (Ranges) (No. of the Samples for Each Plant; 12)

	Chlorine Residual (mg/l)	
Wastewater Treatment Plant	Ranges	Means
Dimbaza	0.93–2.5	1.85
East London	0.59–0.66	0.58
Alice	0.03–0.66	0.24
Fort Beaufort	0.16–4.33	2.07

Performances of Wastewater Treatment Plants for the Removal of Presumptive Coliforms

The four wastewater treatment plants were investigated for their efficiency for the removal of coliforms. The enumeration of coliforms in each zone of different wastewater treatment plant was done in order to assess whether there was in fact a decrease in the number of presumptive coliforms as the wastewater flowed through the treatment processes, a practice that also served to identify possible malfunctioning in any of the wastewater treatment plant zones.

In general, a gradual removal of presumptive coliforms was observed through the different zones of the wastewater treatment plants. The data, however, reflected variations with regard to both the patterns and the efficiency of each plant for the removal of coliform micro-organisms (Figs. 1 and 2).

In the influent samples, both the Dimbaza and East London wastewater treatment plants had higher mean coliform counts (ranging between 4.6 log cfu/ml and 6.6 log cfu/ml for Dimbaza and between 5.3 log cfu/ml and 7 log cfu/ml for East London) than those found in Alice (5–6 log cfu/ml) and Fort Beaufort (4.8–6.2 log cfu/ml). This observation results from the fact that both Dimbaza and East London are urban and semiurban areas, respectively, and they are also both industrialized and, hence, much more densely populated than Alice and Fort Beaufort. Results in Figs. 1 and 2 also show that, although in Dimbaza, East London, and Alice wastewater treatment plants, a noticeable decrease in the mean coliform counts was observed in the clarifier zone, high mean coliform counts were still noted in the Fort Beaufort wastewater treatment plant, which was because of the absence of a functional clarifier.

The mean ranges for coliforms (0–0.2 cfu/ml) in the Dimbaza wastewater treatment's final effluent complied with the South African General and Special Standards, which stipulate that treated sewage effluents must have a standard of nil fecal coliforms (Act 96 of May 18, 1984 No. 9225, Regulation 991). The Dimbaza's effluent was also within the limits set for agricultural purposes (irrigation), which are ≤10,000 count/100 ml for fecal coliform and ≤1 counts/100 ml for *E. coli* (16). In East London, Alice, and Fort Beaufort wastewater treatment plants, the mean coliform ranges in the treated effluent samples were 1.5–2.9 log cfu/ml, 0.8–2.6 log cfu/ml, and 0.6–2.9 log cfu/ml, respectively. These results suggest that the general microbiological qualities of these effluents did not comply with the limits set by the South African Authorities, especially in terms of fecal coliforms.

Generally, an increase occurred in presumptive coliform counts from the final effluent samples to the receiving water body samples of the Dimbaza, Alice (presumptive *E. coli* being the exception), and Fort Beaufort wastewater treatment plants, whereas a decrease occurred in the mean counts of all presumptive coliforms from the East London water receiving body samples (Fig. 2). The means for coliforms in the receiving water bodies ranged between 0.2 and 1.5 log cfu/100 ml for Dimbaza, between 0 and 2.5 log cfu/100 ml for East London plant, between 0.25 and 3 log cfu/100 ml for the Alice plant, and between 1.5 and 3.25 log cfu/100 ml for Fort Beaufort. The results suggest that the receiving water bodies of all the plants did not comply with the limits set for domestic (0–10 counts/100 ml for total coliform, 0 counts/100 ml for fecal coliforms) and recreational (0–130 counts/100 ml for fecal coliform, *E coli* 0–130 counts/100 ml) use (13,14,17).

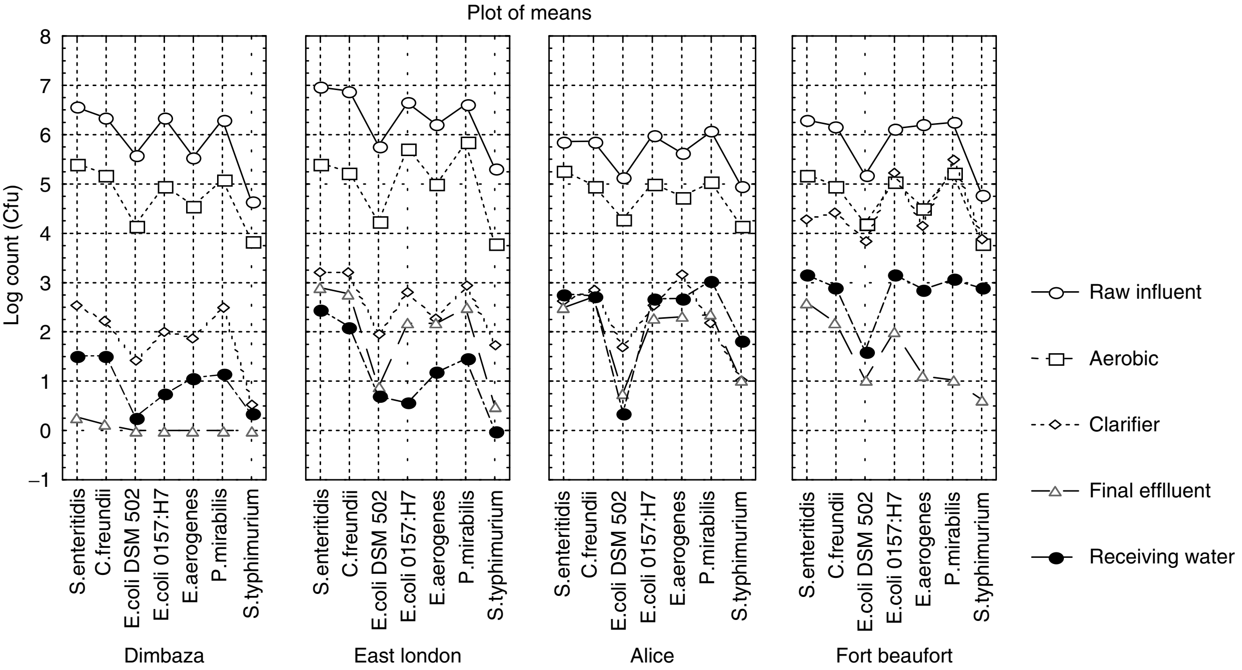

Figure 1. Plot of mean counts for presumptive coliforms obtained from the different zones of the Dimbaza, East London, Alice, and Fort Beaufort wastewater treatment plants and their water receiving bodies.

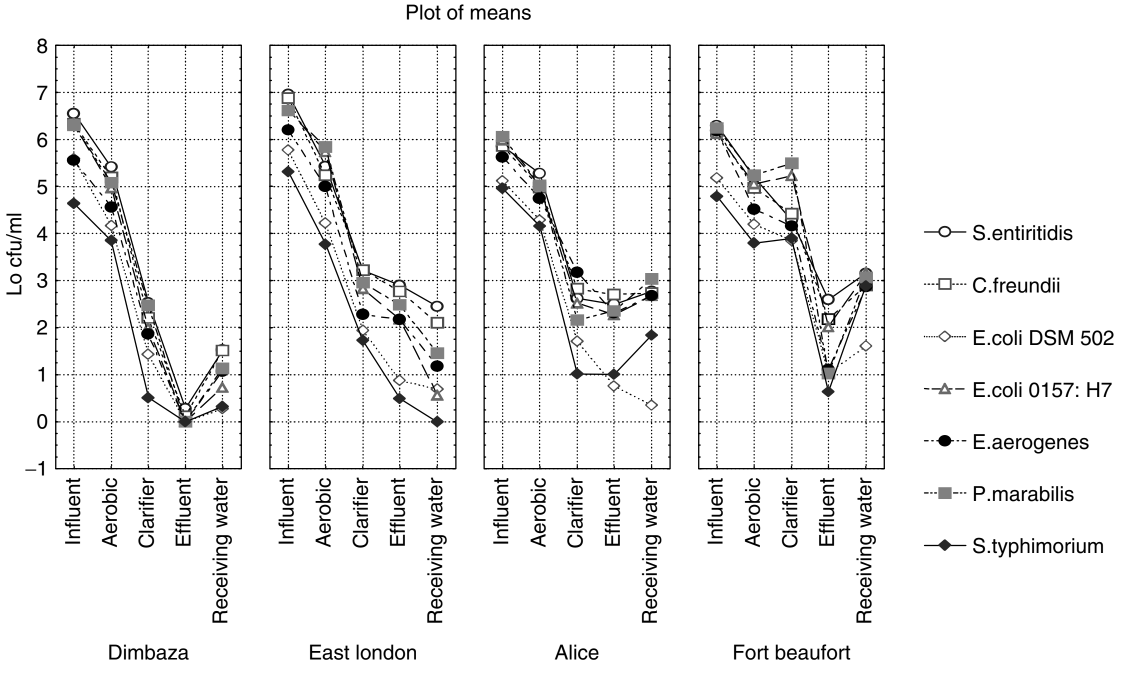

Figure 2. Performance of the different wastewater treatment plants for the removal of the presumptive coliform bacteria.

Identification and Bacterial Isolates

According to the API 20E system, the oxidase test and the gram staining test, species of *Proteus* were not among the identified organisms that belonged to the presumptive coliform species (Table 3). However, species of *Escherichia* (Dimbaza: influent; East London: receiving water body; Alice: influent and final effluent; Fort Beaufort: influent, final effluent, and receiving water body), *Citrobacter* (Alice: influent, final effluent, and receiving water body; East London: influent and receiving water body; Alice: influent; Fort Beaufort: influent and final effluent), and *Salmonella*

Table 3. Bacterial Isolates Identified from the Influent, Effluents, and Receiving Water Body Samples Analyzed (Number of Samples: 12 for each Stage of the Plant)

Wastewater Plants	Water Sources	Bacterial Isolate Identified
Dimbaza	Influent	*Aeromonas hydrophila, Citrobacter freundii, Escherichia coli, Klebsiella ornithinolytica, Vibrio cholerae, Vibrio parahaemolytica, Serratia liquefaciens.*
	Effluent	*Citrobacter freundii*
	Receiving body	*Citrobacter freundii, Enterobacter aerogenosa, Salmonella arizonae, Serratia odorifera*
East London	Influent	*Aeromonas hydophila, Chromo violaceum, Citrobacter freundii, Enterobacter aeogenosa, Klebsiella ornithinolytical, Pseudomonas putida, Vibrio fluvialis, Serratia ficaria, Serratia odorifera, Chromo violaceum.*
	Effluent	*Aeromonas hydophila, Chromo violaceum, Klebsiella ornithinolytica, Pseudomonas putida, Serratia odorifera, Serratia ficaria, Vibrio fluvialis.*
	Receiving body	*Aeromonas hydrophila, Citrobacter freundii, Escherichia coli, Klebsiella oxytoca, Klebsiella ornithinolytica, Morganella morgani, Vibrio fluvialis*
Alice	Influent	*Aeromonas hydophila, Citrobacter freundii, Enterobacter cloacae, Escherichia coli, Klebsiella ornithinolytica, Klebsiella oxytoca, Klebsiella ozaenae, Kluyvera* spp., *Pseudomonas putida, Vibrio cholerae*
	Effluent	*Aeromonas hydophila, Escherichia coli, Klebsiella ornithinolytica, Enterobacter amnigenus, Klebsiella ozaenae, Klebsiella oxytoca, Kluyvera* spp., *Pseudomonas putida*
	Receiving body	*Aeromonas hydophila, Enterobacter amnigenus, Klebsiella ornithinolytica, Klebsiella oxytoca, Pseudomonas aerogenosa, Pseudomonas putida*
Fort Beaufort	Influent	*Aeromonas hydrophila, Citrobacter freundii, Escherichia coli, Klebsiella ornithinolytica, Klebsiella oxytoca, Pasteurella pneumoniae, Salmonella arizonae, Serratia odorifera, Vibrio fluvialis.*
	Effluent	*Aeromonas hydrophila, Citrobacter freundii, Escherichia coli, Klebsiella oxytoca, Vibrio fluvialis*
	Receiving body	*Aeromonas hydrophila, Escherichia coli, Enterobacter cloacae, Pseudomonas putida, Shewan putrefaciens, Vibrio fluvialis*

(Dimbaza: receiving water body; Fort Beaufort: influent) were identified in some zones of the plants. Other organisms belonging to 11 other different species were also identified from different zones of the plants. These species included *Aeromonas* (Dimbaza: influent; Alice, East London, and Fort Beaufort: influent, final effluent, and receiving water body), *Klebsiella* (Dimbaza: influent; East London and Fort Beaufort: influent, final effluent, and receiving water body; Fort Beaufort: influent and final effluent), *Serratia* (Dimbaza: influent and receiving water body; East London: influent and effluent; Fort Beaufort: influent), *Enterobacter* (Dimbaza: receiving water body; East London: influent; Alice: influent, effluent, and receiving water body; Fort Beaufort: receiving water body), *Pseudomonas* (East London: influent and effluent; Alice: influent, effluent, and receiving water body; Fort Beaufort: receiving water body), *Vibrio* (Dimbaza: East London and Fort Beaufort: influent; Alice: influent, effluent, and receiving water body), *Chromo* (East London: influent and effluent), *Morganella* (East London: receiving water body), *Kluyvera* (Alice: influent and effluent), *Erwinia* (Alice: receiving water body), and *Shewanella* (Fort Beaufort: receiving water body) (Table 3). The efficiency of the Dimbaza wastewater treatment plant was also confirmed with the identification tests when compared with the other three plants. Among the 7 species identified from the Dimbaza's influent, only *Citrobacer freundii* was still prevalent in the treated final effluent and also in the receiving water body. It is obvious from the results in Table 3 that the final effluent was not the source of organisms such *Enterobacter aerogenosa, Salmonella arizonae*, and *Serratia odorifera* identified from the receiving water body. *Aeromonas hydrophila*, which was found to be the dominant strain in all influents, was still prevalent in the East London, Alice, and Fort Beaufort's treated effluents and received water bodies.

DISCUSSION

Access to a clean, pathogen-free water supply is a major priority for any community if it is to remain disease-free. In today's highly urbanized society, the best way to achieve this objective is to recycle water by treating used or wastewater through a treatment plant system. The efficiency of wastewater treatment plants in removing pathogenic micro-organisms from their final effluents can only be achieved by disinfection. According to White (18), the most prevalent practice of disinfection is free chlorine, which is also the practice in many developing countries. Disinfection with chlorine is always influenced by indicator organism concentration, disinfection concentration, contact time, temperature, and pH. The availability of the free chlorine residuals in the final effluents gives an indication of the efficacy of the disinfection process and thus a rapid indicator of the probable microbiological safety of the treated effluent.

In terms of the concentration of free residual in the effluents, results indicated the availability of free chlorine residual in all the wastewater plants, although in some plants (Fort Beaufort and Dimbaza, Table 2) these concentrations exceeded the limit recommended by water authorities, which are in the range of 0.3–0.6 mg/l as ideal free chlorine residual concentration and 0.6–0.8 mg/l as good free chlorine residual concentration for insignificant risk of health effects (14). In contrast to the other plants, the free chlorine concentrations complied with (East London) or were lower than the standards (Alice) (Table 2).

Although free chlorine was available in the various final effluents, with the exception of the Dimbaza plant, which showed a removal of coliform organisms at 85.71%, the results suggest that the microbiological quality of the final effluent in East London, Alice, and Fort Beaufort plants exceeded the standards for domestic and recreational use. The results also indicated that the effluents from all the plants were also one of the sources of coliforms in the receiving water bodies. In the Dimbaza plant, the *Citrobacter freundii* found in the final effluent also appeared in the receiving water body. In the Alice, Fort Beaufort, and East London wastewater treatment plants, 62.5%, 60%, and 43% of the organisms found in the final effluent were also prevalent in the receiving water body, respectively (Table 3). The results suggest that the microbiological quality of the effluents examined poses a serious health risk to the community, which is consistent with the findings of previous investigators, such as Muyima and Ngcakani (9), who pointed out that fecal contamination of drinking water supplied by untreated or inadequately treated sewage effluents entering rivers and dams that serve as the source of municipal water supplies creates conditions for the rapid spread of pathogens. It also became clear from the findings that the main reason behind the inefficiencies shown by the wastewater treatment plants for the removal of the coliforms stem from inadequate disinfection practices and/or inadequate maintenance of the facilities, as observed with the Fort Beaufort plant. Although the East London wastewater treatment plant was technically well equipped with five aerators and six clarifiers, this equipment was under repair during the study period and not all the clarifiers were in a working condition. This fact has been reiterated by Pearson and Idema (19), who, commenting on the disinfection of effluents in many cases in the developing countries, stated that a high level of reliability of water supply schemes, particularly the treatment process, is the exception rather than the rule. The authors further pointed out that various factors such as cost, operator training, and problems with maintenance of the infrastructure could be contributory factors to these problems.

A number of different species of potentially pathogenic micro-organisms were isolated from both the final effluents and the receiving water bodies of the different wastewater treatment plants. Although differences existed with the types of species isolated from the various effluents, potentially pathogenic organisms were isolated from all the effluent and receiving water body samples in various degrees of preponderance (Table 3). *Aeromonas hydrophila*, for example, was found as the dominant micro-organism identified from final effluents and receiving water bodies in East London, Alice, and Fort Beaufort wastewater plants. *Aeromonas* can be infectious, producing focal or systemic infections of varied severity. The most common clinical infection that has been associated with this organism is diarrhea (20–23). The preponderance of *A. hydrophila* in the final effluents and receiving water bodies is cause for much concern, because it is common for communities in the Eastern Cape to use the effluent receiving water body such as a river (in Alice and Fort Beaufort), a dam (Dimbaza), or ocean beach (East London) as a water source for drinking, bathing, washing (i.e., clothes, dishes, etc.), or recreational purposes (i.e., swimming) and the final effluent as a water source for irrigation purposes. The microbiological quality of these water sources could influence infection and disease in the communities.

CONCLUSIONS

A relationship existed between the microbiological quality of the final effluent and that of the receiving water body, and the relationship was such that the better the quality of the final effluent, the better the quality of the receiving water body. From the results, it could also be deduced that the appearance of coliform bacteria in the receiving water body, although no evidence exists of such in the final effluent, means that the source of pollution was from a source outside of the wastewater treatment process.

The disinfection practices and guidelines in terms of chlorine residual concentrations were found not to be sufficient for the removal of coliforms from the effluent. Although the chlorine residual concentration may fall within the recommended limits for no risk, the occurrence of coliforms could still be detected in the final effluent. This study, therefore, suggests that other factors, such as the chlorine demand of the water, the contact time, the initial indicator organisms, or the use of powerful disinfectants, be considered by the operators in wastewater treatment plants for the treatment of the effluents before they are discharged into the receiving water bodies.

Acknowledgments

The authors wish to express gratitude to the National Research Foundation who sponsored this investigation and to the late Mr. R.A. Agbandzi from the University of Fort Hare's Programme Unit of Statistics for his help during the study period; may his soul forever rest in peace.

DENITRIFICATION IN THE ACTIVATED SLUDGE PROCESS

Michael H. Gerardi
Linden, Pennsylvania

Denitrification in the activated sludge process is the use of nitrate ions (NO_3^-) by facultative anaerobic (denitrifying) bacteria to degrade soluble carbonaceous BOD (cBOD). Although denitrification most often is observed in the secondary clarifier, denitrification occurs whenever an anoxic condition exists. Denitrification in the secondary clarifier often is referred to as "clumping," "rising sludge," and "dark sludge rising." Clumping is highly undesired, because it results in poor compaction of solids, loss of solids, increased operational costs, and possible permit violations.

Besides the anoxic condition known as clumping, an undesired anoxic condition can occur in the sewer system and other treatment units and a desired anoxic condition can be produced in a denitrification tank or designated anoxic tank. A denitrification tank is used to satisfy a total nitrogen discharge limit, while a designated anoxic tank is used to improve process performance. Desired process performance includes destruction of undesired filamentous organism growth and strengthening of floc particles.

Unless an industry discharges nitrate ions to the activated sludge process, activated sludge processes that denitrify usually nitrify. Industrial discharges that may contain nitrate ions include pretreated leachate, pretreated meat processing wastewater, meat processing wastewater containing flavoring compounds, and steel mill wastewater. The presence of nitrate ions in the sewer system is highly undesired. Here, nitrate ions permit the rapid degradation of soluble cBOD. The degradation of soluble cBOD results in a decrease in the quantity of cBOD in the influent to a wastewater treatment plant. This decrease in cBOD makes it difficult for the operator of an activated sludge process to achieve an 85% removal efficiency for cBOD.

There are four factors that must be satisfied in order for an anoxic condition to occur. First, an abundant and active population of denitrifying bacteria must be present. Second, nitrate ions must be present. Third, free molecular oxygen (O_2) must be absent or an oxygen gradient must present. Fourth, a source of soluble cBOD must be present.

Denitrifying bacteria enter an activated sludge process through fecal waste and inflow and infiltration (I/I) as soil and water organisms. Approximately 80% of the bacteria in the activated sludge process are facultative anaerobes (Table 1). These organisms are present in millions per milliliter of bulk solution and billions per gram of floc particle, and most denitrifying bacteria reproduce every 15–30 min. The most significant genera of bacteria containing denitrifying species are *Alcaligens*, *Bacillus*, and *Pseudomonas*.

Denitrifying bacteria can use either free molecular oxygen or nitrate ions to degrade soluble cBOD. However, the bacteria prefer free molecular oxygen to nitrate ions to degrade soluble cBOD, because the use of free molecular

oxygen to degrade soluble cBOD results in the production of more offspring (bacterial cells or sludge) and more useable cellular energy than the use of nitrate ions. For example, the use of free molecular oxygen to degrade 1 lb of sugar results in the production of approximately 0.6 lbs of bacterial cells or sludge. The use of nitrate ions to degrade 1 lb of sugar in the activated sludge process results in the production of approximately 0.4 lbs of bacterial cells or sludge.

Nitrate ions may enter an activated sludge process from an industrial discharge. Typically, the nitrate ions used by denitrifying bacteria are produced in the activated sludge process through nitrification. Nitrate ions produced in the activated sludge process may be discharged to a secondary clarifier, denitrification tank, thickener, and anaerobic digester. Nitrate ions also may be recycled in the wastewater treatment plant to the headworks, primary clarifier, or influent to the activated sludge process. Depending on operation conditions in each treatment unit, the nitrate ions received in these units may undergo denitrification and may contribute to operational problems.

Nitrate ions are used by denitrifying bacteria in the absence of free molecular oxygen or in the presence of an oxygen gradient. An oxygen gradient is established when the dissolved oxygen concentration outside the solids is <1 mg/L and the size of the solids is $>100\ \mu$m. The oxygen gradient does not permit oxygen to reach the core of the solids. Therefore, bacteria on the perimeter of the floc particle degrade soluble cBOD using free molecular oxygen, while bacteria in the core of the solids use nitrate ions to degrade soluble cBOD. In the presence of an oxygen gradient, measurable oxygen is detected yet denitrification occurs.

The presence of soluble cBOD is the most important factor affecting the occurrence of an anoxic condition. The more soluble cBOD available to the facultative anaerobic bacteria, the more quickly the bacteria exhaust the available oxygen and begin to use nitrate ions. There are several sources of soluble cBOD that can be used by denitrifying bacteria. Chemical compounds that often are used in denitrification tanks include acetate, ethanol, glucose, and methanol. Methanol is the most commonly used source of soluble cBOD for denitrification tanks. Methanol is simplistic in structure, highly soluble, quickly absorbed by bacterial cells, and easily degraded. However, domestic wastewater often is used in an anoxic tank to achieve denitrification and destroy filamentous organisms and strengthen floc particles.

Denitrification proceeds in a step-by-step series of events through the reduction of nitrate ions. Nitrite ions are reduced to nitrite ions (NO_2^-), nitric oxide (NO), nitrous oxide (N_2O), and finally molecular nitrogen (N_2). When denitrification occurs there are three gases that are produced and released by the denitrifying bacteria. These gases in order of quantity produced are molecular nitrogen, carbon dioxide (CO_2), and nitrous oxide. Many bubbles of these gases escape from the wastewater, while some bubbles become entrapped in solids. The entrapped bubbles render the solids buoyant and result in a loss of settleability and solids from the secondary clarifier.

Denitrification also results in the production of alkalinity (Eq. 1).

$$\begin{aligned} 6\ NO_3^- + 5\ CH_3OH \longrightarrow\ & 3\ N_2 + 5\ CO_2 \\ & + 7\ H_2\ O + 6\ OH^- \end{aligned} \tag{1}$$

Alkalinity is returned in the form of the hydroxyl ion (OH^-) and the production of bicarbonate alkalinity (HCO_3^-) from carbon dioxide. Approximately 50% of the alkalinity lost during nitrification is returned to the activated sludge process through denitrification.

Clumping in the secondary clarifier can be prevented or controlled through several operational measures. Appropriate measures should be selected depending on whether a nitrification requirement exists for the activated sludge process.

If an activated sludge process is not required to nitrify, then nitrification may be terminated. This can be done by reducing solids inventory in the aeration tank, reducing the mean cell residence time (MCRT), reducing the dissolved oxygen level in the aeration tank, and taking an aeration tank off-line. If an aeration tank is taken off-line, then the remaining on-line aeration tanks have reduced hydraulic retention time (HRT) and increased organic loading. Reduced hydraulic retention time and increased organic loading disfavor nitrification.

If an activated sludge process is required to nitrify, then nitrification must be maintained. Clumping in the secondary clarifier can be prevented or controlled by increasing the return activated sludge (RAS) rate or treating secondary clarifier solids with a polymer or coagulant and increasing the RAS rate. Clumping also can be prevented or controlled by using plug flow mode of operation that incorporates an anoxic tank in the first tank (Fig. 1), or periodically terminating aeration for 1–2 h in an aeration tank while maintaining mixing action. Terminating aeration provides for the use of nitrate ions to degrade soluble cBOD in the aeration tank before they can be discharged to the secondary clarifier. However, once aeration is terminated to a tank, the tank can no longer nitrify.

Indicators of denitrification in the secondary clarifier are numerous. Rising bubbles of molecular nitrogen, carbon dioxide, and nitrous oxide are present in the clarifier. The bubbles may be found rising freely in

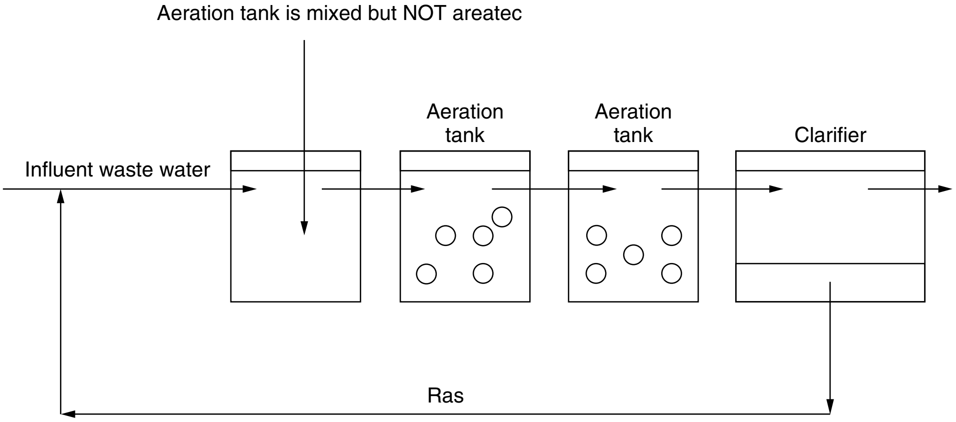

Figure 1. Plug flow mode of operation using an anoxic tank.

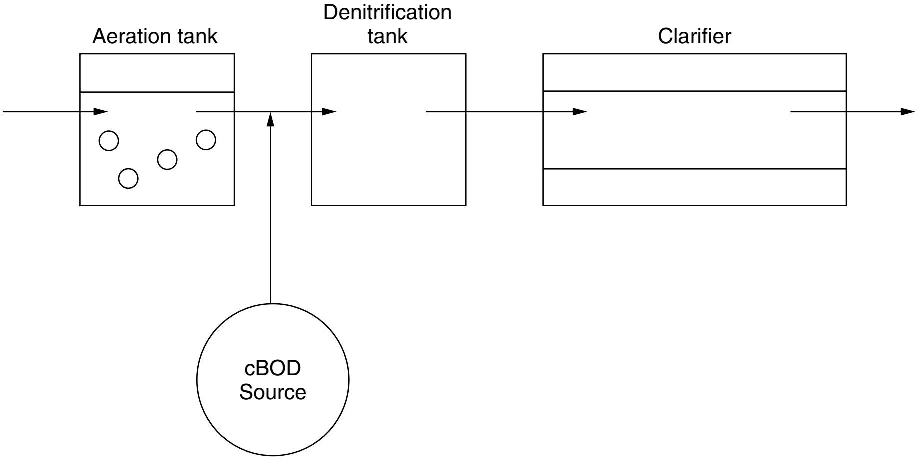

Figure 2. Denitrification tank.

the bulk solution, on the surface of rising solids, or released from the solids when the solids burst upon reaching the surface of the clarifier. The solids rising to the surface usually are dark due to the high MCRT required to grow a large population of nitrifying bacteria. Because nitrate ions are used during denitrification, the influent concentration of nitrate ions to the clarifier is greater than the effluent concentration of nitrate ions. Because denitrification returns alkalinity to the wastewater, the influent concentration of alkalinity to the clarifier is less than the effluent concentration of alkalinity from the clarifier. If sufficient alkalinity is returned to the secondary clarifier, an increase in pH across the clarifier occurs.

A denitrification tank is used to reduce the quantity of nitrogen in the effluent of an activated sludge process as required by permit (Fig. 2). A denitrification tank is located downstream of the activated sludge process. The denitrification tank receives the nitrate ions produced through nitrification in the aeration tank as well as the aeration tank's facultative anaerobic bacteria, residual dissolved oxygen, and residual soluble cBOD. In order to denitrify in the tank, slow subsurface mixing action is used to suspended large numbers of facultative anaerobic bacteria and place them in contact with the residual dissolved oxygen. Because the quantity of soluble cBOD entering the tank from the aeration tank is relatively small, soluble cBOD must be added to the denitrification tank. Approximately 3 mg/L of soluble cBOD are consumed in the denitrification tank for each mg/L of nitrate ion present. The soluble cBOD compound most often used in the denitrification tank is methanol. Retention times in the denitrification tank vary greatly, but most retention times are usually 30–60 min in length.

DETERGENTS

Kauser Jahan
Rowan University
Glassboro, New Jersey

Detergents are formulations that have cleaning and solubilization properties. Their main fields of application are industry (cleaning products, food, industrial processing), household (laundry, dishwashing), and personal care (soaps, shampoos, cosmetics). Detergents consist of surface-active agents known as surfactants and other subsidiary components that include boosters, builders, and fillers. In 1996, the production of surfactants including soaps was reportedly around 30×10^9 kg per year worldwide (1). Detergents are thus environmentally important because they are used in huge quantities. Historically, potential detergent contamination of the environment followed when the use of soap-based detergents changed to synthetic detergents. Detergents are discharged to the environment typically through wastewater treatment plant effluent and the use of sewage sludge on land. Industrial discharges to surface waters, oil spills, and surfactant-enhanced remediation of contaminated soil can also be other sources. Biological treatment of wastewater typically removes 95% of the detergents and their metabolites (2). However, recent research has generated scientific and regulatory concern because certain detergents and their metabolites appear toxic to aquatic organisms (3–7). These studies also indicate that detergent metabolites are also more toxic than their parent compounds. The complexity of detergent products, it has also been shown, leads to synergistic effects (8).

DETERGENT STRUCTURE AND USE

Detergents consist of surface-active agents, known as surfactants, and other subsidiary components that include boosters, builders, and fillers (9). Surfactants, as defined by Rosen (9), are substances that adsorb onto surfaces or interfaces and alter the surface or interfacial free energies of those surfaces when present at low concentrations in a system. The term interface means a boundary between any two immiscible phases: the term surface implies an interface where one phase is a gas. Surfactants have a characteristic molecular structure consisting of a structural group that is solvent hating (*lyophobic*) and a group that is solvent loving (*lyophilic*). This type of structure is called *amphipathic*. A typical surfactant molecule is shown in Fig. 1.

This nature of the surfactant causes concentration of the surfactant at a surface and the reduction of surface tension and also the orientation of the molecule at the surface: its *lyophilic* group is in the solvent phase, and its *lyophobic* group is oriented away from it. In an aqueous solution, the *lyophobic* term is *hydrophobic*, and the lyophilic term is *hydrophilic*. The hydrophobic group is typically a long-chain hydrocarbon, whereas the hydrophilic group is an ionic or highly polar group. Depending on the nature of the charge of the hydrophilic group, surfactants are classified as anionic (negative charge), cationic (positive charge), nonionic (no charge), and zwitterionic (both charges).

Anionic surfactants are used extensively in toilet soap bars, toothpaste, hair preparations and shampoos, wax strippers, textile lubricants, and degumming silk. Various types of anionic surfactants are listed in Table 1.

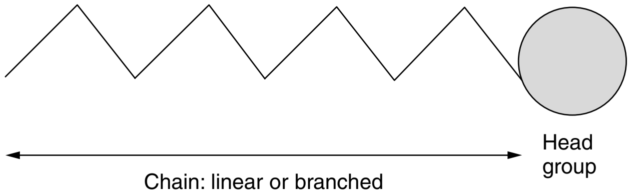

Figure 1. Structure of a surfactant molecule.

Table 1. Types of Anionic Surfactants[a]

Type	Example
1. Carboxylic acid salts	Soap
2. Sulfonic acid salts	LAS—linear alkyl benzenesulfonate in industrial detergents; petroleum sulfonates for oil recovery
3. Sulfuric acid ester salts	Na lauryl sulfate—toothpaste, fabric detergent
4. Phosphoric and polyphosphoric acid esters	Emulsifying agents in pesticides and herbicides
5. Perflourinated anionics	Control of oil and gasoline fires

[a] Reference 9.

Cationic surfactants are compatible with nonionic and zwitterionic surfactants. They carry a positive charge, so they strongly adsorb onto most solid surfaces. These surfactants exhibit poor detergency and are more expensive than other surfactants. Typical types of cationic surfactants and their uses are shown in Table 2.

Nonionic surfactants are widely used because they are compatible with other types of surfactants. They are generally available as 100% active material, free of electrolyte. They have poor foaming properties and are excellent carbon dispersing agents. Typical types of nonionic surfactants and their use are shown in Table 3.

Zwitterionic surfactants are compatible with all other kinds of surfactants. They are used as bactericides, corrosion inhibitors, pigment dispersion aids, cosmetics, fabric softeners, and soap detergent formulations.

Of all the types of surfactants mentioned, LAS (anionic) and APE (nonionic) are the major forms of surfactants found in detergent wastewater. APEs are further classified as OPEs (octylphenolethoxylates) and

Table 2. Types of Cationic Surfactants[a]

Type	Example
1. Long chain amines and their salts	Corrosion inhibitors; anticaking agents for fertilizers; flotation agents for metal ores
2. Di- and polyamines and their salts	Pigment coating; ore flotation
3. Quaternary ammonium salts	Textile softeners; germicides; disinfectants; sanitizers; health products
4. Polyoxyethylenated long-chain amines	Emulsifying agent for herbicides, insecticides, polishes, and wax emulsions
5. Quaternized polyoxyethlenated long-chain amines	Textile antistatic agent; dyeing leveler; corrosion inhibitor;
6. Amine oxides	Foam stabilizer for detergents, shampoos, and dishwashing liquids

[a] Reference 9.

Table 3. Types of Nonionic Surfactants[a]

Type	Example
1. Polyoxyethylenated alkylphenols; alkylphenol ethoxylates (APE)	Foam control; paint emulsifier; cosmetic emulsions; liquid detergents; dyeing retarders
2. Alcohol ethoxylates (AE)	Heavy-duty liquid detergents
3. Polyoxyethylenated polyoxypropylene glycols	Dispersants for pigments in latex paints; scale removal in boilers; petroleum deemulsifiers; foam control in laundry detergents
4. Polyoxyethylenated mercaptans	Cleaning and scouring of wool; metal cleaning; shampoos
5. Long-chain carboxylic acid esters	Food and pharmaceutical industries; cosmetics; textile antistats;
6. Alkanolamides	Foam stabilizers; thickeners for shampoos and liquid detergents
7. Tertiary acetylenic glycols	Wetting agents for use in powdered solids and emulsion paints
8. Polyoxyethylenated silicones	Wetting agents for polyester and polyethylene

NPEs (nonylphenolethoxylates), depending on the number of carbons. The general chemical structures of LAS and APE are presented in Fig. 2.

Analytical Methods

The qualitative and quantitative analysis of surfactants using titrimetric, spectrometric, and chromatographic techniques has been reported (3,4,10). Dissolved surfactant can be separated from dilute aqueous solution using the Wickbold method (11). This method is independent of the type of surfactant and isolates the surfactant as a residue suitable for analysis. The method, however, is lengthy and requires large sample volumes. Therefore, some studies have investigated and reported the use of SPE (solid-phase extraction) columns (12–13). The MBAS method (10) is useful for estimating the anionic surfactant content in water and wastewater samples. The CTAS (10) method is used to estimate the nonionic surfactant content in water if interference from other surfactants such as cationic and anionic can be eliminated. For more accurate and individual oligomers, normal-phase, high-performance liquid chromatography (HPLC) techniques have been reported for both LAS and APE surfactants. Ahel et al. (3,4,7) outlined analytical methods for APEs and their metabolites using normal-phase and reverse-phase HPLC for water, wastewater, and sludge samples. Ethoxylated nonionic surfactants are not volatile; therefore, their analysis is not well suited to gas chromatography. Typically, only lower molecular mass surfactant components can be analyzed by gas chromatography but only at high column temperatures (14). LAS analysis by HPLC has been described in detail by Matthijs and De Henau (15). Major metabolites for APE surfactants such as nonylphenol (NP) and octylphenol (OP) can also be analyzed by HPLC techniques (16–18).

OCCURRENCE OF DETERGENTS IN WASTEWATER AND SEWAGE SLUDGE

PT benzene (propylene tetramer benzene sulphonate) was used as the major surfactant in detergents until 1960. It was found that PT benzene is recalcitrant and causes foaming in rivers. This led to the use of more biodegradable straight-chain alkyl surfactants such as LAS. LASs currently represent 40% of all surfactants used (19). The other commonly used class of surfactants is APEs; the worldwide production is reportedly around 500×10^3 tons pa (19). Therefore, literature has focused more on the environmental impacts of LASs and APEs. Measured concentration of surfactants in municipal sewage effluents reportedly range from 0.008 to 6.2 mg/L and in river waters from 0.0042 to 2.6 mg/L (20–21). Literature indicates that a significant portion of the surfactants in raw sewage adsorbs to particulate matter. Primary sludge removed from primary settling tanks are reportedly rich in LAS, and concentrations vary from 5,000–15,000 mg/L (19). Most surfactants also do not biodegrade under anaerobic conditions. Therefore, sludge treated via anaerobic processes is rich in surfactants. Anaerobically digested sewage sludge reportedly contains 0.3–1.3% LAS (19).

Dentel (22) reported the load of LAS and APE in a typical WWTP and their subsequent fate. His data are presented in Fig. 3. The figure indicates that significant

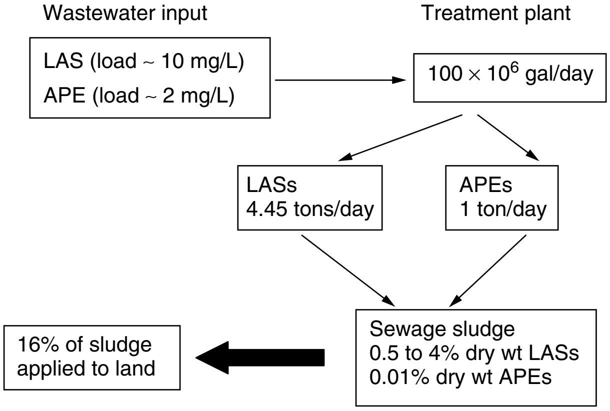

Figure 3. Surfactant transport through a typical WWTP (22).

amounts of surfactants are transported to the environment through WWTP effluent discharge and sludge disposal.

BIODEGRADATION OF DETERGENTS

Biodegradation of surfactants can be classified as primary or ultimate. Primary biodegradation is the loss of detergency, whereas ultimate indicates complete conversion to CO_2, CH_4, water, salts, and biomass. The biodegradation of LASs and APEs is well documented. LASs are highly biodegradable—rates are as high as 97–99% under aerobic conditions. Typically, the process involves breakdown of the straight-chain alkyl chain, then the sulphonate, and finally the benzene ring. There is no evidence for comparable LAS degradation under anaerobic conditions. Biodegradation of LAS, it has been shown, is dependent on dissolved oxygen concentrations, the presence of other organic contaminants and other surfactants, and pH.

In contrast to LASs, APEs are less biodegradable: values of 0–20% have been reported (19). APEs undergo complete primary degradation in aerobic environments, and metabolic products accumulate. APEs consist of NPES and OPEs. Nonylphenol (NP) and octylphenol (OP) have been identified as the major metabolites of these two classes of surfactants. Both are toxic and xenoestrogenic; octyplenol is more toxic than nonylphenol (23). NP is approximately 10 times more toxic than its ethoxylate precursor. Biodegradation is accomplished by stepwise shortening of the ethoxylate chain. This produces a complex mixture of compounds that can be divided into three main groups: short-chain ethoxylates, alkylphenoxy carboxylic acids, and alkylphenols such as NP and OP. As the chain gets shorter, the molecule becomes less soluble. The alkylphenoxy carboxylic acids and longer chain APEs are soluble in water; the shorter chain APEs are insoluble in water, particularly NP and OP. Both compounds have low water solubility and tend to adsorb onto suspended solids or sediments.

The biodegradation of surfactants in sewage sludge poses some problems. Typically a common initial step in WWTP is primary settling of particulates. Sludge from this tank can be rich in surfactants because surfactants tend to adsorb to particulates. Anaerobic sludge treatment at high temperature is typically the norm for WWTPs. Most common surfactants are not biodegradable under anaerobic conditions. Therefore, anaerobically digested sewage sludge is a potential source of surfactants for the soil.

LAS are not biodegradable either by mesophilic or thermophilic anaerobic digestion. Therefore, anaerobically digested sludge can contain 0.3–1.2% LAS and thus be a potential source. Jensen (24) reported that LAS concentrations in sludge are highly dependent on the sludge treatment method employed. LAS in sludge-amended soil, however, was rapidly biodegraded in the aerobic soil. Concentrations of APE are much higher in anaerobically digested sludge (900–1,100 mg/kg) than in aerobically digested sludge (0.3 mg/kg) (19). Marcomini (25) reported that sewage-amended soil in aerobic environments exhibited rapid NP degradation.

Cationic surfactants are considered readily biodegradable under aerobic conditions. These surfactants carry a positive charge, so they have a strong affinity for negatively charged particulate surfaces in sewage sludge. The adsorption of cationic surfactants to particulate matter makes the sludge treatment method employed important. However, there is no evidence of anaerobic biodegradation for this class of surfactants.

Data for soap indicates that it is readily biodegradable in both aerobic and anaerobic environments (26). Fatty acid esters (FES) are also readily biodegradable under aerobic conditions (27) but poorly degradable under anaerobic conditions (28). Steber and Werich (29) found rapid degradation of FES in aerobic soils amended with anaerobically treated sludge.

Fatty alcohol sulphates (FES) are readily biodegradable under both aerobic and anaerobic conditions (30). Research also indicates that alcohol ether sulfates (AES) are readily biodegradable under aerobic and anaerobic conditions. Fatty alcohol ethoxylates (AE) are known to be readily biodegradable and thus maybe a suitable replacement for APEs.

TOXICITY OF DETERGENTS

Toxicity of detergents has received a lot of attention in recent years. Detergents and their metabolites are common constituents of municipal effluents, so they also contribute to the toxicity. Toxicity data for surfactants to various marine species of freshwater and marine life have been documented as early as 1950 (31). In most cases, these data were generated from standard toxicity tests in the laboratory under controlled conditions. Detergent products and their ingredients are relatively toxic to aquatic life. Lewis (35) has provided an extensive review on the toxicities of surfactants to freshwater and marine life. Household washing detergents and softeners, it has been shown, are toxic from 0.07 to 35.4 mg/L (32). Both LAS and NPE exhibit relatively high acute toxicities; 48-h LC_{50} values are typically in the range of 5 to 10 and 0.1 to 2.0 mg/L. There is a large and growing body of literature on the acute and chronic toxicity of NP and NPEs toward aquatic organisms (33–36). Exposure of fathead minnows to 22.7 mg/L of NP in water for 20 days resulted in a bioconcentration factor of 344 (34). Selected values for NP toxicity determined by Naylor (36) are presented in Table 4.

REGULATORY STANDARDS

There are no regulatory restrictions on the use of APEs in the United States. Massive monitoring studies conducted in the United States (36) indicate that NP does not pose a significant risk to aquatic organisms. The USEPA is clarifying the regulatory status of NPEs by issuing water quality guidance (37–38). The draft guidance indicates the following levels for nonylphenol:

Freshwater 6.6 ppb water (4-day average) and 25 ppb (1-hour average)

Saltwater 1.6 ppb (4-day average) and 6.2 ppb (1-hour average)

The APE Research Council supports the draft EPA water quality guidelines for NP.

The Soaps and Detergents Association found that the present use of NPES in detergents and cleaning products poses little or no risk to the environment in the United States. Environmental monitoring studies (39–41) demonstrate that APEs and their metabolite concentrations in rivers and lakes in the United States are below toxic levels. These studies also demonstrate that 92 to 99% of NPEs are effectively removed in wastewater treatment plants in the United States. Based on research conducted in the USA, APEs do not appear to pose a significant ecological risk.

The Canadian Government is currently reviewing the environmental and health characteristics of NP and NPEs under its PSL2 program. European countries, however, have started phasing out the use of APEs in their products. In 1986, Germany instituted voluntary restrictions and Switzerland banned the use of surfactants in laundry detergents (39). A voluntary ban on APE use in household products began in 1995 throughout northern Europe (42). Denmark has introduced an environmental quality standard for NP and NPEs of 1 μg/L. Studies conducted in Japanese wastewater treatment plants (43) indicated widespread pollution by NPEs and their metabolites.

CONCLUSIONS

Literature indicates that the presence of detergents in wastewaters may pose problems, depending on the treatment methodology for the wastewater and sludge. Most detergents are biodegradable under aerobic conditions. However, concerns with degradation products of APEs, particularly nonylphenol, remain. There is also concern over the resistance of all major classes of detergents to biodegradation in anaerobic environments, especially because this is the predominant method of sludge treatment from primary tanks. The amphiphilic nature of surfactants makes them prone to adsorption to the sludge during primary tank settling. Therefore a significant portion of the surfactants in wastewaters may be passed untreated into the sludge. Studies indicate that application of sludge in aerobic soil environments can lead to further biodegradation. However, more studies are required to determine the fate of toxic intermediates in soil.

ECOLOGICAL WASTEWATER MANAGEMENT

GUENTER LANGERGRABER
BOKU—University of Natural
Resources and Applied Life
Sciences
Vienna, Austria

Conventional sanitation concepts are neither an ecological nor an economical solution for rural areas in both industrialized and developing countries. Ecological sanitation (EcoSan) represents a holistic approach toward ecologically and economically sound sanitation. The underlying aim is to close nutrient and water cycles with as small an expenditure on material and energy as possible to contribute to sustainable development. EcoSan is a systemic approach and an attitude. Single technologies are only a means to an end. Therefore, EcoSan-technologies may range from nearly natural wastewater treatment techniques to compost toilets, simple household installations, and to complex, mainly decentralized systems. These technologies are not ecological per se but only in relation to the observed environment. Promotion of EcoSan concepts, therefore, is the strategy for achieving the goal—closing the loop in wastewater management and sanitation.

DEFINITION OF ECOLOGICAL SANITATION

A sanitation system that provides ecological sanitation (EcoSan) is a cycle—a sustainable, closed-loop system (Fig. 1). The EcoSan approach is resource minded, not waste minded. Human excreta are treated as a resource and are usually processed on-site and then, if necessary, processed further off-site until they are completely free of disease organisms. The nutrients contained in excreta are then recycled by using them, for example, in agriculture.

The basic motivation behind the need to reshape the management of nutrients and streams of organic residuals in society may be found in the so-called "basic system conditions for sustainable development" for water and sanitation management, formulated in Agenda 21 (1):

1. The withdrawal of finite natural resources should be minimized.
2. The release of nonbiodegradable substances to the environment must be stopped.
3. Physical conditions for circular flows of matter should be maintained.
4. The withdrawal of renewable resources should not exceed the pace of regenerating them.

If a sanitation system shall contribute toward the goals of ecological sanitation, it has to meet or at least to be on the way toward meeting the following criteria, as given by Esrey et al. (2):

1. *Prevent disease*: A sanitation system must be capable of destroying or isolating pathogens.
2. *Affordable*: A sanitation system must be accessible to the world's poorest people.
3. *Protect the environment*: A sanitation system must prevent pollution, return nutrients to the soil, and conserve valuable water resources.
4. *Acceptable*: A sanitation system must be aesthetically inoffensive and consistent with cultural and social values.
5. *Simple*: A sanitation system must be robust enough to be easily maintained within the limitations of

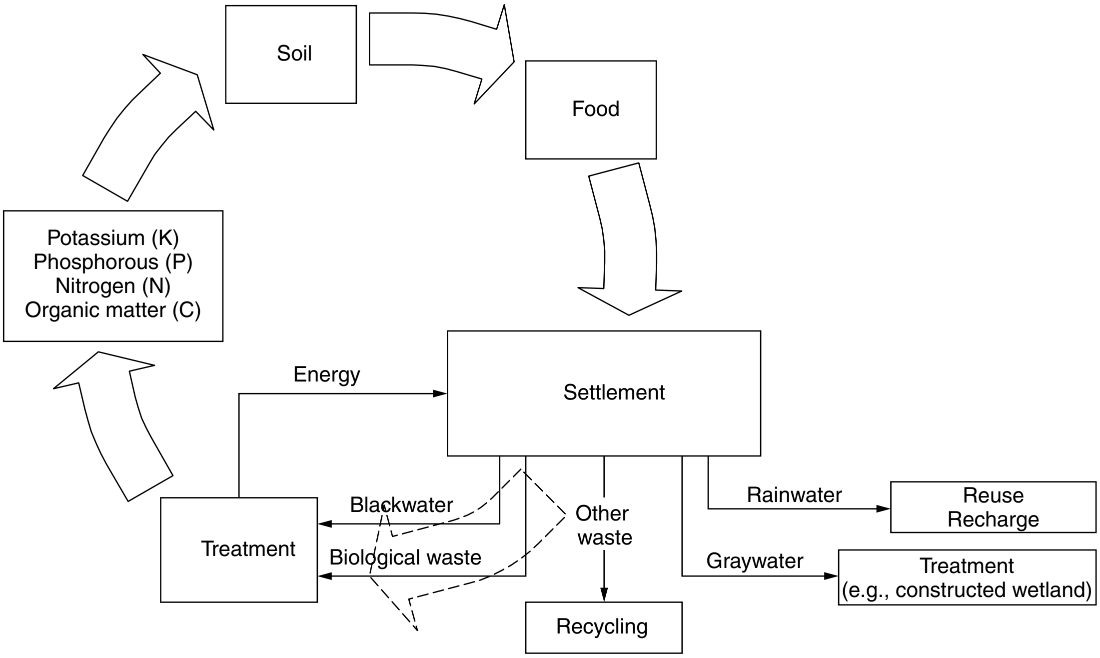

Figure 1. An ecological sanitation system.

the local technical capacity, institutional framework, and economic resources.

6. *Comfortable*: A sanitation system must be nearly as comfortable as a flush toilet. That means it has to be indoors or accessible under the same roof of the house.

Successful implementation of sanitation systems requires understanding all components of the system. The components have to be considered together when designing and making sanitation systems work. Following are the main components (Fig. 2):

- *Nature*: The most relevant natural variables are climate (humidity, temperature), water (amount available, groundwater level), and soil (stability, permeability).
- *Society*: The factors that describe the society include the settlement pattern (concentrated/dispersed, low/high rise), attitude (fecophobic/fecophilic), habits, beliefs and taboos related to human excreta, and the economic status of the community.
- *Process*: Physical, chemical, and biological processes turn human excreta into a nondangerous, inoffensive, useful product. Dehydration and decomposition are the principal processes.
- *Device*: The device is the on-site structure specifically built for defecation and urination.

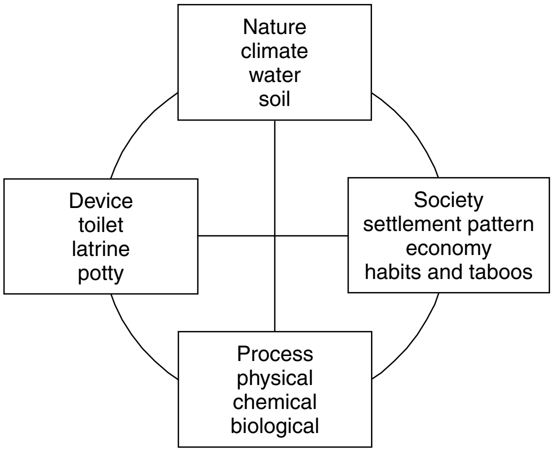

Figure 2. Main components of the “sanitation” system.

It is essential to sanitize human excreta before they are recovered and reused. Figure 3 shows the different approaches for handling human excreta:

- *Mix and drain*: In conventional sanitation systems, urine and feces are mixed and flushed away with water.
- *Mix and evaporate*: Excreta are mixed; however, they are not flushed away but treated on-site, for example, composted.
- *“Don’t mix” and dehydrate*: Urine and feces are collected and treated separately.

The principles underlying EcoSan are not novel. Sanitation systems based on ecological principles have been used in different cultures, for hundreds of years. EcoSan systems are still widely used in parts of East and Southeast Asia. In Western countries, this option was largely abandoned, as flush-and-discharge became the norm, but in recent years, there has been a revival of interest in EcoSan (2).

WASTEWATER IS A RESOURCE

Wastewater from households contains urine (yellowwater), feces (brownwater), and graywater. Graywater is the part of the wastewater which is not mixed with excreta (from kitchens, bathrooms, and laundries). If urine and feces are mixed, the resulting mixture is called blackwater.

For a long time, wastewater has been regarded as a problem because wastewater involves hygienic hazards and contains eutrophying substances in the form of organic matter, nitrogen, and phosphorus. These substances cause problems in seas, lakes, and streams, but, on the other hand, they would be valuable to farmers. Nitrogen (N), phosphorus (P), and potassium (K) in wastewater can be used instead of artificial fertilizer, and the organic material increases the humus content. Recirculating nutrients from wastewater as fertilizer reduces the need for industrially produced fertilizer and also reduces

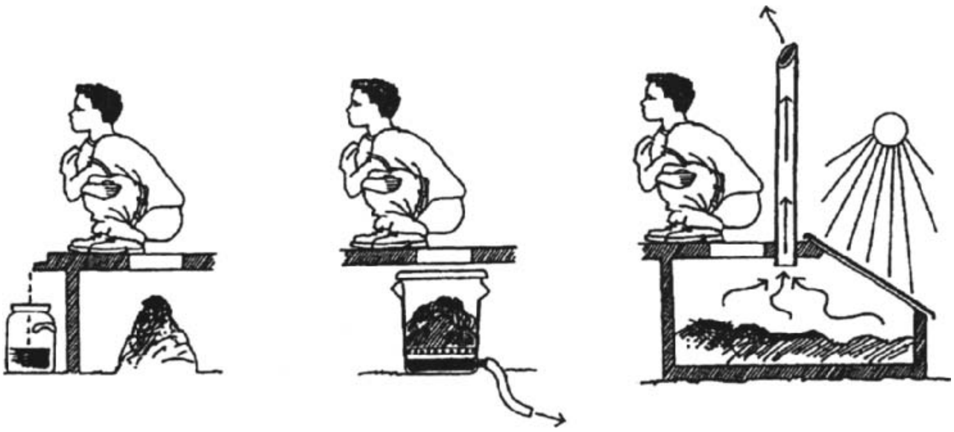

Figure 3. Different approaches for handling excreta: “Don’t mix” and dehydrate (left); mix and drain (middle); mix and evaporate (right).

discharges of nutrient-rich water from treatment plants into watercourses.

Wastewater Characteristics

One person produces about 500 liters of urine and 50 liters of feces per year. The same person, additionally, produces a range of 25,000 to more than 100,000 liters of graywater. Blackwater and graywater have very different characteristics (Table 1). Most of the nutrients essential in agriculture (N, P, K) occur in urine. Feces contain smaller amounts of nutrients, and the quantities in graywater are insignificant. If blackwater is collected separately at low dilution, it can be converted, for example, to a safe natural fertilizer that replaces synthetic products and prevents the spread of pathogens and other pollutants to receiving waters.

Sources of Hygienic Hazards

Watersheds may be affected directly by excreta that contain large amounts of pathogens from humans and animals, or indirectly through wastewater outlets, from large-scale wastewater treatment plants and from smaller units of wastewater or graywater on-site sanitation. Stormwater and runoff from agricultural lands may also carry large amounts of pathogens to watersheds emanating directly from excreta, or pathogens occurring in sludge, excreta, and manure applied to land. Stormwater and runoff water may also carry pathogens from domestic and wild animals and birds that may affect humans. Organic waste from human settlements and activities may also be a source of pathogenic organisms.

- *Human fecal excreta* may be harmless but can contain large amounts of pathogenic organisms. The risk depends on the frequency of infected persons and symptomless carriers in the population. Anyway, human fecal excreta are responsible for the major part of hygienic hazards.
- *Human urine* does not normally contain pathogenic organisms that will transmit enteric disease to other individuals. Fecal material is thus the main source of infectious organisms. Only in special cases, for example, a systemic infection with fever, will pathogenic organisms be present in urine.
- All microorganisms in *wastewater* originating from human excreta occur in amounts reflecting their occurrence in infected persons or carriers connected to the system. Their concentrations also depend on the dilution of the water. Untreated wastewater should always be regarded as a potential carrier of pathogenic organisms.
- *Graywater* normally contains small amounts of pathogenic organisms. However, due to a relatively high load of easily degradable organic substances, regrowth of indicator organisms of fecal pollution may occur.
- *Stormwater* may have high loads of fecal contamination. This is of special concern in areas of the world where open-air defecation is practiced, because high loads of pathogens, as in wastewater, may occur. Stormwater may also contain high loads of zoonotic pathogens originating from animal or bird feces.

Table 1. Typical Characteristics of the Main Components of Household Wastewater[a]

		Graywater	Urine	Feces
Volume (l.p^{-1}.yr^{-1})		25,000–100,000	∼500	∼5
Yearly loads (kg.p^{-1}.yr^{-1})				
N	∼4–5	∼3%	∼87%	∼10%
P	∼0.75	∼10% (P-free detergents)	∼50%	∼40%
K	∼1.8	∼34%	∼54%	∼12%
COD	∼30	∼41%	∼12%	∼47%

Resource Wastewater?

Summarizing the characteristics of wastewater and the sources of hygienic hazards, the following conclusions can be drawn:

- Most of the soluble nutrients are found in urine. If urine is segregated and converted to agricultural usage, the biggest step toward nutrient reuse and highly efficient water protection will have been taken.
- The hygienic hazards of wastewater originate mainly from fecal matter. Segregation opens the way to sanitation and finally to an excellent end product.
- Wastewater that is not mixed with feces and urine is a great resource for high quality reuse of water.
- Source control should include evaluating all products that end up in the water. High quality reuse will be far easier when household chemicals are not only degradable (original substance disappears, even if metabolites do not degrade) but can be mineralized by the available technology. Additionally, pipes for drinking water should not emit pollutants (e.g., copper or zinc).
- To reduce stormwater runoff, local infiltration and/or trenches to surface waters for relatively unpolluted rainwater can be used. Prevention of pollution includes avoiding copper or zinc gutters and roof materials that can cause heavy metal pollution of rainwater runoff.

TREATMENT SYSTEMS

Limitations of Conventional Sanitation

In conventional sanitation systems, human excreta are mixed with water and flushed away by conventional flush toilets. The wastewater is then collected and transported in sewers and treated in a centralized plant.

This results in high water demand, the spread of potentially dangerous pathogens and micropollutants (e.g., residues of pharmaceuticals) in a large volume of water and also the loss of the option to reuse graywater and to produce fertilizer. The initially small amount of feces could be hygienized easily by cheap methods.

For the strange mixture called "municipal wastewater," hygienization is an expensive further treatment step. Hormones and medical residues reveal another weakness of sanitation systems. These substances reach receiving waters easily especially because of their polarity and usually very low degradation rates in treatment plants.

Sewerage systems have a couple of severe disadvantages. In general, they are a very costly part of the infrastructure (if sufficient rehabilitation is done) and drain large amounts of water from the region. Combined systems emit raw wastewater into receiving waters with overflows. Storage tanks are very expensive if the number of overflows is low. Separate systems often have a large number of wrong connections (4).

Centralized Versus Decentralized Wastewater Treatment

Sanitation systems can be classified as follows:

- *Decentralized or 'on-plot' systems* in which safe disposal of excreta takes place on or near a single household or a small settlement.
- *Centralized or 'off-plot' systems* in which excreta are collected from individual houses and carried away from the plot to be treated off-site.

The selection of the most appropriate sanitation system is influenced by ecological, technical, social, cultural, financial, and institutional factors.

Proper decisions on where to connect houses to a sewerage system and where to build on-site facilities or small decentralized plants are the key issue for the economics of the whole wastewater infrastructure. Good regional planning can avoid the deadlock of very expensive sewerage systems that use all the money which could serve the environment in highly efficient decentralized treatment and collection systems.

There are cost calculation procedures that include long-term development to balance operating- and investment costs and products (reuse water, fertilizer, soil improver). The price of secondary products can be very relevant in economically weak and water-scarce countries where water and industrial fertilizers are no longer subsidized. Reuse-oriented sanitation can easily exceed the performance of the most advanced high-tech end-of-the-pipe plant often at much lower costs (4). Water and sanitation projects and programs will fail to be sustainable if they are not planned and designed to meet the needs of the end user (5).

Decentralized Wastewater Treatment Systems

The use of decentralized wastewater treatment systems offers these advantages (6). They save money, protect the homeowner's investment, promote better watershed management, offer an appropriate solution for low density communities, provide a suitable alternative for varying site conditions, and furnish effective solutions for ecologically sensitive areas.

Decentralized systems prevent unnecessary costs by focusing on preventive measures (assessment of community conditions/needs and maintenance of existing systems), instead of reacting to crises. They further maximize the potential for homeowners, who have existing septic systems, to continue to benefit from their original investment and avoid the potentially large transfers of water from one watershed to another that can occur in centralized systems. In small communities of low population density, decentralized systems are the most cost-effective option. These systems are variable, can be designed for various sites that have, for example, shallow water tables, shallow bedrock, low-permeability soils, and small property lot size. Additionally, decentralized systems can provide cost-effective solutions for areas that require advanced treatment, such as nutrient removal and/or disinfection, while recharging local aquifers and providing reuse opportunities close to points of wastewater generation.

Technology Options

Decentralized wastewater treatment alternatives for small communities can be broadly placed in the following categories that represent the basic approaches to wastewater conveyance, treatment, and/or disposal (6, revised):

- *Natural systems* use soil as a treatment and/or disposal medium, including land application, constructed wetlands, and subsurface infiltration. Some sludge and septage handling systems, such as sand drying beds, land spreading, and lagoons, are included.
- *Conventional treatment systems* use a combination of biological, physical, and chemical processes and employ tanks, pumps, blowers, rotating mechanisms, and/or mechanical components as part of the overall system. These include suspended growth, fixed growth, and combinations of the two. This category also includes some sludge and septage management alternatives, such as digestion, dewatering and composting systems, and appropriate disposal.
- *Alternative collecting systems* that use lightweight plastic pipe buried at shallow depths, have fewer pipe joints and less complex access structures than conventional gravity sewers. These include pressure, vacuum, and small-diameter gravity sewer systems.
- *Alternative treatment systems* use source control and separating systems. An example of an alternative treatment system for ecological sanitation is given later.

None of the described systems is a priori or not an EcoSan system. A number of criteria as given above have to be met for a sanitation system to be called an EcoSan system.

Low Water Consumption and Water-Free Toilets and Urinals. A major part of alternative treatment systems are devices suitable for reducing water consumption and/or for separating feces and urine. Therefore, the available systems of low water consumption and water-free toilets and urinals are described:

1. *Conventional water-flush toilet* (listed as the reference system): The conventional water-flush toilet is

standard in most industrialized countries. A precondition to the effective disposal of excrements in this manner is sufficient availability of flushing water (about 6–8 liters per flush) as well as a corresponding disposal system (sewer system and wastewater treatment plant or other disposal). At the high dilution of human excretions (approximately 100 to 250 g feces and 1 to 1.5 liters urine), the use of a conventional flush toilet requires about 40 liters of water per day, and the wastewater produced contains both nutrients and pathogens.

2. *Water-conserving toilet*: The water-conserving toilet reduces the required consumption of water to 1.0 to 4.5 liters per flush. Together with a reduction in water costs and an increase in the available capacity of the existing wastewater collection system (e.g., collection pits), water-conserving toilets produce a more concentrated wastewater that can be used further more easily (e.g., biogas extraction, solid waste separation). Due to the smaller volume of flushing water, blockages in the pipes must be prevented by a flushing device, and certain structural requirements must be observed (e.g., minimum gradient in the downstream pipe).
3. *Water-conserving toilet with waste segregation*: In addition to the reduction in water consumption, the water-conserving toilet with waste segregation allows the division of feces and urine. Therefore, urine can be used for, for example, agricultural purposes, and costs can be reduced by avoiding removal of nutirents in sewage treatment. The installation of a waste-segregation toilet is only possible in combination with a corresponding collection system (urine collection tank in the house, regular emptying of the tanks, agricultural application). Feces and urine are divided in a user-friendly manner by an adapted effluent vent in the toilet bowl.
4. *Vacuum toilets*: Vacuum toilet systems dispose of flushing water and excrement by using a pipeline network under vacuum (approximately 0.5 bar) connected to a collection tank. Water is required only to rinse the toilet bowl, not for facilitating transport (approximately 0.7 to 1.0 liter per flush). Until now, the vacuum system has been used mostly in ships, trains, and aircraft (limited flush and wastewater capacities). The wastewater is very concentrated, so it is suitable for energy generation in a biogas plant. Drawbacks to the system are the technical requirements (operation and maintenance of the vacuum unit) and the associated financial costs (with susceptibility to breakdown, for example, blockages).
5. *Toilet systems without water (dry toilets)*:
    - *Compost toilets*: The compost in this system is formed from an aerated mixture of excrements and composting earth held in a container. For proper function, a minimum air temperature of 10 °C is required as well as regular checks (approximately once/month) of the structural composition and equipment. Regular extraction of the humus is necessary.
    - *Dehydration toilets* are based on drying excrements, which are odorless and almost sterile in dehydrated form and can be used as a soil conditioner. It is therefore important to segregate urine and feces. Urine can then be collected for agricultural applications, drained away, or evaporated. The dehydration process can be accelerated by using moisture-absorbing material or heat, such as exposure to the sun. Dehydration toilets are ideal for dry and arid climates.
    - *Water-free urinals* are made of ceramics or plastics, that must be regularly impregnated with an antibacterial agent. Odor is contained by an insert with a special sealant that has a lower specific mass than urine and is buoyed upward or by using a float. As crystalline precipitation occurs only on contact of urine with water, such deposits cannot occur in the down pipe. A further advantage of the water-free urinal is the low installation and maintenance costs (no connection to a water supply and no mechanical or electrical flushing fixtures).

It has been clearly demonstrated that urine sorting toilets are feasible (e.g., Sweden has more than 3000 installations; Ref. 7). Drawbacks have been observed from too small diameters of urine pipes that clog from scaling. For waterless separating toilets, one major problem remains: Men are often reluctant to sit down to urinate. This would cause a loss of urine and mix urine with feces. A luxury solution for this problem would be a private waterless urinal.

Dry toilets will fail if those who plan/design do not understand the basics, wrong materials are used, or there is poor workmanship, and users are not involved and sufficiently instructed. “Fail” usually means that the content of the processing chambers turns wet, resulting in odors, fly breeding, and incomplete sanitation.

Example of an Alternative Treatment System

Figure 4 shows an alternative treatment system that is suitable for single houses and rural settlements and is based on sorting toilets (6). The example presented is more suitable for developed countries due to the number of technical systems used.

Urine from separating toilets and waterless urinals flows into a storage tank where it stays until it is used mainly for agricultural purposes. The storage period should be at least half a year because this is an appropriate time for collection and part of the eventual medical residues can be destroyed during this period.

Feces are flushed by an appropriate amount of water (e.g., 4 or 6 liters) and discharged into one chamber of a two-chamber composting tank (with filter floor or filter bag) where the solids are precomposted. After a 1-year collecting, dewatering, and composting period, the flow is directed to the second chamber; the first one is not fed for 1 year. This allows further dewatering and precomposting and makes removal from the tank safer (although the matter is not sanitized then).

The products removed from the composting tank are brought further to full composting. They could be

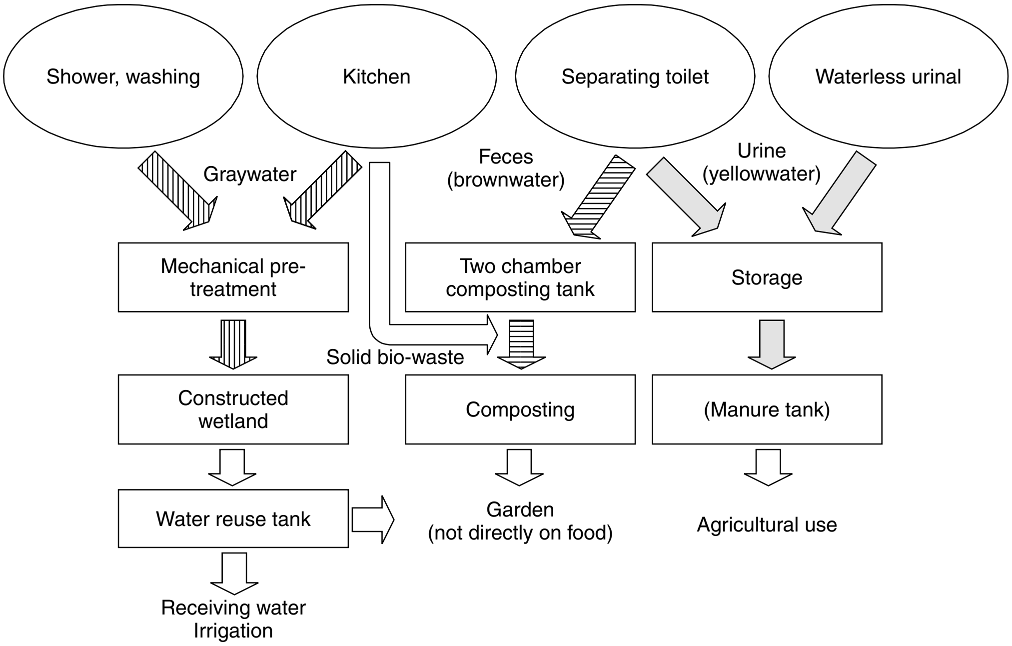

Figure 4. Concept for an alternative treatment system.

mixed with solid kitchen and garden waste to decompose completely and allow further sanitizing. The filtrate from the composting tank is low in nutrients due to the previous separation of urine. Therefore, the filtrate can be treated together with the graywater unless high-quality reuse is planned.

Graywater is pre-treated mechanically and afterward treated by a vertical-flow constructed wetland, intermittently loaded. The treated graywater is either stored and used in the garden and for irrigation or is discharged.

SUMMARY

The underlying aim of ecological sanitation (EcoSan) is to close nutrient and water cycles to contribute to sustainable development. Single technologies are only a means to an end to reach EcoSan goals. EcoSan-technologies, therefore, may range from nearly natural wastewater treatment techniques to separating toilets, simple household installations, and to complex, mainly decentralized systems. Technologies are not ecological per se but only in relation to the observed environment.

The main objectives of sanitation systems are that they have to minimize health risks and protect the environment. Ecological sanitation systems, additionally, have to return nutrients to the soil and conserve valuable water resources. They have to be affordable and therefore accessible to the world's poorest people, acceptable, aesthetically inoffensive, and consistent with cultural and social values, simple and robust in design and operation, and as comfortable as conventional systems.

A sanitation system consists of the following components: nature (climate, water, and soil as main factors), society (including settlement pattern, attitudes, beliefs and taboos related to human excreta, and the economic status of the community), the processes occurring (that convert human excreta into a nondangerous, inoffensive, useful product), and the device (the on-site structure specifically built for defecation and urination). These components have to be considered together when designing sanitation systems and making them work.

EcoSan systems have a number of advantages that can be summarized as follows:

- *Advantages to the environment*: If EcoSan systems could be adopted on a large scale, it would protect groundwater, streams, lakes, and the sea from fecal contamination. Less water would be consumed. Farmers would require smaller amounts of commercial fertilizers, much of which today washes out of the soil into water, thereby contributing to environmental degradation.
- *Advantages to households and neighborhoods*: Urine separating systems, if properly managed and maintained, do not smell or produce flies and other insects. This is a great advantage over ordinary pit toilets. Urine and feces do not come into contact and produce odor. Moisture levels are too low for fly breeding. Over half the population of the developing world has no sanitary system for excreta disposal. The market for appropriate sanitation devices is enormous, and there is a big demand. The majority of separation toilets do not require expensive or high-tech equipment. Jobs could be created for builders and for collectors of urine and sanitized feces. These products can be sold to farmers or used in the garden.
- *Advantages to municipalities*: Municipalities all over the world are experiencing greater and greater difficulty in supplying water to households and neighborhoods. EcoSan systems do not use these scarce water resources and may create therefore,

a more equitable allocation of water to rich and poor households.

A wastewater infrastructure is usually built for extremely long service. The lifetimes of existing house installations, sewerage systems, and treatment facilities have to be considered. A change to EcoSan systems is easier for newly constructed settlements or rehabilitation of complete houses. The lifetime of a house installation is far shorter than that of sewerage systems. Components of source control sanitation could be installed in each renovated flat and be connected to conventional systems first. This can be economical based on the water saving from the beginning; later, after conversion of a group of houses, separate treatment can be implemented.

WASTE TREATMENT IN FISH FARMS

WASTE TREATMENT: GENERAL ASPECTS

With increasing aquacultural production, there is a greater need to reduce the amount of waste in fish farm effluents. These days, simple dilution is no longer considered an appropriate treatment (1). Generally, waste in fish farms is treated for two reasons: (1) in recirculating systems, it can negatively affect the fish and (2) in open systems, it can negatively affect the environment. Pollution control in general and in fish farming in particular should aim first at prevention rather than a cure, which can be achieved by using the best available technology (BAT) and best management practices (BMP). These have been reviewed and critically discussed in a recent comprehensive workshop (2). The use of highly digestible diets and stress-free husbandry have greatly reduced waste production per quantity of produced fish; for example, salmonid farms have achieved a reduction of about 80% in the last twenty years (3). However, despite BAT and BMP, the effluent often still needs to be treated and aquacultural waste management still relies heavily on end-of-pipe solutions. For treatment to be economically sustainable in terms of capital costs, running costs, and space requirements, some specific features of aquacultural waste loading must be taken into account.

The waste loads in aquacultural facilities have some properties that make treatment difficult. These include very low but strongly fluctuating concentrations of solids and nutrients and high flow. Table 1 compares some important effluent load parameters in salmonid farms with those in municipal waste waters. (Fig. 1). The average effluent load from a land-based flow-through fish farm is normally much lower than that in the treated water leaving a sewage plant. However, the flow from fish farms can be very high—greater than 500 $L\cdot s^{-1}$—and the total solid load can vary by two orders of magnitude in the course of a single day. Aquaculture treatment devices have to meet these diverse challenges but without the benefit of many of the technologies applied in sewage plants such as flocculation chemicals or biological treatments, which are often too expensive or otherwise impracticable under fish farm conditions.

With respect to effluent treatment, it is important to differentiate between four types of fish culture systems: (1) flow-through fish farms, (2) recirculating aquaculture systems (RAS), (3) open net cages, and (4) pond or integrated aquaculture.

In flow-through fish farms, the water quality for the fish is ensured by the steady discharge of wastes with the bulk flow. The relative loading is usually low, but due to the high flow rates, the total load in the recipient water body may become elevated, thus causing environmental problems. Waste treatment in flow-through systems is almost exclusively restricted to mechanical techniques. In RAS, where only compensatory water is added, wastes accumulate and remain within the system. The accumulated wastes must be removed to maintain physiologically adequate conditions in the culture water. In this case, waste control usually involves mechanical separation for the removal of particulate matter and the use of some kind of biofilter to remove dissolved compounds. In open net cages, waste control is very difficult as the waste can pass freely in nearly all directions. Particle traps provide the only means of collecting settled uneaten feed or fecal pellets. New

Table 1. Waste Loads of Flow-Through Fish Farms (Range of Values from Germany) Compared With Municipal Waste Loadings (11)

Source	Total Suspended Solids, mg·L^{-1}	Total Phosphorus, mg·L^{-1}	Total Nitrogen, mg·L^{-1}	BOD$_5$^{a}, mg·L^{-1}
Salmonid farms	0.5–10	<0.1	<1.4	0.5–5
Municipal wastes				
Low strength	350	4	20	110
Medium strength	720	7	40	190
High strength	1230	12	70	350

^{a}BOD$_5$, biological oxygen demand in 5 days.

advanced waste control measures use adjacent cultures of seaweeds, filtering organisms like mussels, or sediment feeders to transform the wastes near the net cages into valuable products. In pond or integrated aquaculture, the waste from one species is beneficial to other species and treatment is generally not desired. Some pond systems employed in Asian countries raise ducks or chickens on platforms from which manure falls directly into ponds stocked with filtering and omnivorous fish. The overflow may be used to irrigate paddy fields.

The principal wastes that can reasonably be expected to be removed from fish farm effluents comprise solids, biodegradable organics, and phosphorus and nitrogen compounds, including toxic ammonia and nitrite. Particles can be removed in a comparatively easy and effective manner; but the removal of the soluble components of effluents requires more sophisticated methods that must often be designed specifically for the culture system in use, taking account of the individual circumstances. Table 2 gives an overview of different waste handling systems and their capacities and restrictions. Irradiation and ozonation to control pathogens are special cases and will not be considered further here.

SOLID REMOVAL

Solids can be removed using settling basins, microscreen filters, granular media filters, and flotation (by air or foam fractionation as well as by ozonation). The two latter techniques are rarely applied in fish farming practice. The effectiveness of mechanical treatment depends on the particle size distribution and the ratio of bound particles to dissolved wastes. Results of empirical studies show considerable variations in the size distribution of suspended solids and in the efficiency of mechanical treatments (4).

Settling basins are the most traditional and widespread method for removing solids. They are simple to operate and have moderate costs; but as they are dependent on flow and sinking velocity of the particles, they require large

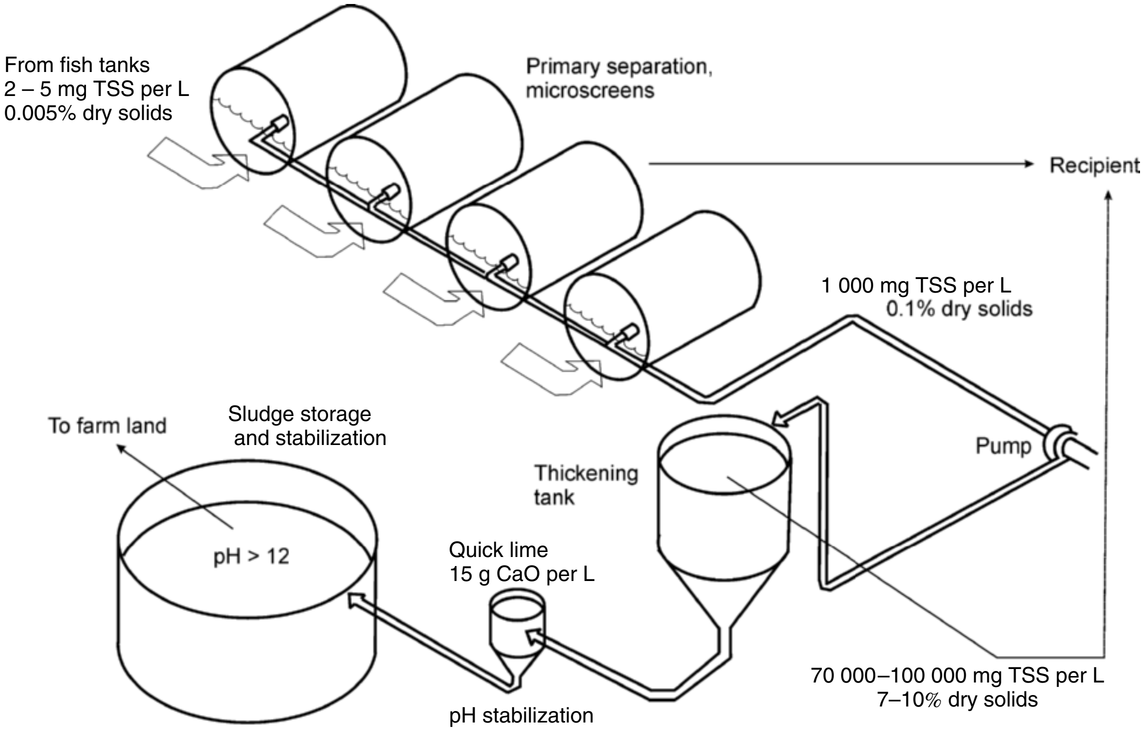

Figure 1. Diagram of an integrated effluent treatment and sludge processing system (2).

Table 2. Different Separation Processes for Aquacultural Facilities, Removal Potential, Advantages, and Disadvantages

Waste System	Treatment Types	Effective Removals	Advantages	Disadvantages
Sedimentation	Settling basin, swirl settler	Solids larger than 100 μm	Robust, easy to handle, cheap	High space requirements, re-release of wastes from settled solids, efficiency depends on TSS concentration
Microscreen	Drum filter, disk filter, Triangel filter	Solids larger than 30 μm	Low space requirements, easy to handle, tolerating high hydraulic loads, little TSS dependency	High capital and energy costs
Granular media filter	—	Solids larger than 15 μm, dissolved matter	Dual system removing particles and dissolved matter, low space requirements	Large amount of backwash water, suboptimal removal of solids and dissolved matter, high energy costs
Flotation	Dissolved air systems, dispersed air systems	Solids smaller than 30 μm	Capable of removing very small solids, low space requirements	Insufficient removal of large solids, high energy costs, dependent on bubble sizes and foam stability
Ozonation	—	Organic solids and dissolved matter, disinfections	Combines waste removal and control of pathogens	Toxic substance, system must be built with inert materials to avoid corrosion, high costs, underflow only
Biofilter	Submerged filter, trickling filter, rotating biological contactors, pressurized-bead filters, fluidized-bed biofilters	Solids and dissolved matter	Able to treat total wastes including toxic ammonia and nitrite	Costs sensitive to pH fluctuations, temperature, growth phase etc., low hydraulic loading capacity
Constructed wetlands	No standards available	Solids and dissolved matter	Very high removals (more than 90% of most compounds), can be integrated into the environment	High capital costs, each constructed wetland has to be developed for the individual situation, no long-term data available, dependent on climatic conditions

spaces. Solids settle as a result of their density. As the density of solids in aquaculture is typically close to that of water with values of 1.005–1.2, very small solids settle very slowly. Effective removal therefore requires very long hydraulic residence time. As a result, settling basins are often unable to effectively treat total suspended solid (TSS) loads lower than 10 mg·L^{-1} (dry weight) or solids smaller than 100 μm, and they do not attain solid effluent concentrations of less than 6 mg·L^{-1} (dry weight) (5,6).

Microscreen filters act as sieves that strain suspended particles larger than the mesh size. The collected particles are cleared from the screen with a dispersed hydraulic jet, thereby generating a backwash volume of 0.2–2% of the bulk flow. According to Cripps (7), mesh sizes below 60 μm give little advantage in solid removal but superproportionally decrease hydraulic capacity and increase backwash water. TSS removal in flow-through farms averages 68–80% compared with 22–70% in RAS. In practice, there are three main varieties of microscreen, namely, drum filters, Triangel filters, and disk filters.

Swirl settlers or hydroclones utilize the "tea-cup effect" generated by water injected at the outer radius of a conical tank. This effect improves settlement of the particles and forces them to the center of the tank, where they are removed from the flow. This process has a distinct advantage over classical sedimentation, and in fish farming, swirl settlers are used in small underflows comprising just 5–10% of total flow.

In recirculating aquaculture systems—in contrast to the other systems mentioned above—small solids (less than 50 μm) constitute most of the solid mass. Small solids are difficult to remove by the methods described above, but flotation is an efficient measure. In a flotation chamber, bubbles from the bottom float upward against the bulk flow, "collecting" surface-active particles, which become attached to the bubbles. The particles are carried to the surface where the bubbles break and form a foam layer. The small solids are released into the foam, which can be separated from the bulk flow by a weir. Another method sometimes used in recirculating systems employs granular media filters, which function as both mechanical and biological filters (8). Buoyant, inert beads up to 5 mm in diameter are carried through by the water stream and small particles are strained out or precipitated on the bead surface. The effects of microbial settlement on the beads are described in the next section. To clear the filter, the flow is stopped and the beads are washed forcibly backward. The backwash volume is 1–5% of the bulk flow. The dual function of this kind of filter brings considerable advantages but does not allow optimal removal of both solids and dissolved or colloid compounds.

Settling basins, flotation, and granular media filters provide opportunities for significant microbial degradation, leaching processes, and resuspension of settled waste, all of which lead to re-release of wastes back into the bulk flow. Only microscreen filters and swirl settlers ensure steady and permanent separation of solid-bound wastes from the flow that is treated.

DISSOLVED AND COLLOID COMPOUNDS REMOVAL

Ammonia and dissolved organic compounds are accessible for degradation by microorganisms attached to submerged or wetted surfaces. Ammonia is oxidized by autotrophic bacteria in a two-step process called nitrification. Biodegradable organic compounds are oxidized by heterotrophic bacteria, protozoa, and micrometazoa. When applied in aquacultural situations, this natural process is called biofiltration. The capacity of a biofilter depends on the surface area available for biological growth and on the oxygen supply. The efficiency of the biofilter depends on the accessibility of the media surface and the rate of mass transfer into the biofilm. It also varies with the growth phases of the filter (lag, log, stationary, or death phase). The voids ratio is critical for the hydraulic performance. A large variety of biofilters are available and the appropriate one must be chosen according to the individual fish farm. An overview is given by Summerfelt (6).

INTEGRATED TREATMENT SYSTEMS

Recently, there has been an increasing effort to use artificially or naturally constructed wetlands of different types for the removal of waste loads from fish farm effluents. This kind of treatment is very effective for both solids and dissolved or colloidal compounds. A current study by Michael (9) showed that an abatement pond coupled with a constructed wetland was able to remove more than 98% of solids, over 90% of biodegradable organics and phosphorus, and more than 84% of ammonia. However, further studies and monitoring are needed to assess the long-term effectiveness and economic viability of such treatments.

REUSE AND DISPOSAL OF SLUDGE

For each separation technique leading to an accumulation of sludge, it is crucial that the sludge is thickened to minimize its volume. Figure 1 gives a diagram of integrated effluent treatment combined with sludge processing. On average, the solid concentrations are increased from 2 to 5 $\mathrm{mg{\cdot}L^{-1}}$ in the effluent entering the microscreens to 7–10% dry solids in the thickened sludge, an increase of more than 20,000 times. Beneficial reuse of aquacultural sludge includes four possibilities: agricultural application, composting, vermiculture, and reed drying bed. Sludge from fish farms is rich in organic nitrogen (3–9% of dry matter) and phosphorus (1–4% of dry matter) but poor in potassium (less than 0.3% of dry matter) (10). Decomposition processes are necessary to make the nutrients accessible for plants. Heavy metal concentrations are usually below regulatory limits.

This brief review gives an insight into the tasks, challenges, and possibilities for treating aquacultural wastes. In reality, effective waste removal is often based on a combination of different waste treatment systems (11). Standard proceedings can seldom be recommended unmodified. Thus, the consultation of experts for the individual situation is often necessary.

The importance of the flotation process to the economy of the whole industrial world is considered enormous.

Without this process, many familiar metals and inorganic raw materials would be exceedingly scarce and costly because the high-grade ores that could be processed by simple physical and mechanical methods have long since been used up (1). Flotation initially originated from the field of mineral processing, usually termed froth flotation. For many years, various particulate solids besides minerals have been extracted from water by using this effective gravity separation method that is based on the idea of applying rising gas bubbles as the transport medium; the attachment of bubbles to particles transfers the solids from the body of water to the surface. As opposed to settling, flotation is a solid–liquid separation technique that is applied to particles whose density is lower or has been made lower than the liquid they are in. These flotation applications include mainly the treatment of water and wastewater (2,3); in the former paper, a useful discussion forum was placed on the Internet by the conference secretariat, Mr. Eero Teerikangas. Today, for example, applications of flotation exist in paper manufacturing for deinking and waste paper recycling (4), emulsified oil from various industrial wastewaters (5,6), and the separation of used plastics (7).

The typical classification of flotation processes is based on the method used to generate bubbles; so, two broad categories exist:

1. dispersed-air flotation (including electroflotation), and
2. dissolved-air flotation (DAF).

These are essentially two different techniques for bubble size, flow conditions, separation aim, and economics. Very few comparison studies, in similar experimental conditions, of these techniques are in the literature (8).

Dispersed-air flotation uses aeration, a well-known step in wastewater treatment as also is its design (guides are given by various companies, for example, Sanitaire). Fine bubble aeration is a subsurface form of diffusion, in which air is introduced in the form of very small bubbles; fine pore diffusers are usually made from ceramic, plastic, or flexible perforated membranes. Several papers have been published on bubble size and distribution, such as (9,10).

Dissolved-air flotation (see Fig. 1) is the dominant flotation technique in water and wastewater treatment. It is based on the theory of a recycle chemical reactor for its operation and on Henry's law for the dissolution of air in water as a function of pressure (1,11).

Computational fluid dynamics (CFD) codes have been also used to study the flow characteristics of this system. Multiphase flow equations for the conservation of mass, momentum, and turbulence quantities must be solved using an Eulerian–Eulerian approach in which the phases

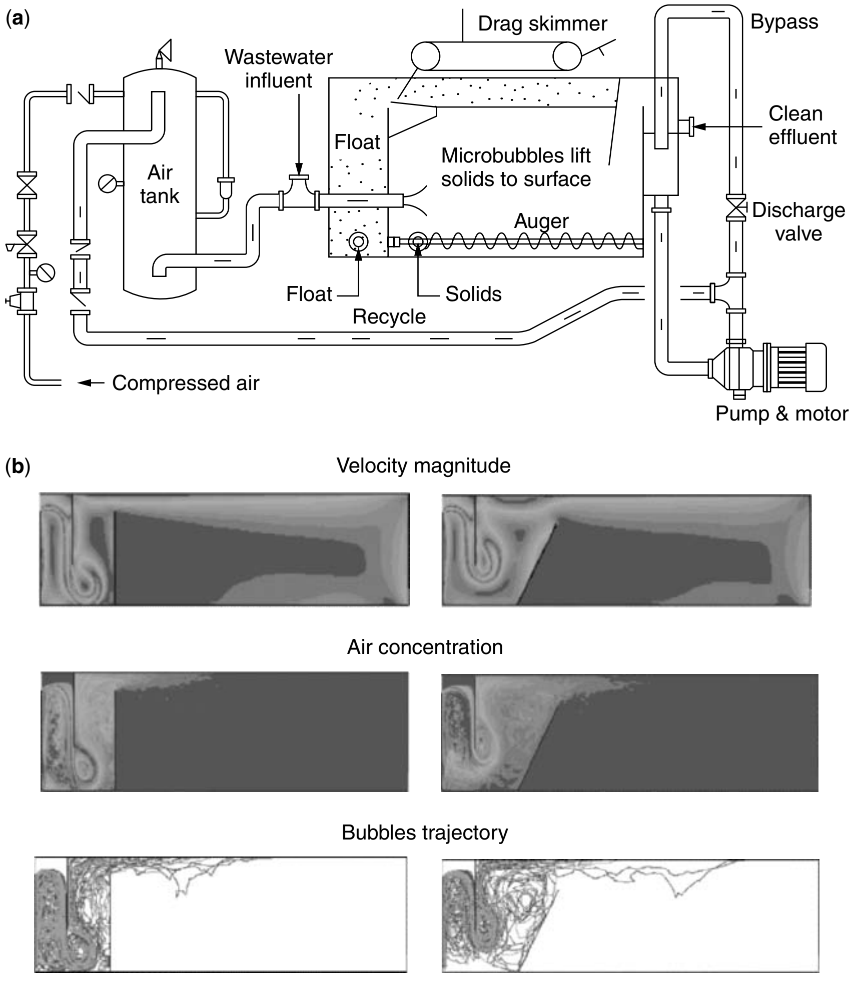

Figure 1. (**a**) The dissolved-air flotation technique (Courtesy Ecologix Environmental Systems) (top). (**b**) Impact of inclined internal baffle on the separation process obtained by CFD simulation—(unpublished results of EU METASEP project) (bottom).

are treated as interpenetrating continua. A four-phase model has been used for water, air bubbles, solid particles, and the aggregate of bubbles with particles (Fig. 1b).

Generally, low air volumes are available for dissolved-air flotation; this is not a parameter easily changed, and the reason is that the pressure in the saturation tank is raised up to 5–6 atm. For this reason, effective flocculation is a prerequisite mainly for dissolved-air flotation (12).

The trend in the development of DAF technology for potable water is to very thick microbubble beds with high flow rates, advertised as 3rd generation technology (2). A flow rate of more than 60 m/h was given, where flotation operation approaches turbulent flow. A compact (downstream filtration in the same basin) so-called re-flotation plant with hydraulic flocculation was built, for instance, for the Tampere, Finland, water and sewerage works in 1997 by the company OY Rictor AB. One of the advantages of flotation is its speed, hence its ability to operate inside a factory (Fig. 2).

Sorption combined with flotation has been investigated (8). The combination of processes is a necessity because of high existing standards and media pressure, not to mention the scarcity of water in many places. The process examined (often termed sorptive flotation) involves abstracting metal ions onto sorbents, in a fine or ultrafine size range, followed by flotation to separate metal-loaded particles. The sorbents used in the first stage were also industrial by-products (1,3). In this way, treated clear water is produced as an underflow and a foam concentrate, from which recovery of metals is possible, leading to clean technology.

A comparison between dispersed-air and dissolved-air flotation, applied to metal-loaded goethite, is presented in Fig. 3a. The recycle was the main parameter studied (at least 20% was necessary) for dissolved-air flotation (8). A flocculant was also required, particularly for DAF. Generally both flotation techniques gave good flotation recoveries; nevertheless, dispersed-air flotation looks preferable. Metal removals were near 100%.

Many industrial wastewater streams with large flow contain toxic metals, which have to be removed prior to water recycling, indirect discharge into a sewage system, or direct discharge into surface waters. Metal compounds such as copper, zinc, manganese, lead, and arsenic dominate the list of greatest releases. Mines and processing plants are often situated in water catchment areas (mountain slopes), and so environmental action plans are required to limit acid drainage and prevent pollution.

Copper recovery was investigated with a wastewater from the Assarel mine (in Bulgaria) composed of Cu(II) 240, Mn(II) 40, Fe(III) 8, Pb(II) 0.2, SO_4^{2-} 4200, Ca(II) 270, and Mg(II) 260 mg/L as the main constituents (13). Almost complete copper removal was obvious for all cases (Fig. 3b), even though the requisite xanthate dose was doubled for real effluents; the quantity needed was around 1 g/L for synthetic wastewater and around 2 g/L for real effluents. In all cases, the residual copper concentration was lower than 0.11 mg/L; the limit in Europe for indirect discharge of chemical industry effluents is 0.5 mg/L copper.

Xanthates are known to exhibit a high level of chemical reactivity for heavy metals. Precipitate flotation is the mechanism that involves first the immobilization of ions as precipitates, for example, raising the respective concentrations may lead to precipitation of the ions as a surfactant floatable product before air is injected (1). This means that it is not a solution any longer but rather a dispersion. In Reference 13, economic considerations of the various processes were also given, including microfiltration downstream.

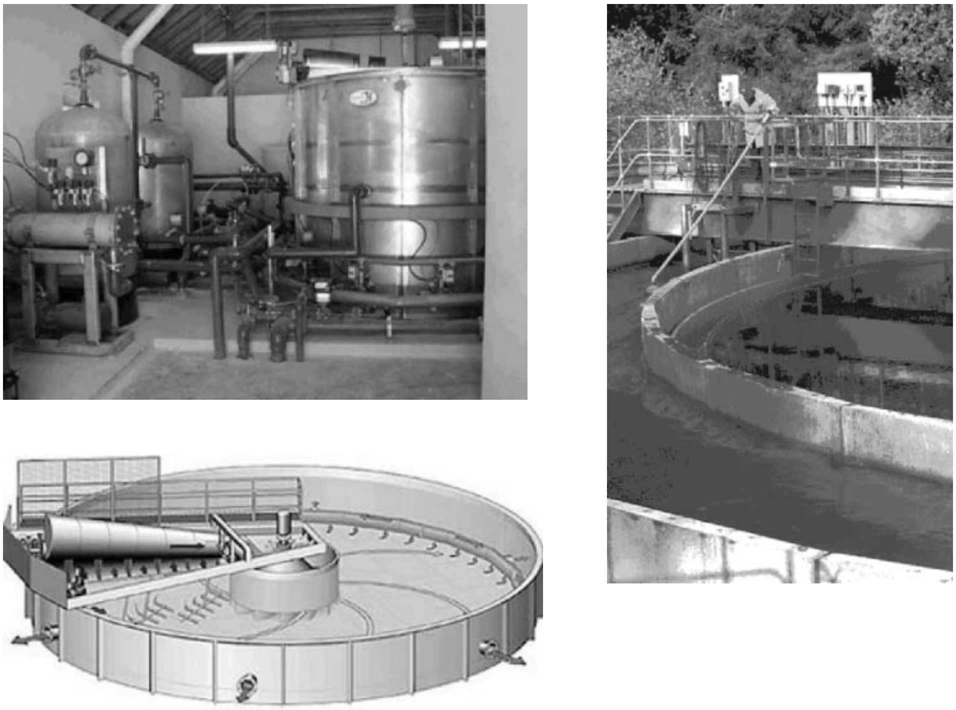

Figure 2. Possibility for the flotation process to operate in a closed factory (top) or open air. Gratitude is given to the companies Krofta (Sandfloat design), Meri Technologies (Deltapurge clarifier), and Purac Ltd. (bottom right).

(**c**) Biosorptive electroflotation of cadmium on anaerobically digested activated-sludge biomass (denoted as AS): effect of solution pH. Reprinted from Ref. 2.

To the various abnormal reasons for serious contamination of water and soil by toxic heavy metals, one has to add ecological accidents. Like those at Aznalcóllar, Spain, in 1998, an accident in an area close to the Doñana Natural Park in South Andalusia released 2 million m^3 of tailings and 4 million m^3 of water contaminated by heavy metals into the Guadiamar River and that at Baia Mare, Romania, in 2000 where a tailings pond burst releasing approximately 100,000 m^3 of waste water containing up to 120 tonnes of cyanide and heavy metals into the Lapus River; this then traveled downstream into the Somes and Tisa Rivers into Hungary before entering the Danube.

Electrolytic flotation or electroflotation constitutes an unconventional technique in which the bubbles necessary for the flotation are produced by electrolysis of the medium. Electrodes are usually mounted horizontally and receive a low voltage current (6,14). A large amount of very small bubbles is formed with minimum turbulence. Clarification can be effected with effluents that previously would not have been considered suitable for treatment by flotation. The electric field gradient between the electrodes aids flocculation of suspended matter. Gas production, residence time, and the other operating conditions can be checked quickly and are easily controlled. No high-pressure pumps, pressurized vessels, or other complex machinery are needed, and moving parts are minimal.

When aluminum alloy electrodes were used (Fig. 3c), the results were improved; biomass recovery was possible from pH 7 approximately. Results were not highly affected by shorter process duration (10 min) and even lower current density (65 A/m^2). The two curves (of cadmium removal on biomass and of floated Cd-loaded biomass almost coincide with pH variation. Attention should be paid to metals aqueous speciation.

Since the discovery that the activated sludge treatment process can also remove metals from wastewaters, much progress in research has been made. Nowadays, it is known that biosorption, using appropriate usually nonliving biomass, is one of the innovative methods for removing toxic metals from effluent; the more conventional methods are precipitation, adsorption, and ion exchange. The process is based on several mechanisms; the most important are physical adsorption, ion exchange, surface complexation, and surface precipitation. The source of biosorbents can be an industrial waste material, as in the application of biomass from large-scale fermentation processes such as filamentous fungi and bacteria from pharmaceutical production (8).

The cost of an electroflotation device plus a sand filter compared favorably with a conventional treatment system using cyanide oxidation/alkaline precipitation/polymer-aided clarification (15). By the former system, a saving of approximately 43% was found when cyanide is present in the groundwater.

If required, the sorbents may be recycled after metal desorption, which is also no problem. A two-stage countercurrent scheme was selected based on extensive studies, with one parallel of elution; flotation was included following each respective biosorption stage (16). This scheme is similar to a conventional activated-carbon system for separating liquids. The partially loaded biomass was guided from the polishing to the leading biosorption stage, where the wastewater feed was introduced.

Concluding, flotation applications (apart from mineral processing) include mainly the treatment of water and wastewater, but also bacteria, coal, clays, corn, resins, protein, fats, rubber, dyes, glass, fruit juices, and cane sugar. Flotation is beneficial for a large variety of dissolved chemical species (e.g., ions and molecules), which can either be concentrated from the solution/dispersion or may be selectively separated from one another, leading to sustainability. Sustainable water and wastewater treatment plant is a combination of technology and practice that meets the multiple and changing requirements of the society in optimal economical and ecological ways during the life cycle of a treatment plant. The flotation techniques applied are often based on the differences in surface activity of the various substances. They have been called, according to the removal mechanism followed, ion flotation or sorptive flotation. Usually, the separation action is aided or induced by introducing appropriate chemical reagents.

Acknowledgments

Many thanks are due to my good colleagues in the Flotation group at AUTh, for the more than 20 years of fruitful collaboration and to the European Union for funding our environmental research projects.

DEGRADATION OF CHLORO-ORGANICS AND HYDROCARBONS

Frank J. Castaldi
Brown and Coldwell
Austin, Texas

Chloro-organics include chlorinated aromatic and aliphatic compounds. The chemical characteristics of chlorinated aromatic compounds cover a range of compounds that include chlorophenols, chlorobenzenes, chloroanilines, polychlorinated biphenyls, and many pesticides. Chlorinated aliphatic compounds make up a major portion of the Environmental Protection Agency (EPA) Hazardous Substances List of halogenated volatile constituents.

Typical chlorinated aliphatics include trichloroethylene, tetrachloroethylene, 1,1-dichloroethylene, 1,2-dichloroethylene, carbon tetrachloride, chloroform, 1,1, 1-trichloroethane, and chloroethylene. Hydrocarbons are petroleum-based compounds that contain carbon and hydrogen. Hydrocarbons can be separated into aliphatic, alicyclic, and aromatic hydrocarbon groups. Aliphatic hydrocarbons are straight or branched-chain hydrocarbons of differing length. These hydrocarbons are divided into alkane, alkene, alkyne, and unsaturated alkyl groups. Alicyclic hydrocarbons include the components of petroleum oils and complex substituted compounds. These hydrocarbons can be grouped into cycloalkanes and cycloalkenes. Aromatic hydrocarbons are comprised of benzene and its derivatives and polynuclear aromatic hydrocarbons. The potential and extent of substance degradation of each of these compound groups differs with the complexity of the compound and the nature of the aquatic environment. The principal focus of this discussion is that of microbial degradation in water and wastewater.

DEGRADATION OF CHLORINATED AROMATIC COMPOUNDS

Chlorinated aromatic compounds are typically produced for direct commercial use and as chemical intermediates during chemical synthesis. They are used in industrial operations to produce dyes, pharmaceuticals, pesticides, synthetic rubbers, solvents, cleaners, deodorants, pigments, and related formulations.

Microbial Transformations

Chlorinated aromatic compounds include chlorophenols, chlorobenzenes, chloroanilines, polychlorinated biphenyls, and many pesticides. Bacteria can remove chlorine from aromatic compounds by several different mechanisms. In aerobic systems, a hydroxyl group prior to ring cleavage can replace the chlorine atom. However, the more usual route involves removing the chlorine after ring cleavage through bacterial metabolism by a modified ortho pathway. Opening of the aromatic ring under aerobic conditions requires the presence of two hydroxyl groups. The hydroxyl groups derived from molecular oxygen can be added to the ring in reactions catalyzed by either monooxygenase or dioxygenase enzymes. Generally, the enzymes involved in the biodegradation of chlorinated aromatic compounds have broad substrate specificity that allows them to degrade or detoxify a number of other compounds (e.g., benzene, toluene, ethylbenzene, phenol) that also support growth (1).

Monochlorophenols are readily biodegradable compounds; degradation proceeds rapidly when they are exposed to acclimated cultures of activated sludges in conventional biological wastewater treatment processes. Dichlorophenols are also readily biodegradable, but degradation proceeds at a lower rate than that of monochlorophenols. Pentachlorophenol (PCP) is also biodegradable, but its degradation is very slow, and bacteria must be acclimated for prolonged time periods before effective biological treatment can be achieved. The biodegradation of chlorophenols is characterized by an increasing period of acclimation and a decreasing degradation rate in the following order (2):

Acclimation period for

Phenol < monochlorophenol < dichlorophenol
< trichlorophenol < tetrachlorophenol
< pentachlorophenol

Rate of biodegradation for

Phenol > monochlorophenol > dichlorophenol
> trichlorophenol > tetrachlorophenol
> pentachlorophenol

The rate of biodegradation is inversely proportional to the number of chlorine atoms in the molecule for most chlorinated aromatic compounds. This is demonstrated by chlorobenzoic acids. Monochlorobenzoic acids are readily biodegradable, but most dichloro derivatives and trichlorobenzoic acids are much more stable. For polychlorinated biphenyl (PCB), there is also a relationship between the rate of biodegradation and the number and position of chlorine atoms in the molecule. The resistance of PCB in the environment is directly proportional to the number of chlorine atoms in the molecule. Chloro-substituted diphenylmethanes behave similarly. The rate of chlorinated aromatic compound biodegradation in the activated sludge process usually decreases in the order of mono-, di-, tri-, tetra-, and pentachloro derivatives, depending on the position of the chlorine in the molecule (3).

Chloroanilines are biodegraded more slowly than chlorophenols because of the presence of both Cl and NH_2 groups that retard the biodegradability of the compound. As for chlorophenols, an increased number of chlorine atoms in the chloroaniline molecule results in increased resistance to biological treatment by the activated sludge process. There is also a retardant effect due to the number, type, and position of substituents on the aromatic ring. In addition to the halogens, the substituents that retard biodegradation are NH_2, NO_2, and SO_3H. These substituents retard the rate of biodegradation by decreasing the electron density on the aromatic ring (3). Alternatively, substituents that facilitate biodegradation by increasing electron density on the aromatic ring are OH, COOH, CHO, and CH_3. Consequently, the susceptibility of chloroaniline to biodegradation depends on whether the NH_2 group is readily transformed to OH by oxidative deamination. In certain compounds, a substituent (e.g., halogens) is not eliminated before the bacterium cleaves the aromatic ring. Chloroanilines are biodegraded most slowly when the $Cl–NH_2$ group is meta-substituted, whereas para-substituted derivatives are degraded rapidly (4).

The enzyme toluene dioxygenase catalyzes the hydroxylation of chloro-substituted benzenes (e.g., chlorobenzenes) as well as methyl- and chloro-substituted phenols. The dioxygenase system for initial attack, combined with the chlorocatechol degradation pathway, allows complete degradation of a range of industrial chemicals (1). Because of the nonspecific nature of the enzymes that transform benzoate to catechol, many aerobic bacteria can cometabolize chlorinated aromatic compounds. However, this biodegradation is not complete because chlorinated benzoates and catechols are the final end product of the oxidative biodegradation (5). The complete aerobic mineralization of chlorinated aromatic compounds is not typically seen, and the persistence of these compounds in the environment illustrates the ineffectiveness of bacteria for these degradations.

It is known that bacteria can mediate the anaerobic dehalogenation of chlorobenzoate compounds. Reductive dehalogenation has been confirmed for a number of chlorinated aromatic acids, chlorobenzenes, chlorophenols, chlorophenoxyacetate, herbicides, and PCBs (6). During reductive dechlorination, the chlorinated aromatic compound serves as the electron acceptor. Theoretical calculations of the Gibbs free energy available from dehalogenation indicates that bacteria can benefit from the use of chlorinated aromatic compounds as electron acceptors under anaerobic conditions (7). Nevertheless, most anaerobic dehalogenation is probably the result of cometabolism.

Methanogenic metabolism has been used successfully to dehalogenate a number of chlorinated aromatic compounds, including 2,4,5-trichlorophenoxyacetate, 3-chlorobenzoate, 2,4-dichlorophenol, 4-chlorophenol, 2,3,6-trichlorobenzoate, and 2,4-, 2,5-, 2,6-, 3,4-, and 3,5-dichlorobenzoates (6,8). Haggblom et al. (9) found that methanogenic bacteria preferentially remove ortho-substituted chlorine and that the meta- and para-substituted chlorine atoms are removed at much slower rates. Methanogenic metabolism does not result in the final mineralization of chlorinated aromatic compounds. To achieve mineralization, a balanced microbial consortium is required to perform the sequential biodegradations so that the transformation products are not more toxic than the parent compound.

Anaerobic dechlorination of aromatic compounds can be stimulated by adding electron donors. The addition of volatile fatty acids (i.e., acetate, butyrate, propionate) and ethanol increases the rate of dechlorination and the extent of biodegradation of many chlorinated aromatic compounds (8). Haggblom et al. (9) found that the addition of *p*-cresol and propionate enhances the methanogenic degradation of 2,4-dichlorophenol.

The presence of electron acceptors also influences the extent of anaerobic dechlorination in the environment. Certain electron acceptors may block the desired reduction reactions through competitive inhibition of methanogenic metabolism. However, Haggblom et al. (9) report that sulfate-reducing conditions actually enhance the apparent rates of biodegradation of 4-chlorophenol, 3-chlorophenol, 2-chlorophenol, and 2,4-dichlorophenol. Chlorophenols act as a source of carbon and energy and are degraded under sulfidogenic conditions by sulfate-reducing bacteria. In groundwater environments that contain sulfate-reducing bacteria, sulfate may be the preferred electron acceptor, and methanogens and sulfate reducers probably compete for suitable electron donors.

DEGRADATION OF CHLORINATED ALIPHATIC COMPOUNDS

Chlorinated aliphatic compounds are typically used as solvents for cleaning and reagents for chemical synthesis. The uses include paint and ink formulations, dry cleaning, synthetic rubber production, fumigants, paint and varnish removers, degreasers, pesticide solvents, adhesives, photographic supplies, pharmaceutical products, and household and office supplies.

Microbial Transformations

Microbial degradation of chlorinated aliphatic compounds can use one of several metabolic processes. These include oxidation of chlorinated alkanes for an energy source, cometabolism under aerobic conditions, and reductive dechlorination under anaerobic conditions. The response of different chlorinated aliphatic compounds to these metabolic processes differs, depending on the nature of the contamination, the redox condition, and the available electron acceptors.

When molecular oxygen is the electron acceptor, one- and three-atom substituted chlorinated aliphatic compounds are transformed by three types of enzymes: oxygenases, dehalogenases, and hydrolytic dehalogenases (10). The transformation products of oxygenases are alcohols, aldehydes, or epoxides. Dehalogenase transformation products are an aldehyde and glutathione. The glutathione is required as a cofactor for nucleophilic substitution by the dehalogenase enzyme. Hydrolytic dehalogenases hydrolyze the aliphatic compound and yield alcohols as a transformation product. Higher chlorinated compounds, particularly when all available valences on carbon are substituted (e.g., tetrachloride or tetrachloroethylene), have not been transformed under aerobic conditions. They must be transformed by reductive dechlorination.

Chlorinated aliphatic compounds may be either oxidized or reduced, depending on their structure and the redox potential of the aqueous environment where they are found. Reduction is possible because of their electron negative character. Consequently, polychlorinated aliphatic compounds often behave as an electron acceptor or the oxidant in a redox reaction. The more chlorinated a compound, the higher its oxidation state, and the more susceptible it is to reduction. This explains why the rate of dechlorination decreases under anaerobic metabolic conditions as, for example, tetrachloroethylene is dechlorinated to vinyl chloride. The reaction proceeds as follows:

$$\text{tetrachloroethylene} >>>> \text{trichloroethylene} >>> \text{1,2-dichloroethylene} >> \text{vinyl chloride} > \text{ethylene}$$

Vinyl chloride (monochloroethylene) is more reduced, so the thermodynamic equilibrium tends to stabilize vinyl chloride as the typical end product of trichloroethylene degradation in aquifers that have negative redox potentials (i.e., an anaerobic environment).

Aerobic Processes

Biotransformation of some chlorinated aliphatic compounds has been demonstrated under aerobic conditions (11). Under aerobic conditions, many soil microorganisms can oxidize vinyl chloride. Most chlorinated aliphatic compounds are eventually mineralized to carbon dioxide. The aerobic degradation capabilities of these microorganisms for chlorinated aliphatic compounds have provided successful treatment processes in seeded (i.e., cultured) activated sludge reactors.

Some chlorinated aliphatic compounds are degraded by cometabolism under conditions that support aerobic metabolism. These aerobic microbes generate oxygenase enzymes of broad-substrate specificity that oxidize chlorinated aliphatic compounds. These include microorganisms that belong to the genera *Alcaligenes, Mycobacterium, Pseudomonas, Nitrosomonas, Xanthobacter*, and *Ancylobacter* (12). For example, *Nitrosomonas europaea* catalyzes the aerobic transformation of vinyl chloride, *cis*- and *trans*-dichloroethylene, *cis*-dibromoethylene, and trichloroethylene (13).

During the cometabolism of chlorinated alkenes, other microorganisms derive their energy from organic compounds such as methane, propane, phenol, and toluene. Several toluene-using microorganisms can degrade trichloroethylene by cometabolism. Even under varied pH and temperature, significant rates of microbial degradation are measured (14). Trichloroethylene degradation decreased by 30% at 4 °C compared with that at 30 °C (14). Phenol-oxidizing bacteria have a much higher capacity to degrade trichloroethylene than methane-oxidizing microorganisms (i.e., methanotrophs). Trichloroethylene degradation by phenol-oxidizing bacteria reportedly removed greater than 90% of TCE after phenol injection (15). *In situ* studies of trichloroethylene degradation have demonstrated that phenol-using microorganisms can be readily stimulated in the environment. Phenol addition is a good primary substrate; it achieves degradation of *cis*- and *trans*-dichloroethylene and trichloroethylene *in situ*. The apparent rate of chlorinated alkene transformation increases as phenol concentrations increase.

Many investigators have confirmed the biotransformation of trichloroethylene by methanotrophic bacteria using methane as a primary substrate. These methanotrophs have the monooxygenase enzyme that will incorporate one oxygen atom from molecular oxygen into methane to produce methanol. The monooxygenase enzyme can hydroxylate many alkanes and aromatic compounds and form epoxides from chlorinated alkenes because it is not compound-specific (10). The products of these reactions are not further oxidized by methanotrophs, so a diverse community of microorganisms is needed to achieve complete mineralization of a given constituent. Trichloroethylene has been successfully degraded aerobically to carbon dioxide with methane in air, although the rate of transformation was less than that for dichloroethylenes (16). However, there are toxicity problems because some trichloroethylene oxidation products are toxic to many methanotrophic bacteria. It also appears that trichloroethylene concentrations greater than 50 mg/L inhibit methane use by methanotrophs (10).

Another serious limitation of methane-oxidizing bacteria is that they cannot transform tetrachloroethylene (i.e., perchloroethylene) or higher chlorinated aliphatic compounds. The less chlorinated the compound, the greater the rate and extent of the transformation under aerobic conditions, as expected from thermodynamics. The lower the oxidation state of the compound, the less difficult it is to oxidize. Trichloroethylene is more oxidized than vinyl chloride, so it is more difficult to oxidize this compound further. As noted previously, the opposite is true when reducing an oxidized compound. The higher the degree of oxidation, the easier it is to reduce that compound.

Anaerobic Processes

Many chlorinated aliphatic compounds are transformed under anaerobic conditions. These compounds are mineralized in the presence of a diverse community of microorganisms. One of the predominant mechanisms for transforming chlorinated aliphatic compounds is reductive dechlorination. Reductive reactions result in replacing the chlorine atom by dihaloelimination. The reductive process usually occurs through cometabolism.

Chlorinated aliphatic compounds are transformed by reductive dechlorination even at low concentrations of less than 200 parts per billion (ppb). During reductive dechlorination, the chlorinated organic compound serves as an electron acceptor. The rate of dechlorination under anaerobic conditions is linked to the rate of primary substrate oxidation. Electrons from the oxidation of a primary substrate carry out the dechlorination. The control of these reactions for bioremediation requires an understanding of the redox conditions and the influence and availability of specific electron acceptors and donors on the overall metabolic condition of the bacteria that perform the reduction.

The availability of electron acceptors in anaerobic systems affects reductive dechlorination by competing with the chlorinated compounds for reducing potential. For example, nitrate and sulfate can inhibit the dechlorination of some chlorinated alkenes. It has been reported that the addition of nitrate to natural soil microcosms completely blocked the dechlorination of tetrachloroethylene (17).

According to thermodynamic principles, microorganisms couple half reactions that yield the greatest free energy. As redox conditions become more reducing, more chlorinated compounds undergo transformation. Thus more compounds are transformed under methanogenic conditions than under other anaerobic respirations (e.g., sulfate or nitrate). Additionally, several biologically active donors (e.g., acetate and H_2) and the ferrous ion have lower reduction potentials than most chlorinated aliphatic compounds. As a result, they can be involved in chlorine removal by reduction.

Sulfate also influences these reactions. Using sulfate as the electron acceptor (e.g., sulfate reduction by *Desulfovibrio sp.*), the dechlorination of tetrachloroethylene proceeds at a slower rate than if carbon dioxide is the electron acceptor (e.g., methanogenesis). Sulfate may also block the dechlorination of trichloroethylene (18). The specific influence of sulfate and other electron acceptors cannot be generalized. Different microbial systems and different aquifer and groundwater chemical conditions shift the thermodynamic equilibrium. Therefore, treatability studies are always required to assess the particular situation.

Chlorinated aromatic hydrocarbons can serve as both the electron acceptor and the electron donor in a reductive dechlorination reaction (7). However, chlorinated alkenes need an additional electron donor to support anaerobic dechlorination. Typical electron donors are the following: methanol, ethanol, glucose, sucrose, benzoate, lactate, formate, acetate, and butyrate. Volatile fatty acids produced under methanogenic conditions are generally considered the most effective electron donors for enhancing dechlorination. Because some methanogens consume hydrogen as an electron donor, microbial fermentations involve the reoxidation of a reduced electron carrier, such as nicotinamide adenine dinucleotide (NAD)H_2, as part of the metabolic reaction. This means that $NADH_2$ is oxidized to NAD and H_2 in the presence of methanogens. Usually, nonmethanogenic bacteria provide the hydrogen for methanogenesis (19).

Abiotic Transformations

Chlorinated aliphatic compounds include trichloroethylene, tetrachloroethylene, 1,1-dichloroethylene, 1, 2-dichloroethylene, carbon tetrachloride, chloroform, 1,1,1-trichloroethane, and chloroethylene (vinyl chloride). In addition to biological transformations, these compounds undergo abiotic transformations in the environment. The important abiotic transformations include substitution, dehydrohalogenation, and reduction in water (20). A typical substitution is the addition of water resulting in hydrolysis. The nucleophiles of OH^- and H_2O are the principal species responsible for abiotic dehydrohalogenation

Table 1. Ions Capable of Abiotic Displacement of Halogen[a]

Oxygenated Waters	Anaerobic Waters
H_2O	$SO_3{}^{2-}$
OH^-	$S_2O_3{}^{2-}$
Cl^-	NH_3
Br^-	$NO_2{}^-$
$SO_4{}^{2-}$	$S_n{}^{2-}$
$HCO_3{}^-$	$R\text{–}C_6H_{13}S^-$
—	$C_6H_5S^-$

[a] Reference 20.

of chlorinated aliphatic compounds in water. However, a variety of other species can displace the chlorine. These are presented in Table 1. Under anaerobic conditions, the sulfur nucleophiles are generally the most powerful. Sulfides react with chlorinated aliphatic compounds via substitution to produce mercaptans.

These reactions proceed slowly in the absence of biological activity. The half-lives for the monochloroalkanes are approximately a month at 25 °C (20). Polychlorinated species can have half-lives as long as 40 years. Stronger nucleophiles such as HS^- can reduce the half-lives of the abiotic degradation of chlorinated aliphatic hydrocarbons. Microbial enzymes also catalyze these reactions and reduce half-lives significantly.

A variety of transition metals, including nickel, iron, chromium, and cobalt, can reduce chlorinated aliphatic compounds. As a result of this oxidation–reduction (redox) reaction, the metals are oxidized. Vogel et al. (11) defined the reduction products and metals that mediate such reactions. The transition metal reduces a chlorinated compound, removing the chlorine and creating an alkyl radical that readily picks up a hydrogen atom from water, resulting in the formation of an alkane. The reduction of polychlorinated alkanes can result in both alkanes and alkenes.

DEGRADATION OF PETROLEUM HYDROCARBONS

Petroleum hydrocarbons include the common components of petroleum oils and products. They are found in wastewaters from petroleum refineries, petrochemical facilities, fuel storage and transportation facilities, and industrial organic chemical production facilities. Benzene and other single-ring aromatic hydrocarbons are used as solvents in industrial processes. Substituted forms of single-ring aromatic compounds are used in many industrial processes for preparing dyes, resins, antioxidants, polyurethane foams, fungicides, stabilizers, coatings, insulation materials, fabrics, and plastics. Polynuclear aromatic hydrocarbons (PAHs) are associated with petroleum refining and coal tar distillation. PAHs are also associated with waste by-products from coal gasification and coke production.

Microbial Transformations

Petroleum hydrocarbons can be classified into aliphatic, alicyclic, and aromatic hydrocarbon groups. Aliphatic hydrocarbons are divided into alkane, alkene, alkyne, and unsaturated alkyl groups. Alicyclic hydrocarbons can be grouped into cycloalkanes and cycloalkenes. Aromatic hydrocarbons are comprised of benzene and its derivatives and polynuclear aromatic hydrocarbons.

The presence of molecular oxygen as a terminal electron acceptor is required for successful microbial degradation of petroleum hydrocarbons. Nitrate and sulfate also serve as alternative electron acceptors during anaerobic respiration of hydrocarbons. Generally, the biodegradation rate decreases with decreasing redox potential. Only negligible biodegradation is observed under strictly anaerobic (i.e., fermentative) conditions. Consequently, hydrocarbons remain for a relatively long period of time in bottom sediments and other anaerobic portions of the aquatic environment.

Petroleum hydrocarbons are generally hydrophobic compounds. Bacteria and fungi frequently attach to oil droplets because intimate contact between a microorganism and the surface of the petroleum hydrocarbon is necessary for biodegradation. Consequently, dispersing the petroleum oil in water makes it more susceptible to microbial attack. Bacteria often produce extracellular surfactants that aid in solubilizing petroleum hydrocarbons. These bacterial surfactants are complex mixtures of proteins, lipids (e.g., rhamnolipids, phospholipids), and carbohydrates (21).

Aliphatic and Alicyclic Hydrocarbons

The biodegradation potential of alkanes is a function of carbon chain length. Short carbon chains of less than 10 carbons are more difficult to biodegrade than longer chains. Because of their higher solubility, short-chain hydrocarbons also exhibit a high degree of toxicity in the aquatic environment (22). Longer chain aliphatic hydrocarbons are more easily biodegraded than the short-chain variety. A large number of facultative anaerobic bacteria are prevalent in the aquatic environment that can use aliphatic hydrocarbons as a source of carbon and energy. These bacteria include the genera *Acinetobacter, Alcaligenes, Arthrobacter, Flavobacterium, Methylococcus, Mycobacterium, Nocardia*, and *Pseudomonas* (21). Numerous fungi and yeast also biodegrade aliphatic hydrocarbons. Although fungi are more versatile than yeast in biodegrading short-chain hydrocarbons, both are effective in using long-chain alkanes.

Aerobic biodegradation of a long-chain aliphatic hydrocarbon requires incorporating molecular oxygen into the compound. Oxygenase enzymes (i.e., monooxygenases and dioxygenases) mediate this degradation reaction (23). The pathway of alkane biodegradation is oxidation at the terminal methyl group of an alcohol and then of the corresponding fatty acid. The terminal oxidation proceeds by successive removal of two carbon units, termed the beta-oxidation sequence.

Alkene biodegradation is more varied because bacteria attack at either the methyl group or the double bond. Unsaturated straight-chain hydrocarbons are usually biodegraded less easily than saturated compounds. Consequently, bacterial metabolism results in forming intermediates that consist of unsaturated alcohols and fatty acids, primary or secondary alcohols, methyl ketones, epoxides, and diols (21). The methyl group oxidation is the more likely biodegradation pathway.

Petroleum hydrocarbons that have branch chains are less susceptible to biodegradation. Quaternary carbon and β-alkyl-branched compounds are generally considered recalcitrant and accumulate in the environment. However, combining chemical oxidative processes with biodegradation is effective for treating recalcitrant hydrocarbons.

The biodegradation of cycloalkanes is usually by oxidation of the terminal methyl group and yields a primary alcohol. Hydroxylation must occur to initiate the biodegradation of cycloalkanes. The bacteria that can oxidize noncyclic alkanes can also hydroxylate cycloalkanes. Several alternate metabolic pathways exist for microbial attack on alicyclic hydrocarbons, and numerous intermediate compounds have been identified during their degradation. Substituted cycloalkyl compounds vary in their capacity for biodegradation, but those that contain carboxylic acid groups are readily biodegraded. Bacteria capable of degrading cycloalkyl carboxylic acids are numerous in the environment (24).

Aromatic Hydrocarbons

The nature and extent of the biodegradation of aromatic hydrocarbons depends on the number of rings in the structure, the number of substitutions, the type and position of the substituted groups, and the nature of the atoms in heterocyclic compounds. The solubility of the aromatic hydrocarbon greatly affects its potential for biodegradation under either aerobic or anaerobic conditions. Mixtures of aromatic compounds can also influence the rate of biodegradation.

Aerobic microbial attack on single-, double-, and triple-ring aromatic compounds involves the foundation of a dihydrodiol compound. Oxidative attack on the dihydrodiol compound results in forming an alkyl catechol, a common intermediate formed during the oxidation of many aromatic hydrocarbons. Additional metabolic oxidation results in ring fission, forming either an aldehyde or an acid. This step results in the destruction of the aromatic ring leaving an oxidized aliphatic hydrocarbon, which is easily biodegraded, releasing hydrogen (25). Bacteria of the genus *Nocardia* can oxidize substituted aromatic hydrocarbons, such as *p*- and *m*-xylene, and use these compounds as a sole source of carbon and energy (4).

A second metabolic pathway for degrading aromatic hydrocarbons involves oxidation of alkyl substitutes, which results in forming aromatic carboxylic acids that are then oxidized to dihydroxylated ring fission products (i.e., aldehydes and acids). The aldehydes and acids are then readily biodegraded by the beta-ketoadipic and meta fission pathways (26). In general, alkyl-substituted aromatic hydrocarbons are less biodegradable, the longer the chain length, or the more numerous the alkyl groups.

Single-ring aromatic hydrocarbons can be transformed anaerobically by denitrifying, sulfate-reducing, iron-reducing, and methanogenic bacteria (27). These are all anaerobic respirations where the nitrate, sulfate, ferric, and carbonate ions act as terminal electron acceptors (TEA) for energy metabolism. The use of these compounds as electron acceptors in microbial energy metabolism is called dissimilative metabolism. During dissimilative metabolism, a comparatively large amount of the TEA is reduced, and the reduced product is excreted into the aquatic environment. The possible end products of these reductions are HS^-, N_2, $NO_2{}^-$, N_2O, Fe^{2+}, and CH_4.

The presence or absence of oxygen in the structure of an aromatic compound impacts both the degradation mechanism and the rate of biodegradation. The initial step in the degradation of aromatic hydrocarbons is conversion of the compound to an oxygenated form. Under anaerobic metabolic conditions, oxygen is incorporated from water into the aromatic structure by hydroxylation (28). The microbial fermentation of benzene and toluene is characterized by end products that are both partly oxidized and partly reduced. The oxidation might include both methyl group oxidation and ring oxidation. The reduction generally results in forming saturated cyclic rings (3).

Grbic-Galic (29) observed that the biodegradation of benzene is initiated by ring oxidation, resulting in the formation of phenol. Three pathways are possible for toluene, starting with ring oxidation to *p*-cresol or *o*-cresol and methyl group oxidation to benzyl alcohol. Thereafter, the biodegradations proceed along pathways that are similar to the anaerobic transformations of oxygenated aromatic compounds (30).

The biodegradation of multiring aromatic hydrocarbons (PAHs) is a function of the complexity of the chemical structure of the compound. In general, PAHs that contain four or more aromatic rings are much less biodegradable than compounds that contain only two to three rings (3). Several of the higher ring number PAHs and the intermediate products of their biodegradation are either toxic or carcinogenic. They are also strongly hydrophobic, which predicts that their concentration in the aqueous phase is always relatively low. Therefore, significant portions of the PAHs are found adsorbed on particles and possibly trapped in the micropores of these particles. Consequently, the rate of biodegradation is controlled by the sorption–desorption kinetics of the strongly sorbed PAH compounds. Enhancing solubilization by introducing bacteria that produce extracellular surfactants improves the *in situ* biodegradation of PAHs in groundwater.

Biodegradation of the unsubstituted di- and tri-ring PAHs in marine and freshwater is well documented in the literature (25,31,32). The bacterial degradation rates for phenanthrene and anthracene appear to be related to the water solubilities of these compounds. As for benzene and its derivatives, the oxidation of di- and tri-ring PAHs involves the formation of dihydrodiol intermediates. Catechol is the principal intermediate product of these microbial degradations (25). Bacteria that can degrade anthracene and phenanthrene include the genera *Aeromonas, Beijerinckia, Flavobacterium, Nocardia*, and *Pseudomonas* (31).

Biodegradation of unsubstituted PAHs that contain four or more aromatic rings (e.g., fluorene, pyrene, benzo(a)pyrene, benzo(a)anthracene, dibenzo(a)anthracene) has been documented in the literature (33–35). The bacteria that can degrade the higher molecular weight PAHs were also identified in this literature; they include the genera *Alcaligenes, Beijerinckia, Mycobacterium*, and

Pseudomonas. These research studies have indicated that cometabolism coupled with analog substrate enrichment may be necessary to treat PAHs that contain four or more aromatic rings. Cometabolism appears to be the principal mechanism for biodegrading benzo(a)anthracene (35). The presence of biphenyl, *m*-xylene, and salicylate were necessary to induce oxidation of benzo(a)anthracene to carbon dioxide and a mixture of *o*-hydroxy polyaromatic compounds. Because the high molecular weight PAHs do not induce enzyme production in many bacteria, the addition of naphthalene as an analog substrate was necessary to biodegrade benzo(a)anthracene in this study.

LANDFILL

Jim Philip
Napier University
Edinburgh, Scotland, United Kingdom

INTRODUCTION

All countries rely to a greater or lesser degree on landfilling to dispose of the huge quantities of municipal solid waste (MSW) generated. For example, the United Kingdom has traditionally relied very heavily on landfilling of MSW as it has a relatively poor recycling infrastructure compared with some other European countries. The United Kingdom produces roughly 28 million tons of MSW per annum, of which about 80% is landfilled. Only some 12% is recycled and about 8% incinerated with energy recovery. Moreover, the amount of waste being generated is growing some 3–4% per annum.

Globally, landfilling has had a checkered history, and poor practice in design and operation of landfills has led to serious environmental problems. With regard to the threats to water bodies, the production of landfill leachate is by far the most significant. Liquid leachate develops at a site when its water holding capacity is exceeded. If the site is unlined, the leachate makes its way off-site to groundwater or to a surface water body and can cause drastic water pollution.

The Landfill Directive of the EU (1) has the overall aim "to prevent or reduce as far as possible negative effects on the environment, in particular the *pollution of surface water, groundwater* (authors' italics), soil and air, and on the global environment, including the greenhouse effect, as well as any resulting risk to human health, from the landfilling of waste, during the whole life-cycle of the landfill." This succinctly crystallizes the objectives of modern landfill design, and the Directive has far-reaching consequences for the way we handle and dispose of MSW. There are various stringent requirements of the Directive, the most important of which for preventing water pollution are:

- Higher engineering and operating standards are to be followed.
- Biodegradable waste has to be progressively diverted away from landfill. By 2020, the amount going to landfill will be 35% of that of 1995.
- Banning of disposal of liquid wastes to landfill sites, along with certain hazardous and other wastes, will be implemented.

THE MICROBIOLOGY OF REFUSE DECOMPOSITION

One view of a landfill is as an enormous, solid-state fermenter in which naturally selecting microbial populations, usually bacteria, anaerobically decompose refuse components, ultimately to their mineral constituents. The process of anaerobic decomposition is microbiologically complicated, and a great many details remain to be elucidated. However, the overall process can be summarized as in Fig. 1. Although this image seems to separate the various processes, it should be kept in mind that all happen contemporaneously. As the landfill is microbiologically active over long periods, often decades, only the anaerobic processes (those in blue in Fig. 1) concern us here: hydrolysis and fermentation, acetogenesis, and methanogenesis. One of the reasons that these processes occur over decades is that

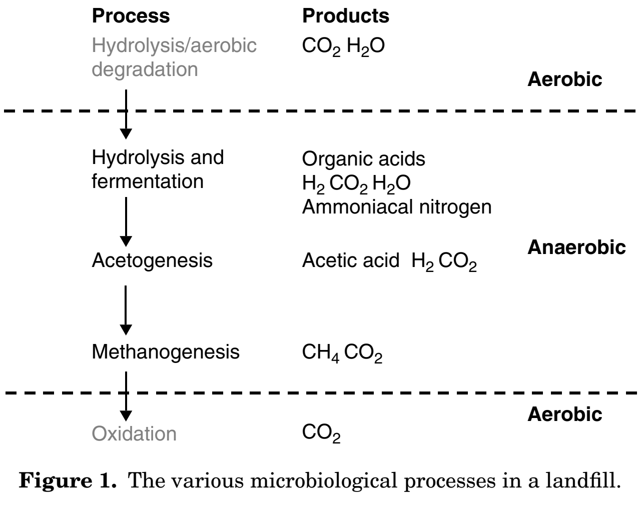

Figure 1. The various microbiological processes in a landfill.

the energy available from anaerobic processes is much lower than that from aerobic processes. For example, the aerobic mineralization of glucose to CO_2 and H_2O liberates more than seven times as much energy as the anaerobic mineralization of glucose to CO_2 and methane (CH_4).

Hydrolysis and Fermentation

Long-chain, insoluble carbohydrates, lipids, and proteins are not in a form in which they are readily metabolized by microorganisms. Hydrolytic reactions break down these long-chain molecules to smaller, more water-soluble molecules that can then be metabolized. Fermentation reactions produce soluble fermentation end products such as short-chain volatile fatty acids (VFA) and gaseous products of variable water solubility such as CO_2 and hydrogen.

Acetogenesis

The soluble acids from fermentation are converted to acetic acid, CO_2, and hydrogen by acetogenic bacteria. Other bacteria, acidogenic bacteria, convert carbohydrates, CO_2, and hydrogen to acetic acid. An important point is that the conversion of fermentation products to acetic acid occurs only at low concentrations of hydrogen. Hydrogen is produced at several stages, so it must be removed to prevent the inhibition of acidogenesis. If the partial pressure of hydrogen is too high, reduced organic acids, such as propionic, lactic, butyric, valeric, and caproic, start to accumulate, producing smells. Either from lowering the pH, mobilizing toxic metals, or inhibition due to the presence of high concentrations of these acids, there would be subsequent inhibition of methanogenesis.

Methanogenesis

Hydrogen concentration is kept low as a result of consumption by strictly anaerobic sulfate-reducing bacteria and methanogenic (methane-producing) bacteria. The methanogenic pathways of all species have the conversion of a methyl group to methane in common; however, the origin of the methyl group is variable. Although most isolated species can reduce CO_2, the majority of biological methanogenesis (about 70%) originates from conversion of the methyl group of acetate to methane, although in most cases acetate is not used as an energy source. Others acquire the methyl group directly from substrates such as methanol or methylamines.

Syntrophism

The low-energy yields involved in the anaerobic conversion of refuse to methane forces these different organisms into very efficient cooperation. Such cooperations are known as syntrophic relations. Syntrophism is a special case of symbiosis between two metabolically different types of bacteria, which depend on each other for degradation of a certain substrate, usually for reasons of energetics.

There is a classic example in landfill microbiology. Metabolism of low molecular weight fatty acids, such as propionate by *Syntrophobacter* and caproate and valerate by *Syntrophomonas*, produce acetate, hydrogen, and carbon dioxide, which are used by methanogens. The result is the overall conversion of fatty acids to methane. The conversion of fatty acids to acetate is energetically unfavorable, and the reaction depends on the removal of hydrogen by methanogens. Likewise, the methanogens need hydrogen for their metabolism.

Landfill Microbiology Is Mass Transfer Limited

Very often mass balance calculations of methane generation at landfills suggest that the overall process is not working nearly as efficiently as it might, even considering that several steps along the way have poor thermodynamics, which leads to very protracted timescales for return of the site to stability, and the consequent need is for long-term monitoring. If the bottleneck is not in thermodynamics, then where is it? The answer lies in a very common observation; that newspaper, although very rich in calories, can still be read after excavation from a landfill site decades after its disposal there.

Cellulose, the most abundant polymer on the planet, represents about 50% of the organic material going to landfills. The rate limitation in a landfill is much more likely to be associated with solid substrates, such as paper. Here the limitation is not thermodynamic, but mass transfer. The substrate has to be converted from the solid form into an aqueous form before other metabolic associations can continue the degradation. The enzymatic hydrolysis of polymers to monomers has long been known as the rate-limiting step in the conversion of cellulose to methane and in the digestion of refuse.

ENVIRONMENTAL IMPACTS OF LANDFILLS

Landfilling domestic refuse creates a whole host of negative environmental impacts, summarized in Fig. 2. These impacts have variable magnitudes and can be categorized as *localized* (odor, noise, litter, transport risks, public health risks created by birds and vermin, explosive gas migration), *diffuse* (groundwater, surface water, drinking water contamination), and *global* (greenhouse gas generation). In the present context, the effects on water pollution are the primary concern. And the water pollution problems are a direct result of leachate generation and its off-site migration.

Leachate Composition

Leachate is the result of water infiltration to the site that exceeds the water holding capacity of the waste and other site materials. The water balance of a landfill site can be summarized as

$$\mathrm{LC} = \mathrm{PR} + \mathrm{SRT} - \mathrm{SRO} - \mathrm{EP} - \mathrm{ST}$$

where LC = leachate
PR = precipitation
SRO = surface run-off
SRT = surface run-to (zero on a well designed site)
EP = evapotranspiration
ST = change in water storage

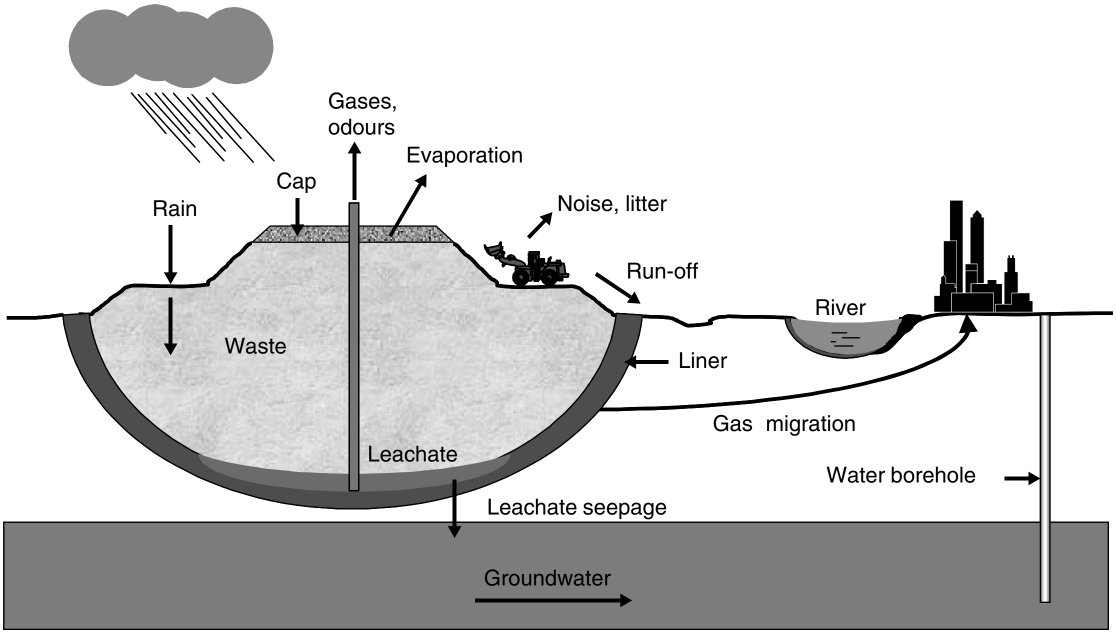

Figure 2. Environmental impacts of landfill practice.

Leachates vary in composition from site to site and also according to the age of the leachate. Leachates generated during the early stages of anaerobic decomposition are characterized by high concentrations of VFA, acidic pH, high BOD:COD ratio, and high levels of ammoniacal nitrogen and organic nitrogen. Ammonia is largely produced from the degradation of proteins. The low redox potential of such leachates facilitates the production of soluble, reduced-state metals, including chromium, iron, and manganese. These "young" leachates are much more environmentally damaging than mature leachates produced during the stable methanogenic phase.

By the time that methanogenesis is occurring at a high rate, many of the fatty acids have been converted ultimately to methane and CO_2. Methanogenic leachates are more likely to have a higher pH (resulting in lower heavy metal concentrations due to precipitation), lower levels of ammoniacal nitrogen, and a lower BOD:COD ratio (from the biodegradation of fatty acids).

LANDFILL DESIGN AND CONSTRUCTION IN RELATION TO ENVIRONMENTAL MITIGATION

It is not an objective to discuss detailed engineering design. Rather, in modern landfills, several design and construction measures can be taken to minimize the environmental effects of the site; and it is these that are summarized here. For example, a critical element of any landfill design is capacity, which is influenced by factors such as waste density, amount of daily cover, and the thickness of the final cap. However, for this discourse, capacity has little relevance to environmental effects.

Phasing and Cell Construction

A phase is a subsection of the total landfill to be filled; generally, it has an operational period of 12 to 18 months. Longer than 18 months results in excessive leachate production in wet areas. Cells are subsections of phases, which vary in size according to operational exigencies. Cell sizes are minimized according to the surface area required for maneuvering large machinery on the site. It may also be possible to size each cell in which the rate of vertical filling exceeds the rainfall plus water holding capacity to minimize leachate generation.

The practice of phasing (Fig. 3) has the objective of progressive excavation and filling of the site. As a result, at any one time, part of the site may be restored, part may be in the process of being capped, part is being prepared to receive waste, and only a relatively small part is being actively filled. When properly done, there will also be sufficient space for storage and protection of materials for subsequent restoration, and also coordination of haul roads and access routes. The environmental benefits of the phase/cell strategy are:

- reduction of leachate generation;
- progressive installation of leachate and gas control systems;
- segregation of clean surface water run-off within and outside the site;
- protection of local amenity.

Phases are generally filled from base to cap in a continuous operation, then capped and restored, leaving a temporary unrestored face sloping to the landfill base (Fig. 3). In deep landfills, such as those constructed in old quarries or opencast mining sites, the phases are vertically tiered so that, overall, the site is a three-dimensional honeycomb of cells.

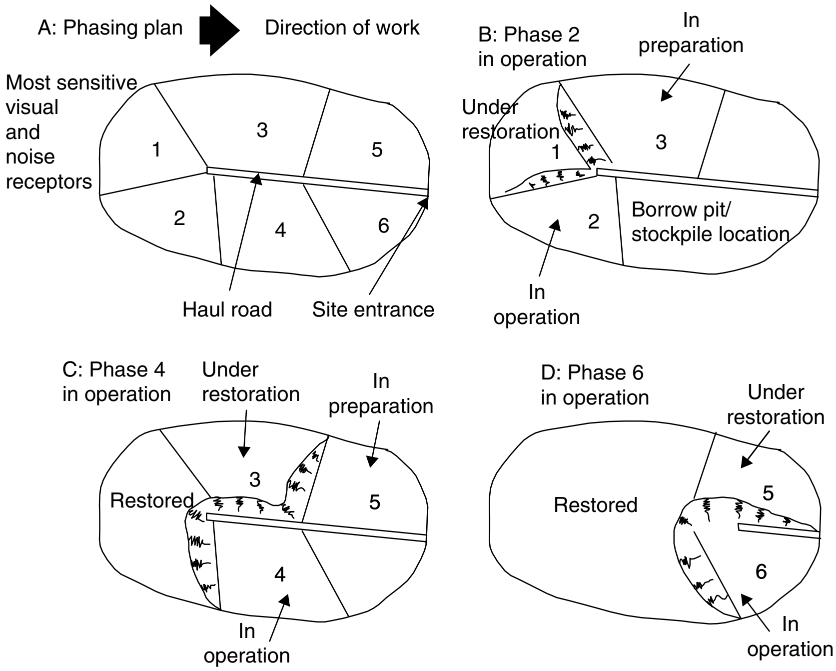

Figure 3. The phased approach to site management (adapted from Ref. 2).

Daily Cover

This practice involves covering refuse to a certain minimum depth daily with the following environmental benefits:

- prevention of wind-blown litter;
- suppression of odor;
- deterrence to vermin and birds;
- improvement of the site appearance.

From the point of view of water (and therefore leachate) and gas management, the material used for daily cover should be sufficiently permeable that it does not impede water or gas flow. Impermeable material creates perched conditions and makes it difficult to extract leachate. Ideally, the material of daily cover is soil excavated from within the boundaries of the landfill to prevent net consumption of void.

Liners

A key design parameter for MSW is to attain an impermeability of 10^{-9} m/s and so prevent leachate breakthrough to the unsaturated zone. The objective should be to select a new site on soil with a hydraulic conductivity lower than this. If this is not possible, then a variety of materials can be used to line the new site, either as single or multiple layers.

Clay liners varying in thickness from about 0.5 m (for imported clay) to 2 m (for *in situ* clay) are natural liners of high ion exchange capacity to retard the movement of toxic metals. Bentonite, the typical clay, is extremely absorbent. The hydraulic conductivity of dry, unconfined bentonite is 10^{-9} m/s. When saturated, however, it drops to less than 10^{-12} m/s^{-1}.

Synthetic liners, normally made of high-density (HDPE) or low-density (LDPE) polyethylene, are available in thicknesses of 0.5 to 2.0 mm. Although of very low permeability, their installation requires great care to prevent tearing.

Geosynthetic clay liners (GCL) (Fig. 4) are relatively new products gaining acceptance as barrier systems in municipal waste landfills. These offer some advantages over traditional bottom liners and covers and retain low hydraulic conductivity. Advantages include

- fast and easy to install;
- self healing of rips and tears due to the swelling property of bentonite;
- cost-effective in regions where clay is not readily available;
- their thin cross-section compared to a clay liner maximizes the capacity of a landfill and still protects groundwater.

Tests show that holes up to 75 mm diameter will self-heal when the clay hydrates and swells. Stitch-bonding or needle-punching creates small holes in the geotextile that heal due to swelling of the bentonite. The geotextile is often a blend of HDPE and very low-density polyethylene (VLDPE).

Drainage and Leachate Collection/Recirculation/Treatment

Leachate collected by the liner system must be removed to accelerate stabilization of the site and prevent liner damage, which is accomplished by drainage to collection sumps at low points via a granular layer containing perforated pipes of sufficient slope to allow gravity drainage. Leachate is then removed from the sumps, either by pumping in vertical wells or by gravity drains in a valley

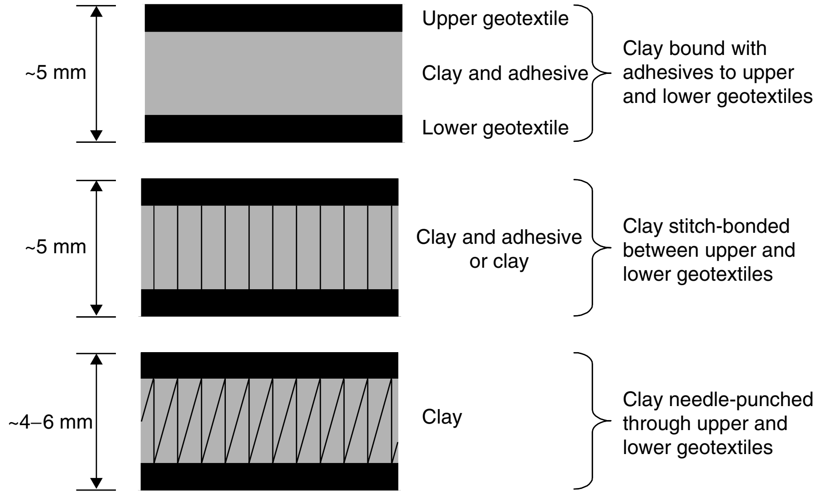

Figure 4. Geosynthetic landfill liner types.

site, where the leachate can either be treated on-site by a dedicated wastewater treatment plant or transported off-site for treatment.

Using a proper leachate collection system, it is possible to spray leachate back onto emplaced waste, which effectively uses the landfill site as a flushing anaerobic bioreactor and can improve landfill gas generation by uniformly wetting the waste.

Gas Abstraction and Use

This is mentioned here for completeness, although methane is highly insoluble in water and therefore contributes very little to the water-related environmental problems of landfills. During the stable methanogenic phase of a landfill, by far the longest phase, landfill gas, consists mainly of methane and carbon dioxide, both of which are greenhouse gases; the former is highly explosive; the latter is relatively water-soluble and corrosive. Most of the landfill gas management systems for landfills are designed with the characteristics of methane in mind. By appropriate siting of vertical or horizontal gas abstraction wells, it is possible to collect the gas, flare it, or, if economically viable, burn it for energy generation.

INTRODUCTION

Sanitary landfilling is the most widely used method for disposing of urban solid wastes around the world. The extensive use and the public awareness of this disposal method have raised concerns, over the negative environmental impacts and the pollution potential that this practice creates, as well as by the by-products of landfills (e.g., leachates, biogas, odors, etc.). Among them, leachates are considered the most important environmental burden. Depending on the composition and extent of decomposition of the disposal of refuse, as well as on the hydrological parameters existing in the landfill site, leachates may become highly contaminated wastewaters.

Landfill leachate, as defined in the U.S. Environmental Protection Agency Code of Federal Regulations (CFR) Title 40, Part 258.2, is the liquid that has passed through, or emerged from the disposal of solid wastes and contains soluble, suspended, or miscible materials from these wastes. Over time, the seepage of water through the landfill mainly from precipitation increases the mobility of pollutants and the potential for transferring them into the surrounding environment. As water passes through the layers of disposed solid wastes, it may "leach" pollutants from them, moving them deeper into the soil. The mobility of pollutants may present a potential hazard to public health, as well as to the environment, causing significant pollution problems in the groundwater aquifer and in adjacent surface waters. As a result, understanding and predicting leachate generation routes, as well as containing it and the subsequent appropriate treatment are required for environmentally proper handling of these heavily polluted wastewaters.

A simple measure to prevent the movement of toxic and hazardous waste constituents from a landfill is a liner operated in conjunction with a leachate collection system. Leachates are typically collected from a collection system placed at the bottom of the landfill. Leachates may also be collected by using slurry walls, trenches, or other containment systems. The leachate generated may vary from landfill site to site, based on a number of factors, which include the types of waste accepted for disposal, the operating practices (such as shredding, daily cover with soil, or capping), the depth of fill, the applied compaction of wastes, the annual precipitation at the landfill site, and the landfill operational age.

LEACHATE GENERATION

Leachates are the combined wastewater, containing organic and inorganic constituents, produced when water and/or other liquids seep through solid wastes, deposited in urban or hazardous solid waste landfills. The quantity of leachates is influenced by several interacting factors, such as annual precipitation, runoff, infiltration, evaporation, transpiration, mean ambient temperature, waste composition, waste density, initial moisture content, and underlying soil conditions (depth) (1). A number of techniques have been reported, using the water budget analysis through a landfill site, to estimate the amount of leachate generated (2). The various components of moisture used in the water budget are shown in Fig. 1. According to this analysis, the primary source of moisture is precipitation over the landfill site. A part of this moisture results in surface runoff, another part is returned to the atmosphere in the form of evapotranspiration from the soil and the surfaces of plants, and the remainder is added to soil moisture storage.

The maximum moisture that can be retained, without continuous downward percolation by gravity, is known as field capacity. Whenever the moisture content exceeds the field capacity of the soil, water percolates down into (through) the solid waste. The addition of moisture to solid waste over a period of time saturates the solid waste to its field capacity, resulting thereafter in leachate generation. The various moisture components, which constitute the processes taking place in a landfill that produce leachate, are affected by several parameters, such as (3):

1. Precipitation, which varies geographically and seasonally.
2. Surface runoff and infiltration, which depend on the intensity and duration of storms, surface slope, permeability of soil cover, and amount and type of vegetation.
3. Evapotranspiration at a landfill site, which is affected by the type of the soil and vegetation.
4. Soil moisture storage capacity, which is continually changing; it increases due to infiltration and decreases due to evapotranspiration.

Several methods used water balance calculations of these components to assess leachates generation rates. In general, following are the characteristics of the leachates produced (4):

1. A higher leachate generation rate is expected in humid than in dry areas.
2. Leachate generation follows a pattern similar to that of precipitation (rain), then remains at constant flow for a time period.
3. Production of leachates may be minimized by proper and efficient covering operations, careful drainage design, selection of vegetative cover, etc.
4. The quantity of leachate generated and its qualitative characteristics are significant for designing and constructing the most appropriate collection and treatment devices.

In general, leachates are generated over a long time period, unless percolation is prevented by the closure procedures and the final land use (5). In this case, leachate generation will cease shortly after the completion and closure of the landfill. However, for the proper design of

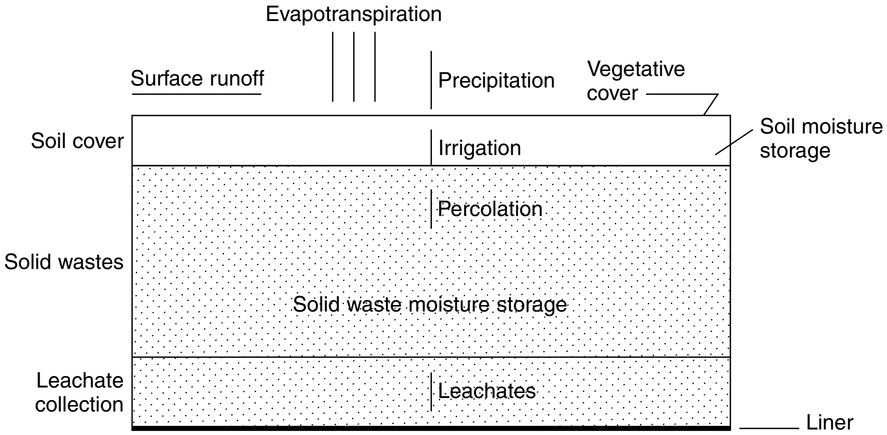

Figure 1. The various moisture components in a sanitary landfill.

a leachate treatment system, the characteristics of the leachate are necessary in addition to quantitative data.

LEACHATE CHARACTERISTICS

As leachates pass through or emerge from deposited solid wastes, they may contain soluble, suspended, or miscible materials from the wastes. Several factors may affect leachate quality, such as (6)

- specific types of solid waste accepted/deposited
- operating practices (shredding, cover, or capping)
- amount of infiltration
- depth of fill
- compaction
- age

The specific waste types received for disposal are the most representative characteristic of a landfill and, therefore, of the respective wastewater generated because the main contaminants in this wastewater are derived from the materials deposited in the site. The amount of infiltration and the age of a landfill are the primary factors that affect the concentration of contaminants in the leachate produced. The remaining factors influence mainly the rate of infiltration.

The highest concentrations of contaminants are typically present in leachates of new or very young landfills (7). However, the overall loads (i.e., the mass) of pollutants are generally not very large because new landfills typically generate low volumes of leachate. As the volume of waste approaches the capacity of the landfill and the production of leachate increases, both the pollutant loadings (i.e., flow × concentration) and the concentrations of certain contaminants, which are mainly organic pollutants, tend to increase. The increase of pollutant concentration is attributed to the onset of decomposition within the landfill and to the leachates that traverse the entire depth of the refuse. Therefore, large pollutant loadings from a typical landfill occur during the period of high leachate production and contain high levels of contaminants. The periods of varying leachate production cannot be quantified readily because they are site specific and depend on each of the aforementioned variables.

Over a period of time (as the landfill ages and leaching continues), the concentration of contaminants in the leachate decreases. The landfill may continue to generate substantial quantities of leachate; however, gradually the load of pollutants become lower because of the lower concentrations of soluble, suspended, or miscible contaminants that remain in the landfill. As the decomposition process within the landfill continues, the landfill attains a stabilized state of equilibrium, where further leaching produces leachates with a pollutant load lower, than during the period of peak leachate production. This stabilized state is presumably the result of decomposition of landfill waste by indigenous microorganisms that remove (biodegrade) many of the organic contaminants usually susceptible to further leaching.

Leachate characteristics change over time because there is a shift from the initial relatively short period of aerobic decomposition toward a longer period of anaerobic decomposition that has two distinct subphases (6, 8). The biological decomposition of landfilled municipal refuse is often based on the anaerobic breakdown of organic wastes. The biological activity occurs in a landfill shortly after the deposition of urban wastes, containing a large percentage of organic materials. Initially, the solid wastes, which contain high moisture content, can be decomposed rapidly under aerobic conditions, creating large amounts of heat. As oxygen is depleted, the intermediate anaerobic stage of decomposition begins. This change from aerobic to anaerobic conditions occurs unevenly through the landfill and depends upon the rate of oxygen diffusion into the fill layers.

In the first stage of anaerobic decomposition, the so-called "acidic phase," extra-cellular enzymes convert complex organic wastes, including carbohydrates, proteins, and fats, to more soluble organic molecules. Once the organic wastes are solubilized, their conversion to simpler organic molecules, such as acetic, propionic, butyric, isobutyric, valeric, isovaleric and hexanoic acids takes place; acetic acid is the main catabolic product of anaerobic fermentation. As a group, the low molecular weight, but highly polar, organic acids are termed volatile fatty acids (VFA). These soluble organic acids enter the leachate percolating through a landfill, resulting in a decreased pH of the leachate and increased oxygen demand. VFA impart to the leachate from this phase their characteristic "barnyard" odor and comprise the majority of its organic load. Anaerobic activity in the landfill can also lower the oxidation–reduction (redox) potential of the wastes, which under low pH conditions, can cause an increase in the concentration of dissolved inorganic contaminants.

Eventually, in the second or "methanogenic" phase of anaerobic decomposition, methane gas-forming bacteria within the landfill begin to convert the organic acids to methane and carbon dioxide, reducing the organic strength. The fraction of organic carbon, remaining after this degradation process, tends to be more oxidized, but has a higher molecular weight, higher than 500 amu. The absence of organic acids in the landfill increases the pH of the leachate, toward neutral or alkaline, which can subsequently decrease the solubility of inorganic contaminants and lower their concentrations in the resulting leachate.

The age or degree of decomposition of a landfill may be ascertained by observing the concentration of various leachate "gross" parameters, such as BOD_5, COD, TDS, or the organic nitrogen (N_{org}) concentration (9). The values of these leachate parameters can vary over the decomposition life of a landfill, depending on the specific phase. Typically, leachates from the early, acidic phase of anaerobic decomposition may be up to 35 times stronger than domestic wastewater and can have a COD content of more than 20,000 mg/L, BOD_5 greater than 12,000 mg/L, high volatile fatty acids concentration of about 6000 mg/L, and high content of inorganic compounds, such as 1300 mg/L chloride, but low phosphorous concentration (less than 1 mg/L) (10). Leachates from the older landfills have lower values of BOD_5 and COD, as well as of most organic pollutants, indicating the presence of smaller amounts of degradable compounds, derived from the aged stabilized waste.

The COD of leachates from the "methanogenic" phase tend to be lower, between 1500 and 4000 mg/L, and the significant decrease in the VFA concentration results in an increase in the pH to 7, or even higher. In addition, aged leachates can contain high levels of compounds existing in reduced form, such as ammonia (greater than 1000 mg/L), as well as a high concentration of chlorides because of the anaerobic environment of the landfill. Furthermore, certain metals such as iron, lead, and zinc tend to form stable complexes with the high molecular weight organic compounds (i.e., higher than 50,000), increasing their respective concentrations in the leachate (6).

However, using only these parameters, other refuse-filling variables, such as the processing of wastes prior to disposal or the fill depth, would not be taken into consideration. To compensate for these additional variables, several researchers have proposed examining certain ratios of leachate parameters over time (7). The most important (and widely used) such ratio is BOD_5:COD. Leachates from younger landfills typically exhibit BOD_5:COD ratios of approximately 0.8, whereas older landfills exhibit lower ratios (in many cases as low as 0.1). The decline in the BOD_5:COD ratio with age is due primarily to readily biodegradable material (e.g., phenols, alcohols, VFA) that degrade faster than the more recalcitrant compounds (such as the heavy molecular weight organic compounds, including humic and fulvic acids), which are much more difficult to treat biologically. As a result, as the landfill ages, the BOD_5 of the leachate decreases faster than the COD. Other ratios that decrease over time include the volatile solids to fixed (inorganic) solids (VS:FS), volatile fatty acids to total organic carbon (VFA:TOC), and sulfate to chloride (SO_4:Cl), which is inversely related to the redox potential (ORP).

As a result of the variation in leachate strength, leachates are commonly distinguished as young, acid-phase leachates and old, methanogenic ones, as well as medium- and low-strength leachates (11). For "young" leachates, a typical ratio of BOD_5/COD around 0.7 has been suggested; the corresponding values for mature leachates are 0.5, for aging 0.3, and for "old" 0.1. A typical time period for the transition from young to older leachate types is between 3 to 10 years from the landfill start-up, but may be as short as, 2 years in specific cases.

In summary, the following conclusions can be drawn regarding landfill leachate quality and their treatability (3):

- Leachate characteristics are highly variable.
- The quality of leachates changes with age, and therefore, the treatment facility should be flexible enough to handle/treat appropriately the changing leachate quality.
- A reliable estimate of the chemical quality of leachates should include analytical experimental data measured under the particular conditions prevailing in the landfill area.

The characteristics of leachates are usually very different from those of domestic wastewaters and similar to heavily loaded industrial wastewaters, indicating the need to use advanced treatment methods for the effective removal of pollutants before leachates are discharged.

INTRODUCTION

The characteristics (composition) of sanitary landfill leachates are very different from domestic wastewaters, and their quality varies from landfill to landfill, as well as with the particular landfill age. Hence, their treatment is based largely on industrial wastewater treatment processes. However, no single treatment method is considered efficient enough to achieve the high removal rates of pollutants, usually required; therefore, several treatment trains are currently used, including combinations of aerobic/anaerobic processes and several modes of physical–chemical treatment systems. The selection and design of leachate treatment facilities requires knowledge of several parameters, such as leachate quantity and quality, degree of necessary treatment, disposal methods, and effluents guidelines. These are the main problems that have to be considered:

- Specific treatment schemes applied in a particular landfill may not be transferable to other sites.
- Leachate quantity and quality vary seasonally, depending on climatic and hydrologic factors.
- The composition of disposed of solid wastes greatly affects the composition of leachates.

During plant design, the fluctuations in the leachate generation rate and its composition should be considered. Furthermore, the treatment system should also be flexible enough to treat the “young” leachates during the preliminary stages of landfill operation, as well as the “older” leachates produced during landfill aging.

During the early development of appropriate methods for leachates, the main efforts were focused on the application of treatment processes commonly used for municipal wastewaters; they were based mainly on biological processes. Physical and chemical systems used were later complementary, aimed at the development of more efficient overall techniques (1).

BIOLOGICAL PROCESSES FOR TREATING LEACHATES

Both aerobic and anaerobic biological units have been used to treat landfill leachates. The number of landfill facilities that use variations of biological treatment as part of landfill wastewater treatment systems in the United States has been reviewed by the EPA (2), and it is shown in Table 1. According to this table, most of the biological treatment systems use aerobic processes, including suspended growth processes (i.e., activated sludge, sequencing batch reactors, lagoons, etc.), as well as fixed-film processes (i.e., trickling filters or rotating biological contactors). However, the use of anaerobic systems is rather limited; these systems are most effective for treating high strength leachates (i.e., whose COD values are over 4000 mg/L) and for wastewaters containing refractory (not easily biodegradable) contaminants because of the effectiveness of methanotropic microorganisms in metabolizing these compounds. An important disadvantage of anaerobic treatment systems is the sensitivity of the applied methanotropic microorganisms to certain toxic substances, commonly found in many leachates.

The design of aerobic systems is based mainly on the requirements for removing organic loading in terms of BOD_5 and COD or on requirements for nitrogen removal. The selection of the design estimates depends on the effluents guidelines that have to be met and the problems anticipated from the existing high ammonia concentrations. A rule of thumb proposed for selecting the most appropriate design criteria is the ratio of BOD_5/N-content: when this ratio is less than 1, leachates are characterized by very high nitrogen (mainly ammonia) concentrations, and then nitrification criteria prevail; when this ratio is greater than 1, then the organic removal criteria dominate (3).

Table 1. Biological Treatment Facilities for Leachates in U.S. Landfills[a]

Type of Biological Treatment	% of Nonhazardous Facilities	% of Hazardous Facilities
Activated sludge	9	33

Denitrification systems	1	—
Other biological treatment systems	13	—

[a] Reference 2.
[b] In combination with activated sludge.

Suspended growth biological treatment systems usually include mechanically based aerators to provide the required oxygen to the microbial population and for mixing the liquor components. The ranges of typical design and performance parameters of activated sludge systems are as follows (4):

- hydraulic retention time: 1–10 days.
- solids retention time between 1 and 10 days.
- food to microorganism (F/M) ratio from 0.02–0.4 kg BOD_5/kg MLVSS/day.
- average nutrient requirement ratio BOD_5: N:P = 100:3.2:0.5.
- Removal efficiencies in terms of BOD_5 and COD from 90–99%, depending on experimental conditions and the properties of raw leachates.

Several measurements of operational parameters have indicated that a large part of the organic compounds in raw leachates are usually not readily biodegradable and require prolonged reaction times and extensive biological activity to oxidize them. Efforts to determine the removal rates of various compounds in an aerobic reactor resulted in discriminating four distinct and successive steps of substrate use by microorganisms, in order of gradually increased degree of difficulty: carbohydrates, fatty acids, amino acids, and humic substances of high molecular weight (4). Residual organics consist mainly of fulvic-like materials with molecular weights in the range 500–10,000, which are not readily biodegradable.

Introducing an anoxic stage may enhance the removal of nitrogen from leachates, achieving more than 70% total nitrogen removal. However, the highest removal rates may be achieved by adding an organic carbon source, such as methanol. High metal removal rates (up to 99%) have also been observed in activated sludge treatment systems of leachates; this was attributed to the oxidation of metals, forming insoluble compounds, and the incorporation of the respective precipitates into bacterial flocs (2). However, when metal content is high (e.g., 80 mg/L iron and 10 mg/L manganese), a pretreatment step may be necessary for their efficient reduction to prevent the resulting low MLVSS/MLSS ratios and certain mixing problems.

Stabilization ponds and aerated lagoons have also been used as pretreatment steps for leachates, prior to disposal in municipal sewers or recycling into the landfill. Although extended aeration and lagoon-type systems are favored for treating leachates because of low manpower requirements and operational simplicity, however, this application has a primary drawback, the extended land required. Additional problems connected with suspended growth systems include the intense foaming of leachates, high power consumption, potential inhibition of biological activity by increased concentrations of metals, high sludge production rate, filamentous bulking of sludge, and decreased biological activity due to deficiency in certain nutrients (usually phosphorous) (5).

Fixed-film aerobic systems provide an appropriate substrate for attaching and growing aerobic and facultative (anaerobic) bacteria. However, their use is currently limited for treating leachates. Typical loading rates for such systems are detention time about 10 h and loading rates from 2 to 5 g of NH_3-N/m^2/day. The systems achieve high removal efficiencies and result in effluents whose ammonia content is lower than 1 mg/L and BOD_5 lower than 20 mg/L (2).

Anaerobic biological systems used for treating leachates are often based on fixed-film type reactors using inert media, as well as on suspended growth systems, such as the upflow anaerobic sludge blanket (UASB) reactor. Detention times reported for these systems range from 1–15 days for anaerobic filters and from 1–6 days for UASB units; for the latter systems, removal capacities greater than 80% have been observed, and for anaerobic filters, the corresponding values range from 70–99% COD removal efficiency. The determination of BOD_5/COD and COD/TOC ratios in effluents from anaerobic treatment units showed that the composition of these effluents compared with those of leachates created from landfills of intermediate age. It may be concluded that a substantial part of biodegradable organics can be removed by the landfill itself, acting as an anaerobic bioreactor, and thus, the subsequent application of biological treatment methods and in particular of anaerobic processes are only moderately effective for the removing the remaining organic matter from "older" leachates (1).

In general, aerobic biological treatment of leachates is possible for "young" leachates that have high BOD_5/COD ratios, higher than 0.4, as well as low ammonia content. Activated sludge systems are the most common treatment techniques, and fixed-film systems are best used for nitrification of "older" leachates rich in ammonia. In this case, phosphorous addition may be necessary to provide the proper nutrient balance for sufficient cell growth. Anaerobic treatment systems may also be successful for treating leachates because of the advantages of relatively simple design; low capital, operating, and maintenance costs; and the ability to treat leachates with high BOD_5/COD ratios. However, anaerobic systems also present certain drawbacks that limit their application: slow biomass establishment, requirement for higher (at least mesophilic) temperatures (i.e., difficult use in cold climates); and poor solids separation (2,5).

Combined treatment of leachates in an existing municipal wastewater treatment plant is considered convenient; it has been applied in several cases, and it is the preferred disposal method for leachates, when the principal following requirements are met: availability of a sewer system, wastewater treatment plant capacity high enough to accept the heavily loaded leachates, process compatibility with the specific (composition) characteristics of leachates, and a sludge treatment facility large enough to handle the increased sludge production rates (4). Several studies of the cotreatment of municipal wastewaters and landfill leachates concluded that the overall treatment process and the effluent quality are not seriously affected by the addition of leachates up to 10% by volume at the municipal sewage, although this depends mainly on the loading strength of the leachates (6,7).

However, several problems may arise during the cotreatment that are connected to the possible negative effect and accumulation of heavy metals, the conversion of ammonia, the variations in temperature, the (much higher) sludge production, the (usually intense) foaming, and (poor) solids settleability. As a result, the cotreatment of leachates and municipal wastewaters has to be studied case-by-case, considering the significant problems that may appear due to the presence of toxic compounds, as well as the specific portion of leachate that has to be cotreated. The introduction of a pretreatment facility, such as a simple aerated lagoon, may satisfy the requirements for a preliminary polishing step in these cases.

PHYSICAL–CHEMICAL TREATMENT OF LEACHATES

Physical–chemical techniques are becoming increasingly common for treating industrial wastewater and for reclaiming municipal wastewaters, especially when intended for reuse. These techniques include mainly processes such as equalization, neutralization/pH adjustment, chemical precipitation and coagulation, chemical oxidation, activated carbon adsorption, air-stripping, ion exchange, and membrane separation. The application of physicochemical treatment methods to leachates offers the advantages of short start-up periods, relative stability to temperature variations, and the potential for automation.

Equalization

The composition and generation rates of leachates at landfills may vary widely due to their direct relationship to rainfall, storm water run-on and runoff, groundwater entering the waste-containing zone, and the moisture content and absorptive capability of disposed of wastes. To allow equalization of pollutant loadings and flow rates, the leachates are often collected, prior to treatment, in tanks or ponds that have sufficient capacity to hold the peak flows generated at the landfill facility (2). A constant flow is delivered to the treatment system from these holding tanks to dampen the variation in hydraulic and pollutant loadings to the wastewater treatment system. This reduction in hydraulic and pollutant variability increases the performance and reliability of treatment systems applied downstream and can reduce the size of subsequent treatment tanks as well as the chemical or polymer feed rates of supplementary reagents by reducing the maximum flow rates and the concentrations of pollutants to be removed.

The equalization systems consist of steel or fiberglass holding tanks or lined ponds that can provide sufficient capacity to contain peak flow. Detention times determined by using a mass balance equation and depend on site-specific generation rates and treatment design criteria. Detention times can range from less than a day up to 90 days; the median value is about 2 days. Equalization systems usually contain either mechanical mixing or aeration systems; they enhance the equalization process by keeping the tank contents well mixed and prohibiting settling of solids.

pH Adjustment

The pH of wastewater generated by landfills may have a wide range of values, depending on the specific types of wastes deposited in the landfill. In many instances, the raw wastewater may require neutralization to eliminate either high or low pH that may upset the treatment system subsequently applied, such as an activated sludge biological treatment. The landfill facilities may use neutralization systems in conjunction with chemical treatment processes, such as chemical precipitation, to adjust the pH of the wastewater and to remove metals to optimize process control. Acids, such as sulfuric acid or hydrochloric acid, are added to reduce pH, whereas alkalis, such as sodium hydroxide or lime, are added to raise the pH. Neutralization may be performed in a holding tank, in a rapid mixing tank, or in an equalization tank. Typically, the neutralization systems applied at the end of a treatment system are designed to control the pH of the final discharge between 6 and 9.

Chemical Precipitation and Coagulation

Suspended particulates and colloidal matter contained in surface waters or wastewaters can be removed by coagulation using multivalent cations, such as Ca^{2+}, Fe^{3+} or Al^{3+}. As a result, several investigations of the treatment of leachates dealt with the use of chemical precipitation and coagulation (8).

In chemical precipitation, soluble metallic ions and certain anions, found in landfill wastewaters, are converted to insoluble forms that precipitate from the solution. Most metals are relatively insoluble as hydroxides, sulfides, or carbonates. Coagulation is used in conjunction with precipitation to facilitate their removal by agglomerating suspended and/or colloidal materials. The precipitated metals can be subsequently removed from the wastewater stream by filtration, settling clarification (sedimentation), or some other type of gravity-assisted separation. Other treatment processes such as equalization, chemical oxidation, or reduction (as in the case of hexavalent chromium) usually precede chemical precipitation. The performance of the chemical precipitation process is affected mainly by other chemical interactions, temperature, pH, the solubility of waste contaminants, and mixing effects (2).

Common precipitating reagents used at landfills usually include lime, sodium hydroxide, soda ash, sodium sulfide, or alum. Other chemicals also used in precipitation and coagulation, as well as for pH adjustment, include sulfuric and phosphoric acids, ferric chloride, and polyelectrolytes (synthetic organic polymers). Often, landfills use an appropriate combination of these chemicals. Precipitation by sodium hydroxide or lime is the most conventional method for removing metals from leachates. Hydroxide and coagulant precipitation has proven effective for removing several metals, such as trivalent chromium, pentavalent arsenic, copper, lead, nickel, and zinc. However, sulfide precipitation may also be used, instead of hydroxide precipitation, to remove certain metal ions, such as mercury, lead and silver more effectively.

Carbonate precipitation is another method of chemical precipitation; it is used primarily to remove antimony or lead. Use of alum as a precipitant/coagulant agent results in the formation of aluminum hydroxides in wastewaters, containing calcium or magnesium bicarbonate. Aluminum hydroxide is an insoluble gelatinous floc, which settles slowly and entraps suspended materials. It is considered particularly effective for removing certain metals, such as arsenic or cadmium.

Lime is less expensive than sodium hydroxide, so it is used more frequently at landfills employing hydroxide precipitation. However, lime is more difficult to handle and feed, as it must be slaked, prepared in a slurry, and mixed intensively, often plugging the feed system lines. Lime precipitation also produces a larger volume of sludge.

In addition to the type of chemical agent selected for treating leachates, another important design factor in the operation of chemical precipitation is the pH. Metal hydroxides are usually amphoteric, meaning they can react chemically both as acids or bases; as such, their solubilities increase at both lower (acidic) and higher (alkaline) pH levels. Therefore, there is an optimum pH value for the precipitation of each metal, which corresponds to its minimum solubility. Another key consideration in chemical precipitation is the necessary detention time during the sedimentation phase of the process. The optimal detention time depends on the wastewater being treated and on the desired effluent quality.

The first step in chemical precipitation is pH adjustment and the addition of coagulants. This process usually takes place in separate mixing and flocculation tanks. After mixing the wastewater with the appropriate chemical reagents, the resulting mixture agglomerates in the flocculation tank, and it is mixed slowly by mechanical means, such as mixers, or by recirculation pumping. The wastewater then undergoes further separation, by clarification (by settling) or filtration, where the precipitated metals are removed from the (cleared) solution. In a clarification system, an organic flocculant, such as a synthetic polymer (e.g., polyacrylamide), is sometimes added to help the settling. The resulting sludge from the clarifier or from the filter must be further treated, disposed of, or recycled.

Several studies have been reported on the examination of coagulation–flocculation for the treating landfill leachates, aimed to optimize performance, by selection of the most appropriate coagulant, determination of experimental conditions, assessment of the pH effect, and investigation of flocculant addition (9,10). Aluminum sulfate (alum), ferrous sulfate, ferric chloride, and ferric chlorosulfate are commonly used as coagulants (3). Iron salts proved more efficient than aluminum salts, resulting in COD reductions of up to 56%, whereas the corresponding values for alum or lime were 39 and 18%, respectively (11). Additionally, high COD removal capacities have been observed during the combined action of alum and lime on stabilized leachates (12). Furthermore, the addition of flocculants together with coagulants may substantially enhance the floc settling rate (9).

The coagulation–precipitation process has been investigated mainly by using stabilized or biologically pretreated landfill leachates, as a final polishing treatment stage. However, limited information exists on the efficiency of this physicochemical process, when used to remove pollutants from leachates, partially stabilized by recirculation or from recently produced ("fresh") leachate. This technique may be important for enhancing leachate biodegradability prior to biological treatment. High COD removal capacities (about 80%) have been obtained during the addition of ferric chloride to partially stabilized leachates, whereas low COD reductions (lower than 35%) have been measured during the addition of coagulants to raw samples (13).

In general, the coagulation and/or precipitation of raw leachates by the addition of lime resulted in the removal of multivalent cations, suspended solids, and color from raw leachates, but the effect on organic matter removal was rather negligible. In an early work of Slater et al. (14), it was found that only a small percentage (about 4–6%) of organic compounds with molecular weight of 10,000 or more was contained in an industrial raw leachate, whereas most of the organics had a molecular weight of 500 or less. However, after lime addition, the higher MW fraction disappeared, whereas the other fractions of MW 500 or less and between 500 and 10,000 remained almost untouched. As a result, lime addition to "young" leachates is not expected to be effective for removing organics because this type of leachate contains mainly high amounts of lower MW volatile fatty acids. Coagulation by lime may be an efficient method for treating "older" or biologically treated leachates that contain a large fraction of high MW substances, such as humic and fulvic acids (1). However, the use of ferric salts or of alum has proven more effective than lime, possibly due to different optimum pH process conditions that range between 4.5 and 5.5.

Chemical Oxidation

Chemical oxidation processes can generally be used in wastewater treatment to remove ammonia, to oxidize cyanide, to reduce the concentration of residual organics, and to reduce the bacterial and viral content. Chemical oxidation for treating leachates has been successful, based on several oxidants, including chlorine gas, calcium hypochlorite, potassium permanganate, hydrogen peroxide, and ozone (2). Both chlorine and ozone are two chemicals that are commonly used to destroy residual organics in biologically pretreated wastewater. When these chemicals are used for leachate treatment, the resulting disinfection of the wastewater is usually an added benefit.

Chemical oxidation is a potential treatment option for removing certain organic pollutants from leachates or groundwater. The amount of oxidant required in practice is generally greater than the theoretical mass calculated. The reasons for this are numerous and include incomplete oxidant consumption and oxidant demand caused by the simultaneous presence of other oxidizable species in solution. Oxidation reactions depend on the presence of appropriate catalysts, as well as on pH control, which is an important design variable. For many facilities using chemical oxidation, partial oxidation of organics, followed by additional treatment options, may be more efficient and cost-effective than using a complete oxidation treatment scheme alone.

The use of chlorine gas in leachates has been tested and resulted in high color and iron removal rates, but in limited reduction of organic matter, which is possibly due to (1) the presence of ammonia, which has to be initially destroyed by break-point chlorination before any organic oxidation and (2) the presence of relatively difficult to oxidize organics. On the other hand, the use of hydrogen peroxide presents several benefits: control of odor from stored leachates, removal of sulfides discharged to municipal sewers, and growth control of undesirable microorganisms near discharge of leachates. In addition, the study of the MW distribution of organics in leachates treated with hydrogen peroxide showed that it enhances the percentage of compounds of MW less than 1000 and therefore, increases the possibility of further biological treatment.

Ozone treatment of leachates provides several benefits, such as the removal of color, the degradation of particular organics (such as polyaromatic hydrocarbons), and the reduction of phenols and toxicity (15,16). Furthermore, ozone application may enhance the biodegradability of leachates by converting pollutants to end products or to intermediate products that are more readily biodegradable or can be more easily removed by adsorption (17). Ozone application proved very effective for removing color and iron, but was less efficient in removing COD. It was concluded that ozonation should not be used in leachates of high volatile fatty acid content, especially when acetic acid is present, due to their strong resistance to chemical oxidation (8).

Activated Carbon Adsorption

Activated carbon adsorption is a physical separation process, in which organic and inorganic materials are removed from wastewaters by sorption, attraction and accumulation of the contaminants on the surface of carbon granules. Most organic compounds and some metals typically found in landfill leachates can be effectively removed by using granular activated carbon (GAC). Although the primary removal mechanism is adsorption, biological degradation and filtration are additional pollutant removal mechanisms, also provided by an activated carbon filter. Adsorption capacities of 0.5 to 10% by weight are rather typical in many industrial applications. Spent carbon can be either regenerated on site by thermal processes, such as wet-air oxidation or steam stripping, or for smaller operations, it can be regenerated off site or sent directly for disposal in to hazardous waste landfills.

Several studies have been presented concerning the use of activated carbon adsorption for treating landfill leachates. In general, this process is very effective in removing residual organics that remain after prior biological treatment of leachates, and thus it could be used as a final polishing step for biologically pretreated leachates and/or for well-stabilized "old" leachates (8). Furthermore, the combination of powdered activated carbon with an activated sludge system results in enhanced removal capacities of organic matter up to 98% of BOD_5 (2).

In conclusion, the adsorption of higher MW organic compounds is enhanced by the properties of these compounds. As the MW of organics increases, their polarity, solubility, and branching properties decrease, resulting in an increase in carbon adsorption. As a result, lower MW volatile fatty acids representative of "younger" leachates are poorly adsorbed on activated carbon particles, whereas higher MW compounds, such as fulvic acids, found in "old" leachates, are adsorbed on activated carbon to a greater extent. Both powdered and granular activated carbon may be used for leachate treatment, but special consideration should be given during the design period, because of the high cost of this material.

Air Stripping

Stripping is an effective method for removing dissolved volatile organic compounds from wastewater. Removal is accomplished by passing air or steam through the agitated waste stream. Air stripping is used to the treat leachates, mainly to remove ammonia. In this case, the pH must be increased to between 10.8 to 11.5, usually by adding NaOH or $Ca(OH)_2$ solutions; ammonia stripping takes place by blowing large volumes of air upward through the leachate bulk volume. This process is carried out in towers, where leachates trickle down over some type of inert material or in a shallow aerated reaction vessel. Air stripping has been proved efficient for the extensive reduction of ammonia (up to 93%); the residual concentrations no longer inhibit nitrification (18). However, this method has two drawbacks; the cost of chemicals for pH adjustment and the problem of freezing as the air and the leachate temperature approach 0 °C (2).

Ion Exchange

Ion exchange is an adsorption process that uses appropriate (usually synthetic organic) resins as media to remove charged contaminants from wastewater. Ion exchange is commonly used to remove heavy metals from relatively low-concentration waste streams. A key advantage of the ion exchange process is that it allows recovery and reuse of the removed metals. Ion exchange can also be designed to be selective for certain metals and can effectively remove them from wastewater that contains high concentrations of "background" metals, such as iron, magnesium, and/or calcium. A specific disadvantage of this treatment method is that the resins used are subjected to fouling by oils or other natural (high MW) polymers. However, the use of ion exchange to treat leachates is limited, by the high operating costs of this method, including the cost of the exchange media, the necessary chemical reagents used as regenerants, and the regenerants disposal costs. As a result, this method is appropriate for the supplementary removal of metals, as posttreatment final polishing step, that results in low residual ion concentrations of less than 1 mg/L (2,8).

Membrane Filtration

Membrane filtration systems employ a semipermeable polymeric membrane and a pressure differential to separate constituents of different size (from microparticles down to soluble ions) from an aqueous phase. Nanofiltration, ultrafiltration, and reverse osmosis are the most commonly used membrane filtration processes.

Ultrafiltration uses a semipermeable microporous membrane, through which the wastewater is passed under pressure. Water and low molecular weight solutes, such as salts and surfactants, pass through the membrane and can be removed as permeate. Emulsified oils and suspended solids are rejected by the membrane and are removed with part of the wastewater as a more concentrated liquid. The concentrate is usually recirculated through the membrane unit, until the permeate flow drops substantially. Ultrafiltration is commonly used for removing substances whose molecular weights are greater than 500, including suspended solids, oil and grease, large organic molecules, and complexed heavy metals. Ultrafiltration is commonly used, when the solute molecules are greater than 10 times the size of the solvent molecules (usually water) and less than 0.5 μm.

Reverse osmosis is a separation process that uses selective semipermeable membranes to remove dissolved solids, such as metal salts, from water. The respective membranes are more permeable to water than to contaminants or impurities. The wastewater is forced through the membrane at a pressure that exceeds the osmotic pressure caused by the dissolved solids. Molecules of water pass through the membrane as permeate, and the contaminants are rejected along the surface of the membrane and exit as a concentrated stream. The concentrate (rejection) flow from a reverse osmosis system ranges from 10–50% of the feed flow; the concentrations of dissolved solids and of contaminants within this stream approach at least 10 times that of the feed (raw) wastewater. The percentage of permeate that passes through the membrane is a function of operating pressure, membrane type, and concentration of the contaminants in the feed.

Cellulose acetate, aromatic polyamide, and thin-film composites are commonly used membrane materials. Membrane pore sizes for a typical reverse osmosis system range from 0.0005–0.002 μm, and pressures of 20–30 bars are usually required. Therefore, reverse osmosis feed water must be very low in turbidity to avoid direct blocking of the membrane. As a result, pretreatment of landfill wastewater prior to reverse osmosis may be necessary, including chemical addition and clarification or cartridge filtration (using 5-μm filters), to remove suspended particulates from the influent and protect pumps and membranes. Carbon adsorption is also recommended as a pretreatment for membranes sensitive to chlorine. Biofouling can be prevented by chlorination and dechlorination of the feed water. To maintain sufficient solubility of metals, such as calcium, magnesium, and iron, and avoid the formation of precipitates, the pH should be appropriately adjusted with acid. Aside from pH adjustment, chemical reagents may also be used as bactericides, as well as for dechlorination (2).

Several reports on the use of ultrafiltration and especially on the application of reverse osmosis membranes for treating leachates showed that these methods are best used, following biological pretreatment, or for treating "older" leachates (19). In addition, during the treatment of leachates by membranes, compounds whose MW was lower than 200 were not rejected, in comparison with those having a MW higher than 200. The performance of reverse osmosis membranes may be further optimized, after careful adjustment of pH to values around 8 and by using polythylamine membranes that results in almost 94% reduction of total organic carbon (TOC) (8). However, severe membrane fouling was experienced in several cases, suggesting that reverse osmosis is most effective as a posttreatment step (following biological treatment) for removing residual COD and dissolved solids. Trebouet et al. (20) have shown that high pollutant removal can also be achieved by nanofiltration, especially for "older" leachates. Nanofiltration can be run at lower pressures than reverse osmosis, hence presenting lower operating costs and less membrane fouling.

Recirculation of Leachates into the Landfill

The recirculation of leachates is the redistribution of leachates that have been collected at the bottom of a landfill back to the top of it. The recirculation can usually be performed by spraying leachates onto the exposed surface of the landfill or by distribution through perforated pipes, located just beneath the surface of the landfill. As the recirculated leachate trickles downward through the fill, the disposed of solid waste materials in the landfill become an appropriate medium for developing anaerobic microorganisms, and as a result, an anaerobic treatment process is initiated.

Therefore, the landfill becomes an uncontrolled anaerobic digester and the biodegradable organics in the leachates are initially converted to volatile fatty acids and then to methane. Under these conditions, an initially low BOD_5 leachate, which is similar in composition to that of "older" leachates, may be produced during periods up to 18 months of recirculation. It has been suggested that the recirculation of leachates can more rapidly develop an active anaerobic bacterial population of methane-forming bacteria within the landfill. The rate of removal of organic compounds may be further enhanced by the addition of excess sewage sludge, acting as additional carbon source, which is produced in biological wastewater treatment plants, as well as by appropriate pH control (8,21).

The problems of recirculation usually include the development of odors, the high capital and maintenance cost of the recirculation system for leachates, and the precipitation of carbonates and iron oxides that may clog both the spraying equipment and the surface of the landfill and decrease the percolation rate. However, recirculation of leachates has a number of benefits, such as production of leachates with more uniform properties, the acceleration of overall landfill stabilization, the delay in the starting time for the application of other treatment systems, and reduction in the strength of the treated leachates. Nevertheless, the recirculation of leachates does not finally result in reduction of generated wastewater volumes and cannot provide a sufficient treatment process for leachates, because the treated leachates may have relatively high COD content (higher than 3000 mg/L), as well as high ammonia concentrations (2).

In general, physical–chemical treatment methods are considered an effective means for treating leachates, which contain organic compounds of MW less than 500 and a BOD/COD ratio lower than 0.1. This is particularly important for the use of chemical coagulation and activated carbon adsorption because these methods are very sensitive to the MW distribution of organics. Chemical oxidation may be used for removing dissolved metals (mainly iron), but has little effect on COD, when applied separately. Air stripping can be highly effective in removing ammonia, but at highly alkaline pH. Finally, membrane separation processes may have some potential for the treating leachates, but they are subject to membrane fouling.

In conclusion, neither physical–chemical treatment alone, nor biological methods may be able to treat leachates completely, when applied separately. As a result, the integration of several treatment processes is required to produce an effluent of acceptable quality; the selection of the most appropriate treatment train is very significant for an integrated leachate management system.

SELECTING THE APPROPRIATE COMBINATION OF TREATMENT PROCESSES

The characteristics of leachates may vary from place to place, as well as with time; thus, the construction of an appropriate treatment scheme is a difficult task, requiring the development/design of appropriate processes, consisting of the following subsequent steps: the first step involves assessment of leachate quality, an estimate of the (seasonal) quantity, and the type of treatment techniques available; the second step includes selection of the optimum biological treatment method for removing major pollutants from the leachate, followed by selection of the applicable polishing (final) stages as a third step (4,22).

Selecting Treatment Techniques Based on Leachate Quality

During this phase, the influent leachate quality is assessed, and the corresponding effluent characteristics are determined, based on the estimates of BOD_5, COD, nitrogen (as ammonia, i.e., NH_3-N), phosphorous, and metal content. Additional data that might be used in this phase include the concentration of volatile fatty acids, TOC, and total suspended solids.

The most important parameter for the preliminary screening of treatment techniques for leachates is the BOD_5/COD ratio. Leachates from a relatively new landfill have high COD values, usually higher than 10,000 mg/L; low NH_3-N content; and BOD_5/COD ratios ranging from 0.4–0.8. These leachates are representative of "young" leachates, containing high amounts of easily biodegradable organic substances, which are amenable to both aerobic and anaerobic biological treatment. However, physical–chemical treatment may not be an appropriate method for such leachates due to the presence of low molecular weight volatile fatty acids, prevailing over higher molecular weight compounds.

"Old" (mature) leachates are characterized by lower COD values, usually less than 3000 mg/L; higher NH_3-N concentrations, due to the anaerobic decomposition of organic nitrogen content within the landfill; and BOD_5/COD ratios lower than 0.4. In this case, aerobic biological treatment is required because it can provide extensive nitrogen removal through nitrification, in addition to removing organic matter (COD values). However, for BOD_5/COD ratios lower than 0.1, the remaining organics consist mainly of nonbiodegradable materials, and physical–chemical treatment becomes a more attractive option.

A second parameter, which can be used as an indicator for the preliminary selection of a treatment process, is the molecular weight partitioning of the organic content. In this case, biological treatment would be an effective technique for leachates that contain organic substances of MW lower than 500, whereas physical–chemical treatment is favored for removing organics, of molecular weights higher than 1000. However, this parameter is not easily measured in samples of leachates, and it is not used as a general index. Other less important parameters may include the BOD_5/NH_3-N ratio and the metal content, which are usually considered in the following steps of the design procedure.

Selecting the Appropriate Biological Treatment Method

To treat "young" leachates that have high BOD_5/COD ratios and high amounts of low MW (i.e., easily biodegradable) organics, biological treatment is the most efficient technique for reducing organic (carbonaceous) matter. The first option in this case is the examination of recirculation as a cost-effective method for preliminary reduction of leachate strength. However, when recirculation is not feasible, then aerobic or anaerobic biological treatment should be used.

Anaerobic biological treatment is the most appropriate method for handling leachates of high BOD_5/COD ratio, low NH_3-N content, high temperature, and high VFA content; the optimum process in this case is the application of anaerobic filters. The effluents from anaerobic processes would be similar to "old" leachates that have COD values between 1000 to 3000 mg/L and require an additional posttreatment step to reduce residual organics.

Aerobic biological treatment is a common method, which may be applied either for anaerobically pretreated or for raw leachates. In addition, biological denitrification may also be included in the aerobic process for effective removal of nitrates. Two significant problems are associated with the aerobic treatment of leachates; the first is the phosphorous deficiency in leachates that requires supplementary phosphorous, and the second is the high ammonia content that may inhibit the nitrification capacity of the system. In this case, the initial high ammonia concentration should be reduced by preliminary air stripping of the leachate. Additional problems include possible high metal content; long sludge retention time (up to 30 days), hence requiring the use of larger basins; foaming of leachates during aeration; and the potential for metal precipitate formation that affects the operation of aeration systems. The effluents from the aerobic processes usually have low BOD_5 values, lower than 100 mg/L, but rather high COD values, up to 1500 mg/L, that require subsequent physical–chemical treatment (22).

Selection of Physical–Chemical Treatment Method

The third step in the treatment design procedure for leachates is selecting a process for posttreating the effluent. "Old" and biologically pretreated leachates may contain nonbiodegradable high MW organic compounds, particulates, and metal ions. Residual organics may be removed by chemical oxidation, using hydrogen peroxide and/or ozone, but these techniques are expensive, due to the high dosages of the necessary chemicals. Coagulation is an alternative method, which is effective for removing higher MW organics that represent about 50% of the residual organic matter. Activated carbon adsorption is also a viable process for removing lower MW organics. Membrane separations may be used for removing organics, but these methods are best applicable as final polishing stages, due to high costs and problems of membrane fouling.

Chemical precipitation using lime or chemical oxidation followed by sedimentation and/or filtration has been suggested to decrease the metal content of leachates. Similar techniques can be also used to reduce particulates and metals content, such as coagulation followed by sedimentation/filtration, chemical oxidation, membrane separation, or ion exchange.

Several alternative units for treating leachates are operating currently worldwide, consisting of a combination of subsequently applicable treatment steps. The

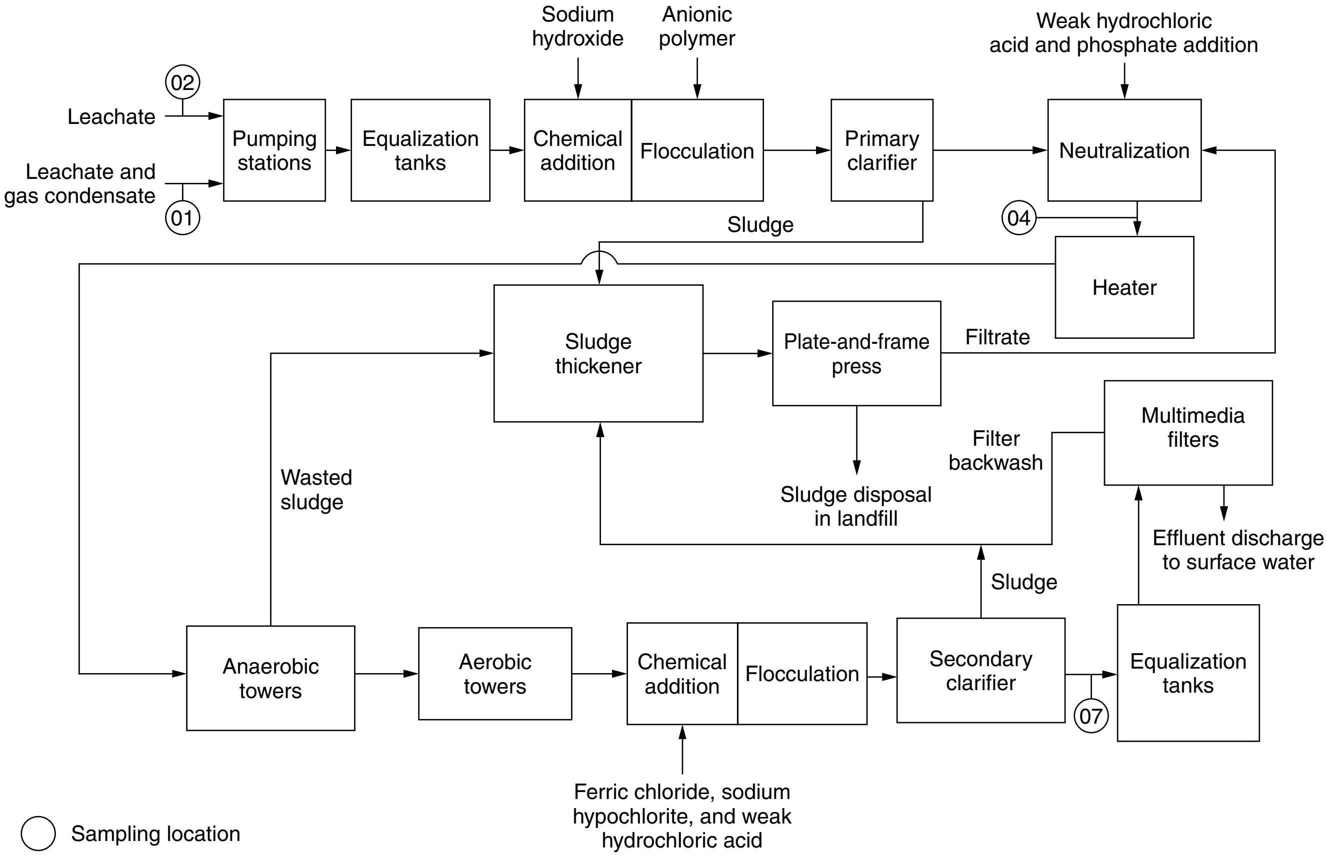

Figure 1. Flow sheet of a typical leachate treatment plant (2).

U.S. EPA (2) has evaluated the performance of a number of treatment systems and representative results are presented in the following. A typical treatment system for leachates from a sanitary landfill is shown in Fig. 1 (2). The system employs equalization tanks, coagulation/sedimentation, pH adjustment, biological treatment consisting of anaerobic towers followed by aerobic ones, coagulation/sedimentation, and multimedia filtration; the sludge treatment unit includes a sludge thickener and a plate-and-frame filter press. The results of the system operation are presented in Table 2.

As shown in Table 2, the biological treatment unit experienced good overall removal for TOC (93%), COD (90.9%), and NH_3-N (99.1%). The biological unit operation alone did not demonstrate high removals of BOD_5 (10.2%), TSS (9.3%), or for various metals (showing in general less

than 10% removal) because the pollutants were generally not present in the biological treatment unit influent at treatable levels. The influent BOD_5 in the treatment unit was rather low (39.2 mg/L), TSS was 11.8 mg/L, and most metals were not at detectable levels, even though the raw wastewater at this facility exhibited an initial BOD_5 of 991 mg/L, TSS of 532.8 mg/L, and several metals at treatable levels.

The biological treatment unit influent had low concentrations of pollutants because this facility employed large aerated equalization tanks and a chemical precipitation system prior to biological treatment. The equalization tanks had a retention time of approximately 15 days and were followed by a chemical precipitation system using sodium hydroxide. Due to the long retention time and the aeration of wastewater, significant biological activity also occurred in these tanks. The resulting insoluble pollutants were removed in the primary clarifier prior to entering the biological towers. The entire treatment system showed good removals for BOD_5, TSS, NH_3-N, COD, TOC, and total phenols. Most metals had good percentage removals or were removed to nondetectable levels.

Another leachate treatment plant was evaluated by the EPA, including ammonia removal, hydroxide precipitation, biological treatment using a sequencing batch reactor, granular activated carbon adsorption, and multimedia filtration. A flow diagram of the landfill wastewater treatment system is presented in Fig. 2 (2). The wastewater treatment process used at this (nonhazardous) facility was primarily treated landfill generated wastewater and a small amount of sanitary wastewater flow from the on-site maintenance facility. A summary of percentage removal data collected for the biological treatment unit operation (SBR) and for the entire treatment system is presented in Table 3.

As shown in this table, the SBR treatment unit showed moderate overall removals for TOC (43.45%), COD (24.7%), and BOD_5 (48.7%). Improved removal efficiencies were observed for TSS (82.9%), total phenols (74.2%), and NH_3-N (80.7%). Metals, such as barium, chromium, and zinc had low removal efficiencies. However, these metals in the influent of the biological treatment system were measured at low concentrations, often close to the detection limit. Other metals also had poor removal efficiencies, including boron and silicon. The entire treatment system showed good removals for BOD_5, TSS, NH_3-N, COD, TOC, and total phenols. Each of the metal parameters also experienced good removal rates through the treatment system.

An alternative system for treating leachates from a nonhazardous facility was also constructed; it employed a two-stage reverse osmosis system and a multimedia filter. The flow diagram of this unit is shown in Fig. 3, and the corresponding performance data are given in Table 4.

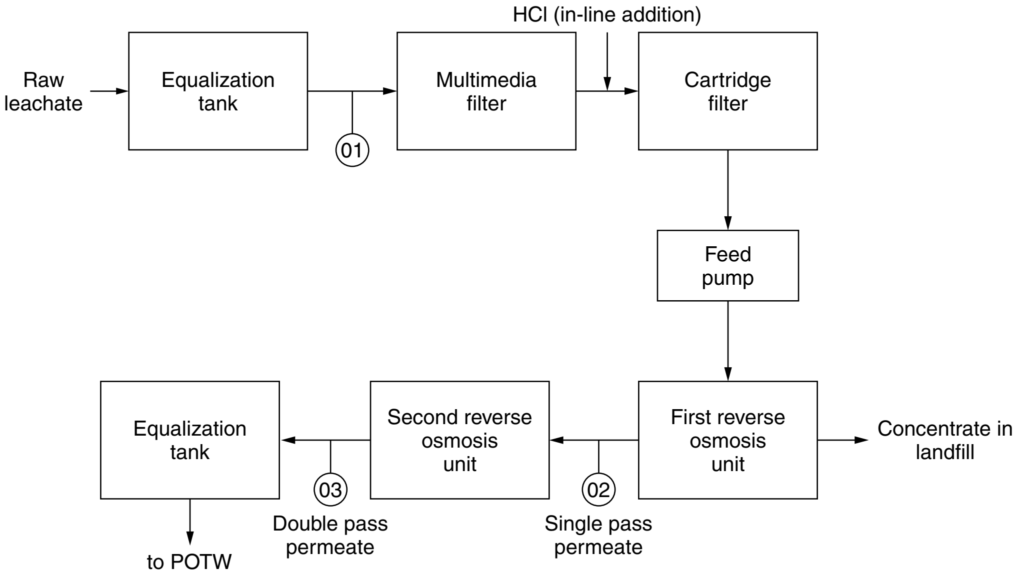

Figure 3. Flow diagram of a leachate treatment plant using a two-stage reverse osmosis unit.

As shown in Table 4, the single-pass reverse osmosis treatment system demonstrated good overall removals for a number of parameters, including TSS, TOC, BOD_5, TDS, and COD. Total phenol and NH_3-N% removals were observed at 75.1 and 76.7%, respectively. Metals with quantitative percentage removals included arsenic (87.4%), boron (54.1%), and strontium (92.9%). The additional polishing reverse osmosis unit caused the removal efficiency of most parameters to increase further. These parameters include BOD_5, NH_3-N, COD, TDS, TOC, and total phenols. The percentage removal for boron also increased from 54.1% in the single-pass reverse osmosis system up to 94.4% in the two-stage reverse osmosis treatment system.

In general, selecting the most appropriate treatment train should be based on leachate characteristics and cost estimates. For "young" leachates, which have BOD_5/COD ratios higher than 0.4, biological treatment will prevail in the overall treatment system. For the highest BOD_5/COD ratios (in the range of 0.6 to 0.8), recirculation of leachates should be included as a preliminary treatment stage, followed by anaerobic or aerobic treatment. For BOD_5/COD ratios lower than 0.4, aerobic biological treatment becomes the most important method, especially when nitrification is required; in all cases, physical–chemical treatment is necessary, as a polishing step for biologically pretreated effluents.

In some cases, physical–chemical treatment may precede aerobic treatment, aiming, for example, to reduce ammonia or metals. When the BOD_5/COD ratio is lower than 0.1, physical–chemical methods are the most appropriate, and aerobic biological treatment may be additionally used for nitrification/denitrification. During the design period, it is very important to consider the variation of

INTRODUCTION

The freshwater, estuarine, and marine ecosystems around the world are now being increasingly subjected to greater stress from various human activities. As a result of several contaminants, significant changes in freshwater and marine plant communities have occurred (1).

Polychlorinated biphenyls (PCBs) are one of the more ubiquitous and toxic organic pollutants. Altogether, some 209 different individual PCB compounds exist, although only about 130 of these are found in commercial mixtures. PCBs have a number of physical and chemical characteristics that have contributed to their persistence in the environment, such as low aqueous solubility, resistance to oxidation and hydrolysis, and high volatility (2). The use of PCBs is now restricted to nondispersive systems (e.g., as dielectric fluids in condensers and transformers), but until few years ago, they were important constituents of a number of industrial chemical formulations, including paints, inks, plastics, pesticides, and copying papers.

In most industrialized countries, the use of PCBs has been banned since the late 1970s, resulting in a decline in PCB releases in the environment. However, in several aquatic ecosystems, the biota contamination remained relatively stable since the mid-1980s (3–5).

The concern about the presence and effects of PCBs on the biota and, ultimately, on human health, have mobilized worldwide research in order to find remediating PCB levels in the environment and therefore prevent possible future undesirable consequences. Toxic effects in animals include reproductive impairment, mutagenesis, carcinogenesis, and teratogenesis (6). Recently, several studies have demonstrated the ability of PCBs to induce oxidative stress (a cellular situation characterized by an elevation in the steady-state concentration of reactive oxygen species) (7) in fishes, birds, reptiles (8), and dinoflagellates (9); but in plants, a lack of studies about this subject exist. PCBs are very hydrophobic contaminants and preferentially adsorb onto sediment particles. Particle size distribution and organic carbon content seem to be important factors in determining the extent of partitioning of PCBs to natural sediment (10). In particular, the high octanol/water partition coefficient (Kow) indicates that PCBs have a high affinity for suspended solids, especially those rich in organic carbon. Mobilization of PCBs from sediments is one of the causes of the persistence of these contaminants (11,12), because sediments were, in the past, the most important sink of these pollutants.

THE ROLE OF MACROPHYTES IN THE AQUATIC ECOSYSTEM

Macrophytes include various emergent, submergent, and floating leaved species. Together with algae, periphyton, and phytoplankton, macrophytes form the base of most aquatic food chains. Macrophytes are important in nutrient cycling and respond rapidly to water quality changes. It is well known that aquatic vascular plants can enhance a freshwater ecosystem in many ways, such as by improving water clarity, contributing oxygen via photosynthesis, and providing spawning sites and protection for fish, mollusks, crustaceans, and other invertebrate species (13,14).

Plants interact with their environment through processes that include contaminant bioconcentration and excretion, shading, and organic matter production and decomposition. As a result of these interactions, aquatic plants may significantly affect water and sediment quality (15).

As plants are the base of most food chains, they will experience the effects of toxic compounds released into the aquatic media sooner than will organisms occupying higher trophic levels. In this respect, plants may be able to act as an “early warning signal” of impending contaminant impacts on other trophic levels of aquatic environments.

Contaminants present in aquatic macrophytes may be transferred to higher levels of the food chain, when consumed as live plants by herbivores or as detritus by detritivores (16,17).

Aquatic macrophytes in the littoral zones of lakes have two fundamental properties, which make them attractive as limnological indicators. First, they react slowly and progressively to changes in nutrient conditions, in contrast to bacteria and microalgae, i.e., over several years. Macrophytes, therefore, function as integrators of environmental conditions to which they are subjected, and thus can be used as long-term indicators with high spatial resolution. Second, the littoral zone may experience patterns of nutrients and pollutant concentrations (18,19), caused by natural or artificial inflows as well as by diffuse and nonpoint sources. The latter are difficult to localize and quantify, but even chemical analysis of point sources is often neglected in limnological routine work (20).

Vascular plants like bulrushes (*Schoenoplectus* spp.), duckweeds (*Lemna* spp.), and pickerel weed (*Pontederia* spp.) are the more common species used in North American wetlands treatment systems to improve water quality in a variety of ways, including binding soil and reducing the resuspension of muds (15). Bioaccumulation by plants can remove substantial quantities of potential toxicants (like organochlorines) and nutrients of water entering and passing through wetlands. Thus, Menone et al. (21) calculated that about 75 μg of Heptachlor-epoxide per square meter of cordgrass marsh exists, or over the 32 km^2 of cordgrass marsh, roots of *Spartina* densiflora concentrates 2 Kg of this contaminant. Total PCBs in the same estuary can be estimated as 22 μg per square meter or 0.7 Kg over the 32 km^2 of cordgrass marsh.

EXPOSURE AND UPTAKE OF MACROPHYTES TO CONTAMINANTS

The uptake of contaminants depends on the physicochemical characteristics of the compounds and on the life form of the macrophyte (floating-leaved, free-floating, well-rooted, or rootless species). Free-floating plants, such as *Lemna spp., Eichornia spp.*, and *Pistia spp.*, take up contaminants from the water by roots and/or leaves. Likewise, the rootless *Ceratophyllum spp.* takes up contaminants mainly through its finely divided leaves. The situation of species with a well-developed root-rhizome system and totally submersed foliage, such as *Myriophyllum spp., Potamogeton spp.*, and *Vallisneria spp.* species, is much more complex. Thus, these submersed aquatic macrophytes grow at the interface of two distinct environments, being their leaves exposed to the water column while their roots are in contact to the sediment. Both media (the water column and the sediment pore water) are potential sources of uptake of contamination (22,23). Indeed, the rooted aquatic macrophyte *Hydrilla verticillata*—common throughout the southern United States—has been shown to take up contaminants from both the sediment pore water and the overlying water column. It also has the ability to translocate sediment-incorporated contaminants from the roots into the vegetative portion of the plant (24).

Other species, such as *Schoenoplectus californicus, Spartina densiflora* (mainly from the Southern Hemisphere), and *Spartina alterniflora* (mainly from the Northern Hemisphere), have the root-rhizome system well developed, but have not totally submersed foliage. The first two macrophytes form the bulk of the emergent vegetation in many of the shallow lakes and estuarine areas of the Southern America regions. The pollutant sequestration in these macrophytes occur across many interfaces, sediment, water, and air (21,25,26).

Several environmental factors, including water and sediment pH, water current, sediment texture, organic carbon, and mineral composition, are known to influence contaminant adsorption by sediments and macrophytes growth, so they may contribute to overall site quality.

BIOMONITORING

During the past, direct chemical measurement of the concentrations of toxic and hazard substances have been carried out for the evaluation of water quality in contaminated natural environments. However, for environmental management, contaminant concentrations do not necessarily account for, or enable prediction of, the impairment of biota. If the objective is to monitor and improve environmental quality of the ecosystems, biotic measurements of contamination are more useful than only measures of water or sediment contaminant concentrations. Furthermore, the cost of evaluation and measurement of persistent and toxic organochlorines, such as PCBs, is substantial. Therefore, for ecologic and economic reasons, it is important to develop biological monitoring that is useful and valuable. The use of biomonitoring to assess and control discharges of toxic chemicals into the environment has been promoted as being a desirable alternative to more expensive, less realistic, and time-consuming chemical analysis (27). Thus, the presence of indicator organisms (biomonitors) provides a measure of cumulative exposure to contaminants over time and avoids the need for frequent sampling. The use of biomonitors *in situ* to identify and quantify toxicants in an environment is referred to as biomonitoring (28). This technique takes advantage of the ability of organisms to accumulate contaminants in their tissues through bioaccumulation and bioconcentration. The primary objective of biomonitoring investigations is to assess the quality of water in an area by relating observed responses of organisms that live within a suspected polluted site to the concentrations of contaminants detected within their tissues. An additional and very significant advantage of biomonitoring is that the bioaccumulated sublethal levels of contaminants within the tissues of organisms indicate the net amount of contaminants that have been integrated over a period of time (27).

The response of biota to pollution stress can be observed at the ecosystem, community, population, individual, and suborganismal levels of organization (29). Environmental assessments may be made by establishing quantitative relationships between (a) concentrations of pollutants that are accumulated within the tissues of organisms residing within a particular area and (b) manifest biological effects (30).

In general, three historical stages exist in the biomonitoring with plants, based on the use of different parameters:

1. various physiological, morphological, and community parameters (pigment content, photosynthetic activity, diversity indices, biomass, etc.)
2. environmental concentrations of pollutants in plant tissues
3. early warning systems or biomarkers for assessing contaminant exposure and effects (histological, biochemical, or genetic)

The presence of certain toxicants may induce a physiological response in an organism, often involving a heightened production of enzymes that are capable of metabolizing and/or degrading the toxicant in question. In this way, the quantity and activity of such xenobiotic-metabolizing enzymes may be used as indicators of the bioavailability of a specific contaminant in the environment. An increasing number of studies have used biochemical as well as physiological endpoints for assessing toxic effects on plants. These effects are often more sensitive, but their environmental relevance and their relationship to the impact of toxic chemicals on biomass are not known. However, they can be combined with other parameters of chemical exposure to predict the ecological consequences of chemical-specific contamination (31). For a biomarker to be applied in the field, it should be correlated with a significant effect, such as survival, growth, or reproduction. Although many biomarkers have been validated for use in evaluating animal health and exposure to toxic substances, both in the laboratory and in natural ecosystems, very few biomarkers have been validated and used to assess plant exposure and health effects under field conditions (31). Padinha et al. (32) has shown that variations in some indices of physiological stress, like thiolic protein concentrations in *Spartina maritima*, could be used as a tool to monitor contamination by heavy metals. On the other hand, Wall et al. (33) have found no adverse influences of PCBs in terms of peroxidase activity (POD), glutathione concentration (tGSH), photosynthesis, and transpiration on *S. alterniflora* from a Superfund site contaminated with $46.0 \pm 52.7\ \mu g\, g^{-1}$ dry weight in sediments. Therefore, the utility of POD as well as other detoxication enzymes as biomarkers of PCB stress deserves attention but needs further study.

In addition, laboratory research can complement and contribute to the best understanding of data from field studies (biomonitoring). Among laboratory experiments, we can mention:

— *Toxicity tests*: Toxicity tests involve exposing a well-defined test organism to a dilution series of a suspected toxicant under controlled laboratory conditions. The goal of toxicity tests is to correlate the level of toxicants to observed organismal responses. Of the multitude of organismal responses that could be observed as endpoints in toxicity test, the one most frequently used is survivorship. In ecotoxicology, survivorship is usually expressed as LD_{50}, which is the dosage of the suspected toxicant that is seen to cause mortality in half of the individuals tested within a specified time period.

— *Bioassays*: Bioassays are often used to assess the toxic effects of mixtures of compounds on biota by exposing test organisms to naturally contaminated water or sediment samples.

When a pollutant enters an aquatic environment, it is expected that its initial effect on an exposed organism will be a suborganismal one—either biochemical or genetic. In this manner, biochemical and genetic indicators may be able to detect the presence of minimum contaminant concentrations compared with the levels of toxicants required to elicit a response at the level of the entire organism (e.g., death) (28).

MACROPHYTES AS BIOMONITORS

Plant biomonitors provide an integrated description of pollution within an ecosystem (34). Freshwater species were used as sentinels of contaminant stress for many years, such as in the biomonitoring study of Wang and Williams (35), who used *Lemna minor* to examine the phytotoxicity of industrial effluents. Macrophytes have also proved to be useful for assessing organochlorine contamination in laboratory experiments (36,37) and in the field (27,28). The organochlorine bioaccumulation in submersed macrophytes may be very high; macrophytes may be three to four times more contaminated than sediment, and 6000 to 9000 times more contaminated than the water (38).

Under field conditions, *Schoenoplectus californicus* has already shown potential as a biomonitor of organochlorine pesticides. Moreover, this species has demonstrated the ability to function as phytoremediator—plant use for the remediation of contaminated environments—of these pesticides, because, in combination with other aquatic biota, about 40% of the more hydrophobic pesticides have been retained in the lake environment, leading to their lower release through the effluent creek (25,26,39). *Spartina densiflora* grows abundantly and contributes significantly to the primary productivity of the estuarine ecosystems on the Southern America coast. In Mar Chiquita coastal lagoon (Argentina), it can bioaccumulate both organochlorine pesticides and PCBs, and the total amount of these compounds in cordgrass biomass may represent a significant proportion of the total PCBs burden in the estuary system (21). The same species is the dominant plant in Humboldt Bay salt marshes. *S. densiflora*'s ability to rapidly expand in bare areas has implications for marsh mitigation and restoration activities (40).

Other known macrophytes, like *Vallisneria americana*, var. americana—one of the most abundant macrophyte in the Great Lakes (41,42)—*Potamogeton spp., Najas spp., Myriophyllum spp.*, and *Elodea spp.*, accumulate contaminants within its tissues and have also shown potential as biomonitors of organic contaminants in the field (27,28).

MACROPHYTES AND PCBS

Laboratory studies indicate that uptake of PCBs from contaminant water or sediments in aquatic macrophytes is expected (43). In addition, considering their limited mobility and their abundance in many aquatic systems, they could function as *in situ* biomonitors of water contaminants, like PCBs. However, the extent of sequestration in natural populations remains almost unknown. Thus, little impetus has developed for studying the role of submersed aquatic macrophytes in PCBs biogeochemical cycling in freshwater ecosystem, as evidenced by our literature survey, which revealed a lack of field data documenting the incidence of hydrophobic organic contaminants in feral aquatic macrophytes.

Exposure to sediment-borne PCBs is particularly important for rooted macrophytes. As a result of the hydrophobicity of these compounds, sediments frequently contain higher concentrations of contaminants than the surrounding water (44,45). Thus, plants grown in contaminated environments typically have higher concentrations of hydrophofobic pollutants in below-ground tissues than in foliage and, because their mobility within the plant tissues is very limited (23), they tend to accumulate in roots (28). Macrophytes collected from different sites may contain different concentrations of contaminants within their tissues, reflecting sediments, water, and air loads at each location (26,28). In a shallow lake from Argentina, it has been demonstrated that *S. californicus* accumulate PCBs in direct relationship to the sediment PCB concentrations. Moreover, the higher PCB levels were found in root tissues revealing the high ability of this macrophyte to function as PCB biomonitor (Miglioranza, personal communication).

The Bioaccumulation Factor (BF) is the ratio of the concentration in the biota and the concentration in the soil/sediment. It primarily depends on the properties of the soil/sediment and the biota, particularly the ratio of lipid in the biota and the organic carbon content of the soil/sediment (2). Root Bioaccumulation Factors (RBF) have been calculated for *Schoenoplectus californicus* and *Spartina densiflora* from Los Padres lake and Mar Chiquita coastal lagoon, respectively. The values in *S. californicus* ranged between 49 and 600 for different congeners of PCBs, being the highest RBF for the lower chlorinated congeners. In *S. densiflora*, the RBF ranged between 0.75 and 26.5. These results show the magnitude of bioaccumulation of PCBs in freshwater and estuarine macrophytes species and their importance in the ecology of these environments.

The investigations of Butler et al. (46) demonstrated for the first time that plant cells are capable of hydroxylating and glycosylating a chlorinated biphenyl in a manner similar to what has been reported for animals (47). The metabolism of PCBs varies between the plant species and is affected by the substitution pattern and the degree of chlorination (48,49). Wilken et al. (49) analyzed 12 different terrestrial plant species and showed that lower chlorination grade is associated with higher metabolism rates. Recent studies (50,51) have shown the important role of plant cytochrome P450 in metabolism of different toxicants, but have admitted involvement of peroxidases too (52,53).

Despite the scarce information about PCB concentrations in macrophytes under field conditions, we can conclude that macrophytes can play a crucial role in the biomonitoring and remotion of these toxic organic compounds from the environment, not only accumulating but also transforming them. For this reason, phytoremediation has been proposed as an alternative or complementary technique to treat sediment polluted by PCBs, but still needs much basic research.

WASTEWATER MANAGEMENT FOR DEVELOPING COUNTRIES

KONSTANTINOS P. TSAGARAKIS
University of Crete
Rethymno, Greece

INTRODUCTION

A country is characterized as a developing one according to specific economic indicators. The World Bank has linked gross domestic product (GDP) to pollution for developing nations (1) (Fig. 1). This link breaks when incentives to protect the environment are introduced, followed by the adoption of cleaner and more efficient technologies, which can be adjusted to the case of water pollution originating from the disposal of untreated wastewater. Once increasing pollution has had negative effects on the wellbeing and economy of an area, incentives for wastewater treatment are induced. Legislation is introduced requiring polluters to pay for the treatment of wastewater at a certain level. Construction of wastewater treatment plants (WTPs) in compliance with legislation reduces pollution from wastewater and has a positive effect on a quality index based on a combination of treated effluent qualitative parameters.

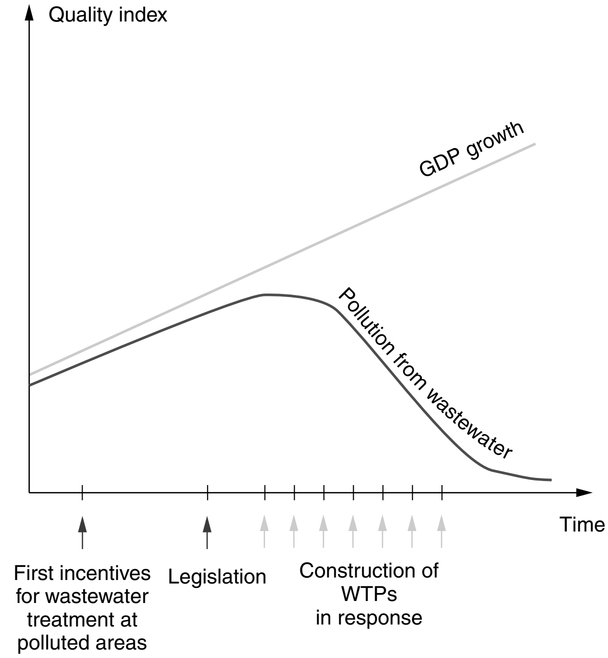

Figure 1. Breaking the link between economic growth and pollution from wastewater (1).

Wastewater management involves collection treatment and disposal/reuse. Potable water supply is inevitably related to them, hence some principles discussed below will include or directly apply to such issues. Ujang and Buckley (2) summarize sanitation problems for developing countries as lack of environmental awareness, insufficient expertise, inappropriate policies, insufficient funding, insufficient water resources, inappropriate management systems, and institutional support.

Following this introduction, the application of existing technologies to developing countries (DC) is discussed, focusing on technology and knowledge transfer and the role of international experts. Some differences over wastewater production and its quality are stressed with special reference to the high standards often set by decision makers in DC. Finally, issues on sustainable technology selection and key points referring to methodologies and indexes are discussed.

APPLICATION OF EXISTING TECHNOLOGIES TO DEVELOPING COUNTRIES

Wastewater management must be considered as an integral part of the development process and national plans should be formulated (3). Conditions applicable when planning wastewater treatment facilities for DC are not identical to those prevalent during planning in developed countries in the past. Although some similarities exist, many differences also exist. One reason is that water pollution issues are not the main concern in DC because of other more pressing issues such as national or racial security, food availability, and epidemic control (2).

Technology Transfer

Today, technology is available for the treatment of wastewaters of any origin and strength. DC cannot be expected to play a key role in the development of cutting edge technology in wastewater management or water research. However, research is needed in order for available technology to be applied to specific country-region conditions. This kind of research is an investment for those countries concerned. The existing transfer of technology should be done wisely because today, developed countries are regarded as an area of investment for water companies. For example, the design approach in rural Egypt was to select well-established technologies; little stress was placed on selecting more innovative technologies. However, less sophisticated treatment technologies, such as stabilization ponds, have proven capable of meeting the required effluent standards (4). A similar situation was reported in Greece. From the 147 small ($<$10,000 p.e.) WTPs, 80% were activated sludge systems, resulting in one out of three being out of operation. If some natural treatment technologies had been properly installed instead of activated sludge systems, failures would have been less frequent (5).

An approach by UNIDO (6), for the acquisition of foreign technology in DC, recommends the following steps:

a. It should be determined that the technology has been commercially proven yet is not obsolete;
b. Alternative technologies that may be available should be evaluated comparatively covering the following points: cost of obtaining such technologies, principal inputs required and their local availability, and estimation of manufacturing costs and profitability.
c. When a country cannot use a certain technology because of foreign exchange limitations or other constraints, a comparative evaluation should still be made, as in (b) above, for purposes of negotiation.

In most cases, when a project is to be evaluated for a DC, shadow pricing should be undertaken to adjust market prices to reflect opportunity costs. A conversion factor, i.e., shadow rate, should be calculated, which then needs to be multiplied with the market prices for unskilled labor wage, the foreign exchange rate, the opportunity cost of capital, and the shadow price of land, water, and other direct inputs (7).

In DC, institutional barriers often exist for hampering the effective application of projects. In many countries, emphasis has been given to increasing the coverage of service facilities to all parts of the population. However, the absence of institutional safeguards, at both the community and government levels, to ensure that these service facilities can be operated and maintained in a sustainable way has caused the facilities to deteriorate, creating an unacceptable financial burden on governments using traditional supply-driven projects (8).

Knowledge Transfer

Knowledge is less available in DC than in developed countries. At the same time, contemporary means of communication have made knowledge more accessible. The World Wide Web, international organizations, networks of excellence, and textbooks all play a positive role in its availability. Textbooks and other sources of knowledge are invaluable tools for design engineers but should always be used wisely. Not all information is applicable to all areas without screening. In fact, if necessary adjustments to local conditions are not made, projects may face serious problems (9).

International Experts and Advisors

Very commonly, advice is sought from international experts/advisors who are asked to give assistance on a specific project. Such assistance is useful when it applies to the technology itself, but to make any wastewater project or plan work, the adaptation should incorporate local conditions. Local experts should therefore always be involved. International experts or advisors can also be employed for solving specific operational problems. The selection of international experts/advisors should be done carefully. Reid (3) pinpoints nine cases of problems associated with advisors. He discusses how some may act like promoters of specific projects to a government resulting in low returns or even losses. In addition, too many advisors on the same project can cause confusion. When advisors are given a difficult task but not given all the information they need to solve a problem, no solution may be found. Although donor countries may offer financial and technical assistance for projects, this can be a misallocation of funds if they do not also take the recipient country's more immediate needs into account.

WASTEWATER QUALITY AND QUANTITY FOR DEVELOPING COUNTRIES

Wastewater Production and its Quality

Historical data on the flow rate is necessary for design purposes, therefore daily, seasonal, and annual variations should be acquired where possible. Reid (3) supports urging each country to establish their own resources agency with responsibility to collect pertinent data and to plan with a regional approach rather than a case-by-case approach.

Where this is not possible, accurate estimations should be taken according to local conditions and information. Crites and Tchobanoglous (10) proposed a domestic base flow rate of 245–300 L/inh.·d. These values apply mostly to developed countries. Uncritical adoption of the above values or other values may lead to overdesigning of the installation. The size of the community served, its socioeconomic conditions, and other parameters may influence the per inhabitant flow rate. Pujol and Lienard (11) proposed 150 (±50) L/inh.·d for rural areas of less than 5,000 population equivalent (p.e.). Campos and Von Sperling (12) developed a model for wastewater production in Brazil that showed significant variation according to the income of the people served (74–210 L/inh.·d). For Greek urban and rural communities, these values are on average 165 L/inh.·d and 100–120 L/inh.·d, respectively, and for Turkish cities 170 L/inh.·d (13,14). Wastewater production may also vary with time and conditions in the same area. Shaheen (15) reports that, in the West Bank, the water consumption was 58 l/inh.· d in 1991, but under a specific scenario, this will rise to 122 l/inh.·d by 2010.

Usually, wastewater in DC is characterized by having high concentrations of basic pollutants. A study in Jordan showed that the average values for 5 WTP in terms of BOD_5, COD, and TSS, were 616–1419 mg/L, 1159–3707 mg/L, and 458–1647 mg/L, respectively (16). In contrast, average BOD_5/COD/SS concentrations were 187/477/236 mg/L, 268/634/302 mg/L, 171/450/237 mg/L, and 267/581/426 mg/L for Belgium-Flanders, France, Netherlands, and Slovenia, respectively (17). One of the major problems in DC is the illegal discharge of industrial effluents into public sewers, unauthorized connections, and unregistered population (18).

Effluent Quality and Standards

Low levels for effluent requirements and standards are frequently introduced in DC, but these levels are, in reality, rarely met. No means exists of imposing any kind of effluent requirements or of adopting the most advanced technology of wastewater treatment, when no mechanism exists to safeguard the maximum possible efficiency.

Many of the high standards used in the developed world have only superficial environmental justification, and the costs of implementation are often not considered by the quality regulators. The regulation and monitoring of standards carries a cost to society that is often considered or appreciated by those setting standards (19).

A list of common problems associated with setting up and implementing standards in developing countries are discussed by von Sperling and Chernicharo (20). Of those, the most important are:

- Standards are often copied by developed countries.
- Protection measures that do not lead to immediate compliance with the standards do not obtain licensing or financing.
- Developing countries attempt to reach developed countries' status too quickly.
- No institutional development exists that could support and regulate the implementation of standards, thus standards are not actually enforced.

von Sperling and Chernicharo (20) propose a sustainable approach for several situations whereby wastewater treatment systems (and effluent standards) should first implement a less efficient process, or a process that removes fewer pollutants. This entails transferring to a second stage the improvement toward a system more efficient or more wide-reaching in terms of pollutants, and so on.

CENTRALIZED AND DECENTRALIZED TREATMENT

Cities in DC, if no wastewater facilities have been established, usually manage their wastewaters in septic tanks, absorption pits, or collect the wastewater and discharge untreated effluent into the environment. To establish a new treatment plant, they need the support of the population that is to be served.

In order to gain this support, people should be informed about the environmental benefits and be willing to pay for the construction and the O&M costs of the WTP. The acceptability of such projects may decline when direct costs are applied to the population to be served (21).

The task of wastewater treatment comes after the collection of the wastewater. Onsite technologies do not have some of the barriers on efficient wastewater management in DC as management is on the owners. The number and location of the WTP is determined by taking two main directions into consideration. The first is that the centralization of the wastewater produced in a large region will give an additional cost per capita, as more meters of sewer and pumping are needed and second, the larger a plant is, the less per capita it will cost because of economies of scale. Therefore, this will give an optimum degree of centralization as shown in the theoretical case of (Fig. 2).

Centralization indicates an increasing number of houses or clusters of houses connected to a main sewerage network instead of being treated onsite. Each cluster of houses, suburb, or neighboring village has an additional cost for connecting itself to a main sewerage network. Although an economy of scale exists in treatment, this is not the case with the cost of centralization of sewers when remote areas are added to the main network. In centralized treatment, extra costs are needed for pumping stations and piping. Furthermore, during the transport of wastewater over long distances, hydrogen sulphide is produced. Extra costs are then needed for odor prevention or reduction. In addition, extra costs are necessary for maintaining the system and pumping energy (22,23). In any case, the cost of centralization should be considered on top of the cost of treatment, with an economic analysis to investigate its feasibility. In a hypothetical case study, after a number of agglomerations have been centralized, it is not worth including others, because the additional cost of connecting them would offset the economy of scale achieved by the treatment of the wastewater.

A combination of onsite and centralized treatment cannot be overruled. In rural areas with a number of

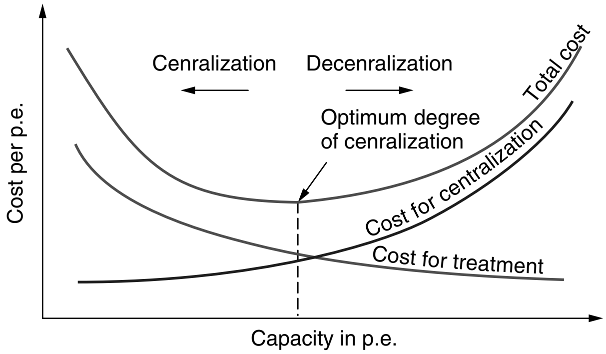

Figure 2. Effect of centralization to the total economic cost of sanitation projects.

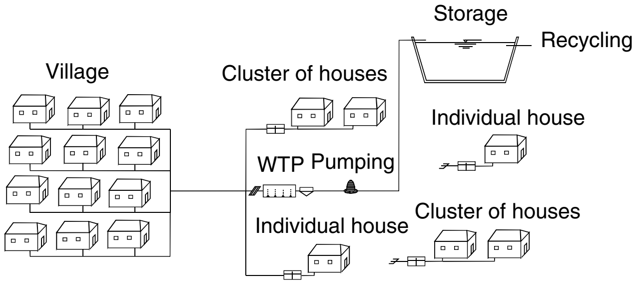

Figure 3. Combined centralized and decentralized wastewater management approaches.

villages, centralized treatment for the villages can exist together with onsite treatment for houses away from the WTP. For some other villages or cluster of houses, onsite septic tanks can be used adjacent to the villages, and then effluent can be carried to the WTP as shown in (Fig. 3).

In a study focusing on small communities of the MENA region, it is proposed that solids are removed in an interceptor tank, which is part of a household connection. Settled sewerage costs are quite low in comparison with conventional sewerage, mainly because of the shallow excavation depths, use of small diameter PVC paperwork, and simple inspection chambers (24).

TECHNOLOGY SELECTION

Sustainable Solutions

A great range of technical solutions are available today. From them are selected those that can produce such effluent quality as to protect receiving surfaces and underground water bodies, in all cases having no negative effects on the environment. These solutions must also protect public health and be acceptable to society. They should be affordable to the users and be operated effectively. The environment, society, and economy are the three aspects that must be given priority when selecting among different solutions (25,26) (Fig. 4).

Reid (3) defines as an appropriate technology for wastewater treatment the one that is acceptable to users and can be maintained by the community. No ideal solution applicable to all conditions exists, and each situation/project should be considered individually (27,28).

Society barriers and limitations may develop from social acceptance, amenity value, community participation, public awareness institutional requirements, local parameters, and stimulation of sustainable behavior (29).

The effluent destination is also a critical factor in the choice of technology for wastewater treatment. Reuse should be encouraged where possible. It is necessary to carry out careful investigations, which are based on local requirements and conditions, rather than uncritically adopting practices from abroad (30).

Methodologies/Indexes

It is possible to use indicators and methodologies to evaluate the different alternatives. These should be used as case study tools and should never lead to a universal classification of all different options. Balkema et al. (25) point out that some of the indicators are hard to quantify and ensure the integration and multidimensional character of the sustainability assessment.

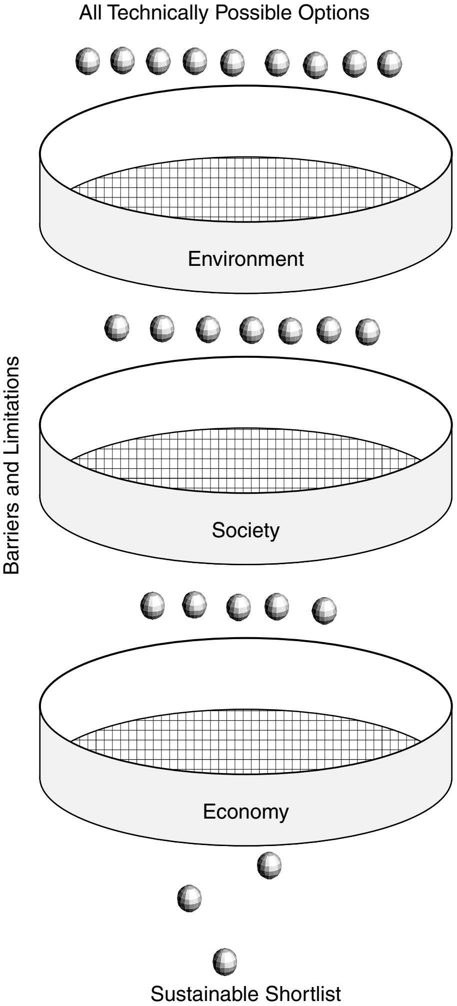

Figure 4. Sustainable short listed wastewater management solutions.

Phybus and Schoeman (31) present various monitoring and performance indicators for developing areas. They conclude that the adoption and use of performance indicators at the community level should be made a stimulating experience for the players involved. It should introduce an element of competition within the initial stages and can lead from there to comparison with neighboring communities.

Schutte (32) suggests that for an organization responsible for water supply and sanitation services in developing areas, five key success factors should be applied:

- Create an organization-wide culture of service to customers.
- Ensure reliability in the water supply.
- Ensure community involvement.
- Create a culture of awareness for focusing on generation and collection of income.
- Create a culture of cost consciousness and focus on minimization of losses.

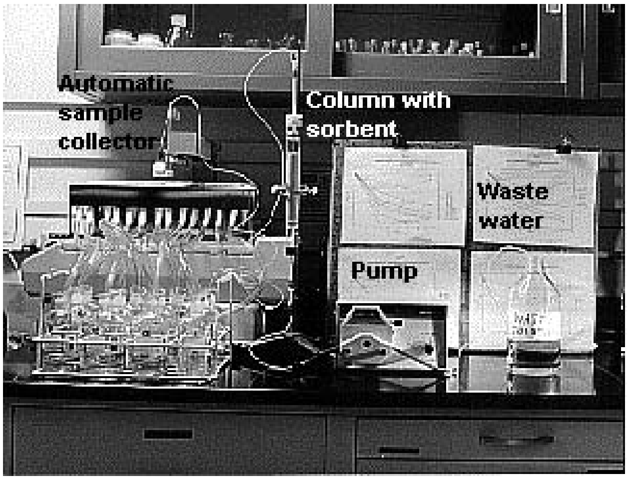

Figure 1. The typical experimental setup for long-term studies employs a continuous flow of waste water through a column packed with sorbent.

the Department of Energy (DOE) complex, and conducts research and development activities to serve end-users.

Mercury-contaminated soils, sludges and aqueous residues at DOE sites usually contain sufficient radioactivity to invoke special handling under the Atomic Energy Act and Resource Conservation and Recovery Act. Typical examples are high-salt acidic wastes stored at Idaho Chemical Processing Plant, alkaline waste stored at Savanah River Site (SRS), and mercury-bearing lithium hydroxide and low-salt neutral pH groundwater at the Oak Ridge Y-12 Plant. Difficulties in removing mercury from these wastes are due to its concentration, speciation, interference from other dissolved species, and pH of the bulk media.

Figures 2 and 3 shows data from a feasibility study conducted on a surrogate waste similar to the SRS waste water. Typically, a large number of sorbents are screened for applicability before an isotherm study is conducted. Based on the results from these experiments, sorbents are selected for continuous column experiments in which data are collected to determine the long-term performance of sorbents. The data collected in these type of experiments can be used to design full-scale systems.

Every waste is different, so there is always a need for these type of experiments. We prefer to work with the actual waste whenever possible; however, sometimes the cost is prohibitive.

In Fig. 2, are the results of isotherm studies with SRS waste. The three sorbents performed quite differently; the Mersorb (sulfur impregnated activated carbon pellets) appeared to be able to adsorb far more mercury than the other sorbents.

Column studies bring another dimension into the project. In Fig. 3, the concentration of the mercury in the effluents from columns packed with SR-3 or Mersorb sorbent are displayed. There is no mercury exiting the column until about 2200 bed volumes (BV) had passed through the system when SR-3 was used as sorbent. The breakthrough was sharp, indicating efficient use of the column and the mass transfer zone was 6.2 mm deep. The flow rate was about 11 BV per hour. In the case of Mersorb about 1000 BV could be processed before mercury appeared in the effluent. In this case the breakthrough was more gradual over time, which is less desirable.

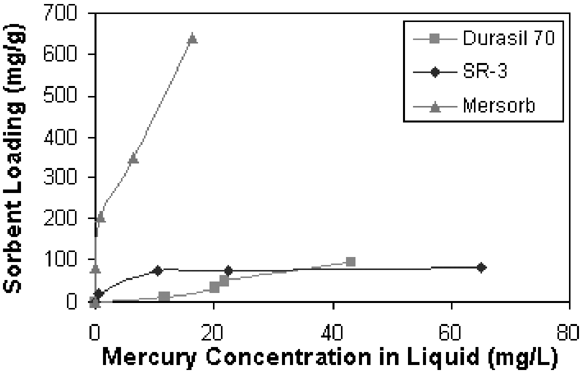

Figure 2. These data are from an experiment conducted with a waste water similar to tho one stored at the Savannah River Site. The original mercury concentration was 108 mg/L. Various amounts of sorbent were placed in contact with 50 mL of water for 24 h before the mercury was measured in the free liquid. The purpose of the experiment was to determine the isotherms.

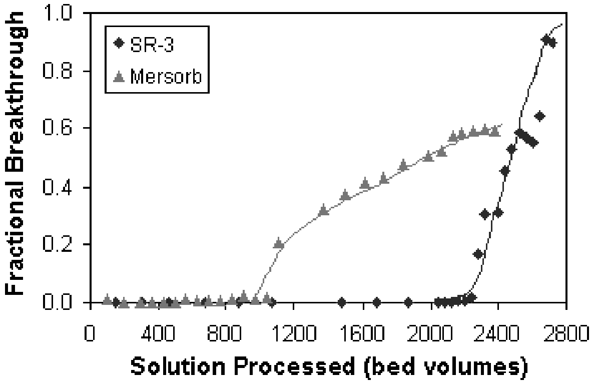

Figure 3. These data are from an experiment conducted with surrogate SRS waste passed through a column packed with a sorbent. As is noted, the effluent from the column is free of mercury until the sorbent becomes saturated.

METAL SPECIATION AND MOBILITY AS INFLUENCED BY LANDFILL DISPOSAL PRACTICES

Samuel C. Ashworth
Idaho National Engineering &
Environmental Laboratory
Idaho Falls, Idaho

Currently, landfills are constructed of a system of liners, leachate collection systems, and gas venting and collection systems. Hazardous wastes normally have two synthetic liners on the bottom and two leachate collection systems, one within the waste and one between the liners. These bottom liners typically rest on bentonite clay. Landfills have one bottom liner (New York requires two) resting on clay and one leachate collection system within the waste. A schematic of a typical landfill system is shown in Fig. 1. The landfill has a top cover system consisting of a synthetic liner with a topsoil cover designed to deflect precipitation. Not all of the liner components are shown, geotextiles and sands are used in various combinations for cushioning and inducement of preferential flow paths.

The following discusses and summarizes the mechanisms involved in metal speciation and mobility, modeling including references that provide more modeling information, and specific research in some of the areas.

Some precipitation inevitably enters the waste from liner permeation, holes, and cracks. However, most precipitation is deflected to stormwater collection, called runoff in Fig. 1. The dominant flow mechanisms into the waste are from the construction defects and not diffusion through the synthetic liners (1).

The precipitation that enters landfill wastes interacts with waste components and leaches metals and other substances. There are very complex interactions between the leachate and waste components that depend on pH, the metal and other component speciation, the presence of ligands, overall waste composition, redox potential, and others. Most of the leachate is collected in the leachate collection and treatment system. However, some of the leachate penetrates the bottom liner system from mechanisms similar to infiltration, and enters the soil column, and subsequently enters the groundwater.

Metal speciation and mobility are influenced by physical, chemical, and biological processes, and complex interactions between these processes may result in transporting specific contaminants at different rates (1). Attenuation of mobile metals depends on the amount of time that the contaminant is in contact with the material, the physical and chemical characteristics of the material, and the characteristics of the leachate.

Physical processes that control the transport of contaminants in the subsurface include advection (convection), the mixing effects of dispersion and diffusion, and physical sorption. Chemical processes that are important in controlling subsurface transport include precipitation/dissolution, chemical sorption, redox reactions, ion exchange, and complexation. These processes are generally reversible. The reversible processes tend to retard transport but do not permanently remove a contaminant from the system. Sorption and precipitation are generally the dominant mechanisms retarding contaminant transport (1). However, as discussed later, complexation can be dominant in landfills.

One model commonly used in chemical and environmental engineering that is often used to estimate leachate concentrations as a function of time and space, $C(t,x,y,z)$, is

$$\left(1+\frac{\rho_B}{\alpha}K_D\right)\frac{dC}{dt} = \nabla\bullet D\nabla C - \vec{v}\bullet\nabla C + R \qquad (1)$$

If the diffusion coefficient is constant and a single dimension is used, this becomes

$$\left(1+\frac{\rho_B}{\alpha}K_D\right)\frac{dC}{dt} = D\frac{\partial^2 C}{\partial x^2} - v_x\frac{\partial C}{\partial x} + R \qquad (2)$$

where C concentration, M/L^3
D diffusion (or dispersion) coefficient, L^2/t
K_D leachate/solid distribution coefficient, L^3/M
R reaction rate, M/L^3/t
x spatial variable, L
t time
v velocity, L/t
α solid porosity
ρ_B solid bulk density, M/L^3

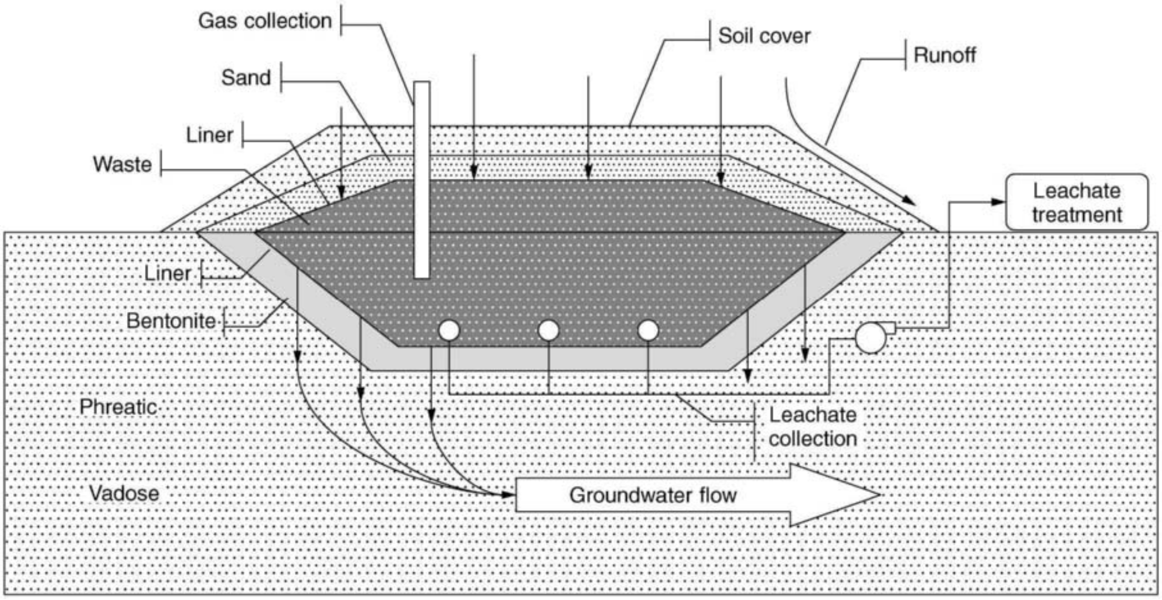

Figure 1. Schematic of landfill system.

The term on the left is the rate concentration change with time modified by the retardation based on sorption. The distribution coefficient for organic compounds can be estimated from the organic carbon content of the waste (2) but is likely to require measurement for metals. The first term on the right is the diffusion and/or dispersion. The second term on the right is the advection and the third term is the chemical reaction term. Equation 2 does not account for all phenomena. However, lumped sum parameters can be used, for example, the reaction rate R can include several types of generation and degradation terms lumped together. This equation or a variation thereof is normally solved numerically using appropriate boundary conditions.

Mathematical models to simulate the expected fate and transport of leachate metals are frequently used in groundwater and waste piles. Travers and Sharp–Hansen provide a thorough review of pertinent factors (3). Each facility is different, and no one generic model is appropriate in all situations. The conceptual model and data are used to select a mathematical model that accurately represents the conceptual model (4). A number of groundwater models, including saturated flow, solute transport, heat transport, fracture flow, and multiphase flow models, are summarized in van der Heijde et al. (5). A report by van der Heijde and Beljin provides detailed descriptions of 64 groundwater flow and solute transport models that were selected for use in determining wellhead protection areas (6). Reviews of groundwater flow and transport models for the unsaturated zone is presented in Oster (7). Groundwater flow and transport models are summarized by Bond and Hwang (8). Finally, Travers and Sharp-Hansen summarize models that may be applicable to problems of leachate generation and migration from landfill units (3). In an idealized situation (e.g., no complexation), metal mobility is controlled by the solubility of the species in the leachate. Precipitation is incipient when the metal exceeds its solubility, for the solubility product constant of a divalent metal,

$$K_{\mathrm{sp}} = [\mathrm{M}^{+2}][\mathrm{OH}^{-}]^2 \tag{3}$$

The precipitation of a dissolved substance may be initiated by changes in pressure, temperature, pH, concentration, or redox potential (9).

Chemical adsorption/desorption is a common mechanism that affects metal contaminant migration in soils. Solutes become attached to the solid phase by adsorption. Adsorption/desorption and precipitation/dissolution are reversible processes. However, adsorption/desorption generally occurs at a relatively rapid rate compared to precipitation reactions (1).

Oxidation and reduction (redox) reactions involve the transfer of electrons. Depending on the redox potential, metals may exist in various oxidation states that can impact their solubility. An example is iron that is very insoluble in the plus-three valence state. The valence state of iron depends on the redox potential and the pH, as shown in Eq. 4 (10):

$$4\mathrm{Fe}^{2+} + \mathrm{O}_2 + 4\mathrm{H}^+ = 4\mathrm{Fe}^{3+} + 2\mathrm{H}_2\mathrm{O} \tag{4}$$

Redox reactions and pH affect the solubility, complexing capacity, and sorptive behavior of constituents and thus control the presence and mobility of many substances in water. Microorganisms are responsible for a large proportion of redox reactions that occur in groundwater and, by inference, wastes in landfills.

Ion exchange occurs primarily at exchange sites on layered silicate clays and organic matter that have a permanent negative charge. The ability of soils and other solids to exchange cations is measured by the cation exchange capacity. The type and quantity of clay mineral present, the amount of organic matter present, and the pH of the soil or solids affect cation exchange capacity. Major cations in leachate (Ca, Mg, K, Na) usually dominate the exchange sites, resulting in little attenuation in soils of trace metals in the leachate, depending on the material selectivity and leachate metals concentrations. A smaller ion exchange effect for anions is associated with hydrous oxides. Soils typically have more negatively charged clay particles than positively charged hydrous oxides. Therefore, the transport of cations is attenuated more than the transport of anions.

Complexation reactions occur when metal ions react with inorganic anions or organic ligands to form coordination compounds. Complexation can either increase the concentration of a constituent in solution by forming soluble complex ions or decrease the concentration by forming a soluble ion complex with a solid. It is often difficult to distinguish among sorption, solid–liquid complexation, and ion exchange. Therefore, these processes are usually grouped together as one mechanism.

The biological degradation cycle of landfills normally occurs in four phases, aerobic, acetogenic, methanogenic that last on the order of 15 years, followed by a humic phase where the relatively refractory humic substances are stable. The degradation refers to organic compounds. The last phase is the phase in which no more organic degradation occurs and the remaining organic compounds consist of humic substances. The aerobic decomposition phase is short; it lasts approximately 1 month when all of the oxygen is used up (11). The second phase can last several years producing simple compounds such as fatty acids with high BOD_5 and an acidic leachate of pH approximately 5–6. The leachate contains high levels of mobile metals. Methanogenesis is slower than acetogenesis, so simple organic compounds are consumed during the third phase. Sulfates can be reduced to sulfides during the third phase that subsequently precipitate metals and hence change their speciation and reduce their mobility. The pH during the third phase is of the order of 7–8.

Recent work provides some specific examples of the way landfill practice influences speciation and mobility of metals. A plethora of information exists in the literature. Therefore, only some of the references found are cited. The general conclusion of the studies is that metal speciation and mobility are highly dependent on the landfill phase. The humic phase of the landfill is when the metals are least mobile and are speciated by chelation with humic substances. This phase may be short or long-lived, depending on the waste exposure to air. Humic oxidation can likely be minimized and/or eliminated by precluding air infiltration. The phase of a landfill can be accelerated by recycling water thus rendering metals less mobile sooner. It is also concluded that metals can exist in colloidal form and can complex with dissolved organic and/or inorganic compounds.

Several of the studies cited below correlate the speciation and mobility with chelation by humic compounds. Therefore, some discussion of these substances is needed. Humic compounds are derived from the amorphous part of dark brown to brown-colored substances in soil, lignite, peat, and brown coal produced during the humification of decaying organic materials. A conceptual model of a humic acid structure (12) is shown in Fig. 2. Figure 2 shows a possible sequestration mechanism of nickel, cadmium, and plutonium by humic acid. Humic acid/humic substance chemical structures have not yet been clearly defined. Approximate models describe humic acids as three-dimensional macromolecules whose molar mass is between 25,000 and 100,000. Their basic structure always has two distinctive features: (1) a central core with high aromaticity and (2) strong cross-linkage and peripheral functional groups linked by bridge binding (13). A substantial fraction of the mass of the humic acids is in carboxylic acid functional groups, which endow these molecules with the ability to chelate positively charged multivalent ions (Mg^{2+}, Ca^{2+}, Fe as well as hazardous metals such as Cd^{2+} and Pb^{2+}) (14). A major effect of humic acids in the speciation and mobility of metals is detoxification of heavy metals by chelation.

Organic matter degradation and hence the potential efflux of heavy metals in a long-term perspective was studied by defining some scenarios for waste deposits containing organic compounds, different longevity and functions of covers, and different water and air intrusion rates. The scenarios were based on various transport processes as well as different landfill constructions. The main conclusion is that the degradation of humic matter and hence the release of toxic metals can be substantially decreased if potential buildup of hydraulic gradients is avoided and if the landfill is located below the water surface (15). The amount of oxygen available for oxidation of the humic material and sulfides is reduced by water saturation. The assumption is that humic material and sulfides are readily oxidized and thus release the metals upon oxidation. The fifth phase of the landfill is the humic oxidation stage, if sufficient air can contact the waste and oxidation rates are fast. Additional research is needed in this area.

A conceptual model has been developed for waste deposits (16). The important processes occurring during the humic phase were quantified. The scenarios included the main mechanisms based on various transport processes as well as different landfill constructions, for example, binding capacities of sulfides and humic substances. They also included transport mechanisms by which the reactant oxygen can intrude into a deposit, sorption capacities of hydrous ferric oxides, and pH-buffering reactions. Scoping calculations have shown that the binding capacity of humic substances is sufficient to bind all toxic metals Cd, Cr, Pb, Zn, and Hg. In addition, the humics could also bind a smaller part of Ca, Fe, and Al, provided that much of the organic wastes remain as humic substances. Sulfides, on the other hand, can bind approximately twice the amount of all toxic metals. The binding capacity of hydrous ferric oxides, which can be formed by oxidation reactions during the humic phase, is estimated at three times the total content of metals that can sorb on hydrous ferric oxides. The alkalinity of the wastes is high enough to buffer the acidity produced by the oxidation of sulfides and by the degradation of organic matter, as well as that added by acid precipitation. Therefore, the main conclusion is that higher remobilization rates of heavy metals due

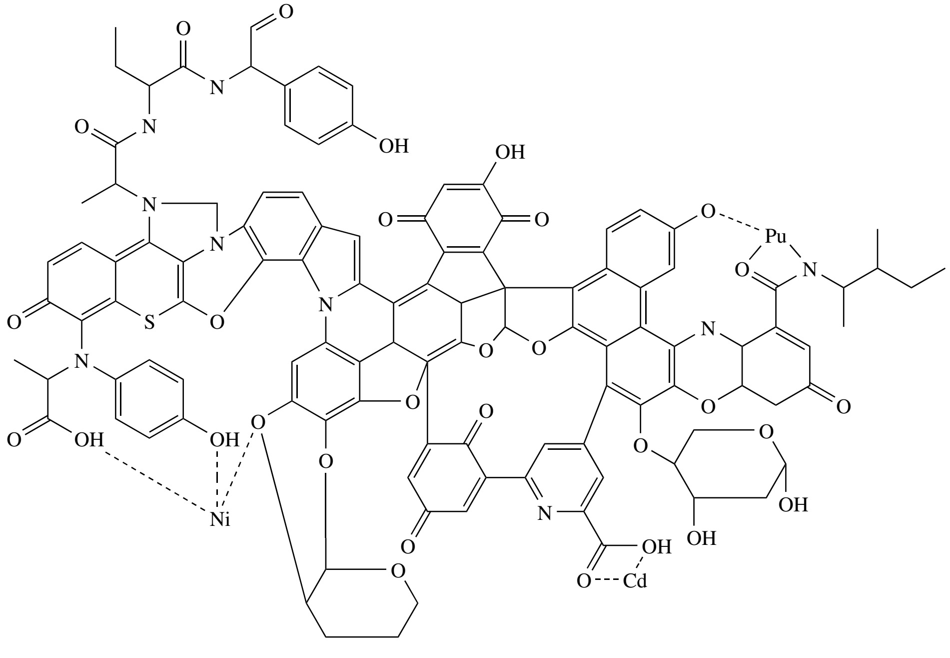

Figure 2. Model structure for humic acid.

to lowering of pH are not expected for many thousands of years.

Dissolved organic compounds can also complex with metals that increase mobility. Leachates after treatment from a landfill in Japan contain the same order as the influent (17). This was attributed to complexation with organic compounds, as treatment by elevated pH precipitation was effective when the organic compounds were removed. The ability of dissolved organic carbon (DOC) from landfill leachate-polluted groundwater to form complexes with the heavy metals cadmium (Cd), nickel (Ni), and zinc (Zn) was investigated (18). The DOC samples originated from the leachate pollution plume at Vejen Landfill, Denmark, and were studied in the original matrix with a minimum of manipulation. The results showed that DOC from landfill leachate-polluted groundwater can form complexes with Cd, Ni, and Zn and that the distribution coefficients were a factor of 2–6 lower in the presence of DOC. The migration velocity of the metals was increased by the presence of DOC but did not exceed 1.2% of the water migration velocity, indicating that the effect of DOC on the mobility of Cd, Ni, and Zn may have only minor environmental importance.

Rainfall and the recycling of leachate impact landfill leachate metal speciation and mobility. Leachate volume increases linearly with rainfall, and the leaching coefficient decreases, according to studies in Taiwan (19). Landfill bioreactor technology offers important advantages in managing and treating municipal solid waste, including accelerated waste stabilization rates, enhanced gas production, facilitated leachate management, volume reduction, and minimized long-term liability. These advantages have been documented in laboratory, pilot, and full-scale investigations. Although challenges remain in implementing the technology, bioreactor landfills are designed and operated at increasing frequency (20). Metal washout is initially one of the important mechanisms in conventional landfills, but sulfide and hydroxide precipitation followed by complexation with humic compounds are the primary mechanisms in recirculating landfills. However, metals can be remobilized, once humic oxidation starts. Recycling of leachate and/or addition of water through the waste accelerates stabilization. Water addition is a means of decreasing the degradation time span and thus accelerating metal stability. The water helps spread nutrients and bacteria to other parts of the landfill (21) and provides a medium conducive to biochemical reactions.

The physical forms of the species are also important in considering leachate metal speciation and mobility. Some of the metals can exist in colloidal form as, very small particles that are not easily filterable. This can have a large impact on characterization and leachate treatment processes. According to research on Danish landfills, metals exist in colloidal form. The dominant part of the colloidal material was in the smallest colloidal size fraction (0.001–0.40 mm); total organic carbon (TOC) was one of the major components of the colloidal mass. Si, Al, Ca, Fe, and S were also found in the colloidal fractions. This indicated that clay type particles, organic matter, and precipitates (most likely sulfides) were present in the leachate samples (22). The behavior of the colloidal mass can be markedly different from a dissolved metal speciation and needs to be accounted for in leachate treatment systems. In another similar study, anaerobic leachate-polluted groundwater samples were collected downgradient of a Danish landfill (23). The groundwater samples were spiked with heavy metals at concentrations within the range of metal concentrations found in landfill leachates and divided under anaerobic conditions into colloidal (screen-filtration and cross-flow ultrafiltration), organic (anion-exchange), and dissolved inorganic species of the heavy metals. The distribution of the heavy metals among the different size fractions showed that a substantial, but highly varying part of the heavy metals was associated with the colloidal fractions. These colloidally bound metals were, furthermore, associated primarily with the organic fraction, except for Zn, which was associated mainly with the inorganic fractions. Dissolved Cd, Cu, and Pb were mainly associated with dissolved organic carbon; Ni was also present as carbonate complexes and Zn as carbonate complexes and free divalent Zn. The results indicate that heavy metals in leachate-polluted groundwater are strongly associated with small-size colloidal matter and organic molecules.

MICROBIAL FOAMING IN THE ACTIVATED SLUDGE PROCESS

MICHAEL H. GERARDI
Linden, Pennsylvania

The production and accumulation of microbial (bacterial) foam in activated sludge processes is common and often contributes to increased operational costs and permit violations for total suspended solids (TSS), biochemical oxygen demand (BOD), and floating solids. There are several significant operational conditions that permit foam production in the aeration tank and its accumulation throughout numerous tanks in the treatment process. Each condition allows for the production of foam with its own characteristic texture and color (Table 1). Operational conditions responsible for microbial foam production include the undesired growth of foam-producing filamentous organisms, the presence of a nutrient deficiency, increasing sludge age, and undesired zoogloeal growth or viscous floc.

Table 1. Operational Conditions Associated with the Production of Microbial Foam

Operational Condition	Microbial Foam
Foam-producing filamentous organisms	Viscous chocolate-brown
Nutrient deficiency at a young sludge age	Billowy white
Nutrient deficiency at an old sludge age	Greasy gray
Sludge aging (young to old)	Billowy white to crisp white to crisp brown to viscous dark brown
Zoogloeal growth	Billowy white

Foam consists of entrapped air or gases beneath a thin layer of solids or biological secretions. Gases entrapped in foam consist of those released during the aerobic and anaerobic degradation of carbonaceous wastes. These gases include carbon dioxide (CO_2), molecular nitrogen (N_2), and nitrous oxide (N_2O).

Microbial foam is produced in the aeration tank and is discharged from the aeration tank to other treatment units such as the secondary clarifier, thickener, digester, dewatering facilities, and chlorine contact tank. In these units the accumulation of foam often results in increased operational costs. As foam is discharged from the aeration tank to other treatment units, the air and gases escape, and the foam collapses. The collapsed foam is sometimes referred to as scum.

FOAM-PRODUCING FILAMENTOUS ORGANISMS

In order of occurrence in activated sludge processes in North America, foam-producing filamentous organisms include nocardioforms, *Microthrix parvicella*, and type 1863. These organisms produce viscous, chocolate-brown foam.

Foam production by filamentous organisms is due to the presence of a large population of living organisms and a large population of dead organisms. The living organisms release insoluble lipids that coat floc particles and entrap air and gases. Dead organisms undergo autolysis and release surfactants (biosurfactants) that reduce the surface tension of the wastewater and permit microbial foaming. Surfactants released include ammonium ions (NH_4^+) and fatty acids. Because dead organisms release surfactants, control measures that destroy large numbers of foam-producing filamentous organisms over a relatively short time period often result in the rapid production of a copious quantity of foam.

The rapid and undesired growth of each foam-producing, filamentous organism can be associated with specific operational conditions (Table 2). By monitoring and preventing these conditions, the undesired growth of these organisms and their production of foam can be reduced.

Nocardioforms are a specialized group of bacteria that are known as actinomycetes. These organisms display some growth characteristics such as true branching that are found in the fungi. Nocardioforms and related

Table 2. Operational Conditions Associated with the Undesired Growth of Foam-Producing Filamentous Organisms

Operational Condition	Filamentous Organism		
	Nocardioforms	*Microthrix parvicella*	Type 1863
High MCRT (>10 d)		X	
Fats, oils, and grease	X	X	X
High pH (>8.0)		X

Slowly degradable substrates	X	X	
Winter proliferation		X	

genera that are most often associated with foam production in activated processes include *Actinomadura, Arthrobacter, Corynebacterium, Micromonospora*, and *Nocardia*. *Nocardia* is the most commonly observed foam-producing actinomycetes, and the most frequently reported species of *Nocardia* include *N. amarae, N. asteroides, N. caviae, N. pinesis*, and *N. rhodochrus*. These organisms are relatively short (<50 μm), highly branched, and gram-positive. Nocardioforms can be found in the foam and mixed liquor within floc particles, extending into the bulk solution from the perimeter of the floc particles, and free-floating between the floc particles. Usually, nocardioforms as well as *Microthrix parvicella* and type 1863 are found in higher concentration in the foam than in the mixed liquor.

Because foam-producing filamentous organisms are found in high concentrations in the foam, the foam represents a source of "reseeding" of the mixed liquor with filamentous organisms. Therefore, treatment of the foam should be addressed when attempting to control the growth of foam-producing filamentous organisms (Table 3).

Microthrix parvicella is a nonbranched, relatively short (<200 μm), gram-positive filamentous organism. Intracellular granules in the filamentous organism may appear as a string of "beads." *Microthrix parvicella* usually is found in tangled mats in the floc particle or bulk solution.

Table 3. Treatment Measures for the Control of Filamentous Organism Foam

- Collapsing foam with the application of cationic polymer
- Collapsing foam with the application of effluent through "bib" sprinklers
- Collapsing foam with nonpetroleum-based defoaming agent
- Digesting foam with the application of bacterial cultures that contain the lipid-digesting enzyme lipase
- Physically removing the foam
- Spraying foam with a 10–15% sodium hypochlorite solution and spraying foam with effluent after 2–3 h of foam exposure to the sodium hypochlorite solution

Blooms of *Microthrix parvicella* often are associated with cold wastewater temperatures (winter proliferation). The proliferation of *Microthrix parvicella* during cold wastewater temperature may be due to the congealing of fats, oils, and grease. These compounds are preferred substrates for this filamentous organism.

Type 1863 also is a nonbranched, relatively short (<50 μm), gram-negative filamentous organism. Type 1863 is found free floating in the bulk solution and extending into the bulk solution from the perimeter of the floc particles. The filamentous organism possesses "chains" of rod-shaped cells that are constricted at each end.

NUTRIENT DEFICIENCY

Nutrient deficiencies are commonly observed in activated sludge processes and usually are due to the presence of nutrient-deficient industrial wastewater (Table 4). Nutrients that are most often deficient are nitrogen and phosphorus.

During a nutrient deficiency, soluble substrate that is absorbed by bacterial cells in floc particles cannot be degraded. The nondegraded food is converted by bacterial cells to insoluble polysaccharides and stored outside the bacterial cells. The polysaccharides are less dense than water and hinder the settleability of floc particles. Often, polysaccharides are deposited in the floc channels that permit the moving of water, air, and gases through the floc particle. When these channels become heavily laden with polysaccharides, air and gases are entrapped in the channels and desired settleability continues to deteriorate and foam appears on the surface of the aeration tank.

Foam produced during a nutrient deficiency is billowy white at a young sludge age and greasy gray at an old sludge age. The difference in texture and color of nutrient-deficient foam is due to the accumulation of oils in the floc particles. Young bacterial cells produce relatively little oil that accumulates in floc particles as compared to old bacterial cells. The transfer of oil to the foam from the floc

Table 4. Nutrient-Deficient Industrial Wastewaters for Nitrogen or Phosphorus

particle results in the production of greasy gray foam as the sludge age increases.

A nutrient deficiency within an activated sludge process can be corrected by identifying nutrient-deficient industrial wastewaters and ensuring that adequate nutrients are added to these wastewaters. Also, nutrients can be added to the activated sludge process as needed. Chemical compounds that release ammonium ions (NH_4^+) or orthophosphate (HPO_4^{2-}) can be added to the mixed liquor influent or primary clarifier effluent. Appropriate recycle streams also can be discharged to the activated sludge process when needed, if these streams contain adequate quantities of ammonium ions or orthophosphate and relatively low quantities of soluble wastes. Recycle streams include decant from digesters, centrate, and filtrate.

INCREASING SLUDGE AGE

Several types of foam are produced through changes in microbial activity with increasing sludge age. Billowy white foam is produced at a young sludge age when the bacterial population or mixed liquor suspended solids (MLSS) value is relatively small, that is, <1000 mg/L. This small population of bacteria lacks sufficient enzymatic ability to adequately degrade the surfactants that are discharged to the activated sludge process. The nondegraded surfactants produce billowy white foam.

With increasing sludge age the bacterial population or MLSS value increases. This population has sufficient enzymatic ability to adequately degrade the surfactants. With degradation of the surfactants, the foam becomes crisp white.

As the bacterial population (or MLSS) continues to age, large quantities of oils secreted by the bacteria accumulate in floc particles. The color of the oils darkens crisp white foam to crisp brown foam.

Finally, as the bacterial population becomes very old, large numbers of slow-growing filamentous organisms such as nocardioforms and *Microthrix parvicella* may proliferate. The growth of these lipid-producing organisms contributes to the production of viscous dark brown foam.

Undesired quantities of foam as a result of young or old sludge ages can be corrected by decreasing or increasing the sludge age by regulating sludge wasting rates. Sludge wasting rates should be uniform over as long a period of time as possible in order to prevent the development of pockets of young bacterial growth and old bacterial growth. If these pockets of growth do develop, concentric circles of light foam and dark foam can be observed on the surface of the aeration tank when aerators are turned off.

ZOOGLOEAL GROWTH

Zoogloeal growth or viscous floc is the rapid and undesired proliferation of floc-forming bacteria such as *Zoogloea ramigera*. This growth is associated with the production of large quantities of insoluble gelatinous material that entrap air and gases. The gelatinous material and entrapped air and gases result in the production of billowy white foam.

The occurrence of zoogloeal growth in activated sludge processes is due to high MCRT, long HRT, nutrient deficiency, organic acids, and significant changes in F/M. Zoogloeal growth and its foam can be controlled by exposing the growth to anoxic periods.

The texture and color of foam may vary due to changes in operational conditions. Generally, foam becomes more billowy and lighter in color with decreasing sludge age and more viscous and darker in color with increasing sludge age. Also, several operational conditions for the production of foam can occur at the same time, resulting in a mixture of textures and colors. For example, nutrient-deficient foam and filamentous organism foam can occur simultaneously.

Additional foaming conditions that often occur in activated sludge processes include surfactant foam, alkalinity foam, and polymer foam. If surfactants are not quickly degraded in the aeration tank, surfactants change the surface tension of the wastewater and produce billowy white foam. Also, an increase in alkalinity in the wastewater changes the surface tension of the wastewater, resulting in the production of billowy white foam.

If cationic polymers containing amino groups ($-NH_2$) are applied in an excess quantity for sludge thickening or sludge dewatering, and the excess quantity of polymer enters the aeration tank, billowy white foam is produced. When the polymer is degraded in the aeration tank, ammonium ions are produced from the release of amino groups. The ammonium ions represent an increase in alkalinity and a change in the surface tension of the wastewater. The change in the surface tension of the wastewater results in the production of billowy white foam.

INTRODUCTION TO WASTEWATER MODELING AND TREATMENT PLANT DESIGN

David L. Russell
Global Environmental Operations, Inc.
Lilburn, Georgia

INTRODUCTION

There are many ways of approaching the design of a wastewater treatment plant. Of the many methods, the field of practice generally uses three or four: design codes, rules of thumb, simple Monod calculations; and rigorous mathematical modeling. Most states still subscribe to variants of the first two methods because they work and are written in code documents. Depending on the backgrounds of designers, they may or may not have been exposed to the Monod equation and/or mathematically rigorous approaches to development of a static or dynamic model.

We confine this article to discussing readily available activated sludge and related models. Anaerobic digestion or film type of biological treatment systems is not discussed because the modeling effort for film modeling is not well enough defined to permit accurate modeling, and anaerobic modeling is still relatively new and has not become widely available. Another reason is that many of the models would require a full book to summarize adequately, and their use and calibration are often the subject of Ph.D. theses.

The older design code approach is often characterized by reference to individual state and national design codes such as the Ten States Standards. This approach is acceptable but produces a design which is between 30 and 50% in excess of that required and leads to sloppy and wasteful operation.

The rationale model is a group of codified experience based principally on food to microorganism ratio, mixed liquor suspended solids (MLSS), and a number of rules of thumb about the amount of air to supply per pound of waste treated, the quantity of cells produced per pound of biochemical oxygen demand treated, and hydraulic retention time.

For example, one could find rationale in the literature and the codes for designing a treatment plant with an F/M ratio of 0.4 to 0.05, a retention time between 12 and 30 hours, an MLSS of between 1000 and 4000 mg/L, and an oxygen transfer rate of 2.2 lb oxygen supplied per horsepower/hour per pound of BOD removed. That plant would probably work well, but under the ranges of the assumptions given, one could wind up with tankage that varies by a factor of 10 times or more. Still, no discussion of the rules for designing a clarifier system to remove solids has occured. The clarifier design can vary over a smaller range of perhaps 4:1. There is a wide latitude in what works, but the principal objective is to get the best combination of size and efficiency for the cost.

To varying degrees, the individual and company design groups have computerized their designs on spreadsheets (principally Excel®) or in limited versions for numerical calculators. These programs are adequate as far as they go, but designing an expensive and energy-intensive facility should consider the dynamic behavior of the wastewater and the performance of the plant.

It can be argued, because I have done so, that repeated running of the static models at varying conditions is an adequate substitution for dynamic modeling. At one time I believed that. However, the static models available are just not up to the performance of the dynamic models, and they do not address the different types of conditions and alternatives that can be evaluated using dynamic models.

Modeling the operation of a wastewater treatment plant is neither easy nor simple. Rather, it requires a concerted effort to acquaint oneself with the process of model development, the development of a mindset, and a willingness to research the somewhat arcane area of mathematical modeling formulations and development.

Modeling a wastewater treatment plant requires mastery of the elements of modeling and a basic understanding of the fundamentals of model development and chemistry. It also requires understanding the limitations of the model(s) used and their interactions.

STATIC AND DYNAMIC MODELS AVAILABLE

A number of wastewater models are currently available. The principal static models are available on the World Wide Web or from individuals via e-mail:

The Steady© model was developed by Luis Aburto Garnica and Gerald E. Speitel, Jr. It is available from the University of Texas via its website. It solves the activated sludge equations by an iterative approach. The graphics are limited, and the model is also very limited, but it is free. It can be obtained from: http://www.ce.utexas.edu/prof/speitel/steady/steady.htm.

Dr. William McHarg developed a spreadsheet model that is also free. The documentation is available online from Dr. McHarg, and a copy of the spreadsheet is available from him. The documentation is very good, and it is available at: http://www.wideopenwest.com/~bmcharg/bioxmdl/bioxmdl.htm.

The Wisconsin Department of Natural Resources has developed a model for the activated sludge process, named ENBIR. The ENBIR model is available from the following web address: http://www.dnr.state.wi.us/org/water/wm/ww/biophos/enbir.htm. The model is DOS-based and may not run under all versions of Windows. The documentation and theory development are available in a Power Point® slide from the following address: http://www.dnr.state.wi.us/org/water/wm/ww/biophos/remproc.ppt. The model was developed by Dr. Jim Park in 1996 to address Wisconsin's concerns about cold weather effects on wastewater treatment plants and the decrease of nutrient removals during cold weather. The documentation is reasonably good but does not consider all the ramifications of design and has limited ability to handle industrial wastes and nonstandard conditions.

Dynamic models come in all shapes and sizes. As far as can be ascertained, the only two free dynamic models are from Clemson University, called simulation of single sludge Processes (SSSP), and the corresponding program from University of Uppsala, Sweden, called Java activated sludge process simulator (JASS).

The SSSP model was developed by Dr. Les Grady and one of his graduate students around 1986. It is a DOS-based model. It was one of the earliest works that incorporated dynamic modeling and is now available free from Clemson. As far as can be ascertained, it was developed about the same time as the ASM1 model (see below), and it can model a multitank activated sludge plant. Steven Birstrip was one of Dr. Grady's graduate students, and he developed the DOS code for the model. The model is relatively easy to use, has good documentation, and can be learned and used in a matter of hours. It is limited in that it does not model the clarifier portion of the wastewater treatment plant well, but other than that, it is functional. The model can be obtained from the following website at the Rich Environmental Research Center of Clemson University: http://www.ces.clemson.edu/ees/sssp/index.htm.

The JASS model can be found at http://www.syscon.uu.se/~psa/. It is free, but it runs on their network and cannot be downloaded to a private personal computer. The graphics are unsophisticated, and the modeling is based on the ASM1 model. In times past, when the site was under development, some of the comments on the bulletin board accompanying the site indicated that there were mistakes in the program that were being fixed. The site is not necessarily convenient, nor is it reliable, and it lacks the power and flexibility of some of the commercial software packages.

Based on my own research, I prefer the SSSP program to the JASS program. This does not say that others cannot and have not developed free spreadsheet and other dynamic models, but none are as well documented as the SSSP Model.

For those of you who have the Mathcad® program, there is an activated sludge simulator that can be freely downloaded, but can be used only with Mathcad®.

The next group of programs is available for operation on mainframe computers where the base operating program is Matlab. Matlab is designed for solving large groups of complex equations, and a number of models of the activated sludge programs are available on Matlab. Matlab is not for everyone and is primarily a research tool. A single site license for Matlab costs in excess of $2500 per year.

The last group of programs is commercially available. They are made by several different groups. The principal programs are BIOWIN, GPS-X, SIMBA, STOAT, and WEST. All models have good graphical interfaces. Some are slightly easier to use than others. Depending on the desires and personal tastes of the user, one particular program may suit a user need better than others. The pricing structure and the modeling capabilities are somewhat similar but differ in outcome and computation time, graphical interface, and ease of use. All products allow the user to develop plant configurations of any type or size and readily make changes in the configuration.

Some programs offer a variety of models and configurations; others offer only a single model with adapted differences for enhanced performance. The real advantage of dynamic modeling lies in its ability to model an entire plant and show the designer or operator how the system operates. In all programs, it is possible to come up with an almost infinite variety of configurations and plant arrangements. For example, there are at least six dynamic models of clarifiers. Some models are only for primary clarifiers, others are for secondary clarifiers. When combined with the many variants of activated sludge and other process models, there is almost an infinite variety of plant configurations one can develop for modeling an activated sludge process before one has to consider tank and reactor dynamics and before one considers the various control systems and parameters. The result can often be quite overwhelming because the models construct and then solve more than 50 differential equations for a simple plant configuration.

The differences in the software are qualitative: power, flexibility, user base, development, features, and pricing structure. There is also a trend toward using a simulator software as a supervisory control and data acquisition system (SCADA), but, at this time, only WEST offers that capability.

The author of this article is affiliated with HEMMIS, the producer of WEST software, and, accordingly, all descriptions of competitors could be construed as commercial criticism or endorsements, but are very general in nature. Nothing should be construed as either an endorsement or as a criticism of a particular software product.

BIOWIN® is produced by EnviroSim Associates in Canada. The web address is http://www.envirosim.com/products/. It is very popular and has a reasonable interface.

GPS-X has a very good graphical icon interface, and it is reasonable to work with. It is produced by Hydromantis in Toronto, Canada. The Web address is http://www.hydromantis.com.

SIMBA is a German product produced by Ifak System GmbH, Schleinufer 11, D-39104 Magdeburg, Germany. SIMBA 4.0 is shipped together with the Matlab®/Simulink™ software of MathWorks Inc.; it runs under the Windows 9x, 2000, and NT 4.0 operating systems.

STOAT is produced by WRc Plc Ltd. in England. It is a very intuitive program, and one can quickly set up a configuration, but the targets on the connecting graphical elements are a bit small. The completed program creates an output to an Excel® file, and all the calculations are done at one time. The program is mathematically rigorous and good to use. It was designed by engineers, so it is quite intuitive, and the documentation is very good. Because it does the computation at one time, it is relatively quick compared with other programs. The Internet link for information on the WRc program is http://www.wrcplc.co.uk/asp/wastewater_tmnt.asp.

WEST® is the product of HEMMIS in Kortrijk, Belgium. It is an extremely rigorous and powerful program and has good graphics. Several features of WEST® include the ability to adjust the modeling parameters (such as oxygen uptake rate) on the fly; to adjust flow, control, and other parameters during the run; and instantaneously see the output. The program has a wide variety of models and options, including all the IWA models, plus others that have been rigorously tested by the Biomath Department at the University of Ghent. On the HEMMIS website, there is a free download of a sample of WEST®. The website is http://www.hemmis.com.

A word about pricing. Prices vary significantly with user needs. Base prices start at somewhere around $3,000 and go up to about $20,000 or higher depending on the user needs and the package. The cost of an adequate system for modeling a variety of conditions is between $10,000 and $15,000. Do not be fooled by different marketing offers, and make sure that the program you buy has the features you need and want. Some sites provide a simple matrix of programs at a modest to low price, and then if you want more complexity and power, you have to buy advanced models at a much higher price. Plan on a $10,000–$22,000 price tag for a complete system.

IWA

In the software packages discussed, all models have been developed by, or are based on, work performed by the International Water Association (formerly the International Water Quality Association) in London. The oldest of the models is Activated Sludge Model Number 1 (ASM1). The model formulation and description are presented by the IWA, and anyone who wishes can take the documentation and prepare an individual version of the model. If one is planning on doing any modeling, it is imperative that one has the IWA model documentation.

The available models are:

Activated Sludge Model Number 1 (ASM1), the oldest model and the most widely accepted. It allows computation of nitrification and denitrification.

Activated Sludge Model Numbers 2 and 2d. These models are similar but not identical to ASM1. The models were developed to consider nitrification, denitrification, and phosphorous uptake and release by the cells. The difference between Model 2 and Model 2d is that ASM2d allows for chemical precipitation and removal as well as for uptake and removal by the biomass.

Activated Sludge Model Number 3 is a BOD-based model that differs in formulation from the other three models. It has been tested and produces reliable results, but many of the experienced modelers do not like the general formulation of the model, and to date, it has not gained wide acceptance. It is handy because it is a BOD-based model, whereas all other models are COD based. In the United States, where the standards are BOD based, it is a bit easier to use because the model outputs can be used directly and do not have to be converted from COD back into BOD.

Anaerobic Digestion Model Number 1 is the newest of the IWA models. It has been released relatively recently and has not yet gained wide acceptance.

OTHER DYNAMIC MODELS AVAILABLE

This discussion has been primarily about modeling an entire plant, so a brief digression is in order. Most of the IWA models deal with the aeration portion of the plant and do not deal with the clarifier or other portions of the plant. Of specific interest are the associated or "ancillary" programs that often make up a plant configuration. These include the selection of primary and secondary clarifiers, sludge thickeners, dissolved air flotation units, centrifuges, filters, filter presses, disinfection units, and various types of headworks such as degritters and equalization systems. A word about these models and their characterization is necessary.

First, degritters and some headworks devices are nice showy pieces for modeling but do not really affect the plant modeling effort very greatly because we, as engineers and scientists, often do not characterize the grit and sand loads in the wastewater stream for two reasons. First, grit and sand often fall to the bottom of a pipe and are not sampled or characterized. Second, they are not characterized in models because they represent inert solids and the driving models for wastewater treatment are mostly COD based, not TSS based. In many systems, they represent a distraction as they add some numbers but affect the outcome by less than 5%.

Sand does not have any measurable COD, and most degritters are designed to remove particles of sand and rocks. The removal is proportional to the difference in settling velocities by Stokes' law and is proportional to the difference between the fluid and the particle density. Organic particles often have a specific gravity of 1.01–1.15; sand and rock have SG of 2.65. So, a model designed to remove sand may look impressive, but it provides only a minimal removal of the organic loading for the dynamic modeling of the wastewater treatment plant.

Clarifier models are for primary or secondary treatment. To some extent, they may be the same model with slightly different applications or literature on which the model was built. For example, the Lessard–Beck primary clarifier model (1) is similar in many aspects to the Takacs secondary clarifier model (2) and the Mars–Libelli clarifier model. The similarities include the manner in which the mass balance in the clarifier is analyzed, the location of the inlet port, and the approach to settling versus upward bulk flow. The clarifier is analyzed in ten layers in all models, and the mass balance is taken across the layers. The solids settle against the rising bulk velocity of the fluid and, as they reach the lower levels of the clarifier, depending on the model used, they collect and compress and generally follow the research work of Vesilind on sludge accumulation and compression (3).

When the sludge reaches the bottom of the clarifier, it is drawn off by different methods. Lessard–Beck uses a scour coefficient for primary clarifiers that could just as easily be adapted to a secondary clarifier. Mars–Libelli uses a slightly different configuration, and Takacs still a different configuration for sludge withdrawal and thickening. The point is that the model assumptions do make a difference in behavior. Where thickening behavior is to be investigated, the Mars–Libelli model is often preferred. For general behavior, the Takacs model is preferred, and for primary treatment, use the Lessard–Beck Model.

Where sludge thickening and centrifugal processing are involved, it is well to look carefully at the equations. The modeling assumptions often come down to a complex set of equations and elaborate calculations with a very interesting simplifying assumption. For example, several of the dissolved air flotation system and centrifugal models look very complex, but finally resolve down to a "stickiness factor" or a collection or efficiency factor, often experimentally determined, which controls the degree of separation. After all the trouble in the calculations, one finally has a simple constant on which the removal hangs, and that can be simulated by a single line equation or a simple clarifier model without any difficulty.

COD, BOD, and Modeling

BOD is a common but useless parameter. Unfortunately, we use it for much of our historical data and much of the permit work in the United States and elsewhere. It is useless because it is so unreliable. A quick check of Standard Methods indicates that the BOD test has a variability of around 20% at a 200 mg/L level. At lower levels, it is so unreliable that the issue of using it for permits is laughable, which makes for bad control and even worse permitting. Single-digit BOD permit values may be unrealistic, but, unfortunately, they are finding their way into the permit structure in some watersheds.

Another reason that BOD is useless as a control parameter is that the test takes too long for the results. Given that most tests take 5 days or 20 days (ultimate BOD), we still have to adjust the BOD test to prevent oxidation of ammonia and make sure that the seed is acclimatized. Even under extreme conditions, the retention time of wastewater in a treatment plant, except for very large lagoons, is seldom over 48 hours and is often between 4 and 24 hours; a standard activated sludge plant takes 12 hours.

As a control or performance parameter, it is also useless. Hoover, Jacewizc, and Porges made this appropriate comment about the BOD test in 1953 (4):

> The BOD test is paradoxical. It is the basis of all regulatory actions and is used routinely in almost all control and research studies on sewage and industrial waste treatment. It has been the subject of a tremendous amount of research, yet, no one appears to consider it adequately understood or well adapted to his own work.

Question: How do you control a plant when you can only find out what happened 5 days later?

Answer: You cannot, which is one reason why many plants are not operated but are maintained and marginally operated. There is a fundamental lack of understanding and appreciation of the basics underlying the operation and the value and the role of the operator. When an operator only finds out what happened to his plant a week later, there is no positive feedback. Dissolved oxygen and ammonia and VSS/TSS are more important control parameters. But we cannot run a plant intelligently on those parameters alone.

There are many other reasons for a lack of operation as well, but fundamentally underlying all of them is the idea that we cannot control the process, and it is a series of operator experience and guesses that get the plant through rather than any intelligent control decisions. About the only reason that an operator will get out of the air-conditioned office on a hot Friday afternoon is if the air conditioner breaks, the plant is in crisis, or the office catches fire. And who can blame them. We have set up our systems with so much slop that a typical design has between 30% and 50% excess capacity before any allowance for expansion or population growth (5).

This discussion is about how to get better process control and how to set up and evaluate a plant for this control and evaluation.

Relating BOD and COD

Both BOD and COD are measures of the amount of carbon in wastewater. There are two types of COD in use, permanganate and dichromate. Permanganate is a weaker oxidizer and gives lower results than dichromate COD. The U.S. standard is dichromate oxidation. If you apply European or foreign COD data, you have to make sure that you know the basis for the test.

For many municipal wastewaters, the relationships in Table 1 apply (6).

Table 1. Various Indicator Strengths

	Concentration		
	Weak	Medium	Strong
TSS	350	720	1200
TDS	250	500	850
Fixed TDS	145	300	525
Volatile TDS	105	200	325
BOD-5	110	220	400
COD	250	500	1000
TOC	80	160	290
TKN	20	40	85
NH_3	12	25	50
P-Total	4	8	15
Organic P	1	3	5
Inorganic P	3	5	10

The BOD does not measure ammonia uptake because we inhibit the test to prevent ammonia demand. COD does not measure ammonia either.

Various sources have estimated the relationships between COD and BOD. The overall range is that the BOD is between 40% and 60% of the COD. In Table 1, the three ratios are approximately 40%. A rough figure of BOD = 50% COD is not a bad estimate and depends on whose text is used. A standard figure of about 50% has often been employed. Figure 1, from Eckenfelder (7), would seem to contradict that, but given the variability of the BOD test, the 50% figure holds reasonably well. If one is considering the effluent BOD after biological treatment, then it is about 25% of the COD.

For modeling purposes, however, BOD is generally not used because it does not represent what is happening in the reactor tanks, it is not a consistent parameter, and the

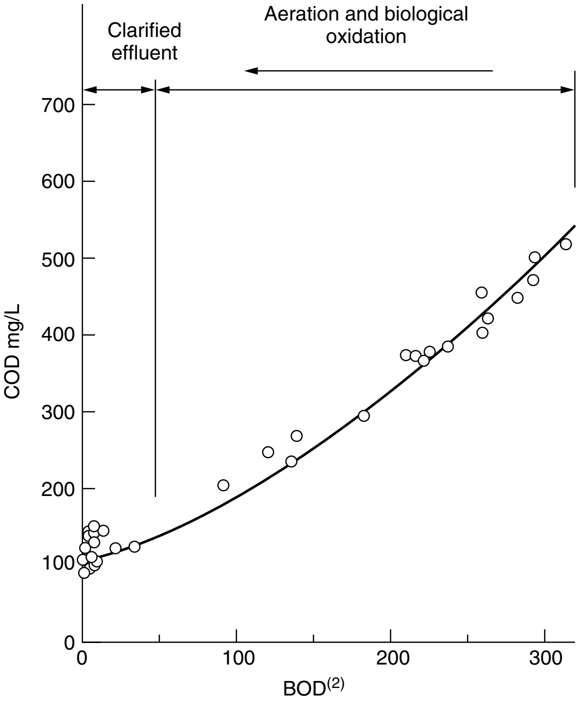

Figure 1. Relationship between COD and BOD (7).

Table 2. Various Indicator Strengths

Ratio	Low	Typical	High
COD/BOD	1.5–2.0	2.0–2.5	2.5–3.5
COT/TKN	6–8	8–12	12–16
COT/Tot. P	30–35	35–45	45–60
BOT/TKN	3–4	4–6	6–8
BOD/Tot. P	10–15	15–20	20–30
VSS/SS	0.4–0.6	0.6–0.8	0.8–0.9
COD/TOC	2–2.5	2.5–3	3–3.5

reproducibility of the test is uncertain. It does not make a good basis for modeling.

Additional Guidance on BOD/COD Relationships

Table 2 gives typical values for BOD/COD and other relationships in wastewaters. A high COD/BOD ratio indicates that organic matter is difficult to degrade. A high COD/TKN ratio indicates a waste that may require denitrification. A high VSS/SS ratio indicates a high organic matter relationship in the suspended materials (8).

MODELING THE BIOLOGICAL PROCESS

In the material that follows, we look briefly at the Monod equation and some of the mass balances around a typical activated sludge system. Then we continue briefly through the model development associated with the Peterson Matrix—which is used by the IWA in presenting and describing the mathematical development of the various models. Finally, we look at some of the balances around an activated sludge plant and consider the variables in the ASM1- Activated Sludge Model Number 1, which handles both nitrification and denitrification. The notation used and the pictures are taken from some of the modeling documents associated with HEMMIS' WEST® modeling platform and software and are used by permission.

Biological Growth Occurs According to the Monod Equation

The Monod equation is

$$\mu = (\lambda S)/(K_s + S)$$

where μ = specific growth rate coefficient
λ = maximum growth rate coefficient, which occurs at 0.5 μ_{max}
S = concentration of limiting nutrient: BOD, COD, TOC, etc.

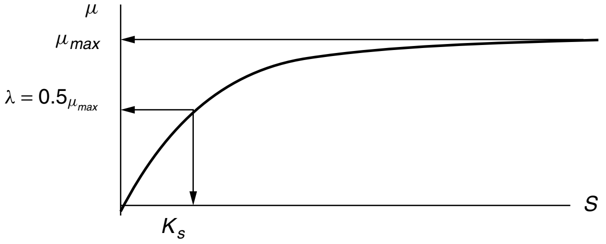

Figure 2. Graph of Monod equation.

K_s = Monod coefficient, also called the half-saturation coefficient because it corresponds to the concentration at which μ is one-half of its maximum, which can be seen from the Monod equation by setting S equal to K_s. K_s occurs at $\lambda = 0.5\ \mu_{max}$ (Fig. 2).

The curve is a plot of specific growth rate coefficient versus concentration of growth-limiting substrate when there is no inhibition.

$$\text{Organics} + \text{Bacterial} + \text{Nutrients} + \text{Oxygen} \longrightarrow \text{New Bacteria} + CO_2 + H_2O + \text{Residual organics} + \text{Inorganics}$$

$$\text{Rate of bacterial growth} = Rg = \mu X$$

where X is the microorganism concentration in mass/volume and μ = specific growth rate per unit of time.

$$\text{Cell Yield Coefficient} = Y_{obs} = \frac{-R_g}{R_{su}}$$

where Y_{obs} = observed yield coefficient, R_{su} = substrate utilization rate, and R_g = cell growth rate.

If we are looking only at the carbon variable, we get the following relationships:

$$Q = \text{Influent} = \text{Effluent} - \text{waste} = Q - Q_w + Q_w$$

= or if we define a new variable, Q_e, as the effluent, then

$$Q = Q_e + Q_w$$

For convenience, define the flow between the aeration tank and the clarifier as Q_2 with variable X_2. X_2 representing the combined flow of MLSS out of the tank and S_2 representing the substrate in the tank.

COD Relationships in Modeling

The models for activated sludge and biological processes use COD. The following are the relationships of the variables, and they will walk you through the formulation of the basics of the activated sludge models (ASMs).

In this example, we will first look at the carbon variable and then at the fractionation of the wastewater for treatment.

The basic activated sludge plant looks something like the schematic shown in Fig. 3.

Starting with a water balance, $Q_1 = Q_3 + Q_w$.

Running a mass balance around the system, we get

$$Q_1C_1 - r_{vs}V_2 = Q_3C_3 + Q_wC_r$$

where r_{vs} is the reaction rate for substrate utilization.

Note that in the above equation, no specific definitions are implied, so C can be NO_2, NH_3, COD, or anything else. However, one must define the unit of volume as well as the reaction rate, which means that the reaction rate can be r_{vs} or r_{xs} together with the unit of the volume V_2 and for r_{sx}, the activated sludge concentration X_2.

The units must be internally consistent. The activated sludge concentration X_2 can be measured in kg of SS/m^3,

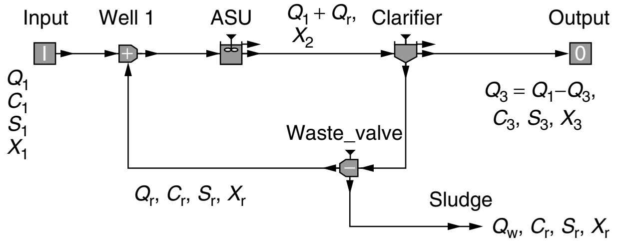

Figure 3. Activated sludge plant. Plant model was created using graphics from WEST® Software.

kg of VSS/m^3, or kg of COD/m^3, but the units must be consistent in the numerator and denominator.

Another way of looking at the mass balance is the following. The materials must be hydrolyzed before they can be accessed by the bacteria. So if you have some substrate such as BOD or COD, it cannot be used until it is solubilized, which means that the basic balance will look like the following when we consider the same mass balance as in Fig. 3, only now we have added the growth and hydrolysis terms to the equations:

$$\text{input} + \text{hydrolysis} + \text{growth} = \text{effluent}$$

$$\text{Input} + \text{sludge return} + \text{growth}$$

$$Q_1 S_{s1} + K_h * X_{S2} V_2 + [-(1/Y)]\mu[\mathrm{Ss2}/(S_{sw} + K_s)]$$
$$[S_{O_2}/(K_{sO_2} + S_{O_2})] X_{BH} V_2 = Q_3 S_3 + C_r$$

(note that the growth term removes the substrate).

X_{BH} is the heterotrophic biomass and S_{O_2} is the oxygen concentration, etc as shown below.

We can also add other terms to the equations to compensate for the oxygen and substrate terms, and those are most conveniently multipliers expressed in the form of the Monod equation: $S/(S+K)$. A few of them are shown below, and you will note that a few of them act as "switches" because when S goes below a specific value, the term tends toward zero, and the entire multiplier falls out of the balance equation.

Some of those terms are:

Now the Matrix:

Component	S_s	X_s	X_I	X_{BH}	S_{O_2}	Reaction Rate r_v
Process						
Aerobic heterotrophic growth	$-(1/Y)$			1	$(1-Y)/Y$	$\mu[S_s/(S_s+K_s)]*$ $[S_{O_2}/(K_{sO_2}+S_{O_2})]$ X_{BH}
Heterotrophic decay		$1-f_{XB}$	f_{XB}	-1		$b_H * X_{BH}$
Hydrolysis	1	-1				$K_h * X_s$
Units			kg COD/m^3			
	Easily degraded organic matter	Slowly degradable organic matter	Inert suspended organic matter	Heterotrophic biomass	Oxygen	

This is the start of formulating the equations for most of the activated sludge models developed by the IWA.

How to Use the Matrix and the Equations. Given the plant depicted in Fig. 3 and an effluent concentration of 10 mg/L COD (about 20 mg/L BOD). Arbitrarily, we use a flow rate of 5 million gallons per day which is a Q of 3.785 L/Gal*5 MGD= 18.925 M L/D = 18925 m^3/D at a strength of 500 mg/L (= 0.5 kg COD (S)/m^3. The plant has no recycle. Find the aeration tank volume.

Moreover, we have the following information provided: r_{xs} = 3 kg COD (S)/kg(B) COD 3 kg of substrate consumed per kg of bacteria, and the yield for substrate is 0.4 g COD(B)/kg COD (S) – 0.4 kg COD of bacteria per kg of substrate consumed.

Look at the equations above, and find the necessary volume for the tank:

$$\mathrm{V} = (Q_1 C_1 - Q_3 C_3)/(r_x X_b)$$

and

$$X_b = Y * (C_1 - C_3)$$
$$X = 0.4(500 - 10) = 0.4 \times 490 = 196.0$$

and

$$V = (Q_1 C_1 - Q_3 C_3)/(r_x X_b)$$
$$= (18925 \times 500 - 18925 \times 10)/(3 \times 196)$$
$$= 15770.83 \text{ cubic meters}$$

Now if the plant has recycle, $Q_w > 0$.

We can go on and look at the overall process doing mass balances in any of a number of ways and at various points. The critical element is to take the internal tank reactions and the recycle rate into consideration.

If we performed a mass balance around the aeration tank and use that to calculate the tank effluent concentration, we get the following:

$$X_1 C_1 + X_r C_r + (Q_1 + Q_r)(C_{\mathrm{ATIn}} - C_{\mathrm{ATOut}})$$
$$Y = (Q_1 + Q_4) * X_2$$

Obviously, that requires a bit more information.

The overall substrate removal rate is

$$r = (\mu/Y)(S_2/(S_2 + K_s)(S_{O_2}/(S_{O_2} + K_{sO_2}) * X_2$$

where S_2 is the concentration of organic matter in the aeration tank.

The mass balance for the entire plant is

$$\text{Input} + \text{hydrolyzed} - \text{removed} = \text{Output}$$
$$Q_1 * S_1 + r_x V_2 v_{xs} - r_{vs} V_2 = Q_3 S_3$$

where v_{xs} is the hydrolysis coefficient.

All the above is for a simple set of reactions, but it forms the basics for modeling.

The IWA models currently in use are ASM1, ASM2, ASM2d, and ASM3. ASM1 is the oldest, dating from about 1987, and ASM3 is the newest. The problem with ASM1 is that it is difficult to fractionate the influent in the manner required for the model without a lot of trouble. ASM1 and ASM3 can be used to model nitrate removal.

ASM2 and 2d are written with the phosphorous variable in mind. They are rewritten rather to consider the fact that activated sludge is comprised of cellular biomass that has the ability to store and use phosphorous. ASM2d is specifically for phosphorous removal with the addition of precipitates (metal hydroxides).

ASM3 is a BOD-based model, and it is somewhat easier to use but still requires a basic understanding of how the model works and the kinetics. ASM3 is not as widely used because it is newer and because of the model formulation with regard to cellular internal storage.

The ASM models are written in the same matrix notation used above in the table, and in the simplest model, ASM1, there are eight rate equations: aerobic growth of heterotrophs, anoxic growth of heterotrophs, aerobic growth of autotrophs, anoxic growth of autotrophs, decay of heterotrophs, decay of autotrophs, ammonification of soluble organic nitrogen, hydrolysis of entrapped organics, and hydrolysis of entrapped organic nitrogen. So, eight equations that have 13 variables all expressed in matrix form.

The use of the words heterotroph and autotroph refers to the wastewater bacteria that can use exterior or interior sources of carbon to oxidize the wastewater.

Heterotrophs are assumed to be the utility organisms, capable of doing a wide variety of things in a biomass system. They grow aerobically, anoxically, and may be active in anaerobic fermentation. They are responsible for hydrolysis of particulate substrates and can use all degradable organic substrates under all conditions.

Autotrophs are nitrifying organisms that are responsible for nitrification. They are obligate aerobes, classified as chemo-litho-autotrophs, and are responsible for ammonia oxidation to nitrate (*Nitrosomonas* and *Nitrobacter*).

The variables and their notation in WEST are as follows:

For ASM1

Note that the IWA model description uses almost identical notation, but uses subscripts: thus S_i would be expressed by the IWA rather than the S_I notation used here

Name	Description
H2O	Water
S_I	Inert soluble matter
S_S	Readily biodegradable matter
S_O	Dissolved oxygen
S_NO	Nitrate and nitrite
S_NH	Free and ionized ammonia
S_ND	Soluble biodegradable organic nitrogen
S_ALK	Alkalinity
X_I	Inert particulate matter
X_S	Slowly biodegradable matter
X_BH	Heterotrophic biomass
X_BA	Autotrophic biomass
X_P	Particulate products resulting from biomass decay
X_ND	Particulate biodegradable organic nitrogen

These components are also used to characterize the influent of the wastewater treatment plant.

Additionally, the following parameters are also required for specifying the state variables in the modeling process.

Variable	Description	Units
Y_H	Yield For heterotrophic biomass	g COD/g COD
i_XB	Mass of nitrogen per mass of COD in biomass	g N/g COD
Y_A	Yield for autotrophic biomass	g COD/g N
f_P	Fraction of biomass converted to inert matter	—
i_XP	Mass of nitrogen per mass of COD in products formed	g N/g COD
K_S	Half-saturation coefficient for heterotrophic biomass	g COD/m^3
K_OH	Oxygen half-saturation coefficient for heterotrophic biomass	g O_2/m^3
K_NO	Nitrate half-saturation coefficient for denitrifying heterotrophic biomass	g NO_3-N/m^3
b_H	Decay coefficient for heterotrophic biomass	1/day
mu_H	Maximum specific growth rate for heterotrophic biomass	1/day
n_g	Correction factor for anoxic growth of heterotrophs	—
K_OA	Oxygen half-saturation coefficient for autotrophic biomass	g O_2/m^3
K_NH	Ammonia half-saturation coefficient for autotrophic biomass	g NH_3-N/m^3
b_A	Decay coefficient for autotrophic biomass	1/day
mu_A	Maximum specific growth rate for autotrophic biomass	1/day
k_a	Maximum specific ammonification rate	m^3/(g COD.d)
K_X	Half saturation coefficient for hydrolysis of slowly biodegradable substrate	g COD/g COD
k_h	Maximum specific hydrolysis rate	g COD/(g COD.d)
n_h	Correction factor for anoxic hydrolysis	—
-Kla	Oxygen transfer coefficient	1/day
S_O_Sat	Oxygen saturation concentration	g/m^3

Y_H and Y_A must be larger then zero ($Y\_H > 0$ and $Y\_A > 0$).

Fortunately, many of these values are published in the IWA Model and are constant for many waste streams. The documentation considers published values plus ranges of these values in the models.

In the next article on plant modeling and hydraulics, we consider some of the challenges and opportunities associated with setting up a plant model.

PRACTICAL APPLICATIONS OF WASTEWATER MODELING AND TREATMENT PLANT DESIGN

David L. Russell
Global Environmental
Operations, Inc.
Lilburn, Georgia

INTRODUCTION

In this article, we consider some of the specifics for setting up a model and plant hydraulics, and some of the practical considerations and limitations of modeling.

NOTES ON PLANT MODELING

The following notes on setting up a mathematical model of a wastewater treatment plant were prepared as a part of a training document for using WEST software. The proprietary parts have been removed, and the generic suggestions and ideas have been incorporated as a trial procedure based on personal experience. The procedure is designed for an ASM 1 model.

By following the steps outlined below, you will be able to set up and run a model and either match existing conditions or proposed conditions:

1. Information gathering
2. Model selection
3. Reactor hydraulics
4. Laboratory and other data organization
5. Flow sheet setup & model organization in WEST—the WEST C
6. Model compilation and setup—the WEST-S
7. Input and output file preparation
8. Initialization of model parameters and first runs
9. Parameter adjustments

Step 1: Information Gathering

Your objective is to make a model that represents a form of reality. That reality may represent either the dynamic behavior of a new facility or the dynamic behavior of an existing facility. The purposes are predictive and or historical. In the first case, you may want to find out how the facility will work and whether a specific design is adequate. In the second case, you may be looking to duplicate the performance of a real plant by preparing a model and matching the data from the model to the data from the real plant. In this latter instance, you can then use the data to predict future performance or investigate plant modifications.

Modeling is a very good but imperfect process. In the process of gathering information about a facility, you may never have enough information to satisfy your requirements. It will be easier to make assumptions about a new facility than to model the behavior of an existing one.

When you are dealing with an existing facility, you will almost never have enough information about the facility to satisfy your model and requirements. You will have to make some intelligent and reasonable guesses at certain things. You also may never know all that you want about a particular facility, but at the same time, you may know more about the facility than you ever dreamed of knowing because the data are often in the wrong place or of the wrong type.

This is not quite an "abandon all hope—ye who enter here" type warning, but rather a practical admission that you will be trying to reconstruct an event or make estimates of what may be happening with a model in an imperfect world.

You will need:

- An initial idea of which model you might want to use and the requirements of that model.
- Plant drawings and flow sheets.
- Aerator sizes and capacities.
- Physical dimensions of units.
- Maximum flow to each unit, which is particularly important in pumped flow where you have maximum capacities for pumps. Locations include clarifier underflow, and in nitrification plants, the return rates or recirculation rates for the system.
- Chemical data on the plant:
  - Influent data
  - Effluent data
  - Water quality data and effluent requirements
  - Internal plant operating records and logs
  - Chemicals added and operating set points

Most of the models are based on COD and most of the data you have are BOD. You may have to go back into the laboratory for more information to establish the necessary correlations to create the partition for the influent file.

Depending on how the model is established, you may or may not need additional data. If there is a system to enable you to transform your data into corresponding data for the model, it may be used after examination and careful consideration. One of the problems you may encounter is that the conversion routine makes some arbitrary decisions about the relationship between BOD and COD and the other parameters, and so you may have to consider that in the setup of the model. Also, the relationships (parameters and fractions) may change over time and with temperature and other influences. The program does not make those changes.

If you are working on a new design, you can make many choices about the type and kind of data you use.

Depending on the need for accuracy and performance, you may have to go into the laboratory and reproduce oxygen uptake rate (OUR) data, as well as yield and specific growth data, and also data for settling characteristics. If you are not going to be reproducing data from an existing plant, the effort in gathering detailed data may not be worth the trouble or expense.

A major caution should be raised here. If you are seeking to model any type of industrial waste, you probably should perform some minimum characteristics testing and should include some pilot plant testing as well as testing for settling characteristics because toxicity and hindered settling can often be associated with industrial waste treatment systems.

Step 2: Model Selection

Table 1 lists the input variables for each of the three principal activated sludge models, ASM1, ASM2d, and ASM3.

Model ASM1 is the oldest and has the most history behind it. It can be used for nitrogen removal in BNR plants. ASM2 and ASM2d were formulated later to consider the specific ability of the cell to store food materials. The ASM2d is formulated to allow the addition of metal hydroxides for phosphorous precipitation.

The ASM3 model is the newest, and many in the modeling community do not like it because of its formulation. They have indicated that the lumping of wastewater fractions and overall formulation of the model away from observed cellular behavior is objectionable. The difference in model formulation between ASM1 and ASM3 is substantial. ASM3 was formulated to address some of the deficiencies and difficulties with ASM1 resulting from assignment of the COD fractions of the influent. (See the discussion on COD and BOD and preparation of the influent file.)

Quoting and paraphrasing from the IWA description of ASM3 and ASM1 differences:

- ASM1 does not include kinetic expressions that can deal with the nitrogen and alkalinity limitations of heterotrophic organisms. The result is that the computer code cannot be based on the original form of ASM1, where a negative concentration of ammonia may occur under certain circumstances.
- ASM1 includes biodegradable soluble and particulate organic nitrogen as model compounds. These cannot be easily measured.
- ASM1 differentiates inert particulate organic material depending on its origin, influent or biomass decay, but it is impossible to differentiate these two fractions in reality.
- ASM1, ASM2, and AMS3 do not directly predict the MLSS or TSS concentration or the BOD concentration in a waste stream.
- In ASM1, hydrolysis has a dominating effect on predicting oxygen consumption and denitrification by heterotrophs. In reality, the process contains a number of coupled reactions.

ASM3 is a different model formulation all together.

An example of the differences among the models is shown in Table 1. These are the listed variables in the ASM1, ASM2d, and ASM3 models (not the parameters) expressed in the notation used in the WEST modeling platform.

Before we leave model selection, a couple of points are particularly important.

- The models do not define the conventional parameters as conventionally measured by the wastewater treatment industry. Everything is related to COD, and moving backward and forward through COD may introduce errors in modeling that are both frustrating and easily made.
- In most experiments, the researcher is often interested in modeling reductions in BOD, TSS, ammonia, phosphorous, and, perhaps, MLSS and COD. MLSS is often a control parameter for plant operations. The problem is that the values for many of these parameters are 'reconstructed' or measured indirectly from the COD. Ammonia and phosphorous are often directly modeled and measured, but MLSS, TSS, and BOD are calculated from COD data, and they can be difficult to obtain for control purposes.

In a recent modeling experiment, this point was again driven home by the frustration of trying to model conventional parameters. The experimenter was trying to model TSS accumulation in a membrane bioreactor system and was being frustrated by the model's internal composition.

The ASM2 model (and the other models as well) has a complex definition of TSS. The definition of TSS includes part of the soluble and insoluble fractions of the particulates; part of the heterotrophic and autotrophic bacterial mass; and part of the internal storage product of phosphorous accumulating organisms, metal phosphates, and polyphosphates. Each factor is multiplied by partitioning coefficients, and a change in heterotrophic concentration or other parameters may influence the measurement of TSS. In the other models, the definition of TSS is somewhat less complex and more easily measured.

Table 1. Variables in ASM Models

ASM1 Variables		ASM2d Variables		ASM3 Variables	
Name	Description	Name	Description	Name	Description
H2O	Water	H2O	Water	H2O	Water
S_I	Inert soluble matter	S_I	Inert soluble matter	S_I	Inert soluble organic matter
S_S	Readily biodegradable matter	S_O	Dissolved oxygen		
		S_N2	N_2	S_S	Readily biodegradable organic substrate
S_O	Dissolved oxygen	S_F	Fermentable, readily biodegradable organic matter		
S_NO	Nitrate and nitrite			S_O	Dissolved oxygen
S_NH	Ionized and un-ionized ammonia			S_NH	Ammonia
		S_A	Fermentation products considered to be acetate	S_N2	Dinitrogen
S_ND	Soluble biodegradable organic nitrogen			S_NO	Nitrate
				S_ALK	Alkalinity
S_ALK	Alkalinity	S_NO	NO_2^- and NO_3^- nitrogen	X_I	Inert particulate organic matter
X_I	Inert particulate matter				
X_S	Slowly biodegradable matter	S_PO	Inorganic soluble phosphorus, primarily orthophosphates	X_S	Slowly biodegradable substrates
X_BH	Heterotrophic biomass			X_H	Heterotrophic organisms
X_BA	Autotrophic biomass	S_NH	Ammonium nitrogen, NH_4-N	X_STO	Cell internal storage product of heterotrophic organisms
X_P	Particulate products resulting from biomass decay	S_ALK	Alkalinity of the wastewater	X_A	Nitrifying organisms
X_ND	Particulate biodegradable organic nitrogen	X_I	Inert particulate matter	X_TS	Total suspended solids
		X_S	Slowly biodegradable matter		
		X_H	Heterotrophic biomass		
		X_PAO	Phosphate accumulating organisms: PAO		
		X_PP	Polyphosphate		
		X_PHA	A cell internal storage product of phosphorus accumulating organisms		
		X_AUT	Autotrophic biomass		
		X_TSS	Total suspended solids TSS		
		X_MeOH	Metal hydroxides		
		X_MeP	Metal phosphate ($MePO_4$)		

This is also true of BOD. In some of the models, BOD is calculated through the COD where it factors into the ultimate BOD, and then to the 5-day BOD. Needless to say, the conversion factors play a large part in the conversion. Another example is that the COD to BOD conversion formula is different for the influent and effluent parameters.

- At least one company, WRc, Ltd., in England, has a model that is formulated strictly on BOD (STOAT).
- The ASM3 model is still COD based, but it is a lot easier to use than ASM1 and ASM2. The ASM3 model has its limits, discussed above, but it is generally more forgiving, if, arguably, less accurate than the ASM1 and ASM2 models.

Step 3: Reactor Hydraulics

Reactor hydraulics is an extremely important consideration in modeling. Reactor hydraulics are critical in determining both the type of model used and the relationships involved in the plant design. For complete mix plants, the concentration of solids in the aeration tank is the same at both influent and effluent, or $X_{\text{in}} = X_{\text{out}}$.

But for a plug flow plant, the concentration of X varies through the aeration tank. The characteristics of the concentration in the effluent depend on the reactions and the tank hydraulics.

The computer models of activated sludge systems use continually stirred tank reactors (CSTRs). The ideal flow pattern in a long narrow tank approaches plug flow. The reactor flow patterns need to be addressed in the model so that the hydraulics of the model match the hydraulics of the wastewater tankage.

The subjects of reactor hydraulics and dispersion are beyond the scope of this article but need to be considered to ensure adequate hydraulic modeling for the plant.

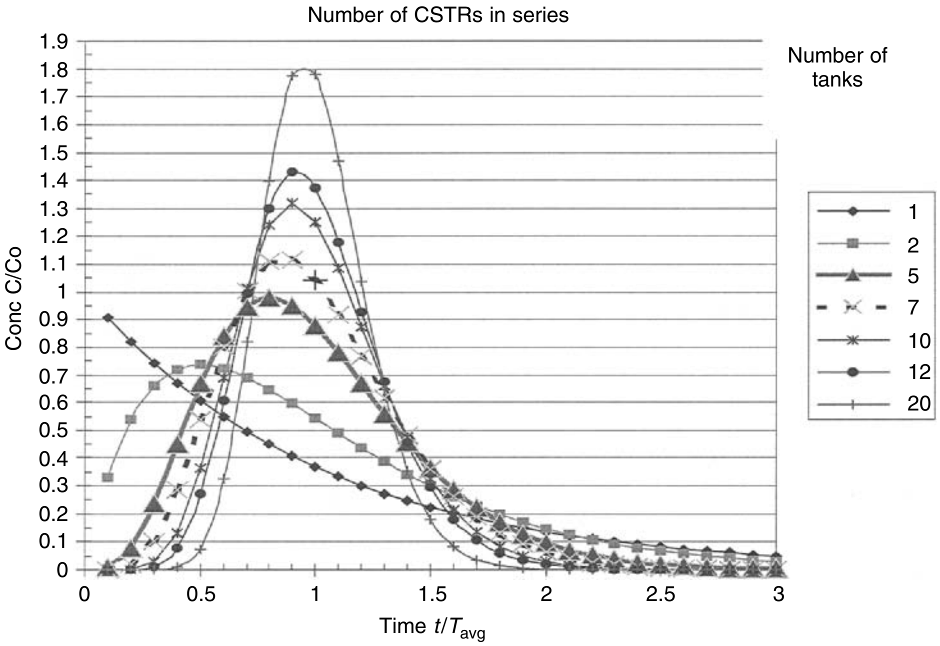

Figure 1. Changes in concentration with time.

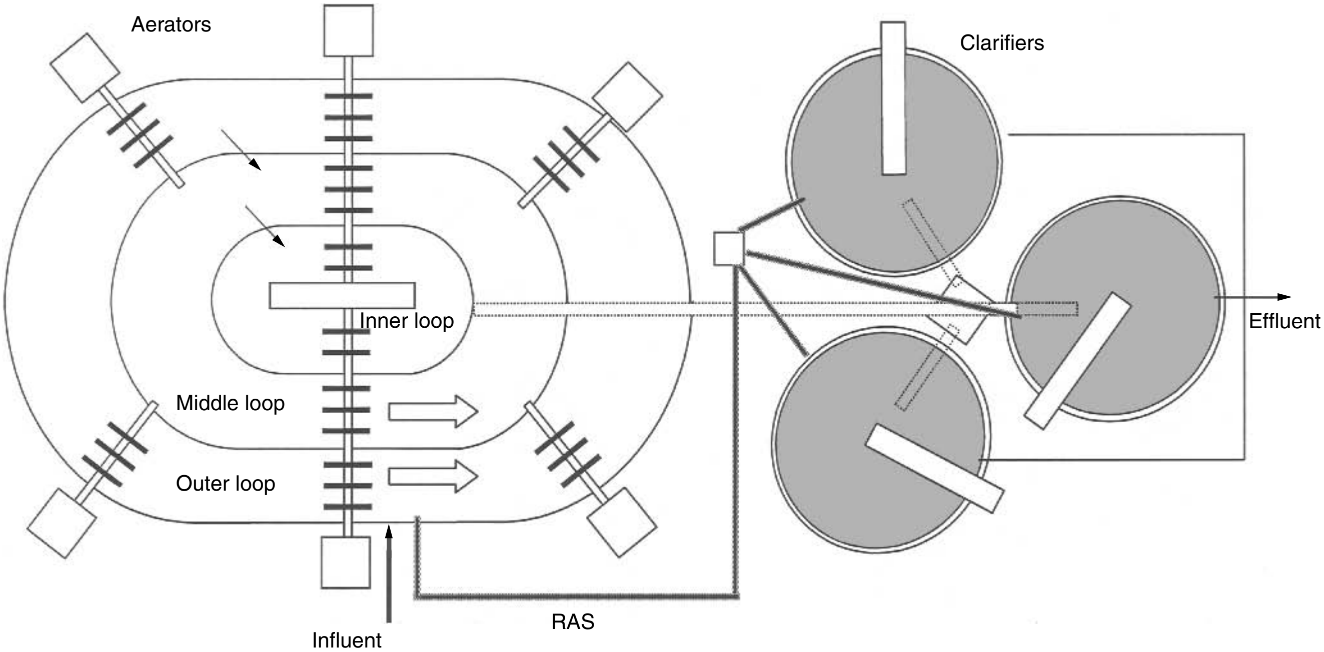

Figure 2. The general configuration of the ORBAL followed by configuration in WEST.

The relationship between the number of CSTRs in series and the concentration is shown in Fig. 1.

The difference between a true plug flow reactor and a true complete mix reactor is defined in terms of the axial turbulent diffusion coefficient, average flow velocity, length of the reactor, and the inverse of the Peclet number, or D/UL. The important thing to consider is that the higher the peak and the sharper the curve, the more the reactor acts like a plug flow reactor. (This also means that, for a greater number of tanks, one will have to do a lot more work in setting up the model.)

In Fig.1, the value for one tank is comparable with a complete mix reactor, whereas the value for 20 tanks approaches that of a plug flow reactor. There is a balance formula for this computation that is given by the following:

A correlation that relates the internal mixing characteristics (number of compartments or stages) to the physical properties (for diffused air systems) was used. The correlation, in SI units, is

$$N = 7.4\, Q_S\, (1 + R)\, L/WH$$

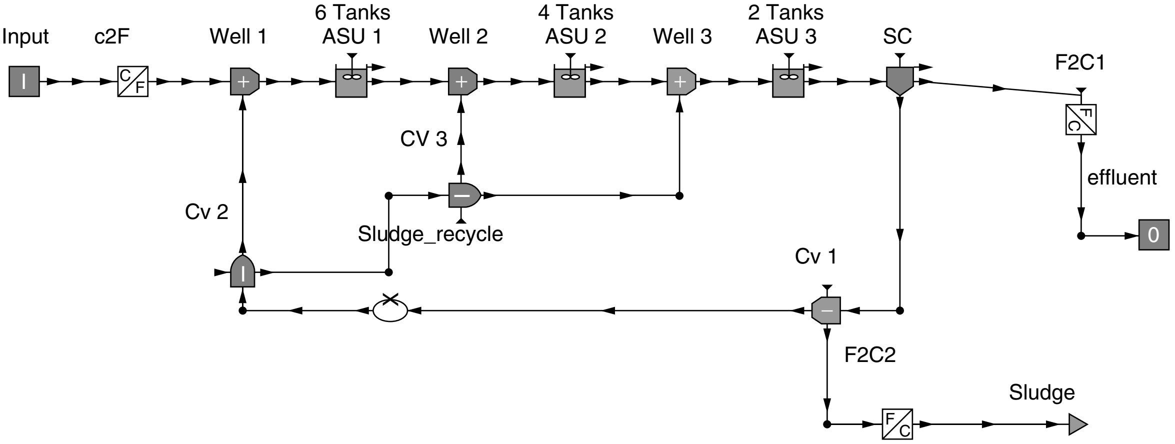

Figure 3. ORBAL plant configuration in WEST (*Source*: Dynamic calibration of the Orbal extended aeration plant by Peter A. VanRolleghem and H. Gucu Insel, Biomath Department, University of Ghent, October, 2002).

where N = number of compartments;
Q_S = flow, m^3/s;
L = length, m;
W = width, m; and
H = depth, m.
R = RAS ratio;

This formula was first published by Chambers (1). The units have to be in the overall range of the following:

$$28 < L < 500$$

$$2 < B < 20$$

$$2.4 < H < 6$$

$$0.7 < R < 1.5$$

$$1.3 \text{ hours} < t < 3 \text{ hours}$$

where $t = 3600\ Q\ (1 + R)$.

The following example may provide some guidance.

Recently, we had to model an ORBAL plant using WEST (Fig 2). The ORBAL has three concentric circles and a number of aerators with complex flow patterns because there is a submerged opening or, in some cases, a wall opening between the concentric tanks to allow the waste to pass from the outer tanks to the inner tanks.

The purpose of the figures is to introduce the reader to a practical application of the consideration of reactor hydraulics. In the ORBAL, there is a natural break point for each of the series of ORBAL channels, and those are the aerators (Fig. 3). The location of the aerators naturally divides the channels into logical units because of reaeration considerations. It can be argued that the channels could be divided into twice as many tanks for more accurate modeling, where the first tank would reflect the aeration input by the aerator and the second tank would reflect the lack of aeration input, which might be a better model, but it is definitely twice as complex and will require at least twice as long to compile and run. It may or may not be worth the effort.

Step 4: Laboratory and Other Data Organization

The objective is to gather enough data to be able to make an estimate of the magnitude and change in the flow sufficient to characterize the waste stream and its elements.

Depending on the model you are planning to use, you may have to go into the laboratory and obtain additional information. The number of samples and complexity of the sampling program is up to you and the budget you have available. We have observed everything from 12–15 samples run to establish some basic correlations, to a complete sampling campaign using automated equipment that will allow you to collect and analyze up to six sampling points and multiple analyses for each sampling location. This latter equipment program is described by Dr. Bruce Beck in his Environmental Process Control Laboratory or EPCL. The web address for the EPCL is http://hilbert.forestry.uga.edu/epcl/issues&info/flowchart.html.

It is difficult to provide specific guidance on the sample reliance for an unknown waste stream, but it would be nice if the laboratory data one obtained were reproducible to within about 10–20%. The entire discussion of precision and accuracy and the number of samples required therein is outside the scope of this paper. For a discussion of the issues involved in sampling and analysis, see Ref. 2.

Here are some suggestions for running the ASM1 testing and ASM2 and ASM2d testing from a proposal to a client. For additional guidance, you will want to see the descriptions of the models themselves.

> Any modeling or characterization effort requires a substantial amount of data. In this instance, we will probably need access to the plant analytical and operating records, chemical addition, and other records for at least 6 months, and perhaps a full year. The scope of the request is somewhat more extensive than the description might indicate, as it includes such routine operating data as the pump characteristics and rate, hours of operation, timing of the operations, aerator horsepower and hours of operation for each day, etc. The data should also include the quantity and type of chemicals used in various parts of the plant.

> Wastewater characteristics are divided into several elements. The principal elements include
>
> - Total and filterable COD
> - Total and filterable TKN
> - Total ammonia and nitrate
> - TSS & VSS
> - Total phosphate, filterable phosphate, and orthophosphate
> - Alkalinity
> - Volatile fatty acids (measured as acetate) (only for ASM2 and ASM2d)
>
> Analyses should be run in parallel with routine influent and effluent analyses for a period sufficient to determine reliable parameter variation and fractionation with routinely measured variables.
>
> A sampling campaign between 1 and 2 week long is suggested for the wastewater characterization study. The study should collect and analyze daily composite samples of influent and effluent. The study should be conducted in parallel with the routine sampling data being collected at the plant now.

Automatic sampling equipment that collects hourly grab samples of water and wastewater is often as good as can be obtained in a sampling campaign. Daily composite samples can be used but are often unreliable because the waste stream fluctuates with time and composite data will mask the diurnal and other variations.

Flowmeter readings are often unreliable, even when the flowmeter works. Calibration and inspection is suggested.

For internal calibration, you will need some data relating to TSS and VSS (filtered and unfiltered in various parts of the plant), along with DO measurements, and possibly some respirometry data, recycle rates, sludge levels in the clarifier, sludge wasting data, and just about everything you can imagine that an operator would need to run the plant properly. The trouble is that the data do not often exist or exist in the wrong form.

An example might be the notation in the plant operating log—"wasted sludge for two hours". That tells you that the operator wasted sludge at between 1.5 and 2.5 hours, but nothing else unless you have either the valve settings and the MLSS at the time of the wasting.

If you are fortunate, you will find that he took an MLSS sample immediately before or after the wasting. If not, you may have to guess from the pump flow rate and talking to the operator. The key is that the operators almost always have a favorite method of operation that can often be recovered. They may know that if they turn the valve wide open, something will happen that will cause them work down the way, and so they leave the valve partially shut so that they do not have to clean up the floor of the sludge treatment facility.

The operation of the aeration equipment is often manual as well. It is safe to assume that about the only instrumentation you may find is the flowmeter, and that may not even work.

Generating the Flows When You Do Not Have the Data. When you have only BOD data or BOD, COD, and TSS data, WEST and some other programs have both a BOD transformer and/or a BOD/COD transformer that can be used to fractionate the flow into the necessary components. Remember the cautions expressed on letting a program fractionate the data for you.

If you have little data and have to generate dynamic and/or diurnal flow patterns from your source, you may want to use a sinusoidal pattern to generate the data. All good books on environmental engineering have some form of generic flow pattern for domestic wastewaters. The flows are often highest between 9 A.M. and 4 P.M. and lowest in the early morning hours when most people are asleep. Often there is a secondary peak in flow during the dinner and early evening hours when food preparation is the greatest.

You may want to look at your time data when it was collected from the influent and try to fit a time curve with each flow and concentration element to see if there is any variability in the data and determine whether you need to have the biosolids and chemical composition run counter or with the hydraulic basis. The following example may help to explain this point:

> Assume that a process discharges a uniform concentration of material and the flow varies. Then the concentration of contaminants would vary directly with the flow.
>
> If, however, the process discharged at a constant rate and contaminant level and if we add periodic boiler blowdown and filter backwash to the waste stream and some kitchen wastewater (which peaks from about 1–2 hours either side of midshift), then the flows and the concentration may vary inversely with each other or may spike at midshift. It may depend on the quantity of blowdown and backwash.

Getting the Hydraulics and the Tankage Correct. As part of the overall process and before you set up the flow sheet, you will need to address the issue of hydraulic similitude for the system, which really compares how well the model you are using models the hydraulic performance and hydraulic mixing of the system you are modeling. The best way to determine how well your system is performing is to conduct dye or tracer studies on the tank system. The purpose of the dye testing is to find out whether you are operating in a plug flow or complete mix or some other regimen. The differences among the types of reactors were discussed earlier in this article.

If you cannot perform dye testing to determine the mixing requirements, you should examine the system you are modeling carefully. There may be some logical divisions in the system that suggest that it should be modeled using a specific number of tanks. For example, an extended aeration system, such as an oxidation ditch, may have a number of aerators, and the physical positioning of the aerators may suggest a logical number of tanks to use for modeling the flow.

Each tank or tank division will have its own aeration capacity (*Kla*) that can be adjusted. Multiple aerators may suggest a configuration that needs more than one tank and an interlaced flow diagram to suggest the right type of flow connections, which is a matter that is settled by the judgment of the engineer.

At this point, it may be a good idea to rough out the flow sheet for your model, which is also a first

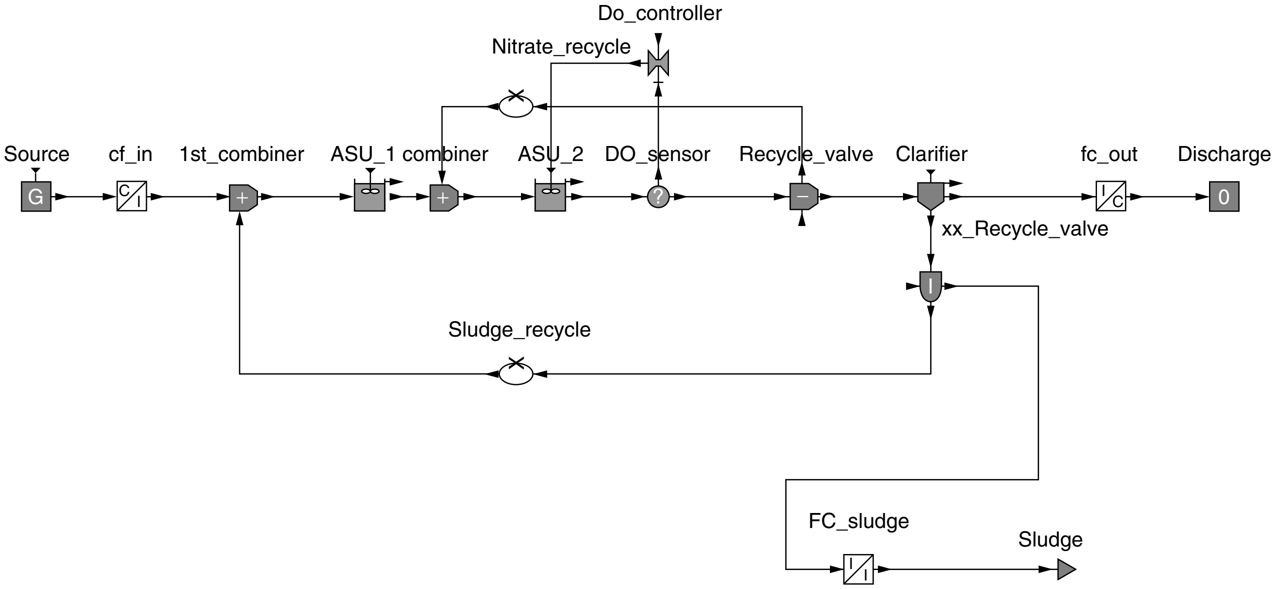

Figure 4. Labeled flow sheet in WEST.

draft of the process and instrumentation diagram (P & ID). It may not be detailed but rather simple. You can always fill in controls and details later when you set up the compositional model. Clarifier selection is also an important choice for both the model and the complexity of the models.

A simple flowsheet is shown in Fig. 4.

Start with an elementary drawing, and put the basic icons in place. Annotate it with the details you need to prepare the drawing of the plant, so that it reflects the P & ID as shown above. Then start your process simulator, and begin your work.

After you have completed the physical placement of the model elements and the selection of the model, you still have to several steps to go.

Step 5: Model Compilation and Setup

Setting up a model is a multipart process:

1. Initial definition of the model critical model parameters
2. Initialization of the variables
3. Setting up the integrator

Start by initializing the model. First, start with the parameters. Most of them are biological parameters that you will not have to adjust and probably should not adjust.

Concern yourself with the physical parameters first. You will want to look at the physical parameters and set things like tank volumes and initial guesses to determine the *Kla* (oxygen transfer and uptake rates), suspended solids levels in the tanks, and various physical parameters.

You will also have to go through and estimate the initial operating conditions for the reactors by going into the variables and filling them out.

One of the other types of errors that can be generated in ASM1, particularly, is *negative ammonia*. Negative ammonia is caused by an unbalanced waste in the model. The configuration of ASM1 is such that it does not have a “trap” for negative ammonia, and what the model is really saying is that the feed conditions are such that the ammonia is consumed at a faster rate than it is supplied by degradation of the organic material in the waste. Obviously it is an impossible condition, but the model does not know the difference. Sometimes, the autotrophs in the waste are too high, and a simple adjustment in the feed will correct that problem.

This is one reason why it is often more convenient to set up and run a steady-state model for the initial run. The steady-state system allows you to balance the model before you begin dynamic modeling.

After the steady-state model is balanced and running properly and after you have set the various values at the approximate levels you need for your initial conditions, then it is time to go back and recalibrate the model using your successful run data from the steady-state case. The purpose of this step is to bootstrap the model with the values you will be using rather than wait for it to reach equilibrium.

Integrator Settings and Data Collection. All equations in the IWA models are expressed as rate equations that need to be integrated. The simulator package you are using does this. In some packages, you have a choice of how fine you want your integration settings. On other simulators, you may not. Remember that if you use too large an increment, your program may be fast, but you sacrifice accuracy. Fine steps in the integrator provide nice smooth curves but take additional computation time and can produce very large effluent files.

Step 6: Input and Output File Preparation

The setup of the influent file is strongly dependent on which model is being used. Some models use comma delimited files, other tab delimited files, and some use an input and output from Excel files.

Step 7: Initialization of the Model Parameters and First Runs

The first run of a model may produce unexpected results. The unusual results are not unexpected, and to some extent, that is why one sets up a static model first. When the static model has been evaluated and balanced, then it is necessary to use the final values for variables and modify them to represent starting variables for the first runs.

What to Balance or Adjust. A limited number of things can be adjusted in most models:

- Primary clarifier underflow rate (removes solids).
- Oxygen transfer rates (*Kla* values) can be adjusted in each tank.
- Flow proportion in each tank (if flow sheet permits).
- Recycle rate on loops (can take almost infinite adjustment).
- Secondary clarifier underflow (increases sludge return and improves effluent solids).
- Sludge wasting rate (decreases solids in the system).
- *Adjustment of the rate coefficients and parameters is not recommended on initial runs!* (Adjusting these coefficients prematurely may mess up your results in later runs.)

What to Key in on During Your Modeling. Key in on the same things that the plant operator keys in on: suspended solids, oxygen levels, sludge wasting rates, hours of operation of certain processes, and flow rates. Look specifically at weekends because many plants are essentially unmanned on weekends.

These are the operator's only tools. The two or three hardest to measure are, frequently, the MLSS values in the tanks, the oxygen levels in the tanks when and where it is measured, and any other chemical parameters.

When you have the model balanced for steady-state flows, then start dynamic modeling. If you are fortunate enough to have good quality data on the plant, you may be able to get traces where peaks and valleys in the model results can be compared with the peaks and valleys in the performance data for the plant. It is almost like curve matching, but you are looking to see that any disturbances in the plant (and there will always be some) match disturbances in the model. The results may be very interesting; the peaks may not match in height, but they should be at about the same times and for the same duration as obtained from the plant data.

Step 8: Parameter Adjustment

Adjustment of the parameters is often as much art as science. It needs to be done only after a detailed analysis of the waste and the characteristics and after evaluating the modeling results compared with a case where there are sufficient data to enable comparison.

From the literature, the one case where parameter adjustment may be necessary is in phosphorous modeling. The sensitivity of the various coefficients and uptake rates can affect the storage of phosphate and the final results. The adjustment of parameters should be undertaken only after careful consideration and experience and probably substantial laboratory testing and/or a number of model runs to compare results with actual performance.

Unless you have specific chemical data or parametric data to indicate that a specific change in a model is desirable, do not plan on changing the given model parameters as it may cause problems later, which is especially true for dynamic modeling. If you do not have any good indication of what and where to change things, try leaving them alone and make adjustments only as a last resort after you have tried everything else and need to make those adjustments based on dynamic data or specific knowledge of the plant.

FINAL NOTES

Look carefully at your data and your modeling system. If you understand it and the way it is put together, fine! If you do not understand what is happening, and why, you are like the student who says, “Don't bother me with the theory, just show me where to plug in the numbers!”. That is uncertain territory and can cause difficulties for the modeler. Unexpected results do occur and one has to understand both the results and how they relate to the physical model.

Acknowledgments

I need to provide special thanks to Mr. Youri Amerlinck of Hemmis, NV, and Mr. Dirk Van der Stede, President of Hemmis, NV, and Dr. Peter Van Rolleghem at the Biomath Department of the University of Ghent, Belgium, for their invaluable technical assistance. Without their help and education about modeling and WEST in particular, this article could not have been written.

NEW YORK CITY HARBOR SURVEY

David J. Tonjes
Cashin Associates, PC
Hauppauge, New York

The New York City Harbor Survey, begun in 1910 and conducted continuously since 1912, may have the longest operational history of any annual water quality monitoring program in the world. Initiated to document decaying water quality in New York Harbor and, therefore, cause changes in waste management practices, it now demonstrates the effectiveness of New York City's comprehensive wastewater treatment program. Data from the 53 stations of the Survey (some of which are monitored year-round using the dedicated Harbor Survey vessel) show general compliance throughout the Harbor with New York State water quality standards today, despite historical pollution problems.

INTRODUCTION

New York City is composed of islands and shorelines. The proximity of so much water to so many people has meant that much of the wastes produced by its residents during the past 300 years has been discarded into the waterways (1).

One impetus to understanding the impacts of water pollution has been to document damage to the environment (and associated threats to human health) from these releases. It is easier to provoke action when the magnitude of the problem is displayed. This concept was understood by the New York City Metropolitan Sewage Commission in 1909. To quantify conditions in the Harbor, parts of which were described as open sewers, where swimming was called a dangerous health hazard, and where a once unmatched oyster industry was soon to be abandoned, the Commission established the Harbor Survey (2).

The first New York Harbor Survey was undertaken in 1910; samples have been collected every year since 1912 (generating 91 years of data as of 2001). This appears to make it the longest continuously conducted water quality monitoring program in the world.

PHYSICAL SETTING

Water quality is determined by the amount of chemical contaminants present and by their fate and transport. New York Harbor (Fig. 1) has a complex physical oceanographic setting that must be understood to interpret sampling data.

Generally, the Harbor can be considered a drowned river valley (3), formed as the continental glaciation receded from Staten Island 20,000 years ago (4). The Hudson River is tidal to the Troy Dam, 150 miles north of Manhattan, and its flow is entirely freshwater only for the 90 miles north of Poughkeepsie. Flow over the Troy Dam (90% of the freshwater in the river) has an average annual peak of 40,000 cubic feet per second (cfs), usually in spring due to snowmelt and greater groundwater discharges. The other major rivers feeding the Harbor (the Passaic and Hackensack Rivers into Newark Bay and the Raritan River into Raritan Bay) contribute a quarter of the Hudson River flow (5,6).

Generally, the Harbor is a partially stratified estuary (the Hudson River, Upper Bay, Lower Bay, Raritan Bay, Newark Bay, the eastern portion of the Upper East River, and western Long Island Sound), where tidal currents mix salt water into riverine water. The earth's rotation causes concentration of less dense (fresher) water on the west side of each waterbody (7). Mixing of tidally advected salt water dilutes the freshwater, so that flows at The Battery often exceed 400,000 cfs (8). Strong tidal currents can break down the stratification caused by the Coriolis effect, especially in the Upper and Lower Bays (9).

However, this straight-forward depiction of water flows is complicated by the multiple ocean connections (most estuaries have only one), where the Upper Bay connects to the Atlantic Ocean through the Lower Bay and also through the East River into Long Island Sound and to the Ocean. In addition, minor, well-mixed tidal straits, including the Harlem River (connecting the East River to the Hudson River), the Kill van Kull (connecting Newark Bay to Upper Bay), and the Arthur Kill (connecting Newark Bay to Raritan Bay), are not partially stratified. Jamaica Bay, which tends to be well mixed, and although not contiguous with the other parts of the Harbor, is also considered part of the Harbor (8).

Flow patterns in the Lower East River are not simple. Flow is driven by the mismatch in tides between the Upper Bay and Long Island Sound. Velocities can reach 4.5 knots (still much less than 10 knot currents once measured before a large rock was removed) (10), and it tends to be well mixed. There are six water pollution control plants (WPCPs) along the East River, and they input 750 million gallons per day (MGD) of effluent [15% of the total flow of 6 billion gallons per day (BGD)] (11).

Jamaica Bay also contains an abundance of sewage effluent; its natural tributaries were captured by sewers during urbanization. Up to half of its water can be sewage effluents (12), partially because water residence time is more than a month (up from 11 days due to dredging, which increased the depth of the Bay from 3 feet to 16 feet) (13). The Bay is generally shallow enough that stratification caused by summer insolation is of short duration due to mixing by winds (12).

New York Harbor was once famed for its natural beauty and seafood resources (14). The physical changes in the Harbor have caused impacts which in many cases cannot be differentiated from those from pollution. The predredged Harbor was 18–20 feet deep (9). Ships sailed Long Island Sound to avoid the shoals of the Lower Bay (10). Channels criss-cross the harbor, at depths as great as 45 feet, and plans are to increase some to more than 50 feet (15). The Harbor used to hold gently sloping coastal marshes and mudflats but now has hardened, steep-sided, deepened channels. Losses include 61,000 acres of tidal marsh (17), and fills have created 7,000 acres in the City (18). The islands in the Harbor have been removed, expanded, connected to other islands, and otherwise altered (19).

SOCIOLOGICAL SETTING

New York was attractive to immigrants in colonial days because of its natural resources. Its location made it (and the Hudson Valley) the key site of the Revolutionary War. The construction of the Erie Canal made New York City the economic capital of the United States (20). New York Harbor and water power available in New Jersey made the region a center of the Industrial Revolution and, ultimately, the country's economic engine (21).

Thus, New York City and its environs grew with time. It had 25,000 residents at the turn of the nineteenth

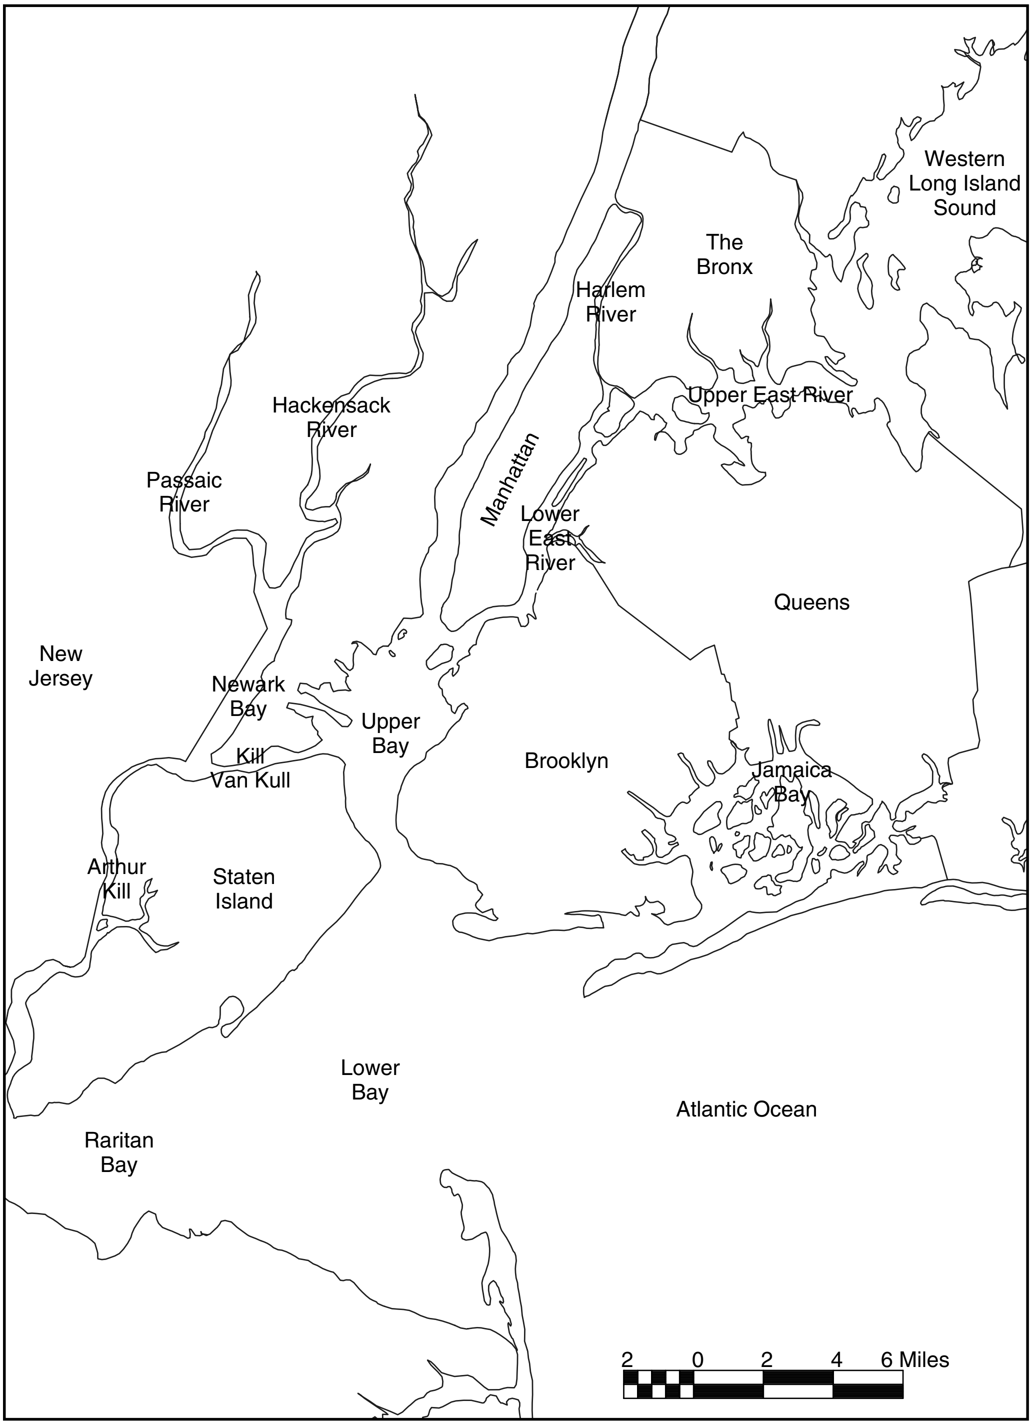

Figure 1. New York Harbor.

century (1). Population in the Harbor drainage area exceeded four million by the twentieth century (22) and more than 20 million at the turn of the twenty-first century (23). These multitudes produced solid and septic wastes, and the Harbor was the local disposal point since the 1600s. City solid waste was deposited into the Harbor or nearby waters until the early 1900s (24). Untreated sewage, likewise, was sent to the Harbor for dilution and transport away from land. As of 1905, 5.3 million people in New York and New Jersey sent sewage to the Harbor (25), augmented by industrial effluents (26).

In 1910, seven small WPCPs in New York City processed approximately 19 MGD, but the "process of purification has not materially reduced either the suspended matter or matters in solution." Typhoid outbreaks occurred in 1904 and 1918. In 1925, oyster fishing was banned. The result was construction of a sewage system for the City in the 1930s (25), although complete waste treatment was not achieved until 1989 (27).

CURRENT NEW YORK CITY SEWAGE TREATMENT INFRASTRUCTURE AND PROGRAMS

The 8.0 million residents of New York City are served by 14 WPCPs that generate 1.3 BGD of effluent (Table 1). All of these plants achieve secondary treatment (defined as 85% removal of BOD and TSS) (28).

New York City uses a combined stormwater–wastewater collection system of 1930s' design (1). Its engineers were not anticipating modern pollution controls for stormwater but intended to conduct as much water management as possible using the least amount of piping (which nonetheless totals 6344 miles) (28).

The combined system is stressed in the rain. To prevent volume overloads at the WPCPs, wastewater bypasses the plants. The combined sewer overflows (CSOs) that result remain a serious pollution concern. Water conservation measures led to City-wide decreases in consumption from 1.4 BGD in 1990 to 1.24 BGD in 1999, despite a population increase of 400,000. The reductions mean that dry weather flows to the WPCPs use only 70% of the system's capacity. Thus, the WPCPs can now manage more than 50% of the runoff (annually), and CSOs have decreased (29). The City has further committed to a $1.5 billion program to build CSO abatement facilities (28).

In the 1970s and 1980s, CSOs were the source of a local problem: floatables—washup of medical wastes on local beaches. Close examination of the wastes and transport calculations showed they were washed off City streets into CSOs (30). The problem has diminished due to the capture of materials in the Harbor and at catchbasins and an emphasis on street-cleaning (28).

The NYCDEP has decreased the toxicity of its sewage effluent through source control—700 sewer users have decreased metals loadings from 3000 pounds per day (1974) to 205 pounds per day. The Shoreline Survey Program monitors storm sewers for dry weather flows and then tracks down illegal discharges. The Sentinel Monitoring Program uses coliform to identify contaminated outfalls for investigation and remediation (28).

THE HARBOR SURVEY

Six stations were sampled in 1910. Sampling was continued in 1912 and has been conducted each year since. A special section of the NYCDEP, the Marine Science Section, conducts the Survey. It has its own 55-foot, aluminum-hulled, twin-engine diesel research vessel, the HSV OSPREY. The OSPREY has an onboard laboratory and is crewed by six to eight. It sails 5 days per week from June to September, when all 53 stations (Fig. 2) are sampled biweekly (a subsection of stations is sampled monthly, year-round) (28).

The Survey aims to determine the impacts of sewage treatment on the Harbor. Therefore, the parameters keenly tracked are coliform, dissolved oxygen (DO), and nutrients, especially nitrogen compounds. Temperature and salinity data are collected and used to determine the physical structure of the Harbor waters, placing laboratory results in context. Ecological data (chlorophyll *a* concentrations and some phytoplankton identification) are also collected. Beginning in 1985, samples were collected from the water surface (within 1 meter of the surface) and from the bottom of the water column (1 meter from the bottom). Statistical analyses of the data showed strong correlations between top and bottom data; beginning in 2001, the Survey collected field parameters (temperature, pH, turbidity, salinity, and DO) from top and bottom waters and water quality samples of surface water only (28). Before 1985, nearly all lab data were generated from composite samples (27).

DOCUMENTED WATER QUALITY TRENDS

Harbor Survey data have been used to address two basic questions:

- How bad was water quality? and
- Has a resolution of sewage-related pollution been reached now?

Suszkowski (25) analyzed the first 60 years of Survey data, using basinwide averages of summer data (ie., all summer sample results from the Hudson River were summed and averaged to generate one "Hudson River" value) and Harbor-wide averages (the mean of all basins). The findings were that the mean DO, measured by saturation percent, decreased from approximately 80% of saturation in 1910 to 40% in the late 1930s. In the 1960s, the DO slowly increased to 70%. The lowest values were found in the inner areas of the Harbor. The DO trends were linked to biological oxygen demand loadings from raw sewage and WPCP effluents. The correlation indicated that organic loading from raw and treated sewage was the prime factor in decreased DO levels.

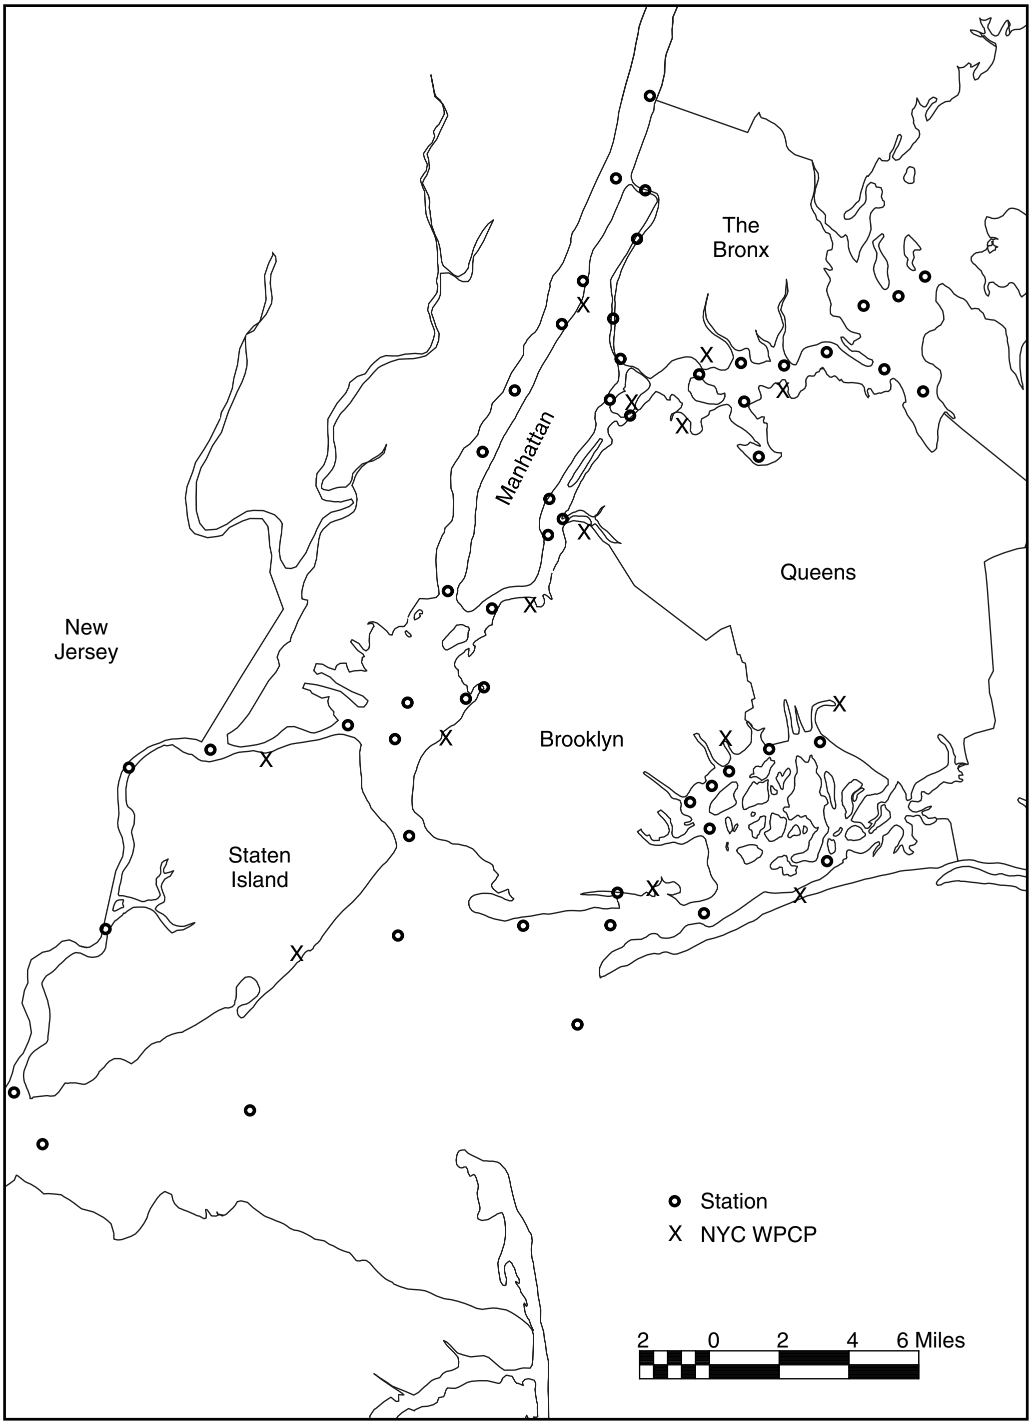

Figure 2. Harbor survey stations.

Beginning in 1989, NYCDEP began to self-report the results of the Survey; that year also marked the end of routine disposal of untreated sewage. NYCDEP had confidence that the Survey would show improvements in water quality, and so these reports could serve as public outreach to tout City environmental programs (27). Beginning in 1999, academic institutions prepared the longer of the two annual reports; the intent was an increase in rigor and a broadened perspective.

The NYCDEP summary reports show improving trends for all analytes nearly harborwide. The improvements have been so great that New York State water quality goals are being met routinely, as measured by DO and fecal coliform summer means, reported both as waterbody means and individual sample results (31).

SUNY at Stony Brook used a more sophisticated statistical analysis to identify trends. Its methodology also resulted in determinations of improved water quality since

1985. Order of magnitude reductions in fecal coliform and striking increases in the DO for nearly every station were found, and most of the linear trends were statistically significant at $p < .05$. The improvements were greatest in the late 1980s, probably from large reductions in raw sewage inputs as the entire City was connected to sewage treatment (28).

THE HARBOR SURVEY AND PUBLIC POLICY

One region where improvements in water quality are not apparent is western Long Island Sound. Long term trends for bottom DO do not show any improvements since the 1940s and may exhibit a declining trend (28). The Long Island Sound Study has identified hypoxia (low bottom DO) as the most serious problem in the Sound. A policy was set to reduce nitrogen inputs to the Sound by nearly 60%, intending to force higher bottom DO by reducing the impact of eutrophication (32).

The New York City East River WPCPs export most of their effluent (and associated nutrient loads) to the Sound. The Sound Study management plan requires multibillion dollar upgrades of the WPCPs to achieve tertiary treatment levels to reach agreed-upon nutrient reductions (33). Data from plant operations and the Harbor Survey show that 30% reductions in nitrogen loadings during the period 1992 to 2000 (caused by operational changes) concur with statistically significant declines in nitrogen concentrations in western Long Island Sound. However, the pattern of water column nitrogen concentrations does not correlate with changes in WPCP nitrogen releases, even using time lags of several months—in addition to the absence of increases in bottom DO in western Long Island Sound (28). The simple conceptual model, used by the Sound Study, that elevated wastewater nutrient concentrations in the East River cause increased phytoplankton concentrations in western Long Island Sound, leading to reductions in bottom DO due to microbial consumption of the deceased plankton (32), appears to be inadequate to explain the data. Cleorn (34), in an analysis of estuarine responses to eutrophication, showed that local physical conditions and biological community structures determine the particular reaction of waterbodies to elevated nutrient inputs. NYCDEP remains hopeful that its monitoring data may allow the City to find another way of addressing this complicated problem of low bottom DO [a situation that affects 25% of all estuarine waters in the northeast United States each summer (35)].

CONCLUSIONS

New York Harbor, a complex estuary, has been polluted by waste disposal for more than three centuries. For nearly 100 years, New York City has conducted a water quality monitoring program to measure impacts from sewage and WPCP effluent. This program, the Harbor Survey, documented the impacted water quality found in the Harbor before the City's wastewater treatment system was completed. Monitoring since 1985 has measured impressive improvements in parameters of concern. The program documents the effectiveness of the City's sewage treatment program, and it also serves as a public outreach and education tool and a means of helping to determine root causes of serious environmental problems in the Harbor.

NITRIFICATION IN THE ACTIVATED SLUDGE PROCESS

Michael H. Gerardi
Linden, Pennsylvania

There are two reduced forms of nitrogen that are of concern to wastewater treatment plant operators and state and federal regulatory agencies. These forms contain hydrogen and consist of nonionized ammonia or ammonia (NH_3) and ionized ammonia or ammonium ion ($NH_4{}^+$). Although ammonia and ammonium ions are both present in wastewater, the amount of each is dependent on the pH of the wastewater (Fig. 1).

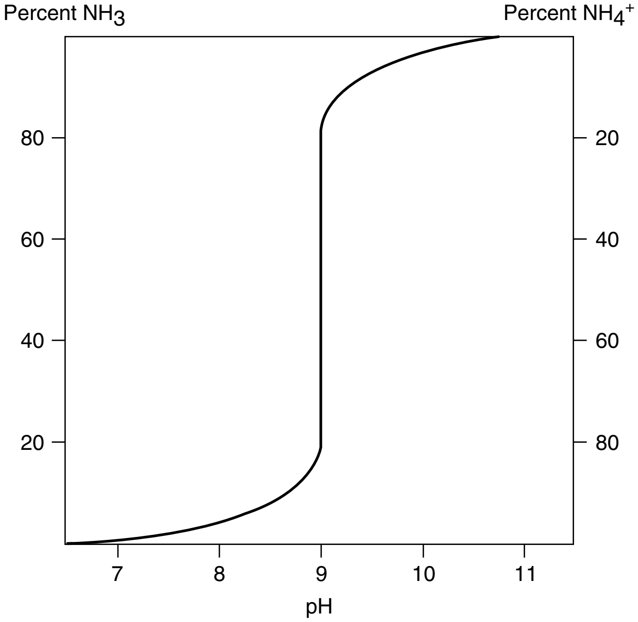

Figure 1. Relative distribution of ammonia and ammonium ions as determined by pH.

Wastewater nitrification is the biological oxidation of ammonium ions to nitrite ions ($NO_2{}^-$) (Eq. 1) or the biological oxidation of nitrite ions to nitrate ions ($NO_3{}^-$) (Eq. 2).

$$NH_4{}^+ + 1.5\ O_2 \xrightarrow{\textit{Nitrosomonas}} NO_2{}^- + 2\ H^+ + H_2O + \text{energy} \tag{1}$$

$$NO_2{}^- + 0.5\ O_2 \xrightarrow{\textit{Nitrobacter}} NO_3{}^- + \text{energy} \tag{2}$$

Nitrification occurs because nitrifying bacteria oxidize ammonium ions and nitrite ions in order to obtain cellular energy. There are two principal genera of nitrifying bacteria, *Nitrosomonas* and *Nitrobacter*. Although both genera of bacteria are strict aerobic organisms, *Nitrosomonas* can oxidize only ammonium ions, and *Nitrobacter* can oxidize only nitrite ions.

There are four nitrogen-containing molecules that are involved in wastewater nitrification. These molecules include ammonia, ammonium ions, nitrite ions, and nitrate ions. Because nitrite ions are highly unstable, they usually do not accumulate in wastewater and are considered to be a short-lived intermediate molecules that are quickly converted to nitrate ions. However, there are operation conditions that do permit the accumulation of nitrite ions (Table 1).

Ammonium ions enter activated sludge processes from nitrogenous compounds that are found in domestic and industrial wastewater. Domestic wastewater contains urea, amino acids, and proteins. Urea and simple amino acids degrade in the sewer system through hydrolysis

Table 1. Operational Conditions that Permit the Production and Accumulation of Nitrite Ions

Operational Condition	Description
Depressed temperature	$\leq 15\,^{\circ}C$
Limiting process conditions	Change in pH Inhibition Low dissolved oxygen level Slug discharge of soluble cBOD

and deamination, respectively. Once degraded, these compounds release ammonium ions. Due to the hydrolysis of urea and deamination of simple amino acids, most municipal activated sludge processes contain 25–30 mg/L of influent ammonium ions.

Stable amino acids and proteins degrade in the aeration tank and release ammonium ions. Urea, amino acids, and proteins are organo-nitrogen compounds. Additional organo-nitrogen compounds that are found and degraded in aeration tanks include surfactants and polymers. Ammonium ions and organo-nitrogen compounds that release ammonium ions can be found in many industrial wastewaters that are discharged to activated sludge processes (Table 2). Nitrite ions and nitrate ions that are found in activated sludge processes usually are produced in the aeration tank. However, there are some industrial dischargers of nitrite ions and nitrate ions (Table 2).

Activated sludge processes that are required to satisfy an ammonia discharge limit or total nitrogen discharge limit must nitrify. Although many activated sludge processes are not required to nitrify, operators of these processes may promote nitrification to ensure process control or use the nitrate ions produced through nitrification during controlled anoxic (denitrification) periods to obtain improved floc particle structure and decrease operational costs (Table 3). Finally, many activated sludge processes that are not required to nitrify may "slip" into nitrification. Regardless of permit requirements, activated sludge processes may enter an undesired form of nitrification that results in increased operational costs, process upsets, and permit violations.

Table 2. Industrial Discharges of Ammonium Ions, Nitrite Ions, and Nitrate Ions

Tanneries	X		

Regardless of the presence or absence of a nitrification requirement, nitrogenous compounds are of concern to operators of activated sludge processes (Table 4) and regulatory agencies (Table 5) due to their undesired impacts on the activated sludge process and receiving body of water, respectively. The nitrogenous compounds of concern consist of inorganic compounds (NH_3, NH_4^+, NO_2^-, and NO_3^-) and organic-nitrogen compounds (total kjeldahl nitrogen or TKN).

There are several forms of nitrification that can occur in activated sludge processes (Table 6). These include one complete and four incomplete forms. The identification of the form of nitrification that occurs in the activated sludge process is of value to an operator to ensure acceptable nitrification and correct undesired incomplete nitrification.

If nitrification occurs as incomplete #3 or incomplete #4, nitrite ions are produced. The accumulation of these

Table 3. Benefits Obtained Through the Use of Controlled Anoxic Periods (Denitrification)

Decrease sludge production
Destroy undesired filamentous organism growth
Improve process control: ensure adequate cBOD removal
Improve process control: ensure the presence of a "healthy" biomass
Return alkalinity to the treatment process
Strengthen floc particles

Table 4. Nitrogenous Compounds of Concern to Operators of Activated Sludge Processes

Compound	Formula	Impact
Ammonia	NH_3	Toxicity
Ammonium ion	NH_4^+	Oxygen demand upon nitrification to NO_2^- Primary nitrogen nutrient for bacterial growth Toxicity upon conversion to NH_3
Nitrite ion	NO_2^-	Denitrification ("clumping") in the secondary clarifier Increased chlorine demand (chlorine "sponge") Oxygen demand upon nitrification to NO_3^- Toxicity
Nitrate ion	NO_3^-	Denitrification ("clumping") in the secondary clarifier Secondary nitrogen nutrient for bacterial growth Toxicity upon reduction to NO_2^- by *E. coli*
Organic-nitrogen(TKN)		Oxygen demand upon degradation Release of cBOD upon degradation Release of nBOD (NH_4^+) upon degradation

Table 5. Nitrogenous Compounds of Concern to Regulatory Agencies

Compound	Formula	Impact
Ammonia	NH_3	Toxicity
Ammonium ion	NH_4^+	Oxygen demand upon nitrification to NO_2^- Toxicity upon conversion to NH_3
Nitrite ion	NO_2^-	Oxygen demand upon nitrification to NO_3^- Toxicity
Nitrate ion	NO_3^-	Causative agent for methemoglobinemia Primary nitrogen nutrient for aquatic plants Undesired growth of aquatic plants, especially algae
Organic-nitrogen(TKN)		Oxygen demand upon degradation Release of cBOD upon degradation Release of nBOD (NH_4^+) upon degradation

Table 6. Forms of Nitrification

Form of Nitrification	Mixed Liquor Effluent Filtrate Concentration, mg/L		
	NH_4^+	NO_2^-	NO_3^-
Complete	<1	<1	As great as possible
Incomplete #1	<1	As great as possible	<1
Incomplete #2	>1	<1	>1
Incomplete #3	<1	>1	>1
Incomplete #4	>1	>1	>1

ions in the activated sludge process is known as the chlorine "sponge," nitrite "kick," and nitrite "lock," because nitrite ions react quickly with chlorine and consume large quantities of chlorine. Approximately 13 pounds of chlorine are consumed per mg/L NO_2^- produced and accumulated per million gallons of flow. Nitrite ions in the activated sludge process interfere with the destruction of filamentous organisms in the mixed liquor or return activated sludge (RAS) via chlorination. Nitrite ions also interfere with the destruction of indicator organisms and pathogens in the final effluent via chlorination. To correct for the chlorine sponge, appropriate operational measures should be used to compensate for depressed temperature or correct for the responsible limiting factor.

Forms of incomplete nitrification occur as a result of depressed wastewater temperature (<15 °C) and limiting process conditions. Limiting process conditions include (1) change in pH, (2) a slug discharge of soluble cBOD, (3) temporary low dissolved oxygen level, and (4) toxicity. Additional factors that influence nitrification include alkalinity deficiency, decreased hydraulic retention time (HRT), and phosphorus deficiency. By identifying and correcting the condition responsible for incomplete nitrification, the return of acceptable nitrification should occur within 2–3 d.

The adverse impact of depressed wastewater temperature upon nitrification can be overcome through the use of appropriate changes in operational conditions. These changes include increasing the HRT of the aeration tanks, removing more colloidal and particulate BOD in the primary clarifiers, increasing dissolved oxygen concentration in the aeration tanks, and using bioaugmentation products. These products consist of commercially prepared cultures of nitrifying bacteria and organotrophic (saprophytic) bacteria that remove carbonaceous BOD quickly.

There are several significant operational conditions that impact nitrification in the activated sludge process. These conditions include temperature, mean cell residence time (MCRT), dissolved oxygen concentration, inhibition, alkalinity, and pH. Of these conditions temperature and MCRT are the most critical.

Due to the relatively small quantity of energy obtained from the oxidation of nitrogenous compounds, nitrifying bacteria reproduce very slowly. The generation times for *Nitrosomonas* and *Nitrobacter* under optimal laboratory conditions are approximately 8 and 10 h, respectively. In the activated sludge process the generation time of these organisms is estimated to be approximately 2–3 days. Therefore, high MCRTs are required at activated sludge processes to permit the growth of large numbers of nitrifying bacteria. However, warm wastewater temperatures provide for increased bacterial activity. Therefore, the number of nitrifying bacteria and the MCRT can be reduced. However, cold wastewater temperatures provide for decreased bacterial activity, and the number of nitrifying bacteria and the MCRT must be increased (Table 7).

Because nitrifying bacteria are strict aerobes, nitrification in the activated sludge process is influenced by dissolved oxygen concentration in the aeration tank. Nitrification is considered to proceed efficiently within the dissolved oxygen range of 2–3 mg/L. At dissolved oxygen concentration above 3 mg/L, nitrification may become more efficient, if carbonaceous BOD is more quickly removed from the aeration tank. If carbonaceous BOD is more quickly removed, then more hydraulic retention time is provided for nitrification. Approximately 4.6 pounds of dissolved oxygen are consumed for each pound of ammonium ions oxidized to nitrate ions (Table 8).

Generally, whatever is inhibitory to the organotrophic bacteria (cBOD-removing bacteria) also is toxic to nitrifying bacteria and is toxic to nitrifying bacteria at lower values. The more sensitive nature of nitrifying bacteria to inhibition is due to the relatively small quantity of energy obtained by nitrifying bacteria from the oxidation of nitrogenous compounds as compared to the quantity of energy obtained by organotrophic bacteria from the oxidation of carbonaceous compounds. The relatively small quantity of energy available to nitrifying bacteria

Table 7. Temperature and MCRT Recommended for Nitrification

Temperature, °C	MCRT, days
10	30
15	20
20	15
25	10

Table 8. Approximate Quantity of Oxygen Consumed During Nitrification

Biochemical Reaction	O_2, lb	O_2, kg
1 kg NH_4^+ to 1 kg NO_2^-		1.6
1 lb NH_4^+ to 1 lb NO_2^-	3.4	
1 kg NO_2^- to 1 kg NO_2^-		0.5
1 lb NO_2^- to 1 lb NO_2^-	1.2	
1 kg NH_4^+ to 1 kg NO_3^-		2.1
1 lb NH_4^+ to 1 lb NO_3^-	4.6	

limits their ability to repair cellular damage caused by inhibitory conditions.

There are several forms of inhibition that can damage nitrifying bacteria and adversely affect nitrification in the activated sludge process (Table 9). Those that commonly occur include inorganic (Table 10), organic (Table 11), and substrate inhibition. A unique form of inhibition that affects nitrifying bacteria is "recognizable," soluble carbonaceous BOD inhibition.

Substrate inhibition occurs through the production of free ammonia (NH_3) at elevated pH values and nitrous acid (NNO_2) at depressed pH values. Free ammonia and free nitrous acid are toxic to nitrifying bacteria. In the presence of relatively high ammonium ion concentrations (>500 mg/L) in the aeration tank, either free ammonia is produced with increasing pH or free nitrous acid is produced with decreasing pH. Therefore, the discharge of high concentrations of ammonium ions to the aeration tank or the release of high concentrations of ammonium ions in the aeration tank should be prevented.

Table 9. Forms of Inhibition that Affect Nitrifying Bacteria and Nitrification

Form of Inhibition	Description or Example
Free chlorine residual	Chlorination of the mixed liquor
Inorganic	Cyanide or heavy metals
Organic	Phenols or recognizable, soluble carbonaceous BOD
pH	<5
Substrate	Free ammonia or free nitrous acid
Sunlight	Ultraviolet radiation
Temperature	<5 °C

Table 10. Inhibitory Threshold Concentrations of Some Inorganic Wastes that Affect Nitrifying Bacteria and Nitrification

Inorganic Waste	Concentration, mg/L
Chromium (hexavalent)	0.25
Chromium (trivalent)	0.05
Copper	0.35
Cyanide	0.5
Mercury	0.25
Nickel	0.25
Silver	0.25
Sulfate	500
Zinc	0.3

Table 11. Inhibitory Threshold Concentrations of Some Organic Wastes that Affect Nitrifying Bacteria and Nitrification

Organic Waste	Concentration, mg/L
Allyl alcohol	20
Aniline	8
Chloroform	18
Mecaptobenzothiazole	3
Phenol	6
Skatol	7
Thioacetamide	0.5
Thiourea	0.1

Recognizable, soluble carbonaceous BOD inhibition occurs in the presence of simplistic organic compounds (Table 12). These compounds are capable of inhibiting enzymatic activity within the nitrifying bacterial cell. This inhibitory effect is not resolved until the organic compounds are either reduced in concentration or removed completely from the waste stream. Many of these inhibitory organic compounds are produced through fermentative reactions that occur in the biofilm and sediment within sewer systems and help to prevent nitrification in the sewer system. Additional factors that prevent nitrification in the sewer system include lack of an adequate population of nitrifying bacteria, short retention time, and absence of dissolved oxygen or a relatively small quantity of dissolved oxygen.

Alkalinity is removed and destroyed during nitrification. Alkalinity is removed from the wastewater by nitrifying bacteria as a source of carbon for growth, repair, and, most importantly, reproduction. Alkalinity is destroyed in the wastewater through the production of nitrous acid by *Nitrosomonas* during the first biochemical reaction of nitrification. As alkalinity is removed and destroyed, the pH of the aeration tank decreases.

Approximately 7.14 mg of alkalinity are consumed for each mg of ammonium ion oxidized to nitrate ion. To ensure adequate alkalinity for proper nitrification, the mixed liquor effluent of the aeration tank should contain at least 50 mg/L of alkalinity after complete nitrification. If an alkalinity deficiency exits for proper nitrification, alkalinity can be added to the mixed liquor with the use of an appropriate chemical (Table 13).

The pH of the aeration time affects enzymatic activity of the nitrifying bacteria. Activated sludge processes

Table 12. Examples of Recognizable, Soluble Carbonaceous BOD

Organic Compound	Formula
Aminoethanol	$CH_3NH_2CH_2OH$
Ethanol	CH_3CH_2OH
Ethyl acetate	$CH_3COC_2H_5$
i-Propanol	$(CH_3)_2CHOH$
Methanol	CH_3OH
Methylamine	CH_3NH_2
n-Butanol	$CH_3(CH_2)_2CHOH$
n-Propanol	$CH_3CH_2CH_2OH$
t-Propanol	$(CH_3)_3COH$

Table 13. Chemicals Suitable for Alkalinity Addition

Chemical Name	Formula	Common Name
Sodium bicarbonate	$NaHCO_3$	Baking soda
Calcium carbonate	$CaCO_3$	Calcite, limestone, whiting, chalk
Sodium carbonate	Na_2CO_3	Soda ash
Calcium hydroxide	$Ca(OH)_2$	Lime
Magnesium hydroxide	$Mg(OH)_2$	Magnesia
Sodium hydroxide	NaOH	Caustic soda

that nitrify efficiently do so at near neutral pH values (6.8–7.2). Nitrification at pH values greater than 7.2 are used, but nitrifying bacteria adjust slowly to significant swings in pH.

Nitrification can be achieved in one-stage systems or two-stage systems. One-stage systems consist of one aeration tank or a series of aeration tanks that remove carbonaceous BOD and also nitrify. Two-stage systems consist of a series of tanks. The first tanks in the series remove carbonaceous BOD only. The last tanks in the series nitrify only. Two-stage systems provide better process control than one-stage systems, and with increasing regulatory requirements to nitrify more and more activated sludge processes, especially in the temperate regions of North America, may need to nitrify using two-stage systems. Regardless of the nitrification requirements placed upon activated sludge processes, a knowledge of the biology of nitrification and its application to activated sludge processes are of value in achieving and maintaining cost-effective nitrification in compliance with permitted discharge limits.

EFFLUENT LIMITATIONS AND THE NPDES PERMIT

THE CLEAN WATER ACT AND INDUSTRIAL DISCHARGES

The Federal Water Pollution Control Act of 1972 was enacted by Congress with the stated objective "to restore and maintain the chemical, physical, and biological integrity of the Nation's waters" (1). The act acquired its common name, the Clean Water Act (CWA), in its first reauthorization by Congress in 1977. CWA in its essence can be considered in three conceptual parts: funding for local agencies to construct wastewater treatment plants; requirement for the states to develop water quality standards, using a set of criteria developed under CWA as goals for the chemical constituent conditions of waters of the United States; and creation of a series of regulations for permitting wastewater discharges from industrial facilities and from treatment plants. The CWA enacted a permit requirement for wastewater discharges, prohibiting discharges in the absence of a permit, and developed a permit system with roles for federal, state, and local agencies. CWA requirements have teeth: substantial financial and criminal penalties are authorized for discharging without a permit as well as for violation of the permits, with enforcing agencies directed to apply a sliding scale related to the severity of a violation, up to $25,000 per day during which the discharge is in violation, and higher fines plus jail time for violations found to be negligent, intentional, and/or to cause injury to humans (2).

The three parts are designed to work together to drive toward protection and improvement of water quality nationwide. The first, funding (and associated regulation) for locally-operated wastewater treatment plants, created an extensive physical and institutional infrastructure over time that implements controls on household, municipal, and industrial wastewater discharges to waters of the United States. The Publicly Owned Treatment Works (POTW) became an instrument of the Clean Water Act, accountable to federal requirements but operated by local agencies and exercising local control over a local network of dischargers.

The second conceptual part of CWA initiated a system of ambient standards for waters of the United States or conditions in which any given water body can be documented to attain those uses the public chooses for that water body. A standard is defined to consist of two parts: a designated beneficial use for the water body and the physical conditions under which that use is supported. The embodied concept of protecting waters for particular, specified uses continues to drive water quality goals in the United States. The conditions determined to meet those uses typically are derived from the federally-developed criteria—logically avoiding conducting the same research multiple times when each state chooses conditions for specified designated uses. As of 1999, water quality criteria had been developed for some 115 pollutants, including 65 named classes or categories of priority (toxic) pollutants (2). In this way, standard development incorporates the federal role of providing scientific information on satisfactory conditions for attaining a given use (e.g., chemical, temperature, and flow requirements to support particular species of sports fisheries) and states' preferences in selecting designated uses for each water body within their borders (although this is limited by a CWA stricture against allowing degradation, which effectively precludes failure to protect designated uses in place as of 1975, without extensive review and justification).

The third conceptual part of CWA is a system of permits for wastewater discharges, applicable to POTWs; industrial wastewater discharges; and other miscellaneous discharges. The controls take a form known as "uniform numeric limitations," and as such are designed to require facilities of a given type nationwide to attain a common standard, recognizing wastewater quality as an equal goal, and equal burden, for discharges in all parts of the United States. The uniform limit has a powerful theoretical basis in the scheme of regulatory systems, which is that by specifying a numeric target rather than a selected technology, dischargers are encouraged to identify the least-cost approach that would attain that target for their own industrial facility, which might be substantially different from the treatment method that serves best for other facilities. This structure provides an incentive to promote research and development of improved, lower cost treatment technologies that would attain the same target in a more effective manner. That incentive is imperfect, as long as the limit remains greater than zero, because research and development is encouraged only to the extent of identifying less costly means to attain the specified limit. In contrast, economic approaches, such as emission trading or charges-and-standards, also encourage research and development on the most cost-effective ways to reduce discharges of pollutants extending below the specified standard, in principal also encouraging research into low-emission or zero-discharge technologies that are not equally encouraged by the numeric limit approach. The uniform numeric limitation approach also foregoes the advantages of a competing system, one that could attain greater economic efficiency by allowing trading pollutants among different dischargers with different attainment costs, of the kind employed by certain Clean Air Act regulations. An extensive body of environmental economics literature addresses these concepts; see, for example, Tietenberg (3).

CWA engendered an interwoven system of regulations and policy goals spanning federal, state, and local agencies across the United States. The Act was envisioned as dynamic, to be revised and refined over time, taking advantage of research advances and the expected water quality improvements; and to some extent, that has occurred. Two major reauthorizations, in 1977 and 1987, encompassed substantial changes, and periodic rulemaking has introduced new directions, such as the emphasis on watershed management in the early 1990s. However, since that time, little of substance has changed (4). Annual updates on CWA and related issues can be found in the Congressional Research Service's Issue Brief series [e.g., (5)]. A legislative and conceptual overview of CWA, its history and intent, can be found in (4) and in a 25-year summary prepared by the Water Environment Federation (1). The entire Clean Water Act may be seen in the Code of Federal Regulations (CFR) under Title 40, Protection of the Environment; Chapter I, Environmental Protection Agency; sections 401–499, Clean Water Act. A searchable version of the CFR is maintained online by the National Archives and Records Administration, updated quarterly as regulations are modified or expanded. The website for CFR Title 40 is http://www.gpoaccess.gov/topics/environment.html.

NPDES: CWA'S NUMERIC EFFLUENT SYSTEM

The National Pollutant Discharge Elimination System (NPDES) is the mechanism developed in the CWA to specify numeric limitations for effluent from both industrial facilities and POTWs. In the 1972 CWA, Congress authorized the newly-organized Environmental Protection Agency (EPA) to develop, promulgate, and enforce NPDES requirements.

Uniform numeric limitations for industry are specified in two forms. The first is by substance: EPA is directed to develop a list of allowable limitations for both "conventional pollutants," which were widely recognized as of 1972, and "priority pollutants," consisting largely of toxic substances about which information was and is still emerging. The second is by industrial category: numeric limitations are listed for each of a range of industry groups (categories) selected by EPA according to facility types likely to have similar wastewater characteristics and problems, and similarity of the treatment technologies likely to be successful in removing pollutants from wastewater typical of that industry's characteristics. These categorical standards within a given industry recognize two types of discharges: direct discharges into waters of the United States and indirect discharges into municipal wastewater systems, known as "pretreatment" standards, because after onsite treatment, the discharges are intermingled and treated again by the receiving POTW. For some substances in some industry categories, the specified numeric limitations are somewhat different for direct and for indirect discharges.

In order to be uniform across the United States, logically it is not possible to select numeric effluent limitations based on water quality. No uniform standard could address the wide variation of water bodies' assimilative capacities, mixing properties, biological communities, and other considerations or the wide variation of discharges' volumes, timing, intermingled substances, and similar characteristics. The NPDES rules were expected to attain water quality improvement simply by specifying a uniform target for all discharges that would require industrial facilities, and POTWs, to provide some treatment to remove pollutants recognized as potentially harmful to the environment. Therefore, the NPDES limitations were of the type we can term "technology based": the numeric limitations were selected by EPA after a thorough review of the kinds of wastewater treatment technologies available, those known to have been constructed and operated by at least some facilities in the United States. The operating characteristics of the technologies provided knowledge of the attainable chemical characteristics of wastewater after treatment and some information about the cost to treat wastewater to achieve a specified standard. EPA was directed to use that information to specify a numeric limit, not a technology that all dischargers must adopt, but a number that all discharges must attain, based on the conclusion that available technologies could successfully attain the number.

Both the substance-specific and the category-specific limitations achieve the same conceptual advantages of any numeric limitation, i.e., the discharger (and the entity responsible for wastewater treatment) may select the most cost-effective technology for his own situation, encouraging innovative research and development to develop lower cost processes if possible. This concept today remains central to the goals of EPA and NPDES: "A facility's drive to identify cheaper, more effective ways to achieve compliance is consistent with EPA's mission of clarifying and simplifying environmental regulatory control" [Sector Notebook series, (6)]. The structure of NPDES regulations does not permit EPA to specify treatment technologies, instead requiring EPA to specify a numeric target (although EPA is allowed to justify its selection of a limitation by documenting that a cost-effective treatment exists that would attain the limitation).

The technology-based structure does, however, generate another conceptual weakness in the NPDES numeric limitation scheme: Limitations based on current technology have the effect of "freezing" the technology at that level. Research and development on lower cost ways to attain the specified limitation are strongly encouraged, but no incentive exists to invest in developing or implementing improved technology that would attain any greater pollutant removal than specified in the limitation. It may be inferred that Congress' intent under CWA was to routinely revise the limitations as more information becomes available through continuing research on the effects and treatability of toxic materials. (In fact, as the term "elimination" in the title suggests, Congress envisioned that industry and POTWs would attain effectively zero discharge of substances found to cause water quality problems in receiving waters.) The history of CWA reauthorizations does not show a robust program of routinely revisiting and revising the limitations for most substances once they have been initially selected.

EFFLUENT LIMITATIONS BY SUBSTANCE

EPA developed the numerical limitations for its NPDES requirements using information about technologies available during the 1970s, when the requirements were written, as well as the best information at the time about technological capabilities expected in the future. The initial set of limitations focused on the "conventional" pollutants and on the kinds of treatment technologies then well known and proven to be economically feasible for typical industrial facilities; these were known as "best practicable control technologies" (BPT). CWA specified a timeframe by which dischargers needed to meet the BPT requirements, which were, of course, specified in the form of a numeric limit, not a specified technology. Conventional pollutants subject to BPT were:

—Suspended solids

—Biochemical oxygen demanding substances (BOD)

—Fecal coliform

—Acidity (pH)

A second set of limits was promulgated that were to be attained on a later timeframe and were termed "best available technology" found to be economically achievable (BAT). These BAT requirements also included more stringent regulations for conventional pollutants. That feature places NPDES into the subcategory of technology-based rules known as "technology forcing," because the increasingly stringent requirements as a rule tended to drive dischargers to develop increasingly effective treatment technologies. The BAT requirements focused on limitations for nonconventional pollutants (heavy metals, pesticides, and other organic chemicals), including a list of 125 "priority" or toxic pollutants. Priority toxic pollutants and their effluent limitations appear in the Clean Water Act section 307(a).

EFFLUENT LIMITATIONS BY INDUSTRIAL CATEGORY

Further BPT and BAT point-source limitations are written for certain substances in discharges from certain industries, specified separately for each of a number of industrial categories. These are uniform within the industry, but may differ from the broader uniform limitations in any of a number of ways: some are more stringent requirements for the same substance; some impose mass-based limitations in addition to the uniform concentration-based limitations; and others specify requirements for different substances, common to the industry category but not included in the broader uniform requirements. These requirements, in general, encompass limitations for both direct and indirect point-source discharges.

Table 1 lists the categories of industrial wastewater discharges subject to NPDES categorical effluent limitations, along with the CFR section where those limitations can be found (for instance at the website given above). Using that information, the searchable CWA referenced above is a good way to locate current categorical standards. The industry categories of NPDES are not grouped according to the familiar Standard Industrial Classification (SIC) system, but instead use the groups developed by EPA in its CWA analyses.

For many of these industry categories, a number of useful descriptive and advisory documents have been prepared by EPA, other government agencies, and a range of private sector and industry-association groups. Two useful sets of documents from EPA are the Sector Notebooks and the Compliance Assurance documents, developed by EPA in the mid- to late-1990s. The last column in Table 1 includes the Federal report number of those documents that address particular NPDES categories, where such documents have been developed. Those guides do not contain the full text of the regulations and are not to be understood as the complete list of actions required by the regulated community, so the reader should refer to complete regulations to ensure compliance. Instead, they summarize the totality of regulatory requirements of which an operator should be aware. These are perhaps at their most useful in summarizing the range of environmental regulations that apply to a particular sector, including placing CWA requirements in the context of other regulations and listing the kinds of measuring, reporting, and documenting that can fulfill one or several of these requirements singly or jointly. Counter to the NPDES approach, many of those useful documents do follow the traditional SIC categorization, so the facility operator needs to find his or her own activities using a broad and flexible definition of his own processes.

Information about other industries, not named as CWA point-source categories, includes:

Dry cleaning	EPA/310-R-95-001
Wood furniture and fixtures	EPA/310-R-95-003
Motor vehicle assembly	EPA/310-R-95-009
Printing	EPA/310-R-95-014
Air transportation	EPA/310-R-97-001
Ground transportation	EPA/310-R-97-002
Water transportation	EPA/310-R-97-003
Shipbuilding and repair	EPA/310-R-97-008
Agricultural crop production	EPA/310-R-00-001
Agricultural livestock production	EPA/310-R-00-002
Aerospace	EPA/310-R-98-001

Table 1. Industry Sectors Subject to Category Numeric Limitations for Wastewater Discharges; Sources of Information

Industry Sector (Point Source Category)	CFR Section (Effluent Limitations Listed)	Additional Information*
Dairy products processing	405	
Grain mills	406	
Canned and preserved fruits and vegetables processing	407

NPDES AND WATER QUALITY-BASED LIMITATIONS

Since its inception, CWA has included the stated intent that water quality considerations would overlay the uniform effluent limitations and, where necessary to attain ambient standards, would justify more stringent requirements for particular discharges, which was to be done by the states' routinely assessing the attainment of water quality standards in receiving waters. In cases where uniform limitations had been fully attained, and the water quality continued to fall short of state-specified standards, the states were to develop plans that would lead to attaining the specified ambient standards in all waters. NPDES is envisioned as a tool to attain the standards: states and/or POTWs may issue more restrictive NPDES limitations than the uniform effluent limits. This condition is identified as water quality-based effluent limitations.

For a variety of institutional reasons, this approach was applied only to a limited extent over roughly the first 20 years of CWA implementation. Since the mid-1990s, largely driven by court findings that the states should be held to water quality-based protections, EPA and the states have been busily developing programs to attain ambient standards, in large part within the Total Maximum Daily Load (TMDL) program of watershed-based planning and water quality protection. That program is addressed more fully in other parts of this encyclopedia. From the standpoint of effluent limitations on industrial wastewater discharges, the key aspect of this program is that specified limitations under NPDES permits may be made more stringent than the uniform limitations specified under CWA regulations. Selection of those limitations is guided not by economic considerations, but wholly by the requirement to attain water quality standards of the effluent's receiving waters and of systems connected to those waters.

STORM WATER EFFLUENT LIMITATIONS

The discharge of storm water runoff appears as a separate category of effluent limitation under CWA, except for a small number of industry categories (petroleum refining, for example) where storm water is included in wastewater to be collected, treated, and discharged under the wastewater NPDES permits. For most industry categories, storm water runoff requirements are a separate set of rules promulgated pursuant to the 1987 reauthorization of CWA, effective in 1992. Storm water runoff was identified in the original CWA as a nonpoint source, separate from the NPDES regulations designed for point sources, and set aside for regulation under future rulemaking. After a court finding in the 1980s that storm water can be considered a point source—in many cases, it does, after all, enter waters of the United States from a discrete channel or pipe leaving a municipal system or an industrial facility—EPA was required to include discharges of storm water runoff under NPDES.

The approach EPA has adopted for storm water runoff is substantially different from that of other industrial point sources in at least two respects. One is that EPA does not specify or require numeric effluent limitations on storm water discharges; instead, storm water discharges both by industrial facilities and by local agencies (through municipal separate storm sewer systems, MS4s) are subject to narrative standards, such as that the discharge not cause or contribute to water quality problems in waters of the United States. The second key difference is the use by EPA and the states of the general permit approach. NPDES permits for storm water discharges associated with industrial activities have been promulgated as permits encompassing rules for the entire regulated community, rather than written specifically for each discharger. That is, the permits identify by type the facilities, and the discharges, that are subject to the permit; specify a series of actions required of facilities subject to the permit; and require dischargers that fit that type to identify themselves and complete the specified requirements (7). Failure to comply carries the same penalties as other discharges without an NPDES permit, and EPA and the states are expected to implement compliance and enforcement actions to promote and require compliance; but facilities do not hold site-specific permits, and in almost no cases are they held to numeric effluent limitations. As a result of these major differences from the overall structure of numeric effluent limitations in other NPDES requirements, industrial discharge of storm water runoff is not treated within this section.

ODOR ABATEMENT IN WASTEWATER TREATMENT PLANTS

JIM PHILP
Napier University
Edinburgh, Scotland, United Kingdom

CHRISTOPHER POLLEY
SUE MCLEOD

Newarthill, Motherwell, United Kingdom

INTRODUCTION

Odorous emissions from sewer systems and wastewater treatment plants are produced generally by hydrogen sulfide (H_2S) and volatile or semivolatile organic compounds at very low concentrations; they are present in the liquid phase and are emitted into ambient air at the liquid–gaseous interface (1). These odors cause serious complaints in the vicinity of wastewater treatment plants. As a result, odor control has become a key issue facing wastewater treatment plant management (2). Developments are under way to improve techniques for assessing odor and producing new technologies for destroying odor.

Volatile organic compounds (VOCs) are often amenable to biological treatment through a variety of reactor formats. However, several other technologies exist that could be used in treating them to abate odor. The eventual choice of a technology largely depends on the efficiency of treatment and capital and operating costs. The advent of the “triple bottom line” now considers sustainability of the technique also, although this concept is in its infancy. Biological treatment undoubtedly represents a sustainable green option, but it must also be proven economically viable and efficient.

HOW IS ODOR MEASURED?

Olfactometry is the most widely used method for measuring odor concentrations (3). Odor is “measured” by diluting the odor-bearing gas in a dynamic system where it is presented to groups of volunteers at various dilutions. The threshold odor number (TON) is the concentration at which half of the panel of volunteers can detect the smell (4) or fail to distinguish it from odor-free air. Although far from perfect at present (5), a quantitative approach to the development of standards in olfactometry is being developed successfully in Europe (6).

Electronic sensing systems—the so-called “electronic nose”—are being researched as a replacement for, or complement to, olfactory measurements. Arrays of nonspecific sensors can respond to many thousands of chemical species due to the broad selectivity of the sensor surfaces (7). This technique can be used to produce a unique odor profile or fingerprint, which can be further interrogated by pattern recognition techniques or neural networks. Although this is far from a complete technology, results have shown that a nonspecific sensor array can measure odor concentration from a specific wastewater treatment works (2).

WHAT CAUSES ODOR AT WASTEWATER TREATMENT PLANTS?

Odor-producing substances created during wastewater treatment are small, relatively volatile molecules whose molecular weight is about 30–150. The odor is composed of a large number of different chemicals. Many of these substances develop from the anaerobic decomposition of organic matter containing sulfur and nitrogen. Inorganic gases produced during wastewater treatment include hydrogen sulfide (H_2S), ammonia (NH_3), carbon dioxide (CO_2), and methane (CH_4), of which only hydrogen sulfide and ammonia create odor problems.

Many of the causal molecules contain sulfur and are produced in trace concentrations during anaerobic decomposition. For example, mercaptans (Table 1) are highly offensive at very low threshold concentrations and are common in wastewater treatment. They are reduced compounds, analogous to alcohols with a substitution of sulfur for oxygen in the OH radical (8). Hydrogen sulfide is the predominant odorant from sewage, and it results from bacterial sulfate reduction, a dissimilatory, anaerobic process using sulfate as a terminal electron acceptor.

Anaerobic decomposition of proteins, amino acids, and urine results in a variety of odorous, nitrogen-containing compounds (Table 1). The resulting amines

Table 1. Odorous Chemicals from Wastewater Treatment[a]

Compound	Formula	Odor Character
Hydrogen sulfide	H_2S	Rotten eggs
Diallyl sulfide	$(CH_2CHCH_2)_2S$	Garlic
Diethyl sulfide	$(C_2H_5)_2S$	Nauseating
Dimethyl disulfide	$(CH_3)_2S_2$	Putrification
Allyl mercaptan	CH_2CHCH_2SH	Garlic
Butyl mercaptan	C_4H_9SH	Unpleasant
Crotyl mercaptan	$CH_3CHCHCH_2SH$	Skunk, rancid
Methyl mercaptan	CH_3SH	Decayed cabbage, garlic
Thiocresol	$CH_3C_6H_4SH$	Skunk, rancid
Thiophenol	C_6H_5SH	Putrid, nauseating, decay
Ammonia	NH_3	Sharp, pungent
Methylamine	$CH_3\ NH_2$	Fishy
Trimethylamine	$(CH_3)_3N$	Fishy, ammoniacal
Cadaverine	$NH_2(CH_2)_5\ NH_2$	Decomposing meat
Indole	$C_8H_6\ NH$	Fecal, nauseating
Skatole	$C_9H_8\ NH$	Fecal, nauseating
Acetic acid	CH_3COOH	Vinegar
Butyric acid	C_3H_7COOH	Rancid, sweaty
Valeric acid	C_4H_9COOH	Sweaty
Formaldehyde	$HCHO$	Acrid, suffocating
Butyraldehyde	C_3H_7CHO	Rancid, sweaty
Acetone	CH_3COCH_3	Fruit, sweet
Butanone	$C_2H_5COCH_3$	Green apple

[a] (Adapted from References 8 and 9)

have an offensive, fishy smell, and indole and skatole smell strongly of feces. Anaerobic fermentation end products include a range of short-chain volatile fatty acids that have a rancid, disagreeable odor. Aldehydes, alcohols, and ketones are byproducts of carbohydrate fermentation. Although many of these compounds have an odor described as sweet or fruity, their contribution with the other components leads to odors characteristic of wastewater treatment plants. Thus, it is hardly surprising that over 40% of respondents in a study of 100 German wastewater treatment plants (10) identified sludge treatment processes as sources of odor.

VOLATILITY

VOCs can be defined as those compounds whose vapor pressure is 0.01 kPa or more. The volatility of a compound is a function of its vapor pressure. Vapor pressure may be thought of as the pressure exerted by a chemical on the atmosphere. Compounds that have high vapor pressure exert higher pressure on the atmosphere and therefore have an increasing driving force to volatilize. High water solubilities and low vapor pressures tend to decrease the potential for volatilization of dilute species from water. However, compounds that have a low vapor pressure may still have a high tendency to escape if their water solubility is low. For example, methanol as a pure compound is highly volatile but has a low tendency to evaporate from aqueous solution as it has infinite water solubility. So vapor pressure alone is not the best guide to volatility.

Henry's law constant is the best indicator of the tendency of a compound to volatilize from water. It can be expressed in two forms; one has units and one has a dimensionless form. Henry's law in the dimensionless form (H_D) can be expressed as

$$H_D = C_A/C_W \tag{1}$$

where C_A = the concentration in air (mol/m^3)
C_W = the concentration in water (mol/m^3).

Henry's law is the ratio of the partial pressure of a compound in the atmosphere to its concentration in water. Henry's law constant H_D has units of atm-m^3/mole and can be converted to its dimensionless form by

$$H = H_D(RT)^{-1}$$

where R = the universal gas constant [8.2×10^{-5} m^3-atm (mole-K)$^{-1}$]
T = the temperature on the Kelvin scale (K)

Thus, high values for Henry's constant indicate that the compound is volatile and low values indicate low volatility. Figure 1 is a working guide to the volatility of compounds based on Henry's law constants.

BIODEGRADABILITY

The ability of microorganisms to degrade environmental pollutants depends on the chemical functional groups present; some are more easily attacked than others. Although there is a well-accepted order of biodegradability of functional groups, the predictability of biodegradation is not yet an exact science:

$$\begin{aligned}&\text{Ester} \rightarrow \text{anhydride} \rightarrow \text{carbonyl} \rightarrow \text{sites of unsaturation}\\ &\rightarrow \text{methyl} \rightarrow \text{amide} \rightarrow \text{hydroxyl}\\ &\rightarrow \text{epoxide} \rightarrow \text{benzene} \rightarrow \text{methylene}\end{aligned}$$

$$\xrightarrow{\hspace{10cm}}$$

Decreasing biodegradability

As the knowledge of biodegradability is woefully incomplete (less than 0.01% of known organic compounds have been tested) at present, there has been an initiative started to gather the information available and organize it systematically (12).

AQUEOUS PHASE PARTITION

When dealing with VOCs, a rate-determining step is likely to be aqueous solubility. Convincing evidence now exists that microbial biodegradation happens only in the aqueous phase, and therefore the overall rate of biodegradation of hydrophobic pollutants may be mass transfer limited. Of relevance to VOCs is the concept of threshold (13). If a chemical is so volatile that only a very low concentration exists in aqueous solution, then this may limit microbial growth. At some lower value, all the energy available from the carbon entering the cell may be used to keep the cell alive, and none is used for growth. The substrate (the VOC in this instance) is being metabolized, but the population size and biomass are not increasing. This concentration represents the threshold.

Hydrophobicity is the final key determinant of bioavailability and thus biodegradability. As a general rule, polar,

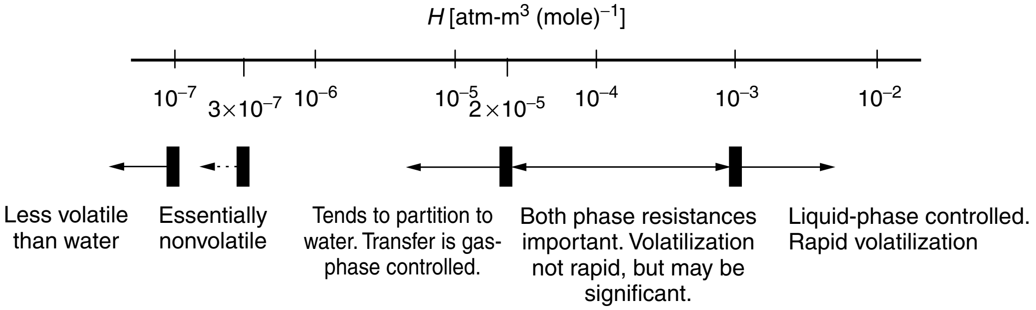

Figure 1. Ranges and relative values of Henry's law constants (adapted from Reference 11).

water-soluble, hydrophilic chemicals are more readily available to organisms than nonpolar, water-insoluble, hydrophobic ones. The polarity of a chemical has a strong negative correlation with its log octanol–water partition coefficient (log K_{ow}). K_{ow} is the ratio of a chemical's concentration in octanol to its concentration in water at equilibrium. K_{ow} was developed by the pharmaceutical industry as an index to predict the behavior of a drug in the body because partitioning between octanol and water roughly mimics partitioning between body fat and water. It is used as a convenient measure of hydrophobicity.

The above highlights the fact that the biodegradability of individual VOCs depends on the interplay of several factors. But it is also used to stress that VOCs have to be made available to an aqueous phase before biodegradation is feasible.

COMPETING TECHNOLOGIES

There are several noteworthy technologies for treating VOCs to abate odor.

Recovery/Removal

Recovery/removal treatments extract the VOC from the air stream for recycling. Whereas recovery has obvious benefits in industries using solvents, there is no benefit in the animal rendering business.

Adsorption. This is the physical adhesion of molecules to the surfaces of an adsorbent without chemical reaction. The adsorbent is usually present as a finely powdered material to maximize the surface area for contact. For activated carbon, the surface area available is very high, of the order of 1000 m^2/g. Where both the VOC concentration and the flow rate are low, activated carbon is the normal absorbent of choice. In such instances, the carbon is removed periodically and sent for regeneration or disposal. When the VOC concentrations or the flow rates are high, an *in situ* regeneration system is usually used.

Scrubbing. Water is the most common scrubbing liquid. Alkaline solutions are used for acidic components and acid solutions for alkaline compounds such as ammonia (14).

Condensation. At high VOC concentrations, an air stream may be cooled sufficiently to allow condensing the VOC as a liquid. Cryogenic condensation may be required to achieve sufficiently low concentrations. Such techniques are relatively energy-intensive, which contributes to high running costs (See Fig. 7).

Destruction

Destructive technologies aim to break down VOCs to carbon dioxide and water.

Oxidation. Oxidation can destroy most organic compounds. It is currently the most widely used technology for VOC treatment, but both thermal and catalytic oxidation systems have very high capital and running costs. Thermal oxidation requires raising the exhaust gas temperature to over 800 °C; heat recovery is employed to improve cost-effectiveness. Catalytic incineration operates at around 350 °C.

A summary of the available technologies for treating VOCs is shown in Fig. 2.

BIOLOGICAL TREATMENT TECHNOLOGIES

The biotreatment plants available for VOC treatment are adaptations of traditional, highly successful fixed film

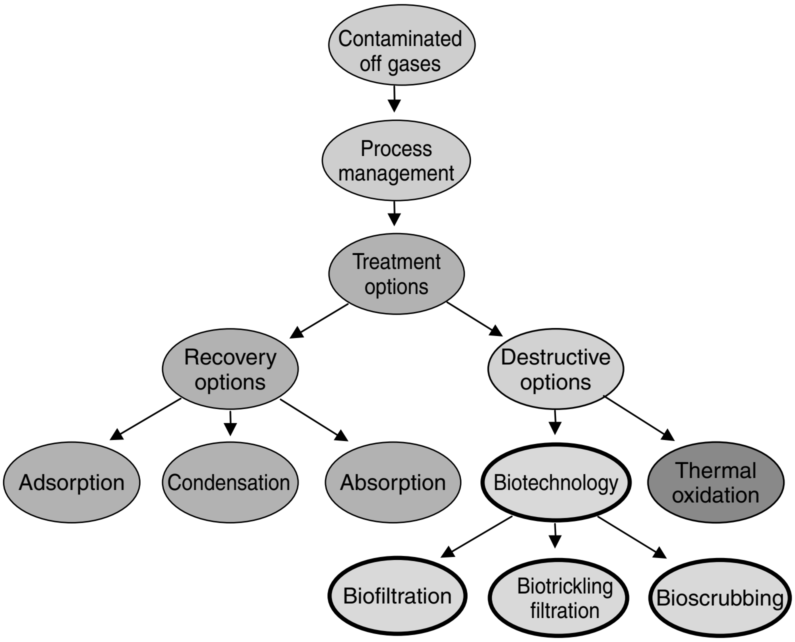

Figure 2. Available options for treating VOCs.

technologies used for wastewater treatment. The most crucial modification is the means of dissolving the VOC in the aqueous phase. They are simple mechanically, which means that maintenance and operation are simple and inexpensive. Expected life spans are of the order of 20 years. The most frequent maintenance required is periodic cleaning of the filter support material and sludge disposal.

Biofilters

VOC-containing stream(s) are humidified and discharged to the top of a reactor filled with an inert support medium to which the appropriate microorganisms attach and form a treating biofilm. Treatment is in the down-flow mode (Fig. 3); thus treatment is only effected by biofilm organisms and not by freely suspended biomass. Natural supports (e.g., bark, peat, compost, heather) improve the sustainability of the operation. Plastic supports can be used, but those available for wastewater trickling filters are probably too large; the void volume is so large that short-circuiting may be possible.

Biotrickling filter. The VOC-laden airstream enters at the bottom of the reactor and passes upward through the biofilm immobilized on a high surface area synthetic support (Fig. 4). Water downflow ensures the delivery of inorganic nutrients and keeps the biomass moist. The VOCs dissolved in the aqueous phase are mineralized in the process. Note that filter is a misnomer—filtration plays only a small part in the operation; the major contribution comes from biological oxidation.

Bioscrubber. VOCs are first absorbed in a liquid phase (usually water) in a tower packed with an inert biomass support (A, Fig. 5). The solution is then pumped to an aerated tank containing a suspended flocculating biomass in an activated sludge process (B) where biodegradation takes place. The treated water is settled to return biomass to the process, and the wastewater discharged.

CHOICE OF OPTIONS

A wide range of factors other than costs govern the technology choice. The principal factors are concentration and flow rate. Figure 6 gives a technology selection based on these two factors. However, bear in mind that plants are application-specific. For example, biofilters appear to be the best option (of the biological and other treatments) for dealing with animal carcass disposal VOCs (14).

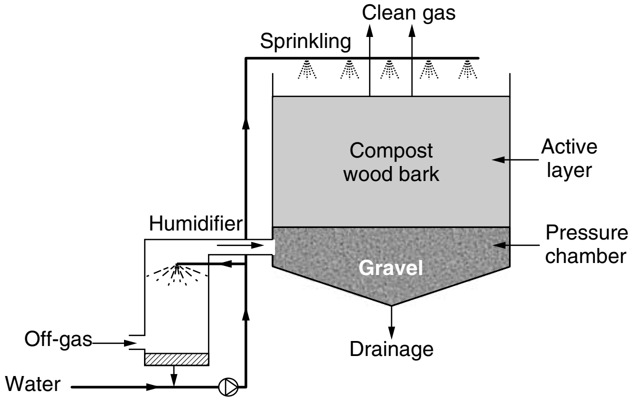

Figure 3. Biofilter characteristics.

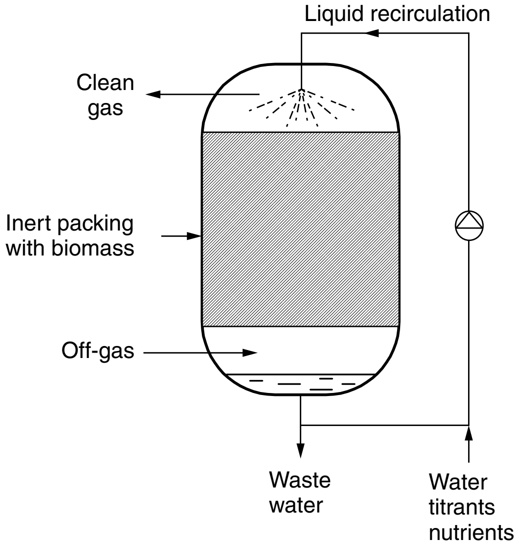

Figure 4. Biotrickling filter characteristics.

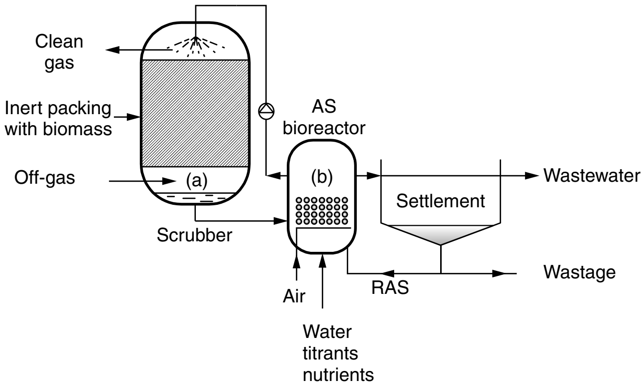

Figure 5. Bioscrubber characteristics.

THE BOTTOM LINE

Biological treatments for VOC degradation must compete with the other available technologies in treatment efficiency and also cost. The ambient conditions for treatment, low maintenance, and reasonable capital costs mean that biological methods compare very favorably with other competing technologies (Fig. 7). The size and the complexity of the plant are the determining factors that affect treatment cost. Plant size is a function of the volume of off-air to be treated daily and how well the VOCs dissolve in water.

AQUEOUS REACTIONS OF SPECIFIC ORGANIC COMPOUNDS WITH OZONE

James B. Duncan
Kennewick, Washington

Ozone is an allotropic form of oxygen and exists as a pale-blue gas (O_3) with a pungent odor. It is very reactive chemically and decomposes without difficulty ($2O_3 \rightarrow 3O_2$). Within the arena of water treatment, it is used for disinfection and for taste and odor control. Ozone is 13 times more soluble in water than in oxygen, with a half-life of approximately 40 minutes at 14.6 °C at pH = 7.6. The density of ozone ranges from 1.09 kg/m at 0 °C to 0.14 kg/m^3 at 60 °C (1). From the table presented by Ullmann, the data fit a polynomial regression of Eq. 1.

$$y = -1.66\text{E-}06x^3 + 3.9\text{E-}04x^2 - 3.3\text{E-}02x + 1.086 \qquad R = 0.9998 \qquad (1)$$

where $y = O_3$, kg/m^3 and x = temperature, °C.

At higher temperatures and pH, the half-life decreases significantly. Although an excellent disinfectant, ozone oxidizes ammonia in a negligible amount in water treatment operations and ozone has little to no residue within a water distribution system. In addition to the above-mentioned aspects of ozone use, the other uses of ozone are:

- Control of excessive color
- Oxidation of iron and manganese
- Oxidation of organics
- Flocculation aid
- Does not form trihalomethanes (THMs); ozone has the ability to remove precursors to THM formation (2)

To analytically determine the amount of ozone residual in water, the 1995 edition of *Standard Methods, Method 4500-O_3 B.*, calls out the Indigo Colorimetric Method as the approved method (3).

Ozone-induced oxidations in aqueous environments can generally be described in the sequence of reactions as depicted in Fig. 1 (4,5). An amount of the ozone dissolved in an aqueous environment reacts directly with solutes (M). Usually these reactions are highly selective and demonstrate slow kinetics, on the order of minutes. Part of the ozone will decompose before reaction with solutes leading to free radicals. Among the free radicals, the hydroxyl radical is one of the most reactive oxidants. The hydroxyl radical can easily oxidize all types of organic contaminants along with several inorganic solutes. The hydroxyl radicals demonstrate rapid kinetics and are consumed in microseconds while demonstrating little substrate selectivity. In measured oxidations in model solutions, the indication is that up to 0.5 mole of hydroxyl radical ($OH^\bullet$) is formed per mole of ozone decomposed. As the pH increases, so does the decomposition of ozone, which is catalyzed by the hydroxyl ion (OH^-). Ozone decomposition may be accelerated by an autocatalyzed sequence of reactions in which radicals formed from decomposed ozone act as chain carriers. Some solutes will react with the hydroxyl radicals and from secondary radicals ($R^\bullet$), which may still act as chain carriers. Other species, such as bicarbonates, will inhibit chain reactions, which transform the primary radicals to terminal species (Φ). The rate of ozone decomposition is a function of the ozone concentration and pH as well as the solutes present (6,7).

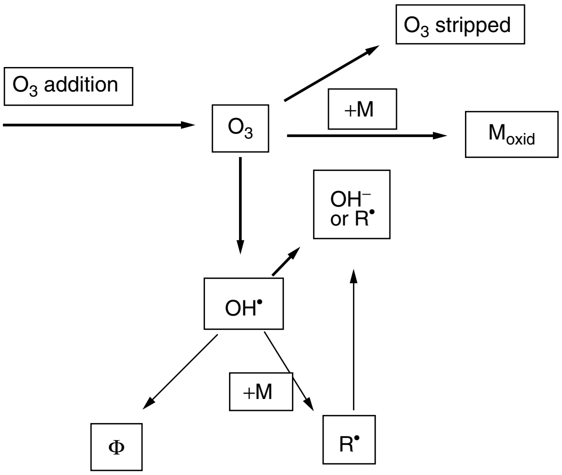

Figure 1. Ozone-induced oxidation.

When ozone attacks an organic carbon–carbon double bond (alkene), it first forms a molozonide, which quickly rearranges itself to an ozonide before the release of product (8) (see Fig. 2). Likewise, ozone will attack an alkyne bond in the following manner (8) (see Fig. 3). In an aqueous environment, ozone has different reactions because of its electronic configuration and may directly oxidize organic compounds. The reactivity of ozone is strongly influenced by electron density at sites of attack. Reactions of ozone with aromatics substituted with electron donor groups (OH, CH3, and NH_2) are exacerbated. However, aromatics substituted with electron withdrawing groups (COOH and NO_2) are retarded. The direct reactions can be divided into two categories: (1) the cyclo addition (Criegee mechanism) and an electrophilic reaction. The Criegee mechanism is selective to carbon–carbon double bonds, which then forms carbonyl compounds. An excellent review of the above-mentioned reactions may be found in Refs. 4 and 9. Rice reported on the following organic groups open to reactions with ozone (10) (see Fig. 4).

Discussions of ozone reactions with aliphatic compounds are found in Refs. 6 and 11–14. References 15–19

THE FATE OF PERSISTENT ORGANIC POLLUTANTS (POPs) IN THE WASTEWATER TREATMENT PROCESS

C. Samara
A. Katsoyiannis
Aristotle University of Thessaloniki
Thessaloniki, Greece

INTRODUCTION

Municipal wastewaters may contain a wide range of organic compounds deriving as components of domestic sewage, the urban runoff, including wet and dry deposition from the atmosphere, and industrial discharges (1,2). Among them are chlorinated biphenyls, dioxins and furans, polycyclic aromatic hydrocarbons, pesticides, pharmaceutical and personal care products, detergents, dyes, and solvents (3–7). Modern wastewater treatment plants (WWTPs) can effectively accomplish carbon and nitrogen removal, as well as microbial pollution control. However, conventional treatment technologies have not been specifically designed for the different organic contaminants of wastewater (natural or synthetic). The removal efficiencies of these compounds are influenced, apart from their physicochemical properties, by microbial activity and environmental conditions (2,8). Several studies have shown that the elimination of organic contaminants is often incomplete (2,7,9), rendering WWTPs important sources of toxic chemicals to the receiving environment (10–15).

Persistent organic pollutants (POPs) are a class of chemicals with pronounced persistence to biological/chemical degradation and, as such, are expected to be less efficiently eliminated in the conventional biological treatment of wastewater. Included in this class are the intended industrial products organochlorine pesticides (OPs), among them Dieldrin, Aldrin, Endrin, DDT, Toxaphene, Mirex, Chlordane, hexachlorobenzene, hexachlorocyclohexanes (HCHs), chlorinated biphenyls, and PCBs and the unintended polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs). In addition to their

persistence, POPs are hydrophobic compounds with a strong tendency for bioaccumulation. They have toxic effects on animal reproduction, development, and immunological function. POPs span a large range of volatility and condensation temperatures, and some may present high mobility through the global distillation process (16). Several actions have been taken by environmental organizations and governments to restrict the inputs of POPs to the environment. The emissions of PCDD/Fs from their major sources—waste incinerators—have been strictly regulated. The production of PCBs and OPs has been banned in the United States and in Europe since the mid-1970s, although some of them were still being used until lately in developing countries, and in 2001 the Stockholm Convention for POPs banned the manufacture and use of these chemicals worldwide.

Several studies worldwide have indicated the presence of POPs in wastewaters treated in WWTPs (2,6,12,15, 17–23). Their influent concentration levels depend on the origin of the wastewater, and mainly on the contribution of industrial discharges. The fate of POPs in WWTPs is influenced by several factors: the physicochemical properties (Table 1) of the compounds, their biodegradability potency, and the composition of treated wastewater and the operational characteristics of the plant.

THE ACTIVATED SLUDGE TREATMENT PROCESS

Conventional WWTPs include two reactors—the primary reactor (primary sedimentation tank) and the biological reactor (aeration and secondary sedimentation tanks)—and, finally, a disinfection stage. The sludge that is produced during the primary and secondary sedimentation also undergoes treatment comprising digestion (usually anaerobic), thickening, homogenization, and dewatering (Fig. 1).

Behavior of POPs in the Primary Reactor

POPs entering the primary treatment stage of a WWTP are likely to be removed through sorption onto suspended solids and subsequent sedimentation, advection out of the tank to the biological reactor (either in the dissolved or the adsorbed phase), volatilization to the atmosphere through diffusional exchange at the air–water interface, and biotransformation (30). Given the hydrophobic character of most POPs and their resistance to biodegradation, the principal removal mechanisms from this stage are sorption, advection, and possibly volatilization, whereas biotransformation is considered to have only a minor influence. Sorption to the sludge has been shown to remove considerable fractions of POPs, in general between 18% and 90% for individual compounds (2,31–33). The physicochemical parameter that best describes the tendency of POPs to be sorbed onto suspended particles is the *n*-octanol–water partition coefficient (K_{ow}). The tendency of POPs to be sorbed could be generalized as follows (34):

$\log K_{ow} < 2.5$	Low sorption potential
$\log K_{ow} > 2.5$ and < 4.0	Medium sorption potential
$\log K_{ow} > 4.0$	High sorption potential

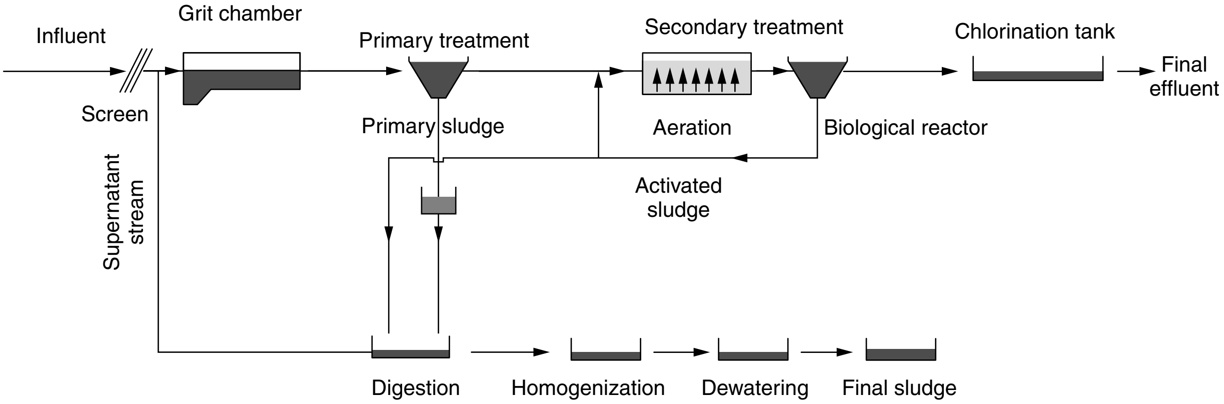

Figure 1. Flowchart of a conventional wastewater treatment plant.

The log K_{ow} values of individual POPs vary between 3.8 for HCHs and 8.2 for highly chlorinated dioxins and furans (Table 1), suggesting different sorption rates for different compounds within this class of chemicals.

Katsoyiannis and Samara (35), investigating the distribution of 20 POPs (13 OPs and 7 PCBs) between the sorbed and the aqueous phase of untreated and treated wastewater and sludge in a conventional WWTP, found that phase partitioning, expressed by the distribution coefficient K_d is influenced by two parameters: the concentration of solids, either suspended or settling (SS), and the concentration of dissolved organic carbon (DOC). For both parameters, an inverse relationship with log K_d was observed, suggesting that DOC and nonsettling microparticles can be an important carrier of POPs in the dissolved phase of treated effluents. Morris and Lester (32) also suggested that the existence of miscible organic solvents and nonsettling fine particles ($<100\ \mu$m) in the wastewater can increase the percentage of hydrophobic chemicals that remain in the effluent of the primary sedimentation tank.

The removal efficiency of POPs in the primary stage due to sorption can also be affected by the operational characteristics of the plant. According to Byrns (30), the removal of POPs due to sorption in settled sludge from the primary sedimentation stage might be influenced (decreased) following a reduction in sedimentation efficiency resulting, for instance, from an increased influent flow rate.

Volatilization and biodegradation/biotransformation are not expected to have significant contribution to the removal of POPs in the primary sedimentation tank. However, remarkable losses have been observed in the mass balance of DDT around the primary reactor, which were attributed to biodegradation under aerobic conditions (35,36).

Behavior of POPs in the Biological Reactor

In the activated sludge stage, a similar array of mechanisms controls the fate and intermedia transport of POPs. In this stage, air stripping due to the forced injection of air into the mixed liquor is considered as opposed to the diffusional exchange under the quiescent conditions characterizing the primary stage.

Sorption on activated sludge has been shown to remove up to 65% of Heptachlor, 18% of Lindane, and 60% of Aroclor 1254 entering the biological reactor (22,37). Byrns (30) suggested that almost 96% of DDT and 2,3,7,8-TCDD but only 34% of Dieldrin are likely to be adsorbed to surplus sludge. The secondary sorption rates are usually lower than the primary ones.

Data for the biodegradation/biotransformation of POPs in biological treatment plants are sparse and relatively few studies have been undertaken to determine rate coefficients (rate coefficients as low as 0.0001 have been reported in Ref. 38 for DDT, Dieldrin, and 2,3,7,8-TCDD). Biotransformation of a chemical in the dissolved phase is governed by the hydraulic retention time of the mixed liquor in the biological reactor, whereas for chemicals strongly sorbed to the biomass solids, the average reaction time for biodecay will be governed by the operating solids retention time as a result of the biosorption phenomenon (30). Biodegradation/biotransformation in the secondary treatment has been suggested for certain POPs, such as for Lindane (33,39), for Aldrin to Dieldrin, for Isodrin to Endrin, for Heptachlor to Heptachlorepoxide (37), and for DDT to DDE and DDD (21,35). Highly chlorinated compounds such as PCBs and PCDD/Fs are considered as resistant to degradation under aerobic conditions and would only degrade under anaerobic conditions (34).

Volatilization of POPs during the secondary treatment is facilitated by the forced injection of air in the aeration tank, which is important for some POPs. Volatilization occurs from the dissolved fraction since the fraction sorbed to the solid phase is not directly available, under equilibrium conditions, for mass transfer across the water–air interface. The significance of volatilization losses of specific organic compounds during sewage treatment can be estimated using the following empirically defined categories based on Henry's law constant (H_c, in atm·m^3·mol^{-1}) (34):

$H_c > 1 \times 10^{-4}$	High volatilization potential
$H_c < 1 \times 10^{-4}$	Low volatilization potential

The H_c values of POPs vary between 3×10^{-4} for PCBs to 5×10^{-7} for Endrin (Table 1), suggesting that removal due to volatilization is also a compound-specific mechanism. Bamford et al. (40), studying the air–water exchange of PCBs, suggested that approximately 10% of the dissolved PCB content in a water column exchanges with the atmosphere each day. In their study, Petrasek et al. (37) showed that Heptachlor and Aroclor 1254 might be removed up to 50% by volatilization, whereas Lindane would hardly be volatilized. Finally, Byrns (30), modeling the fate of organic xenobiotics in conventional WWTPs, predicted very low removal percentages (<0.1%) for DDT, Dieldrin, and 2,3,7,8-TCDDs due to volatilization in the activated sludge stage.

Behavior of POPs in the Disinfection Stage

Disinfection is the final treatment step in a WWTP before the discharge of the effluent wastewater. Disinfection is usually done by use of free chlorine, which is followed by formation of chlorinated disinfection by-products, especially when the wastewater contains high concentrations of natural organic matter. These chlorinated by-products are basically trihalogenated methanes (THMs), but it has been suggested that formation of some POPs might also occur (41). No formation of POPs has been reported when other disinfection reagents are used (e.g., ClO_2).

The Fate of POPs in the Sludge Treatment Stream

The amounts of POPs that are removed primarily and secondarily by sorption/sedimentation are transported to the sludge treatment stream. It has been estimated that compounds with log $K_{ow} > 3.5$ will concentrate in sewage sludge in concentrations more than 200 times higher than the ones found in the raw wastewater, while for compounds with log $K_{ow} > 5$, the concentration factor may be even 1000 (30).

The persistence of POPs during the digestion of sludge under anaerobic conditions has not been completely clarified and many controversial studies have been published on this issue. Hill and McCarty (42) investigated the effect of anaerobic conditions during sludge digestion on the degradation of DDT, Aldrin, Dieldrin, Endrin, Heptachlor, and γ-HCH. They noticed enhanced degradation in comparison to the aerobic conditions for all the compounds except Dieldrin. The resistance to degradation followed the order Dieldrin > Aldrin > DDD > DDT > Endrin > Heptachlor > γ-HCH. Zitomer and Speece (43) reported that reductive dehalogenation takes place under anaerobic conditions, reducing the level of chlorination of organochlorine pesticides, thus making them more amenable to further degradation and in general rendering residues less toxic. Dechlorination of OPs is facilitated by the presence of suitable microorganisms in sewage sludge; for instance, the anaerobic bacterium *Clostridium rectum* is capable of degrading γ-HCH (44). In the case of PCDD/Fs, the dechlorination pathway is from the higher chlorinated 2,3,7,8-subtituted PCDD/Fs to the lower ones, which, in antithesis to PCBs and pesticides, have a higher toxic equivalence factor (TEF) rating, something that increases the overall toxicity of sewage sludge (45,46). Fu et al. (47) reported that abiotic dechlorination of PCDD/Fs in sludge leads to DiCDD/Fs as end products. This suggestion was also prompted by Stevens et al. (48), who found that DiCDFs were the predominant congeners in U.K. sewage sludges. However, this suggestion was not confirmed by Klimm et al. (49) and by Disse et al. (50), who under strictly anaerobic conditions did not observe any formation or destruction of PCDD/Fs. On the contrary, Klimm et al. (49) observed formation of hepta- and octa-CDDs under semianaerobic conditions, something that led to a twofold increase in the concentration of these congeners. Under the same conditions, there was no formation of other PCDD/Fs or PCBs congeners.

From the above-mentioned, it is difficult to decide if the POPs degrade or do not degrade during the anaerobic digestion of sewage sludge. The fact that POPs can be detected in almost all sewage sludges after treatment (46) suggests that they are rather resistant to this process.

The concentration of POPs, especially of PCBs and of PCDD/Fs, in sewage sludges is of great importance, since sewage sludge is often used in agriculture for soil amendment. The European Union (51), in order to improve the long-term protection of soils, is working on a new directive, which includes maximum permissible concentrations for use of sludge in agriculture. According to this upcoming directive (51), the sum concentration of 7 PCB congeners (IUPAC −28, −52, −101, −118, −138, −153, −180) should not exceed 800 μg/kg (dry matter, dm), the concentration of PCDD/Fs should not exceed 100 ng TEQ/kg (dm), and the sum of organochlorine compounds should not exceed 500 mg/kg (dm). In studies dealing with the occurrence of POPs in sewage sludges, ΣPCB levels have been found to vary dramatically from 22.7 to 8000 μg/kg (dm) (1,2,52–62). The reported PCDD/Fs concentrations are also greatly variable ranging between 0.7 and 4100 ng TEQ/kg (dm) (52,63–67).

The Fate of POPs Throughout the Overall Treatment Process

Studies have shown that POPs are recalcitrant to the conditions prevailing in typical biological WWTPs and persist in one or more phases within the treatment plant. Reported removal efficiencies throughout the overall treatment process range within 18–100% for PCBs and 75–90% for several OPs (2,6,31). There are no available data concerning the removal of PCDD/Fs in WWTPs. The distribution of POPs within the WWTP is dependent on the physicochemical properties of the chemicals and the operating conditions within the plant. The principal removal mechanism for the most hydrophobic POPs is through sorption to sludge particles and transfer to the sludge processing system. Advective transport into the final effluent, in association with suspended solids or in the dissolved phase, is also important for less hydrophobic compounds. It has been reported that from the 50 kg of all PCBs annually entering a WWTP, 60% is removed through the wasted sludge, 26% is discharged into the recipient with the final effluent, while 14% is lost due to volatilization or biotransformation (35). Therefore, the long-term ecotoxicological effects on both terrestrial and aquatic organisms need to be assessed for safe disposal of the products of the wastewater treatment process.

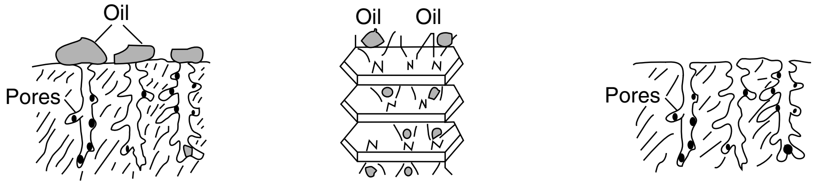
THE ROLE OF ORGANOCLAY IN WATER CLEANUP

George R. Alther
Biomin, Inc.
Ferndale, Michigan

Organically modified clays, also called organoclays, have been used to clean up water since 1985. Their prime function is as a prepolisher for activated carbon, ion exchange resins, and membranes. They are also used in a stand-alone mode after dissolved air flotation (DAF) and oil/water separation units. Their main use is to remove oils, greases, and other large hydrocarbons of low solubility from water. They are very adept at removing chlorinated hydrocarbons. In this application, organoclays are usually blended with anthracite in a ratio of 30% organoclay and 70% anthracite. The reason is that the organoclay, in its pure form, would collect so much oil in its interstitial pore spaces, and due to swelling of the clay, that it would last no longer than activated carbon, which removes 8–10% of oil based on its weight, before its pores are blinded. The organoclay blend, on the other hand, removes 50–70% of oil based on its weight, some seven times as much as activated carbon. The economic benefit for the end user, the one who pays for the cleanup, is a savings of 50% or more of operating costs.

Organoclays can be called prepolishers to carbon, but it can also be said that carbon is a postpolisher to organoclay. The reason is that the organoclay also removes other compounds, such as PNAHs, BTEX, PCBs, and other hydrocarbons of low solubility, with extreme efficiency. This has been shown in many publications through the last 15 years (1–5).

Organoclays are bentonites modified with quaternary amines. Bentonite is a volcanic, chemically altered rock that consists primarily of the clay mineral montmorillonite. Montmorillonite contains inorganic exchange ions, particularly sodium, calcium, and magnesium that hydrate in the presence of water and produce a hydrophilic environment on the surface of the clay. Mixing a cationic quaternary alkyl ammonium chloride or bromide compound with the bentonite makes the clay organophilic. Bentonite, which is hydrophilic in its natural state, becomes hydrophobic and organophilic when modified with



Activated carbon granule pore spaces of activated carbon, blinded by emulsified oil.

Activated carbon downstream of organoclay, ready to remove more soluble compounds.

Figure 1. How activated carbon and organoclay remove oil from water.

quaternary amines (6,7). The positively charged end of the amine chain, which consists of a carboxylic head that includes a nitrogen ion, exchanges for a sodium or calcium ion on the surface of the bentonite. The cationic amine now becomes neutral, and the thus formed organoclay has turned into a nonionic surfactant that has a solid phase. The swelling capacity of sodium bentonite in water is up to 15 times its volume, but nearly zero in hydrocarbon fuels and solutions (8). After the organic modification, the organoclay swells some 15 times in a fuel such as gasoline and by some 20% when placed into a column and exposed to fuels such as gasoline (9–11). Its swelling capacity in water is very low. If alcohol is added to a fuel, the organoclay will swell even more and turn the system into a gel, or even grease. For this reason, organoclays have been used as thickeners for paints, drilling muds, greases, printing inks, and many other systems since the 1950s.

Figure 1 shows how the two media differ in removing oil from water. The organoclay removes it by partition, whereas the activated carbon removes oil and other hydrocarbons by adsorption. Partition takes place outside the clay particle; adsorption takes place inside the pores, which is the reason that they become blinded by organic compounds equal to or exceeding the diameter of the pores.

During the late 1950s, it was discovered that organoclays remove organic compounds from water, including benzene (12). It was found that organoclays can remove chlorinated organic hydrocarbons of low solubility efficiently (13,14). Excellent descriptions of the mechanisms of organoclay interactions with organic compounds are also given by Lagaly (15,16).

The removal of these compounds from water by organoclays is the result of a partition mechanism similar to the process when immiscible organic compounds such as octanol are added to water contaminated with organic compounds (16,17–19). The interlayer phase of the organoclay acts as a partition medium for oils, greases, and other hydrocarbons (1,20–24). A portion of these organic compounds moves out of the water and into the organic compound where it is more soluble; like dissolves into like. The relative solubility of the contaminant determines the amount retained in each phase. The terminology can be extended to contaminants partitioning from the water phase into a solid phase such as organic cations sorbed to a clay surface. The higher the solution concentration of a compound and the lower its solubility, the larger the quantity removed by the organoclay by partitioning. The organic compounds are held closely by the quaternary amine by coulombic forces (25), and the contaminant is not easily leached off. If an amount of amine is exchanged into the bentonite that exceeds its stoichiometric capacity, the amine chains will still attach to the organoclay in a tail-to-tail interaction. The result is that this organoclay now has a positive charge and will remove organic and inorganic anions from water, such as humic acids and hexavalent chromium (Fig. 2) (26).

Only part of the clay surfaces is covered with the quaternary amines, so a portion remains free, available for cation exchange with heavy metals such as lead, zinc, nickel, cadmium, and iron. The cation exchange capacity of bentonite ranges from 70–95 meq/100 gram. Column studies were conducted with pure organoclay and an organoclay/anthracite blend, testing for a number of metals simultaneously, and then testing for the removal capacity for single metals (27).

The main application of organoclays has been in groundwater remediation. Removal of oil from water is the organoclay's main function. Figure 3 shows a column test with organoclay/anthracite to determine the sorptive capacity of this medium for a vegetable oil. A 30-inch long (76.2 cm) by 3-inch diameter (7.62 cm) column was constructed from polyvinyl chloride (PVC) and filled with about 6 pounds of sorbent material to be studied. A peristaltic pump forced an aqueous solution containing 680 mg/L of vegetable oil through the column, after the column was backwashed with water to displace any air pockets. Samples were collected periodically at the outflow of the column and analyzed for their organic content using chemical oxygen demand (COD) analysis. The results are shown in Table 1 and Fig. 3.

The percent removal capacity for a mineral oil such as Bunker C would be much higher because it is less soluble than vegetable oil. Figure 3 is a graphic description of these data.

Figure 4 shows the results of a column study comparing the removal capacity for oil between organoclay/anthracite and bituminous activated carbon. To gain some background data, the ability of powdered, nonionic organoclay to remove a variety of oils from water was tested in jar tests (26,28). The results displayed in Figs. 5–8 show that organoclay removes all oils from water exceptionally well, as long as they are refined. It is far superior to activated carbon, which is why it is used as a prepolisher. If oil is not refined, which means its composition includes polar compounds, either a cationic organoclay has to be used, or the oil, which is now partially chemically emulsified, must be deemulsified (1,21,23,28–30). Figure 9 shows

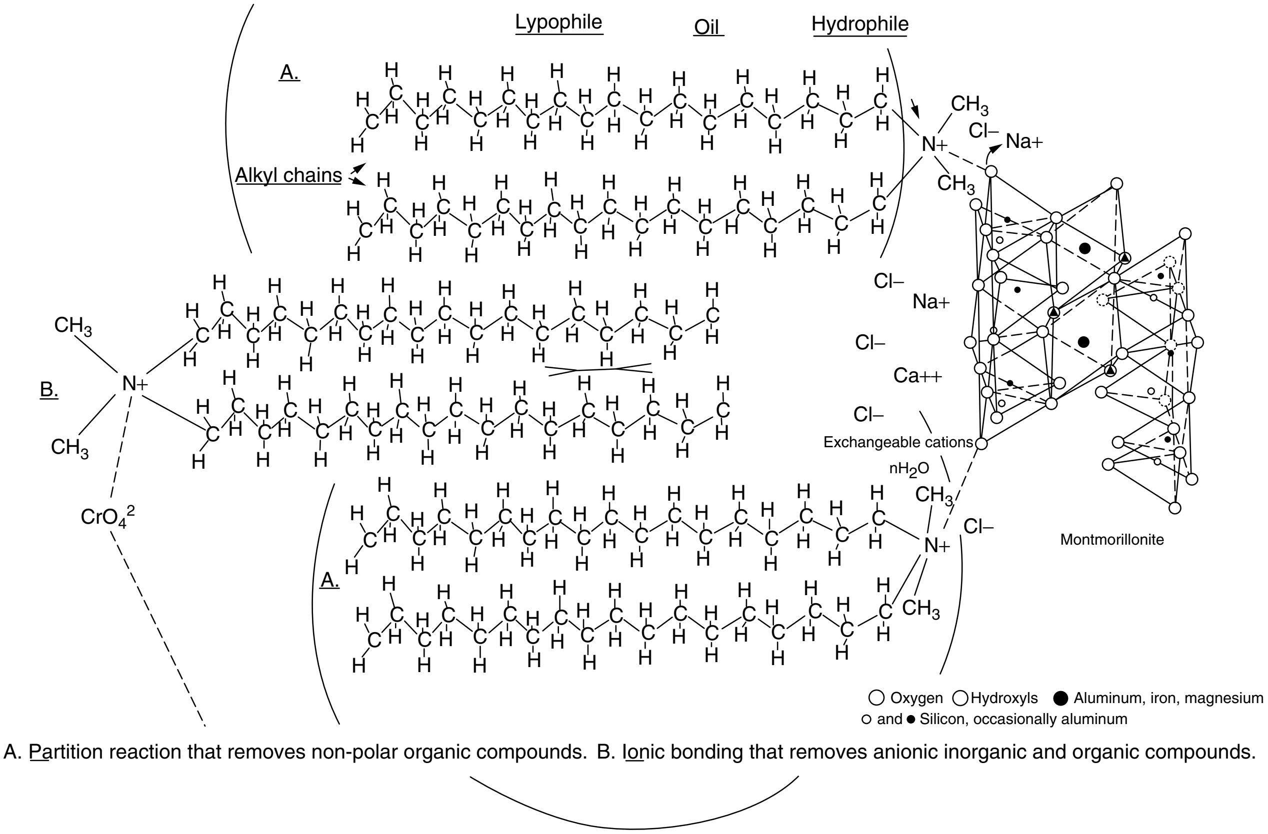

Figure 2. Model of an organoclay indicating partition and ion exchange adsorption mechanisms.

the effect of surfactants, which act as emulsifiers for oil, on the performance of organoclay. The effects are the same as on activated carbon; as solubility increases due to emulsification, the sorptive capacity decreases. Only the nonionic surfactant shows little effect on organoclay performance; probably it does not polarize the oils to any significant extent. Tests have shown that organoclay is just as effective in the removing surfactants from water as activated carbon (30). However, organoclay always prefers oil to any other compound; thus once the emulsion is split, the organoclay is used to remove the oil, followed by carbon which removes the surfactants.

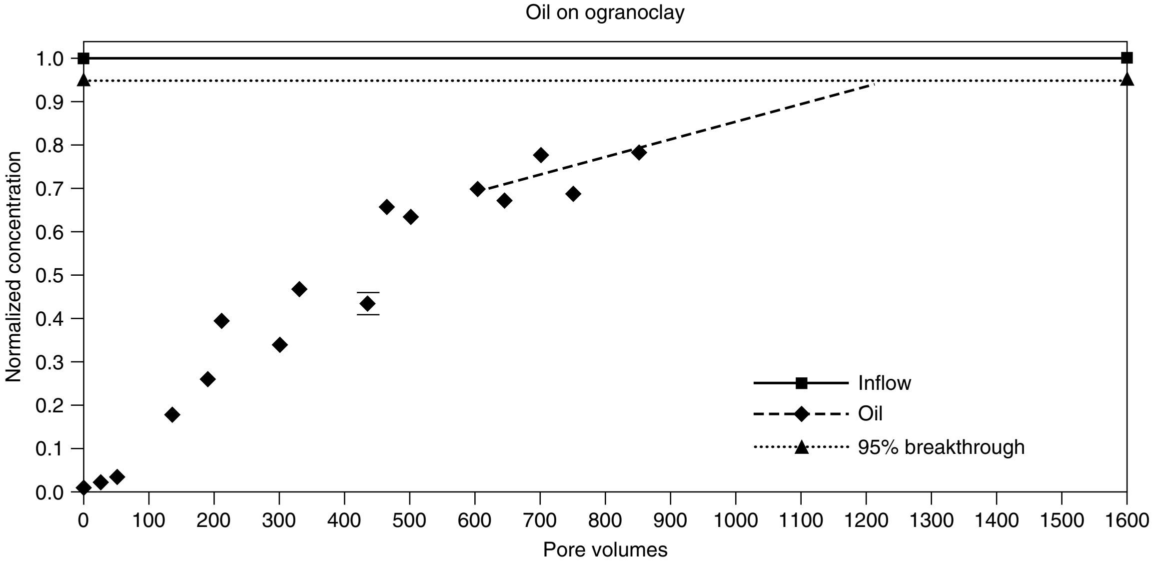

Figure 3. Breakthrough curve of oil on organoclay.

Table 1a. Sorbent Mass, Porosity, Flow Rate, and Residence Time

Mass Sorbent,		Porosity	Flow Rate,		Residence Time
kg	lb	%	mL/min	gal/h	min
0.141	0.31	0.3	15.45	0.23	8

Breakthrough		Mass Sorbed		Mass Sorbed per Mass Sorbent		
PV	min	g/lb		g/kg	lb/lb	% by sorbent
1150	9,200	65.8	0.14	475	0.475	47.5

A minicolumn test was used to determine the ability of organoclay to remove such compounds as benzene, toluene, xylene, naphthalene, and PCB, and to be able to compare the data with those of bituminous activated carbon. The minicolumn method consists of spiking water with the compound to be evaluated and pumping that water through 1 gram of sorbent powder, which is tightly packed into a very small column. Pumping is performed until the influent concentration equals that of the effluent concentration (26). The sorbents are of 200 U.S. mesh size. This method is more comparable to large-scale, real situations than isotherms.

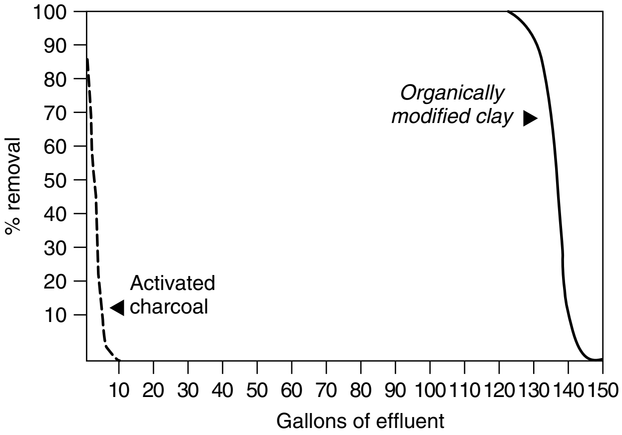

Figure 4. Removal of oil from water.

RESULTS

Figure 10 is a graphical illustration of minicolumn tests. When testing the removal capacity of the sorbents for benzene, toluene, *o*-xylene, and naphthalene, the organoclay performs similarly to carbon and performance improves as the solubility of the compounds decreases. Nonionic organoclay outperforms activated carbon with PCB 1260, as well as with motor oil, which is nearly insoluble in water. Surprisingly, organoclay removes methylene chloride much more effectively than activated carbon. The reasons are unclear, except that organoclay has an affinity for chlorinated compounds. Earlier results for vinyl chloride proved similar. It is theorized

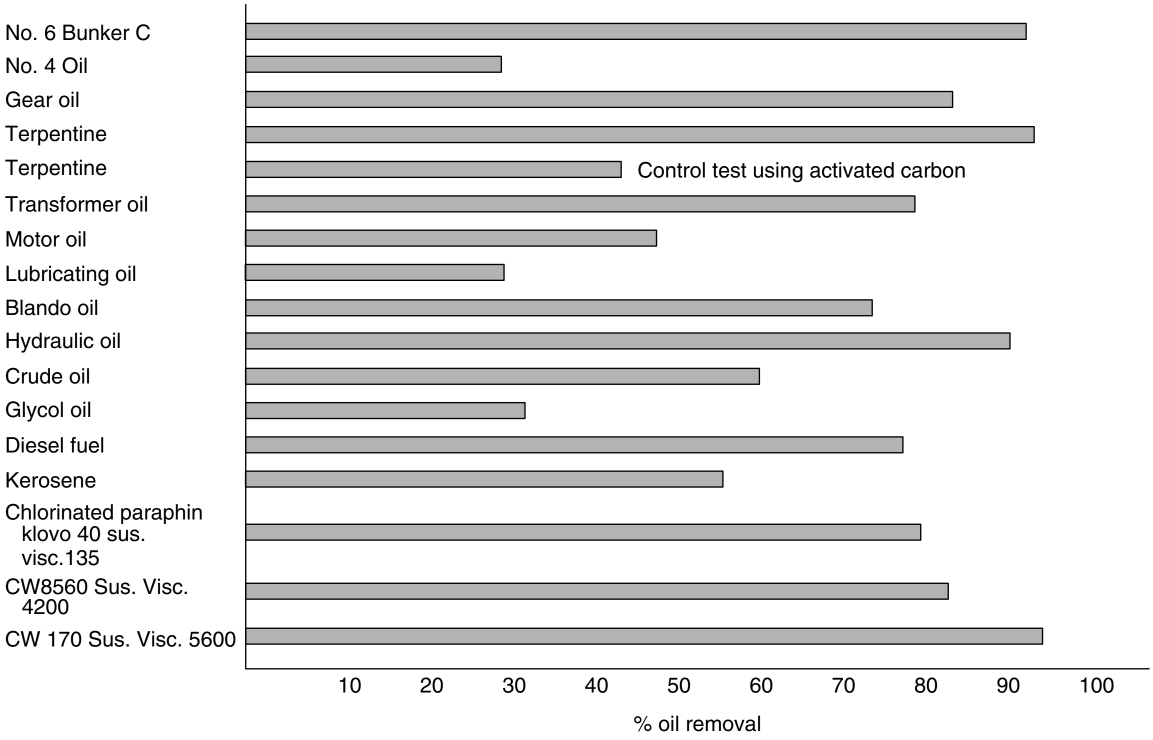

Figure 5. Removal of mineral oils from water by organoclay.

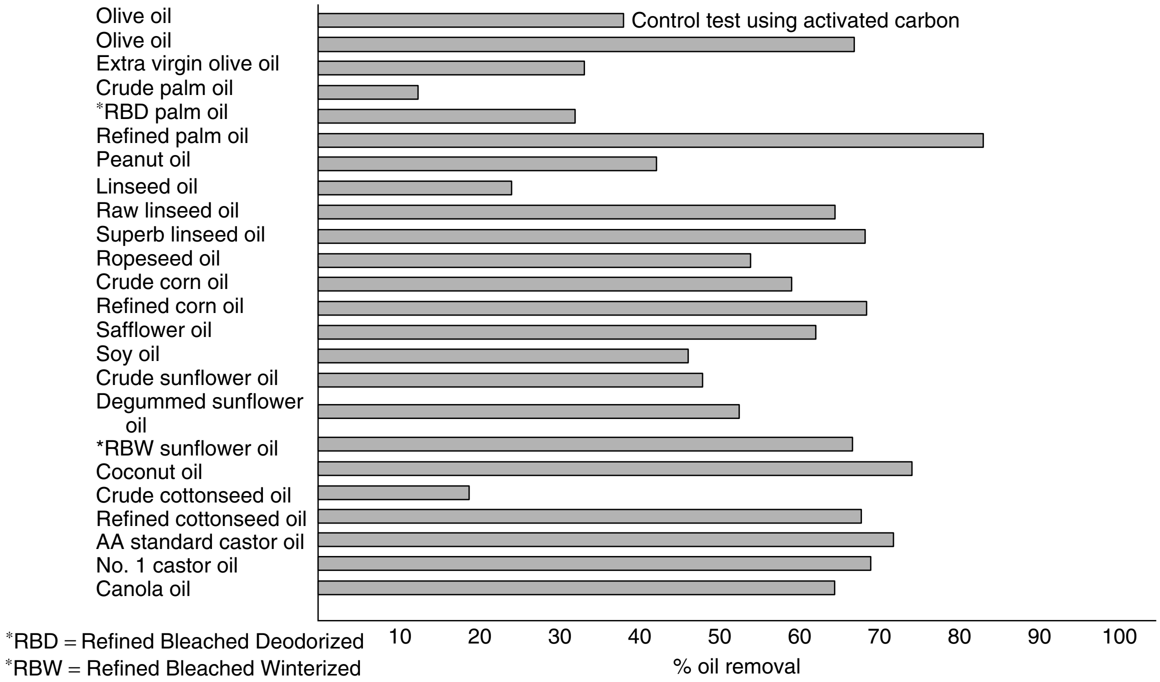

Figure 6. Removal of plant oils from water by organoclay.

that compounds such as methylene chloride have high electronegativity due to the presence of large amounts of halogens such as chlorides. The organoclay possesses positive charges on the surface due to the presence of inverted quaternary amine chains, so methylene chloride could chemically bond to these charges via their electronegativity. Therefore, two removal mechanisms, partitioning and ionic bonding, account for organoclay removal capacity for these compounds.

These tests were followed by a set of tests using a ternary effluent, which is a wastewater containing three different organic hydrocarbons, naphthalene, benzene, and toluene. This allowed the observation of competition among these compounds for adsorption sites. Of each compound, 900 mL/gram were added to water. It was possible to add that much naphthalene because benzene and toluene helped dissolve it. Usually, its solubility is only 10 mg/L. This concentrate was pumped separately through a column of organoclay, powdered activated carbon, and organoclay/carbon combined. In that case, the bottom of the minicolumn contained 0.5 grams of activated carbon, and the upper half contained 0.5 grams of organoclay. This was done to determine if the organoclay/carbon combination is more effective than each sorbent alone.

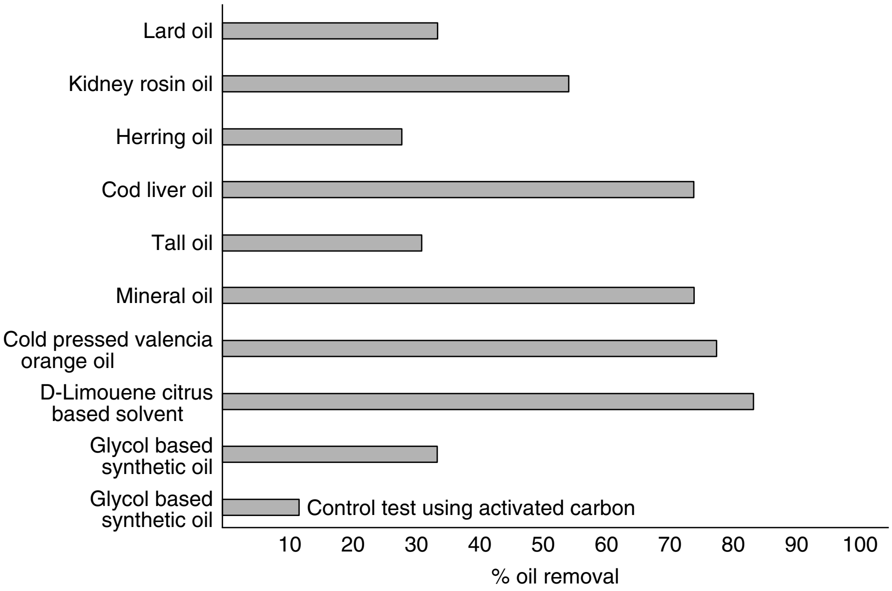

Figure 7. Removal of miscellaneous oils from water.

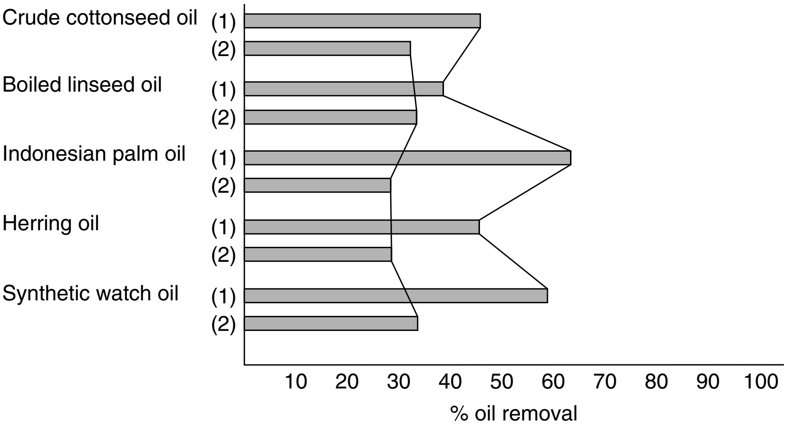

Figure 8. Removal of miscellaneous oils from water by different organoclays.

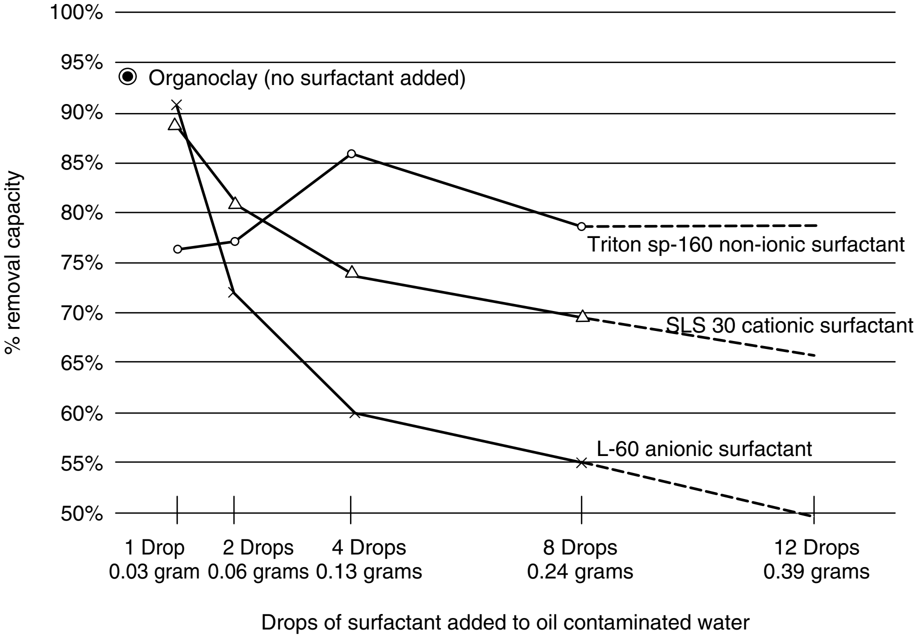

Figure 9. Percent removal capacity of organoclay for oil after adding a surfactant.

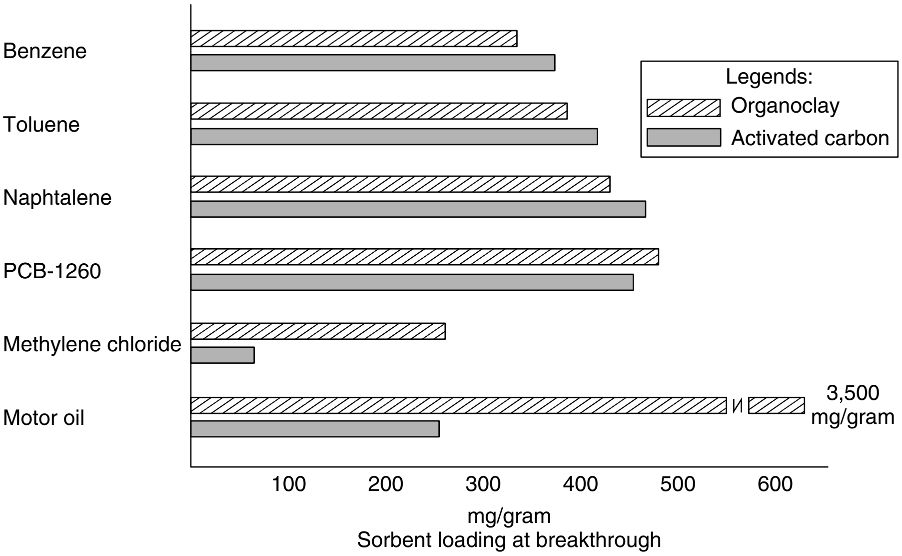

Figure 10. Minicolumn tests.

The results in Fig. 11 illustrate that benzene breaks through first, followed by toluene, and lastly naphthalene. This was expected based on their solubilities in water. The competition, however, is not 100% proof. The total adsorbed amounts are higher than the individually adsorbed amounts of the three solvents at breakthrough, probably because the geometrically arranged packing of the solvents of different sizes, either within the carbon pores or around the amine chains, favors a higher packing density.

The most important result is shown in the "total combined" graph. By placing the organoclay in front of the carbon, the removal capacity is doubled compared with the removal capacity of carbon and organoclay individually. This is also shown in a standard permeation column experiment with gasoline (Fig. 12). Again, the combination of organoclay/anthracite, followed by activated carbon, is much more effective in removing gasoline from water than either sorbent by itself, even though the amount of sorbent in each column is twice that in the combined column. Table 2 shows results from an actual groundwater cleanup project. The organoclay removes the oil completely and also a significant amount of other solvents and increases the effectiveness of activated carbon in removing volatile organic compounds. Because of the roll-off phenomenon, where less soluble compounds such as toluene and xylene, knock benzene off sorption sites within activated carbon, thus recontaminating the effluent, it is important to prepolish the water with organoclay, followed by activated carbon, which these results clearly illustrate.

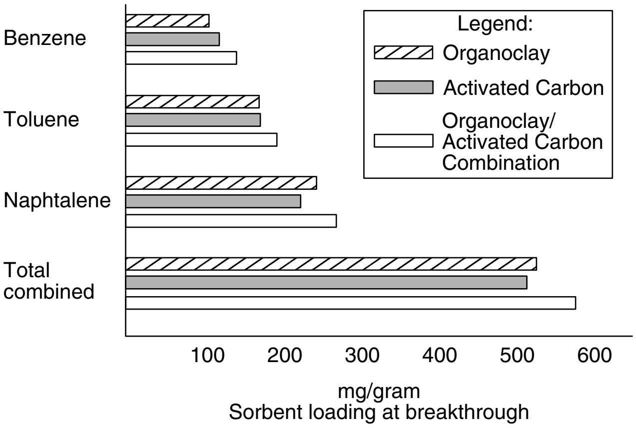

Figure 11. Minicolumn tests.

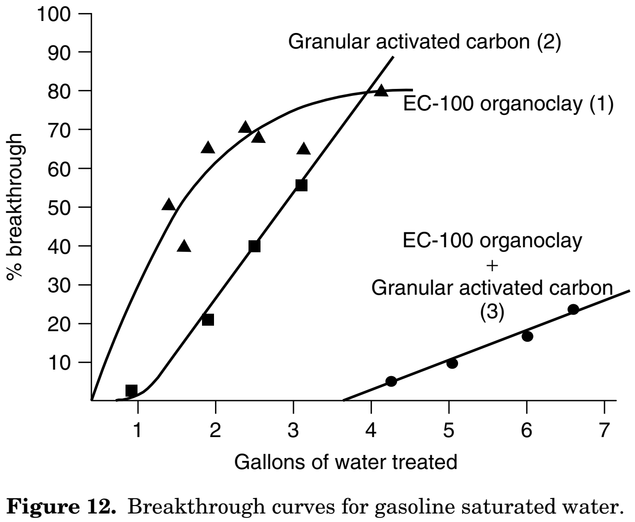

Figure 12. Breakthrough curves for gasoline saturated water.

The improved performance of an organoclay as the chlorination of the organic compound increases, along with a corresponding decrease in solubility in water, is shown in Figs. 13 and 14 (8). Organoclay is effective in removing phenol from water, but much more so, and far superior to activated carbon, for pentachlorophenol (PCP).

Freundlich isotherms confirm the results previously discussed, illustrated in Figs. 15–18. Figure 19, which shows the effectiveness of organoclay in removing methylene chloride, is impressive.

Figure 20 shows a time study, comparing how effectively nonionic organoclay and activated carbon remove turpentine from water. This test was conducted by pumping water spiked with turpentine through minicolumns and removing and analyzing a water sample every 50 minutes. Once the curve flattens out, saturation of the sample has occurred. These test results confirmed that the retention time of 6–10 minutes for water in an adsorber

filled with either medium as is standard operating procedure, is applicable to both media. Another test showed that the organoclay may need a slightly longer retention time (8–12 minutes?) for more soluble benzene.

Bentonite is a natural ion exchange resin. Thus is an organoclay, even though a portion of its surface is covered with the chains of the quaternary amines. Some capacity for removing metals is still available in both media.

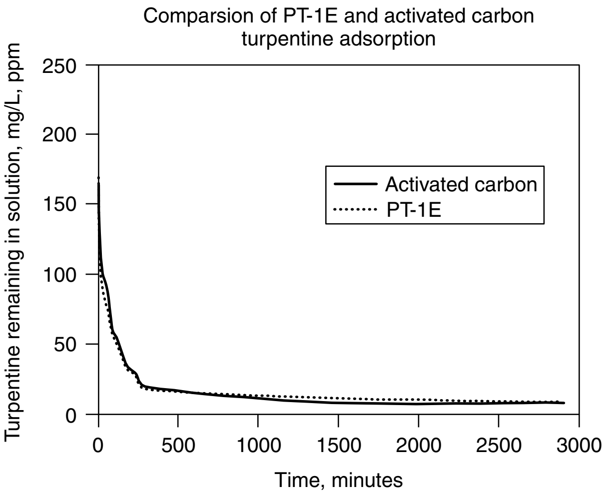

Figure 21. Time study showing a comparison of organoclay and activated carbon for the adsorption of turpentine from water.

same manner as that described for oil removal (Fig. 3), and the capacities of organoclay/anthracite and straight organoclay for removing various metals were determined. Bar charts were then constructed to illustrate the results, shown in Figs. 21 and 22 (24). The fact that the straight organoclay is not much better than organoclay/anthracite suggests that the diluting action of the anthracite results in improved access to sites on the organoclay. The U.S. Standard mesh size of the medium is 8 × 30 mesh. This capacity to remove small amounts of metals is not of great importance, but it can be a factor in calculating whether an ion exchange resin needs to be added to the treatment train if metal removal is required.

Figure 23 shows the ability of a cationic organoclay to remove chlorine from water. This isotherm proves that a cationic organoclay is an excellent medium for removing humic and fulvic acids (natural organic matter) and is far superior to bituminous activated carbon (Fig. 24). A minicolumnn test compares the removal capacity of cationic organoclay, bituminous activated carbon, and an "organotrap" ion exchange resin, again showing superior results for the cationic organoclay (Fig. 24). These results are thoroughly discussed in Alther (26).

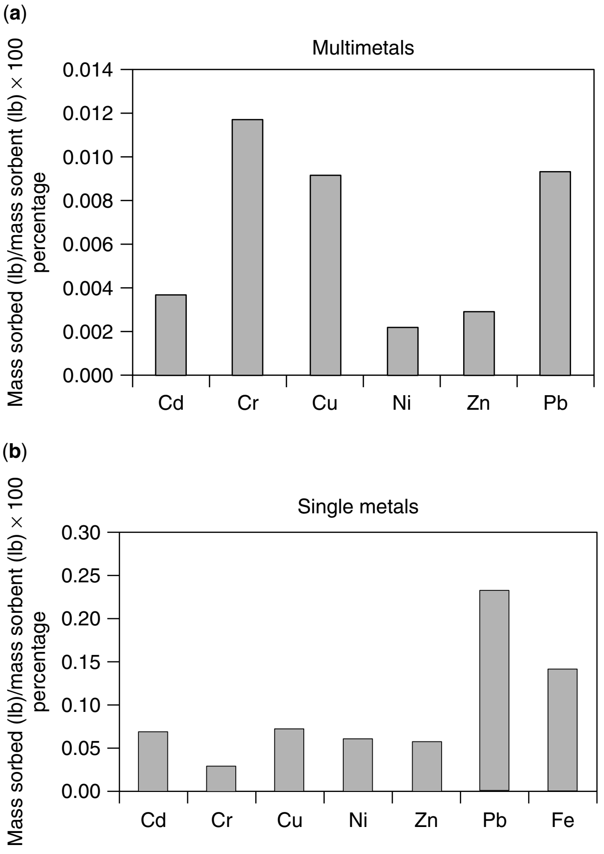

Figure 22. Adsorption of heavy metals from water by an organoclay/anthracite blend: Column study.

Table 3 shows the results of minicolumn tests to determine the removal capacity of cationic organoclay for negatively charged metals, including hexavalent chromium, selenite, arsenate, and fluoride. These results are in line with the capacity of this clay for chlorine removal.

An anionic organoclay was developed and tested in a minicolumn to show its capacity to remove cations, including ethylenediaminetriacetate (EDTA) (Fig. 25). The results are that coal based activated carbon removes 21.8% EDTA from the spiked solution, nonionic organoclay removes 47.3%, and anionic organoclay removes 70% of the EDTA.

Another set of minicolumn tests (Fig. 26) on water spiked with monoethanol amine revealed the following results: coal-based activated carbon removed 41.4%, nonionic organoclay removed 45.2%, anionic organoclay removed 29%, and cationic organoclay removed 79% of the monoethanolamine from the spiked water.

These results reveal the extreme versatility of organoclays in removing a variety of contaminants.

As a final test, the iodine numbers were determined for the organoclays, using the ASTM D-4607-94 testing method, to see if this test could be used to compare the two media. The results are as follows:

activated carbon (coal based): 700–900
nonionic organoclay: 275
cationic organoclay: 190
anionic organoclay: 410

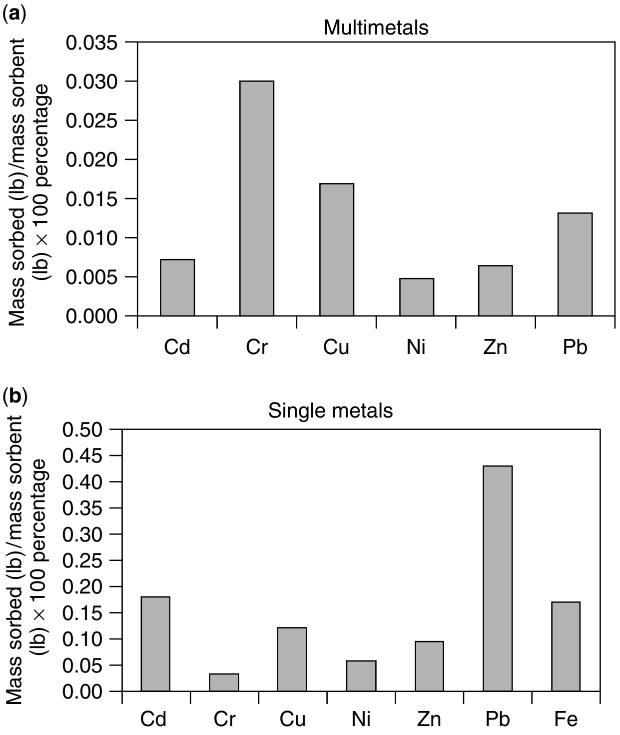

Figure 23. Adsorption of heavy metals from water by straight organoclay: Column study.

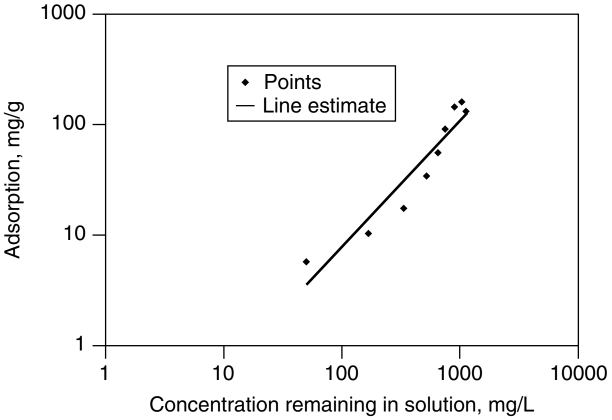

Figure 24. Isotherm showing the adsorption capacity of cationic organoclay for chlorine from water.

Table 3. Laboratory Column Study with Cationic Organoclay

Arsenate

Amount of cationic organoclay used: 16.5 grams (16 × 30 mesh)

Amount of spiked water passed through column: 8.31 liters

Removal capacity of cationic organoclay for arsenate by weight: 0.3%, or 3 grams per 1000 grams cationic organoclay

Fluoride

Amount of cationic organoclay used for fluoride removal: 16.5 grams (16 × 30 mesh)

Amount of spiked water passed through column: 0.54 liters.

Removal capacity of cationic organoclay by weight: 0.1% or 1 gram fluoride per 1000 gram of cationic organoclay

Chromate

Batch test: 100 mL water spiked with 5 mg/L hexavalent chromium, added 2 grams powdered cationic organoclay:

Removed 96% of 5 mg/L.

Conclusion

Aside from the extreme efficiency with which cationic organoclay removes humic acids from water, it also removes negatively charged metals, such as those shown above, and selenite.

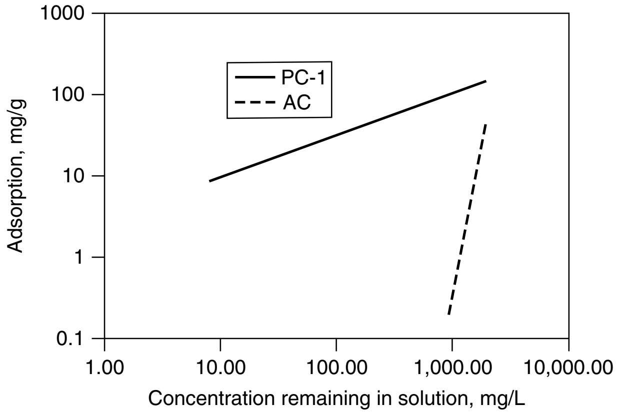

Figure 25. Isotherm showing the adsorption capacity of cationic organoclay with that of activated carbon.

Performance of activated carbon in this test is superior because iodine molecules fit inside the pores and do not cause blinding and all adsorption on the organoclay takes place outside the clay platelets. Therefore, it is concluded that this test is of no use for organoclay, although the results are interesting.

Below are several case histories, which give a practical appreciation of organoclays to the engineer who designs remediation systems.

Case Histories

1. A creosote superfund site on the East Coast installed a pump and treat system consisting of two filter vessels, each containing 20,000 lb activated carbon. The flow rate was 170 gpm. The COD consisted of 40–60 ppm, including benzene, VOCs, and phenols. The activated carbon lasted about 2 weeks with a breakthrough of 7–12 ppm COD; then it had to be replaced. After another vessel containing 19,000 lb of organoclay was installed, the effluent after the activated carbon was not detectable. Furthermore, there was a TSS content of 32–35 ppm (discharge limit is 40 ppm), primarily due to the presence of ferric iron. Once the organoclay was installed, the TSS content in the effluent was 3 ppm because the organoclay, a bentonite, also removes heavy metals by ion exchange.

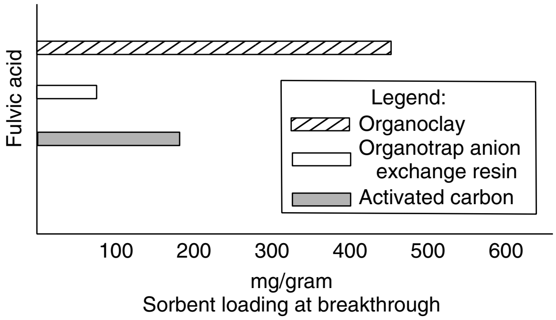

Figure 26. Microcolumn study data comparing the adsorption capacity of cationic organoclay and activated carbon for fulvic acids.

2. An old wood-treating site in Colorado is situated above an aquifer, which had a concentration of 30 ppm of an oil and 25 ppm of PCP. The discharge limit for PCP is 50 ppb. When an activated carbon system was installed, replacement was required within 1 month. After 20,000 lb of organoclay was installed prior to the activated carbon, discharge limits were met, and replacement was required only after 12 to 15 months.
3. An old railroad site in southeastern United States, where railroad ties were once treated with creosote, required excavating the soil and thermally treating it to destroy the creosote. A condensate built up that contained PCP. Rather than accepting the high cost of incinerating the condensate water, it was passed through an organoclay/carbon system and discharged locally.
