Rhizodegradation (phytostimulation, rhizosphere bioremediation, or plant-assisted bioremediation)	Plant exudates, root necrosis, and other processes provide organic carbon and nutrients to spur soil bacteria growth by two or more orders of magnitude. Exudates stimulate degradation by mycorrhizal fungi and microbes. Live roots can pump oxygen to aerobes and dead roots may support anaerobes.	Polyaromatic hydrocarbons, BTEX, and other petroleum hydrocarbons, perchlorate, atrazine, alachlor, polychlorinated biphenyl (PCB), and other organic compounds
Rhizofiltration (contaminant uptake)	Compounds are taken up or sorbed by roots (or sorbed to algae and bacteria).	Hydrophobic organic chemicals
Phytodegradation (phytotransformation)	Aquatic and terrestrial plants take up, store, and biochemically degrade selected organic compounds to harmless by-products, products used to create new plant biomass, or by-products that are further broken down by microbes and other processes to less harmful products. Reductive and oxidative enzymes may be used in series in different parts of the plant.	Munitions (TNT, DNT, HMX, nitrobenzene, picric acid, nitrotoluene), atrazine, halogenated compounds (tetrachloromethane, trichloromethane, hexachloroethane, carbon tetrachloride, TCE, tetrachlorethane, dichloroethant), DDT and other chlorine and phosphorus based pesticides, phenols, and nitrites
Phytovolatilization	Volatile organic compounds are taken up and transpired. Some recalcitrant organic compounds are more easily degraded in the atmosphere (photodegradation).	Chlorinated solvents (trichloroethane), organic VOCs, BTEX, MTBE

Table 2. Types of Phytoremediation for Inorganic Constituents

Type of Phytoremediation	Process Involved	Contaminant Treated
Phytostabilization	Plants control pH, soil gases, and redox conditions in soil to immobilize contaminants. Humification of some organic compounds is expected.	Proved for heavy metals in mine tailing ponds
Rhizofiltration (contaminant uptake)	Compounds are taken up or biosorbed by roots (or sorbed to algae and bacteria).	Heavy metals and radionuclides
Phytoaccumulation (phytoextraction or hyperaccumulation)	Metals and organic chemicals are taken up by the plant with water, or by cation pumps, sorption, and other mechanisms.	Nickel, zinc, lead, chromium, cadmium, selenium, other heavy metal radionuclides
Phytovolatilization	Volatile metals are taken up, changed in species, and transpired.	Mercury and selenium

Source: Adapted from Reference 1.

the result of the decay of dead roots and root hairs. Also important are carbonaceous root exudations, such as leakage from epidermal cells, secretions resulting from metabolic activity, mucilages from root tips (which act as lubricants for root penetration), and lysates from sloughed cells. Exudates are composed of a wide range of chemicals that include sugars, amino acids, organic acids, fatty acids, and numerous other compounds. It is estimated that 7–27% of the total plant mass is annually deposited as carbonaceous material in the rhizoshpere, amounting to 85–155 tons/acre. This carbonaceous material stimulates overall bacterial activity as well as providing substrate to support cometabolic degradation of xenobiotic hydrocarbons.

The capability to support oxygen transfer can be divided into three categories of plants: nonwetland herbaceous and woody plants with poor oxygen transfer capacity; wetland woody plants with moderate capacity; and wetland herbaceous plants with high oxygen transport capacity. Plants of the first variety will ultimately die with their roots under saturated conditions. Wetland plants adsorb oxygen through their leaves, twigs, stems, bark, and unflooded roots. This oxygen is in turn transported to the roots, where it diffuses out into the rhizosphere. Consequently, wetland plants are able to support aerobic biooxidation in the rhizosphere at rates that are significantly greater than that seen through saturated zone diffusion alone. Due to the processes described above, it is not uncommon to find bacterial population levels in the rhizoshpere elevated a magnitude or more above surrounding undeveloped soils.

The primary *in situ* remediation potential of plants for hydrocarbons lies in their capacity to enhance oxidation rates in the subsurface and provide cometabolic substrate. However, plants also have the ability to remove compounds, a process termed phytoextraction, which can be applied to organic or metal contaminants. In the case of hydrocarbons, the compound must be water soluble and have a moderate degree of lipid solubility. Lipid solubility is a function of the octanol–water partition coefficient (K_{ow}) for the compound. Compounds most readily mobilized by plants have log K_{ow} values in the range of 1–3. Compounds with values of K_{ow} in this range include BTEX hydrocarbons, chlorinated solvents, and other short-chain aliphatic hydrocarbons.

Once in the interior of the plant, the adsorbed hydrocarbons may be stored via lignification, volatilized, partially degraded through metabolization, or completely mineralized.

Compounds with values of log K_{ow} higher than 3 such as PNAs are incapable of entering the root; those with log K_{ow} values lower than 1 are rejected by the root membrane. In addition, the desorption and mass transfer of contaminant hydrocarbons from the geologic matrix may be the rate limiting step in the remediation process.

In phytoremediation of metals, the dominant active mechanism is phytoextraction and accumulation in the tissues of the plant, which is a process that has long been familiar to exploration geologists in the mining industry. Geobotany is concerned with the identification of plants or plant conditions common to metal-rich soils and biogeochemistry is concerned with actual metal concentrations in parts of plants.

The mechanisms for metal accumulation include:

- Chelation
- Precipitation
- Compartmentalization
- Translocation

These same mechanisms often contribute to the metal tolerance of the plant. To date, accumulators of lead, cadmium, chromium, nickel, cobalt, zinc, and selenium have been identified. To successfully apply this technology to a metal contaminated site, it is important that pH, organic complexes, and interfering elements be assessed and that plant species with the appropriate metal selectivity be utilized. In some instances, it may be necessary to apply soil amendments to enhance the process.

A key part of the metal extraction process is played by phytochelatins, which are low molecular weight peptides that have the capability to bind metals. Their presence in plants has likely evolved because toxicity to the plant is reduced by having the metals bound by the phytochelatins. Currently, there are several hyperaccumulating plants that have been discovered such as Indian mustard and pennycress. However, these plants are small and slow growing and thus lack enough biomass to remove significant amounts of metals. For example, there are 26 known plants that are hyperaccumulators of cobalt and exhibit desirable properties of common crops such as high growth rates and easy harvesting.

Lastly, plants have other properties with potential remediation applications. In semiarid climates, sufficient numbers of trees are capable of depressing the water table through transpiration, up to the equivalent of 3 ft of rainfall per year. Phytoremediation can be used as a form of hydraulic control. In tight soils, root penetration can improve the overall mass transport properties.

Plants can also aid in the surface stabilization of soils, preventing the windblown migration of soil with adsorbed contaminants.

Planting costs have been estimated to be in the range of $10,000 per acre, with monitoring costs parallel to those associated with other remediation technologies. Total phytoremediation costs are estimated to range from $60,000 to $100,000 per acre. The potential of phytoremediation is significant given proper design for its application. Contaminant type and distribution, soil chemistry, and climate are all important factors that must be considered.

BACTERIA ROLE IN THE PHYTOREMEDIATION OF HEAVY METALS

Anthea Johnson

P. Takis Elefsiniotis
University of Auckland
Auckland, New Zealand

INTRODUCTION

Rapid industrialization in the last century has led to the release of numerous contaminants, including heavy metals, to the environment. The release of heavy metals is of particular concern as they cannot be degraded, but only transformed from one form to another, and can accumulate in natural systems. Examples of heavy metals of particular significance include cadmium, copper, chromium, iron, lead, mercury, nickel, and zinc. They are released into the environment from a wide range of anthropogenic sources. Vehicles, industrial activities, building materials, and even the atmosphere contribute heavy metals to the water and soil, resulting in their occurrence at some sites in higher concentrations than is acceptable.

Heavy metals may remain dissolved in water or attach (referred to as sorption) to the mineral and organic components of soil. Although some heavy metals are required in minute quantities as micronutrients for the growth of plants and bacteria, at high concentrations they present a toxic threat to ecosystems. Bacteria and plants are susceptible to toxic effects of heavy metals, as are animals and humans who consume vegetation and crops grown in contaminated soils. Heavy metals are capable of bioaccumulation in plant and animal tissues and, therefore, can be biomagnified through the food chain.

Currently, heavy metal contaminated sites are treated by various immobilization and extraction methods. Pump-and-treat systems aim to wash heavy metals from the soil, using water alone, or metal-solubilizing compounds such as chelators and surfactants. Other methods involve thermally volatilizing or vitrifying contaminants in soil. At some sites, the soil is simply removed and dumped elsewhere. The existing treatment methods for contaminated soils are, in many cases, prohibitively expensive, which may postpone or preclude any treatment action. To gain wider acceptability and implementation, remediation technologies must be a low cost, sustainable, and effective alternative to physical and chemical treatment methods. Phytoremediation is one such emerging technology that can be used effectively for at-source contaminant mitigation.

The three basic components of phytoremediation systems are plants, bacteria, and the contaminated soil. Heavy metals are sorbed to the minerals in soil by cation exchange or to soil organic matter by complexation with organic acids. The complex interactions that have evolved between plants and bacteria in the rhizosphere (root zone) can be harnessed to remediate metal-contaminated soils. Bacteria and plants mobilize metals for uptake by excreting a vast array of organic compounds such as lipids, sterols, enzymes, and surfactants. Alternatively, they can immobilize metals via chemical transformation or precipitation of insoluble compounds. Labile metals can be sorbed to bacterial cells or taken up through plant cell membranes. Metals taken up by roots are translocated in the xylem (woody tissue) to the aboveground plant biomass, which can be harvested, thereby providing the basis for developing a decontamination technology using phytoremediation. Here we discuss the major processes by which bacteria and plants mobilize/immobilize heavy metals within the rhizosphere.

MOBILIZATION PROCESSES

The mobilization of metals from soil has a direct influence on their bioavailability to plants and hence the potential for their uptake and removal from the soil. There are a number of mechanisms by which bacteria and plants facilitate the dissolution of precipitates or the desorption of ions attached to mineral and organic fractions of soil.

Acidification/Protonation

Plant and bacterial exudates can alter the pH of soils and hence the bioavailability of contaminants and nutrients to both plants and bacteria (1). Soil acidification occurs due to proton efflux, the release of organic acids, or the addition of respiratory carbon dioxide to the soil (1). Free protons (H^+ ions) are added to the soil by a number of bacterial processes. Organic and amino acids are secreted by plant roots and over time may lower the pH of soils, increasing metal solubility. Bacterial respiration results in the addition of carbon dioxide to the soil, forming carbonic acid. The dissociation of acids in soil water causes the release of protons, which compete with metal ions for sorption or complexation sites. In this way, the protons may displace the metal cations into solution.

Plants too have a number of specialized mechanisms to increase the solubility of metals and nutrients. For example, iron is a micronutrient required for plant growth. To mobilize iron from the soil, plants may release protons to convert iron(III) to iron(II) and thus increase its solubility (2,3).

Solubilization by Biosurfactants

Biosurfactants are surface-active agents that are secreted by plants and bacteria within the rhizosphere (4). Microbially produced biosurfactants have many of the same properties as synthetic surfactants but have several advantages for *in situ* bioremediation. They are nontoxic to most plants and bacteria and are biodegradable, which prevents their accumulation in soil or groundwater. In addition, biosurfactants can be produced by bacteria localized around plant roots where they are needed.

Biosurfactants have both a hydrophobic and a hydrophilic region, which allows them to partition across interfaces of varying polarity. The hydrophobic region is often a nonpolar hydrocarbon chain, which reduces the surface tension at the interface (5). For example, it has been found that surfactin, a biosurfactant produced by *Bacillus subtilus,* reduced the surface tension of water from 72 to 27 mN/m at a concentration of only 0.005% (6). The lowering of the interfacial tension between the aqueous solution and substrate enables bacteria to access metals and degrade lipophilic substrates in the aqueous phase.

At low concentrations, surfactant molecules behave independently as monomers. On a solid surface, the surfactant molecules may form one or more layers (admicelles) with regions of similar polarity associated with each other. At concentrations above a nominal value, the surfactant molecules aggregate into micelles in the bulk phase, in addition to the interface. This value is dependent on the biosurfactant and is known as the critical micelle concentration (CMC) (7).

Biosurfactants have the capability to solubilize heavy metals that are sorbed to soil particles or soil organic matter. The surfactant molecules are adsorbed to the surface of the soil particle where they form complexes with attached metal ions (8). These complexes may then dissociate from the solid to the liquid phase, where similar surfactant molecules form micelles.

Plants produce surfactants such as lipids and sterols for root lubrication to aid root progression through the soil (9). These surfactants are also able to facilitate the desorption of contaminants and nutrients from soil particles. For example, saponins are plant-derived biosurfactants that are capable of binding to heavy metals such as cadmium, copper, lead, and zinc (10).

Chelation

Another mechanism by which bacteria and plants influence the bioavailability and toxicity of heavy metals is via the production of chelators. These are ligands that bind to metal ions forming chelates—ring-like structures that can increase the solubility of metals in solution. The production of chelates by microbes in the rhizosphere is greater than that in the bulk soil (11,12). Chelation enhances the uptake of ions with larger valence than ions with lower valence; Parker et al. (13) found that chelators reduced the uptake of divalent metal ions while increasing the uptake of trivalent ions such as aluminum. In addition, dissociated organic anions such as citrate and oxalate may also be capable of forming complexes with metal ions sorbed to soil minerals or organic matter (1).

Chemical Transformation

Bacteria are capable of altering metal speciation between soluble and insoluble forms through reduction processes. The change in oxidation state of metals influences their solubility and hence their bioavailability. Reduction under anaerobic conditions is carried out by a range of heterotrophic bacteria. During respiration, these bacteria can use a metal cation as a terminal electron acceptor, reducing to a lower valence state (14), which can cause an increase in the solubility of metals such as iron and manganese since iron(II) and manganese(II) are more soluble than iron(III) and manganese(IV) (15). Similarly, the reduction of Hg(II) to Hg(0) within bacterial cells causes the diffusion of elemental mercury out of cells (1). However, in some cases reduction can decrease the available metal in solution, such as the reduction of chromium from VI to III valence results in lower solubility and mobility (1).

IMMOBILIZATION PROCESSES

Sorption

Binding to Cells. Bacteria have a net negative charge due to the presence of hydroxyl (OH^-), carboxyl (COO^-), and phosphate (PO_4^{3-}) functional groups on the membrane surface. This causes the attraction and sorption of free metal cations to negatively charged external sites on bacterial cells. The binding capacity is dependent on the type of bacteria. For example, the binding capacity of gram-positive bacteria is greater than that of gram-negative bacteria due to the difference in the structure and polymer content of membranes and the cell wall. The binding of metal ions by bacteria increases with temperature and is greater at lower pH (16).

Heavy metal cations can form complexes, which reduces their positive charge and increases their size, which causes the cations to be less favored for transport through plant and bacterial cell membranes and instead they are retained by the surface sites on cells.

Binding to Extracellular Molecules. Bacteria and plants excrete organic substances that are capable of binding heavy metals in ionic or solid forms. Simple organic molecules include acids and alcohols, which can attach to free metal ions. Macromolecules include long-chain organic acids such as humic and fulvic acids, which are capable of binding metal cations (17). Exopolysaccharides are a major component of biofilms and other microbial assemblages and are capable of trapping particulates and ions. Bacteria can also secrete specific metal binding proteins (metallothioneins) in response to the presence of toxic metals (1).

Uptake and Intercellular Sequestration

The uptake of heavy metal cations is an energetically favorable process for plant and bacterial cells due to their negative internal charge. Negative transmembrane potentials encourage the uptake of metal cations into the cell (13). Bacteria may store metals within inclusion bodies and thus render them temporarily unavailable and hence nontoxic.

Precipitation/Crystallization/Mineralization

Bacteria are capable of reducing metals to insoluble forms, lowering their bioavailability and hence toxicity to bacteria, plants, and animals. The bacterial reduction of chromium(VI) to chromium(III) immobilizes the metal in soil (1). Researchers have identified a strain of *Xanthomonas maltophyla* that is capable of catalyzing the reduction and precipitation of chromium as well as the transformation of other toxic metal ions including lead and mercury (18).

Volatilization

Biomethylation involves the microbial transfer of methyl ($-CH_3$) groups to a metal or metal-containing compound, often forming methylated species with increased volatility. Methylation of metals such as arsenic, lead, mercury, selenium, and tin can occur in either aerobic or anaerobic environments (1). Volatile methylated species can then escape from the soil into the atmosphere. However, methylated species of metals such as mercury and arsenic can be more toxic. For example, methylmercury is a neurotoxic compound formed via the methylation of ionic mercury. Some bacteria are capable of reducing mercury from its ionic to elemental form, increasing its volatility and decreasing its toxicity (2).

INTERACTIONS BETWEEN PLANTS, BACTERIA, AND CONTAMINANTS

Plants as Energy Sources for Microbes

The growth of bacteria in the rhizosphere is carbon limited (19). Most organic carbon in the rhizosphere is derived from plant sources. Root cap mucilage, root exudates, photosynthate, and plant debris provide organic carbon for microbial cell growth. Plant roots directly or indirectly foster rhizospheric bacteria by producing exudates that bacteria and fungi may use as a carbon source. Plant root exudates consist primarily of organic acids (of low and high molecular weight) as well as sugars and amino acids. These substrates can be easily degraded and utilized as an energy source by many types of soil bacteria, encouraging a higher concentration of soil microbes in the rhizosphere than in bulk soil (20). An increase in microbial biomass usually results in higher rates of contaminant degradation or mobilization due to the increased total activity of the rhizospheric community.

Transpiration Effects on Contaminant Movement

Plant root uptake of water influences the rate and direction of contaminant migration through the soil.

Soluble metals contained within the groundwater are drawn toward the roots by the transpiration stream. In this way, the contaminants move into the region where they may be taken up by the roots and the surrounding rhizospheric community, which facilitates access to contaminants by nonmotile bacteria and improves the possibilities for microbial action resulting in transformation or degradation (21). In addition, the network of plant roots intercepts contaminants drawn downward by the infiltration of rainwater. This reduces the loss of nutrients and contaminants from the upper regions of the soil.

Secondary Plant Metabolites

Secondary plant metabolites (SPMEs) comprise a wide range of organic compounds produced by plants and exuded by their roots. Although SPMEs are not essential for basic metabolic processes, they have an important role in the nutrition and defense of plants (22).

There are many theories as to the purpose of SPME production (23). It is generally accepted that many SPMEs are effectively natural pollutant analogues (24). The resemblance of many SPMEs to organic pollutants may encourage the bacterial production of enzymes that are capable of degrading both types of compounds. Thus, the plant reduces the time needed for bacteria to develop the enzymes required for the degradation of pollutants in the rhizosphere.

SPMEs are also produced by plants for defense against herbivory as well as insect and microbial attack (25). Allelopathic SPMEs are produced to reduce competition between plant species (26). SPMEs are also produced to act as chemical signals to other plants and microbes. However, this is not always to the benefit of the plant, as this trait can also encourage the growth of parasitic plants (27).

Cometabolism of Contaminants. Secondary plant metabolites may include enzymes that are intended for the degradation of one compound, but are also capable of degrading other, perhaps xenobiotic, compounds with no additional benefit to the plant in terms of energy or nutrition. In this case, the primary compound is referred to as a cometabolite as it provides the energy source for the degradation of the secondary compound (22). As cometabolism does not require the population to produce a specific enzyme for contaminant degradation, cometabolism of contaminants is improved by increasing the microbial biomass and diversity in the rhizosphere.

Exudates as Chemical Signals. Walton et al. (28) proposed the theory for the plant production of exudates as chemical signals to bacteria. When a plant detects the presence of a toxicant, it alters the composition of the root exudates produced. In turn, the plant root exudates alter the rhizospheric community in such a way as to increase the bacterial detoxification of the soil for the benefit of the plant, which may be achieved by the release of specific enzymes, cometabolites, or energy sources to increase the number and activity of rhizospheric bacteria or to change the bacterial exudates produced (28). Associations between plants and bacteria may be both specific and nonspecific and are thought to have evolved over time for the mutualistic benefits they offer.

Selection for Metal-Resistant Bacteria. Hyperaccumulating plant species may directly or indirectly increase the selection for metal-resistant bacteria in their rhizosphere. Hyperaccumulating plants are generally defined as variants capable of accumulating metals such as nickel, cobalt, copper, zinc, cadmium, manganese, and lead within tissues to concentrations 100 times or more greater than normal plants (29). Such plants usually prefer one particular metal, although some multimetal accumulators have been encountered. More than 400 hyperaccumulating species have been identified (30). One of the better known zinc hyperaccumulating species is *Thlaspi caerulescens*, which has been well researched for its phytoremedial potential. Higher ratios of metal-resistant bacteria are seen to exist around the roots of *T. caerulescens* than the nonaccumulating plant species growing in the same zinc-contaminated soil. This behavior is attributed to the release of metals for uptake via acidification of the plant rhizosphere, resulting in selection for bacteria that can tolerate higher zinc concentrations (31).

Plant Pathogens

Plants are subject to attack from insects and microorganisms. Insects eat plant tissues, such as leaves, or suck the sugar-rich phloem from the stalks. Bacteria can produce toxins that affect plant growth and hence reduce competition for soil nutrients. These bacterial phytotoxins may have been a reason for the evolution of detoxification mechanisms by plants and the production of allelopathic compounds as a defense mechanism. Bacteria also have a role as plant pathogens, causing disease to plant tissues and affecting the ability of plants to remove metals from soil. However, bacteria may also defend plants against attack from insects, fungi, and viruses. For example, the production of toxins by endophytic bacteria may protect plants from herbivory by chewing insects.

Nutrient Requirements

In many soils, the availability of nutrients is limited, which causes competition between bacteria and plants for nutrients. Bacteria are capable of forming mutualistic or antagonistic relationships with plants with respect to nutrient availability.

The presence of rhizospheric bacteria may have beneficial effects for plant biomass production. An increased microbial population results in greater mobilization of nonlabile nutrients and increased uptake by plant roots. Limiting nutritional elements are mobilized from soils by bacterial exudates. For example, siderophores (mugineic and avenic acids) are iron-chelating ligands that solubilize iron from the soil, which assists plants in assimilating iron and increases plant resistance to iron deficiency (12).

Some species of hyperaccumulating plants require heavy metals for normal growth, in concentrations that would be toxic to most species. Bacteria may assist these plants in meeting their high demand for metals. Studies have shown that the total uptake of zinc by shoots of *Thlaspi caerulescens* was increased by a factor of 4 due to the presence of bacterial species, which increase was attributed to the twofold increase in the concentration of zinc in the shoots and a similar increase in the shoot biomass (12).

Root Area Augmentation

The presence of rhizospheric bacteria and plant mycorrhizal associations can increase the surface area of the plant root system. In addition, the presence of rhizospheric communities can also increase the biomass of plants. It has been found that bacterial seed inoculates increase plant root biomass, length, and exudate production (32). Hadas and Okon (33) demonstrated that the root growth of tomato seedlings was improved by inoculation with the bacteria *Azospirillum brasilense*. The roots had greater surface area due to the increased length and density of root hairs, with a subsequent increase in the uptake of water and minerals from the soil (33).

Soil Detoxification

Mutualistic relationships may develop between plants and bacteria living in contaminated soils. The presence of organic and inorganic contaminants may prevent the normal growth of plants and hence the supply of nutrients and energy for rhizospheric bacteria. Therefore, bacteria benefit from the nutritional gains brought about by their ability to detoxify soils. Where high concentrations of metals are present, the rhizospheric bacteria may mediate their immobilization or transformation, reducing metal bioavailability by binding metals to the negatively charged surface of bacteria, which may reduce their toxicity to plants. Additionally, rhizosphere communities may assist their host plants by mineralizing or degrading toxic organics to less hazardous forms.

CONCLUSION

At many sites around the world, heavy metals have built up to toxic concentrations in soils. High concentrations of soil metals are harmful to most forms of life including plants, bacteria, and humans. Bacteria interact with plants and heavy metal contaminants in a variety of ways to mediate the mobilization and immobilization of heavy metals within the soil. Plants may directly or indirectly stimulate these microbial processes through the release of a diverse range of root exudates. Recent research has shown that phytoremediation systems may be improved by building on the natural processes and interactions between plants and bacteria that occur in the rhizosphere. Phytoremediation may present a more sustainable solution to the worldwide problem of contaminated soils by further developing the remedial processes present in natural systems.

PHYTOREMEDIATION OF LEAD-CONTAMINATED SOILS

Th.A. Ioannidis
A.I. Zouboulis
Aristotle University of Thessaloniki
Thessaloniki, Greece

Several treatment technologies have been investigated for treating heavymetal-contaminated soils, such as lead. Recently, among the most promising methods is "phytoremediation," the use of certain plants to remove/accumulate or neutralize/degrade pollutants, of inorganic or organic nature. The systematic examination of plants, especially for removing lead from polluted soils has drawn serious attention, especially during the last decade. The overview of the specific technology and a brief description of the results obtained so far is briefly presented. Specific aspects that are of critical importance, such as the chemistry of soil and the interaction with the toxic metals, are also outlined.

SOURCES OF LEAD

Lead (Pb) is a bluish-gray metal that occurs naturally in minute amounts within the earth's crust. It has also been referred to as plumbum, lead metal, and pigment metal. The frequent use of this element in many industrial processes is the main reason for the widespread contamination (especially of soil) by lead. There are a variety of industrial processes that involve the production/use of lead, such as mining, smelting, manufacture of pesticides and fertilizers, dumping of municipal sewage, and burning of fossil fuels that contain a lead additive (leaded gasoline). Many commercial products and materials may also contain lead, including paints, ceramic glazes, television glass, ammunition, batteries, medical equipment, such as X-ray shields or fetal monitors, and electrical equipment. The applications of lead for roofing and for the production of ammunition have increased during the last 20 years. Lead battery recycling sites, of which 29 have been labeled as Superfund sites in the United States, and other manufacturers use more than 80% of the lead produced in the United States. On average, recycled lead products can satisfy only half of total U.S. lead requirements.

HEALTH EFFECTS

Lead has been listed as a potential carcinogen in the EPA Toxic Release Inventory (TRI). Inhalation and ingestion are the two main routes of exposure, whereas the health effects from both are the same. Pb accumulates in the body organs, such as the bones and the brain, which may lead to poisoning (plumbism), or even to death. The gastrointestinal tract, kidneys, and especially the central nervous system are also affected by the presence of lead. Children exposed to lead are at risk for impaired development, lower IQ, shortened attention span, hyperactivity and mental deterioration; children under the age of six are at a more substantial risk. Adults usually experience decreased reaction time, loss of memory, nausea, insomnia, anorexia, and weakness of the joints, when exposed to lead.

CHEMISTRY OF LEAD-CONTAMINATED SOIL

The chemistry of metal interaction with the soil matrix is fundamental to the phytoremediation concept (Fig. 1). Once introduced into the soil matrix, lead is very difficult to remove due to a series of chemical reactions that are likely

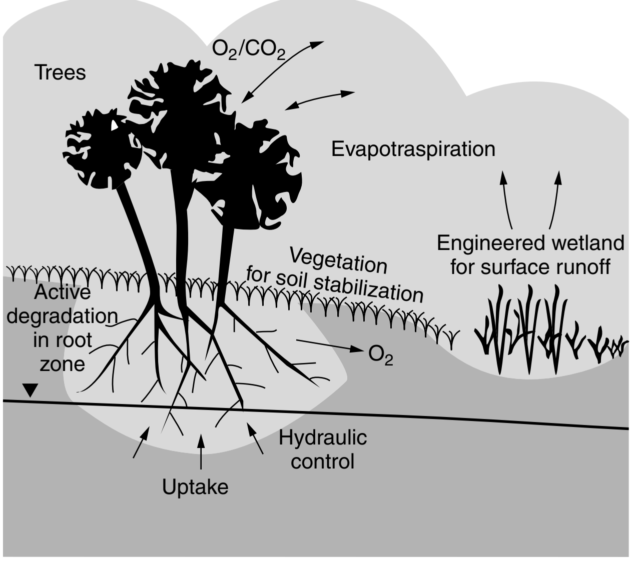

Figure 1. Plant processes that lead to environmental remediation.

to take place, such as mineralization. This transition metal resides within the upper 15–20 cm of the soil, where it is strongly bound by adsorption, ion exchange, precipitation, and complexation with existing organic matter. Lead found within the soil matrix can be classified into six general categories: ionic lead dissolved in soil water, exchangeable, carbonate, oxyhydroxide, organic, or the precipitated fraction. Sequential extractions of soil can be employed to isolate and quantify specific metallic forms, associated with different fractions (1).

The combinations of all these forms make up the total content of lead in soil. Water-soluble and exchangeable lead are the only fractions readily available for uptake by plants, whereas the oxyhydroxide, organically bound (occassionally), hydroxy carbonate, and precipitated forms of lead are the most strongly bound to the soil.

All these interactions that occur throughout the soil matrix are highly pH-dependent. The pH of soil has a significant effect on the mobility of lead from soil, as well as of other metals. The pH of soil generally ranges from 4.0–8.5. Under acidic conditions (pH values lower than 5.5), metal cations are more easily mobile, whereas anions tend to be sorbed to mineral surfaces. Metals become more available to plant roots under these conditions; however, due to the increase in toxic metal solubility, plant growth may be inhibited by phytotoxicity. The opposite occurs when the soil matrix is at an alkaline pH; anions are mobilized and cations are adsorbed to mineral surfaces or form precipitates, hence decreasing the bioavailability of metal cations and their subsequent plant uptake. The capacity of soil to bind lead increases with an increase in pH, cation exchange capacity (CEC), organic carbon content, soil/water E_h values (“mixed” redox potential), and phosphate levels (2).

Another important factor in the phytoremediation process is the presence of specific ionic species of lead, derived by respective hydrolytic reactions. Lead ions exist as Pb^{2+} at low (acidic) pH. As the pH increases (at pH values lower than 6), Pb^{2+} and $[Pb(OH)]^+$ cations are the principal species, but gradually several polynuclear species, including $[Pb_3(OH)_4]^{2+}$, $[Pb_3(OH)_5]^+$, $[Pb_4(OH)_4]^{4+}$, and $[Pb_6(OH)_8]^{4+}$, form. They become abundant at even higher (alkaline) pH levels. Nevertheless, in a recent study, the existence of polynuclear species was seriously questioned; it was concluded that mononuclear complexes $Pb(OH)_q{}^{(2-q)+}$ (aq) (where q = 1–4) are the only hydrolyzed species likely to be significant under typical environmental and biological conditions (4).

The predominant insoluble lead compounds are lead phosphates, lead carbonates and hydroxy carbonates (this form exists when the pH is above 6), and lead (hydr)oxides. Lead sulfide (PbS) is the most stable solid form within the soil matrix and can be formed under reducing conditions, when increased concentrations of sulfides are present. Under anaerobic conditions, a volatile organolead compound (tetramethyl lead) can also be formed by microbial alkylation.

PROPOSED MECHANISMS FOR THE PHYTOREMEDIATION OF LEAD IN CONTAMINATED SOILS

Depending on the nature of the specific pollutant (organic or inorganic), the biology and the properties of the plant and other factors that could act synergistically, such as soil properties, it has been proposed that different mechanisms take place during phytoremediation.

Phytoextraction, rhizofiltration, and phytostabilization are the principal mechanisms that have been proposed, when the pollutants to be removed/treated are inorganic (e.g., toxic metals or radionuclides). Rhizodegradation, phytodegradation, and phytovolatilization are the main mechanisms proposed for the removal/treatment of organic pollutants, whereas the latter mechanism (phytovolatilization) has been also proposed for the removal of certain inorganic pollutants (e.g., Se, Hg, As). Hydraulic control, vegetative cover, and riparian corridors have been suggested as methods for treating inorganic or organic pollutants in contaminated soils; these methods are considered a combination of the aforementioned mechanisms, however, with certain differences that derive mainly from the way that these technologies are engineered (5).

The basic phytoremediation mechanisms, in which lead may be involved, are phytoextraction, rhizofiltration, and phytostabilization.

Phytoextraction

Phytoextraction is the uptake of contaminants by plant roots and their translocation within the plants; the contaminants are generally removed by harvesting the plants (e.g., Fig. 2 for nickel). This concentration technology leaves a much smaller mass to be disposed of than the excavation of soil (applications of *ex situ* treatment technologies), or other media. The specific technology is most often applied to metal-contaminated soil (5).

Lead hyperaccumulation by plants has not been documented in a natural setting. However, certain plants have been identified which can take up lead.

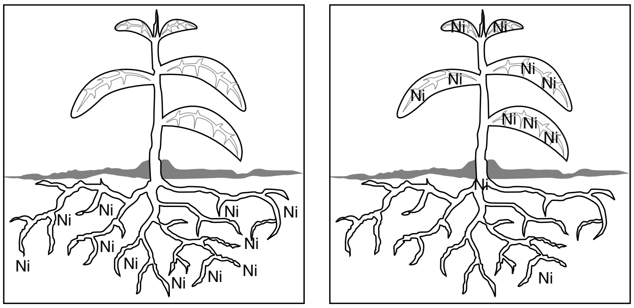

Figure 2. Phytoextraction of nickel from contaminated soil.

Many of these plants belong to the following families: *Brassicaceae, Euphorbiaceae, Asteraceae, Lamiaceae*, and *Scrophulariaceae*. *Brassica juncea*, commonly known as Indian mustard, shows especially good ability to transport lead from the roots to the shoots, which is an important characteristic in the phytoextraction of lead.

The *phytoextraction* coefficient is the ratio of the metal concentration within the biomass of the plant, compared with the metal concentration in the soil. Thus, the greater the coefficient, the greater the uptake of contaminant. Some calculations indicate that *Brassica juncea* can remove 1550 kg of lead per acre. The phytoextraction coefficient for Indian mustard was determined as 1.7; it has also been found that lead concentrations up to 500 mg/L are not phytotoxic to this Brassica species. *Thalspi rotundifolium ssp. cepaeifolium*, which is a noncrop Brassica, commonly known as pennycress, grows in soils contaminated with lead (at concentrations up to 0.82% w/w) and zinc, originating from nearby mine operations. Bench-scale studies have also shown that certain crop plants are capable of phytoextraction. Corn, alfalfa, and sorghum are effective due to their fast growth rate and large amount of biomass produced (2,5).

Rhizofiltration

Rhizofiltration is the adsorption or precipitation of contaminants, which are in the solution surrounding the root zone, onto the plant roots, by biotic or abiotic processes. Plant uptake, concentration, and translocation might occur, depending on the contaminant. Additionally, exudates from the plant roots might cause the precipitation of certain metals, depending on localized conditions. Rhizofiltration results initially in the containment of contaminants, in their immobilization or accumulation on or within the plant roots. Contaminants are then removed by physically removing the plant. Some of the experimental results are summarized in the following:

1. Pb^{2+} at a solution concentration of 2 mg/L accumulated in Indian mustard roots with a bioaccumulation coefficient of 563 after 24 h. Pb^{2+} (at solution concentrations of 35, 70, 150, 300, and 500 mg/L) accumulated in Indian mustard roots, although the root adsorption of Pb reached saturation at 92 to 114 mg Pb/g dry weight of roots. Lead was removed from the 300 and 500 mg/L solutions mainly by precipitation of lead phosphate. Lead absorption by the roots was rapid, although the amount of time required to remove 50% of the Pb from the solution increased, as the Pb concentration increased.
2. Lead accumulated in the roots of Indian mustard in (aqueous) concentrations of approximately 20 to 2,000 g/L with bioaccumulation coefficients of 500 to 2,000.
3. It has been also reported that lead at concentrations of 1 to 16 mg/L was accumulated by water milfoil (*Myriophyllum spicatum*) at a minimum residual concentration below 0.004 mg/L (5).

Phytostabilization

Phytostabilization is defined as (1) the immobilization of a contaminant in soil through absorption and accumulation by roots, adsorption onto roots, or precipitation within the root zone of plants and (2) the use of plants and plant roots to prevent contaminant migration via wind and/or water erosion, leaching, or soil dispersion.

Phytostabilization occurs through root-zone microbiology and chemistry, and/or alteration of the soil environment, or of contaminant chemistry. Soil pH may be changed by plant root exudates or through the production of CO_2. Phytostabilization can change metal solubility and mobility or impact the dissociation of organic compounds. A plant-affected oil environment can convert metals from a soluble to an insoluble oxidation state. Phytostabilization can occur through sorption, precipitation, complexation, or metal valence reduction. Plants can also be used to reduce the erosion of metal-contaminated soil. The term *"phytolignification"* refers to a specific form of phytostabilization, in which organic compounds are incorporated into plant lignin. The contaminants can be also incorporated into the humic material of soils, following a process related to phytostabilization.

It has been reported that the concentration of lead in soil leachate was 22 mg/L, when Indian mustard was present, compared to a concentration of 740 mg/L in soil leachate, without the plants. In another case, mine wastes containing lead were reportedly stabilized by grasses. Soil containing 1660 mg Pb/kg appeared to support less than 50% of plant coverage. Plants in soils containing 323 mg/kg Pb exhibited heavy *chlorosis*, whereas plants could grow in mine wastes, containing up to 4500 mg of Pb/kg of soil (5).

An overview of the correlation between the mechanisms examined and the respective media, the plants used, and the other pollutants that might be treated in parallel, when phytoremediation of lead is applied, is presented in Table 1.

THE ROLE OF SYNTHETIC CHELATES IN PHYTOREMEDIATION OF LEAD

The pH of soils, as well as the specific forms in which lead exists in the soil, might limit the potential bioavailability of lead to plants. The use of certain synthetic chelators

Table 1. Typical Plants and Mechanisms Used in Various Phytoremediation Applications Concerning Lead[a]

Mechanism	Media	Contaminants	Typical Plants
Phytostabilization	Soil, sediments	Metals (Pb, Cd, Zn, As, Cu, Cr, Se, U) Hydrophobic organics (PAHs, PCBs, dioxins, furans, pentachlorophenol, DDT, dieldrin)	Phreatophyte trees to transpire large amounts of water for hydraulic control Grasses with fibrous roots to stabilize soil erosion Dense root systems are needed to sorb/bind contaminants.
Phytoextraction	Soil, brownfields, sediments	Metals (Pb, Cd, Zn, Ni, Cu). Selenium (volatilization)	Sunflowers, Indian mustard, rapeseed plants, barley, hops, crucifers, serpentine plants, nettles, dandelions
Rhizofiltration	Groundwater, water and wastewater in lagoons or created wetlands	Metals (Pb, Cd, Zn, Ni, Cu) Radionuclides (^{137}Cs, ^{90}Sr, U) Hydrophobic organics	Aquatic Plants: — Emergents (bulrush, cattail, coontail, pondweed, arrowroot, duckweed) — Submergents (algae, stonewort, parrot, feather, Eurasian water milfoil, Hydrilla)

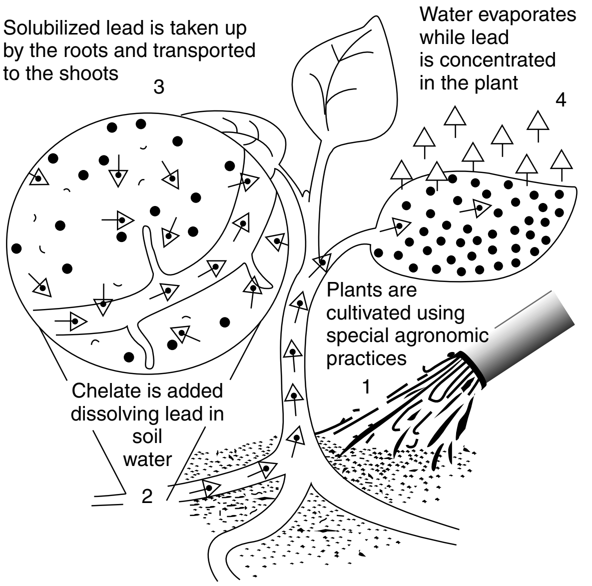

Figure 3. Enhancement of plant uptake of Pb through the use of synthetic chelates (2).

(such as EDTA) by several researchers was examined to overcome this drawback (Fig. 3).

The use of synthetic chelates in phytoremediation increases heavy metal uptake by the plants, through the increase of metal bioavailability, but also increases micronutrients availability, therefore decreasing the possibility of plant nutrient deficiencies. The goal of commercial phytoextraction is to remove or reduce the level of toxic metals within the contaminated soils (*in situ* treatment technology) to meet regulatory standards within 1 to 3 years following the application. The regulatory standard (achievement goal) for lead-contaminated soils set by the U.S. EPA is 500 mg of metal/kg of soil. Plants that can accumulate more than 1% of the target contaminant in the harvestable portion and can produce more than 20 metric tons of shoot biomass per hectare per year are usually required to achieve this goal.

Several researchers have found that this goal can be achieved by applying soil amendments and chemical chelates. Based on relevant studies, it has been shown that only 0.1% of the total amount of lead in contaminated soils exists in soluble form and, therefore, is considered bioavailable to plants for remediation. By adding synthetic chelators, the total amount of (bioavailable) lead in solution can be increased up to 100 times.

Increasing the mobility and bioavailability of lead in the soil through the application of certain chelators, organic acids, or other appropriate chemical compounds allows hyperaccumulation of metals in some plants. For lead, a number of different chelators have been tested, such as EDTA (ethylene dinitrilotetraacetic acid), CDTA (trans-1,2-cyclohexylene-dinitrilotetraacetic acid), DTPA (diethylene trinitrilopentaacetic acid), EGTA (ethylebis-[oxyethylene-trinitrilo]-tetraacetic acid), HEDTA (hydroxyethylethylene dinitrilotriacetic acid), citric acid, and malic acid. The addition of these chelates resulted in enhanced shoot lead concentrations (2). The soil additive EDTA can form hexahedral metal ion complexes with commonly found metals, such as Pb[II] or Fe[II], which can enhance their uptake by roots and translocation throughout the plant (7).

Although there are certain advantages in using synthetic chelates, environmental concerns for their impact on contaminated sites still need research. The major concern for using chelates to enhance phytoremediation and to increase the bioavailability of toxic metals, such as Pb, is the fear of lead leaching or running off into the ground or surface water, creating secondary contamination. By making the metals more soluble in the soil matrix, leaching is more probable and threatens to contaminate nearby water sources (2). The use of synthetic chelates necessitates careful mass balances to confirm that metals mobilized by chelators are not subsequently leached to groundwater.

The use of synthetic chelators (complex chemical compounds) is a questionable practice from the environmental standpoint. Natural chelators originating from plants or from microorganisms seem to be more promising. The

Table 2. Advantages and Disadvantages/Limitations of the Phytoremediation Process[a]

Advantages	Disadvantages/Limitations
Amenable to a variety of organic and inorganic compounds.	Restricted to sites with shallow contamination within rooting zone of remediative plants.
In situ/*ex situ* applications for treating contaminated soils.	May take up to several years to remediate a contaminated site.
In situ applications decrease the amount of soil disturbance, compared to conventional methods.	Restricted to sites with rather low contaminant concentrations.
Reduces the amount of waste to be landfilled (up to 95%).	Harvested plant biomass from phytoextraction may be classified as a hazardous waste.
In situ applications decrease the spread of contaminant via air and water.	Climatic conditions.
Does not require expensive equipment or highly specialized personnel.	Introduction of nonnative species may affect biodiversity.
Easy to implement and maintain.	Consumption of contaminated plant tissue is also of concern.
Low cost compared to conventional treatment methods.	
Environmentally friendly and aesthetically pleasing to the public.	

[a] Reference 2.

microbial protection of plants against phytotoxic concentrations, however, is often based on excluding heavy metals; therefore, it is uncertain whether an approach based on chemical chelators is practical for improving phytoremediation (8). Naturally secreted organic acids, such as mugenic and avenic acids, may exhibit the same mechanism (similar to EDTA) to scavenge soils for metals (7).

ADVANTAGES AND LIMITATIONS

The phytoremediation of lead involves a number of advantages and certain limitations. Both of them derive from the fact that the use of plants to treat lead-contaminated soils would affect the soil and the surrounding media; as a result, some other pollutants (e.g., other metals) might be treated as well. For this reason, the advantages and limitations of lead phytoremediation are generally regarded as similar to those found in all relevant phytoremediation applications.

The most important advantages are the low cost and the aesthetic result, which is the sight of plants. On the other hand, the most important limitations are that the biodiversity of the site might be altered and that the uptake of pollutants by the plants may change their biology (2,5,9). The specific factors that can be characterized as advantages or limitations of phytoremediation are summarized in Table 2.

CURRENT STATUS AND FUTURE TRENDS

Although the phytoremediation of lead-contaminated soils is a rather new technology, the initial results from the respective laboratory research in pilot plants as well as from field applications, can be characterized as rather promising (5). Nevertheless, a better insight that will illuminate the overall picture will be given after at least 10 years, when the field data would be adequate to help in drawing safe conclusions.

Although the research effort for already existing plants is ongoing, the use of genetic engineering for plant improvement has been proposed. However, before such plants can be used for the phytoremediation of contaminated sites, the questions that arise from these applications should be carefully answered in an appropriate time frame following extensive research.

(from *Phytoremediation: Transformation and Control of Contaminants*, Wiley 2003)

SUMMARY OF PRACTICAL IMPLICATIONS

The capability of plants to remediate methyl *tertiary*-butyl ether (MTBE) at contaminated sites is promising to the point that at least one field test is underway and others anticipated. Both hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings and alfalfa (*Medicago sativa*) facilitate the removal of MTBE from saturated soil in the laboratory. The primary removal of MTBE is by soil volatilization facilitated by plant transpiration. Very little of the contaminant is metabolized or accumulated in laboratory studies. The MTBE that volatilizes and the small amount that diffuses from stems or transpires through leaves do not represent a risk in the atmosphere due to the rapid dispersion and degradation. Despite the different behavior of MTBE in groundwater, plants, and the atmosphere, concurrent phytoremediation of gasoline spills containing MTBE and other contaminants is expected to be very useful in the future.

INTRODUCTION

Methyl *tertiary*-butyl ether was first developed as a fuel oxygenate in the late 1970s to enhance the octane of gasoline and to improve air quality. In 1990, the U.S. Clean Air Act Amendments required fuel oxygenates to be added to gasoline in an effort to reduce atmospheric concentrations of carbon monoxide and ozone in some urban areas. The use of MTBE increased 16-fold from 1984 to 1993, to 24 billion pounds (approximately 10×10^6 metric tons). By 1998, MTBE was the fourth most common chemical product in the U.S. (Johnson et al. 2000). Oxygenates are added to over 30 percent of the gasoline used in the U.S., and MTBE is the most commonly used of these additives (Squillace et al., 1996). After formulation, MTBE constitutes up to 15 percent of gasoline by weight, giving rise to a daily usage of more than 10 million gallons (3.8×10^7 liters) in the U.S. (Johnson et al. 2000). However, continued use of MTBE is being questioned because of reports of adverse health effects, uncertainty about the efficacy of air pollution control, and the potential for contamination of groundwater (Anonymous 1997, Mehlman 1998). Several U.S. states have required that MTBE be phased out over time. A recent proposal was that the U.S. President use the authority under the Toxic Substances Control Act to ban MTBE across the U.S., but production continued in late 2000 at a rate of more than 11 million gallons or nearly 40 million liters per day.

As a part of the U.S. Geological Survey National Water Quality Assessment program from 1993 to 1994, 60 volatile organic compounds were analyzed for occurrence in groundwaters and surface waters. Of these 60 organic compounds, MTBE was the second most frequently detected chemical in samples of shallow groundwater from U.S. urban areas (Zogorski et al. 1998). Very little was detected in agricultural areas or deep groundwater wells. Surveys have reported finding MTBE in 5 to 10 percent of U.S. potable groundwater supplies (Stuckey 2000). Based on current distribution of MTBE sources and well pumping rates, Johnson et al. (2000) assessed the likelihood that more wells will become contaminated by MTBE. Although new and much more extensive databases are needed, the projected number of U.S. wells likely to experience contamination is in the thousands due to a large fraction of all community water supply wells lying within 1 kilometer of leaking underground storage tanks.

Methyl *tertiary*-butyl ether contamination of soil and groundwater can be separated into two categories: point sources, such as leaking underground storage tanks, and nonpoint sources, including infiltration and diffusion from urban air into shallow groundwater. General urban air contamination arises from fugitive emissions at gasoline stations and from gasoline-powered engines. Point sources are typically known quantifiable oxygenated gasoline spills onto the ground or leaks from underground storage tanks. Contamination by MTBE commonly occurs in conjunction with BTEX gasoline constituents (benzene, toluene, ethyl benzene, and xylenes). Gasoline from leaking underground storage tanks is the most frequent source of significant groundwater pollution with as much as one million gallons (approximately 4 million liters) of gasoline released into the ground each year (Hartley and Englande 1992), implying MTBE releases of hundreds of tons. It is estimated that out of three million underground storage tanks in use in the U.S., as many as 500,000 may be leaking petroleum into the ground (Hartley and Englande 1992). Actual leakage may be much higher than this implied level of 2 gallons per tank per year (8 liters per tank per year).

Properties of Methyl Tertiary-Butyl Ether

Methyl *tertiary*-butyl ether is an aliphatic ether with a molecular weight of 88.15 grams per mole (Fig. 1) (Squillace et al. 1997). This compound is volatile, colorless, and flammable (Caprino and Togna 1998). Because chemical structure influences many of the properties such as solubility, volatilization potential, and resistance to microbial degradation, it is useful to compare the physical and chemical properties of MTBE with those of the BTEX compounds with which it usually occurs in the environment (Table 1).

There is good evidence for microbial degradation of MTBE by several processes, as well as field data showing natural attenuation. Several processes for MTBE have been identified.

Anaerobic Microbial Transformation

Mormile et al. (1994) tested both pure and mixed cultures to anaerobically degrade MTBE. Two acetogens, *Acetobacterium woodii* and *Eubacterium limosum*, known to degrade phenyl methyl ethers, showed to MTBE transformation. However, the microbial cells consumed other gaseous substrates from the headspace of the incubation system and produced formate and acetate with no apparent toxicity caused by MTBE (Mormile et al. 1994). The capability of mixed cultures to anaerobically transform MTBE and *tertiary*-butyl alcohol was investigated under denitrifying and methanogenic conditions, with rates of transformation increasing with nutrients added (Yeh and Novak 1994). Methyl *tertiary*-butyl ether was shown to degrade in the soil taken from only one site out of three and only when nutrients were added. The degradation rates were much slower than those of the *tertiary*-butyl alcohol and complete degradation took

approximately 270 days. More recently Landmeyer et al. (1998) and Finneran and Lovley (2001) observed anaerobic degradation of MTBE under Fe(III) reducing conditions and Bradley et al. (2001) observed MTBE biodegradation under nitrate-reducing conditions

Aerobic Transformation in Mixed Cultures

Aerobic microbial transformation of MTBE was first successfully shown by Salanitro et al. (1994) using a mixed culture isolated from the sludge of an industrial chemical biotreatment operation. This culture, consisting of organisms from *Corynebacterium, Pseudomonades*, and *Achromobacters* was able to utilize MTBE at 2 milligrams per liter as a sole carbon source although none of the organisms were shown to grow alone on MTBE. Approximately 80 percent of the [^{14}C]-MTBE was mineralized to $^{14}CO_2$ or incorporated into new microbial cells after an incubation period of approximately 8 hours (Salanitro et al. 1994). *Tertiary*-butyl alcohol was observed as an intermediate. With 20 milligrams of MTBE per liter, little or no [^{14}C]-MTBE was metabolized to $^{14}CO_2$ or cellular material, suggesting that MTBE may be inhibitory to aerobes at high concentrations (Salanitro et al. 1994).

A consortium of aerobes from refinery activated sludge was also effective in transforming MTBE (Cowan and Park 1996), as was an aquifer consortium studied by Borden et al. (1997). Bradley et al. (1999) and Landmeyer et al. (2001) observed rapid metabolism of [^{14}C]-labeled MTBE using naturally occurring streambed microorganisms under mixed aerobic and anaerobic conditions in microcosms. Eweis et al. (1998) examined a compost-based biofilter microbial community and found MTBE degradation.

Aerobic Cometabolism

A fungus of the genus *Graphium* has been shown capable of cometabolizing MTBE with butane (Hardison et al. 1997), and Garnier et al. (1999) observed cometabolism with pentane by *Pseudomonas*. Steffan et al. (1997) reported indigenous propane-oxidizing bacteria isolated from contaminated and uncontaminated soils that could degrade MTBE. Isolate ENV425 that degrades MTBE was identified by fatty acid analysis to be most closely related to members of the genus *Nocardia*. All isolates were first grown with propane, then fed concentrations of MTBE in the range of 20 to 100 milligrams per liter, which was used as a sole carbon and energy source (Steffan et al. 1997). The cells were fed 20 milligrams per liter metabolized MTBE at a rate of at least 3.8 nanomoles per minute per milligram of cells without a significant lag period. Complete degradation occurred after approximately 4 hours, with *tertiary*-butyl alcohol accumulating nearly stoichiometrically, and with evolution of $^{14}CO_2$ from the methyl group. The microorganisms were capable of transforming *tertiary*-butyl alcohol at a rate of 1.8 nanomoles per minute per milligram of cells, about half that of

MTBE. Following 10 hours of transformation of *tertiary*-butyl alcohol, approximately 70 percent of the radiolabeled compound was still present in solution, suggesting the formation of water-soluble *tertiary*-butyl alcohol metabolites. Continued incubation showed 60 percent conversion to $^{14}CO_2$ after 24 hours and greater than 90 percent conversion after several days (Steffan et al. 1997). Figure 1 is a pathway for MTBE degradation proposed by Steffan et al. (1997).

Aerobic Transformation in Pure Cultures Lacking Other Substrates and Prior Induction

Four pure cultures of diverse genera have been shown capable of transforming at least a fraction of MTBE in a defined medium (Mo et al. 1997). The three strains investigated by Mo et al. (1997) represented *Methylobacterium, Rhodococcus*, and *Arthrobacter*. Also, a proteobacteria strain was derived from the biofilter examined by Eweis et al. (1998).

Potential Biotreatments for Methyl Tertiary-Butyl Ether

Salanitro et al. (2000) have successfully used bioaugmentation and oxygenation with a consortium designated MC-100 to enhance degradation of MTBE within an aquifer. Landmeyer et al. (2001) successfully used oxygenation only to enhance biodegradation of an MTBE-contaminated aquifer. Successful treatment was achieved in laboratory studies through cometabolism in an upflow fluidized-bed bioreactor (Stringfellow and Oh 2002) and in a vapor phase treatment using a trickling filter (Fortin and Deshusses 1999). In the latter case, contaminated soil from two different locations was used as an inoculum. Prince (2000) has reviewed most of the earlier literature on microbial MTBE degradation. Despite several instances of successful metabolism, MTBE appears to transform only slowly under typical field spill conditions, resulting in a need for additional cost-effective treatment methods.

A potentially useful alternative is phytoremediation. Plants have the benefit of absorbing large quantities of subsurface water by solar driven pumping (transpiration) and the roots support diverse microbial populations (Shimp et al. 1993, Davis et al. 1998a, Narayanan et al. 1999). Deep-rooted poplar (*Populus* spp.) trees have been studied in several contexts but there is little information on the capability to transpire or metabolize MTBE. Davis et al. (1998b) showed by use of Fourier transformed infrared spectroscopy that MTBE passes freely through hybrid poplars (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) in 1- to 2-day experiments although no effort was made to determine metabolic processes that might occur within the plant. Landmeyer et al. (2000) detected MTBE in cores of trees above a gasoline-contaminated aquifer but no effort was made to track the movement through the trees.

Rubin and Ramaswami (2001) have also investigated the uptake and phytoremediation of MTBE using hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’, & IC) cuttings. They reported transpiration of MTBE through plants with no evidence of MTBE transformation in the poplar (*Populus* spp.) saplings (Ramaswami and Rubin 2001).

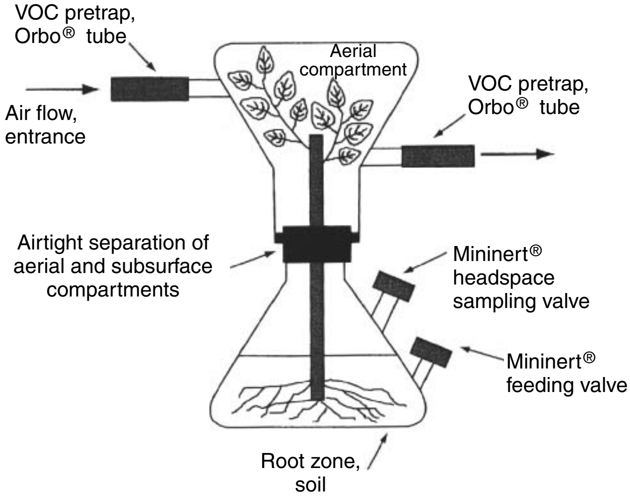

Figure 2. Schematic of the reactor design used to investigate hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) cuttings growing in soil.

UPTAKE OF METHYL TERTIARY-BUTYL ETHER BY HYBRID POPULUS IN HYDROPONIC SOLUTION

Experimental Setup

To determine the potential for hybrid poplars (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) to take up, metabolize, and translocate MTBE, a hydroponic experiment was performed, measuring the capability of hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) cuttings to remove [^{14}C]-MTBE from aqueous solution. Uptake of [^{14}C]-radiolabeled MTBE by hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) cuttings was investigated in a manner similar to methods pioneered by Burken (1993) and Burken and Schnoor (1996). A schematic of the reactor design is provided in Fig. 2. However, in the first experiment, there was no attempt made to collect gases volatilizing from plant leaves. The study included varying concentrations of MTBE in solution to determine any toxic response. Hydroponic studies used one-quarter-strength Hoagland’s inorganic nutrient solution, fed to the root zone of batch reactors containing hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) cuttings. Eight-inch (200-millimeter) long cuttings (0.75 to 1 inches or 19 to 25 millimeters in diameter) were affixed with pre-drilled screw caps and pre-drilled Teflon®-lined septa. Teflon® tape was wrapped around the stem and acrylic caulk was used to seal the caps and septa to the cutting. Hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) cuttings were first rooted in hydroponic solution until a vascular root system appeared, then placed in 1-liter bioreactors containing 400 milliliters of nutrient solution. The bioreactors consisted of a 1-liter Erlenmeyer flask modified by attaching a sampling port to the bottom and top of each flask. The cuttings were maintained in a laboratory growth chamber at 28 °C under artificial grow lights that provided a photon flux at the leaf surface of 100 to 160 micromoles of photons per square meter per second, the full photosynthetically active range.

Controls were included in triplicate to distinguish the uptake of MTBE by hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings from losses out of the system. First, a capped control with only nutrient solution and [^{14}C]-MTBE was included to determine the contribution of bio-degradation possibly occurring inside the hydroponic solution and sorption to the glass. To determine loss of compound through leaks in the system, controls were used with solid glass rods in place of a tree cutting. Finally, two sets of planted cuttings were cut off just above the cap to create decapitated controls, which were necessary to observe the effect of an excised tree on [^{14}C]-MTBE removals. Two sizes of cuttings were used; the first was approximately the same diameter as the glass rod and the second was similar to the intact tree reactors.

After being sealed, all reactors were spiked with a combination of [^{14}C]-radiolabeled MTBE ("hot," *i.e.*, radioactive), 6 microcuries per reactor, and pure MTBE ("cold," *i.e.*, nonradioactive) to a total aqueous concentration of 10.18 milligrams per liter, (creating a cold:hot MTBE ratio of 12 037:1). Concentrations of cold MTBE were then increased to 100, 1000, and 10 000 milligrams per liter. Reactors were prepared for all concentrations in triplicate. Samples were collected daily to monitor the disappearance of [^{14}C]-MTBE from hydroponic solution. Transpiration was measured gravimetrically each day, and replacement nutrient solution was added through the lower Mininert® port. Prior to adding nutrient solution, all headspace gas surrounding the root system was removed through a series of traps to capture any MTBE that was present in the headspace above the hydroponic solution. The air was pumped out through an activated carbon trap capturing pure compound and other organic metabolites (Orbo® tube 32, large, Supelco), and a trap that allowed air to bubble through 1 molar sodium hydroxide (NaOH) to capture any carbon dioxide (CO_2). To extract the trapped MTBE, the activated carbon was placed into 4-milliliter glass vials and submerged in 2 milliliters of methanol (Fisher) for 24 to 48 hours. Samples of 100 microliters were taken and injected into 15 milliliters of Scintiverse® for counting on a liquid scintillation counter. One milliliter samples were taken from the sodium hydroxide (NaOH) in the carbon dioxide (CO_2) traps and injected into an Ultima Gold scintillation cocktail (Packard) for scintillation counting.

After 10 days, total [^{14}C]-uptake was quantified in the roots, lower stem, upper stem, leaves, and petioles of the hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings *via* oxidation to $^{14}CO_2$ in a R.J. Harvey Bio-Oxidizer, and subsequently by scintillation counting. Oxidation efficiency was determined to be 92 percent and was calibrated with pre- and post-analysis efficiency testing.

Results from Hydroponic Solutions

Based on recorded observations of visual symptoms, biomass, and transpiration rate, MTBE was found not toxic to hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings at concentrations as high as 1000 milligrams of MTBE per liter. However, the trees dosed with 10 000 milligrams of MTBE per liter died after only a few days. Transpiration rate correlated well with biomass measurements and was a good measure of growth and vitality. Hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings were healthy and grew well in all experiments at concentrations as high as 1000 milligrams of MTBE per liter.

Figure 3 displays removal of [^{14}C]-MTBE from solution by the full and excised cuttings as well as the controls. The data for the full ($n = 5$) and excised ($n = 3$) cuttings are shown as an average with the error bars representing one standard deviation. Uptake of MTBE occurred immediately in all planted reactors and continued throughout the investigation. For the five planted reactors, 66.98 ± 6.09 percent of the total MTBE was removed from hydroponic solution at the end of the 10-day experiment.

Methyl *tertiary*-butyl ether removal after 10 days for the excised cuttings was 42.97 ± 3.32 percent. The data from the toxicity portion of the experiment yielded a comparable result for the cuttings dosed with 10 000 milligrams per liter—51.52 ± 2.29 percent was removed from solution after 11 days. The removal rate was similar for the excised cuttings ($k = 0.060 \pm 0.002$ per day and the correlation coefficient $r^2 = 0.994$), and for the cuttings that died at 10 000 milligrams of MTBE per liter ($k = 0.067$ per day) as evidenced by the first order rate coefficients. The reproducibility of the removal rates and percent removed from solution are a strong indication that the cause is attributable to movement of MTBE through the dead stem as opposed to leaks from the enclosed system. Excised cuttings are apparently capable of volatilizing MTBE (and very little water) from solution to the atmosphere.

After 10 days, the experiment was terminated and the cuttings were sacrificed. The various components were bio-oxidized and the radioactivity measured with the liquid scintillation counter to determine the amount of radiolabeled compound in the plant tissue. Figure 4

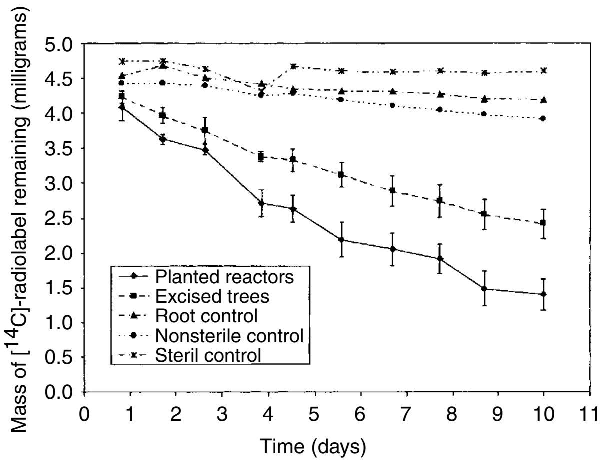

Figure 3. Hydroponic experiment with hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings: mass of methyl *tertiary*-butyl ether remaining in aqueous solution as determined by liquid scintillation counting. At time = 0, 4.3 milligrams of methyl *tertiary*-butyl ether was added for an initial concentration of 10.2 milligrams per liter in solution. Error bars on the data for full trees ($n = 5$) and excised trees ($n = 3$) represent one standard deviation.

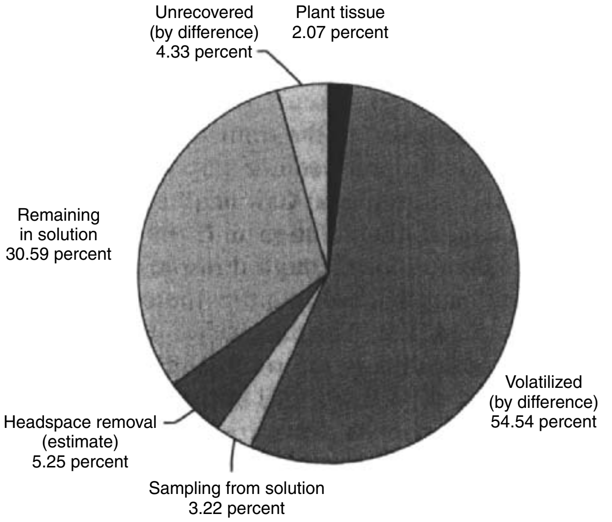

Figure 4. Hydroponic experiment: graph depicting [^{14}C]-radiolabel distribution and recovery results for the reactors containing hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings as determined by liquid scintillation counting at the termination of the 10-day investigation. Results are given as a percent of the total [^{14}C]-MTBE initial spike (6 microcuries) added to reactors at time = 0. The amount of radiolabel that was reported as volatilized was determined as the difference in the amount remaining in solution at the termination of the experiment between the unsterilized and planted reactors. The amount reported as unrecovered was the difference between the unsterilized and sterile reactors.

summarizes the radiolabel recoveries for the full cutting and displays the overall mass balance. The amount of MTBE volatilized through plants was found to be 54.5 percent. This was estimated by the difference in the amount of radiolabel remaining in solution between the planted cuttings and the sterile controls. This estimate assumes that any removal from the excised tree reactors was due to uptake and not to leaks (Winnike 1998). However, leaks of MTBE through the septums and seals can be substantial, and leaks have been shown to rival transpiration of MTBE through leaves in such experiments (Hong et al. 2001).

The average [^{14}C]-radiolabel remaining in solution was 33.02 ± 6.09 percent. This is approximately twice as much as that found in the toxicity investigations in the same reactors at the same concentration. This value was expected to be similar due to the similar experimental conditions and duration. The reason for this difference lies in the relationship between cumulative transpiration and uptake of MTBE. A comparison of average transpiration rates shows that the cuttings in the toxicity experiment transpired more (32.3 ± 11.24 milliliters per day) than the cuttings in the hydroponic experiment (26.5 ± 10.0 milliliters per day). Because the leafy portion was exposed to the atmosphere, the amount of radiolabeled MTBE transpired through the leaves was not measured directly.

UPTAKE EFFICIENCY AND TOXICITY

Methyl *tertiary*-butyl ether was taken up by the plants and translocated up the vascular system of the plant in the transpiration stream. The efficiency of uptake of MTBE from hydroponic solution by hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings was estimated by the change in MTBE mass in the solution and the volume fraction of water transpired each day. Because of the high transpiration rates of all cuttings, it was necessary to add nutrient solution to the reactors daily, diluting the initial concentration of MTBE. This resulted in a continual decrease in concentration and mass of MTBE in the root compartment. For chemicals that are readily taken up and not transformed in the roots, the efficiency of uptake is identical to the dimensionless transpiration stream concentration factor (*TSCF*). The *TSCF* is defined as the chemical concentration in the xylem water divided by the chemical concentration in the external solution (Briggs et al. 1982). The TSCF was estimated to be in the range of 0.5 to 0.8 for MTBE for hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings based on

$$U = (TSCF)\,(C)\,(T) \tag{1}$$

in which U is the rate of mass uptake (milligrams per day), C is the concentration in solution (milligrams per milliliter), and T is the rate of transpiration (milliliters per day). The concentrations used to estimate *TSCF* were based on initial experimental concentrations of 10, 100, and 1000 milligrams per liter. The *TSCF* value was not calculated for the toxic concentration of 10 000 milligrams per liter.

UPTAKE OF METHYL TERTIARY-BUTYL ETHER BY HYBRID POPULUS PLANTED IN SOIL

Experimental Setup

To assess the capability of hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings to remove MTBE from soil, an Iowa agricultural silt-loam soil (Nodeway-Ely series) was taken from an uncontaminated field site with a fraction organic matter of 0.025 (Burken 1993). The soil was air-dried, pulverized, and passed through a 2-millimeter sieve. The cuttings were allowed to root hydroponically for 2 weeks until a full vascular root system developed. Four cuttings were transplanted to individual reactors containing 500 grams of air-dried soil, and 180 milliliters of nutrient solution was added intermittently to the flask to achieve uniform soil moisture content (Fig. 2). The reactors were initially at 100 percent saturation and acclimated for 7 days. During this time, the trees transpired and the soil-water saturation level was reduced 70 to 90 percent.

After this acclimation, the leafy portion of the cutting was enclosed by attaching an inverted 1-liter Erlenmeyer flask modified with an inlet port for air flow near the top and an outlet near the bottom. The perimeter of the open end was sealed with acrylic caulk to fit snugly around the screw cap. Parafilm® tape was used to seal this joint, and a Mininert® valve was placed on the top sampling port of the bottom flask to create a fully encapsulated system. Reactors were treated with doses of 3.95 milligrams of cold MTBE and 7.1 microcuries of [^{14}C]-MTBE mixed with the feed water (resulting in a ratio of cold:hot MTBE of 10 069:1). Air was purified and pumped through the aerial portion of the reactor at 1.0 to 3.0 liters per minute. The air inlet and outlet ports of the Erlenmeyer flask were fitted with activated carbon traps to capture [^{14}C] transpired through the plants (two traps were used in series on the outlet port to ensure capture). The scrubbed air then passed through traps to capture any $^{14}CO_2$ that was mineralized by soil microorganisms or by the plant in the aerial portion of the reactor.

Results with Hybrid Populus in Soil

The primary goal of this test was to quantify volatilization of [^{14}C]-MTBE from leaf tissue. By enclosing the leafy portion of the cutting, a total mass balance was achieved. The total recovery was lower than expected (67.4 ± 6.3 percent). However, this test provided valuable information with regard to the major pathways for MTBE removal. The unrecovered portion seemed to be partially the result of leaks from the enclosed reactor vessel (Fig. 2). The four planted cuttings remained healthy throughout the test, which was terminated after 33 days because the leaves grew too large and were pressing into the sides of the aerial compartment. The longer duration of this experiment (compared to the prior experiment in hydroponic solution) was possible because of slower growth of the cuttings in the soil. Transpiration was monitored by gravimetric analysis.

The rate of transpiration varied widely throughout the test because of excess humidity in the aerial compartment. As humidity increased to high levels, transpiration decreased dramatically due to aerodynamic resistance. In addition, the average transpiration rates for all reactors were significantly lower than under hydroponic conditions as a result of the decreased water availability in the soil. Although [^{14}C]-MTBE uptake was not quantified daily, the fluctuation in transpiration rates very likely influenced the rate of MTBE uptake from the soil water. The full set of transpiration data is provided in Winnike (1998).

Radiolabel recoveries on a percent mass basis are presented in Fig. 5. Because only liquid scintillation counting was utilized, it was uncertain whether the radiolabel recovered was [^{14}C]-MTBE or a [^{14}C]-metabolite. Only a small percentage of the initial [^{14}C]-radiolabel remained in the soil (4.75 ± 1.76 percent), indicating that 33 days were adequate to remove a majority of the MTBE from the soil. In subsequent tests, the vast majority of the radiolabel exists as parent compound, MTBE, in hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') tissues.

The [^{14}C]-radiolabel that was transpired constituted the most significant flux of MTBE movement (55.55 ± 1.85 percent). Assumedly the recovered radiolabel from the activated carbon traps was [^{14}C]-MTBE. Subsequent analyses in the laboratory indicated that MTBE was predominant over other potential metabolites such as *tertiary*-butyl alcohol. The air also bubbled through a sodium hydroxide (NaOH) trap to capture $^{14}CO_2$ from the mineralization of MTBE. A small percent of the initial MTBE input was recovered as $^{14}CO_2$ (1.62 ± 0.63 percent), which indicates that either hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings or microorganisms in the soil were able to mineralize a portion of the MTBE to carbon dioxide (CO_2).

The headspace in the root compartment was sampled and analyzed for both [^{14}C] and $^{14}CO_2$ prior to watering and at the end of the test. This amount was shown to be fairly significant with recoveries of 0.63 ± 0.55 percent and 2.03 ± 1.85 percent for [^{14}C] and $^{14}CO_2$, respectively. The observed range of 0.41 to 4.50 percent demonstrates the high variability in $^{14}CO_2$ recovery. The amount of [^{14}C] remaining in plant tissue was approximately 3 percent. On the basis of total plant mass, the leaves contained 14.72 ± 4.02 milligrams of MTBE per kilogram, the petioles 11.10 ± 3.86 milligrams of MTBE per kilogram, and roots ±3.76 milligrams of MTBE per kilogram. The leaves contained the largest total percentage (34.27 ± 9.55 percent) and the roots accounted for the smallest (11.14 ± 2.12 percent).

CHANNEL TESTS WITH ALFALFA

Tests were carried out in a 6-channel system (Zhang et al. 1998). Table 2 provides information on the experimental system and the tests that were conducted. The results are described fully elsewhere (Zhang et al. 1998, Zhang 1999, Zhang et al. 1999, 2000, 2001). Table 3 and Fig. 6 show that vegetation affects the upward movement of MTBE from the saturated zone to the soil surface. Channel 4 has a much smaller fraction of MTBE and water moving to the soil surface. The recovery of MTBE was larger for Channel 4, which was barren of vegetation and unseeded with microbial cultures capable of biodegrading MTBE. As shown in Table 3, the measured loss of MTBE to the atmosphere at the soil surface was much greater than that which entered the plant and then passed into the atmosphere. The fraction of water that was lost as vapor to the atmosphere was considerably larger than the measured fraction of MTBE that entered the atmosphere (Zhang et al. 1999). The total recoveries of MTBE in the vegetated channels were less than 100 percent for all of the tests. The incomplete recovery of MTBE was probably due to enhanced rhizosphere biodegradation in the soil. Microcosm experiments with soils from the channel system were conducted, and a disappearance rate for MTBE of up to 5 milligrams per kilogram of soil per day was observed.

The water transpired daily by the plants increased from the time the alfalfa (*Medicago sativa*) was cut until the next harvest as shown in Fig. 7. The transpiration rate was on average 5 millimeters per day (0.5 cubic centimeter per square centimeter per day) at the end of July 1999. This value was in agreement with predicted transpiration rates (Davis et al. 1998a). Figure 8 provides information on the concentration of MTBE in the plant water as a function of plant height. Experiments conducted with plant stems show that MTBE diffuses through the stem surface into the atmosphere (Zhang et al. 2001). The estimated values of the diffusivity for MTBE range from 8×10^{-8} to 8×10^{-7} square centimeters per second for alfalfa (*Medicago sativa*) plant stems (Zhang et al. 2001).

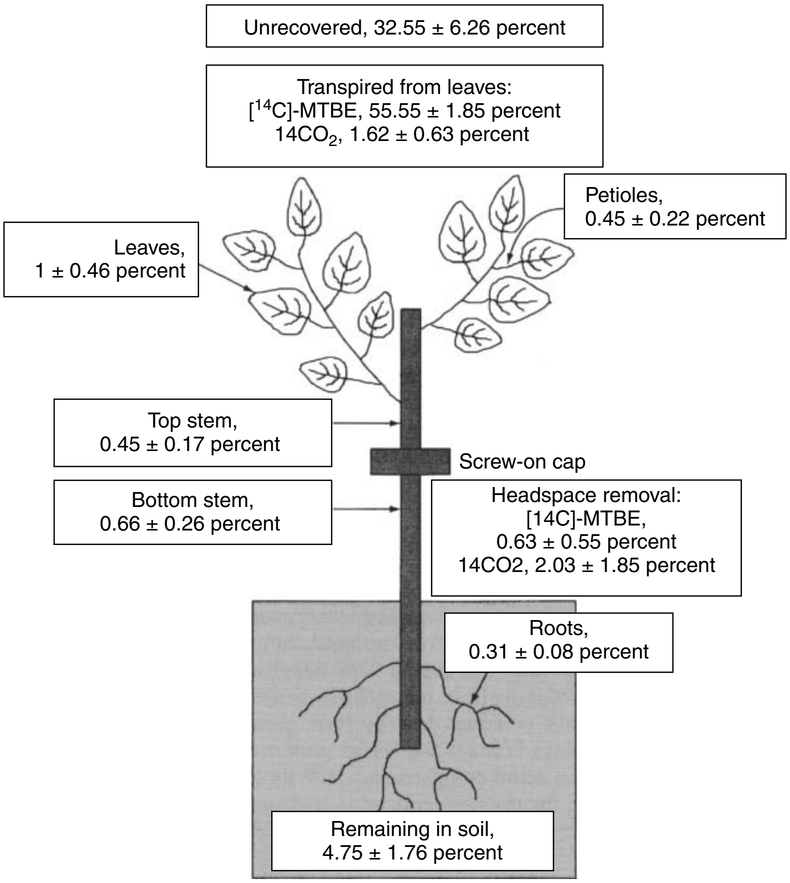

Figure 5. Schematic and mass balance of methyl *tertiary*-butyl ether uptake by hybrid poplars (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') in soil reactor.

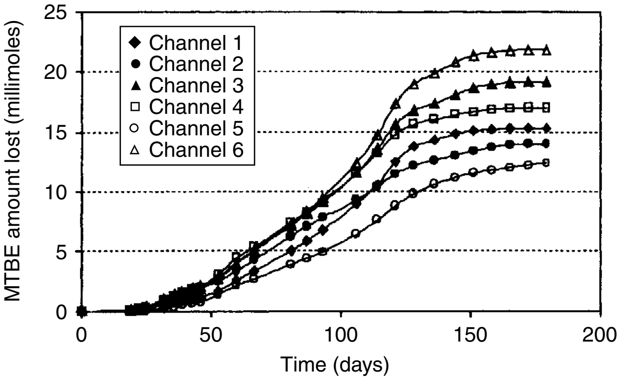

Figure 6. Cumulative loss of methyl *tertiary*-butyl ether to the atmosphere through the soil surface for each of six channels. Tests conducted from June 30 to December 25, 1998.

FATE OF METHYL TERTIARY-BUTYL ETHER IN THE ATMOSPHERE

Site-specific determinations are necessary to ensure that the amount of MTBE transferred to the atmosphere does not exceed air quality standards. This analysis takes into account the total amount of compound volatized per unit time and the mixing zones in the atmosphere. This can be compared to the large quantities of MTBE introduced into the atmosphere because of gasoline pumping at refueling stations and engine operation. The MTBE introduced to the atmosphere caused by phytoremediation is significantly less.

Table 2. Experimental Conditions and Treatments in Each Channel for the Six-Channel Experimental System

	Planted with 10 alfalfa (*Medicago*) *sativa* plants	Air sparged at 0.24 liter per channel per day	Additional bacteria (2 liters of suspension added on June 20, 1998)
Channel 1	Yes	Yes	#33 (*Rhodococcus*)
Channel 2	Yes	No	#33 (*Rhodococcus*)
Channel 3	Yes	No	No
Channel 4	No	No	No
Channel 5	Yes	No	#41 (*Arthrobacter*)
Channel 6	Yes	Yes	#41 (*Arthrobacter*)

Note: Channel dimensions were 1.1 meters long, 0.65 meter deep, and 0.10 meter wide. The soil was alluvial silty sand soil (with less than 10 percent silt) collected near a landfill in Riley County, Kansas. The system was illuminated with 12 cool white fluorescent lights (40 watts) at a height of 0.50 meter above the soil; light intensity was approximately 160 micromoles of photons or microeinsteins per square meter per second. The channels were fed with an MTBE-water solution of 0.84 millimole per liter at 1 per day from June 30, 1998 to September 20, 1998 (83-day duration). Distilled water was fed from September 21 to December 25, 1998 (96-day duration) and the channels fed with an MTBE-water solution of 0.84 millimole per liter at 1 per day from Feb. 6, 1999 until the data in Figs 7 and 8 were collected during the summer of 1999. Strain #33 (*Rhodococcus*) and Strain #41 (*Arthrobacter*) were obtained from C.F. Kulpa (Mo et al. 1997, Zhang et al. 1999).

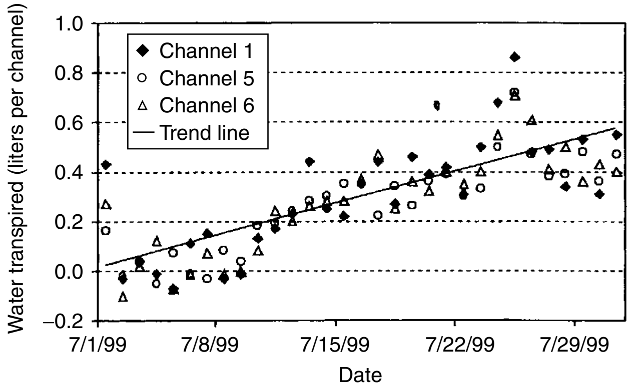

Figure 7. Water transpired daily by alfalfa (*Medicago sativa*) in three channels during July 1999; plants were cut back to 60 millimeters on July 1.

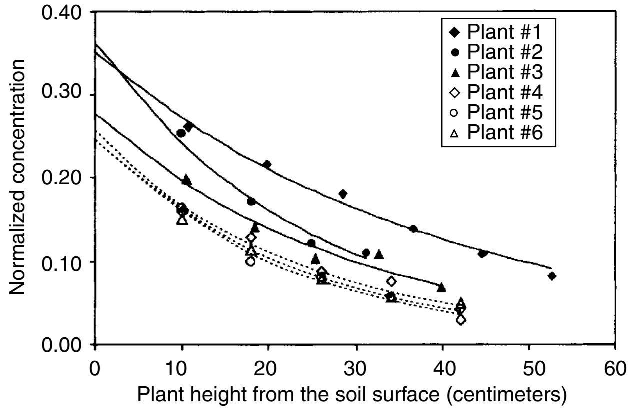

Figure 8. Methyl *tertiary*-butyl ether dimensionless concentration in plant water as a function of alfalfa (*Medicago sativa*) stem position from the soil surface. Dimensionless feed concentration of methyl *tertiary*-butyl ether is 1 which corresponds to 0.84 millimoles per liter.

The MTBE released to the atmosphere is rapidly dissipated. The published information on the degradation half-life of MTBE in the atmosphere indicates that MTBE readily degrades chemically because of the hydroxyl radicals (OH^-) present. Squillace et al. (1997) have reviewed the fate of MTBE in the atmosphere and report that the half-life of MTBE can be as short as 3 days at 25 °C.

The following method to estimate the concentration of MTBE being released through vegetation is based on mass balance considerations. If the MTBE flows upward into the unsaturated zone together with the water drawn up by transpiration, the air required to hold the associated water vapor is the critical control volume. For example, consider the case in which there is 88 milligrams of MTBE per liter in the groundwater, and the water and MTBE move into the atmosphere together at 25 °C where the vapor pressure of water is 3173 pascals (23.8 millimeters of mercury) or a mole fraction of 0.0313 at saturation in air with 1×10^5 pascals (1 atmosphere) pressure. A liter of water contains 55.6 gram moles which requires 43,434 liters of air to dissolve the water under saturation conditions at 25 °C and 1×10^5 pascals (1 atmosphere) of pressure. The 88 milligrams of MTBE per liter is 1 millimole per liter in water, but only $0.001/1776 = 0.56$ parts per million by volume in air. Thus, the concentration of MTBE in air is diluted because of the water vapor dissipation process that partially controls the rate of evapotranspiration. Because (1) MTBE concentrations in groundwater are often much smaller than 88 milligrams per liter, (2) the air is usually not saturated with water vapor, and (3) the ambient air contains some water vapor, the values of MTBE in the atmosphere as a result of phytoremediation are very small. This is especially true compared to values at a refueling station where MTBE vapors in equilibrium with the liquid fuel may be as high as 50,000 parts per million by volume.

FIELD STUDIES

The basic processes observed at the laboratory scale (*i.e.*, biodegradation, volatilization, and transpiration), also take place at a field scale. Salanitro et al. (2000) observed aerobic biodegradation in the field with and without bioaugmentation using MTBE-degrading microorganisms. Wilson et al. (2000) reported biodegradation under anaerobic conditions. Hong et al. (2001) demonstrated the beneficial contributions of vegetation with respect to plume control. Landmeyer et al. (2000) reported the uptake of MTBE into vegetation.

Phytoremediation is an effective technology for remediation of fuel-contaminated sites as shown elsewhere in this book. Based on the results of laboratory and field studies reviewed in this chapter, vegetation increases the rate of evapotranspiration and the upward movement of MTBE into the unsaturated zone and the atmosphere. The beneficial effects of vegetation for MTBE are similar to those for BTEX compounds in fuel-contaminated soils; however, MTBE tends to persist longer in the atmosphere compared to BTEX compounds because MTBE is more resistant to photochemical degradation. Furthermore, MTBE is more mobile in soil and groundwater, and MTBE is not degraded readily in the root zone. Where these different properties of BTEX and MTBE are taken into account, simultaneous phytoremediation of shallow groundwater plumes from fuel spills should be feasible at many sites (see Weaver et al. this book).

CONCLUSIONS

Methyl *tertiary*-butyl ether is a compound of concern because of possible carcinogenic effects, persistence in soil and groundwater, and potential resistance to degradation by microorganisms. The widespread occurrence of this compound in groundwater is relatively recent, and conventional treatment is either ineffective or expensive. Phytoremediation provides an inexpensive, esthetically pleasing, and effective alternative for treating numerous organic contaminants. These investigations show that hybrid poplar (*Populus deltoides* × *Populus nigra* ‘DN34’ ‘Imperial Carolina’) cuttings and alfalfa (*Medicago sativa*) are capable of cleaning up water and soil contaminated with MTBE. Specific conclusions are as follows:

- Hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings tolerate concentrations of MTBE of at least 1000 milligrams per liter. The concentrations observed in the environment near a source of MTBE contamination can be as high as 200 milligrams per liter and hybrid poplars (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') could effectively take up MTBE at this concentration without apparent toxic effects.
- Small hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings are effective at removing MTBE from hydroponic solution. Tests demonstrated that cuttings dosed with 10, 100, and 1000 milligrams per liter were able to achieve an MTBE removal of 30.6 percent remaining in solution within 10 days from 400-milliliter reactors.
- Small hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings and alfalfa (*Medicago sativa*) are effective at removing MTBE from soil. Hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') cuttings removed 95.2 ± 1.8 percent within 33 days when MTBE was initially at a soil water concentration of 22 milligrams per liter (soil concentration of 7 milligrams per kilogram). The evapotranspiration rate and amount of MTBE volatilized are considerably larger in alfalfa (*Medicago sativa*) vegetated soil compared to soil without vegetation. The evapotranspiration rate is small after alfalfa (*Medicago sativa*) plants are cut back; the rate increases nearly linearly with time as the plants increase in size over 29 days.
- The primary removal mechanism for MTBE was volatilization into the soil gas and atmosphere. When soil volatilization was not possible, significant amounts also transpired through hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') leaves and stem. Shown to move with water into the plant (*TSCF* of 0.5 to 0.8), MTBE also volatilized through the stem of excised small hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') plants and alfalfa (*Medicago sativa*) stems. Removal occurred at a slower rate than for actively transpiring hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN34' 'Imperial Carolina') and alfalfa (*Medicago sativa*) plants. However, the volatilization is typically expected to be very small, especially compared to the MTBE volatilized at gasoline refueling stations. The small amount of MTBE that does volatilize into the atmosphere disperses and degrades photochemically with a half-life on the order of days.

This research provides evidence that phytoremediation could be a potential alternative for the remediation of MTBE contaminated sites.

PHYTOREMEDIATION OF SELENIUM-LADEN SOILS

Rupali Datta
Dibyendu Sarkar
University of Texas at San Antonio
San Antonio, Texas

Selenium (Se) is a naturally occurring metalloid that is toxic at high concentrations but is also a nutritionally essential element. In the 1980s, Se-contaminated water at the natural wildlife refuge at Kesterson Reservoir, California was responsible for widespread reproductive failure, developmental defects, and death in migratory aquatic birds and fish. The environmental and health impacts of this incident have resulted in extensive research on the behavior of Se in soils and plants. The cost of using conventional remediation technologies for cleaning up Se-contaminated soils is very high, so recent research has focused on phytoremediation of Se from contaminated soils. Selenium accumulation by plants and its subsequent volatilization are very effective in remediating Se-contaminated soil and water. Natural hyperaccumulator plants such as *Astragalus* growing in seleniferous soils accumulate high concentrations of Se in their tissues. However, the main drawback of using these plants for phytoremediation is their slow growth rate and low biomass. This has prompted researchers to investigate the possibility of developing genetically engineered plants with better Se phytoextracting capacity. Understanding the speciation and bioavailability of Se in soils and the biochemistry of Se in plants and microorganisms is the first step toward developing effective phytoremediation strategies for Se-laden soils.

INTRODUCTION

Selenium is a naturally occurring metalloid, essential for animals, humans, and microorganisms in trace amounts (1). It provides protection against diseases such as liver necrosis, muscular dystrophy, Keshan disease, infertility, and white muscle in livestock (2). At higher doses, it is toxic to animals and humans. The concentration range of Se from trace element requirement to lethality is very narrow. The minimal nutritional requirement for animals is about 0.05–0.10 mg Se/kg dry forage feed, but to 2–5 mg Se/kg dry forage is toxic (3). A chronic form of Se poisoning in livestock is 'alkali disease' caused by ingestion of plants containing high concentrations of Se. Excess Se in diet causes birth defects and sterility in animals; loss of hair, teeth, nail, fatigue; and even death in humans (4).

Selenium is found primarily in sedimentary rock formations in drier areas of the world. It is chemically very similar to sulfur (S); it has five valence states; selenide (2−), elemental selenium (0), thioselenate (2+), selenite (4+), and selenate (6+) (5). Environmental speciation of Se depends on redox conditions and pH; selenate is the major species in aerobic and neutral to alkaline environments, but selenide and elemental Se dominate under anaerobic conditions. Selenium complexes with metals and nonmetals, forming both organic and inorganic compounds (3). Interest in Se has grown during the past couple of decades, primarily due to the Kesterson Reservoir controversy in the 1980s. Selenium-contaminated water at the natural wildlife refuge at Kesterson Reservoir, California, was responsible for reproductive failure, developmental defects, and death in migratory aquatic birds (6) and fish (7). Scientists, regulators, politicians, and the general U.S. public became aware of the dangers of Se contamination as a result of this incident. Selenium toxicity is encountered in several arid and semiarid regions of the world that have seleniferous, alkaline soils derived from weathering of seleniferous rocks and shales. Se leaching from these soils is accelerated by irrigation, and it accumulates in high concentrations in drainage water, mainly as selenate. Selenium is also released into the environment by various industries such as oil refineries and electrical utilities (3).

Conventional remediation technologies for cleaning up Se-contaminated soils depend on physicochemical and electrochemical approaches, which are often prohibitively expensive. Moreover, these methods produce hazardous by-products, which must be transported to landfills, thereby adding to the remediation cost. Phytoremediation is the use of plants to extract, accumulate, and volatilize Se (8). It offers a cheaper, safer, and environmentally friendly solution for cleaning up Se-contaminated soils. This article provides an overview of the various sources of Se contamination, factors affecting Se bioavailability in soils, Se biochemistry and the mechanism of Se accumulation in plants, and future directions in the improvement of phytoremediation through biotechnology.

SOURCES OF SELENIUM CONTAMINATION

Selenium contamination in the environment arises from both natural and anthropogenic sources. Soils that are derived from shale rocks contain high concentrations of Se. As a result of irrigation, Se is leached into the subsurface drainage water and is eventually channeled into evaporation ponds. Evaporation and continual drainage into these ponds, builds up the amount of bioavailable Se to very high concentrations, which can be very damaging to wildlife, which was first demonstrated by the environmental disaster at the Kesterson Reservoir in California (9). Selenium-contaminated irrigation drainage water represents one of the most serious problems confronting agriculture in the western United States and other parts of the world whose geological and environmental conditions are similar (9).

Anthropogenic Se contamination develops from aqueous discharges of electrical power plants, coal ash leachates, oil refinery effluents, and other industrial wastewater (4). Selenium is widely used in electronics, photography, and in the production of steel, glass, ceramics, pigments, paints, pharmaceuticals, rubber, fungicides, and insecticides (10).

Of the 1430 hazardous waste sites on the United States Environmental Protection Agency's National Priorities List, at least 376 have measurable levels of Se (11).

SELENIUM IN SOILS

Most uncontaminated soils contain 0.10 to 2 ppm of total Se (12). Excessive amounts of Se is present only in the semiarid and arid regions of the world in soils derived from cretaceous shales. However, total Se in soils is not a reliable index of the actual amount available to plants. Normal soils contain <50 ppb of water-soluble Se. The chemical form of Se in soils largely determines its mobility and bioavailability to plants and animals. Selenium species in soil solution can be present primarily in three oxidation states; selenates, selenites, and selenides (12). In the oxidized alkaline soils of western San Joaquin Valley, California, selenate is the dominant soluble species constituting 98% of the soluble Se, but selenites and organic Se species are also present. The solubility and mobility of Se in soils depend on processes such as adsorption, precipitation, and transformation, which in turn depend on the chemical species of Se, pH, and redox conditions. Several studies have shown that selenite is sorbed onto soil to a much greater extent than selenate (13), which makes it less bioavailable than selenate. Selenate generally adsorbs weakly onto clays, iron oxides, and other soil phases at neutral to alkaline pH. The low solubility of Se in acid or neutral soils can be attributed to its occurrence as selenite in combination with ferric iron as ferric selenite. In soils containing reactive ferric oxides, ferric selenite–ferric hydroxide adsorption complexes are formed. Oxidation of selenite to selenate in alkaline soils is favored by a decrease in the stability of ferric hydroxide–selenite complexes (12). Oxyanions such as NO_3^- can facilitate the oxidation of Se, resulting in high levels of soluble selenate in drainage effluents from agricultural lands.

The three major mechanisms of Se transformation in soil are: oxidation–reduction, methylation–demethylation, and volatilization. Oxidation leads to mobilization, and reduction results in immobilization of Se. Methylation and volatilization lead to the loss of Se from the soil. A number of microorganisms are capable of forming volatile, alkylated Se compounds from inorganic forms of Se, which are less toxic. Dimethylselenide (DMSe) is the major metabolite of Se volatilization, although other products such as dimethyldiselenide (DMDSe), methaneselenone, methaneselenol, and dimethylselenide sulfide may also be produced (14).

SELENIUM IN PLANTS

Plant Uptake and Transport

Selenium is taken up from soils by plants primarily as selenate or selenite. Selenate is accumulated in plant cells against its likely electrochemical potential gradient through a process of active transport (3). Selenate competes directly with sulfate for uptake, indicating that both anions are taken up by the sulfate transporter protein in the root plasma membrane. Kinetic and expression studies have indicated that sulfate transporters belong to two main classes, transporters that have either high or low affinity for sulfate. The high-affinity transporter is the primary transporter involved in sulfate uptake and is expressed mainly in the roots. The low-affinity transporter is expressed both in roots and shoots and may be involved in intercellular transport of sulfate (3). Unlike selenate, there is no evidence that the uptake of selenite is mediated by membrane transporters. Selenate is taken up by the sulfate transporter, so sulfate salinity drastically inhibits plant uptake of selenate (15).

Plant Assimilation and Volatilization

After uptake, it is believed that selenate is transported to chloroplasts, where it is processed by the S assimilation pathway (1). Selenate is activated by ATP sulfurylase enzyme, forming adenosine 5′-phosphoselenate (APSe), which is a major rate-limiting step for selenate assimilation in plants. APSe is then reduced to selenite by adenosine 5′-phosphosulfate (APS) reductase, which in turn is nonenzymatically reduced to selenide by glutathione. Selenocysteine is synthesized from O-acetyl serine and selenide by cysteine synthase enzyme (1). Selenoamino acids, such as selenocysteine and selenomethionine, are nonspecifically incorporated into proteins, thereby leading to Se toxicity (3). Selenomethionine can be converted to DMSe and then volatilized. Recently, Se volatilization by plants has received attention as a possible method of phytoremediation of Se-contaminated soils.

Selenium Hyperaccumulators and Nonaccumulators

Plants differ in their ability to accumulate Se in their tissues. Certain plants can hyperaccumulate Se in their shoots when grown in seleniferous soils. Such plants, called Se hyperaccumulators, include a number of species such as *Astragalus, Stanleya, Morinda, Neptunia, Oonopsis*, and *Xylorhiza* (3). They can accumulate several hundreds to several thousands of milligrams of Se/kg dry weight in their tissues, whereas nonaccumulators contain less than 25 mg Se/kg dry weight. Secondary Se accumulators include plants such as Indian mustard and canola, which can accumulate several hundred milligrams of Se/kg tissue when grown in soils contaminated with moderate levels of Se.

The pathway for the assimilation of inorganic forms of Se to selenocysteine in Se accumulators, it is believed, is the same as for nonaccumulators (3). The main difference between Se accumulators and nonaccumulators is that accumulators metabolize selenocysteine into various nonprotein selenoamino acids. The best characterized Se accumulator is *Astragalus bisulcatus*. In this plant, selenocysteine is methylated to methylselenocysteine, which prevents its nonspecific incorporation into proteins and helps to confer Se tolerance (16).

PHYTOREMEDIATION

Phytoremediation is the use of plants to remove, contain, or render harmless certain environmental pollutants (4).

It offers a cheaper, safer, and environmentally friendly solution for cleaning up Se-contaminated areas. Plants can be used in conjunction with microbial activity to extract, accumulate, and volatilize Se (8). There are several different types of phytoremediation, which can be classified as

- Phytoextraction, which uses the ability of certain plants to take up contaminants from soil and water and accumulate them in their tissues. Such tissues can then be harvested and removed from the site. Phytoextraction is facilitated by hyperaccumulator plants that grow naturally on heavy metal and metalloid-rich soils (17). Several plant species have been evaluated for their efficiency in phytoremediation, particularly certain species of *Astragalus* (18). However, these are slow growing plants, and the Se accumulated can be leached back into the soil from the leaves by rainfall (3). Another disadvantage of phytoextraction is that the accumulated Se in plant tissues could become available to animals and birds.
- Phytostabilization, which uses plants to immobilize contaminants chemically and physically at the site, thereby preventing their movement to surrounding areas (19).
- Phytofiltration, which takes advantage of the ability of plant roots to absorb or adsorb environmental contaminants, mostly metals, from water and waste streams.
- Phytodetoxification, which involves the ability of plants to change the chemical species of the contaminant to a less toxic form. For example, plants can take up toxic hexavalent chromium and convert it to nontoxic trivalent chromium (15).
- Phytovolatilization, which uses plants and their associated microbes to metabolize certain contaminants to volatile forms, which are removed from the environment. For Se, phytovolatilization is an innovative and potentially effective remediation technology for several reasons.
    1. Volatilization minimizes the production of Se-laden plant material, thereby reducing the risk that contaminants move into the local food chain.
    2. DMSe, the major component of volatile Se resulting from phytovolatilization, is 600 times less toxic than selenate or selenite (20).

The ideal plant species for phytoremediation is one that can accumulate and volatilize large amounts of Se, grow rapidly, produce a large biomass in Se-contaminated soil, tolerate salinity and other toxic environmental conditions, and provide a safe source of forage for Se-deficient livestock (3). Indian mustard (*Brassica juncea*) has most of these preferred characteristics (21). These plants can also be genetically engineered to improve their Se-remediation capacity. Pilon-Smits et al. (22) were able to overexpress the gene encoding ATP sulfurylase in Indian mustard, which resulted in transgenic plants that accumulated two- to three-fold more Se per plant compared to wild-type plants.

GENETIC ENGINEERING TO ADVANCE SELENIUM PHYTOREMEDIATION

Phytoremediation by genetically unaltered plant species is limited by both environmental and biological factors. Hyperaccumulators can accumulate high concentrations of Se in their tissues, but phytoremediation using hyperaccumulators is often very slow due to their slow growth rate and low biomass (23). These limitations can be overcome by conventional plant breeding techniques, but developing accumulators that have suitable characteristics may take decades. Genetic engineering has the potential to produce accumulators with suitable traits for phytoremediation within a short time (4). Genetic engineering could be used to create plants that are more tolerant to contaminants, have greater efficiency in extracting pollutants, or have greater capacity for accumulating and detoxifying pollutants.

Manipulation of the Sulfate Assimilation Pathway

The most popular genetic engineering strategy is to overexpress appropriate genes in suitable plants by inserting extra copies of coding DNA under the control of constitutive or inducible promoter elements. Overexpression of genes involved in rate-limiting steps of Se assimilation and volatilization pathways should enhance such processes in transgenic plants (4), which requires thorough understanding of the mechanisms of Se uptake and metabolism in plants. Plants metabolize Se through the S assimilation pathway, so overexpressing various genes in this pathway is likely to result in increased assimilation and volatilization of Se in transgenic plants. For example, overexpression of sulfate transporter genes could greatly increase plant uptake of Se. Overexpression of ATP sulfurylase gene (coding for ATP sulfurylase protein constituting the rate-limiting step in the S and Se assimilation pathway) or overexpressing the methionine S-methyltransferase gene (coding for the first enzyme in the biochemical pathway resulting in the formation of DMSe, the major volatile form of Se produced by plants) could result in enhanced phytoremediation capacity in transgenic plants. Transformation of Indian mustard with a gene encoding ATP sulfurylase from *Arabidopsis* under the control of a constitutive promoter resulted in higher levels of ATP sulfurylase activity and increased Se accumulation in these plants (22).

Introduction of Genes from Selenium Hyperaccumulators

A second strategy is to introduce additional metabolic pathways into the plant by overexpressing unique genes from Se hyperaccumulator plants. Hyperaccumulators have a unique ability to reduce the toxic effects of Se by depleting the intracellular concentrations of selenocysteine and selenomethionine, which disrupt plant metabolism when incorporated into enzyme proteins. In hyperaccumulators, the levels of selenocysteine and selenomethionine are reduced by the presence of metabolic pathways that lead to the accumulation of Se in nonprotein amino acids (4). Neuhierl and Boeck (24) purified a methyl transferase enzyme from *A. bisulcatus*, which specifically methylated selenocysteine. When the gene encoding the *A.*

bisulcatus methyl transferase was transferred to *E. coli*, the bacteria had increased Se tolerance and reduced incorporation of Se into protein (25).

Introduction of Microbial Genes

Microbes are also likely to provide a new library of genes capable of conferring Se tolerance and phytoremediation capacity on plants. Overexpression of microbial genes has been successfully used in the past to increase heavy metal tolerance in plants (4). Identification and use of these genes to transform plants can enhance the capacity of plants for uptake, detoxification, and volatilization of Se.

Overexpressing Transcription Factors

Overexpression of ATP sulfurylase that catalyzes the rate-limiting step in the Se assimilation pathway results in increased accumulation of Se (22). Many other genes in the S/Se assimilation pathway could be similarly overexpressed, or a similar effect could be achieved by overexpressing a single transcription factor responsible for activating a number of coregulated genes (4). In the Se assimilation pathway, the expression of three genes, ATP sulfurylase, sulfate permease, and APS reductase are regulated similarly (4). It is possible that a common transcription factor can be used to modulate the expression of these genes, resulting in increased Se assimilation in plants.

SUMMARY AND FUTURE DIRECTIONS

The consequences of elevated Se accumulation at the Kesterson Reservoir National Wildlife Refuge in California fueled extensive research on the behavior of Se in soils and plants. Conventional remediation technologies for cleaning up Se-contaminated soils are often prohibitively expensive. On the other hand, Se accumulation and volatilization by plants have been effective in remediating Se-contaminated soil and water (26,27). Selenium volatilization is a particularly attractive option because toxic inorganic Se is converted to a volatile gas DMSe, which is about 600 times less toxic than inorganic Se. Although a number of Se hyperaccumulators are known, their slow growth rate and low biomass make them less than satisfactory for phytoremediation. To enhance the Se remediation potential of plants, understanding the speciation and bioavailability of Se in soils and the biochemistry of Se assimilation and volatilization in plants and microorganisms is of paramount importance.

Recent molecular studies have revealed numerous details of Se physiology and biochemistry in plants. Overexpression of genes encoding transporters and enzymes involved in the uptake, assimilation, and volatilization of sulfate has been highly successful in elucidating the role of these proteins in Se metabolism. Identification of the rate-limiting steps in the Se assimilation pathway will aid in enhancing the phytoremediation capacity of plants by genetic engineering. The role of rhizosphere bacteria in Se volatilization by plants also needs to be further elucidated, because it is well known that plants volatilize relatively low amounts of Se in the absence of bacteria. Primary Se accumulators are a potential source of genetic material that could be used to alter Se metabolism in economically important plants, but secondary accumulators, such as Indian mustard, which are fast growing and have high biomass can also be genetically engineered to improve their phytoremediation capacity.

Disposal of Se-containing vegetation is another problem that needs further study. Se is an essential trace element in humans and animals, so one solution is to use seleniferous plant materials as a forage blend in Se-deficient regions. Plants used for phytoremediation of Se may also be used to generate useful by-products such as fibers for the production of paper and building materials and energy for heat production.

SOIL PIPES AND PIPE FLOW

Joseph Holden
University of Leeds
Leeds, United Kingdom

Natural soil pipes are subsurface cavities of diameter greater than 1 mm that are continuous in length such that they can transmit water, sediment, and solutes through the soil and bypass the soil matrix. Soil pipes are larger versions of soil macropores. Pipes can be up to several meters in diameter, several hundred meters long, and occur in a broad range of environments. They are most common in soils that are subject to cracking in dry periods or are highly dispersible. Soils that have a significant amounts of swelling clays also commonly contain soil pipes (e.g., montmorillonite, illite, and bentonite). Piping is common in arid and semiarid areas where shrinking and desiccation cracking are common. Piping is also common in highly organic soils in humid uplands (e.g., blanket peats). However, soil pipes are found in virtually all climates, in organic and mineral soils, and on disturbed and undisturbed land.

PIPE INITIATION

The wide range of environments in which soil pipes are found reflects the wide range of pipe initiation and development processes (Fig. 1) (1). The initiation of piping is discussed in detail by Jones (2), although there have been relatively few process measurements (3,4). The following factors are considered important in the initiation and development of piping: climate, biota, human activity, pedogeomorphic context, role of soil chemistry (influenced by sodium salts and influenced by systems exhibiting base deficiency), soil texture, erodibility, soil structure and hydraulic conductivity, clay minerals, cracking potential, and dispersivity. The dual need for water supply and desiccation means that pipes are most frequent in semiarid and temperate marine environments (1). Flow through desiccation and biotic and mass movement cracks may enhance the macropores into pipe networks. Jones (5) demonstrates that the vast majority of catchments examined that have piping in Britain, for example, face south, suggesting that desiccation cracking may be very important in the formation of piping there. Gilman and Newson (6) observed that vertical cracks in both the roof and floor of peat pipes were a common feature in mid-Wales during the drought summer of 1976 and suggested that this allowed more water to reach deeper levels and created permanent extensions of the pipe networks when rewetting took place. Faunal activity in many areas, it has been shown, results in active soil pipe formation and affects subsurface movement of water (4,7).

PIPE IDENTIFICATION

Until recently, it has been difficult to find and define soil pipe networks because pipes are often visible only at stream banks or where the pipe roof has collapsed and created a surface opening (Fig. 1b) or formed a gully. Therefore, it is difficult to map the route of a soil pipe or to know its diameter, depth, and length across a hillslope. In some soils, a change in surface vegetation may often indicate the presence of a pipe (8). Jones and Crane (9) extensively mapped 4.4 km of pipes in a drainage area of only 0.23 km^2 by a dye tracing and ground survey. Pipe locations were identified mainly by observation of collapse features, of water jets emerging from pipes, and the sound of flowing water (2). However, these techniques do not give

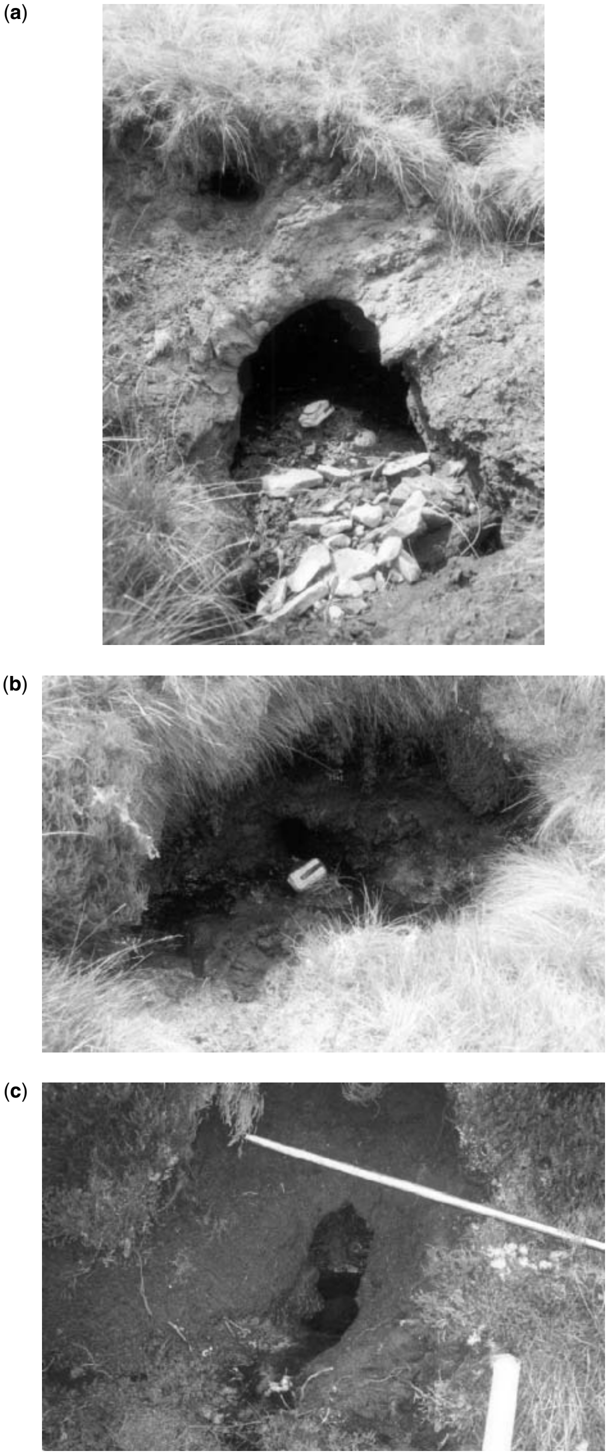

Figure 1. Natural soil pipes. (**a**) large pipe outlet with coarse sediment delivered from its base; (**b**) collapsed surface undermined by pipe erosion; (**c**) typical pipe outlet in blanket peat. Holden, J. and Burt, T.P. (2002) Piping and pipeflow in a deep peat catchment. *Catena* **48**: 163–199.

a detailed or complete picture of the subsurface network and can result in underestimates of pipe density. Often, destructive techniques (e.g., soil trenches) must be used to investigate the pipes (2), and there have been few other attempts to locate and map subsurface piping accurately.

Holden et al. (10) demonstrated that ground penetrating radar (GPR) could be used to sense soil pipes remotely (Fig. 2). The radar transmits short pulses of high-frequency (10–10,000 MHz) electromagnetic energy through the ground surface, which is reflected from boundaries between soil layers or from internal irregularities whose electrical properties are different. Thus, soil pipe cavities can be identified by radar when it crosses over them. GPR work has shown that pipe network densities are much greater than can be detected from surface observation alone. On its own, the radar can detect only subsurface cavities, but when used in conjunction with tracers (e.g., sodium chloride), it can establish the hydrologic connectivity of soil pipes (11), which will be detected by alterations in the reflection of the electromagnetic signal if the electrical conductance of the water in the soil pipe suddenly changes below the radar. Thus, it is possible to determine how pipes are connected to others within a complex subsurface drainage network.

PIPE MORPHOLOGY

The size (mean diameter) of pipes is the most recorded measure of pipe geometry often measured only at outlet locations. However, pipe size can vary significantly just a few meters upslope from the outlet. All areas have a range of pipe sizes, often within the same pipe network. The largest pipes, however, tend to develop in arid and semiarid areas (12). Some evidence suggests that small rounded pipes tend to evolve into larger flat-bedded or rectangularly shaped pipes (2). Fiberscopes have recently been developed to examine internal structures of soil pipes, although these have usually been restricted to short distances from a pipe outlet (13). The average cross-sectional area of pipe outlets per kilometer of stream bank is often taken as a good measure of piping intensity along a stream bank (14), although many reports are of pipes not directly connected to the stream. Pipes can be at any depth within a soil profile, although they are more common at the interface between two distinct soil horizons (especially at organic—mineral interfaces), where there is a sharp transition in hydraulic conductivity or erodibility. In blanket peat, however, pipes have been found that undulate

Figure 2. Ground penetrating radar being used in the field to detect soil pipes. Photo by Vincent Holden.

throughout the soil profile. Pipe floors can run counter to the surface topography such that hydraulic pressures are required to transport the water upward through those sections. An example of a typical vertical section through a soil pipe network is shown in Fig 3. Pipes thus provide rapid connectivity of water, sediment, and solutes throughout the soil profile. Soil pipes are rarely isolated conduits; they often form complex networks that have meandering and anastomosing forms (2,10). Thus, they can extend the stream channel network many hundreds of meters upslope and rapidly transmit water and sediment from great distances away from the stream channel itself.

PIPE HYDROLOGY

Laboratory work (15), modeling (16), and field measurement (17,18) have shown that piping can be a very important hydrologic phenomenon, particularly in humid temperate regions (2,6,14,19). Jones and Crane (9) reported, for example, that 49% of stream flow in the Maesnant catchment, mid-Wales, United Kingdom, was generated through the pipe network. Holden and Burt (10) found that 10% of the discharge in peat catchments moved through the pipe network but at times (depending on antecedent conditions), this could be as high as 30%. Three broad categories of pipe flow can be identified: perennial, ephemeral, and seasonal. There is typically a great variety of hydrologic response between one pipe and another, even within a small area, although some pipe outlets can simply be connections to the same pipe network as others. Jones (20) reports that piping doubles the dynamic source area for rapid runoff response in the upper Maesnant, mainly by linking points well beyond the riparian zones of seepage to the stream.

It is likely that there are several sources of pipe-flow water: overland flow entering collapse features where pipes are open to the surface; water flowing through cracks and root channels to enter the pipe network; diffuse seepage from pipe walls into the pipe system, and groundwater springs forcing water upward from below (Fig. 3). Pipes often receive water more quickly than would be expected from diffuse seepage through soil layers (8,10), and it certainly does not seem that pipe flow in all catchments is restricted by the long time it takes for rainwater to infiltrate down as far as the level of pipes. Nevertheless, Sklash et al. (21), using isotope analysis, showed that pipes in some catchments may transmit predominantly 'old' water (water from previous storms) that is richer in deuterium during storm flow. In an adjacent catchment, however, there was strong chemical evidence that storm flow in the pipes was dominated by fresh storm rainfall. In semiarid zones, pipe flow can occur while the surrounding soil or bedrock remains relatively dry (12).

PIPE EROSION AND WATER QUALITY

Piping, a form of subsurface erosion, has been associated with gully and rill development in many parts of the world. Particular associations were noted in Australia and New Zealand during 1940s soil erosion surveys. Alluvial and loess soils are particularly prone to such pipe–gully coupling. Some pipes are subject to 'episodic cut and fill' in that they can collapse and block the route for water before eventually unblocking and allowing water to flow through them again (17). Thus, pipe discharge can be highly erratic. Pipes can provide the stream system with sediment that is very different from that expected from overland flow because they often connect and erode deeper soil layers (Fig. 3). If piping is very active, then sediment losses from hillslopes can be severe and can cause problems for soil conservation workers. However, very few measurements of pipe-flow sediments have been made around the world. Hauser and Zotl (22) measured 0.5 kg of sand per week from one pipe that had an average discharge of $0.16\,\mathrm{L\,s^{-1}}$ in the Sarmatian mountains of Graz, Austria, and badland pipe sediment loads, it is thought, are an order of magnitude higher than overland flow concentrations (2). Because it is subsurface, pipe erosion can occur, even when the hillslope is densely vegetated (23).

The role of piping in major mass movement is as yet uncertain. There have been some instances where pipes have been identified as the cause of subsidence or landslides, others where pipes are thought to have developed after the mass movement, and still further cases

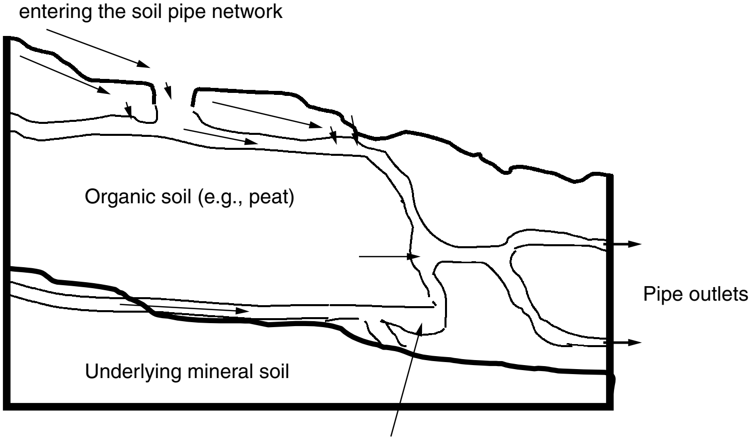

Figure 3. Schematic of a short vertical section through a soil pipe network.

where pipes it is thought, have prevented mass movement. In many circumstances, water flow is too great to be freely transmitted along these subsurface tunnels, and a pressure head builds back up the pipe. If a heavy rainstorm occurs, it is possible that restrictions in the dimensions of the pipes that act as bottlenecks will impede flow. Hence, water builds back up the pipe, and large pressures may build up within the slope. At the same time, pipes might provide a drainage path for water, prevent the buildup of gravitational forces on the slope, and thus prevent mass movements in some areas.

In some catchments, measurements of pipe flow chemistry have failed to determine any significant difference from that of overland flow, suggesting that the sources of the water were the same (24). Piping may therefore exacerbate problems of acid runoff by reducing soil buffering effects as a result of more rapid transmission, reduced soil residence times, and reduced contact between weathering mineral surfaces. Drainage and aeration of large sections of hillslope can also encourage release of sulfates and organic acids, particularly from peaty soils, which increases the acidity of the runoff. Therefore, many pipes tend to issue more acidic water during storms and contribute to acid flushes in streams that can increase acid rain impacts on fish and microfauna.

LOW FLOW GROUNDWATER PURGING AND SURGING

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Groundwater monitor wells are installed primarily as tools to measure the dissolved concentrations of contaminants in groundwater in and around facilities where the release of contaminants has occurred or where the potential exists for such a release to occur (i.e., adjacent to landfills). These wells are installed with the intention of obtaining an accurate assessment of the conditions in the formation adjacent to the well. A significant body of literature and guidance documentation exists concerning the location, drilling, installation, and development of those wells to that end. However, it has become evident that the quality of the data yielded from monitor wells is dependent on screen length and location (addressed during design and installation), purging method, and purge volume. The question becomes how does one collect samples from groundwater monitoring wells that generate representative results?

The regulatory community and those involved in the design and operation of remediation systems are seeking an accurate answer to that question. However, interest is also generated from the economic pressures to reduce the cost of sampling and monitoring procedures. Standard groundwater sampling procedures involve purging three to five well volumes with a pump or a bailer, which entails expense in the form of time (often for two technicians) and disposal of the purge water. These two issues have driven recent research by the scientific community, as well as the regulatory community, which is also beginning to act by introducing new protocols for the acceptable sampling of wells.

The use of screened hydraulic probes is recognized as an accurate sampling method and as the yardstick for comparison with various monitor well sampling techniques. Their practical use is of value for initial plume delineation and assessment in aid of the design of a monitor well network; however, they are impractical as a long-term monitoring system. The groundwater monitor well is essential for that role.

For conventional purge techniques, wherein three to four well casing volumes of water were removed during purging, it was determined that water in a monitor well was “static” and in time grew “stagnant.” The purging of the well casing volumes was to remove the old and “stagnant” water, which allowed for representative aquifer water to enter the well bore for sampling.

Concerns were twofold: (1) the assumption that the mechanisms at work within the well bore that would attenuate the contaminant concentrations such as vaporization and/or biodegradation supported by oxygen diffusion; and (2) the assumption that with time, formation conditions will improve, contaminant concentrations will decrease, and samples will demonstrate that trend.

Recent studies have shown that conventional purging procedures can activate two phenomena that to give false results: vertical mass averaging within the well bore and the introduction of water lower in the formation through vertical (upward) flow paths. Vertical heterogeneity of contaminant concentrations within the well bore occurs when zones of striking hydraulic conductivity contrast are present. Contaminants preferentially flow through the more permeable units intersected by the well screen. Gross purging then simply mixes the entire well bore. Low flow discrete level sampling has been devised to address this specific phenomena. The induction of vertical uncontaminated groundwater flow from beneath a partially penetrating well is a problem in formations at the opposite end of the hydrodynamic spectrum, which are coarsely granular (sand and gravel) and relatively homogenous.

Field testing shows that low flow purging at specific vertical points within the well bore yields results that are similar to sampling via the conventional purging methods. Bailing is likely to produce the lowest concentrations, and low flow pumping slightly higher, but both tend to produce results that are significantly lower than actual concentrations within the adjacent formation. In general, it appears that the more vigorously a well is purged, the more likely it is that the samples will underrepresent contaminant concentrations within the adjacent formation. A detailed description of low flow (minimal drawdown) groundwater sampling is described by the U.S. Environmental Protection Agency.

Physical and chemical processes can potentially impact a monitor well in a static or stagnant state. The processes that could effect the concentration of dissolved components or the degree of mixing of heterogenetic water within a well bore column include:

- The groundwater flow rate through the surrounding formation and its influence via advective flow within the well
- The vertical profile of the contaminant concentration and hydraulic conductivity contrast within the adjacent formation
- Vaporization and volatilization across the air water interface at the top of the well
- Diffusion of oxygen through the air–water interface into the well bore stimulating biodegradation Diurnal and seasonal temperature fluctuations
- Diffusional transport vertically within the well bore as well as horizontally from the adjacent formation
- Barometric pumping, which under some conditions can cause water level fluctuations (and mechanical mixing) in wells located in unconfined aquifers
- Seismic activity
- Tidal forces
- Local heavy auto, truck, or train traffic

In aggregate, these forces impact all monitor wells to various degrees depending on the geologic and geographic site conditions. In some instances, “static” conditions are dynamic enough to ensure that water in a monitor well is representative of the adjacent formation.

Consequently, some regulatory bodies have begun to consider the use of non-purge or low-purge (the EPA) methods of sampling. In California, the Cal/EPA allows non-purge sampling in cases where:

- The monitor well is screened in an unconfined (water table) aquifer
- The screened interval extends above the top of the water table

- The monitor wells are located in moderate-to-high recovery aquifers consisting of sands or gravels

Purging is still required when:

- The well is new and has been sampled less than two times (this also assumes the well underwent an adequate development purge at installation)
- Chlorinated hydrocarbons, PNAs, diesel, or metals are the contaminant
- Slow recovering wells within fine-grained sediments (clays and silts) are used
- Monitor wells associated with sparging or soil vapor extraction activity are used

LOW FLOW TECHNIQUES

Low flow refers to the velocity with which water enters the pump intake and is imparted to the groundwater in the immediate area of the well screen. Low flow does not necessarily refer to the flow rate of groundwater discharged on the surface, which can be affected by flow regulators or restrictions. Flow rates from 0.1 to 0.5 L/min are used; however, on more porous formations, up to 1.0 L/min have been used (1).

Advantages of low-flow sampling (1) include:

- Groundwater samples are representative of the mobile load of contaminants present.
- Minimal disturbance occurs, which minimizes sampling artifacts.
- Less operator variability and greater operator control are provided.
- Reduced stress occurs on the aquifer when minimal drawdown sampling is performed.
- Reduced need exists for filtration and, consequently, less time sampling occurs.
- Smaller purging volume decreases waste disposal costs and sampling time.
- Better sample consistency exists.

Some of the disadvantages include higher initial capital costs, greater setup time in the field, additional training time, resistance to change by regulators or consultants, and the concern that the new data will trigger regulatory action based on new, more accurate concentration data (1). In some settings, low flow purging and sampling is appropriate simply because of the physical setting: low permeability formations where recharge rates are less than 0.1 L/min and fractured rock formations where representative samples may come from selectively oriented fracture networks.

The desire by the regulatory and regulated community to obtain accurate results, the realization of the problems associated with sampling, and the costs associated with conventional approaches are likely to drive the development and implementation of new standard protocols for the sampling of monitor wells. It also presents an opportunity for the development and application of new technology and approaches.

GROUNDWATER QUALITY

John E. Moore
USGS (Retired)
Denver, Colorado

The value of groundwater lies in its widespread occurrence and availability and also its consistent good quality. Groundwater, on the whole, is cleaner than most surface water and maintains a nearly uniform temperature.

As groundwater moves through the subsurface, physical, chemical, and biological processes interact to change its original quality. The earth materials through which groundwater moves act as natural filters to screen out some bacteria and some impurities from the water. Groundwater is usually clear and colorless and of excellent sanitary quality, making it drinkable directly as withdrawn, which does not mean, however, that groundwater is completely free of impurities. In fact, all groundwater contains some dissolved minerals.

Water is a universal solvent (1). From the time rain falls to the ground and begins to run off or pass into and through the soil and rocks, it dissolves these materials and thus picks up various mineral constituents. These dissolved minerals are rarely harmful to health and may give the water a pleasant taste.

The dissolved minerals include sodium, calcium, magnesium, and potassium, which combine with bicarbonates, sulfates, and chlorides. The character of the earth materials mainly determines the composition of groundwater. The longer the period contact of water with rocks, the more minerals are dissolved.

The most common groundwater quality problems are caused by natural hydrogen sulfide (2). A high content of dissolved mineral salts may affect the taste of drinking water and have laxative effects.

Hardness is caused by a high concentration of calcium and magnesium. It can cause scale formation in kettles, pipe systems, boilers, and tanks. The most common negative effect of hardness is its tendency to prevent soap from lathering and to form soap scum. Water hardness can be alleviated at a fairly reasonable cost by installing a water softener. It is not desirable, however, to remove all the minerals that make water hard. Water that is too soft is likely to corrode water distribution systems and tanks as well as to produce a flat, unpalatable taste and render the water less beneficial to the health of most people.

Excessive iron is another common natural problem. Iron concentrations in excess of 0.3 mg/L (milligrams per liter) do not normally cause health problems but are of concern for aesthetic and taste reasons. Water that has a high concentration of iron has a metallic taste and causes reddish stains on fixtures, cookware, and laundry.

Cascading or spraying the water into the air so that it is exposed to oxygen can reduce an excessive iron content. High levels of manganese cause problems similar to those caused by excessive iron. The stains caused by manganese are black and are harder to remove than iron stains.

Iron bacteria in groundwater do not damage health but are a nuisance because they clog the pores in the aquifer near wells and well screens, thereby reducing well yields. Bacteria also produce red-to-brown slime in toilet tanks and plumbing. Iron bacteria can be killed by pouring a small amount of disinfecting solution such as chlorine bleach into the water.

Hydrogen sulfide gas is recognizable by its “rotten egg” smell and taste (3). It is a poisonous gas that can build up in a small, enclosed area such as a well pump house. A person who works in a poorly ventilated space may become nauseated or even lose consciousness. Water containing hydrogen sulfide is corrosive to plumbing systems, a condition that can be reduced by aeration or by chlorination and filtration.

Water quality is commonly characterized as “safe” or “good.” “Safe” water typically means that the water is free from bacteria and disease-causing organisms, as well as from minerals and substances that can have adverse health effects. The term “good quality” water is a relative term whose meaning depends on the intended use of the water. Sanitary quality can be assessed by periodically analyzing water samples for coliform bacteria and nitrate. These substances do not normally occur in groundwater and their presence may indicate contamination.

Coliform bacteria are useful indicators of harmful microorganisms. According to the drinking-water standards of the United States, safe drinking water should not contain more than one coliform bacterium per 100 mL (6 cu in.) of water. If coliform bacteria occur in well water in numbers that indicate the water is unsafe, the water should be disinfected either by chlorinating or by boiling before drinking until further sample analyses indicate that the water is safe to drink. Sources of bacteria are septic tanks and leach fields and surface water contaminating the well.

High nitrate levels may indicate organic contamination from nearby sources of nitrate, such as barnyard drainage, animal waste storage, and percolation from agricultural land, fertilizers, and septic tanks (4). The U.S. national limit for nitrate-nitrogen concentration is 10 mg/L, which is equivalent to 45 mg/L of nitrate (2). The European standard is 11.4 mg/L nitrate-nitrogen (50 mL/L as nitrate. The main reason for this limit is the risk to (young) infants (blue babies) from drinking high nitrate waters.

Well water can be analyzed by either a country or state public health environmental laboratory or by a qualified private laboratory. Municipal authorities (local health departments) have sources on where water may be analyzed. Routine tests for coliform bacteria or inorganic contaminants, such as nitrate and salts, are relatively inexpensive. However, analyses for inorganic and organic industrial chemicals and pesticides can be very expensive. Those concerned about possible contaminants in their water supplies can contact their local health departments. Specialists from these departments can help determine if a cause for concern exists before extensive and potentially expensive water testing is performed. Keeping accurate records of the water tests ensures proper documentation of the water-quality history of a particular well. Even without obvious signs of contamination, it is advisable to have well water analyzed at least once a year.

If water contamination persists even after several tests, an alternative drinking-water supply should be used or a new source obtained. Leading causes of bacterial and nitrate contamination are poor well construction and poor well location. In most cases, nitrate contamination is limited to the shallow part of the water-bearing formation. When the contaminant is a volatile organic compound (VOC), it may cause problems, by drinking and also by inhalation and absorption through the skin.

RADIAL WELLS

Dennis E. Williams
Geoscience Support Services
Claremont, California

Radial wells have a radial or horizontal component that comprises the well screen. Types of radial wells include collector wells, horizontal directionally drilled (HDD) wells, and slant or horizontal wells. The most common type of radial wells are collector wells, which have the basic design of a vertical shaft (or caisson) with horizontal screen laterals to collect groundwater. The vertical shaft typically extends to depths from 9 to 46 m (30 to 150 ft) and has a 5-m inside diameter. The laterals are typically tens to hundreds of meters in length and have a diameter of 305 mm (12 in.). The number of laterals designed for the well is dependent on aquifer characteristics (such as hydraulic conductivity) and water demand. Advances in radial well design have allowed for up to 500 m of horizontal well screen (total of all laterals) to be developed in formations where vertical wells can accommodate only 20 m of well screen. Radial wells take advantage of natural filtration through the aquifer materials, which reduces chemical treatment costs.

The lateral well screens are usually installed near the bottom of shallow aquifers in order to exploit the maximum saturated thickness of the aquifer. The laterals are installed by jacking the well screens through precast ports in the vertical shaft at one or more elevations (Fig. 1).

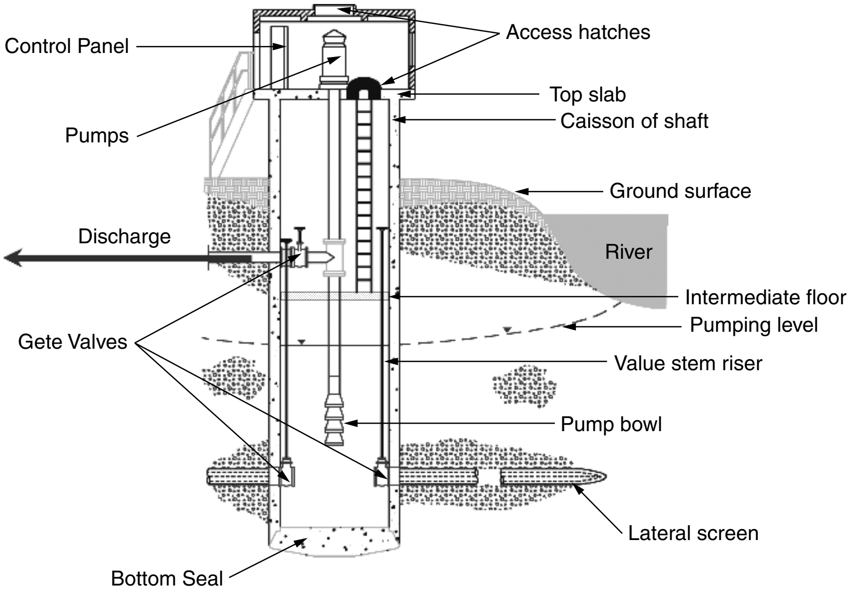

Figure 1. Lateral well schematic (after Bennett & Williams, Inc.).

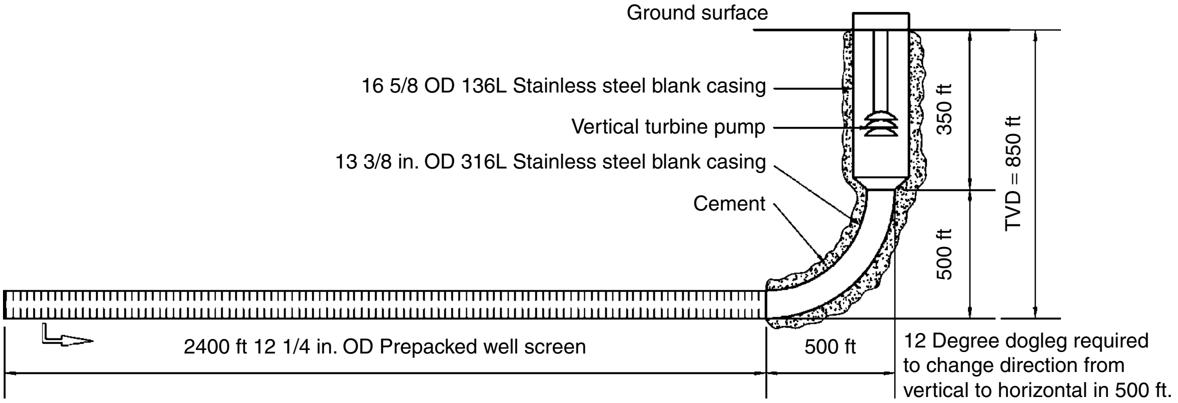

Figure 2. Horizontal directionally drilled (HDD) well.

Radial wells are reported to require less maintenance than conventional vertical wells, as the longer horizontal screens reduce water velocity entering the screen slots, thereby maximizing well efficiency and reducing well head losses and clogging. Existing radials wells can be rehabilitated with the installation of new laterals.

Radial wells are used in applications such as municipal production wells, dewatering operations, and inducing surface water infiltration for groundwater recharge.

An emerging technology in the groundwater supply industry is the use of horizontal directionally drilled (HDD) wells (Fig. 2). HDD technology is widely used in the oil and gas industry; however, HDD technology has not yet been completely transferred to the groundwater supply industry for routine or wide-scale applications. HDD wells utilize a "mud motor" technology along with sophisticated downhole navigation systems to "guide" the drill first vertically and then horizontally (or a combination of both). The application of HDD technology is in its infancy in the water well industry; however, there is potential for specialized applications such as desalination plant intake systems, or specialized recharge or enhancement of a shallow aquifer's saturated thickness. HDD wells may be constructed to extend to over 1000 m.

RECHARGE IN ARID REGIONS

Leo S. Leonhart
Hargis Associates, Inc.
Tucson, Arizona

Groundwater recharge in arid regions or deserts is a process that requires a favorable combination of hydrologic factors. Accordingly, recharge, in arid regions occurs more rarely and supplies annual quantities of water to the groundwater table lower than typical of more humid regions. Many of the processes by which recharge occurs, such as surface infiltration, stream channel loss, and seepage from impounded water bodies, however, are common to both regions.

DEFINITION OF ARID REGIONS

By definition, the aridity of a region is determined by the ratio of mean annual precipitation to mean annual potential evapotranspiration (PET). As shown in Fig. 1, arid regions in both the Northern and Southern Hemispheres are situated mostly between 10° and 35° latitude worldwide. Regions that have average annual precipitation (*P*) totaling less than 250 mm (10 in) make up an estimated 25% of the worldwide land areas outside of the polar regions (1). Arid regions are sometimes further classified as hyperarid, arid, or semiarid, according to the ranges in the *P*/PET ratio (Table 1).

VARIABILITY OF PRECIPITATION AND RECHARGE

For several reasons, estimates of mean annual precipitation are difficult to relate directly to recharge in arid regions. Largely, this difficulty develops from characteristically high temporal and spatial variability in both the distribution of precipitation and recharge in arid regions. Longer term recharge to precipitation ratios (*R*/*P*) for various arid regions in the United States generally are typically less than 5% (3–5).

Table 1. Arid Region Subclassifications

Arid Region Subclassifications	*P*/PET Ratio
Hyperarid	< 0.03
Arid	0.03 to < 0.20
Semiarid	0.20 to < 0.50

[a]After Reference 2.

High temporal variability of precipitation exists across seasonal and multiyear time frames. Average annual precipitation depths for arid regions result from large variances between extreme high and low annual totals. For example, average annual precipitation falling on the town of Arica, located in the Atacama Desert region of Chile, during a 17-year period was only 0.5 mm (0.02 in). Interestingly, this average resulted from just three measurable showers in a 17-year period (6). Such variability in precipitation infers even greater temporal variability in recharge in arid regions.

Similarly, the spatial variability of precipitation in arid regions can be high. If convective, as opposed to frontal, storms characteristically supply a significant percentage of the annual precipitation within an arid region, the areal distributions of rainfall from individual storms can be highly variable. Adjacent gauging stations can indicate significant differences in the total precipitation recorded during any given storm or during an entire year, and in the next year, a completely different pattern could be observed. Recharge, a process that requires a sufficient precipitation threshold to overcome evapotranspiration losses and soil moisture deficits in the soil, can be significantly affected by such spatial variability in precipitation.

Recharge in arid regions might be further limited due to areal variations in hydrogeologic and topographic factors. In arid regions where topographic relief is high, recharge often occurs along mountain fronts, where precipitation is greater and where there may be sustained runoff from snowpack. Other studies have shown that, in some

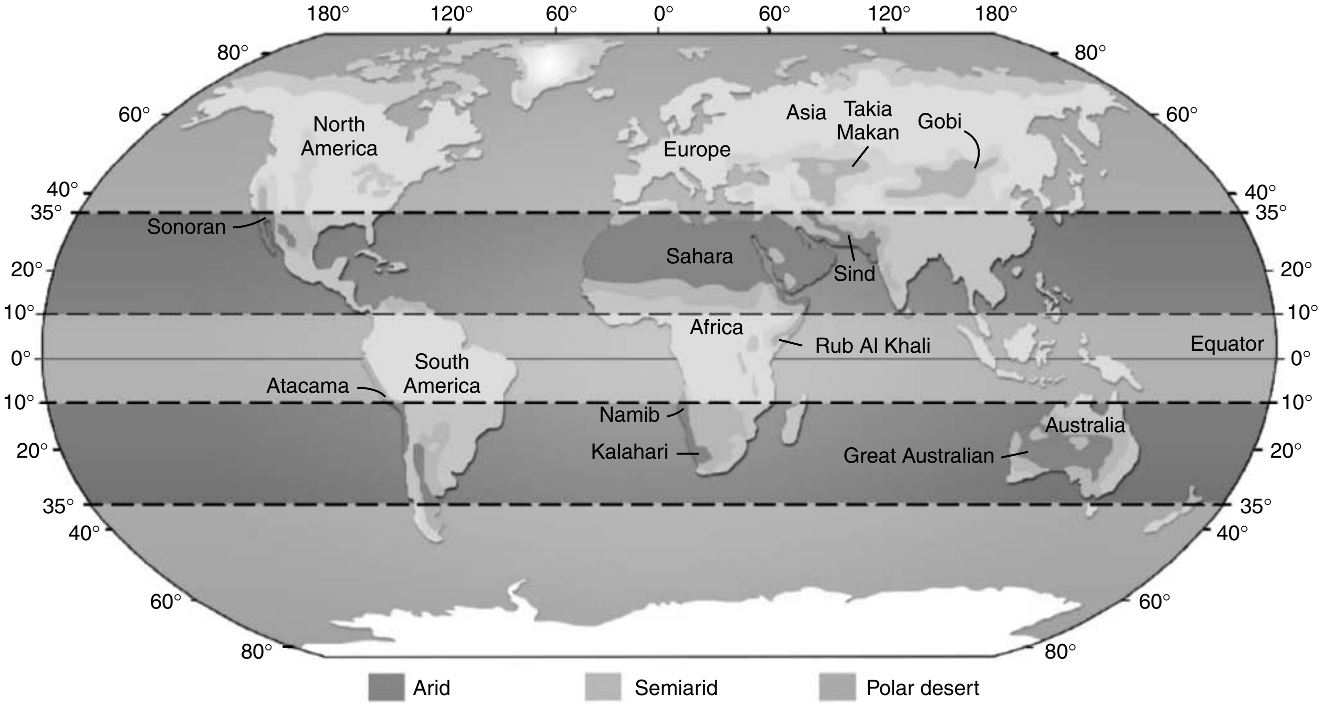

Figure 1. Worldwide pattern of arid regions (copyrighted Fig. 13–15 in Reference 1). Figure preparation/revision by Hargis and Associates, Inc., San Diego, CA.

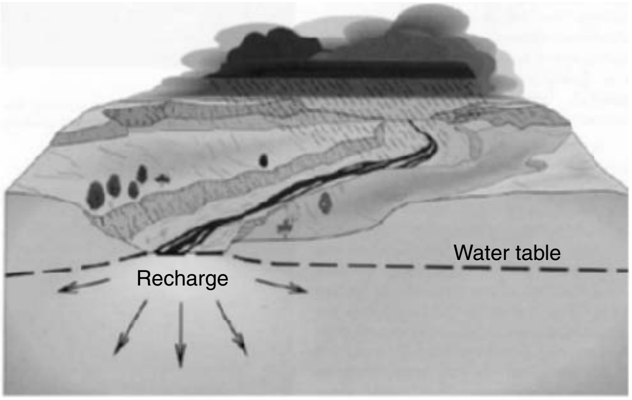
mountainous areas, “mountain block recharge” occurs as a result of diffused infiltration through thin or absent soils overlying fractured bedrock (7). Recharge can also occur along incised alluvial channels during ephemeral or intermittent runoff. In certain low-lying areas or depressions, precipitation or runoff waters might be detained, thereby providing localized recharge through sediments or fractures. In highland areas, exposures of fractured bedrock can facilitate infiltration during precipitation or runoff, creating perched groundwater zones or deeper infiltration to the regional water table. Thus, the overlay of spatial and temporal variability of precipitation onto the areal variability of recharge areas further increases recharge variability temporally and spatially.

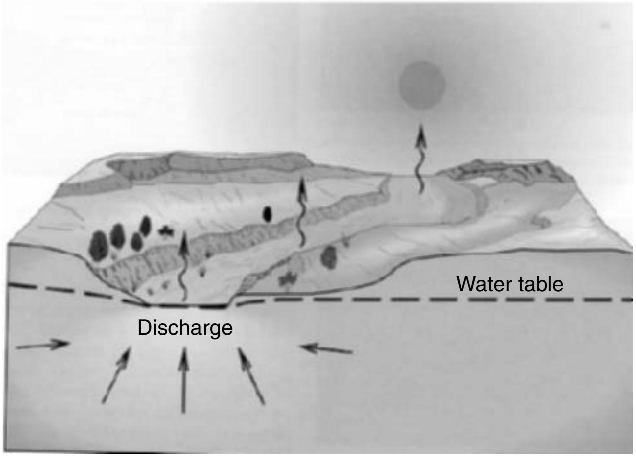
CONDITIONS FAVORING RECHARGE

For recharge to occur in any region, certain initial conditions must be satisfied. First, there must be sufficient surface water to infiltrate into the soil. Such conditions may result from sufficient precipitation (in terms of depth, intensity, and/or duration), runoff, or water impoundment. Second, the moisture storage potential of underlying soils must be satisfied. In other words, the void spaces in the soil matrix must become saturated. Once these conditions are met, recharge to the groundwater table becomes possible through deep percolation of soil water. Subsurface soil or bedrock conditions, however, such as fractures or heterogeneities, can sometimes locally short-circuit these overall requirements, thereby providing more direct “conduits” to the water table.

Recharge from runoff in ephemeral streams in the southwestern United States is depicted in Fig. 2. During wet seasons, sustained runoff in the alluvial channel may result in infiltration, provided there is sufficient vertical permeability in the underlying sediments. This infiltration locally recharges the groundwater table along the course of the ephemeral stream (wash or arroyo). A typical wet season recharge event is depicted in Fig. 3. During dry seasons, phreatophytes rely on the availability of shallow soil water and groundwater in the vicinity of the ephemeral stream channel, discharging groundwater by evapotranspiration. Another fraction is lost to direct surface evaporation from soils.



Recharge through channel bottom in wet season



Discharge via evapotranspiration in dry season

Figure 2. Recharge from runoff in ephemeral streams.

PRECIPITATION VERSUS EVAPOTRANSPIRATION

Theoretically, soil moisture is recharged during periods when precipitation exceeds potential evapotranspiration ($P >$ PET). As discussed earlier, such conditions are rare in arid regions, which is further illustrated in the monthly average relationship between precipitation and pan evaporation (E), shown in Fig. 4. This comparison shows a site in Tucson, Arizona, elevation ~730 m (~2400 ft) above mean sea level (msl), and at Sierra Ancha, Arizona, elevation ~1555 m (5100 ft) msl. Using the average annual value of evaporation for each site as an estimate for the average annual potential evapotranspiration, the P/E ratios for Tucson and Sierra Ancha during the timeframe from 1963 through 1966 were approximately 0.15 and 0.37, respectively. The arid region subclassifications of these sites, according to Table 1 and based on the limited records evaluated, would be arid and semiarid, respectively.

From these plots, it can be seen that the recharge potential in arid regions can vary significantly with seasonal conditions. The effect of elevation differences on the P/E ratios is also evident. Both stations indicate a bimodal (double-peaked) distribution of precipitation during the year, indicating higher precipitation typically in the winter and summer months. On average, a greater amount of precipitation falls during the summer months, but the lower rate of evaporation better favors recharge potential during winter months, which is evident from the closer convergence of the P and E curves on the Tucson plot and the crossover of the two curves on the Sierra Ancha plot.

During the period of record (1963–1966), the monthly average values show that there was always a soil moisture deficit at the Tucson station, whereas a soil moisture recharge potential was present during the winter months at Sierra Ancha. These patterns help to

During runoff event

Two days later

Figure 3. Wet season recharge in Cañada del Oro Wash near Tucson, Arizona.

understand the conditions favoring recharge, but it should be understood that longer term variability might overlay these patterns. Long-term variability results from extreme conditions of drought and precipitation, earlier said to affect the calculation of average values of precipitation and evapotranspiration in arid regions. The example in Fig. 4 is based on averages calculated over a 4-year period. The averages of total annual precipitation for Tucson and Sierra Ancha during these 4 years were 340 mm (13.37 in) and 692 mm (27.25 in), respectively. Longer term records for these stations indicate lower averages of 283 mm (11.13 in) and 676 mm (26.60 in), respectively (8).

RECHARGE ESTIMATION

Recharge is a component of the hydrologic budget often calculated from a water budget equation, whereas other variables, such as precipitation, evaporation, runoff, and use quantities, usually represent field-measured parameters. Another method of estimation involves calibration of groundwater flow models against field measurements of groundwater levels. Generally, these models simulate the water budget dynamics of the study area.

Research is being performed to improve methods for quantifying recharge in arid regions. Methods under investigation include interpreting stable and radioactive isotopic signatures. The most common methods employ ratios between stable isotopes of oxygen (^{18}O/^{16}O) and hydrogen (^{2}H/^{1}H) or simply the graphical relationship between ^{2}H and ^{18}O to estimate the “isotopic age” of the water, and therefore the time since it was recharged (9). Other common methods are based on the decay constants of various radioisotopes such as tritium (^{3}H), carbon (^{14}C), and chlorine (^{36}Cl) (9,10). Recent research has examined silicon (^{32}Si) to estimate long-term recharge rates based on the “loss” of the isotope by adsorption during infiltration (11).

Other methods under current investigation for estimating recharge in arid areas include microgravity networks, temperature profiling, geochemical profiling, and various remote-sensing techniques. Microgravity networking employs finely gridded gravity instrumentation to assess seasonal and long-term changes in the mass of groundwater in storage under a basin (12). Temporal changes in the gravity profile measured across the network infer changes in the volume of groundwater stored in the underlying aquifer and hence, recharge and discharge.

Temperature profiling is based on the difference in the temperature of recharging waters versus ambient soil and groundwater. Research is focusing on both natural and artificial recharge from infiltration through stream channels as well as more diffuse recharge mechanisms. To accomplish this, multilevel temperature probes are emplaced at successive depths within soil borings drilled in known or suspected recharge areas.

Geochemical methods also require depth profiling in the soil column beneath suspected recharge areas. The concept relies on interpreting changes in soil chemistry from water movement during infiltration. Such changes result from either deposition or dissolution of minerals along the infiltration pathway. For example, using a combination of field-measured chloride data and numerical simulations, researchers have estimated long-term recharge cycles in the Badain Jaran Desert in China as far back as 1000 years (13).

Remote sensing techniques involve interpretation of tones, colors, and spectral hues observable in bare soils as well as due to vegetation densities and spectral variations. Such differences can be interpreted from photographic or scanned imagery and infer regions where shallow subsurface water is present. Infrared techniques employ either thermal- or near-infrared spectra. Thermal techniques detect temperature differences in soil moisture variations, whereas near-infrared relies on vegetation inferences.

SUB-SURFACE REDOX CHEMISTRY: A COMPARISON OF EQUILIBRIUM AND REACTION-BASED APPROACHES

Naresh Singhal
University of Auckland
Auckland, New Zealand

Jahangir Islam
City Design Limited
Auckland, New Zealand

INTRODUCTION

The study of subsurface redox chemistry has gained importance because of increased awareness of the relationships between chemical speciation and contaminant behavior in the environment. The oxidation state of a redox component can affect its solubility, sorption to soil, and toxicity. Knowledge of redox processes is therefore fundamental to understanding the fate and transport of organic and inorganic constituents in both pristine and contaminated environments.

Redox reactions involve oxidation, and accompanying reduction, of the reacting species because of transfer of electrons. Such reactions, directly or indirectly, determine the fate and transport of several biologically important elements such as carbon, nitrogen, and sulfur in the soil environment. Elements of environmental significance undergoing redox reactions include heavy metals like lead and zinc, which are multivalent and readily undergo a change in valence.

Redox reactions in natural environments can be biotic or abiotic. Most redox processes encountered in natural aquatic systems are biologically catalyzed or at least indirectly affected by living microorganisms. In subsurface systems, such as groundwater aquifers with microbial activity, the redox state is significantly influenced by microbe-mediated redox reactions. In such environments, a sequence of distinct redox zones can develop depending on the composition of aquifer materials and aqueous constituents and the relative rates of redox reactions and the transport of products or reactants.

Frequently, redox reactions in subsurface environments are evaluated with equilibrium thermodynamics. Although equilibrium thermodynamics is useful for visualizing the potential relationships between the oxidized and reduced phases of various elements, in many cases, redox equilibrium is not established because of the presence of living organisms, dependence of redox transformations on biological catalysis, and the slow kinetics of oxidation and reduction reactions (1). Time spans for attainment of equilibrium for dissolution/precipitation of secondary phases and redox reactions may range from a few hours to years. Many groundwaters are not well posed, and speciation calculations for numerous groundwaters have shown that various redox couples typically exist in a state of disequilibrium. When disequilibrium exists, geochemical model based on equilibrium thermodynamics will provide incorrect speciation results for the redox species. Reliable predictions of solid-phase dissolution/precipitation and redox reactions require knowledge of reaction kinetics. This article presents a comparison of equilibrium and reaction-based kinetic approaches for evaluating subsurface redox chemistry.

MODELING APPROACHES

The two approaches that compute the distribution of chemical species in the subsurface are the kinetic and equilibrium models. Both approaches use the concept of components and species to model systems with multiple chemical reactants. Components are a set of linearly independent chemical entities such that every species can be written as the product of a reaction involving only the components, and no component can be written in terms of components other than itself. For a given system, the set of components is not unique, but once it has been defined, the representation of species in terms of this set of components is unique. The number of components is selected such that it is the minimum number of the set of species necessary to describe the composition of all phases and species in the chemical system.

Equilibrium models focus on the final equilibrium state of a solution composed of several components in a closed system (2). Implicit in this approach is the assumption that the modeled reactions are fast and fully reversible, which results in natural systems with areas where thermodynamic equilibrium has been established, at least locally. Both of the above conditions are frequently violated, as many redox reactions are slow and irreversible. For example, consider the oxidation of organic matter, which is usually an irreversible reaction, and the diagenesis of sedimentary rock, which occurs over decades. The equilibrium composition of soil systems is generally calculated using two methods—the equilibrium constant method (3) and the free energy minimization technique (4). The equilibrium constant method uses the mass action principle to relate the redox species involved in specific reactions. The equilibrium composition is obtained by solving the mass action relations used along with the mass balance equations for different components. The free energy minimization technique involves combining the chemical potential of each species with the mass balance equation for each component. The equilibrium composition is obtained by minimizing the free energy of the system (5). Of these two methods, the equilibrium composition approach has been more commonly adopted in the models developed to date.

Kinetic formulations, typically used in reactive transport modeling, describe the transformation of redox species using rate expressions for reactions affecting specific redox species. These reactions may include sorption to soil, degradation, dissolution/precipitation, complexation, and volatilization to gaseous phase. Additionally, these reactions may be biotic, thereby requiring an additional consideration of biological growth and accompany organic matter degradation. The kinetic models can be grouped, on the basis of the logic coupling the transport and reaction equations, into two categories: two-step and one-step methods. The two-step methods involve solving the transport equations followed by the chemical reaction equations at each time step, whereas the one-step methods involve incorporating the chemical reaction equation into the transport equation and solving the resulting set of nonlinear equations explicitly or implicitly. The use of the kinetic approach to model redox reactions in groundwater systems is a relatively recent development, and much work is continuing in this area.

Equilibrium Models

The equilibrium models describe multispecies reactive chemical transport based on principles of thermodynamics, and they can describe complexation, sorption to soils, and removal via precipitation in batch and flow through systems at equilibrium. The approaches used by different investigators to model redox processes in groundwater systems can be grouped into four categories (2): effective internal approach, external approach, oxygen fugacity approach, and redox couple approach. The first three approaches assume that the system has achieved thermodynamic equilibrium, whereas the last approach handles redox processes under partial equilibrium conditions.

The effective internal approach (6,7) is based on the principle of conservation of electrons, although free electrons do not exist in the aqueous phase (2). Therefore, a redox reaction involving the loss of an electron through oxidation must be accompanied by a simultaneous reaction involving the gaining of electron through reduction. The sum of the valence states of each species in the system remains constant as chemical redox reactions progress. For redox-sensitive species, their redox states equal their valences.

The external approach (8), unlike the internal approach, considers hypothetical electron activity as an aqueous component. For computational purposes, the redox reactions are considered mathematically equivalent to complexation reactions in which the hypothetical electrons are incorporated as a component (2). Reduction half-reactions involve higher valence species reacting with the hypothetical electrons to form lower valence species. For each set of redox species, the ionic species in the highest oxidation state is chosen as master component and all other oxidation states are formed from it.

The oxygen fugacity approach uses oxygen fugacity as a redox parameter in the system (9). The mass balance equation of oxygen provides an additional equation to solve the system of chemical speciation equations involving redox reactions. The use of oxygen fugacity as a redox potential indicator can be illustrated using the following half-cell reaction for water:

$$2\mathrm{H_2O(l)} = \mathrm{O_2(g)} + 4\mathrm{H}^+ + 4e^- \tag{1}$$

Then the redox potential (Eh) and the oxygen fugacity ($\mathrm{f_{O_2}}$), using the equilibrium constant $\mathrm{K_{O_2(g)/H_2O(l)}}$ for the half-reaction, can be related by (10)

$$\log(\mathrm{f_{O_2}}) = \left(\frac{4\mathrm{F}}{2.303\mathrm{RT}}\right)\mathrm{Eh} - 4\log\{\mathrm{H}^+\} + 2\log\{\mathrm{H_2O(l)}\} + \log \mathrm{K_{O_2(g)/H_2O(l)}} \tag{2}$$

where the terms within {} represent the activities of the enclosed species.

The fourth concept, called the redox couple approach (6,9), assumes that partial equilibrium conditions prevail in the system. This approach separates each redox couple into two master species that give rise to two mass balance equations. After the complete calculation of chemical speciation, the redox potential is determined from the activities of this couple and its equilibrium constant (2). Redox couples may be preferred for modeling the redox processes if the analytical data for the couples are available. As the subsurface system may have more than one redox couple, the redox couple approach can test whether these redox couples are at equilibrium with each other. The applicability and validity of redox sequence concept can also be tested. If the aqueous solution exists at a single redox potential, the redox sequence concept requires that all redox reactions in the aqueous solution be at thermodynamic equilibrium. Using the concept of redox zones, the dominant redox couple, which controls the redox potential in a given redox zone, can determine the redox potential of the system. The use of redox zones for classifying the subsurface environment is an important concept in the numerical simulation of subsurface redox chemistry.

Kinetic Models

If the reactions are insufficiently fast, because of chemical kinetics or mass diffusion limitations, relative to the macroscopic transport processes affecting solute concentration (e.g., advection, hydrodynamic dispersion), the assumption of thermodynamic equilibrium, or even local equilibrium, may not apply. In subsurface environments, with the exception of aqueous redox reactions, it is usually valid to model most homogeneous aqueous-phase reactions (including complexation and acid-base reactions) using equilibrium thermodynamics as they are characterized by rapid rates, especially in comparison with subsurface flow. However, increasing evidence suggests that heterogeneous reaction processes (such as adsorption, biodegradation, and precipitation/dissolution) may need to be described by a kinetic model. In a kinetic model for flow-through systems, algorithms have been proposed that integrate the flow processes (advection and dispersion) with the transformation processes. A flow chart that illustrates a typical algorithm adopted for this purpose is presented in Fig. 1.

Various kinetic formulations have been proposed for adsorption, biodegradation, and precipitation of species present in soils. Some common kinetic equations used in the literature for these processes are discussed below.

Adsorption. The kinetic formulations for adsorption to soils include those based on mass transfer, first-order reaction, and nth-order reaction (11).

$$\text{Mass transfer}: \quad \frac{\partial C_s}{\partial t} = \alpha(f(C_w) - C_s) \qquad (3)$$

$$\text{First-order reaction}: \quad \frac{\partial C_s}{\partial t} = k_1 \frac{\theta}{\rho_b} C_w - k_2 C_s \qquad (4)$$

$$\text{nth-order reaction}: \quad \frac{\partial C_s}{\partial t} = k_1 \frac{\theta}{\rho_b} C_w^n - k_2 C_s \qquad (5)$$

where α is a mass transfer coefficient, θ is the soil porosity, ρ_b is the soil bulk density, $f(C_w)$ is some function of the concentration of dissolved chemical, C_w [M/L^3], k_i ($i = 1,2$) are reaction rate constants, and C_s is the mass of chemical sorbed onto the surface of intraparticle pores of the grains per unit mass of the grains (dimensionless).

Biodegradation. The primary microbial redox reactions typically observed in subsurface systems are given in Table 1. The most energetically favorable of these

Table 1. Primary Microbe Mediated Redox Reactions in Subsurface Environments

Redox Reactions	ΔG^o (kcal/mol) (pH = 7)
Aerobic respiration, oxygen reduction $CH_2O + O_2 \rightarrow CO_2 + H_2O$	−120
Denitrification $5CH_2O + 4NO_3^- + 4H^+ \rightarrow 5CO_2 + 7H_2O + 2N_2$	−114
Manganese (manganic) reduction $CH_2O + 2MnO_2 + 4H^+ \rightarrow CO_2 + 2Mn^{2+} + 3H_2O$	−81
Iron (ferric) reduction $CH_2O + 4Fe(OH)_3 + 8H^+ \rightarrow CO_2 + 4Fe^{2+} + 11H_2O$	−28
Sulfate reduction $2CH_2O + SO_4^{2-} + H^+ \rightarrow 2CO_2 + HS^- + 2H_2O$	−25
Methanogenic processes $CH_3COOH \rightarrow CH_4 + CO_2$	−22

Table 2. Kinetic Formulations for Ion Precipitation

Model	Rate Equation	Source
Davies and Jones Model	$R = sk\gamma^2\left(\{\mathrm{Ca}^{+2}\}^{1/2}\{\mathrm{CO}_3^{-2}\}^{1/2} - \frac{K_{\mathrm{sp}}^{1/2}}{\gamma}\right)^2$ k = rate constant, s = surface area of the crystal, K_{sp} = solubility product of $\mathrm{CaCO_3}$, and γ = divalent ion activity coefficient calculated using the Davies equation.	Inskeep and Bloom (13)
Empirical Model	$R_{\mathrm{P}} = sk_{\mathrm{p}}(\Omega - 1)^{\mathrm{n}}$ $R_{\mathrm{D}} = sk_{\mathrm{D}}(\Omega - 1)^{\mathrm{n}}$ Ω = disequilibrium ratio = $\{\mathrm{Ca}^{+2}\}\{\mathrm{CO}_3^{-2}\}/K_{\mathrm{sp}}$ k_{d} and k_{p} = rate constants for dissolution and precipitation, respectively, and n = reaction order.	Inskeep and Bloom (13)
House Model	$R = k((\{\mathrm{Ca}^{+2}\}\{\mathrm{CO}_3^{-2}\})^{1/2} - K_{\mathrm{sp}}^{1/2})^2$	Van Langerak et al. (15)
Nancollas and Reddy Mechanistic Model	$R = sk\gamma^2\left(\{\mathrm{Ca}^{+2}\}\{\mathrm{CO}_3^{-2}\} - \frac{K_{\mathrm{sp}}}{\gamma^2}\right)$	Inskeep and Bloom (13)
Zhang and Dawe Model	$R = k\left(\left(\frac{\left\{\mathrm{Ca}^{+2}\right\}\left\{\mathrm{CO}_3^{-2}\right\}}{K_{\mathrm{sp}}}\right)^{0.5} - 1\right)^{\mathrm{n}}$	Zhang and Dawe (16)

reactions is aerobic respiration, followed by, in order of decreasing free energy yield, denitrification, Mn(IV) reduction, Fe(III) reduction, sulfate reduction, and methanogenesis. The differences in energy yields of these reactions may lead to physical separation (spatial or temporal) of the zones in which each reaction dominates. The rates of reduction of the terminal electron acceptor and the corresponding oxidation of organic substrate are usually represented by zero-order, first-order, and multiple Monod-type expressions. Application of Monod rate expression is justified when the organic compound of interest acts as a primary energy substrate for the microbial community. Assuming an absence of diffusional resistance biodegradation of the substrate and microbial growth in soils can be represented by the following system of equations using the multiple Monod kinetics (12):

$$\frac{\partial S}{\partial t} = -\frac{\mu_{\max}}{Y}\frac{S}{K_{\mathrm{s}}+S}\frac{C_{\mathrm{w,ea}}}{K_{\mathrm{ea}}+C_{\mathrm{w,ea}}}\left(X_{\mathrm{a}} + \frac{\rho_{\mathrm{b}}X_{\mathrm{s}}}{\theta}\right) \tag{6}$$

$$\frac{\partial X_{\mathrm{w}}}{\partial t} = \mu_{\max}\frac{S}{K_{\mathrm{s}}+S}\frac{C_{\mathrm{w,ea}}}{K_{\mathrm{ea}}+C_{\mathrm{w,ea}}}X_{\mathrm{w}} - K_{\mathrm{dec}}X_{\mathrm{w}} - K_{\mathrm{att}}X_{\mathrm{w}} + \frac{\rho_{\mathrm{b}}K_{\mathrm{det}}X_{\mathrm{s}}}{\theta} \tag{7}$$

$$\frac{\partial X_{\mathrm{s}}}{\partial t} = \mu_{\max}\frac{S}{K_{\mathrm{s}}+S}\frac{C_{\mathrm{w,ea}}}{K_{\mathrm{ea}}+C_{\mathrm{w,ea}}}X_{\mathrm{s}} - K_{\mathrm{dec}}X_{\mathrm{s}} - K_{\mathrm{det}}X_{\mathrm{s}} + \frac{\theta K_{\mathrm{att}}X_{\mathrm{a}}}{\rho_{\mathrm{b}}} \tag{8}$$

where S is the substrate concentration in the bulk (mobile) fluid ($\mathrm{M/L^3}$), X_{w} is the aqueous-phase biomass concentration ($\mathrm{M/L^3}$), X_{s} is the solid-attached biomass concentration (M/M), $C_{\mathrm{w,ea}}$ is the concentration of terminal electron acceptor ($\mathrm{M/L^3}$), K_{dec} is the first-order endogenous decay coefficient (1/T), K_{att} is the biomass attachment coefficient (1/T), K_{det} is the biomass detachment coefficient ($1/T$), $\mu_{\max}$ is the maximum specific growth rate of the biomass ($1/T$), Y is the yield coefficient for the biomass (cell mass produced per mass of substrate consumed), and K_{s} and K_{ea} are the saturation constant for substrate and electron acceptor ($\mathrm{M/L^3}$), defined as the concentration for which the specific growth rate is equal to $\mu_{\max}/2$.

Precipitation and Dissolution. Precipitation and dissolution processes have often been described by chemical reactions whose rate is proportional to the deviation from equilibrium (13,14). One such kinetic formulation can be written as follows:

$$\frac{dC_{\mathrm{j}}}{dt} = -a_{\mathrm{j}}k\left(\prod_{\mathrm{j}=1}^{\mathrm{N}}\{u_{\mathrm{j}}\}^{a_{\mathrm{j}}} - K_{\mathrm{sp}}\right) \tag{9}$$

where k is the precipitation rate coefficient, N is the number of components forming the solid precipitate, C_{j} is the dissolved concentration of component j, $\{u_{\mathrm{j}}\}$ is the dissolved free ion activity of component j, a_{j} is the stoichiometric coefficient of the jth component of the solid, and K_{sp} is the equilibrium solubility product for the solid. Several similar formulations for ion precipitation, using $\mathrm{CaCO_3}$ as the precipitating mineral, are presented in Table 2.

MODEL LIMITATIONS AND APPLICABILITY

Geochemical models suffer from inadequacies in two main areas (17):

1. Violation of (local) equilibrium assumption in many environmental systems. Although such processes can be modeled using kinetics, rather than equilibrium, our current knowledge of kinetic rates and mechanisms is primitive.
2. The knowledge of adsorption of solutes on mineral surfaces, an important environmental process, is also at an early stage of understanding.

The "geochemical (and hydrological) models of natural and engineered systems at the present time are, at best, approximations to the real situation. To meet various regulatory requirements, these approximations, and predictions based on these approximations, must be made, and there is no better way to proceed than to construct models based on fundamental science. To this extent, geochemical and hydrological modeling is useful" (17).

REGIONAL FLOW SYSTEMS

Matthew M. Uliana
Texas State University—San Marcos
San Marcos, Texas

DEFINITION

A **groundwater flow system** is a three-dimensional entity that has the following components:

—a recharge area where water enters the flow system
—a discharge area where water exits the system
—boundary conditions and physical dimensions

When dealing with flow systems, we often differentiate between **local, intermediate,** and **regional** flow systems. The distinction is primarily a matter of scale; local flow systems cover a much smaller area than intermediate systems, which in turn are smaller than regional systems. **Regional groundwater flow systems** generally involve a large area (10^1–10^2 km), and usually contain several local flow systems, resulting in areas of local recharge as well as springs or other discharge features within the larger system. Often several different aquifers and geologic formations will be connected by a larger regional groundwater system.

Examples of regional flow systems are shown in Fig. 1.

The following is a discussion of each of the three components.

RECHARGE

Recharge refers to the water that is entering a groundwater system. Areas where recharge is occurring are called **recharge areas** or **recharge zones**. There are several different ways that recharge enters a flow system. Recharge can enter a flow system through direct infiltration of precipitation on the outcrop, or by infiltration through the beds of losing streams or reservoirs. In some parts of the world, especially arid regions, infiltration of storm runoff through the beds of intermittent streams is the dominant form of recharge. Water can also enter a flow system through interformational flow, which is usually in the form of flow through leaky confining layers where water is drawn in by drawdowns at wells, or where

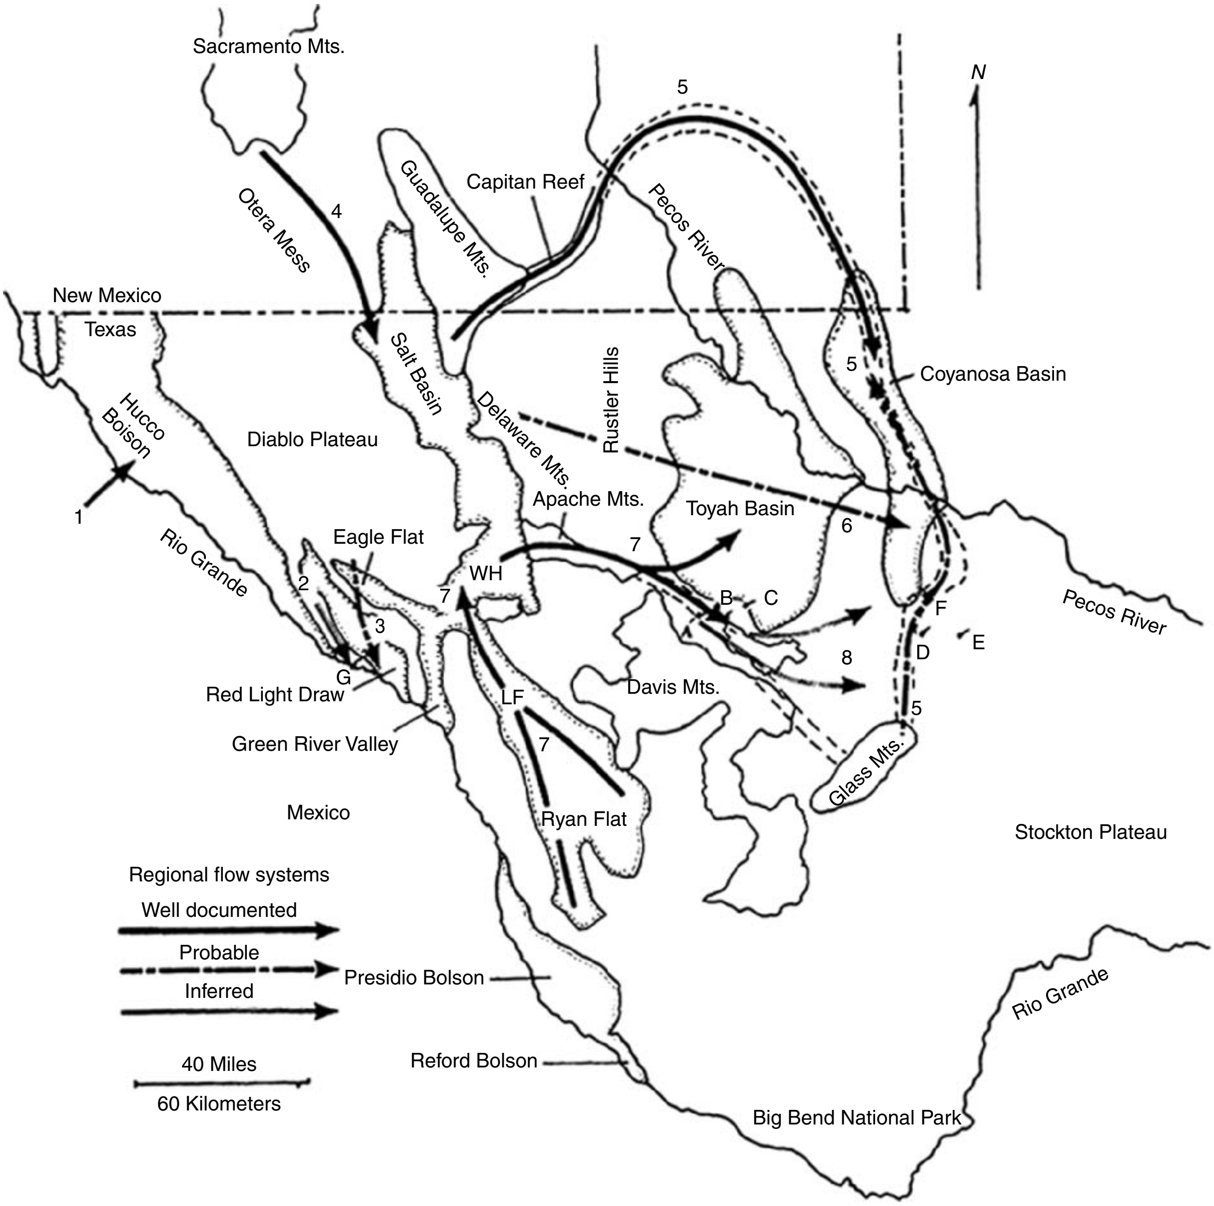

Figure 1. Regional groundwater flow systems of West Texas (after Reference 1).

underlying aquifers have significant overpressuring and are forcing water upwards.

For modeling and other research purposes, recharge is generally considered as some percentage of precipitation. Annual recharge rates in most aquifers are usually between 1–10% of annual precipitation rates. Recharge rates are difficult to quantify; many methods involve measuring precipitation and performing a water balance by quantifying all the other fluxes of water (i.e., surface runoff, evaporation, transpiration) at the surface.

DISCHARGE

There are several ways that water discharges from a flow system. These include discrete discharge to a spring or seep, discharge into a gaining stream or lake, interformational flow, or pumping from a well. In some arid regions, direct evaporation from a shallow water table is the primary mechanism for discharge from the flow system.

Discharge can also be hard to quantify, especially in areas dominated by well pumping or evaporation. Interformational flow is generally small compared to the other mechanisms. Springs and gaining streams can be gauged, and changes in flow across a certain area can be attributed to either recharge or discharge.

BOUNDARY CONDITIONS

Flow systems are three-dimensional bodies that have boundaries. We can consider two basic types of boundaries, or **boundary conditions**, that can characterize the limits of flow systems.

A **no-flow boundary** has a hydraulic gradient of zero ($h/x = 0$), and therefore no flow across the boundary. No-flow boundaries can be actual physical boundaries, such as where permeable aquifer units are in contact with low permeability bedrock at a fault (Fig. 2). A no-flow boundary also exists where flow lines are parallel, creating a **symmetry boundary** (Fig. 3). Modelers often use symmetry boundaries to constrain numerical groundwater models of aquifers. Locally high water levels can create a type of no-flow boundary called a **groundwater divide** (Fig. 4). At a groundwater divide, water flows away from the divide on either side (similar to surface runoff at a drainage divide).

A **constant-head boundary** is one characterized by a set of hydraulic heads that do not change. A nonflowing body of water, such as a lake, pond, or ocean, can create a constant-head boundary (Fig. 5). In this case, the shore of the body of water represents a single **equipotential line** (or line of constant head) in the aquifer, and flow is perpendicular to the shoreline (either into the aquifer from the surface waterbody, or vice versa). A stream can also act as a constant-head boundary (Fig. 6). In a stream boundary, the actual heads will vary along the stream gradient, but each point is considered constant. In this case, each point along the stream gradient represents a point on an equipotential.

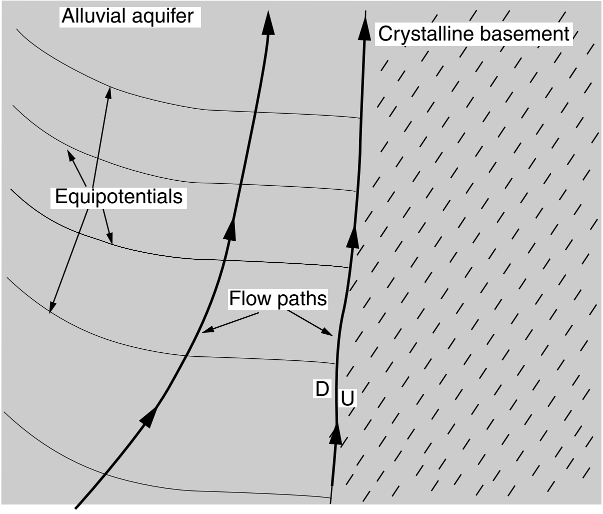

Figure 2. No-flow boundary created by juxtaposition of permeable alluvial sediments and low-permeability crystalline bedrock.

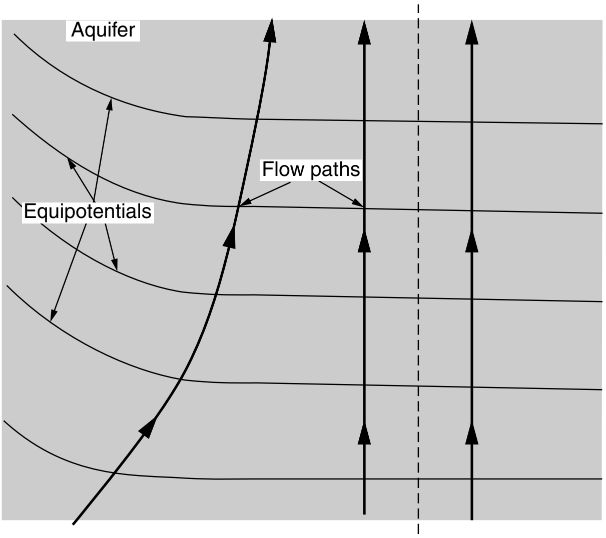

Figure 3. Parallel flow lines create a no-flow symmetry boundary.

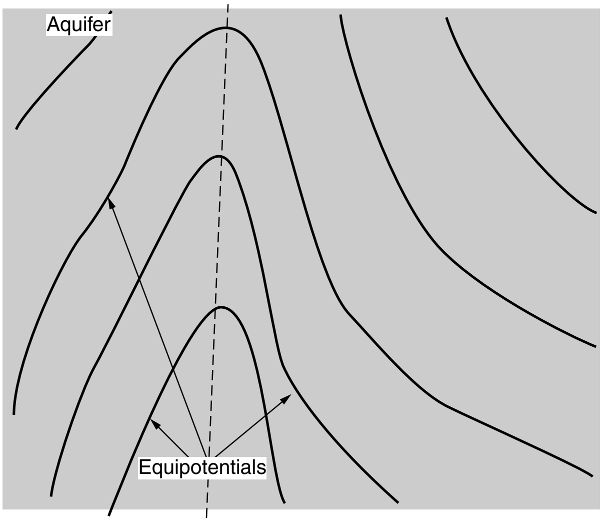

Figure 4. Groundwater divide produced by high water levels.

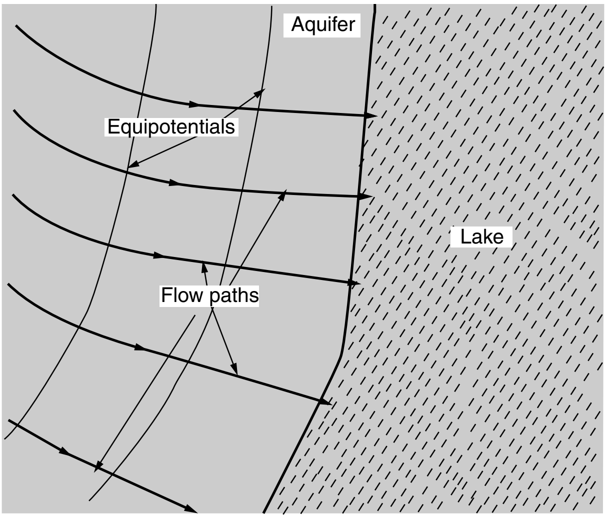

Figure 5. Constant-head boundary at a nonflowing body of water (in this case, a lake).

CHARACTERISTICS OF REGIONAL FLOW SYSTEMS

Water Chemistry

Groundwater in regional flow systems can have residence times ranging from a few decades to 10^4 years. Long residence times usually results in high concentrations of dissolved ions, and regional flow systems frequently

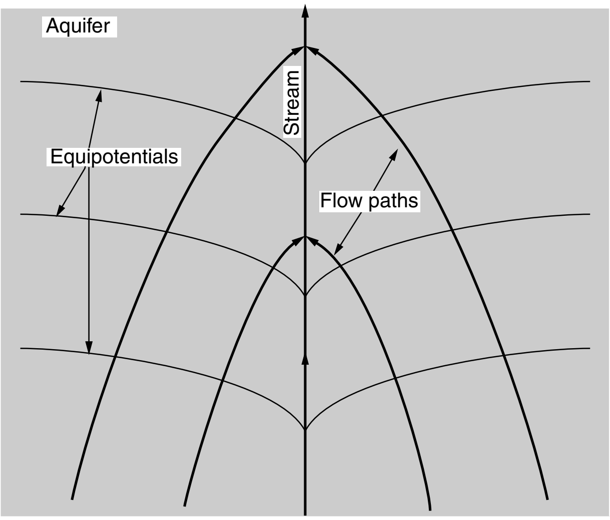

Figure 6. A stream constant-head boundary.

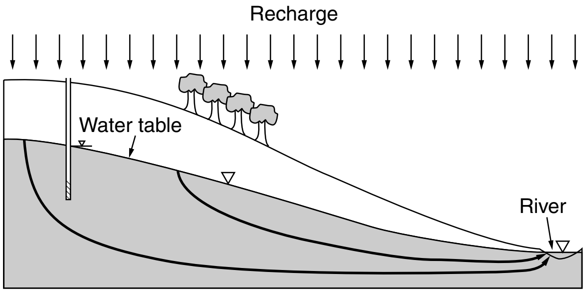

Figure 7. Cross section of water table aquifer showing the relationship between topography and the orientation of the water table.

have total dissolved solids (TDS) concentrations greater than 2000 ppm. The exact distribution of dissolved ions in the water is controlled by the minerals encountered in the subsurface; however, groundwater generally tends to evolve along flow paths toward higher concentrations of sodium and chloride, (2), and groundwater in regional flow systems tends to be dominated by NaCl type waters. Water samples are usually close to saturation with respect to common carbonate (e.g., calcite, dolomite) and sulfate (e.g., gypsum, barite) minerals. Water temperatures are generally higher than average annual air temperatures due to geothermal heating; the difference in temperature is directly related to residence time.

Spring Discharge

Springs in regional flow systems tend to exhibit relatively constant discharge, chemistry, turbidity, and temperature. These springs frequently have both local and regional flow components. These springs respond to local storms with increases in discharge and turbidity and decreases in TDS and temperature but also have a fairly constant baseflow discharge sourced from the regional systems (3). Ecosystems in springs sourced by regional flow systems often have restricted endemic organisms in or near their outlets, and these spring ecosystems often support listed endangered species.

Relationship Between Topography and Flow Systems

King (4) and Hubbert (5) noted the relationship between topography and groundwater flow patterns in unconfined aquifers. Both noticed that the water table tends to be a subdued replica of the topography (Fig. 7), and Hubbert (5) suggested that topography can control flow patterns so that high elevations are recharge areas and low elevations are discharge areas (Fig. 8).

Toth (6) and Freeze and Witherspoon (7) developed computer models that simulated the effects of topography on flow systems. Both of their models supported the conclusions of King and Hubbert. These models also indicated that sinusoidal topography can result in the formation of smaller local flow systems with local recharge and discharge areas within larger regional systems.

GROUNDWATER REMEDIATION BY INJECTION AND PROBLEM PREVENTION

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

A variety of interesting problems can occur in the subsurface as the result of efforts to remediate groundwater. With few exceptions, groundwater remediation requires either an *in situ* injection of reactive chemicals or groundwater recovery, treatment, and disposal. The reinjection of treated water or the placement of chemicals in the subsurface used to treat contaminants can cause unintended subsurface geochemical conditions that may create new contamination issues or impact *in situ* transport properties.

Storm drains, sanitary sewers, and surface streams have been and will continue to be receptors for treated water. However, permit requirements and volume based user fees often contribute significantly to the cost of groundwater remediation systems.

In rural settings, storm or sanitary drains may not be available, and increasingly in urban settings publicly owned treatment works (POTWs) are reluctant (or unable) to accept recovered groundwater. In urban settings, water quality is not the issue; rather, it is stress on the hydraulic capacity of the POTW system. In these instances, the most viable option for water discharge is reinjection.

REINJECTION ISSUES

Treated water may meet the standards for reinjection based on the chemicals analyzed. It is becoming more apparent, however, that there could be contaminants in treated water that are not analyzed. Methyl tertiary butyl ether (MTBE) is a fuel oxygenate used in gasoline. In some pump and treat systems, the MTBE is removed and the MTBE is below the laboratory reporting level. If tertiarty butyl ether (TBA), a breakdown product of MTBE, is not analyzed, it could be present in the treated water and discharged to a stream, storm drain, or into a reinjection well, spreading an otherwise unanalyzed contaminant into the environment. Overlapping plumes of gasoline and undetected perchlorate could also create a new problem if the pumped water is treated for gasoline and then discharged to the storm drain or into the subsurface, with the undetected perchlorate. Lastly, another example is 1,4-dioxane, an extremely soluble hydrocarbon similar in transport properties to MTBE that was used as a stabilizer in percent concentrations for some chlorinated solvents.

Reinjection can be less expensive (at least to set up) than permit fees and flow based discharge fees. As such, it is sometimes implemented even when other options are available. Lastly, an injection regime may be part of a program to obtain hydraulic control of a site.

The most common source of problems for groundwater recharge systems is plugging. Any recharge system will eventually foul, and the design of the system should provide for that eventuality. The goal is to minimize the rate at which the fouling occurs. The purpose here is to examine some of the pitfalls that can occur when the recharge option is selected. Without exception, it is much easier to prevent damage from occurring than it is to remedy a damaged condition.

SUSPENDED SOLIDS

Suspended solids are a major cause of plugging. In most instances, solids will collect within the first 0.5 in. of a well pack. At a flow rate of 10 GPM and total suspended solids (TSS) at 5 mg/L, approximately 0.66 lb of solids will be introduced per day. In a year, this would total 240 lb, or about 2 ft^3 of solids, which would be capable of fouling about 100 ft^2 of injection face (30 linear feet of a 1-ft diameter well). Generally, infiltrated water must have a TSS level <2 mg/L in order to maintain adequate infiltration rates over a long period.

AIR

Entrained air can impact recharge capacity through simple physical blockage or through what is termed the “Jamin effect.” The Jamin effect results when capillary forces act on small advective channels that contain alternating air bubbles and water. These channels are then capable of responding to finite pressure gradients without allowing fluid flow, meaning that surging an impacted well will not displace the entrained air. Once in a formation, air can be extremely difficult to remove.

The problem is particularly exacerbated by allowing injected water to fall into a well (rather than piping below the groundwater surface), thus mixing with air that can be transported into the adjacent formation. Saturated zone *in situ* bioremediation systems using injected air or hydrogen peroxide can also be susceptible to air entrainment problems.

Injection of water that is cooler than the receiving aquifer will cause degassing as the two waters mix. The solubility limit of oxygen in pure water at 40 °F is 13.1 mg/L; at 50 °F it is 11.3 mg/L. Over a 24-h period, at a flow rate of 10 GPM, approximately 0.20 lb of oxygen would degas upon contact with the formation water, which represents about 2.5 ft^3 of gas entrained in the pore spaces directly adjacent to the injection zone (as depth increases the gas volume would decrease). Assuming a 1-ft diameter well, and that entrainment of air through a 1-ft section of the formation would decrease injection efficiency through the Jamin effect, a well with a 30-ft screened interval would have flow inhibited within 10 d.

MICROBIAL FOULING

To prevent microbial growth, care must be taken to ensure there is no source of carbon or nutrients (nitrogen and phosphorus) in the injected water. The carbon content of water should be evaluated through a total organic carbon (TOC) analysis, not just contaminants of concern (such as BTEX). Bacteria will exploit any carbon resource, not just those under regulatory discharge limits. TOC must be <10 mg/L to ensure that reasonable infiltration rates can be maintained over cost effective durations.

In instances where the groundwater is iron or sulfate rich, iron or sulfate reducing bacteria may also create problems.

CHEMICAL INCOMPATIBILITY

Chemical reactions between the injected and formation water are common. Typical reactions result in the formation of precipitants in the mixing zone. These reactions are complex and temperature sensitive. Differences in redox potential (usually due to dissolved oxygen levels) and carbonate chemistry are most often responsible for problems.

When injecting into clay-rich soils, ionic reactions can also come into effect. Clay particles can be dispersed (to cause plugging deeper in the formation) or swell when exposed to recharge water with ionic character different from the formation water. These reactions can be induced through exposure to water of different ionic concentration or through exposure to water with different types of cations present at any concentration (e.g., water discharged from a caustic or lime precipitation system).

Iron precipitation can be a serious problem in groundwater systems that are high in soluble ferrous iron. Iron present in recovered water may precipitate forming TSS that must be removed before reinjection. However, iron precipitation is also possible in the mix zone if the redox conditions of the recharge water are significantly different from the formation water.

OVERDEVELOPMENT

Lastly, injection efficiency has been observed to be reduced by as much as 50% from compaction of the gravel/sand pack around a well through overzealous surging during well development, pumping tests, or redevelopment performed to alleviate some of the problems described above, which is a common problem. In this instance, more is *not* better; well development should be judiciously applied based on the composition of the pack around the casing.

Impact from all of the above can be minimized in an injection system during the design stage of a project. It requires a thorough evaluation of the chemistry of the discharge that includes determination of ionic character, redox condition, chemical composition, and temperature. The same must be done for the formation water. Potential reactions and problems should be evaluated by a competent geochemist. It may be determined that a different method of water treatment would be more cost effective (i.e., eliminating air stripping to prevent precipitation reactions driven by elevated dissolved oxygen).

EH/PH CHANGES

A variety of *in situ* injection processes change Eh/pH conditions. Chemical oxidants such as ozone (O_3) and hydrogen peroxide (H_2O_2) release oxygen as part of the reaction. Enhanced bioremediation using oxygen (O_2) diffusion, air sparging, or magnesium peroxide (MgO_2) also are designed to take an anaerobic reducing environment and convert it into an aerobic environment. For example, a petroleum hydrocarbon being treated using ozone in the anaerobic core of a plume would change Eh/pH conditions in the treatment area.

These changes have the effect of changing the valence states of certain metals, such as chromium. If high concentrations of chromium are present naturally or from a release, and there are manganese containing minerals present in the mineral matrix, the formerly reduced chromium compound can be oxidized and converted from chromium (3+) [Cr(III)] to chromium (6+) [Cr(VI)], a toxic and mobile form of chromium. Normally, the oxidized chromium would move with the groundwater downgradient to naturally reducing conditions, which should restore the original Eh/pH. However, when a water supply well or vulnerable surface water is located close to the *in situ* treatment area, there may not be enough of a distance and retention time for the reconversion of Cr(VI) back to Cr(III). One option is to create an Eh/pH restoration treatment wall immediately downgradient from the initial treatment zone. The Eh/pH restoration wall should be constructed to place the liquids (molasses, corn syrup), gases (propane), or solids (nanoscale iron particles) into the aquifer through trenches, wells, ports, or other delivery means that could be supplied on a constant basis to restore the Eh/pH of the environment. After all the petroleum hydrocarbon treatment is performed in the center of the hydrocarbon plume treatment area, the Eh/pH restoration wall could be shut down after the last of the remaining oxidized water has passed the Eh/pH restoration wall. Changing Eh/pH requires redox reaction kinetics that may favor certain reactions. For example, it is much easier to convert Cr(VI) to Cr(III) than the reverse.

An oxidizing Eh/pH treatment wall would be required if originally oxidizing conditions were present and reducing chemicals (carbon sources) were used for anaerobic treatments of chlorinated solvents such as perchloroethene (PCE) or trichloroethene (TCE), for example. In this case the reduced conditions might convert the more stable and less toxic arsenic (5+) to the toxic arsenic (3+) that is soluble under normal pH conditions. A further exacerbation of potential arsenic problems occurs under reducing conditions when some portion of the ferric iron in the mineral matrix is converted to ferrous iron. The ferrous iron is soluble and the process will release any arsenic that had previously adsorbed to the iron oxides, which act as a major redardation sink for arsenic in groundwater systems. An oxidizing Eh/pH treatment wall in an area of high arsenic would supply oxygen to restore arsenic to As(V) and oxidize ferrous iron to the arsenic removing ferric oxide species, lowering the potential of creating a new subsurface problem.

Proper bench testing, chemical evaluations, and rigorous planning to prevent future treatment problems is less costly and time consuming than encountering the mistakes after developing a poorly designed project.

GROUNDWATER REMEDIATION: *IN SITU* PASSIVE METHODS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Passive *in situ* remediation technologies (PIRT) use a variety of physical, chemical, or biological processes that act without significant human intervention in the subsurface to reduce the mass, toxicity, mobility, volume, or concentration of contaminants in soil or groundwater. Passive remediation uses the natural movement of water to disperse treatment chemicals or to move contaminated groundwater through a treatment zone.

In many early EPA Superfund site remediations, slurry walls were used. Slurry cutoff walls are a simple passive treatment method to isolate contaminants or prevent migration. Frequently, a pump and treat system is used with a slurry cutoff wall to to maintain groundwater pressure on the wall and to prevent groundwater from rising above and around the wall. Slurry walls are generally constructed of bentonite, polyethylene, or sheet piling. Project depths rarely exceed 15 meters.

PERMEABLE REACTIVE BARRIERS

Early examples of passive remediation are permeable reactive barriers (PRB) (Fig. 1). Within these passive treatment zones are included funnel and gate treatment technologies. The funnel and gate system is a hybrid of both low permeability barriers and a permeable treatment system. Originally proposed by the University of Waterloo, it is most widely used with zero-valent iron to degrade chlorinated volatile organic compounds (VOCs) such as trichloroethylene (TCE) and daughter products. These types of treatment systems are generally less than 15 meters deep.

Deeper treatment methods using drilling rigs and directional high-pressure fracturing technologies developed for depths exceeding 100 meters to inject treatment chemicals have been pioneered by GeoSierra. These deeper PRBs are generally used with zero-valent iron as the treatment material, which is injected under high pressure to form a fracture wall between closely spaced deep boreholes. The passive treatment wall is designed to be perpendicular to groundwater flow.

BIOREMEDIATION

Phytoremediation, another passive method, uses specific plants and trees to extract specific contaminants from soil and groundwater. Some of the targeted contaminants include heavy metals and radionuclides. Common plants used in phytoremediation include mustard plants as well as poplar trees. Phytoremediation has great promise and will increase in acceptance as more case studies are completed. An overview article documents some of the potential of phytoremediation (2).

For passive and semipassive methods of remediation, aerobic and anaerobic bioremediation offer options for a variety of contaminants. For low permeability sediments (clay and silts), the molecules of the dissolved gases (oxygen, propane, and others) and the microbes are much smaller than the pore throat sizes of the sediments, which allows enhanced bioremediation to be considered in geologic settings where other more active technologies such as dual-phase extraction would not be feasible.

Aerobic *in situ* enhanced bioremediation is a cost-effective way to treat residual contamination in groundwater from surface spills or leaking underground tanks of hydrocarbon fuels such as gasoline, diesel, kerosene, motor oil, jet fuels, and used oil. Hydrocarbon degrading microbes will break hydrocarbons down to carbon dioxide and water if the right amounts of oxygen and nutrients are available.

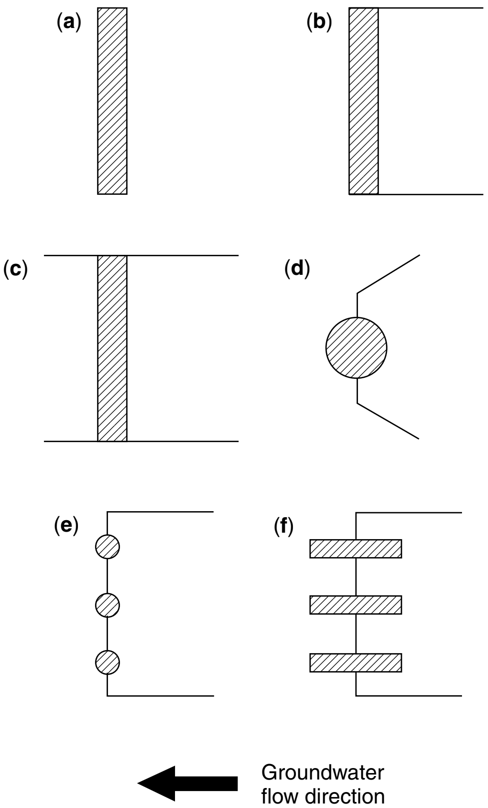

Figure 1. Possible geometries of passive treatment walls: (**a**) continuous trench, (**b**) with lateral hydraulic control, (**c**) with lateral hydraulic control and downgradient lateral barriers, (**d**) with a single treatment caisson, (**e**) with multiple treatment caissons, (**f**) with parallel alleys (1).

Typically, the aerobic microbial degradation of hydrocarbons is limited by the amount of oxygen present. Oxygen can be added in a variety of ways: from peroxygens such as magnesium peroxide, sodium peroxide, calcium peroxide, potassium permanganate, and hydrogen peroxide (H_2O_2). Oxygen sources as gases include oxygen (O_2) and ozone (O_3). Higher concentrations of oxidizers such as hydrogen peroxide and ozone would temporarily destroy microbial colonies, creating a barren zone that might last for a few weeks. Ultimately, the aerobic microbial colonies would move back into barren zones from adjacent areas and reestablish themselves with the benefit of significantly higher oxygen levels.

Anaerobic *in situ* enhanced bioremediation is used for chlorinated solvents such as tetrachloroethylene (PCE) and trichloroethylene (TCE). The same process can be used to reduce heavy metals, nitrates, and perchlorate. Nitrates are generated by agricultural processes and runoff from fertilizers. Perchlorate is an ingredient in rocket fuels and flares. For anaerobic processes, remediation requires carbon sources. Molasses, cheese whey, corn syrup, milk, glucose, as well as hydrogen, methane, and propane have been used. Reductive bioprocesses have been well documented (3).

REMEDIAL CRITERIA FOR DEVELOPING NATIONS

One of the main challenges in assessing and remediating petroleum hydrocarbon contaminated sites is developing an appropriate cost-effective remediation strategy, especially for nonindustrialized countries. For developing nations, technologies would have to match local geologic conditions, use readily available materials and resources, be performed *in situ*, require a minimal amount of equipment and little or no power, have no time constraints, and meet local and national regulatory guidelines. In addition, the technologies would require training that would allow local contractors to perform the work proficiently.

ENHANCED BIOREMEDIATION

Natural attenuation consists of unenhanced physical, chemical and biological processes that limit the migration and reduce the concentration of contaminants in the subsurface (4). The most important process in petroleum hydrocarbon degradation is aerobic bioremediation because it can destroy a large percentage of the hydrocarbon contaminant mass. Destruction occurs because of aerobic bacteria that use oxygen to oxidize hydrocarbons (reduced materials) to obtain energy. Aerobic biological degradation of hydrocarbon fuels and selected other organic compounds have been well documented (3,5–7). Enhanced bioremediation is the process of supplying an appropriate amount of oxygen, nutrients, and other amendments, if needed, to the subsurface to enhance the biodegradation process, significantly increase remediation effectiveness, and decrease treatment time.

Gasoline is a mixture of numerous compounds, including benzene, toluene, ethylbenzene, and xylenes (BTEX). Gasoline sometimes also contains additives, such as methyl tertiary-butyl ether (MTBE). Contaminant concentrations below saturation are degradable. Gasoline floating on the top of the groundwater table, also called free-product, is toxic to hydrocarbon degrading microbes.

Gasoline, MTBE, a gasoline additive, and BTEX compounds degrade aerobically in the presence of dissolved oxygen. Natural attenuation of gasoline constituents has been growing as a remediation technology since the mid 1990s. Presently, a variety of technologies are available that create low to high concentrations (10–60 ppm) of stable dissolved oxygen in groundwater. Once this elevated dissolved oxygen mixes with gasoline-contaminated ground water, natural biodegradation processes occur (3,8).

BENCH TESTS AND OXYGEN DEMAND THRESHOLD

Bioremediation enhanced by the addition of dissolved oxygen has been proven an effective technology to reduce both BTEX and MTBE. However, many groundwater environments contain numerous materials that cause competing reactions for the oxygen from solid and dissolved compounds high in ferrous iron and other metals in the reduced state, and organic and inorganic compounds that have high biological and chemical oxygen demand. These compounds, also called “oxygen sinks,” consume large volumes of injected dissolved oxygen before aerobic bacteria can use the oxygen as part of the process of consuming gasoline and associated compounds.

The oxygen demand parameters significantly affect both enhanced bioremediation and chemical oxidation technologies. Oxygen demand includes the solid and dissolved substances that compete with microbes for oxygen. The parameters include solid oxygen demand (SOD) in saturated soil and biological oxygen demand (BOD) and chemical oxygen demand (COD) in groundwater. By better understanding nonmicrobial oxygen demand, the amount of oxygen required by microbes at a specific site that has specific geologic conditions during enhanced bioremediation can be predicted. Laboratory work generally includes measuring specific variables in the soil and groundwater such as alkalinity, pH, dissolved oxygen, contaminant concentration, macronutrients, heterotrophic plate count, specific degraders, chemical oxygen demand, biological oxygen demand sulfate, nitrate, total iron, ferrous iron, total dissolved solids, total inorganic carbon, and total organic carbon. The oxygen demand threshold must be overcome before significant petroleum hydrocarbon degradation will occur under aerobic conditions.

OXYGEN DELIVERY

For aerobic bioremediation, an efficient oxygen mass transfer method is needed to place high levels of dissolved oxygen in the groundwater. There are many methods of delivering oxygen to groundwater. A spargeless delivery of supersaturated levels of dissolved oxygen into groundwater is one method to ensure an abundance of oxygen to get over the oxygen demand threshold quickly. Use of chemical oxidants such as hydrogen peroxide or ozone can be used to reduce oxygen-competing reactions rapidly.

To deliver dissolved oxygen into the aquifer, a spargeless gas emitter tool that infuses 100% oxygen into groundwater via 50.8-mm diameter (2-inch) monitor wells has been developed (8) by inVentures Technologies, Inc (Fig. 2). There are no power sources or moving parts. The oxygen is released by pressure from an industrial-grade oxygen cylinder. The proprietary structured polymer inside the oxygen diffusion tool provides a large surface area for gas transfer into the gas infusion tool, which is placed into an existing monitor well. The system can be reinstalled and reused on other sites.

The gas infusion tool is connected to a regulated supply of industrial compressed oxygen (100% concentration). Field experience has shown that dissolved oxygen levels of 30–60 mg/L have been achieved in each monitor well where a gas infusion tool is installed. The dissolved oxygen is infused into the monitoring well at a typical rate of 5 to 20 cc/minute, depending on the head pressure in the well. The effective radius of influence is typically 3 to 5 meters, even in low permeability soil such as clay (Mapleshade, New Jersey, U.S. site) or in fractured bedrock (Englewood, Colorado, U.S. site).

Field performance data for a pilot test site in Mapleshade, New Jersey, with MtBE, tert-butyl alcohol (TBA), and BTEX bioremediation illustrates the gas infusion technology (8). Depth to water is 2 to 4 meters below grade. Groundwater velocity is 0.09 to 0.12 meters/day at a gradient of 0.028. Recovery wells yield up to 4 liters per minute. The existing on-site air stripper-GAC system had iron clogging problems from ferrous iron at 30 to 80 mg/L. Dissolved oxygen (DO) concentrations in deep piezometers have increased from low baseline levels to more than 1 mg/L at a minimum of 5 meters downgradient of the infusion point. Shallow piezometers showed little DO change from baseline.

After 6 months of using gas infusion devices at the Mapleshade, New Jersey, U.S. site, an effective barrier of dissolved oxygen was established. Data indicate significant reductions in MtBE (up to 99%), TBA (50%), and benzene (85%) concentrations downgradient of the gas infusion tools.

THE IMPORTANCE OF ADEQUATE HYDROGEOLOGIC CHARACTERIZATION FOR *IN SITU* REMEDIATION

Understanding the subsurface environment is essential to developing a practical, efficient, cost-effective and timely *in situ* remediation strategy. System design is optimized when important geologic factors such as lithology, permeability, porosity, soil and groundwater chemistry, and contaminant type and concentration and their anticipated fate and transport, are fully evaluated with respect to the design and installation of oxygen injection ports or wells and rates of injection. Geologic factors control the movement, distribution, and quality of

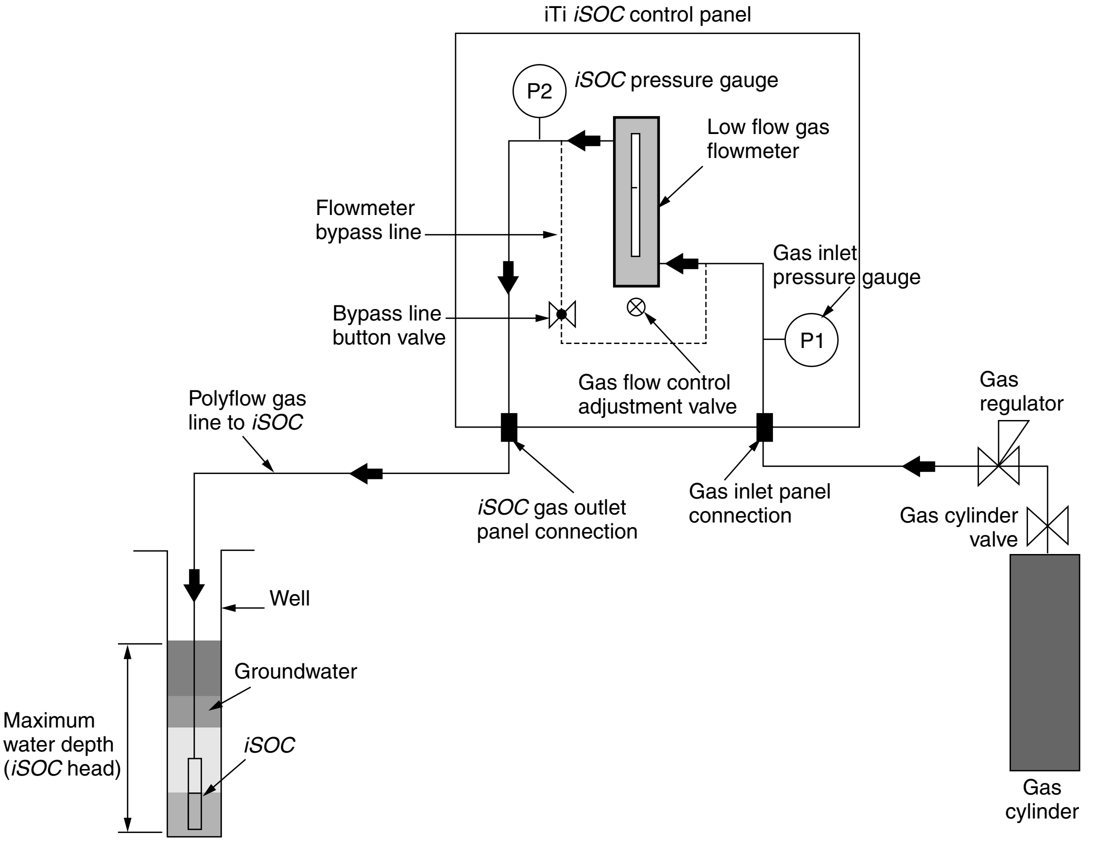

Figure 2. Diagram of semipassive gas diffusion device (iSOC).

groundwater as well as contaminants via a combination of several physical, chemical, and biological processes (9,10).

Shallow groundwater contamination by petroleum hydrocarbons results from surface or near-surface activities, including releases from underground and aboveground storage tanks and pipelines and accidental spills. The largest percentage of environmentally contaminated sites in the world lies on alluvial and coastal plains consisting of complex interstratified sediments. Lithologic contacts, some abrupt and some gradational, significantly influence permeability, porosity, and preferred flow pathways of contaminants in soil and groundwater.

Geology is the prime controlling agent for the movement of groundwater contaminants. A comprehensive understanding of the three-dimensional framework of geologic materials provides data for study of groundwater vulnerability to contamination and the lateral and vertical extent of hazardous and toxic constituents in the subsurface. Effective design and monitoring of subsurface remedial systems requires hydrogeologic characterization.

Lithology and stratigraphy are the most important factors affecting contaminant movement in soils and unconsolidated sediments. Stratigraphic features, including geometry and age relations between lenses, beds, and formations and the lithologic characteristics of sedimentary rocks, such as physical composition, soil type and chemistry, grain size, grain packing, and cementation, are among the most important factors affecting groundwater and contaminant flow in sedimentary rocks. Igneous–metamorphic rocks are geologic systems produced by deformation after deposition or crystallization. Groundwater and contaminant flow in igneous–metamorphic rocks are most affected by structural features such as cleavages, fractures, folds, and faults.

In summary, passive and semipassive remedial methods use minimal or no power, have few or no movin g parts, have few or no time constraints, and meet local and national regulatory guidelines. As for all forms of *in situ* remediation, proper assessment and hydrogeological characterization are the keys to success.

GROUNDWATER REMEDIATION BY *IN SITU* AERATION AND VOLATILIZATION

INTRODUCTION

There are a variety of groundwater remediation processes that use *in situ* aeration and volatilization as a part of their technology. Some of these technologies have a bioremediation component to them as well. These technologies include soil venting, soil vapor extraction, air sparging, bioventing, and biosparging.

Soil venting is a term used for an *in situ* aeration process that is a powerful remediation technology for the treatment of soils exposed to a variety of hydrocarbons. The practice of soil venting includes the following variations in application:

- Soil vapor extraction (SVE) systems are designed to exploit hydrocarbons potential for volatilization.
- Air sparging is an aeration process in which volatilizing air is injected into the saturated zone beneath the water table. Soil venting is used to recover the vapor laden air as it exits the water table.

- Bioventing is an aeration process designed to deliver oxygen to the subsurface for use by indigenous bacteria to degrade hydrocarbons; the focus is on minimizing hydrocarbon volatilization.
- Biosparging is a variant of air sparging in which oxygen stimulated biodegradation is the aim rather than volatilization. As with air sparging, soil venting is used to recover gas discharged through the water table.

Figure 1 illustrates and compares the potential effectiveness of soil vapor extraction and bioventing.

The data illustrated in Fig. 1 was calculated using the following premises:

- The air flow rate is 10 SCFM (Standard Cubic Feet per Minute). For the vapor transport calculations, it is assumed that the 10 SCFM air stream becomes saturated with hydrocarbon vapor. Volatilization driving vapor pressures were calculated at 8 °C.
- For the biodegradation calculations, it is assumed that the oxygen provided by the 10 SCFM air flow is completely used for hydrocarbon biooxidation.
- Biodegradation of each of the hydrocarbons proceeded to carbon dioxide and water.

This data was derived from theoretical calculations predicated on the fundamental principals governing the action of each of the processes (i.e., volatilization or biooxidation). In actuality, these processes and other subsurface interactions (with soil moisture, for example) are more complex. However, the base principals do apply and are, in the overall process, upheld. Although based on a simplified system, the data serves to illustrate the fundamental principals of, and differences between, soil vapor extraction and bioventing.

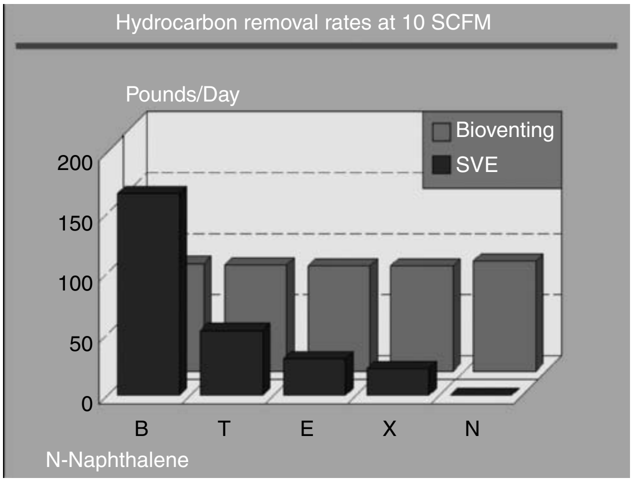

Figure 1. Hydrocarbon removal by SVE and biooxidation.

Following is a more detailed explanation of these processes and a case history that illustrates the use of biosparging technology at a site contaminated with volatile and nonvolatile hydrocarbons.

SOIL VAPOR EXTRACTION

By stimulating an advective air flow through soil venting, adsorbed hydrocarbons are exposed to air that does not carry an existing vapor load. Upon this exposure, equilibrium driven mechanisms will force the hydrocarbons to volatilize into the induced air flow. Every hydrocarbon has a specific temperature-dependent vapor pressure that determines the maximum (saturated) vapor concentration that can be obtained in the air flow. This vapor-saturated air is directed to the surface where it may be discharged to the atmosphere, or more commonly, treated to remove the hydrocarbon vapors before discharge.

The key element in this vapor extraction process is the fact that the mass transport rates are determined by a physical property (the vapor pressure) of the hydrocarbon. Not all hydrocarbons have the same vapor pressure, and the lower the vapor pressure, the lower the overall mass transport rate will be for that compound, thus the dramatic trend seen in Fig. 1 for the SVE portion of the graph. Table 1 presents the basic data used to prepare the soil vapor extraction part of Fig. 1.

Benzene is extremely volatile and offers an excellent mass transport potential of 166 pounds per day. However, naphthalene is at the other extreme; with a vapor pressure less than 1 mm Hg, it is at the lower end of hydrocarbons considered amenable to removal by soil vapor extraction. In this instance, only 0.13 pounds per day would be removed. The other petroleum hydrocarbons fall somewhere between the two.

The dependence of soil vapor extraction on the varying physical property of vapor pressure places serious constraints on the rate of SVE remediation at sites

Table 1. Vapor Pressure and Volatilization Driven Mass Transport Rate

Hydrocarbon	Vapor Pressure*	Molecular Weight	Saturated Vapor Concentration	Lbs Removed in One Day at 10 SCFM
Benzene	41.0	78.1	11.5×10^{-3} lbs/ft^3	166
Toluene	11.1	92.1	3.67×10^{-3} lbs/ft^3	52.8
Ethylbenzene	5.5	106.2	2.10×10^{-3} lbs/ft^3	30.2
Xylene	4.0	106.2	1.53×10^{-3} lbs/ft^3	22.0
Naphthalene	0.02	128.2	9.2×10^{-6} lbs/ft^3	0.13

*mm Hg at 8° Centigrade

impacted with petroleum hydrocarbons. Even gasoline has significant concentrations of hydrocarbons with relatively low vapor pressures. Heavier petroleum products, such as jet fuel, kerosene, diesel fuel, and lubricating oil, are thought to be nonresponsive to soil vapor extraction technology. Based on soil vapor extraction alone, that thought is an accurate one.

Air Sparging

Air sparging is the process of hydrocarbon volatilization stimulated by the injection of air beneath the water table. With air sparging, the volatilization process takes place under saturated conditions, emulating the action of an air stripping surface treatment system. The governing physical parameter that relates a hydrocarbon's volatilization potential from water is Henry's constant. According to Haarhoff and Cleasby (1), Henry's constant is directly related to a hydrocarbon's vapor pressure, water solubility, and temperature of the air/water/hydrocarbon system, which is a more complex physical/chemical system than volatilization of free phase or adsorbed hydrocarbons from soil in a vapor extraction system. In an air sparging system, the injected air and entrained volatilized hydrocarbons are captured above the water table with a conventional soil venting system.

$$P_a = H_a X_a$$

where P_a is the partial pressure of constituent a in air, H_a is the Henry's law constant (atm), and X_a is the solution concentration of the chemical a (mole fraction).

Some Henry's law constants for gasoline compounds include tetraethyl lead (4,700 atm), ethylbenzene (359 atm), xylenes (9266 atm), benzene (230 atm), toluene (217 atm), naphthalene (72 atm), and MTBE (27 atm) (2). Henry's law constants of greater than 100 atmospheres are generally considered volatile, and consequently more likely to be volatilized rather than biodegraded.

BIOVENTING

Bioventing is the term for aerobic biodegradation stimulated by oxygen provided to a hydrocarbon impacted subsurface zone by an air flow induced through soil venting. Many factors exist that affect the outcome and success of bioventing projects.

Intrinsic permeability (k), in cm^2/sec, and product composition are important aspects for biosparging projects. Ineffective permeability for bioventing includes k values of 10^{-16} to 10^{-12}. This range corresponds to lithologies of clay and the lower permeability ranges of glacial till. Moderate to minimal effectiveness for bioventing includes sediments with k values of 10^{-10} to 10^{-5}, including silt, loess, silty sand, and the lower permeability ranges of clean sand. The most effective permeability for bioventing includes k values of 10^{-4} to 10^{-2}, which includes the upper permeability range of clean sand and all gravels. In some generally low-permeability settings, heterogenetic prefererential pathways may exist that can offer influence beyond what would be initially expected.

Petroleum hydrocarbons are generally biodegradable, regardless of their molecular weight, as long as the indigenous microbes have an adequate supply of oxygen and nutrients. The most volatile and most soluble to least volatile and least soluble petroleum products include gasoline, kerosene, diesel, fuel oils, and lube oils. Bioventing is more effective with the more volatile components (2).

Site characteristics that must be evaluated include intrinsic permeability of the sediments, soil structure and stratification, temperature, (10 °C or higher), pH (6 to 8), microbial population density (generally greater than 1,000 colony-forming units per gram of dry soil), nutrient concentrations (ammonia as nitrogen and orthophosphate; carbon-nitrogen-phosphorous ratios are best at 100:10:1), and dissolved ferrous iron concentrations (Fe^{+2} is less than 10 mg/L). The contaminant characteristics also need to be evaluated, which include chemical structure of compounds, concentrations and toxicity, vapor pressure, product composition and boiling point, and Henry's law constant. Approximately 3 to 3.5 pounds of oxygen are needed to degrade one pound of petroleum hydrocarbons. This amount of oxygen does not take into account the oxygen demand in the sediments (sediment oxygen demand) or in dissolved in the groundwater (chemical oxygen demand with the subset of biological oxygen demand).

The power of bioventing lies in the underlying process responsible for it, the biologically mediated oxidation of hydrocarbons to carbon dioxide and water. The data calculated for the bioventing portion of Fig. 1 is based on the stoichiometric consumption of oxygen; that is, each mole of carbon present will require one mole of oxygen (O_2) to be converted to carbon dioxide (CO_2):

$$O_2 + C = CO_2$$

Each mole of hydrogen requires 1/4 mole of oxygen (as an O_2 molecule) to produce one mole of water. It can be more conveniently expressed as follows:

$$O_2 + 4\ H_2 = 2\ H_2O$$

The exact stoichiometry for each of the hydrocarbons illustrated in Fig. 1 is shown in Table 2.

A flow rate of 10 SCFM can deliver 270 pounds of oxygen to a treatment zone in a period of 24 hours. Based on the above stoichiometry, the potential biodegradation rates in pounds per day are indicated in Table 3.

This entire process is independent of any other physical property of these hydrocarbons. The prime issue with regard to *in situ* remediation by bioventing is how much

Table 2. Biooxidation Stoichiometry

Compound	Chemical Formula		Moles O_2 Required		Oxidation Products
Benzene	C_6H_6	+	7.5 O_2	=	6 CO_2 + 3 H_2O
Toluene	$C_5H_5(CH_3)$	+	9 O_2	=	7 CO_2 + 4 H_2O
Ethylbenzene	$C_6H_5(C_2H_5)$	+	10.5 O_2	=	8 CO_2 + 5 H_2O
3-Xylene	$C_6H_4(CH_3)_2$	+	10.5 O_2	=	8 CO_2 + 5 H_2O
Naphthalene	$C_{10}H_8$	+	12 O_2	=	10 CO_2 + 4 H_2O

Table 3. Biooxidation Rate

Compound	Biooxidation Potential—Lbs/Day
Benzene	88
Toluene	87
Ethylbenzene	86
3-Xylene	86
Naphthalene	90

oxygen can effectively be transported to the reaction (contaminated) zone. However, practical limits exist to the effectiveness of biodegradation and the linear effect of the stoichiometric biooxidation reaction with oxygen. The potential problem lies with compounds that are recalcitrant to biodegradation. With respect to petroleum hydrocarbons, these recalcitrant compounds are typically polynuclear aromatic (PNA) compounds having high ring counts. In many products, however, high ring count PNAs are not a significant amount of the total hydrocarbon makeup. In addition, these compounds are most often still biodegradable, but at a slower rate than that observed for the less refractory hydrocarbons.

Indigenous Bacteria

A key concern over the viability of the bioventing approach is the presence of indigenous bacteria capable of being stimulated to degrade hydrocarbons. Figure 2 illustrates soil gas data from a site impacted with petroleum hydrocarbons.

These samples were collected under static conditions, no remediation activity has taken place. This soil gas is representative of equilibrium conditions existing at the impacted site. Although volatilized hydrocarbon vapors (from the contaminant impact) are also present in the soil gas, Fig. 2 only shows the three dominant soil gases: carbon dioxide, oxygen, and methane. Under normal atmospheric conditions oxygen concentration is 21% and carbon dioxide is approximately 300 ppm (0.03%). As a result of the presence of carbonate minerals and natural organic materials, CO_2 in uncontaminated soils is typically found at concentrations from 1.5–3% (3). Methane is present in the atmosphere in trace amounts (1.5 ppm). As Fig. 2 illustrates, the soil gas concentrations at this contaminated site are significantly skewed from those levels. Carbon dioxide is elevated at 11–12%, oxygen is depressed to around 5%, and methane is elevated at 3–5%. Following is an outline of the process responsible for the generation of this soil gas blend:

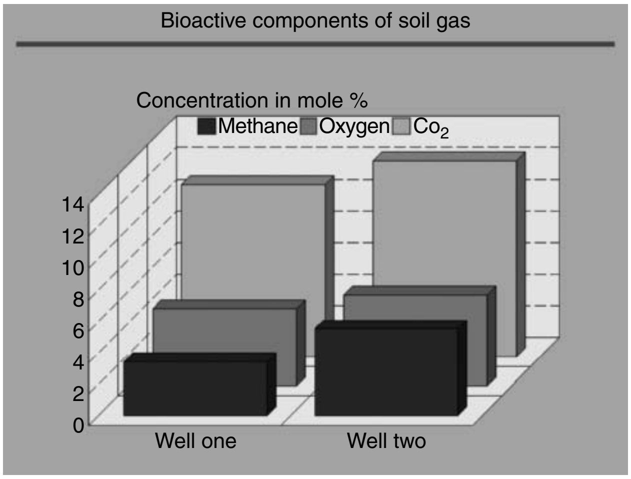

Figure 2. Bioactive soil gases in the vadose zone.

On release of hydrocarbons into the subsurface, the indigenous bacteria began an aerobically driven biooxidization process. The endproduct of this aerobic microbial degradation was carbon dioxide and water (see Table 2).

After the aerobic microbial activity had consumed oxygen in the soil gas to near the observed 5% level, facultative anaerobes became active. These bacteria have the ability to support metabolic activity under full aerobic or oxygen depressed conditions (the transition has been observed in the field and laboratories to normally occur at oxygen levels near 5%). The degradation products (seen in the gas phase) of the anaerobic activity are methane and additional carbon dioxide. The methane is a result of the fact that, in microscale isolated zones within the geologic matrix, deeply methanogenic conditions may be reached under these circumstances.

The fundamentally important point of the data illustrated in Fig. 2 is that this aerobic/anaerobic activity occurred naturally. No bacteria were added to the soil; the existing indigenous bacteria generated these gases. No nutrients were added. The indigenous bacteria were able to become active under natural subsurface conditions, using available oxygen, nitrogen, phosphorous, and trace nutrients. With depletion of the oxygen levels, the facultative anaerobic activity became dominant at the expense of the aerobic biooxidation. This anaerobic degradation occurs at a rate several orders of magnitude slower than that observed for aerobic degradation (4). If this were not the case, it would be cost effective to let the anaerobic degradation occur at its own pace with no other intervention.

What is required for timely bioremediation is the installation of a soil venting system to displace this soil gas (equilibrated to the existing chemical and microbiological conditions) with fresh, fully oxygenated air, thus restimulating the natural aerobic biodegradation of the impacting hydrocarbons, which is the essence of the bioventing process.

Biosparging

The governing processes engaged in a biosparging system are identical to those in bioventing. The biosparging stimulated biooxidation follows the same stoichiometry presented in Table 2. The injected air, biooxidation products (CO_2), and some fraction of volatilized hydrocarbons are collected above the water table with a soil venting system, just as described for air sparging. The last sentence contained a key statement, that “some fraction of volatilize hydrocarbons” are generated by a biosparging (and bioventing) system. The next section analyzes this statement in more detail.

SOIL VAPOR EXTRACTION VERSUS BIOVENTING A SIMULTANEOUS PROCESS

When a soil venting system is operated at a site impacted by petroleum hydrocarbons, both of the discussed mechanisms are engaged. The determination of which process is dominant lies in how the soil venting system is operated.

A soil venting system can be operated such that 60–90% of the impacting hydrocarbons are volatilized and 10–40% are biodegraded, i.e., soil vapor extraction. Bioventing reverses those numbers, 60–90% of the hydrocarbons are biodegraded and 10–40% are volatilized (5). Note that some degree of biodegradation is unavoidable even in a system that is designed and operated as a pure soil vapor extraction system. The site soils would have to be sterilized to prevent it. Conversely, some level of volatilization is equally unavoidable in a bioventing system.

The value of the bioventing approach lies in three areas:

First, every pound of hydrocarbon that is degraded *in situ* is a pound that will not require subsequent treatment on the surface, resulting in significant cost savings.

Second, equipment costs and operational costs (primarily energy) are less using the lower air flow rates capable of supporting the bioventing approach. Oxygen does not need to be brought to the subsurface at a rate faster than the ability of the bacteria to consume it.

Third, as Fig. 1 illustrates, soil vapor extraction does not work well with hydrocarbons that have low vapor pressures.

Remediation by soil vapor extraction is very rapid when applied to hydrocarbons with high vapor pressures. For example, a release of pure benzene could theoretically be cleaned up faster using a straight soil vapor extraction approach rather than bioventing. Although surface treatment expenses must still be taken into account in the overall project costs.

Soil vapor extraction is definitely the preferred approach when remediating biological recalcitrant compounds that have high vapor pressures such as chlorinated solvents. However, in instances where the released materials are petroleum hydrocarbons, such as fuels or lubricants, bioventing is likely to be the most cost and time effective remediation approach.

BIOSPARGING—A CASE HISTORY

Following is a field example of the biosparging process discussed above. This project is ongoing at a facility that was closing an RCRA hazardous waste drum storage area (DSA). The wastes stored in the DSA were “Spent Non-Halogenated Solvents” (F003/F005). Figure 3 shows a plan view of the site, the DSA, and the installed remediation system.

The geology beneath the site consists of:

- approximately 30 feet of sand interbedded with a peat layer 1 to 3 feet thick at a depth of 16 feet; silt and clay underlies the sand.
- depth to groundwater is 6 feet below grade (see Fig. 4).
- soil and groundwater contamination was limited to the sand/peat unit above the clay.

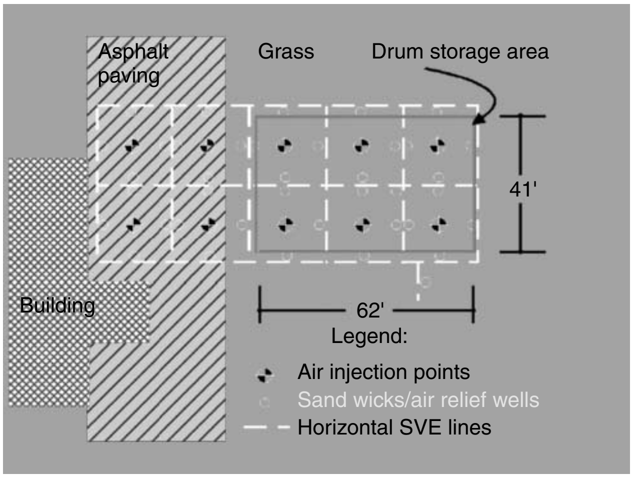

Figure 3. Plan view of biosparging site.

Soil contamination included ethylbenzene (160 mg/Kg), toluene (110 mg/Kg), total xylenes (620 mg/Kg), naphthalene (440 mg/Kg), and other polycyclic aromatics at low mg/Kg levels.

Groundwater contained 2 mg/L ethylbenzene and 16 mg/L total xylenes.

The remediation system put into place was an *in situ* saturated zone treatment using biosparging, the details (Fig. 4) of which are as follows:

- A series of sparge points were installed to a depth of 30 feet just above the surface of the lower clay layer, which placed them about 14 feet beneath the peat layer.
- A series of 4-inch borings, filled with graded sand to act as air relief wells (sand wicks), were installed to a depth of 30 feet. The sand wicks act as a conduit for injected air bubbles through the peat

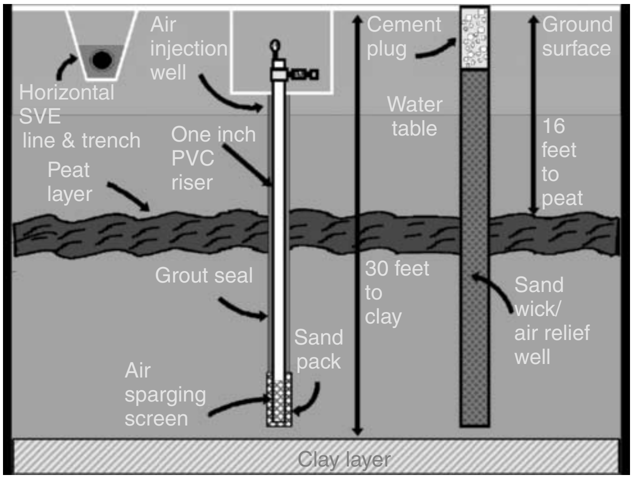

Figure 4. Cross-sectional view of biosparging site with sand wicks.

layer, preventing unacceptable horizontal migration of the injected air and any entrained vapor, which is a common and critical problem for the application of air sparging/biosparging in heterogeneous soils.

- A soil venting recovery system was installed in horizontal trenches above the water table to capture the injected air and hydrocarbon vapors generated from the biosparging system. The area was then covered with a plastic liner and soil to prevent short circuits in the soil venting system.

The discharge of the soil venting system was treated with vapor phase activated carbon.

An important point with regards to this system was the biosparging aspect of the design. Although vapor phase activated carbon was installed as a necessary treatment of coproduced hydrocarbon vapors, the intent of the remedial design was to minimize the actual volatilization and concentrate on oxygen-stimulated biodegradation of the hydrocarbons *in situ*. This approach minimized the carbon usage and also had the potential to remove the nonvolatile constituents of the impacting hydrocarbons. To this end, air injection was only at 12 SCFM, a rate estimated to match the kinetics of the microbiological biooxidation. The horizontal soil venting system was operated at 60 SCFM to ensure that all the injected air (and minimal hydrocarbon vapor load) were adequately recovered.

Although provisions were made for the addition of nutrients (nitrogen, phosphorus, and trace minerals), nutrients were not actually used in this phase of the project. Under many conditions, existing nutrient levels are often adequate to support microbial activity at an acceptable level. Under most circumstances, oxygen supplementation is the dominant factor required for microbial stimulation. Nutrient addition to the vadose and saturated zones (although possible) is a complication that should be avoided unless required. Figures 5 and 6 illustrate the results after system startup. Figure 5 illustrates the trend of the vaporized hydrocarbon and carbon dioxide observed in the recovered soil gas, and Fig. 6 illustrates the trend of dissolved oxygen (DO) in the groundwater and carbon dioxide in the soil gas.

The hydrocarbon versus carbon dioxide in soil gas above the biosparging system shows a sharp increase in the concentration in the VOCs recovered in the soil gas by day ten of system operation (Fig. 5). Initial carbon dioxide levels are quite low. In a manner very typical of microbiological systems, carbon dioxide concentrations steadily increased to a maximum level over a 30-day period.

This period is termed the "lag phase," as the indigenous microorganisms adapt to the sudden introduction of oxygen into their environment and the use of the impacting hydrocarbons as a carbon source.

In turn, the VOC concentrations continue a steady decline as degradation begins to become more dominant. The most striking feature is the continuous generation of significant amounts of carbon dioxide after day 30, with very low concurrent levels of VOC emission, which is primarily because of the biooxidation of nonvolatile hydrocarbon components (such as lighter PNAs), which are not responsive to removal through volatilization. Last, after 50 days of operation, the carbon dioxide levels precipitously decline in conjunction with VOCs becoming almost undetectable, which indicates that the hydrocarbons have been consumed and the stimulated bacteria have ran out of the hydrocarbons serving as their carbon source.

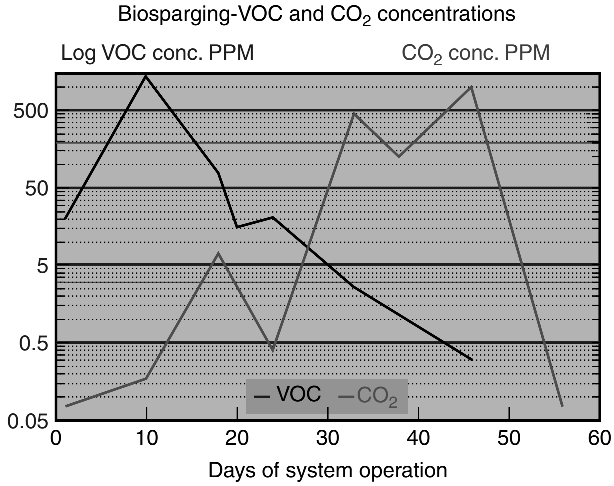

Figure 5. Hydrocarbon vs. carbon dioxide in soil gas above biosparging.

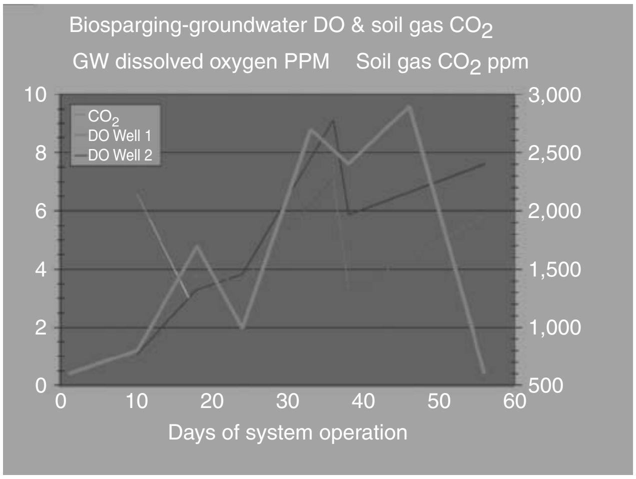

Figure 6. CO_2 in soil gas vs. dissolved oxygen in groundwater.

Figure 6 serves to further illustrate the biological activity in the saturated zone of the impacted soils. The initial low levels of the dissolved oxygen may have been because of chemical oxygen demand within the aquifer matrix (primarily dissolved iron). After meeting that COD, the DO increased in tandem with carbon dioxide production.

Of particular interest is the marked drop in DO between day 35 and day 40, which coincides with the peak biological activity. When the carbon dioxide levels began to drop, the DO increased once again. At the peak level of activity, the microbes were able to consume most of the oxygen provided by the injected air, as planned. With depletion of the food source, more oxygen is free to appear as DO. This site data has been presented to provide a topical field example of biosparging. It is from the early stages of the remediation. The hydrocarbon attenuation indicated by Figs. 5 and 6 is occurring in the advective zone of the impacted saturated zone soils and groundwater.

In conclusion, aeration is a powerful remediation tool in the vadose and saturated zones. The manner in which an aeration system is operated will determine the dominant process stimulated by that aeration: volatilization or biooxidation. Biooxidation has distinct advantages with regard to the range of nonvolatile hydrocarbons that can be remediated and offers lower potential off-gas treatment costs. The core issue is to understand the underlying mechanisms responsible for both processes and apply that knowledge accordingly.

REMEDIATION OF CONTAMINATED SOILS

Dibyendu Sarkar
Rupali Datta
Ali H. Davani
University of Texas at San Antonio
San Antonio, Texas

Soil contamination is caused by a variety of industrial, agricultural, and domestic activities, and poses a major threat to the environment. Although soil contamination can result from a variety of organic and inorganic chemicals, this article focuses on remediation of metal-contaminated soils. Heavy metals such as Pb, Cr, Cd, Zn, Cu, and Hg can cause significant damage to environmental and human health, particularly because of their indefinite persistence in the environment. In the United States alone, 1200 sites are on the National Priority List (NPL) for remediation of contaminated soils, of which 63% are contaminated with toxic heavy metals. A plethora of remediation techniques are now available for the cleanup of such contaminated sites. The selection of the most appropriate site remediation technique depends on various factors such as site characteristics, concentration, types of pollutants to be removed, and end use of the contaminated medium. The major technologies available to date can be grouped under the following categories: isolation, immobilization, toxicity reduction, physical separation, and extraction. This article provides an overview of the various sources of heavy metal pollution in soils, the common remediation technologies available for soil cleanup, and the various factors that influence the type of remediation method that would be most appropriate for effectively remediating metal-contaminated soils.

INTRODUCTION

Environmental contamination due to human activities is an ancient problem that has been further aggravated by growing urbanization and increasing affluence. Dramatic accumulation of pollutants from chemical manufacturing, wastewater treatment, agriculture, mining and smelting, food processing, energy production, and pulp and paper production has led to deterioration of soil and water quality (1). Recent research is increasingly focused on the ecological and human health effects of the contaminants, and guidelines or standards on soil, drinking water, irrigation water, crop tissues, foodstuff, biosolids, and fertilizers are now becoming available (1). Heavy metals released by a variety of industrial, agricultural, and domestic activities are a potential risk to both human population and wildlife. In contrast to many organic pollutants, which are often degraded in the soil, the danger of heavy metals is aggravated by their indefinite persistence in the environment (2). Exposure to heavy metals has been linked to developmental retardation; various cancers; kidney damage; and development of autoimmunity leading to diseases of the joints, kidneys, circulatory and nervous systems. In addition, heavy metals can cause reduction in growth, inhibition in photosynthesis and respiration, and degradation of cell organelles in plants and microorganisms (3).

Remediation of contaminated soils involves reduction, extraction, removal, stabilization and/or containment of contaminants in the subsurface to a level acceptable for site closure. Site closure can be brought about by the reduction of risk posed by the presence of contaminants in the subsurface to an acceptable level. General approaches to remediating metal contamination include isolation, immobilization, toxicity reduction, physical separation, and extraction. Contaminated soil can be remediated by chemical, physical, or biological techniques. The available techniques can be grouped into two categories: (1) *ex situ* techniques that require removing the contaminated soil on- or off-site and (2) *in situ* methods that remediate without excavating the contaminated soil (4). The selection of the most appropriate soil and sediment remediation method depends on the site characteristics, concentration, types of pollutants to be removed, and the end use of the contaminated medium. The United States Environmental Protection Agency (USEPA) included 13 metals in its priority pollution list: Ag, As, Be, Cd, Cr, Cu, Hg, Ni, Pb, Sb, Se, Tl, and Zn (1). This review discusses the various sources of heavy metal pollution, evaluates the remediation methods available for soil cleanup, and the various factors that influence the type of remediation method that would be most appropriate for effective remediation.

SOURCES OF CONTAMINANTS

Major contributors to the metal burden in soils include discarded manufactured products in scrap heaps/landfills (As, Cr, Cu, Pb, Mn, and Zn), coal ashes (As, Cd, Pb, Mn, Hg, Mo, Ni, Se, V, and Zn), and agricultural and livestock wastes (As, Cu, and Zn) (1). Pollution sources can be broadly categorized into two sources: point sources and nonpoint sources. Point sources refer to discrete and localized contamination processes. Local accumulation of pollutants can arise from landfilling, mining, and smelter processes. Nonpoint sources are related to diffuse processes or human activities that cover large areas, for example, agricultural practices resulting in pesticide contamination (1). The major sources of soil metal contamination can be summarized as follows.

Airborne Sources

Airborne sources of metals include stack or duct emissions of air, gas, or vapor streams, and fugitive emissions such as dust from storage areas or waste piles. Some metals such as As, Cd, and Pb can also volatilize during high-temperature processing. These metals convert to oxides and condense as particulates, unless a reducing atmosphere is maintained (5).

Process Solid Waste

Process solid wastes result from a variety of industrial processes. These metal-bearing solid wastes are disposed above ground in waste piles, below ground, or under cover in landfills. Examples of process solid wastes include slag, fly ash, mold sand, abrasive waste, ion exchange resins, spent catalysts, spent activated carbon, and refractory bricks (6). Waste piles are exposed to weathering, which can lead to dispersal of the contamination to the surrounding soil, water, or air (7).

Sludge(Biosolids)

The composition of biosolids depends on the original waste stream and the process from which it was derived. Biosolids resulting from a uniform waste stream (such as wastewater treatment) are typically more homogeneous and have more uniform matrix characteristics. Sludge pits, on the other hand, often contain a mixture of wastes that have been aged and weathered, causing a variety of reactions to occur (5).

Soils

Soils can be contaminated as a result of spills or direct contact with contaminated waste streams such as airborne emissions, process solid wastes, sludges, or leachate from waste materials. The solubility of metals in soil is influenced by the chemistry of the soil and groundwater (1). Factors such as pH, pE, ion exchange capacity, and complexation/chelating with organic matter affect metal solubility directly.

CHEMICAL FATE AND MOBILITY OF METALS IN SOILS

The fate and transport of metals in soils depends significantly on the chemical form and speciation of metals (8). The term speciation means the distribution of elements among chemical forms or species. Heavy metals can occur in various forms in soils and water. For an accurate health risk assessment, not just the total metal concentration, but understanding its speciation is of paramount importance (9). In soils, speciation of metals depends on the physical and chemical characteristics of the soil, such as pH, redox, organic, carbonate, clay, and oxide content (10). A potential method for determining if heavy metals can be removed by a particular remediation technique or for predicting removal efficiencies is to determine speciation by selective extraction techniques. For example, it is believed that exchangeable carbonate and reducible oxide fractions may be amenable to soil washing techniques (11). Removal of the organically and residually bound fractions may not be economical or necessary to recover, as these fractions are generally not considered bioavailable (9).

REMEDIAL APPROACHES FOR METAL CONTAMINATED SOILS

Several technologies exist for the remediating metal contaminated soils (7), that can be broadly classified into five general categories; isolation, immobilization, toxicity reduction, physical separation, and extraction.

Isolation

Isolation technologies attempt to prevent the transport of contaminants by containing them within a designated area. Contaminated sites may also be isolated temporarily to limit transport during site assessment and site remediation (7). Isolation can be accomplished via these methods.

Capping. Capping systems provide an impermeable barrier to surface water infiltration into contaminated soil to prevent further release of contaminants into the surrounding surface water or groundwater (7). Other advantages of capping are control of odor emissions, improving aesthetics, and elimination of risks associated with human contact. Caps can be simple, single layered or complex multilayered systems (12). The selection of capping materials depends on site characteristics, remedial objectives, and risk factors associated with the site (12).

Subsurface Barriers. Subsurface barriers may be used to isolate contaminated soil and water by controlling the movement of groundwater at a contaminated site. Vertical barriers are commonly used to restrict the lateral flow of groundwater. For effective isolation of the contaminated matrix, the barrier should extend and key into a continuous, low-permeability layer, such as clay or competent bedrock, below the contaminated area (12,13). Slurry walls, sheet curtains, and grout piles are some of the widely used vertical barriers. Technologies for constructing horizontal barriers, such as grout injection by vertical boring and horizontal drilling, are also under investigation. Horizontal barriers would enable control of downward migration of contaminants by lining the site without requiring excavation of the contaminated matrix (7).

Immobilization

Immobilization technologies are designed to reduce the mobility of contaminants by changing the physical or leaching characteristics of the contaminated matrix. Mobility is usually decreased either by physically restricting contact between the contaminated matrix and surrounding groundwater or by chemically altering the contaminant to make it more stable with respect to dissolution (7). Immobilization techniques can be performed *ex situ* or *in situ* via these methods.

Solidification/Stabilization. Solidification and stabilization (S/S) immobilization technologies are the most commonly selected treatment options for metal contaminated sites (14). Solidification involves forming a solidified matrix that physically binds the contaminated material. Stabilization, also referred to as fixation, usually uses a chemical reaction to convert the waste to a less mobile form. Inorganic binders such as cement, fly ash, or blast furnace slag, or organic binders such as bitumen are used to form a barrier around the waste. The most important method used to immobilize metals is by precipitation of hydroxides within the solid matrix (15).

Vitrification. The mobility of metals can also be decreased by high-temperature treatment of the contaminated area that results in the formation of vitreous materials, usually a solid oxide. Most soils can be treated by vitrification, and a wide variety of inorganic and organic contaminants can be targeted (16). *Ex situ* vitrification includes steps such as excavation, pretreatment, mixing, feeding, and melting. The vitrified material can be recycled for use as clean fill, aggregate, or other reusable materials (5). *In situ* vitrification involves passing electric current through the soil using an array of electrodes inserted vertically into the soil (17).

Toxicity and/or Mobility Reduction

Chemical and/or biological processes can be used to alter the form of metal contaminants to decrease their toxicity and/or mobility.

Chemical Treatment. Chemical reactions can be initiated that are designed to reduce the toxicity or mobility of metal contaminants (7). The three types of reactions that can be used for this purpose are oxidation, reduction, and neutralization. Changing oxidation states of metals by oxidation or reduction can detoxify, precipitate, or solubilize metals (18). The most commonly used oxidizing agents are potassium permanganate, hydrogen peroxide, hypochlorite, and chlorine gas; some of the common reducing agents used are alkali metals, sulfur dioxide, sulfite salts, and ferrous sulfate. Chemical neutralization is used to adjust the pH of extremely acidic or basic soils. This process can be used to precipitate insoluble metal salts from contaminated water or to prepare for chemical oxidation or reduction. Chemical treatments can be performed both *in situ* or *ex situ*. Chemical agents are non specific, so they target all reactive metals, which might make them more toxic or mobile (18).

Biological Treatment. Until recently, biological techniques were more commonly used for remediating organic contaminants, but they are beginning to be applied for metal remediation. However, until now, most biological treatment applications have been at the bench and pilot scale; very few have been tested on a field scale. Biological treatment exploits natural biological processes that allow certain plants and microorganisms to aid in remediating metals through processes such as adsorption, oxidation/reduction reactions, and methylation (19). Biological treatment technology can be broadly classified.

Phytoremediation. Phytoremediation refers to the specific ability of plants to aid in metal remediation. Some plants have developed the ability to remove ions selectively from the soil to regulate uptake and distribution of metals in their tissues. Potentially useful techniques for metal remediation at contaminated sites include these (20).

Phytoextraction. Phytoextraction employs hyperaccumulating plants to remove metals from the soil by uptake into the roots and shoots of the plants. The aboveground shoots can be harvested to remove metals from the site and subsequently disposed of as hazardous waste or treated for the recovery of metals.

Phytostabilization. Phytostabilization involves using plants to limit the mobility and bioavailability of metals in soil. Phytostabilizing plants are characterized by high tolerance of metals in surrounding soils but low accumulation of metals in the plants.

Bioleaching. Bioleaching uses microorganisms to solubilize metal contaminants in the soil. This process has been adapted from the mining industry for metal remediation (7). Certain microorganisms can oxidize/reduce metal contaminants directly; others produce oxidizing/reducing agents that interact with metals to change their oxidation states, thereby decreasing their mobility and/or toxicity. Methylation by microorganisms involves attaching methyl groups to inorganic metal ions to form organometallic compounds, which can then be removed by volatilization (7).

Physical Separation

Physical separation is an ex-situ process that attempts to separate contaminated material from the rest of the soil matrix by exploiting certain physical characteristics of the metal and soil. Physical separation techniques operate on the basis of particle size, particle density, surface, and magnetic properties of the contaminated soil. These techniques are most effective when the metal is either in the form of discrete particles in the soil or if the metal is sorbed to soil particles that occur in a particular size fraction (21). Screening, classification, gravity concentration, and magnetic separation are some of the most important physical separation techniques used for soil remediation. *Screening* separates soils according to particle size when the soil passes through sieves with particular size openings. *Classification* involves separation of particles based on the velocity with which they fall through water (hydroclassification) or air (air classification) (21). *Gravity concentration* separates particles on the basis of gravity differences (21). *Magnetic separation* subjects particles to a strong magnetic field using electromagnets or magnetic filters and relies on the magnetic properties of minerals for separation (8).

Extraction

Heavy metals can be extracted from soil either by treating the soil with a solution containing chemical extractants or via electrokinetic processes.

Soil Washing. Washing can be used to remove metals from soil by chemical or physical treatment methods in aqueous suspension. Soil washing is an ex-situ process that requires soil excavation prior to treatment. Chemical treatment involves adding extraction agents that react with the contaminant and leach it from the soil (22,23). The type of extractant used depends on the contaminants present and the characteristics of the soil matrix. Many processes manipulate the acid/base chemistry of the slurry to leach contaminants from the soil. Chelating agents such as EDTA selectively bind some metals and can be used to solubilize metals from the soil matrix (22). Oxidizing and reducing agents, such as hydrogen peroxide or sodium borohydride, provide yet another option to aid in solubilizing metal because chemical oxidation/reduction can convert metals to more soluble forms (24). Surfactants can also be used to extract metals from soil (7).

Pyrometallurgical Extraction. Pyrometallurgical technologies use elevated temperature extraction and processing to remove metals from contaminated soils. Soils are treated in a high-temperature furnace to remove volatile metals from the solid phase. Subsequent treatment steps may include metal recovery or immobilization. This process usually produces a metal-bearing slag, from which the metals can be recovered for reuse (25).

In-situ Soil Flushing. This method is used to mobilize metals by leaching contaminants from soils so that they can be extracted without excavating the contaminated materials. An aqueous extracting solution is injected or sprayed onto the contaminated area to mobilize the contaminants, usually by solubilization. The extractant can be applied *via* surface flooding, sprinklers, leach fields, vertical/horizontal injection wells, basin infiltration systems, or trench infiltration systems (26). Similar extracting agents are used for in-situ soil flushing and soil washing, including acids/bases, chelating agents, and oxidizing/reducing agents (18). The liquid containing the contaminants is subjected to pump-and-treat methods. Once the water is pumped from the soil, the heavy metals are removed by sodium hydroxide or sodium sulfide precipitation, ion-exchange, activated carbon adsorption, ultrafiltration, reverse osmosis, electrolysis/electrodialysis, or biological means (9).

Electrokinetic Treatment. Electrokinetic remediation technologies apply a low density current to contaminated soil to mobilize contaminants in the form of charged species. The current is applied by inserting electrodes into the subsurface. This method relies on the natural conductivity of soils (due to the presence of water and salts) to influence movement of water, ions, and particulates through the soil profile. The contaminant metals are concentrated in the solution around the electrodes (5), and are removed by a variety of processes, including electroplating at the electrodes, precipitation/coprecipitation at the electrodes, complexation with ion exchange resins, or by pumping the water from the subsurface and treating it to recover the extracted metals (5).

SUMMARY AND FUTURE DIRECTIONS

Containment technologies, the least expensive, are widely used to control the transport of hazardous materials and to prevent the spread of contamination (9). Containment is the preferred remedial method for sites that have low levels of wastes of low toxicity and low mobility or wastes that have been pretreated to obtain these characteristics. The advantages of containment technologies include relatively simple and rapid implementation, often at a much lower cost than alternatives that require excavation, ability to treat large areas and volumes of waste, and the potential for successful containment as the final action at the site (7). Among the major disadvantages of containment technologies are the high level of uncertainties regarding the long-term effectiveness of the containment process and the need for long-term inspection because untreated contaminants remain on-site.

Metals are considered relatively immobile, so the remediation approaches generally used involve solid-phase processes such as solidification/stabilization and vitrification (9). These techniques are mostly done ex-situ, but they can be also used for in-situ remediation. They are useful at sites that are large, but the contamination is relatively shallow. The benefits of *in situ* remediation systems over conventional methods are the lower final cost for remediation, minimum cost for operations and maintenance, no moving parts that could break, and no discharge permits or waste disposal of liquids for in-situ groundwater treatment. Vitrification is expensive but can be used to remediate mixed wastes, where few technologies are currently available. Electrokinetics and soil flushing methods are also promising, and have been used successfully at a few sites (9). At present, phytoremediation and bioleaching are areas of primary focus of remediation research, because these techniques are environmentally friendly and relatively cheap. These techniques are useful for areas of low contamination, but longer treatment times are generally necessary. Some of the areas where research is still needed to use these technologies commercially are enhancing the metal accumulation capacity of plants by biotechnology, determining the correlation between soil properties and bioavailability, and developing methods to extract metals from plants (27).

GROUNDWATER REMEDIATION PROJECT LIFE CYCLE

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

During the past decade, the groundwater remediation project life cycle has been used to characterize the status of an environmental project. If groundwater or soil contamination is suspected, a general process from assessment to closure occurs. In some cases, the project may involve many stakeholders, including landowners, responsible parties, bankers, operators/tenants, consultants, and regulators. In addition, others in the process might include environmental attorneys, realtors, developers, and interested parties such as neighbors and the community.

Although the timing and specific activities may vary from site to site, a general phased process occurs. Environmental evaluations of potential leakage or spillage of hazardous substances into the subsurface generally consist of four phases (Phase I through Phase IV). The generalized four-phase approach reflects the realistic process required to take a potentially impacted property from assessment phase (Phase I) through to the final monitoring and site closure phase (Phase IV). The phases generally proceed in order starting with Phase I. Some sites where soil or groundwater contamination is already suspected or documented might start with Phase II when a site has an underground tank or even Phase III, in the case of visually stained surface soils.

PHASE I

A Phase I Environmental Assessment is a set of noninvasive techniques to acquire information from site inspection and to obtain data supplied by others, including owners, operators, employees, and regulators. Sometimes, the Phase I Environmental Assessment is performed as part of a due diligence activity for a property transfer, as required by a financial institution on industrial, agricultural, and commercial properties. The transfer of ownership could occur during a corporate merger or acquisition or a routine sale. Other times, a Phase I Environmental Assessment is performed for financing or refinancing a loan on a commercial, industrial, or agricultural property. Other times, these activities might be required by regulatory agencies on properties when contamination is found, but no clear source of contamination is evident.

Phase I Environmental Assessments involve a site inspection, the development of the history of the property, and a review of data supplied by regulators, environmental lists and building permit databases, owners, tenants, and others.

A broad-based facility audit inspection focuses on the utilities, industrial processes, any signs of contamination, and all current and past permits and manifests (1). During the site facility inspection, the sources of all utilities (water, sewage, electrical, natural gas, electrical backup systems) are documented. Aboveground or underground storage tanks are frequently located at facilities that have backup power generators. The processes of the industrial facility from the input of the raw materials to the outflow of the finished products and associated liquid, solid and vapor wastes is reviewed. Recycling systems are documented. Visual clues of process activities such as staining, spillage, or leakage of liquids; and release of vapors or solid residues are documented and photographed. An investigator must also examine the permits for the facility, including any hazardous materials business plans, operating permits, hazardous material storage permits, building permits, waste generator permits, OSHA safety and training files, material safety data sheets (MSDS), environmental fines or compliance memos from regulatory agencies, and manifests for transportation and disposal of any hazardous materials generated on site.

Techniques include interviews of knowledgeable persons, review of historical aerial photography, and examination of published and unpublished historic maps. The maps include both historic topographic maps supplied by the USGS and Sanborn Fire Insurance Maps, as well as other local historic maps. Reverse telephone or address directories, chain-of-title reports, and regulatory databases may be reviewed. Noninvasive data may be collected on a property using handheld vapor meters. Other noninvasive techniques that would generate data include surface geophysics such as ground penetrating radar (GPR) and magnetic or induction surveys to locate buried tanks, pipes, or drums.

A passive vapor survey can be used to locate upward migrating volatile organic compounds that may lie within a few centimeters from the surface. This approach consists of placing a natural (carbon) or synthetic (Gore-sorber) adsorbent a few centimeters into the subsurface. The sorbent is usually placed in the upper end of an inverted glass or plastic container or test tube that has an open bottom where migrating vapors enter and collect. The collection device is left for an extended time, from a few days to a few weeks. Subsequently the adsorbent is removed and analyzed using a gas chromatograph. When the vapor data are evaluated, investigators can plot the various VOCs detected and concentration patterns on site maps. This exercise frequently allows an interpretation on the location of a source of detected shallow VOC contamination.

PHASE II

A Phase II Subsurface Investigation is normally invasive and is designed to evaluate the lithologic and hydrogeologic conditions by collecting soil, soil vapor, and groundwater samples. A variety of techniques and equipment are currently available for assessing the subsurface. Environmental subsurface investigation tools range in size, cost, and operating complexity from hand augers and hand-operated drive samplers to direct push technology (DPT) rigs to hollow stem auger rotary rigs. Samples are collected for field screening and physical testing. Selected soil, vapor, or groundwater samples are submitted under chain-of-custody procedures in a refrigerated environment (for volatile and semivolatile compounds) to a certified laboratory for chemical testing.

As part of Phase II, groundwater monitoring wells may be installed. Several Phase II Subsurface Investigations might be required prior to completing the Phase II process and fully characterizing the vertical and lateral extent of the soil and groundwater contamination.

PHASE III

A Phase III Corrective Action is the remediation portion of an environmental project. This phase involves designing and implementing the corrective action plan for remediation of soil and/or groundwater. A corrective action plan, evaluating remedial options and feasibility, is typically submitted to the regulator for approval prior to commencing the field work. A laboratory bench test might be designed to optimize biological or chemical conditions using soil and groundwater derived on site. This phase may also have a pilot test where the various technologies selected are field tested to verify the successes and failures prior to performing the full-scale remediation. After the bench tests and pilot scale tests, a final remedial action plan is usually prepared with the final selection of the remedial option.

Remediation might include extractive technologies (soil vapor extraction, groundwater pump and treat, dual phase extraction). These technologies remove liquids and vapors and treat the contaminants using a variety of above-ground technologies. Other technologies include bioremediation (*in situ*), chemical oxidation (*in situ*), monitored natural attenuation (*in situ*), soil excavation and removal to a landfill (dig and haul), or other technologies that are first evaluated in the corrective action plan.

Drilling techniques might be used during the remediation phase in designing and constructing vapor or groundwater extraction wells. In Phase III, it is unlikely that all contamination is removed, and therefore some residual amount of contamination will be left in place. A well-planned soil and groundwater confirmation sampling program is key to evaluating the success of a Phase III Remediation Project. As part of a Phase III Remediation Project, additional soil and groundwater sampling (a Remedial Investigation) might be planned if additional new source areas of impacted soil or groundwater are detected that were previously unknown.

Once the technology is selected and approved, the full-scale remediation is performed. Upon completing the full-scale remediation activities, equipment such as free-product pumping systems, soil vapor extraction, and aboveground air and water treatment units are demobilized and removed from the site. All drilling and remediation derived wastes are removed from the property. Site restoration may include replanting or resurfacing in disturbed areas.

PHASE IV

After remediation, the regulatory agencies generally require at least a minimum of 1 year quarterly groundwater monitoring verifying that the majority of the source of the contamination has been removed. This phase includes the proper abandonment of existing groundwater monitoring wells after site closure has been obtained. Phase IV might include a sensitive receptor survey to evaluate human health risks or sensitive environments that might be impacted if residual contamination is left in place. A risk based corrective action (RBCA) is a computer model that evaluates residual contamination as to the type of contamination, contamination levels in soil, vapor and groundwater, possible receptors, depth to the contamination, types of soils, and other factors. As part of the site closure process, deed restrictions may be required and notifications to any future contractors performing subsurface work that certain areas of the site might be impacted.

The Phase I to Phase IV project life cycle is an engineering approach that has been used on tens of thousands of sites. Every site is different, so the logical and stepwise approach is a generally accepted model for moving a project from initial discovery toward site closure.

INNOVATIVE CONTAMINATED GROUNDWATER REMEDIATION TECHNOLOGIES

Thomas B. Boving
University of Rhode Island
Kingston, Rhode Island

INTRODUCTION

Contamination of groundwater is a problem of global proportions. Ever increasing demand for clean water for human, industrial, and agricultural uses, forces society to protect groundwater resources from further pollution and also to restore already polluted aquifers. Groundwater contamination originates from numerous sources, such as accidental spills, illegal dumping, leaking landfills, industrial wastewater discharge, and leakage of underground storage tanks. A major problem is that once toxic compounds have entered the subsurface, they are very difficult and costly to remove using conventional remediation strategies. Conventional remediation methods, such as flushing-out the contamination with water (known as the pump-and-treat method), generally have been proven inefficient. The National Research Council indicated that large sums of money are wasted by implementing these conventional methods (4).

The development of improved methods for remediating of contaminated aquifers has become a major environmental priority (1,2). Many innovative remediation technologies have emerged that promise fast and cost-effective cleanup of contaminated ground water. According to Cherry et al. (3), there are two general types of new technologies, those that destroy or immobilize contaminants *in situ* (e.g., chemical oxidation, chemical reductive dehalogenation, cometabolic and other bioremediation processes) and those that bring the contaminant mass to the surface for treatment or disposal (e.g., enhanced-flushing technologies, thermal treatment).

The following is a discussion of innovative remediation methods. The description of these new technologies is selective and by no means complete. It focuses on the *in situ* remediation of contaminated aquifers and cleanup technologies for vadose zone contamination but neglects *ex situ* treatment technologies (e.g., soil washing, thermal desorption). This is not an attempt to describe the theoretical and technical details involved but rather a summary of the concepts and challenges inherent in subsurface remediation. For a more detailed discussion of innovative remediation technologies, refer to a number of excellent publications (1–5) or good Internet sources (e.g., Ground-Water Remediation Technologies Analysis Center at www.gwrtac.org/html/techs.html, USEPA Technology Innovation Office at www.epa.gov/swertio1/remed.htm, or clu-in.org).

ANATOMY OF A SPILL

The area where a spill occurred and where most of the contaminant mass is concentrated is called the source zone. Sometimes the extent of the source zone is known, but more often it is not—especially in case of older spills and illegal dumping. The source zone can be limited to the vadose (i.e., unsaturated) zone or, if a sufficient volume of liquid contaminant has been spilled, can include the saturated zone. Once in the subsurface, a contaminant can partition into the vapor or aqueous phase, can remain stationary at residual concentration, or can continue to migrate as a free phase. Diffusive vapor phase transport is an important contaminant-spreading mechanism in the vadose zone (6). Dissolved contaminants in the saturated zone are transported away from the source zone by advection and dispersion. The contaminated water emanating from the source zone is called the plume. The general shape of the plume is that of an elongated teardrop; it tends to be much longer than wide. Contaminant concentrations are highest near the source zone and decrease toward the plume's outer edges. Even if the source zone is removed, the plume's center of mass (mean position of solute mass) can continue to move downgradient and spread, causing the plume to become larger. The plume continues spreading until it is intercepted by a natural or man-made hydrologic boundary, such as a river, drain, or well. In absence of a hydrologic boundary, the plume may eventually slow down or stop spreading entirely, which is the case when the contaminant degradation rate is in equilibrium with the contaminant-spreading rate. This equilibrium has been observed in some cases where petroleum products were released from underground storage tanks. Conversely, the degradation rates of many synthetic contaminants (especially those of halogenated compounds) are extremely slow. Thus, there are examples where a plume can grow across large distances, often for many miles.

INNOVATIVE REMEDIATION TECHNOLOGIES

A large variety of toxic compounds have entered the environment, including organic and inorganic compounds, heavy metals, radioactive substances, and biological contaminants. Realizing that each of these compound classes has distinct chemical and physical properties, quite different remediation approaches are required. For instance, a method that works well for removing heavy metals will most likely not work for a gasoline spill and vice versa. Thus, there are as many different remediation strategies as there are classes of toxic compounds. The hydrogeologic setting of a contaminated site may also elude or favor a specific remediation method, and, in some cases, a combination of two or more remediation technologies may be advantageous. The following is a description of innovative remediation techniques that remove or immobilize contaminants and methods that destroy contaminants *in situ*.

Removal and Immobilization Technologies

Removal and immobilization of contaminants are popular subsurface remediation strategies. Immobilization is a technique often used for heavy metal stabilization or fixation. This technology relies on injecting agents that form stable and insoluble metal precipitates with metals such as mercury or radioactive nuclides. Recently, the role of biogenic metal fixation processes has also been investigated. One of the greatest obstacles to *in situ* metal immobilization is delivery of the precipitant to the contaminant because it requires careful control of the subsurface conditions, such as pH. Therefore, immobilization has been most successfully used for treating excavated sediments, such as dredged materials.

Although applicable to many contaminant classes, contaminant removal is most often used to eliminate organic contaminants—especially nonaqueous phase liquids (NAPL). NAPLs have been identified as one of the most important groups of environmental contaminants (4,7). Examples include chlorinated solvents, gasoline, polychlorinated biphenyls, creosote, and coal tar.

NAPL's have distinct physicochemical properties and can exist in different compartments in subsurface environments, occupying the pore spaces as separate liquids or gaseous phases, dissolved in water, or attached to soil particles (8). Fluids whose densities are less than that of water are known as light nonaqueous phase liquids (LNAPL). Examples include gasoline and crude oil. LNAPLs accumulate on the water table and in the capillary fringe zone. They may also migrate downgradient away from the source zone, dissolve into the ground water, or may smear throughout the upper part of the aquifer due to water table fluctuations. In contrast, a DNAPL is a nonaqueous phase liquid that is denser than water. Examples include trichloroethene (TCE) and 1,1,1-trichloroethane. A DNAPL, therefore, can sink below the water table into deeper parts of the aquifer. Due to interfacial forces, a fraction of the contaminant may be retained in pores as immobile globules or ganglia, which tend to dissolve very slowly (9). If a DNAPL encounters less permeable geologic strata (such as fine silt or clay horizons), it may form pools. DNAPL pools, ganglia, and globules are a major problem for site remediation because they tend to be relatively small and dispersed and thus difficult to locate. With an unfavorably low surface area to mass ratio, these DNAPL bodies serve as long-term sources of groundwater contamination (3).

Conventional pump-and-treat systems may work well for plume containment, but it is widely recognized that this method is neither an effective nor economical means of complete remediation of sites contaminated with NAPLs (10). Pump-and-treat methods remove contaminants from the subsurface by forced displacement of the immiscible liquid due to artificially increased pore water velocities and by dissolution into the groundwater. Because most field sites require unrealistically high hydraulic gradients to displace residual NAPLs, dissolution is the primary removal mechanism. Thus, the inefficiency of the pump-and-treat approach is attributed to the low aqueous solubility of most NAPLs and the relatively large interfacial tensions between the groundwater and the NAPL. Overcoming low solubility and large interfacial tension is one major strategy for removing NAPLs from the subsurface. Methods that modify the contaminant solubility and interfacial tension are known as chemically enhanced flushing technologies. Based on the removal mechanism, chemically enhanced flushing technologies can be grouped loosely into two categories: (1) mobilization and removal of NAPL through immiscible displacement and (2) increase of the apparent solubility of a NAPL in the aqueous phase and removal by enhanced dissolution. Chemical agents that have been used for enhanced flushing include cosolvents (5,11), surfactants (5,12), dissolved organic matter (13), and complexing agents, such as cyclodextrin (14,15,18) (see Table 1).

Enhanced flushing of contaminated aquifers generally requires injecting an aqueous solution containing a solubility-enhancing agent. This solution is flushed through the contaminated aquifer and then extracted. Enhanced flushing works best in permeable sediments, such as sand and gravel. Conventional injection and extraction wells can be used to control the flow field of the flushing solution. This application scheme is, in principle, similar to conventional pump-and-treat systems. But due to the solubility enhancing properties of the agent in solution, mass removal rates are much higher, and consequently remediation times are much shorter. Many solubility-enhancing agents, such as most surfactants, also decrease the interfacial tension between the NAPL and the aqueous phase, which can result in mobilization of the NAPL. In some cases, mobilization is desirable because it increases the overall mass removal rate. However, if mobilized NAPL escapes hydraulic control and migrates off-site or into deeper aquifer horizons (as can be expected of DNAPLs), previously uncontaminated areas can become contaminated. Some surfactants are also sorbed to the sediment, which increases the amount of surfactant required to remove the NAPL. In addition, many cosolvents and surfactants are somewhat toxic, and there is concern about residuals left behind in the subsurface after primary remediation has been implemented. Thus, careful selection of appropriate enhancing agents and well-designed injection/extraction systems are crucial for successful application of chemically enhanced flushing technologies.

Thermal *in situ* treatment is a second approach for removing contaminants—especially volatile compounds and NAPL—from the subsurface. This method is based on heating polluted sediment and groundwater by hot air, water, steam, or energetic waves to move or mobilize contaminants toward extraction wells. The extraction wells capture the contaminants and deliver them to the surface for further treatment. In addition, heating can destroy contaminants that are unstable at elevated temperatures. Depending on the heat source, there are several thermal treatment methods available (Table 2). A special case of thermal treatment is *in situ* vitrification, which has been used to destroy or immobilize pesticides, heavy metals, and dioxins. This method requires heating the contaminated sediment by applying strong electrical currents until the contaminated sediment melts. After cooling, the vitrified material bears little resemblance to the original sediment, and it can no longer be considered an aquifer.

Air sparging and soil vapor extraction (SVE) are methods commonly used for removing volatile contaminants from groundwater and the vadose zone, respectively. Air sparging requires installing air injection and vacuum extraction wells. The injection wells are placed in the

Table 1. Chemically Enhanced Flushing Methods for Contaminant Removal from the Subsurface

Method	Removal Mechanism
Cyclodextrin flushing	Hydrophobic contaminant can form a complex within the hydrophobic interior of the cyclodextrin molecule. Because the cyclodextrin's exterior is hydrophilic, the contaminant/cyclodextrin complex has a higher solubility compared to the contaminant in aqueous solution. It can then be flushed out of the ground and treated on the surface.
Surfactant flushing	Above the critical micelle concentration, surfactant molecules cluster together to form micelles. The micelles have a hydrophobic interior into which hydrophobic contaminants can partition. Like cyclodextrin, the micelle's exterior is hydrophilic and therefore water-soluble. The contaminant bound within the micelle can then be flushed out of the ground and brought to the surface for further treatment. In addition, surfactant can lower the interfacial tension between a NAPL and the aqueous solution. This can result in NAPL mobilization.
Cosolvent flushing	The addition of cosolvents, e.g., ethyl or methyl alcohol, decreases the polarity of the aqueous phase. This enhances the dissolution of hydrophobic contaminants, which can then be flushed out of the ground. Sometimes, cosolvents and surfactants are applied together.
Dissolved organic matter flushing	Dissolved organic matter is usually applied as humic acid solution. The humic acid attracts hydrophobic contaminants and facilitates their transport. The humic acid/contaminant solution is then extracted from the ground and treated on the surface.

Table 2. Thermal Treatment Methods for Contaminant Removal from the Subsurface. Based on the Mechanism of Delivering Heat to the Contaminated Zone, Several Approaches are being Used

Method	Source of Heat and Removal Mechanism
Hot air injection	Hot air is injected through injection wells. Volatile contaminants evaporate or mobilize. The contaminant phase is captured by extraction wells. Some instable contaminants may break down when heated.
Steam injection	Similar to hot air injection, but steam is the source of heat.
Hot water injection	Injection of hot water into the source zone. Contaminants are mobilized and can be extracted from the subsurface.
Thermal conduction	Heat is transferred to the contaminated zone from heated steel wells or by using thermo blankets (shallow aquifers). Removal mechanisms are evaporation and destruction.
Radio-frequency heating	Contaminants evaporate when sediment is heated by radio waves. Wells function as antennas from which the radio waves are emitted.
Electrical resistance heating	Steel wells deliver an electrical current that heats up the sediment and groundwater. Contaminants evaporate or break down.

contaminated zone and screened below the water table. Air is pumped into the wells and forced to bubble through the contaminated aquifer. Volatile contaminants, such as gasoline and most solvents, move from the aqueous phase into the air phase. The vapors rise to the water table and into the vadose zone where they can be pulled out of the ground by vacuum extraction wells. SVE works similarly to air sparging, but vapors are removed only from the vadose zone. The vapors are pulled out of the unsaturated sediment using vacuum extraction wells. Additional air vents or air injection wells can aid SVE. In contrast to air injection wells, air vents passively allow fresh atmospheric air to enter the vadose zone. In most cases, injecting oxygen-rich atmospheric air into the subsurface enhances the bioactivity, which, in return, can result in faster breakdown of many contaminants. An extraction well can be converted into an injection well, which allows minimizing dead zones (parts of the contaminated zone that are bypassed). Depending on the size of the contaminated area, the number of wells can range from a few to more than a hundred. SVE and air sparging technologies are widely used because they are comparably inexpensive and require little engineering.

Phytoremediation is another innovative contaminant removal method. This method involves using plants to remediate contaminated water and sediments. The principal processes involved are phytostabilization, phytodegradation, phytoextraction, and phytovolatilization (Table 3). The contaminants are usually taken up in dissolved form. The efficiency of phytoremediation depends on a variety of factors, such as pH, soil properties, climate, and plant physiology. Phytoremediation, for example, has been used for remediating nitroaromatic explosives and heavy metals (19). A shortcoming of this method is that it is inefficient during winter months and it is confined to relatively shallow zones of contamination.

In Situ Destruction Technologies

The innovative remediation technologies that have been discussed so far were mostly aimed at immobilizing or removing the contaminant form the subsurface. A second strategy is based on *in situ* destruction of contaminants. Biotic and abiotic methods are available. Both approaches are discussed in the following sections.

Oxidation Processes. Many organic contaminants, such as petroleum hydrocarbons, solvents, and pesticides, can be destroyed or converted into harmless compounds when exposed to chemical oxidizers. Oxidation is a process by which an oxidant provides the chemical energy (e.g., as free oxygen radicals) to change the chemical composition of the target molecule into an oxidized and less harmful state. A simple example is the oxidation of methanol to carbon dioxide and water.

$$2CH_3OH + 3O_2 \longrightarrow 2CO_2 + 4H_2O$$

Potassium or sodium permanganate ($KMnO_4$, $NaMnO_4$) and hydrogen peroxide (H_2O_2) are commonly used oxidants for site remediation. When dissolved in water and injected into the contaminated zone, the oxidant comes in contact with the contaminant and destroys it. Because not all of the oxidant is consumed in most cases, it may be necessary to extract the remaining solution. The success of *in situ* oxidation is determined by the oxidant's ability to reach the contamination, which is relatively unproblematic in sand and gravel deposits but can be a challenge in dense silt and clay. Because permanganate converts into much less soluble manganese dioxide (MnO_2), precipitation and subsequent reduction in the aquifer's permeability may be problematic.

Another *in situ* oxidation technology is based on Fenton's reaction. Fenton's reagent is a mix of H_2O_2 and iron salts that are injected into the contaminated zone. The presence of the iron salt creates hydroxyl radicals that readily oxidize chlorinated solvents and other contaminants, such as fuel oils and BTEX. The Fenton's reagent reaction is much more efficient than H_2O_2 alone, but a disadvantage is that Fenton's reagent is toxic to microbes, making it incompatible with bioremediation.

Table 3. Phytoremediation Methods for Contaminant Removal from the Subsurface

Method	Removal and Remediation Mechanism
Phytostabilization	Contaminants are bound in the plant tissue.
Phytodegradation	Plant-assisted microbial or enzymatic breakdown of contaminants.
Phytoextraction	Bioconcentration of contaminants within harvestable zone of the plant.
Phytovolatilization	Plant takes up and volatilizes contaminants via its leaves.

The injection of ozone (O_3) has been used to remediate sites contaminated with polycyclic aromatic hydrocarbons (PAHs), fuels, chlorinated solvents, and other contaminants. Ozone is a strong oxidant and, compared to oxygen, is 12 times more soluble. Therefore, it can be delivered to the contaminant much more efficiently. However, the half-life of O_3 limits its ability to migrate through soil across large distances. Ozone is a gas and must be generated on-site, for example, by using ultraviolet light. *In situ* ultraviolet (UV) oxidation is a special case of ozone treatment. This technique exposes the contaminated groundwater to ozone and H_2O_2 generated by intense UV radiation. UV radiation is provided by UV light bulbs that are installed inside a well. The target contaminants are destroyed by direct reaction with the oxidizers and through the interaction with UV light.

Each oxidizing agent has its own special treatment application, and the selection of the oxidizing agent is based not only on the contaminant type but also on sediment and groundwater properties. Some oxidizing agents are corrosive or can cause explosions if not handled adequately. However, when designed properly, chemical oxidation is safe and has been used at hundreds of sites.

Reduction Processes. Environmental hydrogeologists have realized that zero-valent iron effectively reduces many halogenated contaminants if placed within the flow path of contaminated groundwater (16). This revelation resulted in the development of a new remediation technology, permeable reactive barriers (PRB). A PRB requires installing a permeable barrier ("wall") across the flow path of a contaminant plume. The plume moves passively through the wall, and the dissolved contaminants come in contact with reactive materials that either degrade or retain the contaminants. The earliest PRBs were iron walls that consisted of a narrow trench filled with zero-valent iron granules mixed with sand and gravel. These iron walls were first tested for passive treatment of dissolved chlorinated contaminants such as TCE. As the TCE comes in contact with the iron, its chlorine atoms are removed by one or more reductive dechlorination mechanisms. The necessary electrons are supplied by the oxidation of iron. Given sufficient residence time, the TCE degrades to harmless compounds (chloride, water, etc.), and clean groundwater flows out the other side of the PRB. Since then, other active agents such as a palladium-enhanced metal catalyst, chelators, sorbents (e.g., carbon), precipitators (e.g., limestone), and microbes were added to the PRB system to retain or destroy those compounds that the iron walls could not degrade sufficiently. By including a funnel-and-gate system the PRB's efficiency is further enhanced. The funnel-and-gate system for *in situ* treatment of contaminated plumes consists of barriers of low hydraulic conductivity (e.g., slurry walls or sheet piles). Like a funnel, the barriers channel the contaminated water to a gate that contains the *in situ* reactor (17).

PRBs are widely used to control organic contamination in ground water; but they have been applied to metals (e.g., chromium VI) and radionuclide contaminants too. Passive treatment walls are generally intended for long-term control of the migration of contaminants in groundwater. An important advantage of this technology is that no pumping and no moving parts are required. Thus, this technology may be more cost-effective than pump-and-treat methods. In the United States, several dozens PRBs have been installed, but this technology is currently limited to sites with relatively shallow plumes (less than 50 ft). The installation of a PRB requires a comparatively high initial investment and a commitment to long-term monitoring, which is because the treatment approach is limited to the contaminant plume and does not target the source zone itself.

Bioremediation. Microorganisms can use many contaminants as food and energy sources and, in the processes, break down these compounds. *In situ* groundwater bioremediation, also called enhanced biodegradation, is a remediation technology that encourages growth and reproduction of indigenous microorganisms (yeast, fungi, or bacteria) that enhance the biodegradation of toxic organic constituents. Creating a favorable environment for the microorganisms can stimulate the activity of microbes. Generally, this means providing some combination of electron acceptors (oxygen, nitrate), nutrients (nitrogen, phosphorous), moisture, and controlling the temperature and pH. In most cases, electron acceptors and nutrients are the two most critical components of a bioremediation system. These compounds are delivered by pumping air and nutrient solutions into the contaminated zone. Sometimes, microorganisms adapted to degradation of the specific contaminants or additional food sources (e.g., molasses) are added to enhance the biodegradation process.

Bioremediation can take place under anaerobic and aerobic conditions. In anaerobic conditions, no oxygen is present. The microorganisms break down chemical compounds and release the energy they need. Aerobic conditions support biological activity in which microorganisms use available atmospheric oxygen to function. Anoxic conditions exist when nitrate is the base of microorganism respiration. With sufficient oxygen, microorganisms will convert many organic contaminants to carbon dioxide and water. Degradation pathways can be very complex. Sometimes intermediate products that are less, equally, or even more toxic than the original contaminants are produced. Some contaminants are also degraded by enzymes produced by microbiological metabolism. These enzymes aid the degradation of contaminants that are difficult or impossible to treat otherwise (e.g., cometabolic biodegradation of TCE).

In situ groundwater bioremediation is a widely used technology because it can effectively degrade dissolved and adsorbed organic constituents. As a general rule of thumb, short-chain, low molecular weight, and more water-soluble compounds are biodegraded more rapidly and to lower residual levels compared to long-chain, high molecular weight, less soluble compounds. The effectiveness of bioremediation systems is controlled by how well electron acceptors and nutrients can be delivered to the contaminated zone and how bioavailable and biodegradable the target contaminants are. Aerobic degradation has been proven most effective for treating aliphatic and aromatic petroleum hydrocarbons (e.g., gasoline and diesel fuel). Anoxic, anaerobic, and cometabolic approaches are sometimes used for remediating chlorinated solvents, but remediation rates are generally slower compared to aerobic respiration of petroleum hydrocarbons.

Natural Attenuation. Dilution, dispersion, volatilization, biodegradation, adsorption, and chemical reactions with subsurface materials are processes that occur naturally and help to reduce the concentration, toxicity, and mobility of chemical or radioactive contaminants. Natural attenuation relies on these processes. Therefore, natural attenuation is not a technology as such, but rather is a cleanup strategy that uses nature's own decontamination capabilities. Nonetheless, natural attenuation is not a "do nothing" solution because it requires careful monitoring and testing of the processes that take place in the subsurface. For example, long-term contaminant degradation rates have to be sufficient to ensure public health and compliance with regulatory criteria. Therefore, monitoring of plume spreading or changes in hydrogeological, geochemical, or microbiological conditions that might reduce the effectiveness of natural attenuation is required.

Because natural attenuation does not require direct human intervention, it has become a very popular remediation strategy at many contaminated sites. However, natural attenuation may not be a viable method for removing the source of the pollution, because many of the natural attenuation mechanisms may be inactive in the presence of high contaminant concentrations. In these instances, other remediation methods must be used to remove the bulk contamination first.

CONCLUSION

Innovative remediation technologies have greatly improved the effectiveness of subsurface cleanup operations. Some technologies have already progressed into full-scale commercial applications; others remain in the developmental stage or have just emerged from research labs. However, remediation costs can be extremely high, and there is an ongoing debate about the economical cost of remediation versus the gains to public health. Against this background, improved risk assessment methods and concepts are necessary to ensure optimum remediation effectiveness—regardless of the remediation technology used.

RESISTIVITY METHODS

Hamid R. Jahani
Water Research Institute
Hakimieh, Tehran, Iran

INTRODUCTION

Many problems connected with groundwater can be investigated by geophysical methods. Of these, situation of water table, thickness of aquifer, delineation of weathered or fracture zone, fresh–salt water interfaces, groundwater quality, and groundwater pollutant flow direction are the most important.

Among all surface geophysical techniques for groundwater prospecting, geoelectrical methods are the most widely applied methods for both alluvial plains and karstic terrains all over the world because of their high capability in detecting water-bearing layers and because they are simple and inexpensive in carrying out field investigation.

The rock matrix of most geological formations is basically highly resistive and does not conduct electricity. There are, however, exceptions such as clay and shale, which are conducting minerals. These formations have low electrical resistivities when compared with other rock formations. Normally, the resistivity of a rock formation reduces only when it contains moisture. This reduction in resistivity depends on the relative quantity and quality of the water it contains.

In nature, groundwater is stored in geologically formed pore spaces. When these pores are interconnected, the groundwater moves from a high potential to a low potential zone. The rock layers at different depths have different "porosities" and, consequently, different water content. The more water in a formation, the lower the electrical resistivity, provided there is no other conducting layer such as clay or shale. If the contained water is brackish or saline, the resistivity of that layer drops even further (1).

The conductivity of an underground formation also varies as its homogeneity varies. The variation in conductivity affects the flow density, which, in turn, affects the distribution of the potential difference under the ground. The size of this effect depends on the size, shape, position, and resistivity of the heterogeneity.

If we suppose that heterogeneity is a spherical void in a karstic limestone filled with water or clay (a good example of a highly conductive material inside one of low conductivity), the concentration of the flow inside the void would be much more than that out of the void and, to the same extent, the variation in potential difference would be different (Fig. 1). This variation can be detected at the ground surface (2).

Thus, by measuring or determining the resistivities of earth layers at different depths, it is possible to infer indirectly the hydrogeologic character of a particular subsurface layer and also the quality of water it contains. The most applicable geoelectrical methods are resistivity methods in which an electrical current is passed into the ground so that the current distributes itself according to the conductivities of the geologic materials coming under the influence of the current.

RESISTIVITIES OF GEOLOGICAL FORMATIONS

The resistivity of rocks and minerals has a wide range (Fig. 2). For example, fresh igneous and metamorphic rocks have resistivities up to 10^5 to 10^6 ohm-m (ohm-meters), whereas shale and clay have resistivities less than 10 ohm-m. No other physical property found in geophysical prospecting varies so widely (3) and this is one of the best reasons for applying resistivity methods.

RESISTIVITY METHODS: THEORY AND APPLICATION

Resistivity (ρ) is a physical property of a substance. It is defined as the resistance to the flow of electric current by a unit cube of the substance when voltage is applied across the opposite faces. It is expressed in ohm-l (l is meters, feet, . . .). The resistance of a substance is a function of the resistivity, size, and shape. If the substance has a regular shape, then

$$R\rho L/A \tag{1}$$

where R = resistance, ohm;
ρ = resistivity of the substance, ohm-m;
L = length of the substance, m; and
A = cross-sectional area, m^2.

The inverse of resistivity is called conductivity.

We usually deal with heterogeneous media in geologic formations, so the term "apparent resistivity" is used instead of resistivity.

Measurement of Resistivity

In general, at least four electrodes are required for measuring the resistivities of subsurface formations. An electric current is introduced between one pair of electrodes, called current electrodes. The potential difference produced by current flow is measured by another pair of electrodes, called potential electrodes or probes. The apparent resistivity measured is (1):

$$\rho_{\mathrm{a}} = K(\Delta V)/I$$

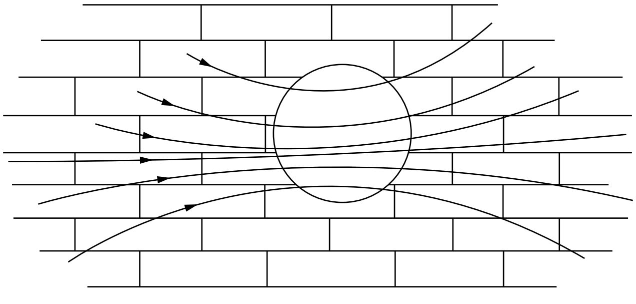

Figure 1. Concentration of electrical current in a spherical void filled with water or clay in a limestone formation (1).

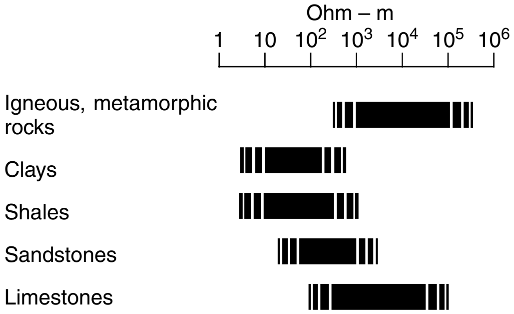

Figure 2. Ranges of resistivity in ohm-meters for some geologic formations (3).

where ρ_a = apparent resistivity, ohm-m;
K = geometric factor, which depends on the type of electrode configuration selected; and
I = electric current, (A).

Electrode Configurations. There are several electrode arrangements for geoelectrical operations (4):

Wenner Array. In this configuration, the four electrodes A, M, N, and B are placed along a straight line (Fig. 3), and $AM = MN = NB = a$.

Schlumberger Array. Schlumberger array is the most widely used method in electrical prospecting. In this configuration, the four electrodes are placed along a straight line in the same order as the Wenner array, but $AB > 5MN$ (Fig. 4).

Lee Partitioning Array. Lee partitioning array is the same as the Wenner array except that an additional potential electrode O is placed at the center of the array between the potential electrodes M and N (Fig. 5).

Dipole–Dipole Array. In this array, the distance between the current electrodes A and B (current dipole) and the distance between the potential electrodes M and N (measuring dipole) are significantly smaller than the distance r between the centers of the two dipoles (Fig. 6).

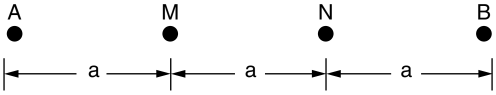

Figure 3. Wenner array (5).

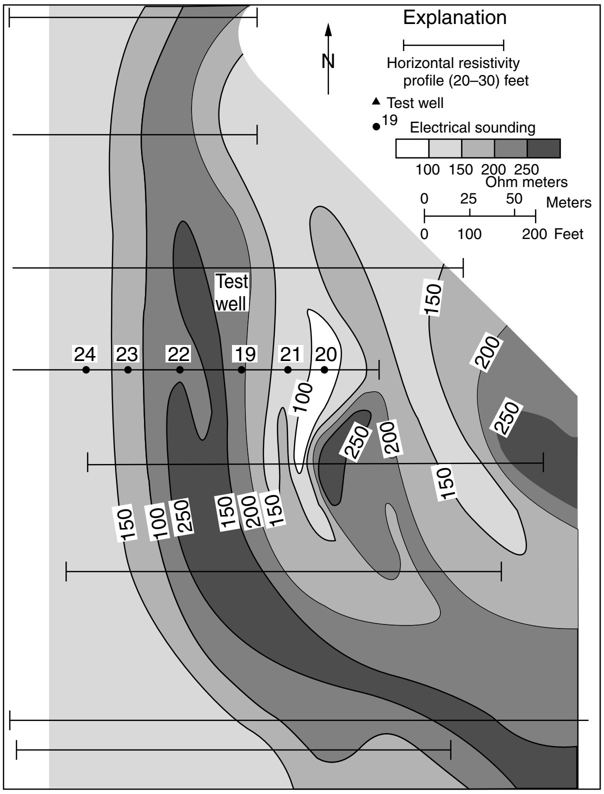

Figure 9. An apparent resistivity map for a site at Campbel, California. The low resistivity zone delineates a buried stream channel (5).

Electrical Sounding and Horizontal Profiling

Electrical sounding is a process for depth investigations, and horizontal profiling is a process for detecting lateral variations in resistivity. The basis for an electrical sounding, regardless of the electrode array selected, is that the farther away from a current source the measurement of the potential is made, the deeper the probing will be. So a curve of electrode spacing against apparent resistivity is made (Fig. 7).

In horizontal profiling, a fixed electrode spacing is chosen (preferably based on the results from a previous

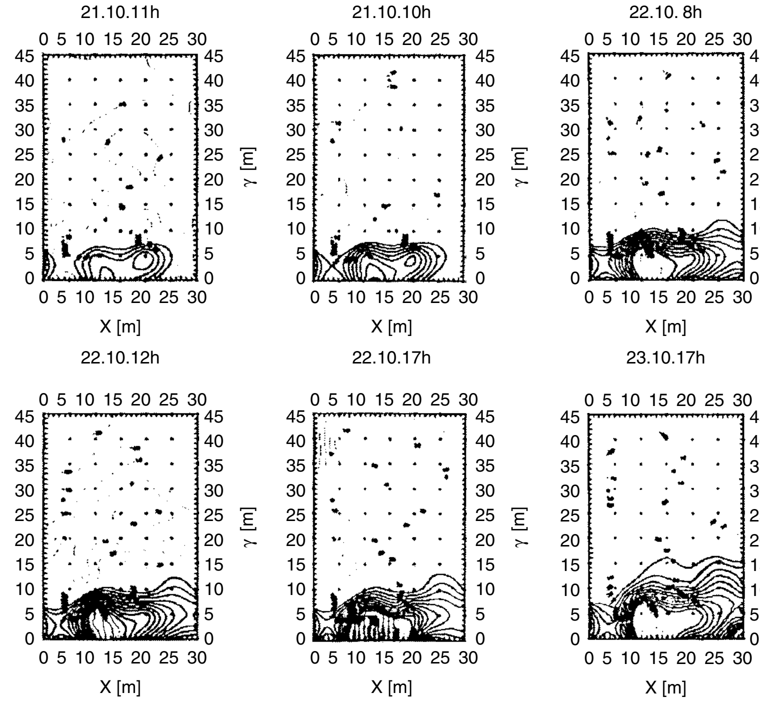

Figure 10. Determining pollution flow direction and velocity by the resistivity method (9).

electrical sounding), and the whole electrode array is moved along a profile horizontally. So a curve shows the variation of apparent resistivity for different points along the profile. Maximum apparent resistivity anomalies are obtained by orienting the profiles normal to the strike of the geologic structures.

Usually, the result of electrical sounding and horizontal profiling are apparent resistivity sections and maps. These plots indicate the variations in geoelectrical properties of the study area in vertical and planar surfaces, respectively. These plots can help in understanding the underground structure and lithology of different geoelectrical behaviors known for different geologic formations (Figs. 8 and 9).

RESISTIVITY METHODS AND GROUNDWATER POLLUTION STUDIES

Geoelectrical methods can be used easily to investigate groundwater contamination because pollution or any dissolved solid in groundwater directly affects its electrical conductivity and resistivity. So this method can be used to detect pollution plumes provided that the pollution has changed the resistivity of the groundwater enough to be detected.

Two case studies will be presented here to show the capability of the technique. In the first, a "tracer" has been intentionally introduced into the groundwater system, and the changes in groundwater resistivity have been investigated to find the velocity and direction of the tracer movement. In the second case, the resistivity method has been used to map the extent of the pollution zone in groundwater beneath a waste disposal site.

Case Study 1

This case is actually a single well technique in which a tracer is injected into the aquifer through a borehole. The tracer is NaCl, which is cheap and also has good electric properties. It is important to remember that this substance is selected to increase the conductivity of the water. If the study site is composed of saline soil and saline groundwater, injection of fresh water would again result in a suitable resistivity contrast. Before injection, geoelectrical sounding and horizontal profiling should be performed so that the base geoelectrical condition of the formation can be understood.

The study case is an unconfined shallow aquifer consisting of coarse gravel in Germany. A network for resistivity measurements is considered along the south–north direction, which, it is thought, is the direction of groundwater flow. After injecting 250 kg of salt, resistivity was measured every 5–6 hours at all points. The result is shown as isoresistivity maps in Fig. 10. The movement of the salt plume is clearly shown on the maps, and its velocity has been calculated as 7 meters per day. Contrary to what was supposed before, the direction of the movement of the plume was almost from west to east (7).

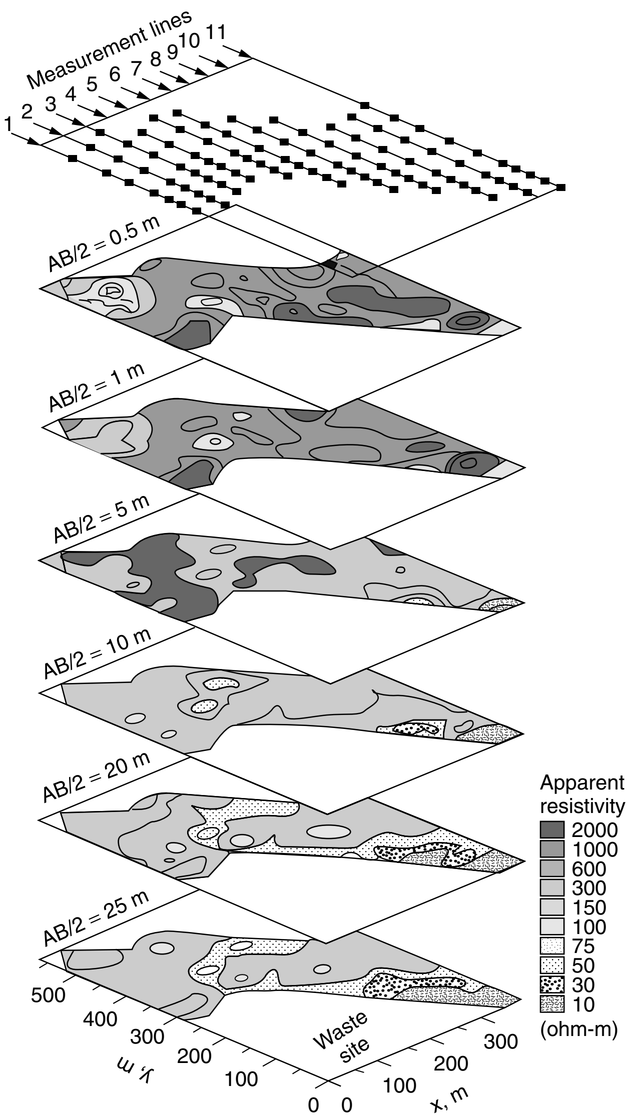

Figure 11. Geoelectrical measurement lines and apparent resistivity maps for different electrode spacings (8).

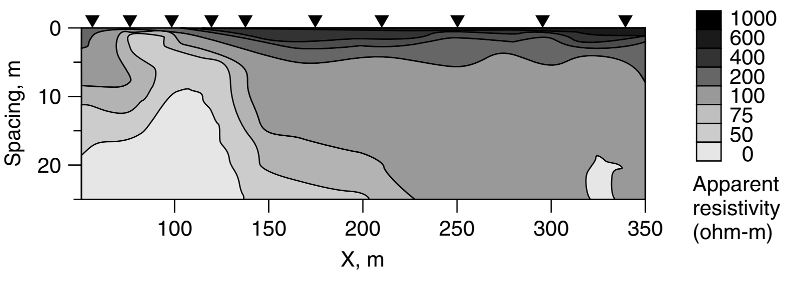

Figure 12. Resistivity pseudosection from south–north along measurement line 9 (8).

Next Page

Case Study 2

In this case, the resistivity method has been used to map the extent of contamination induced by an open waste disposal site and to determine where to locate future monitoring wells. The site is located SE of the city Isparta, Turkey, on a nearly 100 m thick Quaternary alluvial deposit of gravel, sand, and clay. The Schlumberger sounding resistivity method was used to map resistivities from 0.5 down to 25 meters in depth. Figure 11 shows the apparent resistivity maps for different electrode spacings. As expected, leachate from the waste disposal site has decreased groundwater resistivity. The deeper layers are characterized by low resistivities, and the shallower ones by high resistivities.

A resistivity pseudosection along measurement line 9 is performed, and the result is shown in Fig. 12. As can be seen, the low resistivity front from the waste disposal site base is characterized by its low resistivity and is developing northward. So, the extent of groundwater pollution can easily be manifested using geoelectrical mapping (8).

RISK ANALYSIS OF BURIED WASTES FROM ELECTRICITY GENERATION

Bernard L. Cohen
University of Pittsburgh
Pittsburgh, Pennsylvania

An important aspect of generating electricity from nuclear power is the disposal of the high level radioactive waste. The most widely anticipated plan is to convert it into a rock-like material and bury it deep underground, typically 600 meters below the surface. In evaluating the safety of this procedure, a key element is to estimate the probability per year, P, for an atom of this buried waste to be dissolved by groundwater and eventually enter a human stomach. Obviously, this probability is site dependent and depends on present underground characteristics and future events in the region, many of them unpredictable, including climate changes, geological land uplifting causing rivers to change their courses, volcanoes, earthquakes, and human intrusion.

INTRODUCTION

A first estimate of P can be obtained by considering that all properties of the region are the U.S. average (lower 48 states); the purpose of this article is to obtain such an estimate. Most relevant characteristics and future changes in them are occurring somewhere in the United States and are hence taken into account with or including some estimate of their probability of occurrence. The value of P we obtain can be interpreted as the average value of P for a large number of randomly chosen sites. It seems reasonable to assume that the very elaborate site selection efforts by geological and hydrologic experts should choose a site at least as secure as a randomly chosen site.

We assume that the waste converted to a rock-like material behaves like average rock—differences between them will be considered later—and calculate P for average rock. P can be calculated as the dissolution rate, R, the probability per year for an atom of the rock to be dissolved in groundwater, times the probability, p, for an atom once dissolved into groundwater to enter a human stomach:

$$P = R \times p \tag{1}$$

Dissolution Rate for Rock, *R*

We begin by calculating R. From the rate at which rivers carry dissolved and suspended material into the oceans, it is estimated (1) that the surface of the continent is eroding at an average rate of 5×10^{-5} (hereafter, we use the notation 5 E−5) meters per year (hereafter, m/y). About 28% of this material is in solution, corresponding to 1.4 E−5 m/y removed by chemical dissolution. It is estimated (2,3) that 15% of the water flow in rivers is derived from groundwater (aquifers), and the rest comes from surface runoff. If the concentrations of dissolved materials were the same in rivers as in aquifers, this would mean that the latter dissolve $(0.15 \times 1.4\text{ E}{-5}) = 2.1\text{ E}{-6}$ m/y of rock thickness. The average concentrations of a few dissolved materials in aquifers (4) and in river water (5) are listed in Table 1. Silica and calcium are such important

Table 1. Average Concentrations in mg/kg of Dissolved Materials in Aquifers[a] and in River Water[b]

Material	Silica	Calcium	Magnesium	Potassium	Iron	Uranium
Aquifers	20	30	3	2	0.3	3 E−4

RISK ANALYSIS OF BURIED WASTES FROM ELECTRICITY GENERATION

Bernard L. Cohen
University of Pittsburgh
Pittsburgh, Pennsylvania

An important aspect of generating electricity from nuclear power is the disposal of the high level radioactive waste. The most widely anticipated plan is to convert it into a rock-like material and bury it deep underground, typically 600 meters below the surface. In evaluating the safety of this procedure, a key element is to estimate the probability per year, P, for an atom of this buried waste to be dissolved by groundwater and eventually enter a human stomach. Obviously, this probability is site dependent and depends on present underground characteristics and future events in the region, many of them unpredictable, including climate changes, geological land uplifting causing rivers to change their courses, volcanoes, earthquakes, and human intrusion.

INTRODUCTION

A first estimate of P can be obtained by considering that all properties of the region are the U.S. average (lower 48 states); the purpose of this article is to obtain such an estimate. Most relevant characteristics and future changes in them are occurring somewhere in the United States and are hence taken into account with or including some estimate of their probability of occurrence. The value of P we obtain can be interpreted as the average value of P for a large number of randomly chosen sites. It seems reasonable to assume that the very elaborate site selection efforts by geological and hydrologic experts should choose a site at least as secure as a randomly chosen site.

We assume that the waste converted to a rock-like material behaves like average rock—differences between them will be considered later—and calculate P for average rock. P can be calculated as the dissolution rate, R, the probability per year for an atom of the rock to be dissolved in groundwater, times the probability, p, for an atom once dissolved into groundwater to enter a human stomach:

$$P = R \times p \tag{1}$$

Dissolution Rate for Rock, *R*

We begin by calculating R. From the rate at which rivers carry dissolved and suspended material into the oceans, it is estimated (1) that the surface of the continent is eroding at an average rate of 5×10^{-5} (hereafter, we use the notation 5 E−5) meters per year (hereafter, m/y). About 28% of this material is in solution, corresponding to 1.4 E−5 m/y removed by chemical dissolution. It is estimated (2,3) that 15% of the water flow in rivers is derived from groundwater (aquifers), and the rest comes from surface runoff. If the concentrations of dissolved materials were the same in rivers as in aquifers, this would mean that the latter dissolve $(0.15 \times 1.4\ \text{E}{-5}) = 2.1\ \text{E}{-6}$ m/y of rock thickness. The average concentrations of a few dissolved materials in aquifers (4) and in river water (5) are listed in Table 1. Silica and calcium are such important

Table 1. Average Concentrations in mg/kg of Dissolved Materials in Aquifers[a] and in River Water[b]

Material	Silica	Calcium	Magnesium	Potassium	Iron	Uranium
Aquifers	20	30	3	2	0.3	3 E−4
Rivers	7	15	4	2.2	0.5	4 E−4

[a] Ref. 4.
[b] Ref. 5.

components of rock that we interpret these data to indicate that aquifers carry about twice the concentration of dissolved material in rivers, which leads to the conclusion that $[30/(30+85)] = 26\%$ of the dissolved material in rivers, $(0.26 \times 1.4\ \mathrm{E}{-5}) = 3.6\ \mathrm{E}{-6}$ m/y of rock depth, is contributed by aquifer dissolution of rock.

The next problem is to estimate what fraction of this material, f, is removed per meter of depth at 600 m; let us say from between 599 m and 600 m. As a crude gross overestimate, we might assume that rock erosion is constant with depth down to 600 m and zero below 600 m, in which case $f = 1/600 = 16\ \mathrm{E}{-4}$. A more reasonable approach is as follows: The annual circulation of groundwater, defined as the quantity per year entering or leaving aquifers at the stated depth, has been given (2,3) as

shallow (<800 m) : 310 E9 cubic meters per year

deep (>800 m) : 6.2 E9 cubic meters per year

If we assume that the flow decreases exponentially with depth and that the rate of rock dissolution is proportional to this groundwater flow, determining the constants in the relationship from these data, we find (6) that $f = 2.6\ \mathrm{E}{-4}$, one-sixth of our crude gross overestimate.

Using this gives the quantity of rock eroded per year per meter of depth at 600 m below the surface as $(3.6\ \mathrm{E}{-6} \times 2.6\ \mathrm{E}{-4}) = 1.0\ \mathrm{E}{-9}$ m/y. If 1.0 E−9 m/y of depth is dissolved from one meter of rock depth, the probability per year for an atom of that rock to be dissolved must be 1.0 E−9. Thus,

$$R = 1.0\ \mathrm{E}{-9} \tag{2}$$

This result plays a key role in our risk analysis, so it is interesting to seek alternative approaches to calculating it. One such approach follows: A typical aquifer reaching to the waste burial depth of 600 m may be about 100 km long and have a flow velocity of 100 m/y through rock of 10% porosity, discharging into a river The water discharged from it annually per square meter of cross-sectional area is then 10% of the volume of a column of water 100 m long and one square meter in cross section, which is 10 cubic meters, or 10,000 liters (L).

Chemical analyses of groundwater (4) indicate that it typically contains 30 mg/L or 30 E−6 kg/L (milligrams per liter, or kilograms per liter) of Calcium (Ca), so it discharges (30 E−6 kg/L × 10,000L =) 0.3 kg of Ca into the river each year. This is the first entry in Column (2) of Table 2. This calcium was derived by dissolution from the rock through which the aquifer had passed, 100 km, or 1E 5 m, long, one square meter in cross section, and a specific gravity of about 3.0, which gives it a mass of $(3000 \times 1\ \mathrm{E}5) = 3\ \mathrm{E}8$ Kg. Typical rock contains 5% Ca (1), so the Ca contained in this source rock is $(0.05 \times 3\ \mathrm{E}8) = 15\ \mathrm{E}6$ kg; this is the first entry in Column (3) of Table 2. If 0.3 kg of Ca per year is dissolved from 15 E6 kg of Ca in the rock, the probability for a Ca atom to be dissolved must be $(0.3/15\ \mathrm{E}6) = 2\ \mathrm{E}{-8}$ per year; this is the first entry in Column (4) of Table 2. Table 2 includes data for other materials, obtained analogously to that for Ca.

Table 2. Calculation of Fractional Removal per year of Rock Materials by a Typical Aquifer. Columns (2) and (3) refer to a 1 Square Meter Cross Section of the Aquifer. See Discussion in Text

(1) Material	(2) Kg/y into River	(3) Kg in Rock (× 1 E6)	(4) Fraction Removed (× 1 E−8)
Ca	0.3	15	2
Mg	0.03	3	1
K	0.02	3	0.7
Fe	0.003	9	0.03
U	3 E−6	8 E−4	0.3
Silica	0.2	150	0.13
Carbonate	1.3	18	8

Of the materials listed in Table 2, the materials in the radioactive waste are most similar to Fe and U and not at all similar to carbonate ions. Thus, the numbers in Column (4) of Table 2 might give an estimate of about $R = 7\ \mathrm{E}{-9}$, seven times higher than Eq. 2. But the aquifer we have assumed in this calculation is substantially more robust than the groundwater encountered by average rock at 600 m depth, so it seems reasonable to conclude that Eq. 2 is roughly verified.

Probability of Transport from Groundwater to Human Stomachs, *p*

Next we turn to the problem of estimating the probability of transferring an atom of material dissolved in groundwater into human stomachs, p in Eq. 1. We assume that once the material is dissolved in groundwater, it moves with groundwater, eventually reaching shallow aquifers that feed into rivers. Contributions to p derive from our use of rivers and wells drilled into aquifers for potable water, from fish removed from rivers and used for food, and from use of well and river water for irrigating food crops. The potable water path is the simplest to calculate and, it turns out, the most important. The average person ingests 2 L/day of potable water which corresponds to ingestion by the U.S. population of $2 \times 365 \times 2.8\ \mathrm{E}8 = 2.0\ \mathrm{E}11$ L/y (liters per year). Of this, 45% is derived from wells, and 55% comes from rivers (7), corresponding to 9 E10 and 1.1 E11 L/y respectively entering human stomachs. The estimated water flow in U.S. rivers is 1.7 E15 L/y (1) and 1.9 E15 L/y (2,3); we use 1.8 E15 L/y. The estimated water flow in aquifers is 16% of the flow in rivers (3), or 2.9 E14 L/y The contributions to p from the use of rivers and wells for potable water are then

$$p(\text{rivers}) = (1.1\ \mathrm{E}11/1.8\ \mathrm{E}15) = 6.1\ \mathrm{E}{-5}$$

$$p(\text{well water}) = (9\ \mathrm{E}10/2.9\ \mathrm{E}14) = 3.1\ \mathrm{E}{-4}$$

Note that we have ignored removal of material by filtration processes, making these conservative estimates, that is, more likely to be high than low.

Analyses of the fish and irrigation contributions to p will be sketched below. They give results that vary considerably from element to element because of variations in bioaccumulative factors (8). For the fish pathway, $p(\text{fish})$ is rarely larger than 1 E−5, and for most important elements in the waste, it is much smaller. For the irrigation pathway, $p(\text{irrigation})$ is rarely more than 1 E−4 and somewhat less for the most important elements in the waste. We therefore take as conservative estimates

$$p(\text{fish}) = 1\ \text{E}{-5}$$

$$p(\text{irrigation}) = 1\ \text{E}{-4}$$

Summing these four contributions gives $p = 5\ \text{E}{-4}$. Using this and Eq. 2 in Eq. 1 then gives the result we are seeking for P:

$$P = (1\ \text{E}{-9} \times 5\ \text{E}{-4}) = 5\ \text{E}{-13} \tag{3}$$

Alternative Approach for Transfer from Rock to Human Stomachs

We now present an essentially independent method (9) for calculating P, based on our knowledge of quantities of elements entering human stomachs each year (10,11) and the quantities of these materials in rock (5), supplemented by an estimation of the fraction of these that derive from soil rather than from rock.

We begin with the very crude assumption that all material entering human stomachs derives from the top 600 m of rock. We know how much of each chemical element is contained in this rock (5), and we know how much of each chemical element enters human stomachs each year (10,11), so the ratio of these gives a crude estimate of P for each element. An average of these, weighting for the importance of each element in the waste, gives

$$P(\text{very crude}) = 1\ \text{E}{-11}$$

Some of the crudeness of this estimate may be reduced by dropping the implication that all depths of rock down to 600 m are equally likely to contribute and assuming that the contribution from various depths is proportional to the groundwater flow at that depth. Using the exponential decrease in this flow alluded to before, it turns out that the flow at 600 m depth is 16% of the average for the top 600 m, giving an improved, but still rough estimate:

$$P(\text{rough}) = (0.16 \times 1\ \text{E}{-11}) = 1.6\ \text{E}{-12}$$

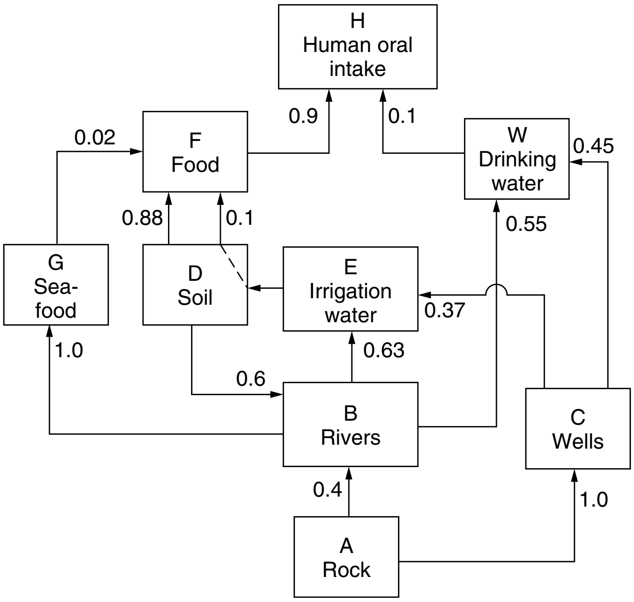

Figure 1. Pathway diagram for transmission of materials from rock and soil into food and water ingested by people. Numbers attached to each line show the fraction of the input to the target box that is derived from that line.

This result is still an overestimate because most of the material entering human stomachs derives from the top layers of soil rather than from the underlying rock. To analyze this problem, a pathway analysis was developed (9) as shown in Fig. 1. The numbers attached to the arrows are the fraction of the input into the compartment derived from that arrow. For example, 90% of human oral intake is from food, and 10% is from drinking water; 2% of the minerals in food comes from seafood (derived from rivers), 88% comes directly from soil, and 10% comes from soil via irrigation water (which is derived 63% from rivers and 37% from wells). Using Fig. 1, the various pathways from rock to human stomachs and their fractional contributions to human intake are then calculated as

$$\begin{array}{lr}
\text{ABWH} & 0.4 \times 0.55 \times 0.1 = 0.022; \\
\text{ACWH} & 1.0 \times 0.45 \times 0.1 = 0.045; \\
\text{ABEFH} & 0.4 \times 0.63 \times 0.1 \times 0.9 = 0.023; \\
\text{ACEFH} & 1.0 \times 0.37 \times 0.1 \times 0.9 = 0.033; \\
\text{ABGFH} & 0.4 \times 1.0 \times 0.02 \times 0.9 \underline{= 0.007}; \\
 & \text{TOTAL} \ = 0.13
\end{array}$$

Our final value for P is then

$$P(\text{final}) = (0.13 \times 1.6\ \text{E}{-12}) = 2\ \text{E}{-13} \tag{4}$$

This result, Eq. 4, is in substantial agreement with the estimate from Equation 3 derived from essentially independent approaches.

HIGH LEVEL WASTE VERSUS AVERAGE ROCK

This result applies to average rock, but our interest is in applying it to the rock-like material, probably a borosilicate glass, into which the waste has been converted. The principal difference is in leachability by groundwater. Leach rates by distilled water for various rocks and glasses have been measured, and the results were correlated with the Gibbs free energy of hydration (12). It was concluded that the leach rate for borosilicate glass is similar to that for basalt and about three times more rapid than the leach rate for average rock. Applying this to the results in Eqs. 3 and 4 gives the rate of transfer for an atom of buried high level waste into a human stomach as about 1.0 E−12 per year.

Concerns have been raised that the high level waste glass may be much less secure than average rock because it is not in chemical equilibrium with the local rock–ground water regime. However, chemical equilibrium is a surface phenomenon (13,14). Groundwater is saturated with dissolved silica. If a foreign silica-based material such as glass is emplaced, there is initially rapid dissolution, removing a very thin surface layer. But this brings more silica into the water which then becomes supersaturated with silica, resulting in precipitation of silica from the water onto the surface—this would be the most insoluble component of the silica originally in the water. The result is a buildup of highly insoluble silica on the surface. Waste can then be dissolved only by diffusion through this surface layer, a very slow process. Moreover, this leads to further thickening of the surface layer, which further retards the diffusion process. Consequently, the rate of dissolution decreases exponentially, only a tiny fraction of the waste becomes involved in the process, and dissolution proceeds only as for the surrounding rock.

GROUNDWATER CONTAMINATION FROM RUNOFF

NITISH PRIYADARSHI
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

Groundwater is water that lies below the soil surface and fills the pore spaces in and around rock, sand, gravel, and other materials. Groundwater, under most conditions, is safer and more reliable for use than surface water because surface water is more readily exposed to pollutants from factories, for example, than groundwater. This by no means says that groundwater is invulnerable to contamination. Once groundwater is contaminated, it is extremely costly to remove the contaminant. Any chemicals that are easily soluble and penetrate the soil are prime candidates as groundwater pollutants.

HOW MUCH DO WE DEPEND ON GROUNDWATER?

According to 1985 U.S. figures, groundwater provides an estimated

- 22% of all freshwater withdrawals
- 53% of drinking water for the total population and 97% of drinking water for the rural population
- 40% of public water supply withdrawals
- 46% of domestic and commercial use
- 24% of industrial and mining use
- 34% of agricultural use (mostly for irrigation)

CAUSES OF URBAN RUNOFF

Urban runoff can be attributed to many things, including the amount of rainfall, the soil conditions, and the degree of urbanization. Rainwater can go in many directions once it has reached the earth's surface. Rainwater can be absorbed by the soil on the land surface; absorbed by surrounding vegetation; directly deposited into oceans, streams, and rivers; and infiltrate through the surface and subsurface soils into the groundwater.

Urban runoff can happen anytime of the year when excessive water use from irrigation, car washing, and other sources carries litter, lawn clippings, and other urban pollutants into storm drains.

The majority of people live in cities that are becoming larger and larger and are sprawling into vast suburban neighborhoods. Roofs, parking lots, streets, and other impervious surfaces of an urban environment cause rainwater to collect and be forced out through a storm drain system. If the drainage system does not connect to a wastewater treatment facility, then the rainwater and everything that is carried with it travels into groundwater, local streams, and rivers.

GROUNDWATER CONTAMINATION FROM URBAN RUNOFF

Not too long ago, urban runoff was considered an insignificant contributor to groundwater contamination. Urban runoff is now recognized as a significant source of contamination in water. Effluents from urban areas contain large concentration of oils, greases, nutrients, heavy metals, and detergents. Detergents that are soluble can pass through the soil and pollute groundwater. Raw sewage dumped in shallow soakpits and seepage from polluted lakes, ponds, and streams also pollute groundwater. Rainfall could pick up substantial contaminants from dust and air and join the aquifer below. The infiltration of liquids containing toxic pollutants may cause pollution in sandy soils and well waters.

Some of the contaminants expected in urban runoff are shown in Table 1. Groundwater moves through rocks and subsurface soil, so it has lots of opportunity to dissolve substances as it moves. For that reason, groundwater often has more dissolved substances than surface water. Even though the ground is an excellent mechanism for filtering out particulate matter, such as leaves, soil, and bugs, dissolved chemicals and gases can still occur in large enough concentrations in groundwater to cause problems. Underground water can be contaminated through urban runoff containing industrial, domestic, and agricultural chemical wastes, which includes chemicals such as pesticides and herbicides that many homeowners apply to their lawns. Contamination of groundwater by road salt is of major concern in northern areas of the United States. Salt is spread on the roads to melt ice, and salt is so soluble in water that excess sodium and chloride is transported through runoff after ice melts and finally contaminates subsurface groundwater.

In the United States today, there may be more than 20,000 known abandoned and uncontrolled hazardous waste sites, and numbers grow every year. If there is a leak, these contaminants may be carried away with runoff and finally make their way down through the soil and into the groundwater.

Landfills are another major source of contamination. Landfills are the places where our garbage is taken to be buried. Landfills are supposed to have a protective bottom layer to prevent contaminants from getting into the water. After rainfall, contaminants from the landfill (car battery acid, paint, household cleaners, etc.) are washed away with surface runoff and make their way down into the groundwater. The problem of pollution from landfills is greatest where high rainfall and shallow water tables occur. Important pollutants frequently found in leachate include BOD, COD, iron, manganese, chloride, nitrate, hardness, and trace elements. Hardness, alkalinity, and total dissolved solids are often increased.

Chemicals include products used on lawns and farm fields to fertilize plants. The primary fertilizers are compounds of nitrogen, phosphorus, and potassium. Phosphate and potassium fertilizers are readily adsorbed on soil particles and seldom constitute a pollution problem. But nitrogen in solution is only partially used by plants or adsorbed by the soils, and it is the primary fertilizer pollutant (1). When the rain comes, this chemical is washed away with the surface runoff and eventually goes into the groundwater.

Animal wastes are confined within a limited area, in beef or milk production, so large amounts of waste are deposited on the ground. Thus, for the 120 to 150 days that a beef animal remains in a feedlot, it produces more than a half ton of manure on a dry weight basis. When thousands of animals are in a single feedlot, the natural assimilative capacity of the soil becomes overtaxed. Surface runoff in contact with the manure carries highly concentrated pollutants to subsurface waters. Animal wastes may transport salts, organic loads, and bacteria into the water and soil. Nitrate-nitrogen is the most important persistent pollutant that may reach the groundwater (2).

Sanitary systems have a significant impact on shallow aquifers in urban areas. Field observations revealed that contamination of groundwater is caused by infiltration of surface runoff polluted by municipal waste and sewage and/or leakage of sanitary effluents. It has increased the salt content of groundwater, particularly nitrates

Table 1. The Contaminants that may be Expected in Runoff[a]

1. Asbestos from brake and clutch linings
2. Bacteria and viruses from animals and birds, soils, litter, livestock hauling, livestock waste hauling and on-site sewage tanks and fields
3. Bromide from auto exhaust
4. Cadmium from tire fillers and insecticides
5. Chromium from moving engine parts and brake linings
6. Copper from bearing and bushing wear, moving engine parts, brake linings, and radiator repair
7. Cyanide and chloride from deicing road salts
8. Pesticides (fungicides, herbicides, and insecticides) from roadside maintenance
9. Iron from auto bodies, moving engine parts, bridges, guardrails, overpasses, lamp standards, and other structures
10. Manganese from moving engine parts and gasoline additives
11. Nickel from diesel fuel, lubricating oil, bushing wear, brake linings, and asphalt paving
12. Nitrogen from animal wastes, on-site sewage systems, vegetative matter, and fertilizers
13. Petroleum compounds from paving, fuels spills, engine blow-by, lubricant leaks, antifreeze, and hydraulic fluids
14. Phosphorus from animal wastes, on-site sewage systems, vegetative matter, and fertilizers
15. Potassium from fertilizers
16. Sulfate from roadbeds, road salts, and fuels
17. Zinc and lead from tire fillers, motor oil additives, automotive and radiator repairs, grease, and paint manufacturing

and chlorides, and has reduced the oxygen content. In addition, introduction of pathogenic bacteria and viruses into groundwater has caused many outbreaks of waterborne disease.

Solid materials are frequently stockpiled near industrial plants and construction sites. These may be the raw materials awaiting use, or they may be solid wastes placed for temporary or permanent storage. Precipitation falling on unsheltered stockpiles may transport heavy metals, salts, and other inorganic and organic constituents as pollutants to the groundwater.

Urban runoff pollutants are many and varied, depending on land uses and pollutant sources in an urban area. Typically, loadings of urban pollutants are greatest from industrial and commercial areas. Although sources of specific pollutants may vary widely in urban areas, motor vehicles are recognized as a major source of pollutants; they contribute oils, greases, hydrocarbons, and toxic metals such as lead, zinc, copper, chromium, and arsenic.

SALINE SEEP

JOHN E. MOORE
USGS (Refired)
Denver, Colorado

Jackson (1) defines saline seep as an intermittent or continuous saline water discharge at or near the soil surface under dryland conditions that reduces or eliminates crop growth. Human induced salinization of land and water resources due to water table rise is as old as the history of human settlement and irrigation (2). Early settlements in the valleys of the Tigris and Euphrates flourished about 4000 B.C.: however, the irrigated farming of wheat resulted in salt accumulation, and in time the area was abandoned. Historic evidence from Russia, China, India, Pakistan, South American, United States, Canada, and Australia show that saline seeps are a worldwide problem. The number of saline seeps will probably increase in the future because an increase in world population will be accompanied by increases in irrigation.

Saline seeps result from a combination of geologic, climatic, and management factors. Development of a seep starts at the recharge area. As the water moves through the aquifer, the water dissolves and accumulates salts. Saline seeps are formed by mobilization of salt stored in the soil profile. The very act of irrigation is the cause for salinity because every irrigation event adds some salt to the soil. Land clearing or irrigation can cause the groundwater to rise. The additional water moves the water table closer to the land surface. When the water table is within 2–3 feet of the surface, capillary action can lift the water to the surface where it evaporates and leaves salts behind (Figs. 1 and 2).

The salt can also move laterally to affect streams. The common soil forming minerals calcium, sodium, magnesium, and potassium form water-soluble salts in the soil.

Techniques for controlling seeps originated in Montana and Alberta (3). The two major methods to control seeps are (1) cut off the recharge water and (2) reclaim the seep area. Installing subsurface tiles to intercept the groundwater flow might cut off recharge water. The second method is to increase water use in the recharge area by changing the type of crop. Alfalfa is an excellent crop substitute because it is a deep-rooted perennial capable of

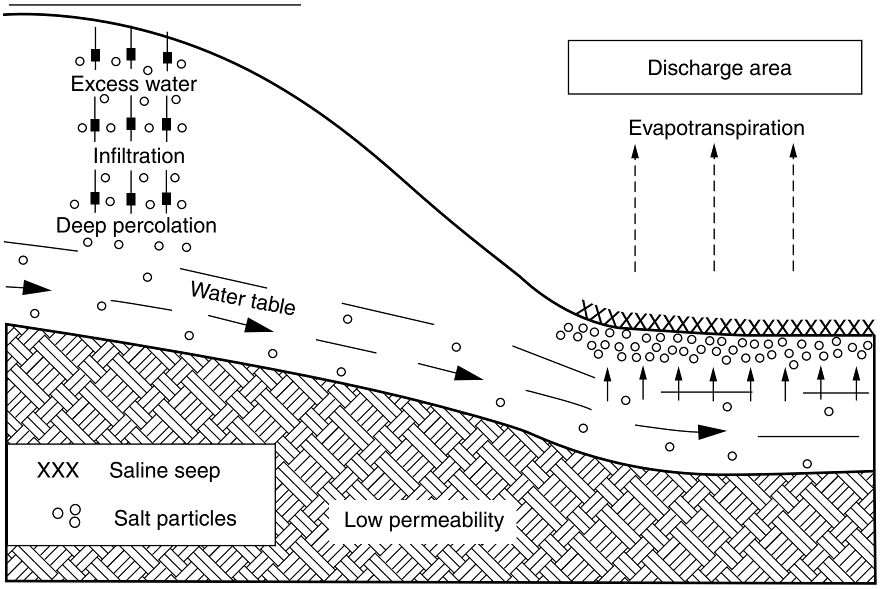

Figure 1. Water movement to seep.

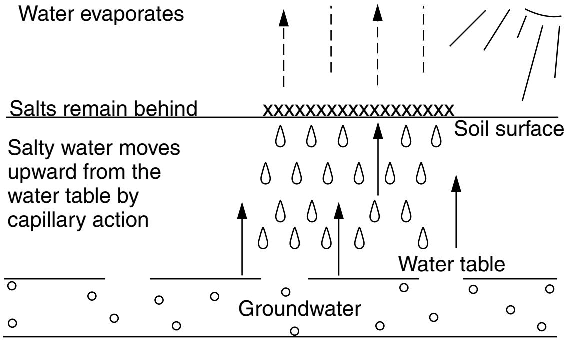

Figure 2. Evaporation and salt concentration.

using large amounts of water. Seeps have been reclaimed within 5 years by planting alfalfa in the recharge area (4).

In southeast Australia, the replacement of deep-rooted native vegetation by dryland and irrigated agriculture has resulted in a major change in surface water and groundwater systems in the Murray–Darling basin. The Murray River has a salinity of less than 25 mg/L in the headwaters and 480 mg/L downstream. Water that was previously used by vegetation for transpiration is now leaking past the vadose zone and entering the water table. The salinization process is closely linked to groundwater changes. In both irrigation and dryland farming, salts are remobilized into the production zone. The salts were originally stored in the aquifer or the vadose zone. Evaporation concentrates the salts in the near surface zone to levels where the plants are. For salinization to occur, it is necessary to have both a hydrologic change and a source of salt.

Saline soils and sodic soils are quite common in parts of western North Dakota and Montana. Most saline seeps have developed recently (postsettlement). The formation of saline seeps is closely related to the practice of summer fallow for moisture conservation (5).

Colorado River has 25 mg/L salt in the headwaters and 825 mg/L downstream at Imperial Dam. In the San Joaquin River in California, salinity increased from 330 mg/L in the 1930s to 600 mg/L in the 1970s. In the former Soviet Union, the salinity of the Syr Darya River which discharges to the Aral Sea increases from 300 mg/L to 2000 mg/L downstream.

The water table rise in agricultural areas of the world has contributed to the salinization of large areas. The development of land and water resources of the earth will be more difficult and more expensive than in the past. The control of population and the efficient use of developed resources will be essential in the future.

GROUNDWATER SAMPLING TECHNIQUES FOR ENVIRONMENTAL PROJECTS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Groundwater sampling techniques are important for accurate project results and understanding aquifers whether the project is sampling a groundwater monitoring well as part of an environmental assessment or regular sampling of a potable water supply well. Detailed groundwater sampling information can be obtained from Testa (1), Jacobs (2), the American Society for Testing Materials (3), the California Regional Water Quality Control Board (4), and Driscoll (5). Although there are numerous differences in groundwater sampling and record keeping techniques, regional variations, and specific regulatory requirements that vary from state to state, a generalized summary of selected environmental groundwater sampling techniques is given below.

PURPOSE OF GROUNDWATER SAMPLES

Groundwater samples are collected for a variety of reasons. Groundwater can be collected as a "grab" sample or from a monitoring well. Groundwater samples are used to define the vertical and aerial extent of groundwater contamination, to monitor target chemical concentrations over time, to provide a measurement for detecting a contaminant plume front, to evalvate unexpected changes in plume size or direction of flow, to determine the extent of interaquifer movement of contaminants, to determine aquifer characteristics such as permeability, transmissivity, etc.), to estimate the rate of contaminant plume movement, to develop a data base for designing remedial measures, to determine the effects of the remedial measures, to assist in performing the remedial work (provide hydraulic control and contaminant removal), to provide data base for groundwater modeling, and to evaluate the aquifer during regular sampling over the yearly hydrologic cycle (6).

GRAB GROUNDWATER SAMPLING

A "grab" groundwater sample is collected without the use of a fully installed groundwater monitoring well. Methods include using a bailer or jar to collect groundwater from an excavation or trench made with a backhoe or excavator. Other "grab" samples can be collected using a drilling rig wherein a sampler is drilled or pushed to the target depth and the sampler is pushed a bit further into the aquifer. Water is allowed to collect in the sampler. The water is removed from the sampler using a bailer or by using a peristaltic pump and tubing, check-ball valve with tubing or other similar methods. These methods, frequently called punch methods, are commonly used with hollow stem auger rigs or direct push technology rigs. Cone penetrometer (CPT) rigs can use specialized groundwater containers that are inserted into a cavity of the water sampler tip. The groundwater containers are under a vacuum. At the proper depth, the sampler is opened, the groundwater container is pierced, and water enters the container.

Temporary wells are used occasionally in environmental investigations. A temporary well consists of a well screen below a casing riser placed in an open borehole. Several well volumes can be purged prior to sampling. A bailer or other method is used to bring the water to the surface. After groundwater sampling is completed, the borehole is usually tremie grouted to seal the annulus.

WATER WELLS

Water wells are installed using a variety of rigs: hollow stem auger, mud or air-rotary, air percussion, diamond coring, cable tool, and others. After well installation, wells are developed within a day to several days of installation to remove residual drilling materials from the well bore and to improve well performance by removing any fine material in the filter pack that can pass from the native soil into the well. Well development techniques include pumping, bailing, surging, jetting, and airlifting. In most cases, surging and pumping are satisfactory. Development water is inspected for turbidity, product sheen, odors, and sediment. A minimum of several casing volumes is removed during development. The well is considered fully developed when consistent pH, temperature, and conductivity readings indicate characteristic groundwater for the aquifer. If the aquifer is slow to recharge, development will continue until the well is pumped dry. Cross contamination of wells from pumps is avoided by using dedicated equipment and proper decontamination procedures.

Due to the large volumes of purge water generated during groundwater sampling and the costs for storage and disposal of the water, some regulatory agencies are now allowing various low-flow groundwater sampling techniques for compliance groundwater monitoring. Proponents of micropurging suggest that evacuation of a specific volume of water may increase turbidity from agitation or mixing of the well water column. Larger purge volume may increase the risk of colloid mobilization. Proper well development immediately after well construction is essential when using low-flow sampling (7).

Micropurging is the evacuation of tubing, sampling devices, and other items from the well prior to sampling groundwater. There is no purging prior to sample collection with micropurging, so there is no method for determining if the well contains stagnant well water or water representative of the aquifer. For this reason, many regulatory agencies do not approve micropurging. Instead, when minimal purging is requested, low-flow sampling is preferred.

The low-flow sampling method, typically used in 2-inch diameter groundwater monitoring wells, relates to the amount of drawdown in a well during purging. The indicator parameters are collected before and during purging and allowed to stabilize prior to groundwater sample collection. Purge rates may be higher than sample rates to maximize purge efficiency. Prior to the collection of the groundwater sample, the pump rate may be lowered to lower sample turbidity and entrained air in the sample, and to mimic conditions that may exist in the natural aquifer. High turbidity in water samples being analyzed for metals requiores filtering to remove colloidaland suspended sediments that may contain metals.

Discrete sampling systems are designed to collect groundwater samples form the formation at a specific depth or multiple target depths without significant purging prior to sample collection.

GROUNDWATER SAMPLING PROTOCOL

Depth to the top of the water and free-product thickness within wells are monitored by using a water level meter or an interface probe. Water level data collected from areas that have multiple wells are used to develop groundwater contour maps for the project site. Groundwater flow is perpendicular to equipotential lines drawn on the map. If free-product is detected, a product sample is sometimes collected for source identification. In environmental projects, where several chemicals are to be analyzed for a given well, individual samples are collected in order of decreasing volatility. When the results from previous sampling are known, it is recommended to start sampling the cleanest wells first, moving to the most contaminated wells later in the sampling event.

Each chemical analysis requires specific sample preservation techniques or additives. Sealed chemical ice is placed in the coolers to maintain samples at a temperature of 4 °C. Where several types of chemicals are to be analyzed for a given well, individual samples are collected in the following order: volatile organic compounds, purgeable organic compounds, purgeable organic halogens, total organic compounds, total organic halogens, extractable organic compounds, total metals, dissolved metals, phenols, and cyanide.

QUALITY CONTROL OF GROUNDWATER SAMPLES

A QC program, which is independent of the laboratory's program, verifies sample integrity and includes the submittal of duplicates, field blanks, and travel blanks to the laboratory. The QC samples are packaged and sealed in the same manner as the other samples and are assigned independent sample numbers.

A duplicate sample is collected for about 5% of the samples or one per sampling round, whichever is greater. The duplicate sample is acquired by filling separate containers from the same well bailer as the actual sample. The contents of the bailer are evenly divided between the actual and duplicate samples to ensure duplication. The field blank is submitted to the laboratory for the same analyses as the rest of the sampling set. The field blank is acquired by dispensing deionized water from a clean sampling bailer into the containers in the same manner as groundwater samples. When sampling groundwater for analyzing volatile compounds, travel blanks are used to detect the introduction of contaminants during transportation from the field to the laboratory. The travel blank generally contains deionized water, which has been poured into the container prior to being taken into the field.

GROUNDWATER SAMPLING WITH PASSIVE DIFFUSION SAMPLERS

Craig E. Divine
Colorado School of Mines
Golden, Colorado

INTRODUCTION: DIFFUSION-BASED GROUNDWATER SAMPLING METHODS

Passive diffusion-based sampling methods have been used to monitor environmental contaminants, particularly trace metals and certain lipophilic compounds including polychlorinated biphenyls (PCBs), polynuclear aromatic hydrocarbons (PAHs), and pesticides, for many years. In particular, dosimeter-type and semipermeable membrane devices (SPMDs) are commonly used in limnology, oceanography, and ecotoxicology for evaluating ultralow concentrations and potential bioavailability of contaminants (1–4). These types of samplers are most frequently used for sampling sediment porewater and surface water (i.e., rivers, estuaries, harbors) and have occasionally been used for groundwater characterization in contaminant toxicology studies (5). These types of sampling devices are composed of a "trapping" phase, such as hexane, activated carbon, or triolein (a prominent fish lipid), contained within a semipermeable membrane (such as dialysis-type cellulose or a synthetic polymer). On deployment, contaminants diffuse through the membrane and are subsequently retained in the trapping phase until analysis. After the SPMD is removed, the contaminants must typically be extracted from the trapping phase before analysis. A significant disadvantage with SPMDs and dosimeter-type devices for groundwater sampling is that back-calculation to actual *in situ* aqueous concentrations may not be straightforward due to nonlinear and/or nonequilibrium sorption behavior of the trapping phase (5).

Passive diffusion (PD) samplers are similar to dosimeter-type and SPMD sampling methods in that they generally consist of a sealed container with a semipermeable membrane. The PD sampler is suspended in a monitoring well, and the solutes of interest diffuse across the membrane into the sampler. However, unlike dosimeter-type devices and SPMDs, PD samplers do not contain a trapping phase but are instead filled with water or air. Therefore, once the PD sampler is retrieved from the well (after equilibration), the concentration measured in the sampler is assumed to relate directly to *in situ* analyte concentrations at the deployment location. Passive diffusion samplers are less expensive to construct than SPMDs and easier to analyze because no extraction step is required. Furthermore, the correlation between the contaminant concentration measured in the PD sampler and the surrounding environment is straightforward: for water-filled PD samplers deployed in groundwater the concentrations are equivalent.

Passive diffusion-type sampling methods have been used in a variety of applications for many years, including dissolved gas measurement in seawater and groundwater (3,6,7). Generally, PD samplers offer several potential advantages for monitoring many common groundwater contaminants, compared to conventional sampling techniques. For sites with ongoing monitoring programs, significant cost savings may be realized due to reduced sampling-related labor and minimal sampling-related waste generation. For dissolved constituents with large Henry's Law constants, such as volatile organic compounds (VOCs) and dissolved gases, analyte loss due to volatilization can be greatly minimized. In some cases, analytical matrix interferences may be reduced if the membrane is selective against interfering constituents (i.e., the matrix in the PD sampler may be comparatively less complex). Additionally, multiple PD samplers can be deployed to provide solute concentration measurements across very discrete intervals. For example, PD samplers with dialysis-type membranes have been used to characterize ion and trace metal concentration profiles on the scale of a few centimeters in sediment (3).

MEMBRANE MATERIALS AND SPECIFIC CONSTRUCTION EXAMPLES

Because of the potentially significant costs savings and technical advantages noted above, the use of PD samplers for groundwater monitoring at contaminated sites is greatly increasing [particularly water-filled PD samplers using low-density polyethylene (LDPE) membranes].

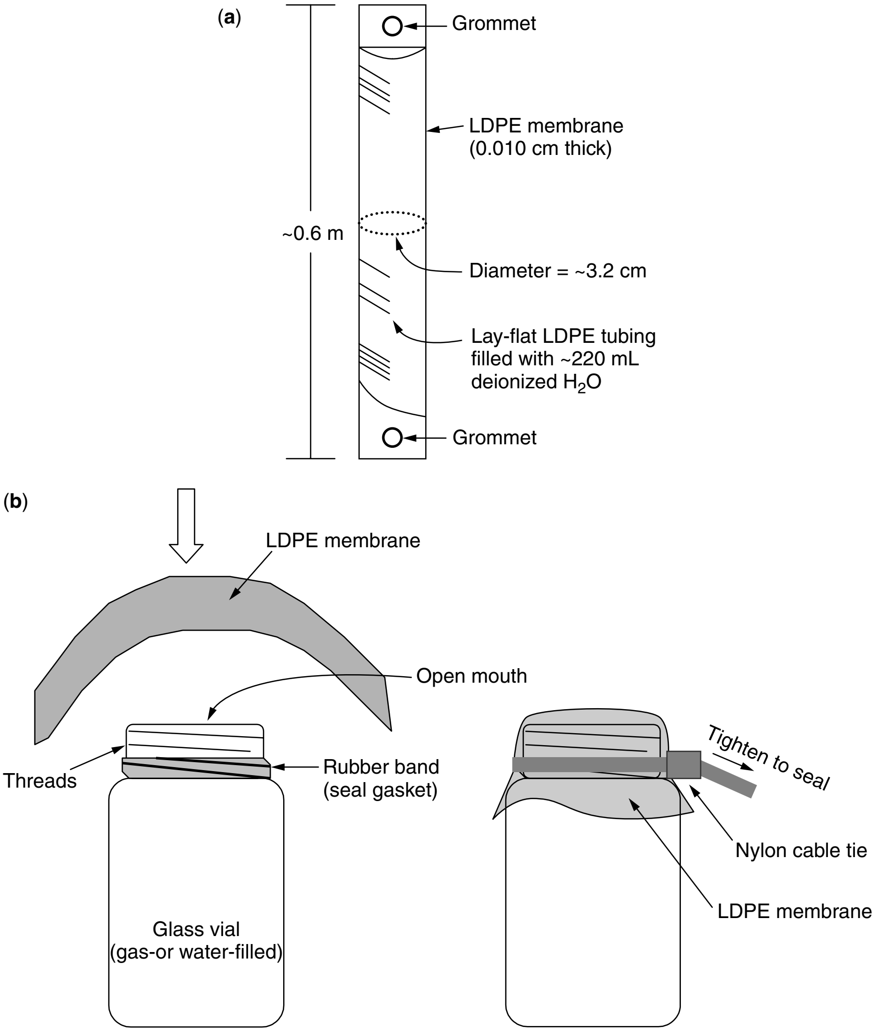

Figure 1. Schematics of passive diffusion samplers.

Laboratory and field compatibility tests indicate that LDPE membranes are suitable for most fuel and solvent VOCs; however, it has been demonstrated that the LDPE membrane is generally not suitable for measuring inorganic ions, metals, pesticides, explosives, semivolatile organics, alcohols, organic acids, and ethers [including methyl-*t*-butyl ether (MtBE)] with PD samplers (8,9). Dissolved gases, such as He, Ne, H_2, O_2, and N_2, can be measured by PD samplers with LDPE (10) or silicone (7) membranes. Passive diffusion-type samplers (also known as dialysis samplers or "peepers") that use other membrane materials, such as cellulose acetate, can be used to monitor major ions, metals, nutrients, dissolved gases, and pH (3,11).

Passive diffusion samplers can be constructed easily from inexpensive materials. As shown in Fig. 1a, the open mouth of a glass laboratory vial can be covered with a membrane and sealed with a rubber band gasket and nylon zip tie. Drop sheeting, which is widely available in the painting supply sections of hardware stores, can be used for LDPE membranes and is offered in a range of thicknesses. PD samplers filled with water can be constructed while submerged in deionized water to prevent entrapment of air bubbles. Passive diffusion samplers made of lay-flat LDPE tubing filled with deionized water are commercially available from EON Products, Inc. (Snellville, Georgia) and Columbia Analytical, Inc. (Kelso, Washington). A schematic of this type of sampler, which is also known as a PD "bag" sampler is shown in Fig. 1b. For a description of peepers and other PD samplers with dialysis-type membranes, see Davison et al. (3).

EQUILIBRATION TIME FOR PASSIVE DIFFUSION SAMPLERS

To prevent biased-low measurements, PD samplers must be deployed long enough in a well for equilibration to occur. Based on empirical laboratory and field studies, a minimum of 2–3 days is required for equilibration for most VOCs using commercially available LDPE PD bag samplers (8). Carnigan (12) found that some dialysis-type samplers require equilibration times of 3–20 days for measuring inorganics in porewater. Based on these general results, a minimum equilibration time of approximately 2 weeks is commonly recommended as a conservative approach in field studies (8,9). However, note that this is a generic rule of thumb. As equilibration is a diffusion process, the specific equilibration time depends on sampler volume, membrane surface area, membrane thickness, and the diffusion coefficient of the solute in the membrane material.

Sanford et al. (2) present the following solution that describes the concentration within the PD sampler as it equilibrates with the surrounding groundwater:

$$C_{\mathrm{s}}(t) = C_{\mathrm{r}}H\left[1 - e^{\left(\frac{-D_{\mathrm{m}}At}{\forall L_{\mathrm{m}}}\right)}\right] \tag{1}$$

where

$C_{\mathrm{s}}(t)$ concentration within the sampler at time t after PD sampler deployment [M L^{-3}],

C_{r} resident concentration at the measurement location [M L^{-3}],

D_{m} effective constituent diffusion coefficient for the membrane material [L^2 T^{-1}],

H solute dimensionless Henry's law constant [ ],

A surface area of the PD sampler membrane [L^2],

t deployment time [T],

$\forall$ internal volume of the PD sample [L^3], and

L_{m} membrane thickness [L].

This solution assumes Fickian solute diffusion across a thin membrane, a constant C_{r} concentration at the measurement location, and a well-mixed reservoir in the PD sampler. As presented, Equation 1 incorporates air–water partitioning and is applicable to gas-filled PD samplers deployed in groundwater, such as those described by Sanford et al. (7) and Divine and McCray (10). For conditions where no phase partitioning occurs (such as a water-filled PD sampler deployed in groundwater), Henry's law constant (i.e., the gas-water partition coefficient) is treated as unity.

As clearly shown in Eq. 1, the rate at which a PD sampler equilibrates relates directly to the D_{m} value of the solute, the sampler dimensions ($A, \forall$), and the thickness of the membrane (L_{m}). Therefore, PD samplers can be constructed to minimize equilibration times by using a thin membrane and increasing the $A/\forall$ ratio. The effective D_{m} value is temperature-dependent and specific to both the membrane and solute. Divine and McCray (10) estimated that a practical range is $1{-}4 \times 10^{-7}$ cm^2 s^{-1} for D_{m} values of several dissolved gases and VOCs for LDPE membranes. Sanford et al. (2) measured D_{m} values for helium and neon of 4×10^{-7} cm^2 s^{-1} for silicone membranes. Based on these D_{m} ranges, equilibration times are predicted using Eq. 1 for several PD samplers, including both constructed (Fig. 1a) and commercially available (Fig. 1b) samplers. The specific parameter values and resulting equilibration times are summarized in Table 1, and the predicted PD sampler concentration histories are shown in Fig. 2.

These results show the relative importance of the various parameters for equilibration times. For example, increasing the $A/\forall$ ratio reduces the equilibration time, and this can be accomplished for constructed PD samplers (Fig. 1a) by filling the sampler with inert sand or glass beads (i.e., compare results of Scenario 3 with Scenario 4). It is also important to note that Eq. 1 is valid only for advection-dominated systems. If the groundwater velocity is very low (diffusion-dominated systems), a concentration gradient will develop outside of the sampler, and equilibration times can be much longer (13). Equation 1 is appropriate, however, for most shallow aquifer systems.

CASE STUDY: APPLICATION OF PASSIVE DIFFUSIONS SAMPLERS AT A HETEROGENEOUS SITE

Passive diffusion samplers measure water quality directly in contact with the membrane surface; therefore, they generally measure concentrations at relatively discrete intervals within a well. Conversely, samples collected by conventional purge-and-bail methods tend to integrate water quality across the entire well screen region and therefore are most significantly influenced by water quality conditions in the highest permeable zones across the well screen interval. In other words, PD samplers tend to measure porewater concentrations over relatively small intervals, and purge-and-bail type methods tend to measure flux-weighted concentrations. For vertically uniform plume distributions and homogeneous aquifer

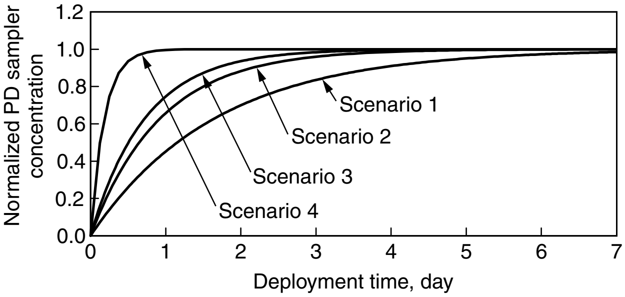

Figure 2. Passive diffusion sampler concentrations after deployment, predicted by Equation 1. The normalized concentration is defined as $C_{\mathrm{s}}/C_{\mathrm{r}}$ (at equilibrium $C_{\mathrm{s}} = C_{\mathrm{r}}$; therefore, $C_{\mathrm{s}}/C_{\mathrm{r}} = 1.0$). The parameter values used in the models are summarized in Table 1.

Table 1. Passive Diffusion Sampler Dimensions, Membrane Thickness, Membrane Diffusion Coefficients, and Predicted Equilibration Times for Various Constructed (Fig. 1a) and Commercially Available (Fig. 1b) PD Samplers. The Equilibration Time is Defined by Equation 1 when $C_{\mathrm{s}} \geq 0.95C_{\mathrm{r}}$)

	A, cm^2	$\forall$, mL	L_{m}, cm	D_{m}, (cm^2 s^{-1})	Equilibration Time, Day

conditions, results from these two sampling methods may be equivalent. However, these two methods may yield significantly different concentration values for a specific well at a heterogeneous site with plume stratification.

To illustrate this potential behavior, the concentrations of 1,1-dichloroethene (1,1-DCE) (a common VOC) measured at a monitoring well by purge-and-bail, low-flow [another discrete-type sampling technique; see Puls and Barcelona (14)]. PD sampling methods are shown in Fig. 3. The aquifer at this study site is highly heterogeneous, and this is clearly expressed in the results of the various sampling methods. Only one value (1300 μg/L) is obtained by the purge-and-bail method; however, the low-flow and PD sampling methods characterize concentrations at various discrete depth intervals and show significant contaminant stratification (approximately an order of magnitude over several vertical feet).

Figure 4 compares the results of purge-and-bail with PD sampling methods at several wells at the same heterogeneous site. The purge-and-bail measurements are generally higher than the average discrete PD sampler measurements, possibly indicating that the majority of the contaminant mass exists in highly permeable zones. These data provide additional characterization information and have potentially important implications for the site. At some sites, a similar targeted dual-method sampling strategy (i.e., use of both purge-and-bail and PD sampling methods) may be useful for evaluating contaminant distribution, remedial system design and performance, and long-term plume behavior.

Clearly, using PD samplers under heterogeneous aquifer conditions, particularly in an ongoing compliance monitoring program, requires careful consideration of ways to interpret measurement data and satisfy monitoring program objectives. For example, determining the appropriate intervals for PD sampler placement may be challenging (i.e., Fig. 3). Additionally, as indicated by the circled values in Fig. 4, the PD sampling method measured low concentrations of some nontarget VOCs at a few discrete intervals in certain wells, but these compounds were not measured above the analytical quantitation limit by the purge-and-bail method. Assuming that these differences are related to the differing averaging natures of the sampling methods, interpreting the discrete interval measurement within site objectives or regulatory requirements may be challenging. For example, an analytical water quality goal or regulatory limit may be met by one method and not by another at the same well simply due to the inherent averaging characteristics of the sampling methods. For additional discussion of the results of this study, see Divine et al. (15).

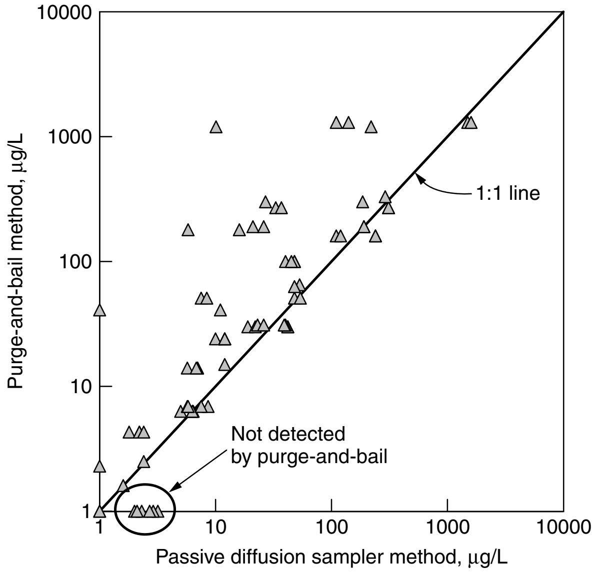

Figure 4. Comparison of sampling results (various VOCs) for purge-and-bail and passive diffusion sampling methods for a series of wells at a heterogeneous site.

SPECIFIC CAPACITY

Eric S. Wilson
E. L. Montgomery & Associates, Inc.
Tucson, Arizona

The specific capacity of a well is the pumping rate of the well divided by the drawdown at that rate:

$$S_c = \frac{Q}{\Delta h}$$

where S_c=specific capacity
Q=constant pumping rate, and
Δh=drawdown

Water well contractors often report specific capacity to characterize the performance of a well and use specific capacity to estimate the optimum depth for installing a pump to obtain the desired yield. Units typically associated with specific capacity are liters per second per meter of drawdown (l/s/m), cubic meters per day per meter of drawdown (m^3/day/m), cubic feet per day per foot of drawdown (ft^3/day/ft), or gallons per minute per foot of drawdown (gpm/ft).

When taking measurements to compute specific capacity, the pumping rate should be constant, and the period of pumping should be sufficiently long that the rate of change in drawdown is small. The specific capacity of a well tends to become smaller as the pumping rate and duration of pumping increase. At high pumping rates, nonlaminar flow losses are larger and result in an increased rate of drawdown. Water level drawdown in unconfined aquifers results in reduced aquifer transmissivity near pumping wells; larger drawdown at high pumping rates then results in progressively smaller transmissivity and smaller specific capacity. A specific capacity value remarkably smaller than expected may result when the well is not screened in the correct water-bearing zone or when well screen openings are clogged due to incomplete well development, precipitation of minerals in the screen openings, or biofouling. After many years of pumping, if the specific capacity declines to about half the original value, well rehabilitation should be considered.

Specific capacity may be used to estimate the maximum potential pumping rate of a well by multiplying the available drawdown by specific capacity. The available drawdown is the difference between the depth at which the pump is set and the depth to the nonpumping water level in the well.

Specific capacity may be used to estimate the transmissivity of aquifer media in the vicinity of the pumping well. Theis (1) suggested that specific capacity could be used to estimate the transmissivity of an aquifer using the equation,

$$T^* = \frac{Q}{\Delta h}\frac{2.3}{4\pi}\log\frac{2.25T^*t}{r^2S}$$

where $\frac{Q}{\Delta h}$=specific capacity
t=time
r=radius of pumping well
S=aquifer storativity
T^*=transmissivity; an initial guess of the value of T is made and substituted in the equation. The equation is then solved for Δh. After the initial solution, the value of T must then be adjusted until the calculated value of Δh is reasonably close to the measured value.

Driscoll (2) indicated that transmissivity could be estimated as

$$T = S_c \times 2,000 \text{ for confined aquifers}$$

or

$$T = S_c \times 1,500 \text{ for unconfined aquifers}$$

where T is in gpd/ft and
S_c is specific capacity.

Razack and Huntley (3) gave an empirical relationship between transmissivity and specific capacity as follows:

$$T = 15.3(S_c)^{0.67}$$

where T is in m^2/day
S_c in m^3/day/m,

or

$$T = 33.6(S_c)^{0.67}$$

where T is in ft^2/day
S_c in ft^3/day/ft.

Using specific capacity data to estimate transmissivity can be useful when trying to estimate potential pumping rates or estimating how much available head is needed to produce a specified pumping rate. But, as in any estimation technique, it is not always applicable or advisable. These instances may include situations where substantial drawdown occurs because the pumping duration is too short for the specific capacity test, too small a pumping rate is used for an adequate specific capacity test, or well construction is inefficient.

SOIL WATER

Todd Rasmussen
The University of Georgia
Athens, Georgia

Soil water is a measure of the quantity of water present within a unit volume of soil. Soil-water content can vary from fully saturated, in which case the water content equals the soil porosity, to oven-dry, in which case all free water has been evaporated.

Wet soils are characterized as having high water contents, which means that more soil pores are filled with water, whereas dry soils have more pores that are filled with air.

The volumetric water content, θ, is defined as the volume of water, V_w, per unit volume of soil, V_s:

$$\theta = \frac{V_w}{V_s} \tag{1}$$

where the range in water content is from a minimum, or residual, saturation, θ_r, to a maximum equal to the saturated porosity, θ_s, so that $\theta_r < \theta < \theta_s$.

The water content can also be defined with a gravimetric, or mass, measurement, θ_g, such that

$$\theta_g = \frac{M_w}{M_s} \tag{2}$$

where M_w is the water mass and M_s is the soil mass. We can readily convert between these two measures by using:

$$\theta = \theta_g \frac{\rho_w}{\rho_s} = \frac{\theta_g}{\rho_s} \tag{3}$$

where $\rho_w = M_w/V_w = 1$ kg/L is the water density and $\rho_s = M_s/V_s$ (kg/L) is the bulk density of the soil.

The soil water content can also be reported as a relative saturation, Θ, which is defined using

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} \tag{4}$$

where θ_r and θ_s are the residual and saturated water contents, respectively. The relative saturation varies from zero for a dry soil to a maximum of one for a fully saturated soil, $0 < \Theta < 1$.

MEASURING WATER CONTENTS

Water contents are commonly measured with time-domain reflectometry (TDR) devices, as shown in (Fig. 1). TDRs determine the water content with the electromagnetic properties of a wave pulse passing through a conducting set of rods (such as 3-mm stainless-steel welding rods) placed in the soil.

The principle of TDRs is that the velocity of electromagnetic waves along a conductor is a function of the *dielectric* coefficient of the media around the conductor. Liquid water has a dielectric constant of 80.2 at 20 °C, whereas ice is 3.2, petroleum is 1.8 to 2.2, quartz is 4.3, and air is only 1.00.

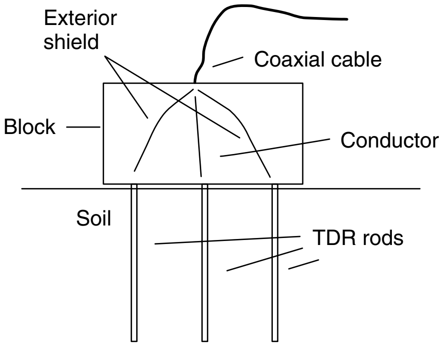

Figure 1. Time-domain reflectometer (TDR) probe that measures soil-water content. The three-rod assembly is placed within the soil. Coaxial cable connects probe to the water content tester. Center wire of coaxial cable connects to the central rod, whereas the exterior shield is connected to the two outer rods.

As the water dielectric constant is so much greater for water than for soil or air, the wave velocity is substantially retarded as the water content of a soil increases, because larger dielectric constants cause slower wave velocities and, hence, longer travel times.

Before the use of TDRs, neutron probes used the thermalization of neutrons to determine the water content (1). This older method has fallen out of favor, however, because of the rigorous licensing and inspection requirements associated with radioactive materials.

MATRIC TENSION

Water molecules in the unsaturated zone are bound by *adhesive* forces to soil surfaces and by *cohesive* forces to other water molecules, which are *surface tension* forces, and they result in fluid pressures that are less than atmospheric.

Rather than use negative pressure heads, $p < 0$, to describe the soil potential, we employ soil, or matric, tensions, $\psi > 0$. The matric tension is the negative fluid pressure head, $\psi = -p$, which increases as the pressure head becomes more negative (more tightly bound) and decreases as the pressure head becomes less negative (less tightly bound).

The total head within the soil pore fluids, h, is the difference between the elevation, z, and the matric tension:

$$H = z + p = z - \psi \tag{5}$$

Capillary theory can relate the matric tension, ψ, to the fluid potential associated with the radius of curvature, r, of fluid films within pores:

$$\psi = \frac{2\sigma \cos \alpha}{\gamma r} \tag{6}$$

where σ (Pa·m) is the surface tension and α is the contact angle at the air–water–solid interface.

The matric tension of a wet soil, $0 < \psi < 0.7$ bar, can be measured with tensiometers, as shown in (Fig. 2), which determine the negative pressure head of fluids inside a probe. The fluid within the probe is allowed to reach equilibrium with the soil fluids using a semiporous ceramic or metal filter that prevents air from entering the probe.

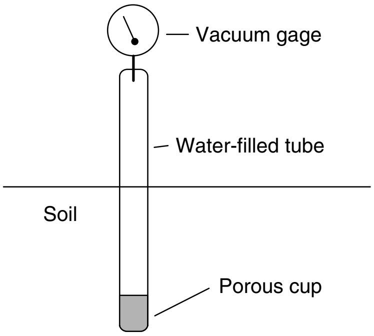

Figure 2. Soil-water tensiometer probe that monitors soil-tension. A porous cup allows water to exchange between the soil and a reservoir of water within the tube assembly. A vacuum pressure gauge monitors the water pressure inside the water reservoir.

Psychrometry is a useful technique in drier soils, $\psi > 5$ bar (2). The dewpoint temperature of the pore atmosphere is measured with a thermocouple psychrometer. The dewpoint temperature can then, along with the pore temperature, determine the relative humidity of the pore atmosphere. The matric tension can be readily determined from the relative humidity, as shown in Table 1.

MOISTURE CHARACTERISTIC CURVES

The amount of water contained within soil can be related to the fluid tension, or negative pressure, present within the water. Dry soils contain water that is held by strong adhesive forces to soil surfaces along with strong cohesive forces to other water molecules. These forces are reflected in the tension that holds the water against the force of gravity.

Each soil has a unique relationship between soil tension and water content. This relationship, termed the soil *moisture characteristic curve*, is a function that describes how water content and matric tension are related. The characteristic curve for each material varies with the pore size distribution—a soil with larger pores releases water at a lower tension than does a soil with smaller pores.

A number of formulations have been proposed that relate the relative saturation, Θ, to matric tension, ψ. The *Brooks and Corey* equation has the form:

$$\Theta = \left(\frac{\psi}{\psi_b}\right)^{-\lambda} \tag{7}$$

where ψ_b is the *bubbling pressure* and λ is a *pore-size distribution index*. This equation only holds for $\psi > \psi_o - \Theta = 1$ otherwise.

Another common formulation is the *van Genuchten* equation:

$$\Theta = \left[1 + (\alpha\psi)^n\right]^{(1-n)/n} \tag{8}$$

where α and n are empirical coefficients.

Moisture characteristic curves are commonly estimated with *pressure plates* (shown in (Fig. 3)) or *Tempe pressure cells*. In both methods, one or more soil samples are placed on top of a *porous plate* within a sealed chamber. Nitrogen gas under high pressure is forced into the chamber, and water is forced out of the soil samples through the porous

Table 1. Measures of Soil Tension

Fluid Pressure (bars)	Soil Tension (m)	Pore Radius	Relative Humidity (%)
0	0	∞	100
0.1	−1	15 μm	99.993
1	−10	1.5 μm	99.93
15	−150	100 nm	98.9
100	−1000	15 nm	93.
500	−5,000	3 nm	70.
1,000	−10,000	1.5 nm	48.
5,000	−50,000	3 Å	2.6
10,000	−100,000	1.5 Å	0.068

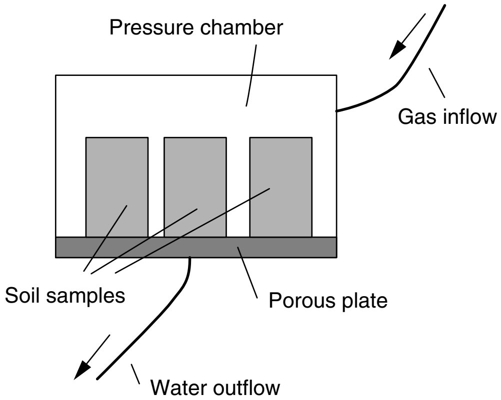

Figure 3. Pressure plate procedure for determining the soil moisture characteristic curve. A gas pressure is applied to soil samples within the chamber, and water is released through the porous plate. The water content, θ, is found for each pressure, ψ.

plate, which is permeable to water but not to air. The resulting water content of the samples can be determined once the outflow has stopped.

SAMPLING SOIL WATER

Soil water samples are more difficult to collect in the unsaturated zone than in the saturated zone because water does not freely flow into a well or piezometer. Commonly, a soil *lysimeter* collects water samples by placing a suction within a hollow tube that has a *porous cup* placed within the soil. Water flows through the porous cup into the hollow tube where it can then be collected.

Soil lysimeters are limited to conditions where the soils are wet, $\psi < 0.7$ bar. For drier conditions, soil samples can be collected and returned to the laboratory, where mechanical or gas pressure can be applied to the samples to force pore fluids out of the sample.

SOIL AND GROUNDWATER GEOCHEMISTRY AND MICROBIOLOGY

Stuart Smith
Smith-Comeskey GroundWater Science LLC
Upper Sandusky, Ohio

DEFINITIONS

Geochemistry can be defined as the study of the chemical composition of, and of actual or possible chemical changes in, a geological matrix, including *soil*, that complex mixture of minerals, life, and organic material on the surface of the earth. *Groundwater*, of course, is water located in the saturated zone of the earth. *Microbiology* is the study of small forms of life, usually including the bacteria and archaea domains and protists and fungi of the eukaryaceae domain, and naturally also covers numerous subcategories.

The interdisciplinary studies of the interactions among microflora, earth materials, and chemical reactions are often linked under *geomicrobiology* or *biogeochemistry*.

ORIGINS

The relationship between life in soil and earth materials appears to go back to the very origins of life on earth. Bacterial and archaeans (superficially bacteria-like microflora that have entirely different genetic operations, biochemistry, and cell membranes) were interacting with iron and other minerals as part of energy transformations since within a few 100 million years of the coalescence of the planet. Many archaeans specialize in methanogenesis and adaptation to extreme environments at the present time, such as geothermal waters, undersea hydrothermal vents, and hypersaline lakes (e.g., Dead Sea, Great Salt Lake, and solar salt lagoons). Biochemical evidence suggests that they may have developed in association with such conditions, which were common early in earth history.

Bacteria and cyanobacteria (colloquially known as blue-green algae) strongly affected the earth environment from early in the Archean era (±4 billion years before present, b.y. BP). Cyanobacteria, with a photosynthetic mechanism similar to algae and plants, used carbon dioxide and expended oxygen as a waste product in shallow anoxic seas. Ferrous iron (Fe), common in water and the earth's crust, scavenged the oxygen, forming various FeIII minerals, including magnetite, hematite (recently confirmed on Mars), goethite, and less-organized mineral forms. Such iron-containing Archean sediments were deposited as banded iron formations, with iron bands in a cherty matrix, which are important iron ores worldwide where they occur (such as the Mesabi Range in Minnesota). When much of the available free oceanic FeII was depleted, oxygen began to build up in the atmosphere, with a recognizably modern atmosphere dating from 1.7 b.y. BP.

Bacteria have the most diverse biochemical and respiratory capabilities among forms of life. Although others require oxygen for respiration, bacteria can respire using sulfur, forms of nitrogen, carbon dioxide, and metals (primarily Fe and Mn) as electron acceptors. Such respiration is used to process a wide variety of organic compounds, including recalcitrant ring structures. Such versatility appears to be a very ancient capability.

In ancient shallow marine settings, cyanobacteria formed stromatolites, laminations of organic and sedimentary structures formed as sand and debris, and coprecipitated minerals were trapped in cyanobacterial masses. Although many stromatolites are found as fossil structures, a number of locations exist on the modern-day Earth where stromatolites are still forming, which are one form of the common microbial phenomenon, biofilm formation.

From there on, microbial processes and mineral-biological interactions, and the environment-manipulating "behavior" known as biofilm formation (all developed in the Archean era), have continued in action until the present.

- Bog ores (important to the development of an iron industry in the United States during the nation-forming period) and gold and copper placer ores are younger manifestations of the ancient microbial practice of depositing metals.
- Bacteria reduce oxides of Fe, Mn, N, and S to accumulate "reducing power" to oxidize ("digest") complex organic compounds. These capacities are exploited in groundwater contamination remediation. The presence of high levels of Fe and Mn in well water samples is also an indicator that organic carbon compounds are present in groundwater accessed by a well.
- Microbe-mediated biogeochemical transformations alter groundwater quality by oxidizing or reducing Fe and Mn, and mobilizing them into solution. Recently, the reduction of insoluble arsenic minerals to soluble forms and As mobilization by microbes has attracted interest as a factor in As presence in groundwater.
- Biofilm-forming microflora coat, clog, and corrode engineered structures such as wells and drains in the saturated zone, resulting in *biofouling* (further discussed in the article BIOFOULING IN WATER WELLS).

SOIL MICROBIOLOGY

Soil microbiology is a special category of geomicrobiology focused on the earth's regolith, and specifically *soil*, which is a complex of mineral, organic, and biological components. Although beyond the scope of a short article, soil microbiology has traditionally been distinguished from groundwater or geomicrobiology. This distinction has origins in academic discipline; however, studies indicate that surficial soils have species richness and total microbial biomass values that are much higher than in earth materials below the soil zone. Protists and fungi are common in soil but limited in type and numbers (but not entirely absent) in aquifers.

Soil microbiology is much more thoroughly known compared with that of less-accessible earth materials. It is also much more thoroughly influenced by human activities, which include cultivation, fertilization, construction, and application of contaminants (both deliberately and accidentally). Soil microflora and soil structure experience close interactions with animals and plants. Changes in such macroflora and fauna communities can trigger sweeping changes in soil microbiology. Clearing and cultivation of forest and prairie soils result in simplification in microbial community structure. The introduction of Eurasian earthworms into North American boreal soils (where they have been absent since the Pleistocene glaciations) has resulted in measurable shifts in the availability of organic matter and nutrients to native plants. In turn, changes in vegetation affect soil and watershed hydrology.

OVERCOMING CHALLENGES IN MICROBIOLOGICAL METHODS IN GROUNDWATER STUDIES

Background

Environmental microbiology and geomicrobiology are the oldest disciplines within the broader field of microbiology. However, industrial, public health, and clinical interests quickly overshadowed the study of the microbiology of natural environments. Until the 1970s, scientific preconceptions in many circles, based on observations of engineered filters, limited methods (and limited reading) and placed limits on groundwater microbiology. Considerations of the chemistry of groundwater assumed that chemical transformations occurred in an environment devoid of life. A notable exception was that of the microbiologists in the Soviet petroleum industry of the 1950s and 1960s, who described the microbiology of petroleum reservoirs and systems.

Analysis

Methods for the analysis of groundwater environments for microbes were very limited prior to the 1980s. The principal analytical method was culturing, which recovers only a small fraction of bacteria. It was generally assumed that water passing through the soil was purified by active microbial processes and by filtration.

Interest in the occurrence of biofouling microflora in groundwater and concerns about groundwater contamination in the 1970s and 1980s motivated innovation in methods suitable for groundwater microbiology. As groundwater contamination became more and more evident in the United States and other western nations during the 1980s, the motivation for understanding groundwater environments increased. In addition, new methods in microbiology, based on advances in molecular biology, provided microbiologists with new tools to explore this difficult-to-sample microbial habitat. Among these are phospholipid fatty acid methyl ester (PL-FAME) and nucleic acid testing, described further in EVALUATION OF MICROBIAL COMPONENTS OF BIOFOULING. Such methods provide the means to describe microbial associations in a meaningful way, as cultivation and phenotypic classification typically fail to do so.

Classification, in particular, is a problem in description. With micro-organisms, it often depends on making comparisons with libraries of known genotypes or phenotypes. Some deep subsurface communities are so isolated and specifically adapted that comparisons with described forms are weak. A general recognition exists in the geobiological community that the task of describing aquifer and other deep subsurface communities compares with the task of describing the recently discovered deep-sea hydrothermal vent ecosystems.

Sampling

Acquiring samples is perhaps the most difficult aspect of the microbiology of the deep subsurface. Such sampling is relatively expensive, at times technically challenging, and prone to sample compromise. Typically, methods for both solid and liquid sample acquisitions are adapted from those developed for other purposes (borehole and core drilling, pumped or zonal sampling). Only coring can deliver solid samples isolated from drilling contamination. A variety of water sampling techniques exist to obtain discrete samples.

However, if properly interpreted, available sampling and analytical techniques appear to be sufficient to gain an understanding of deep subsurface microbial ecology.

NOTABLE DISCOVERIES

1. Microbial community diversity: PL-FAME and rRNA analysis reveal subsurface communities that are diverse and typically adapted to coping with starvation and exploiting resource "windfalls" when they occur. Bacteria can persist in viable but nonculturable and inactive states when conditions dictate. Microbial communities can have biomass that rivals surface soils and may include fungi and protozoa where pore sizes permit.
2. Microbial communities and numbers vary significantly between hydraulically transmissive and confining formations in the same wells and boreholes.
3. Community biochemical adaptability: Bacteria that form biofilms and readily exchange genetic potential can be quite plastic in their ability to exploit resources. Early in the effort to employ bioremediation in treating contaminated groundwater and soil, it was recognized that natural communities were capable of degrading a variety of anthropogenic compounds, especially hydrocarbons.
4. Iron and sulfur biogeochemical cycles are particularly important in deeper systems, whereas nitrogen is strongly cycled in the soil and shallow saturated flow zones. In deeper systems, carbon and nitrogen are cycled locally within biofilms.
5. Groundwater contamination locally alters oxidation-reduction systems, nutrient cycling, and community structure. Microbial communities react to influxes of organic carbon by increasing biomass and tipping toward anaerobic respiration as oxygen is depleted by hydrocarbon-using or other aerobic heterotrophs, which is closely analogous to eutrophication in surface water systems. For energetic reasons, the following are favored sequentially, switching to the next when the electron acceptor is depleted: nitrate, iron (and other metal) oxides, sulfate, and carbon dioxide (reduced to methane).
6. Microbial communities may include very long-lived and ancient lineages. Studies of communities in deep, isolated systems reveal communities that may be very ancient and existing in isolation from the surface.

An article of this length is insufficient to consider the subject comprehensively (considering that entire textbooks, conferences, and hundreds of webpages are devoted to the topic). Related subjects are considered elsewhere in the *Encyclopedia of Water*.

CHARACTERIZING SOIL SPATIAL VARIABILITY

Dennis L. Corwin
Scott M. Lesch
USDA-ARS George E. Brown,
Jr., Salinity Laboratory
Riverside, California

SPATIAL VARIABILITY: DEFINITION, ORIGIN, SIGNIFICANCE, AND MEASUREMENT METHODS

Spatial variability refers to the variation in soil physical, chemical, mineralogical, and biological properties both laterally across the landscape and vertically through the soil profile. The spatial heterogeneity of soils is a consequence of interacting meteorological, pedological, and biological processes and anthropogenic factors over time. Within-field spatial variability of soil properties has been a primary concern within soil science ever since the classic paper by Nielson et al. (1) concerning the variability of field-measured soil water properties. The significance of soil spatial variability stems from its complex influence on any landscape-scale soil-related issue including solute transport in the vadose zone, precision agriculture, and soil quality assessment, to mention a few.

A variety of measurement methods are available for potentially characterizing soil spatial variability including ground penetrating radar (GPR), aerial photography, multispectral and hyperspectral imagery, time-domain reflectometry (TDR), and apparent soil electrical conductivity (EC_a). However, none of these approaches has been as extensively investigated with respect to characterization of within-field soil variability as EC_a (2).

Since its early agricultural use for measuring soil salinity, the application of EC_a has evolved into a widely accepted means of establishing the spatial variability of several soil physicochemical properties that influence the EC_a measurement. Geospatial measurements of EC_a are well suited for characterizing spatial variability for several reasons. Geospatial measurements of EC_a are reliable, quick, and easy to take. The mobilization of EC_a measurement equipment is easy and can be accomplished at a reasonable cost. Finally, and most importantly, EC_a is influenced by a variety of soil properties for which the spatial variability of each could be potentially established.

NEED FOR CHARACTERIZING SOIL SPATIAL VARIABILITY

The prospect of feeding a projected additional 3 billion people over the next 30 years poses formidable, but not insurmountable, challenges. Feeding the ever-increasing world population will require a sustainable agricultural system that can keep pace with population growth. Sustainable agriculture hinges on a delicate balance of economic sustainability, crop productivity, resource utilization, and minimized detrimental environmental impacts. These factors are influenced either directly or indirectly by soil spatial variability.

Spatial variability within a field amounts to an order of magnitude or more for soils (3,4) and to a factor of 2–4 or more for crops (5). Spatial variation in crops is the result of a complex interaction of biological (e.g., pests, earthworms, microbes), edaphic (e.g., salinity, organic matter, nutrients, texture), anthropogenic (e.g., irrigation efficiency, soil compaction due to farm equipment), topographic (e.g., slope, elevation), and climatic (e.g., relative humidity, temperature, rainfall) factors. To a varying extent from one field to the next, crop patterns are influenced by soil-related properties. Conventional farming is not as efficient as it could be because it currently treats a field uniformly. To maintain uniform crop production, conventional farming overcomes the inherent variability of soil and crop conditions between and within fields with an over application of inputs (i.e., irrigation water, pesticides, fertilizers, etc.) intended to meet the needs of areas of lowest productivity. Bullock and Bullock (6) pointed out the imminent need for efficient methods to accurately measure within-field variation in soil physical and chemical properties as a key component for precision agriculture.

The effective utilization of soil as a resource depends on assessing and maintaining its quality. A fundamental component of assessing field-scale soil quality is establishing the spatial distribution of the soil properties affecting the soil's intended management goal (e.g., maximize agricultural productivity, minimize environmental impact, and/or maximize waste recycling) and its intended function (e.g., biodiversity, filtering and buffering, nutrient cycling, physical stability and structural support, resistance and resilience, and water and solute flow). It is not sufficient to take a single measurement within a field to characterize its soil quality. Rather, a sufficient number of measurements must be taken and at specific locations to representatively characterize the spatial distribution of the existing soil conditions that influence the soil's intended use. Therefore, assessing soil quality requires quantitative knowledge of each indicator property associated with a soil's quality and the spatial variability of those indicator properties.

Furthermore, spatial variability has a profound influence on environmental impacts, particularly of non-point source pollutants. This result is because of its influence on the fate and transport of agrochemical inputs (e.g., pesticides, fertilizers, etc.) in an agroecosystem. In fact, it has become clear that the real constraint on modeling solute transport is not the detail of the model structures, but defining the characteristics of individual places (7). Jury (3) provides an excellent fundamental discussion of the spatial variability of soil properties and its impact on solute transport in the vadose zone. As Jury points out, “any hope of estimating a continuous spatial pattern of chemical emissions at each point in space within a field must be abandoned due to field-scale variability of soils.”

The characterization of spatial variability is without a doubt one of the most significant areas of concern in soil science because of its broad reaching influence on all field- and landscape-scale issues. Research in the characterization of spatial variability has advanced tremendously over the past decade in large part because of georeferenced EC_a measurements.

EDAPHIC FACTORS INFLUENCING EC_a MEASUREMENTS

The earliest field applications of geophysical measurements of EC_a in soil science, which occurred in the early 1980s, involved the determination of salinity within the soil profile of arid zone soils. However, it soon became apparent that the measurement of EC_a in the field as a quantification of soil salinity was more complicated than initially anticipated because of the complexity of current flow pathways originating from the spatial heterogeneity of properties influencing current flow in soil.

Three pathways of current flow contribute to the EC_a of soil: (1) a liquid phase pathway via dissolved solids contained in the soil water occupying the large pores, (2) a solid–liquid phase pathway primarily via exchangeable cations associated with clay minerals, and (3) a solid pathway via soil particles that are in direct and continuous contact with one another (8). Of these three pathways, the solid pathway is usually negligible; hence, most soil can be approximated with a dual-pathway parallel conductance equation.

An analysis of this dual-pathway system indicates that EC_a will be influenced by a complex interaction of soil properties including salinity, soil texture, water content, ρ_b, and temperature. The ρ_b is directly influenced by clay content (soil texture) and organic matter (OM). Furthermore, the exchange surfaces on clays and OM provide a solid–liquid phase pathway primarily via exchangeable cations; consequently, the cation exchange capacity (CEC) and OM are recognized as additional factors that can influence EC_a measurements. Measurements of EC_a *must* be interpreted with these influencing factors in mind.

MOBILE EC$_a$ MEASUREMENT EQUIPMENT

An EC$_a$ survey to characterize spatial variability uses mobile geophysical equipment coupled with a global positioning system (GPS) to georeference each EC$_a$ measurement. Mobile EC$_a$ equipment has been developed by a variety of researchers (9–11). The development of mobile EC$_a$ measurement equipment has made it possible to produce EC$_a$ maps with measurements taken every few meters.

Mobile EC$_a$ measurement equipment has been developed for both electrical resistivity (ER) and electromagnetic induction (EMI) geophysical approaches. In the case of ER, four stainless-steel electrodes are inserted into the soil generally at equal distances and connected to a resistivity meter. Current is applied to the two outer electrodes with the two inner electrodes serving as the potential electrodes. Fixing the electrode array and mounting it on or pulling it from a vehicle saves considerable time for measurements. By coupling the fixed electrode array to a datalogger and GPS georeferences the EC$_a$ measurement, geospatial ECa measurements can be taken. Veris Technologies[1] (Salinas, KS; www.veristech.com) has developed a commercial mobile system for measuring EC$_a$ using the principles of ER. In a similar fashion, an EMI unit can be mobilized by pulling a sled-mounted EM-38 unit (Geonics Ltd., Mississaugua, Ontario, Canada) behind a vehicle and logging the EMI data simultaneously along with real-time GPS position information. Measurements of EC$_a$ with EMI generally involve taking readings in the horizontal coil configuration (EM$_h$), which is a shallow reading penetrating to a depth of about 0.75–1.0 m, and/or in the vertical coil configuration (EM$_v$), which is a deep reading penetrating to a depth of about 1.5 m.

EC$_a$-DIRECTED SAMPLING DESIGNS

Despite the complexities of the EC$_a$ measurement, the fact that EC$_a$ is influenced by several soil properties has broadened its utility and enabled it to play a major role in addressing the issue of characterizing spatial variability. Geospatial measurements of EC$_a$ have been successfully used for (1) identifying the soil physicochemical properties influencing crop yield patterns and soil condition, (2) establishing the spatial variation of these soil properties, and (3) characterizing the spatial distribution of soil properties influencing solute transport through the vadose zone (4,12–14).

In a typical field survey, the spatial distribution of various soil properties can often be adequately determined with conductivity survey information in conjunction with some type of soil sampling plan. Either probability (design) or prediction (model) based sampling strategies can identify the soil properties that correlate best with EC$_a$ in a particular field. Prediction-based sampling strategies objectively select sampling locations based on the observed spatial ECa pattern and thus are often referred to as “sensor-directed” sampling plans (15). Characterizing spatial variability with EC$_a$-directed soil sampling is based on the hypothesis that when EC$_a$ correlates with a soil property or properties, then spatial EC$_a$ information can identify sites that reflect the range and variability of the property or properties. In instances where EC$_a$ correlates well with a particular soil property, an EC$_a$-directed soil sampling approach can optimally establish the spatial distribution of that property while minimizing the corresponding sampling and labor costs (2,15,16). Also, if EC$_a$ is correlated with crop yield, then an EC$_a$-directed soil sampling approach can identify those soil properties that are causing the variability in crop yield (13). Details for conducting a field-scale EC$_a$ survey for the purpose of characterizing the spatial variability of soil properties influencing soil quality or crop yield variation can be found in Corwin and Lesch (16).

Figure 1 shows EM$_h$ and EM$_v$ maps of an EC$_a$ survey performed on a 6.5-ha field in Maricopa, AZ, along with the associated soil sample sites selected with a specific type of EC$_a$-directed sampling methodology known as spatial response surface sampling design (15,16). Once soil cores are taken at the selected sites and the corresponding soil physicochemical properties are analyzed, the properties that are well correlated with EC$_a$ can be identified. Statistical prediction models can then be derived that spatially map (predict) these correlated soil properties with the calibrated EC$_a$ survey data. Figure 2 shows the corresponding EC$_a$-predicted 0–0.9-m percent water content patterns for the field shown in Fig. 1.

GUIDELINES FOR CONDUCTING AN EC$_A$-DIRECTED SOIL SAMPLING SURVEY TO CHARACTERIZE SPATIAL VARIABILITY

The basic elements of a field-scale EC$_a$ survey for characterizing spatial variability include (1) EC$_a$ survey design, (2) georeferenced EC$_a$ data collection, (3) soil sample design based on georeferenced EC$_a$ data, (4) soil sample collection, (5) physicochemical analysis of pertinent soil properties, (6) spatial statistical analysis, (7) determination of the dominant soil properties influencing the EC$_a$ measurements at the study site, and (8) GIS development. The outlined steps of an EC$_a$-directed soil sampling survey are provided in Table 1.

LIMITATIONS AND PRECAUTIONS

At present, no other soil measurement provides a greater level of spatial information than that of geospatial EC$_a$ measurements. Even so, are limitations exist to the use of EC$_a$ to characterize soil spatial variability. Awareness of these weaknesses is crucial for the proper use and interpretation of geospatial EC$_a$ measurements. The complex spatial heterogeneity of the soil system has subtle influences on geospatial EC$_a$ measurements that can have significant interpretive impacts. The ability to recognize and interpret these influences can be the difference between the successful or failed application of EC$_a$ measurements for characterizing spatial variability.

First and foremost, in the absence of soil sample information, geospatial measurements of EC$_a$ by themselves do not directly quantify soil spatial variability.

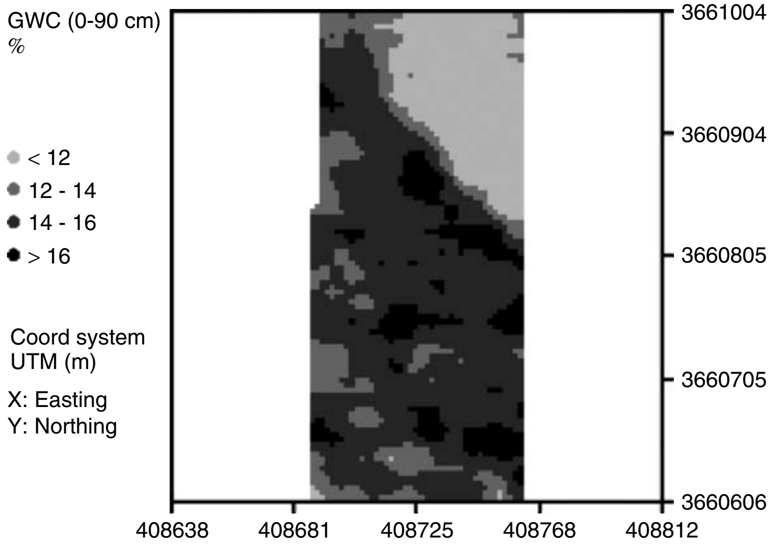

Figure 2. Map of spatial variability of percent gravimetric water content (GWC) for the 0–0.9-m sampling depth, as determined from the survey data and EC_a-directed soil sampling sites shown in Fig. 1 ($R^2 = 0.85$ for predicted and measured GWC). UTM = universal transverse mercator grid system in meters.

Table 1. Outline of Steps to Conduct an EC_a Field Survey

1. Site description and EC_a survey design
   a. record site metadata
   b. define the project's/survey's objective
   c. establish site boundaries
   d. select GPS coordinate system
   e. establish EC_a measurement intensity
2. EC_a data collection with mobile GPS-based equipment
   a. georeference site boundaries and significant physical geographic features with GPS
   b. measure georeferenced EC_a data at the predetermined spatial intensity and record associated metadata
3. Soil sample design based on georeferenced EC_a data
   a. statistically analyze EC_a data using an appropriate statistical sampling design to establish the soil sample site locations
   b. establish site locations, depth of sampling, sample depth increments, and number of cores per site
4. Soil core sampling at specified sites designated by the sample design
   a. obtain measurements of soil temperature through the profile at selected sites
   b. at randomly selected locations, obtain duplicate soil cores within a 1-m distance of one another to establish local-scale variation of soil properties
   c. record soil core observations (e.g., mottling, horizonation, textural discontinuities, etc.)
5. Laboratory analysis of appropriate soil physicochemical properties defined by project objectives
6. If needed, stochastic and/or deterministic calibration of EC_a to EC_e or to other soil properties (e.g., water content and texture)
7. Spatial statistical analysis to determine the soil properties influencing EC_a and/or crop yield
   a. soil quality assessment:
      1. perform a basic statistical analysis of physicochemical data by depth increment and by composite depth over the depth of measurement of EC_a
      2. determine the correlation between EC_a and physicochemical soil properties by composite depth over the depth of measurement of EC_a
   b. precision agriculture applications (if EC_a correlates with crop yield, then):
      1. perform a basic statistical analysis of physicochemical data by depth increment and by composite depths
      2. determine the correlation between EC_a and physicochemical soil properties by depth increment and by composite depths
      3. determine the correlation between crop yield and physicochemical soil properties by depth and by composite depths to determine depth of concern (i.e., depth with consistently highest correlation, whether positive or negative, of soil properties to yield) and the significant soil properties influencing crop yield (or crop quality)
      4. conduct an exploratory graphical analysis to determine the relationship between the significant physicochemical properties and crop yield (or crop quality)
      5. formulate a spatial linear regression (SLR) model that relates soil properties (independent variables) to crop yield or crop quality (dependent variable)
      6. adjust this model for spatial autocorrelation, if necessary, using restricted maximum likelihood or some other technique
      7. Conduct a sensitivity analysis to establish dominant soil property influencing yield or quality
8. GIS database development and graphic display of spatial distribution of soil properties

Rather, EC_a-survey measurements provide the spatial information necessary to direct soil sampling. It is the combined use of both the EC_a-survey and the corresponding sample data that makes this sort of surveying technology invaluable for characterizing spatial variability. In other words, the primary strength of geospatial EC_a measurements lies in their effectiveness as a means to direct soil sampling (using a minimum number of sample sites) that best characterizes the spatial variability of those soil properties influencing EC_a in the landscape of interest.

Second, EC_a-directed soil sampling can only spatially characterize soil properties that correlate with EC_a. This correlation may be caused by a direct or indirect influence on the EC_a measurement, or the correlation may be a complete artifact. For example, salinity and water content will directly influence EC_a and CEC will indirectly influence EC_a through its influence on current flow at the surface of soil minerals. Likewise, in many instances, B and salinity distributions are similar. Consequently, a strong correlation between B and salinity (and thus EC_a) can result, even though no cause-and-effect relationship exists between B and EC_a. Thus, a solid understanding of the soil properties that directly influence and/or are indirectly measured by EC_a at a specific site is particularly essential in temporal surveying applications, because over time these correlations may or may not persist.

Third, as previously mentioned, often a dynamic and complex relationship exists between EC_a and those properties that influence EC_a. Ground-truth soil samples are obligatory if spatial measurements of EC_a are to be used for quantifying soil variability. Geospatial measurements of EC_a do not supplant the need for soil sampling, but they do minimize the number of samples necessary to characterize spatial variability. Additionally, users of EC_a survey data must exercise caution and be aware of what EC_a is actually measuring at the site of interest. Normally, the only way to establish those soil properties that influence EC_a at a specific location is by collecting representative soil samples and then determining the relationship between EC_a and the particular property or properties of interest. This process requires that every EC_a survey has an associated soil sampling design. The location and number of sites can be established (after acquiring the EC_a survey data) using model-based sample design software such as ESAP (17).

Finally, the temporal stability of EC_a measurements at a site may be of potential concern because EC_a is a product of both static and dynamic factors, which adds another dimension to the complexity of understanding and interpreting geospatial EC_a measurements. For this reason, caution must be taken to characterize spatial variability with EC_a when dynamic conditions influencing EC_a are significant. Apparent soil electrical conductivity surveys are generally conducted (1) within a set time frame to minimize the effects of dynamic properties (such as temperature and water content), (2) when the soil is at or near field capacity (to avoid current-flow problems), and (3) with regard for subtle topographic effects (e.g., bed-furrow). Protocols for conducting an EC_a survey that consider all previously discussed limitations are presented by Corwin and Lesch (16).

FUTURE DIRECTION

Because of the heterogeneous nature of soils, characterization of soil spatial variability is a fundamental component of any landscape-scale process that cannot be overlooked or superficially addressed. Significant technological advances have occurred over the past two decades, particularly in the area of sensor technology and in precisely locating a geographic position with GPS. These advances have helped the progress of research in characterizing spatial variability at field and landscape scales.

Geospatial measurement of EC_a stands out among the ground-based sensor technologies, contributing to an improved ability to characterize spatial variability. Numerous soil samples are required for representative estimates of field-scale spatial variability using traditional grid sampling, which makes grid sampling impractical because of labor and cost intensiveness. Soil sampling directed by geospatial EC_a measurements provides a viable alternative for characterizing spatial variability of a variety of soil-related physicochemical properties. Geospatial EC_a measurements provide a means of significantly reducing the number of soil samples needed to characterize spatial variability, provided that the target soil properties are well correlated with the conductivity survey data.

Directed soil sampling with geospatial EC_a measurements has its limitations in characterizing spatial variability, particularly when the soil properties of interest are not measured either directly or indirectly by the EC_a survey data. In these instances, other types of sensors should be used (if available) or a more intensive soil sampling strategy must be adopted. A robust methodology for the integrated use of multiple remote and ground-based sensors has yet to be developed. The successful integration of multispectral and hyperspectral imagery, TDR, GPR, aerial photography, and EC_a sensors is needed to provide the redundant and supplemental data necessary to unravel the spatial complexity of soil. This type of integrated methodology represents the future direction of soil spatial variability research.

DEEP SOIL-WATER MOVEMENT

Todd Rasmussen
The University of Georgia
Athens, Georgia

Soil water refers to subsurface water between the Earth's surface and the regional water table, called the unsaturated, or vadose zone. Figure 1 illustrates the components of flow within this zone. Deep soil-water movement usually implies the migration of water below the root zone, and is also called deep percolation.

Soil water is held by adhesive forces to soil surfaces and by cohesive forces to other water molecules. Measurements of soil-water pressures are usually negative—water does not freely drain into a well. Some soil water may exist with positive pressures, such as water that is perched in a saturated zone above a layer of lower permeability. Water under positive pressure flows freely into a well.

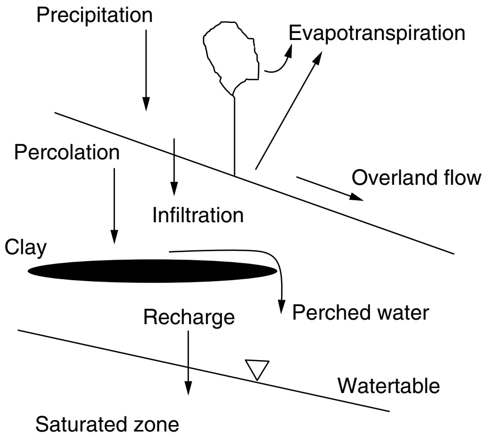

Figure 1. Flow components in the unsaturated zone.

FORCES THAT CONTROL WATER MOVEMENT

Gravity is the dominant force that controls soil-water movement. The downward force of gravity acts in conjunction with geologic media to control the magnitude and direction of fluid flow.

A second important force is the matric tension (or soil-water tension), which causes water to move from zones of lower tension to zones of higher tension. The soil tension, ψ, is the negative of the water pressure head, $\psi = -P/\gamma$, where P is the fluid pressure relative to atmospheric pressure and γ is the freshwater specific weight.

The total head, H, combines the gravitational and tension forces using $H = z - \psi$, where z is the elevation of the point of measurement.

In some circumstances, osmotic forces can also affect water movement. Osmotic forces develop when solute concentration gradients are present, causing water to move from zones of low salt concentration to zones of higher concentration. When osmotic forces are present, the total head must include the osmotic potential, ϕ, as noted in Section GW456 (head).

MATERIAL PROPERTIES

In addition to the total head, the characteristics of the geologic medium are also important for controlling the magnitude and direction of deep soil-water movement (1). The important material properties that affect soil-water movement are the unsaturated hydraulic conductivity functions and the soil-water characteristic curves.

Unsaturated Hydraulic Conductivity

The unsaturated hydraulic conductivity, $K(\psi)$, is commonly written as:

$$K(\psi) = K_r(\psi)\,K_s \tag{1}$$

where K_r is the relative unsaturated hydraulic conductivity function that varies with matric tension, ψ, and K_s is the saturated hydraulic conductivity.

As soil dries, the tension increases and the relative hydraulic conductivity decreases, whereas wetting soils show a decrease in tension and an increase in relative conductivity. The relative conductivity ranges from a theoretical minimum of zero in dry soil, $K_r \to 0$ as $\psi \to 0$, to a maximum of one in saturated soil, $K_r \to 1$ as $\psi = 0$, so that $0 < K_r \leq 1$.

Both the relative and saturated hydraulic conductivities vary with the pore-size distribution of the geologic media. Sandy materials may have a large saturated hydraulic conductivity, but a rapidly declining relative hydraulic conductivity, whereas finer materials may have a smaller saturated hydraulic conductivity but a slowly

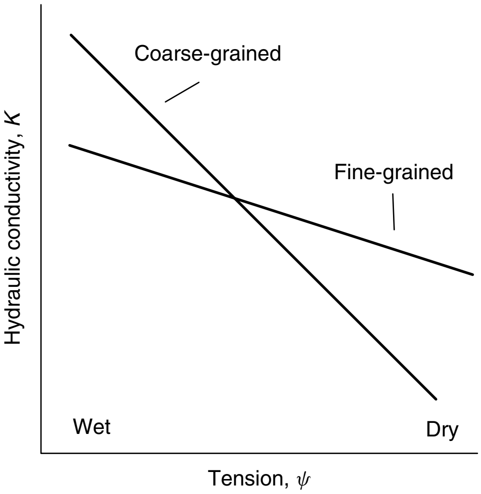

Figure 2. Unsaturated hydraulic conductivity, K, as a function of tension, ψ, for two materials. The coarser material is more conductive under wet conditions (smaller values of tension), whereas the finer material is more conductive under drier conditions.

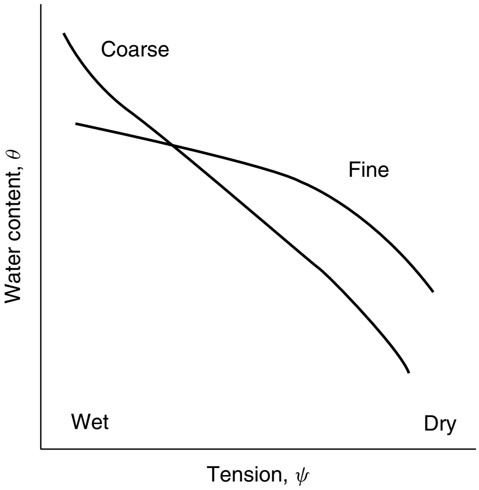

Figure 3. Soil water content, θ, as a function of tension, ψ, for two materials. The coarser material holds more water under wet conditions (smaller values of tension), whereas the finer material holds more water under drier conditions.

declining relative conductivity. This effect is shown if Fig. 2.

The crossover of the two curves shown in Fig. 2 results in the interesting phenomenon that coarser materials have a larger unsaturated hydraulic conductivity than finer material in the wet range, but a smaller conductivity in the drier range.

Thus, the flow behavior for wet conditions may be very different from the behavior under dry conditions in heterogeneous materials. Coarser materials (such as sands, fractures, and other large openings) generally dominate flow under wet conditions, whereas finer materials (such as silts, clays, and consolidated materials) can dominate flow under drier conditions.

Moisture Characteristic Curves

The ability of the unsaturated zone to hold water as a function of the soil tension is called the moisture characteristic curve. The characteristic curve for each material varies with the pore size distribution—a soil with larger pores releases water at a lower tension than a soil with smaller pores.

Figure 3 shows two soil characteristic curves, one for a coarser material and a second for a finer material. Like the unsaturated hydraulic conductivity function, the finer soil can hold more water under dry conditions, whereas the coarser soil holds more water under wetter conditions.

The water retention properties of soils also affect water movement. Changes in water flux with depth can be attributed to the uptake and release of water as the soil tension changes. For example, a wetting front may move downward with time from the surface after a large rain event, only to be absorbed by the dry soil underneath. The ability to absorb the moisture is a function of the ambient moisture tension—an already wet soil will have little ability to absorb additional water.

In some cases, water percolating down from above may not immediately reach the water table because the dry soils mediate the pulse of water. This water is retained by the soil and then slowly released over time. The initial pulse of water at the surface is transformed into a slow drainage at depth.

Only in materials with little water storage capacity (i.e., in wet soils or in materials with limited water holding capacity) will the downward movement of water be rapid. In these cases, the water that reaches the water table may or may not be the same water that was added at the surface. In some situations, the added water merely displaces the water below it, causing an equivalent volume of water to move at depth. In other situations, the added water moves quickly through the unsaturated zone.

Spatial Variability

Local subsurface conditions can also affect deep soil-water movement. Hydrogeologic units that dip in one direction, such as bedded sedimentary materials, can cause water to flow in the down-dip direction. Microscopic layering in features such as sand dunes can also affect the direction of movement.

Vertical features, such as fractures and joints, may focus water movement during wet conditions. Localized zones of preferential flow can also be found in soils with a defined structure, such as in soil with aggregates. These soils form a dual-porosity network consisting of fine pores within the aggregates and larger macropores between the aggregates.

Many explanations exist for preferential flow within soils, including bypass flow, macropore flow, fracture flow, boundary layer flow, mobile zone flow, finger flow, funnel flow, media heterogeneities, ion exclusion, and colloid transport (2).

WATER VAPOR MOVEMENT

Water vapor movement in deep systems can also be important, especially in very dry media where liquid flow is small. Water vapor is generally in equilibrium with the liquid phase and can be related to the matric tension of the pore fluids (3):

$$RH = \frac{e}{e_s} = \exp\left(\frac{g\psi}{RT}\right) \tag{2}$$

where RH is the relative humidity, e is the actual vapor pressure, e_s is the saturated vapor pressure, R is the water vapor gas constant, and T is the absolute temperature. Dissolved solids in soil water can lower the relative humidity—and increase the tension—because of osmotic forces.

The diffusion of water vapor through the subsurface can be predicted using a variety of approaches that depend on the specific conditions within the subsurface, which is because additional forces become important when considering subsurface vapor movement, including thermal effects and barometric pressure changes.

Temperature variation affects water movement because the saturated vapor pressure increases with temperature. The natural temperature increase with depth is called the geothermal gradient. Deeper water is warmer and has a higher vapor pressure than water at a shallow depth. This vapor pressure gradient causes water vapor to move upward toward the cooler zones, where it may condense.

Also, barometric fluctuations cause oscillations in the vertical movement of soil gasses, leading to the vertical advective transport of water vapor. The vertical movement may be amplified when extreme barometric pressure conditions are present, such as during a hurricane when extremely low surface barometric pressures cause an upward air pressure gradient within the unsaturated zone.

SPECIFIC GRAVITY

Todd Rasmussen
The University of Georgia
Athens, Georgia

The density of water and other materials varies with temperature as well as with the amount of dissolved and suspended matter within them. The specific gravity is the observed density of a material divided by a reference density, which is usually taken to be water at its maximum density, i.e., 1 kg/L. Thus, variations in the specific gravity are a direct measure of the variation in density. The specific weight of a material equals the product of its density and the gravitational constant. The specific gravity is important because it is needed to correct for the water density in wells to determine the freshwater head. Well construction also relies on the specific gravity of drilling muds to prevent the collapse of borehole walls in unconsolidated media.

The specific gravity is a measure of the density, or weight, of a fluid or solid. Denser materials have a larger specific gravity than do less dense materials. The specific gravity, ϱ, is defined using

$$\varrho = \frac{\rho}{\rho_o} \tag{1}$$

where ρ is the density (mass per unit volume) of the material and ρ_o is the density of a reference material.

The density of water at 4 °C, $\rho_o = 1$ kg/L, is generally the reference density for liquids and solids. Table 1 provides the specific gravity for a range of elements, including very light metals, such as aluminum and titanium, to very dense metals, such as gold and platinum. Note that for liquids and solids, the specific gravity equals the density because the standard density of water is 1 kg/L. The density of hydrogen is common for gasses.

The specific gravity of a pure substance can be affected by temperature. Table 2 provides the specific gravity and specific weight for water from 0 °C to 100 °C. Note that the specific gravity decreases more rapidly as the temperature increases.

Changes in physical properties of solids, such as their crystalline structure or porosity, can also result in a change in their density. The specific gravity can also be affected by any components present within the material, including dissolved gasses, liquids, and solids, as well as suspended gasses, liquids, and solids.

For example, water with high concentrations of suspended solids (such as drilling fluids) or dissolved solids (such as brines) has higher specific gravities than does clear water. Also, a column of air bubbles rising within a water column can reduce the fluid density.

The specific gravity is also related to the specific weight, $\gamma = \rho g$, where $g = 9.807$ m/s^2 is the gravitational constant. The specific weight commonly converts measured pressures to an equivalent hydraulic head because an increase

Table 1. Specific Gravity of Selected Elements

Material	Specific Gravity
Aluminum	2.70
Titanium	4.51
Iron	7.87
Copper	8.96
Silver	10.50
Lead	11.30
Mercury	13.50
Uranium	19.10
Gold	19.30
Platinum	21.50

Table 2. Variation of Pure Water with Temperature

Temperature (°C)	Density (kg/L)	Specific Weight (Pa/m)
0	0.99984	9,805.4
10	0.99970	9,804.1
20	0.99821	9,789.4
30	0.99565	9,764.3
40	0.99222	9,730.7
50	0.98803	9,689.6
60	0.98320	9,642.2
70	0.97778	9,589.1
80	0.97182	9,530.6
90	0.96535	9,467.2
100	0.95840	9,399.0

in depth, Δz, is accompanied by a concomitant increase in pressure, ΔP, which yields $\gamma = \Delta P/\Delta z$.

MEASURING THE SPECIFIC GRAVITY

A traditional technique for measuring the fluid density uses a *hydrometer*, which compares the weight of the fluid to a standard fluid. The hydrometer is allowed to float within the fluid, and the fluid density is determined from how much higher or lower the hydrometer level is compared with pure water (Fig. 1). Heavier fluids cause the hydrometer to rise relative to clear water because of buoyancy.

An alternative method for determining the fluid density is to employ a differential pressure transducer to measure the change in fluid pressure over a known depth. The resulting ratio between the measured pressure and the depth yields an estimate of the specific weight, $\gamma = \Delta P/\Delta z$.

Pressure transducers have recently measured the concentration and particle size distribution of suspended sediments (1). The particle size distribution is determined using Stokes's law, whereas the sediment concentration is found using

$$C = \frac{\varrho_f - 1}{\varrho_s - 1} \tag{2}$$

where ϱ_f is the measured specific gravity of the fluid and ϱ_s is the specific gravity of the suspended sediments.

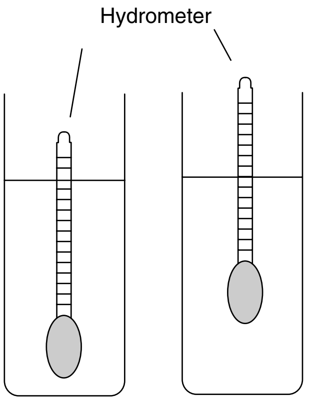

Figure 1. Hydrometer technique for measuring fluid density. Clear water causes the hydrometer to float at a constant level. Denser fluids cause the hydrometer to rise, whereas lighter fluids cause the hydrometer to sink lower in the water column.

IMPORTANCE OF SPECIFIC GRAVITY

Head Measurement

The use of water levels in wells to determine the hydraulic head within an aquifer is complicated when the density of the fluid within the borehole is not a constant (2). As noted in HEAD, changes in density affect the head according to the relationship:

$$H = z_o + \varrho \Delta z \tag{3}$$

where H is the freshwater head, z_o is the midpoint elevation of the screened zone within the aquifer, $\varrho = \gamma/\gamma_o$ is the specific gravity of the fluid within the well, $\Delta z = z - z_o$ is the height of the column of water within the monitoring well above the screened zone, and z is the water surface elevation in the well.

Drilling Fluids

The specific gravity of the drilling fluid is important during well construction. In loose materials, the process of drilling a well is complicated by the tendency of the unsupported walls to collapse.

Borehole walls can be temporarily supported until a casing is emplaced by using drilling fluids that are denser than water. The weight of the drilling fluid places an outward force on the borehole walls that helps to support them.

Heavier drilling fluids place a correspondingly heavier force on the borehole wall. One important drawback is the tendency of the drilling fluid to accumulate on the walls and within the formation, which causes a reduction in well yield if it is not removed during well development.

Lighter drilling fluids, such as foams and air, can also be used. In this case, the inflow of water from the formation into the borehole prevents the buildup of materials on the borehole wall, which eases well development. This technique is suitable in *consolidated media* where borehole collapse is not a problem.

Table 3. Specific Gravities of Selected Drilling Fluids

Drilling Fluid	Specific Gravity
Air	0.001
Mist	0.020
Stiff foam	0.100
Wet foam	0.200
Polymers	1.020
Polymers w/ NaCl	1.200
Bentonite clay	1.300
Polymers w/ CaCl	1.400
Bentonite w/ barite	2.200
Barite ($BaSO_4$)	4.200

Table 3 presents approximate specific gravities for a range of drilling fluids. Notice the wide range in specific gravities, from a low of 0.01 for air to a high of 4.2 for barite.

The values in Table 3 are approximate because the final density is a function of the relative concentrations of the liquids, solids, and gasses within the drilling fluid. Also note that the specific gravity of the air and mist are related to the density of water.

HOT SPRINGS

John E. Moore
USGS (Retired)
Denver, Colorado

Springs have been important in the social, cultural, and economic history of humankind. They have been an important source of water for humans. Our ancestors did not have drilling equipment, so in the absence of surface water, they had to rely on springs. Many early towns in Greece, Egypt, Mesopotamia, India, and China developed around springs. Many towns in the United States have taken their names from springs: Steamboat Springs, Colorado; Glenwood Springs, Colorado; Springfield, Missouri; and Rock Springs, Wyoming, are a few examples.

For centuries, hot springs and mineral springs were considered of medicinal or therapeutic value. Bottled “springwater” is still considered by many people of higher quality than ordinary tap water. This belief is at least partially responsible for the current high-volume sale of bottled water. Unfortunately, this association of springwater with purity is not based on fact. Springwater can contain higher concentrations of dissolved solids than local public water supplies, and springs become easily contaminated. Springs become contaminated because they are open, unprotected, and accessible to human beings and animals. Contamination can also occur from surface water flow or flooding into spring collection systems.

More than 3400 public water supply systems (1992) in the United States obtain part or all of their drinking water from springs. These systems provide drinking water for more than 7 million people. However, the average number of people served by a single public supply system using springs as a water source is small. Springs are an important component of the drinking water supply in many states. Public water supplies that use springs are more numerous in the western United States. Wyoming has 80 springs that are used for public water supply. A box used to collect water from springs is shown in Fig. 1 (1).

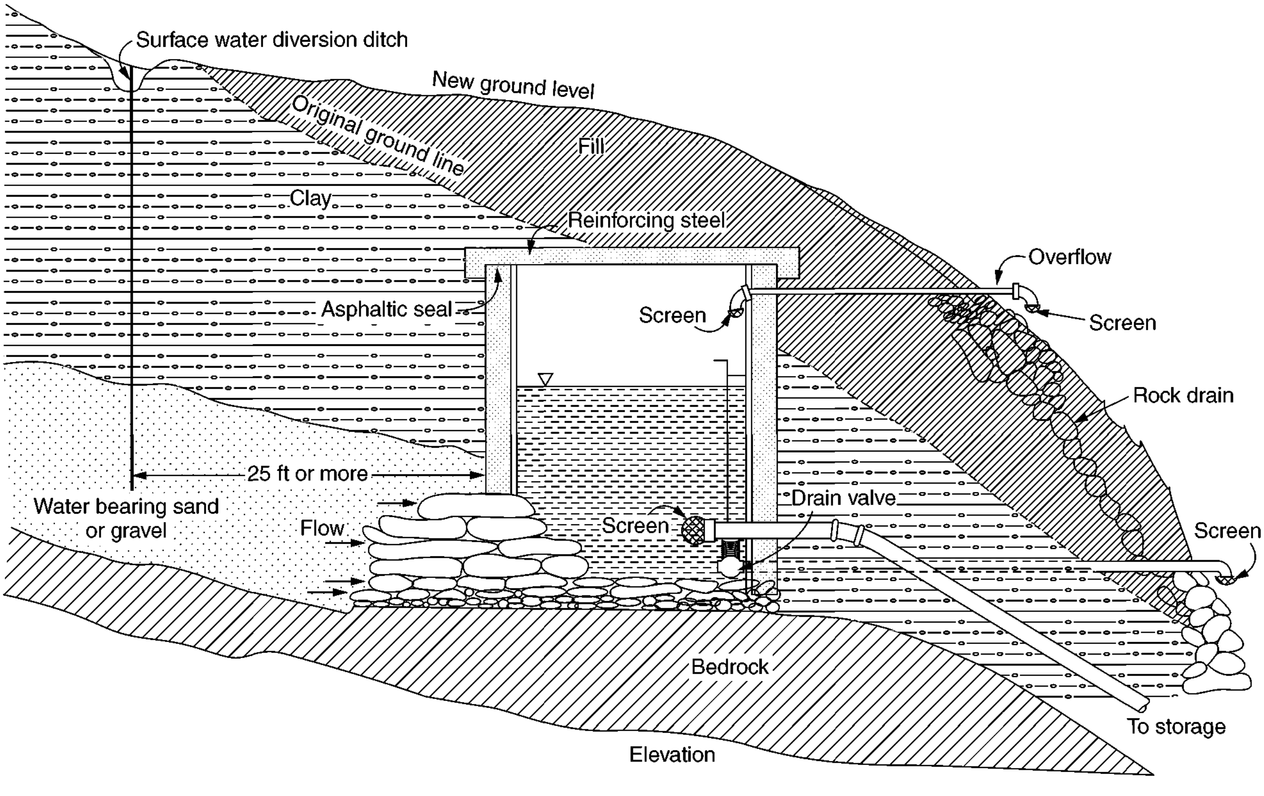

Figure 1. Diagram of a spring collection box (1).

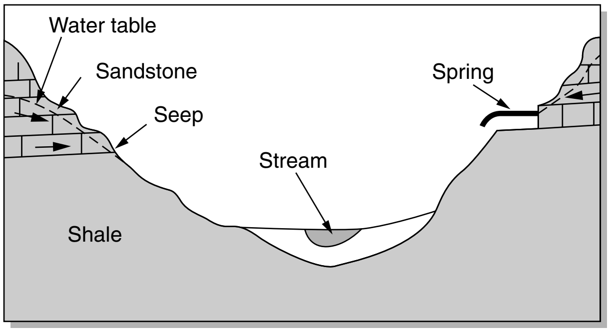
A spring is a source of water that flows naturally from an aquifer or soil onto the land or into a body of surface water. Its occurrence depends on the nature and relationship of rocks (especially permeable and impermeable strata), on the position of the water table, and on topography.

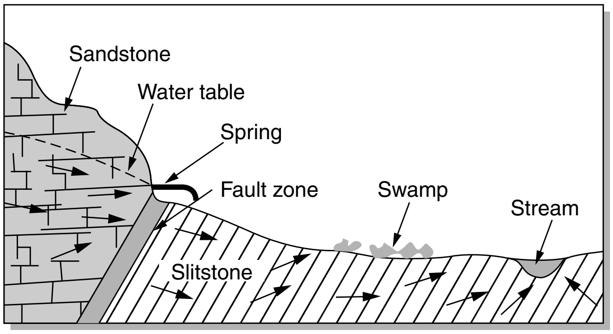
Springs are generally classified as gravity springs and artesian springs. Thermal springs are typically considered a type of artesian spring. The vast majority of springs are gravity springs. Gravity springs are created by water that moves downgradient (downhill) and emerges at the surface. Two gravity springs, contact and fault springs are shown in Fig. 2. Artesian (nongravitational) springs occur when the potentiometric level of the groundwater system is above the land surface and water flows at the land surface under pressure either at the aquifer outcrop or from fractures or faults.

Springs are replenished by precipitation that recharges aquifers. The precipitation seeps into the soil and enters fractures, joints, bedding planes, or pore spaces in sand aquifers and sedimentary rocks. Springs occur when water flows through aquifers and discharges at the land surface through faults, fractures, or by flow along an impermeable layer. They can also occur where water flows from large orifices that result when the water dissolves carbonate rock (karst) and enlarges fractures or joints to create a passage (Fig. 2).

Springwater is sometimes forced to the surface along a fault from deep sources by thermal pressure gradients. Springs are associated with volcanism and fractures that extend to great depths in the earth's crust. Springs are a common feature in some hydrogeologic settings.



Contact spring



Fault spring

Figure 2. Contact and fault springs (2).

For example, springs are common in mountains and in watersheds that are underlain by fractured rock aquifers.

Springs can be regional (long flow paths) or local (short flow paths). Local springs are comparatively small, can have low flow, and are typically from shallow aquifers. The discharge from these springs often fluctuates either seasonally or in greater cycles, sometimes in response to local precipitation. Local aquifers are quickly recharged, and water movement through them is comparatively rapid, resulting in low water mineralization. Springs supported by local aquifers are more likely than regional flow springs to stop flowing periodically. Regional springs more typically have large discharges. Regional springs typically have nearly constant discharge and are more mineralized than local springs. Regional springs rarely stop flowing even during long droughts.

The discharge rate of a spring is a function of three main variables:

1. hydraulic conductivity (permeability) of the aquifer
2. area contributing recharge to the aquifer
3. quantity of recharge.

Springs are also classified based on hydrogeologic characteristics. The Water Resources Division of the U.S. Geological Survey recognizes eight principal types of springs based on hydrogeologic characteristics:

1. An artesian spring is a release of pressurized water from a confined aquifer at the aquifer outcrop or through an opening in the confining unit.
2. A depression spring is formed when the water table intersects a steeply sloping land surface. This type of spring is sensitive to seasonal fluctuations in groundwater storage and frequently disappears during dry periods.
3. A fracture spring (fault spring) is formed in fractured or jointed rocks. Water movement is through fractures, and springs form where the fractures intersect the land surface. This type of spring is particularly sensitive to seasonal fluctuations in groundwater storage and frequently disappears due to reduced flow during dry periods. Daily fluctuations of discharge of small springs are commonly the result of use of water by vegetation.
4. A contact spring occurs where a permeable water-bearing unit overlies a less permeable unit that intersects the ground surface.
5. A geyser spring is a periodic thermal spring resulting from the expansive force of superheated steam within constricted subsurface channels.
6. A perched spring occurs where infiltrating water discharges above the regional water table.
7. A seep spring discharges from numerous small openings in permeable material. These springs typically have very low discharge rates.
8. A tubular spring discharges from rounded channels (karst solution openings, lava tubes).

Springs occur in many sizes, types of discharge points, and locations with respect to topography. They occur in the highest elevations of mountainous areas and on valley floors. Many of the public water supply springs in the western United States are small; discharges are less than 5 gallons per minute. Springs vary in their physical and chemical compositions. They can be cold (50 °F) or hot (more than 10 °C above the air temperature). Shallow groundwater has a temperature within a few degrees of the ambient air temperature. Higher temperatures usually indicate deeper circulation. Thermal springs gain their temperature increases when the water comes in contact with recently emplaced igneous masses. Thermal and hot springs are due to deep-seated thermal sources and are classed as volcanic springs or fissure springs. Springs may occur singly or in groups that can include dozens of habitats in various sizes.

Springs may be highly mineralized, especially thermal springs and sometimes region springs that have a very long flow path. Thermal springs have pH values ranging from 7.2–7.6. Electrical conductance of spring water ranges from 2–10,000 milligrams per million.

A list of question that could be asked to evaluate spring conditions is shown below.

- Are there standing water and surface drainage around the spring?
- Is there deeply rooted vegetation in the spring collection area?
- Are there roots in the collection pits?
- Is there a lock-tight fence around the collection area?
- Is there a diversion channel capable of diverting surface water away from the collection area?
- Are there privies, septic systems, underground storage tanks, or barnyards near the spring?
- Is the collection chamber properly constructed (lockable)?

SQUEEZING WATER FROM ROCK

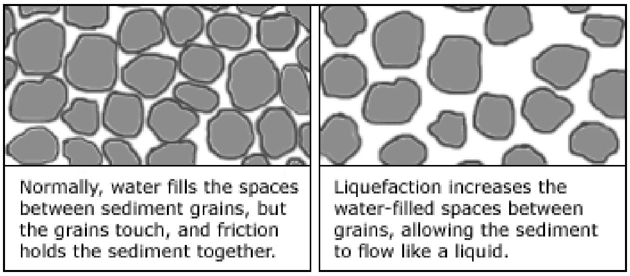
NASA Earth Science Enterprise
Data and Services

On December 16, 1811, an earthquake estimated at magnitude 7.0 to 8.0 on the Richter scale rocked the frontier town of New Madrid, Missouri, in the central United States. It was the first of three powerful earthquakes that would shake the central Mississippi River Valley that winter. Damages were reported as far away as Charleston, South Carolina, and Washington, DC. According to the U.S. Geological Survey, the New Madrid events were the most powerful earthquakes in recorded U.S. history.

Survivors of the New Madrid earthquakes reported not only intense ground shaking and land movement, as would be expected during an earthquake, but also an unfamiliar phenomenon: water and sand spouting up through fissures, or cracks, in the Earth's surface. In a letter published in *Lorenzo Dow's Journal*, New Madrid resident Eliza Bryan (1) wrote in 1816:

> ... the surface of hundreds of acres was, from time to time, covered over in various depths by the sand which issued from the fissures, which were made in great numbers all over this country, some of which closed up immediately after they had vomited forth their sand and water... 25 June 2003

Structures in the village of Bhuj, India, which was 80 kilometers (50 miles) from the earthquake epicenter, sustained considerable damage. (Image Copyright © James Mori, Research Center for Earthquake Prediction, Disaster Prevention Institute, Kyoto University)



Normally, water fills the spaces between sediment grains, but the grains touch, and friction holds the sediment together.

Liquefaction increases the water-filled spaces between grains, allowing the sediment to flow like a liquid.

Modern earthquake researchers refer to this expulsion of water and sand from the ground as *earthquake dewatering*, which results from liquefaction. Liquefaction occurs when an earthquake vigorously shakes and compacts water-saturated sediments. As the compaction process displaces the water between the sediment pores, water and sand shoot upward and out of the ground.

"Imagine a cube full of sand and water. If you press it in from both sides (compressing and releasing it, then compressing it again), you build up what's called pore-water pressure," said Martitia Tuttle, geologist and consultant for the U.S. Geological Survey. "It's like shaking a coke can—when the pressure builds up and you release it, the fluid comes shooting to the surface." These fountains of water can sometimes shoot as high as 30 feet into the air, according to Tuttle (2).

Tuttle is part of a team that has been studying liquefaction in the New Madrid region in an effort to identify large prehistoric earthquakes in the geologic record. "Interpreting historic and prehistoric earthquake events involves a lot of uncertainty, due to the lack of data," Tuttle said. "We often don't know precisely where the earthquakes occurred or how big they were." What researchers needed was a modern-day event in a similar environment with which to compare the New Madrid earthquakes.

On January 26, 2001, a magnitude 7.7 earthquake near the village of Bhuj, located in the Kachchh region of northwestern India, provided scientists with just that analogue. Considered one of the two most damaging earthquakes in India's recorded history, the Bhuj earthquake killed about 20,000 people and caused an estimated $3.3 billion in damages.

The Bhuj earthquake struck the Kachchh region of northwestern India on January 26, 2001. The bottom image is a detail of the area indicated in red in the top map. (Images adapted from maps from the University of Texas at Austin General Libraries)

Earthquake Severity Table Adapted from What is Richter Magnitude? (A New Browser Window Will Open.)

Richter Magnitude	Earthquake Effects
Less than 3.5	Recorded but generally not felt
3.5 to 5.4	Often felt but rarely causes damage
Less than 6.0	Slight damage at most to well-constructed buildings; over small regions, can cause major damage to poorly constructed buildings
6.1 to 6.9	Can be destructive in populated regions up to 100 kilometers across
7.0 to 7.9	Major earthquake that can cause serious damage over areas larger than 100 kilometers across
8 or more	Great earthquake that can cause serious damage over areas several hundred kilometers across

According to Tuttle and co-authors (3) of a paper recently published in *Eos*, local residents and survey teams working in the area after the earthquake reported fountains of water and sediments surging from the ground during and immediately following the Bhuj earthquake. The water flow was significant enough to reactivate streams in previously dry river channels.

"The Bhuj earthquake provided an opportunity to study an earthquake that was very similar to the New Madrid event—it was a very large earthquake, and it occurred in an intraplate-like setting," said Tuttle. The New Madrid and Kachchh regions are both located more than 185 miles (300 kilometers) from active plate boundaries.

"Before the Bhuj earthquake, there was a lot of debate in the seismological community about the magnitude of the New Madrid earthquakes, but based on the similarity in intensity between the New Madrid and Bhuj events, there is a growing consensus among scientists that the New

Madrid earthquakes were probably larger than magnitude 7.5," said Tuttle. "The Bhuj earthquake is a modern event that helps us better understand the historic and prehistoric earthquake record in the New Madrid region."

But despite the unique study opportunity presented by the Bhuj earthquake, the area presented the researchers with some grave challenges. First, the Kachchh region of India is remote and difficult to reach. Second, it shares a politically sensitive border with Pakistan. These factors made it difficult for research teams to conduct field studies to verify liquefaction effects or the presence of water in some areas.

Bernard Pinty (4), research scientist at the Institute for Environment and Sustainability in the Joint Research Centre of the European Commission in Ispra, Italy, and colleagues found that water expelled during the earthquake could be detected in imagery from NASA's Multiangle Imaging SpectroRadiometer (MISR) satellite sensor.

The MISR instrument, which flies aboard NASA's Terra satellite, views the sunlit face of the Earth at nine widely spaced angles simultaneously. As it passes over the Earth, its nine cameras successively view each piece of the planet's surface at a spatial resolution of 300 yards (275 meters).

The change in reflection at different angles provides a means for distinguishing different types of land surface covers. Since bright soils in India's Rann of Kachchh (also known as the Rann of Kutch) reflect most of the sun's near-infrared radiation, and water bodies absorb near-infrared radiation, MISR is able to detect the contrast and indicate where dewatering occurred.

According to Pinty, these features made MISR an ideal tool for studying liquefaction in the Bhuj earthquake. "MISR's multi-angle capability was instrumental in exposing the presence of free water close to the Pakistani border, a region where it is difficult, if not impossible, to take ground measurements," he said.

These cracks in the ground surface north of Chobari, India were caused by liquefaction induced during the Bhuj earthquake. (Image Copyright © James Mori, Research Center for Earthquake Prediction, Disaster Prevention Institute, Kyoto University)

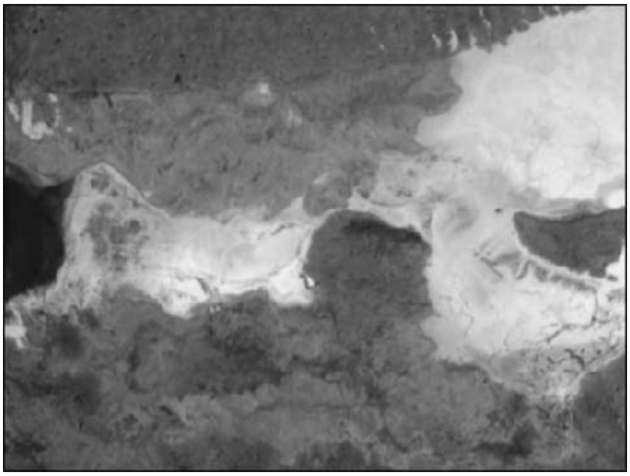
Most other satellite instruments only look straight down or towards the edge of the Earth. "It would take several more passes for another sensor to capture the entire region that the MISR imagery covers," said Tuttle. "The MISR images enabled us to see a large area both during and immediately after the earthquake, and we could see that dewatering was occurring over a huge region."

Scientists now know that the New Madrid earthquakes were not geologic flukes; similar events have occurred repeatedly in the geologic past. In fact, the central Mississippi Valley experiences more earthquakes than any other region in the United States east of the Rocky Mountains.

The New Madrid Seismic Zone, which includes parts of Tennessee, Kentucky, Missouri, Arkansas, Illinois, Indiana, and Mississippi, harbors a large liquefaction field. Scientists estimate the probability of a magnitude 6.0 or greater earthquake occurring in the New Madrid Seismic Zone within the next 50 years at 25–40 percent, according to the U.S. Geological Survey. But a similar event would have much more serious consequences today.

In 1811–1812, the central Mississippi Valley was a remote frontier. Today, the region is home to millions of people and includes the metropolitan cities of St. Louis, Missouri, and Memphis, Tennessee. In addition, most buildings in the region were not built to withstand earthquake shaking, as they often are in California and Japan.

Buildings and engineered structures are at much higher risk in areas where liquefaction occurs, due to increased ground motion. "The liquefaction process is extremely damaging to all sorts of engineered structures; it has



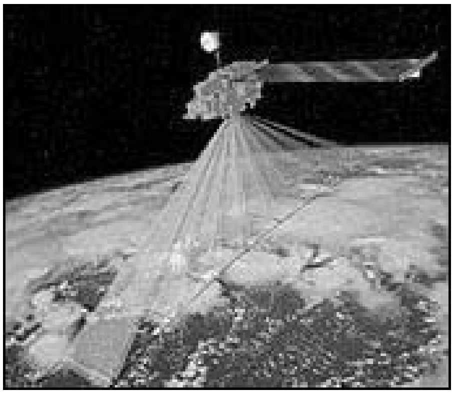
This false-color MISR image was acquired after the Bhuj earthquake, on January 31, 2001. The image shows numerous areas where groundwater flowed up to the surface, including within the Rann of Kachchh, as well as near the Indo-Pakistani border. (Image courtesy of NASA/GSFC/LaRC/JPL, MISR Team) Click here for more information.

caused major destruction in both Anchorage and San Francisco," said Pinty.

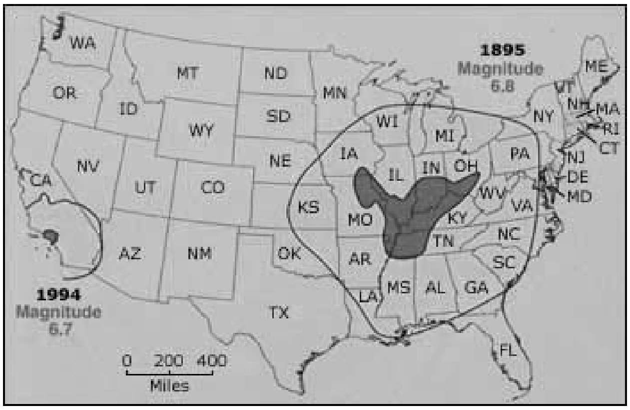
"The ground failure that resulted from liquefaction during the New Madrid earthquakes was severe. We're talking about vertical displacement of 3 to 6 feet (1 to 2 meters), and lateral displacement up to 33 feet (10 meters)," said Tuttle. "A recurrence of that type of event would have severe consequences for engineered structures."

According to Tuttle, in 1988 a magnitude 5.9 earthquake in Quebec, Canada, produced liquefaction. "Basements cracked, septic fields were disrupted, and people described water and sand shooting into their basements, out of their toilets, and into their bathtubs," she said. "And that was just a moderate-sized earthquake, not a big one."

MISR imagery, which is archived at the Langley Research Center DAAC, promises to be a boon to earthquake researchers seeking to minimize hazard risks.



The MISR instrument views the sunlit Earth simultaneously at nine widely spaced angles, providing ongoing global coverage at high spatial detail. (Image courtesy of NASA)



Although earthquakes in the central and eastern United States are less frequent than in the western United States, they affect much larger areas. This is shown by two areas affected by earthquakes of similar magnitude—the 1895 Charleston, Missouri, earthquake in the New Madrid Seismic Zone and the 1994 Northridge, California, earthquake. Red indicates regions of minor to major structural damage; yellow indicates areas where shaking was felt, but little or no damage to objects occurred. (Image courtesy of the U.S. Geological Survey)

"The interesting thing is that this project started as an 'after hours' sort of activity," said Pinty. "But it soon acquired its own momentum, giving us results that are of significant relevance to earthquake study applications. Our findings revealed that MISR can detect water and moist conditions on terrestrial surfaces, even under unfavorable spectral conditions."

"If we study modern earthquakes that produce liquefaction, we can better interpret the geologic record of liquefaction during past events. This helps us anticipate what is likely to happen in the future so that we can make informed decisions about reducing and mitigating hazards," said Tuttle.

For more information, visit the Langley Atmospheric Sciences Data Center DAAC. (A new browser window will open.)

"It's one of those things where people tend to think—if it hasn't happened during my lifetime, then it can't happen here," said Tuttle. "But the liquefaction field in the New Madrid region is very large. We're talking about a huge earthquake that could have a significant impact on society."

STORAGE COEFFICIENT

Matthew M. Uliana
Texas State University—San Marcos
San Marcos, Texas

DEFINITIONS

A coefficient is a mathematical quantity that relates two or more variables in an equation describing some physical process. In equations describing the flow of fluids in a porous medium (e.g., groundwater in an aquifer), the **storage coefficient** is the quantity that relates the change in fluid potential (i.e., hydraulic head) in the aquifer to the change in the amount of water stored in the aquifer at a given point. In practical terms, the storage coefficient tells us the volume of water that can be removed from an aquifer for a given drop in hydraulic head.

There are three storage coefficients used in groundwater flow equations (the units of each are given in [brackets] following each definition):

Specific Storage (S_s) is the volume of water removed from a unit volume of a confined aquifer for a unit drop in hydraulic head [L^{-1}].

Storativity (S) is the volume of water removed from a unit area of an aquifer for a unit drop in hydraulic head; in confined aquifers, it is equal to the specific storage times the thickness of the aquifer, in unconfined aquifers, it is equal to the specific storage times the thickness of the aquifer plus the **specific yield** [–].

Specific Yield (S_y) is the volume of water removed from a unit volume of an unconfined aquifer for a unit drop in water level; this quantity is also defined as the volume of water that will drain by gravity from a saturated unit volume of an aquifer and is equivalent to the effective porosity [–].

Specific Storage (S_s)

The main equation that governs the flow of a fluid in a porous medium is given by

$$\frac{\partial q_x}{\partial x}+\frac{\partial q_y}{\partial y}+\frac{\partial q_z}{\partial z}=S_s\frac{\partial h}{\partial t} \tag{1}$$

where q = specific discharge (i.e., groundwater flow) in the x, y, or z direction [$L \cdot t^{-1}$]
h = hydraulic head [L]
t = time [t]
x, y, z = lengths in the principal directions in our coordinate systems [L]
S_s = specific storage [L^{-1}]

Darcy's law

$$q=K\frac{dh}{dl} \tag{2}$$

where K = hydraulic conductivity [$L \cdot t^{-1}$]
dh/dl = hydraulic gradient, or change in head with length [–]

can be substituted for q to get the expanded version of the flow equation:

$$\frac{\partial\left(K_x\frac{\partial h}{\partial x}\right)}{\partial x}+\frac{\partial\left(K_y\frac{\partial h}{\partial y}\right)}{\partial y}+\frac{\partial\left(K_z\frac{\partial h}{\partial z}\right)}{\partial z}=S_s\frac{\partial h}{\partial t} \tag{3}$$

Equations 1 and 3 are specific versions of the **continuity** (or **conservation of mass) equation**,

$$I-O=\Delta S \tag{4}$$

where I = flux into a volume of a system [$L^3 \cdot t^{-1}$]
O = flux out of a volume of a system [$L^3 \cdot t^{-1}$]
ΔS = change in the amount stored in that same volume of the system [$L^3 \cdot t^{-1}$]

The left side of Eq. 3 corresponds to the left side of the continuity equation and describes the divergence of flux at a point in the aquifer. In other words, it describes the groundwater flow vector resolved into x, y, and z components (see Fig. 1).

The right side of Eq. 3 corresponds to the right side of the continuity equation and describes the change in storage at the given point in the aquifer. The term $\partial h/\partial t$ refers to the change in hydraulic head, with respect to time, at the same point in the aquifer. The term S_s is the **specific storage**, and it relates the changes in head in the aquifer to the change in the amount of water stored in the aquifer at a certain point. In other words, it is a quantity that tells us the volume of water that can be removed from a unit volume of a confined aquifer for a unit drop in head.

CONFINED AQUIFERS—A CONCEPTUAL UNDERSTANDING

Consider a confined aquifer that consists of a layer of sand overlain by an impermeable layer of clay that acts as a confining layer. If a well is drilled into the aquifer and water is pumped from the well, the heads around the well will lower and create a cone of depression in the potentiometric surface (Fig. 2). The more water that is pumped from the well, the larger the cone of depression. In the example shown in Fig. 2, the pumping well has removed a volume of water (represented by the volume in the barrel), and in response, the water levels in

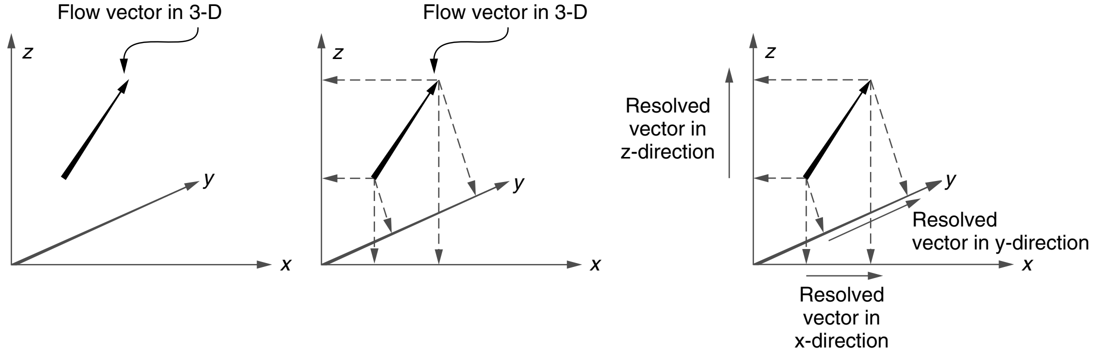

Figure 1. Flow vector resolved into component vectors in three dimensions.

the well and in the surrounding aquifer have dropped. However, the saturated thickness of the aquifer itself has not changed (i.e., the aquifer is still full to the base of the confining layer). What is the source of this water? The conceptual answer deals with elastic deformation and compressibility of the aquifer materials and the water.

This aquifer is made up of sand grains and pore spaces that are full of water. If there is no confining layer and the aquifer is simply recharged by water infiltrating from above, the pore spaces are full of water, and the pore fluid pressure is equal to atmospheric pressure plus the overlying column of water. In this case, the volume of water in the pore space is equal to the volume of the pore space.

However, if the aquifer is confined and an additional component of pressure is added to the water, that pressure will force a greater volume of water into the pores of the sand. It does this by compressing the sand grains slightly, pushing the sand grains around so that pore volume is increased, and compressing the water itself slightly. Increasing the pore fluid pressure causes the aquifer to undergo **elastic** (i.e., recoverable) **deformation**, so that a subsequent decrease in fluid pressure will cause an associated decrease in volume (Fig. 3).

This is the source of the additional volume of water. Pumping water from the confined aquifer lowers the excess fluid pressure (i.e., the pressure head above the top of the aquifer), causing the aquifer to 'relax' and yield water that is stored by the excess pressure.

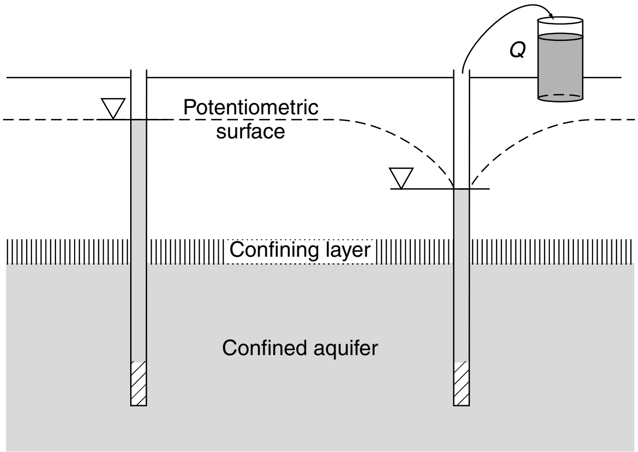

Figure 2. Pumping well in a confined aquifer.

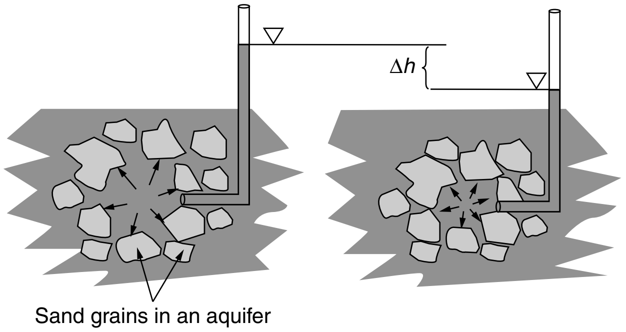

Figure 3. Elastic deformation in a sand aquifer.

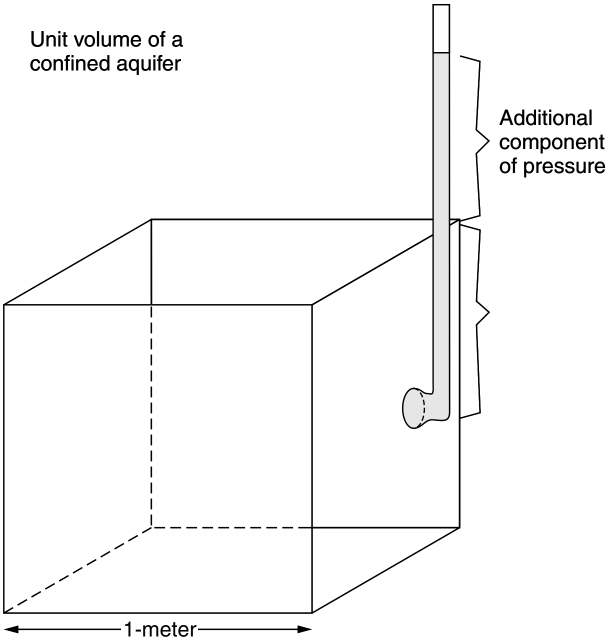

Figure 4. Unit volume of a confined aquifer.

CONFINED AQUIFERS—A MATHEMATICAL UNDERSTANDING

Consider a unit volume of a confined aquifer. This unit volume is saturated with water, and the water has an additional component of pressure that would cause the water level in a manometer to rise above the top of the cube (Fig. 4). If a volume of water is removed from the cube, it will reduce the additional component of pressure and lower the head in the cube. Removing more water will cause more head loss; less water will cause less head loss. Therefore, there is a specific volume of water that, if removed, will cause a unit drop in head. This volume of water that results in a unit drop in head in the unit volume of aquifer is the **specific storage**.

The specific storage is also called the **elastic storage coefficient**; it deals only with the amount of water removed from elastic storage. The specific storage is a function of the compressibility of the aquifer matrix (i.e., the material that makes up the aquifer) and the compressibility of the water and is strictly defined as

$$\mathrm{S}_s = \rho_w g(\alpha + n\beta) \tag{5}$$

where ρ_w = density of water [M/L^3]
g = gravitational constant [L/t^2]
α = compressibility of the aquifer matrix [1/M/Lt^2]
n = porosity [−]
β = compressibility of water [1/M/Lt^2]

STORATIVITY IN CONFINED AQUIFERS

The specific storage actually refers to an infinitesimal point in the aquifer. However, in real aquifers, the thickness of the aquifer influences how much water the aquifer will yield; a thicker aquifer will transmit and yield more water than a thinner aquifer. Multiplying the specific storage by the saturated thickness of the aquifer results in **storativity** (S):

$$S = S_s b \tag{6}$$

where b = saturated thickness of the aquifer [L].

In other words, the storativity describes the volume of water removed from a unit *area* of aquifer for a unit drop in head.

UNCONFINED AQUIFERS AND SPECIFIC YIELD

In a confined aquifer, all the water pumped out through a well is provided by the release of water from elastic storage. In an unconfined aquifer, the same thing occurs—the changes in head result in a release of water from elastic storage in the aquifer. However, in an unconfined aquifer, the pumping well is dewatering a section of the aquifer (Fig. 5), and this part of the aquifer's response adds an additional volume of water to the volume withdrawn from elastic storage.

This additional volume of water is released from the pore spaces and is due to the **specific yield** of the aquifer. Specific yield is the volume of water that drains from a rock under the force of gravity and is directly related to the effective porosity of the aquifer matrix. The volume of water released from a unit volume of aquifer due to dewatering of the aquifer is therefore the unit volume times the specific yield.

So, in unconfined aquifers, the volume of water released from a unit volume of aquifer is a function of both the specific yield (i.e., the water removed from the pore space) and the specific storage (the water released from elastic storage in the aquifer). Therefore, in an unconfined aquifer, the storativity of the aquifer is the sum of the specific yield and the thickness times the specific storage.

$$S = S_y + bS_s \tag{7}$$

However, the magnitudes of these parameters are drastically different: specific yield values in an aquifer generally range from 1% to 50%, or 0.01 to 0.5; specific storage values generally range from 1×10^{-3} to 1×10^{-6}, or 0.001 to 0.000001, which means that, in an unconfined aquifer, the volume of water provided by release from elastic storage is orders of magnitude less than that provided by dewatering the pores; so the specific storage is generally considered negligible, and unconfined storativity is a function only of the specific yield.

QANATS: AN INGENIOUS SUSTAINABLE GROUNDWATER RESOURCE SYSTEM

Bahram Saghafian
Soil Conservation and
Watershed Management
Research Institute
Tehran, Iran

A qanat system consists of an underground tunnel that conveys water by gravity from highland aquifers to the ground surface at lower elevations. Blended with ingenuity, its purpose is simply to collect and bring underground water to the surface for use. Qanat, invented and originated in Iran more than 2700 years ago, is considered a hydraulic engineering system of an Old World era providing water to settlements since its invention. The overwhelming climate of Iran is arid and semiarid; two thirds of the country area in central, southern, and eastern parts receive an average of about 150 mm of rainfall annually. Yet, Iran is considered a farming country where diverse crops are grown. This remarkable achievement in agricultural development of arid lands has materialized partly by building qanats to tap underground water in regions where surface water is lacking or unreliable during seasons of high water demand. Numerous urban and rural qanat-watered settlements are vivid examples that not all civilizations were rooted by the sides of rivers. Qanats have helped to transform barren lands into productive assets. Thanks to its simple and efficient technique, the idea behind this sustainable water resource system was passed from one generation to the next and traversed geographic boundaries. Qanat's use is not confined to Iran and has been adopted in many regions across the world.

QANAT DESCRIPTION

Britannica characterizes a qanat as, "A qanat taps underground mountain water sources trapped in and beneath the upper reaches of alluvial fans and channels the water downhill through a series of tunnels, often several kilometres long, to the places where it is needed for irrigation and domestic use ...." The dictionary of

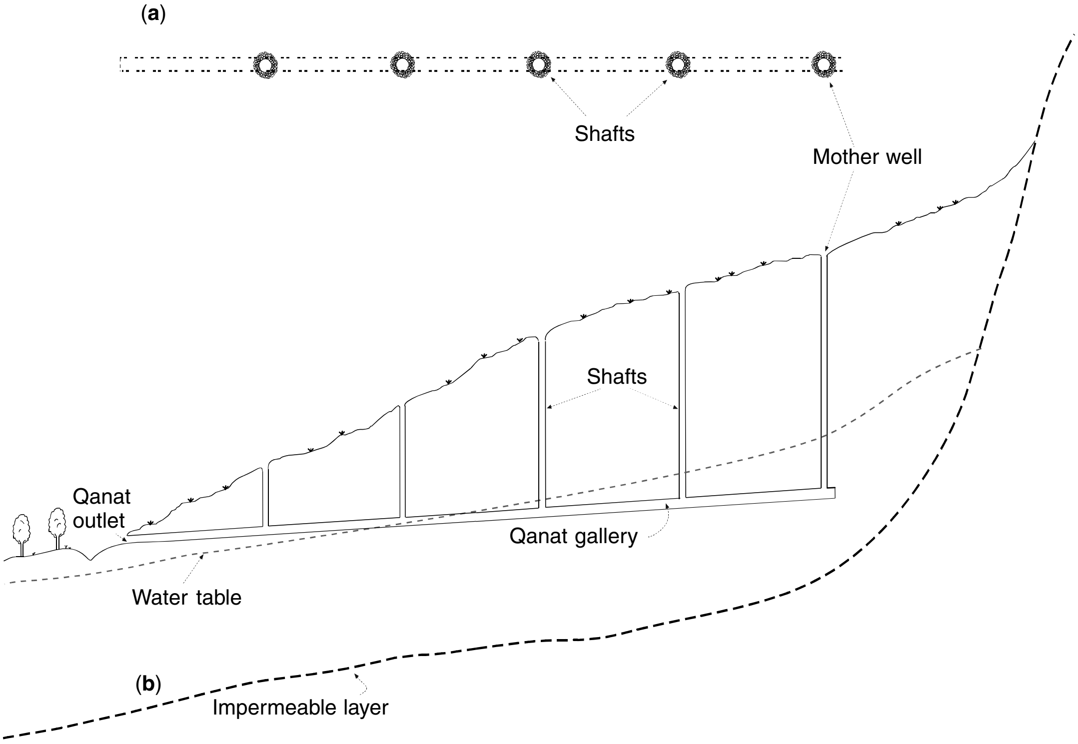

Figure 1. Schematic plan (**a**) and cross section (**b**) of a qanat system.

Islamic Architecture defines qanat as a "subterranean canal system usually used to bring water some distance from a river or mountains." More technically, Lightfoot (1) describes a qanat as "a form of subterranean aqueduct, or subsurface canal, engineered to collect groundwater and direct it through a gently sloping underground conduit to surface canals which provide water to agricultural fields."

As shown in Fig. 1, a qanat consists of a gently sloped underground tunnel, or gallery, penetrating the upland aquifer at one end and appearing in the ground surface at the other end. The gallery, is also vertically connected to the ground by several wells, or shafts, dug along its length, often at 20–30 m to a maximum of 100 m intervals, providing ventilation and access during construction and maintenance. Put differently, a qanat consists of a series of vertical shafts in sloping ground, inter-connected at the bottom by a tunnel with a gradient flatter than that of the ground. The excavated soil is piled up around the entrance of the wells to give some protection in times of storm surface runoff. The first shaft, called the mother well or main shaft, is usually sunk into the alluvial fan to a level below the groundwater table. The line of qanat wells looks like anthills in a distinctive plan view. The typical cross section of a qanat gallery is 1.5 m high and about 1 m wide, which is just sufficient to allow men and boys to do the digging and cleaning.

Qanats can be classified into hill and river-based. Hill qanats have their main shafts based in the aquifers located in hill slopes. This type of qanat is not very long. If this type of qanat taps a deep aquifer, it will enjoy a relatively constant discharge. A river-based qanat is normally recharged from a seasonal river, stretching over a long distance where the tunnel meets the ground surface.

Other terms for qanat, pronounced *kanat*, as it is called in different parts of the world, are karez (e.g., in Afghanistan and eastern Iran), foggora (e.g., in Algeria), hattara (e.g., in Morrocco), and falaj (e.g., in Oman).

HISTORY AND GEOGRAPHIC EXTENT OF QANATS

Written records and recent excavations prove that qanats first appeared in ancient Iran (then Persia). Wulff (2) describes the origin of qanat: "As early as the seventh century B.C., the Assyrian king Sargon II reported that during a campaign in Persia he had found an underground system for tapping water in operation near Lake Urmia. His son, King Sennacherib, applied the secret of using underground conduits in building an irrigation system around Nineveh, and he constructed a qanat on the Persian model to supply water for the city of Arbela." The earliest reports of qanats indicated that the water for the city of Ula northwest of Lake Urmia, located in northwest of Iran, was provided by qanats some 700 B.C. (3). English (4) reports that, based on early mining, the mountains of Kurdistan in western Iran, eastern Turkey, and northern Iraq were the birthplace of the qanat more than 2500 years ago.

The technique was then widely diffused during the expansion of Achaemenid dynasty, ruling the Persian Empire, beginning sometime in the fifth century B.C. Qanats were constructed in Mesopotamia to the shores of the Mediterranean to the west, in Egypt and the Arabian Peninsula to the south, and in Afghanistan, Central Asia, and western China to the east. The Arabs introduced the idea further to the west during the second diffusion phase in the eighth century A.D. The greatest developments of qanat technology outside the Persian core area are in southern Morocco (Marrakesh and the Tafilalet) and southern Algeria (5). Wulff (2) reported the excavation of several particularly interesting qanats constructed by Arab rulers of early medieval times in the Middle East. These include a small qanat built by the caliph of Damascus to supply water for his palace in 728 A.D. A century later, presumably with the aid of Persian engineers, the caliph Mutawakkil in Iraq constructed a qanat that brought water to his residence at Samarra from the upper Tigris River 300 miles away.

Qanats are reported to exist in Spain, Sicily, Cyprus, the Canary Islands, and in South American countries such as Mexico, Peru, and Chile. The Madrid qanat system in Spain, bringing water for urban use, still functions. The qanat systems of Tehuacan and Parras in Mexico are believed of Spanish origin, but those of Parras (Coahuila) and Pica (Chile) may be pre-Columbian (6). English (5) and Beekman et al. (7) discuss scenarios of the diffusion of qanat technology throughout the world.

CONSTRUCTING A QANAT

The laborious construction of a new qanat is a task to be engineered by an expert, who usually heads a team of diggers. The diggers, called *muqannis*, are responsible for building and repairing qanats. The expert must decide on a number of key issues prior to qanat construction: the site of the mother well and the alignment and the slope of the underground gallery. In his work, the expert uses simple instruments such as a long rope and a level. As the mother well of a qanat is usually dug in an alluvial fan at the foot of a mountain or hillside, the expert watches for signs of seepage on the ground, slight variations in the vegetation, and available groundwater. Once the site is chosen, one or sometimes more trial wells are sunk. The muqannis then start digging the trial well, normally 1 m in diameter. They use a windlass at the top and haul up the soil excavated by their teammates. They continue the digging and spoil the material around the rim of the well until the water table is struck. The expert then should determine whether the aquifer water has acceptable water yield. If so, he measures the distance from the mother well to the qanat outlet, where water is planned for use. Once the general alignment of the qanat is determined, the expert calculates the slope of the qanat gallery. This slope must allow the water to flow, yet prevent erosion of the bottom and walls of the gallery. The slope for short qanats may run from 0.5 to 2 in 1000, whereas longer qanats usually have gentler slopes. In steep land, the slope of the gallery is maintained in a looping course. The work then proceeds from the outlet of qanat by excavating the tunnel back toward the mother well. Vertical shafts at a distance of 30 m, or so, are dug to provide ventilation and access. For shafts deeper than 100 m, the muqannis set up another windlass halfway within the shaft for a two-stage haul up of spoil. The muqannis maintain a straight course by sighting along a pair of burning oil lamps. The task requires great skill and endurance. Figure 2 shows a top view of qanat during construction.

Figure 2. A top view of a qanat during construction.

Muqannis may encounter a number of dangers in their work. Soft soil in the tunnel can cause collapse of the roof. In such cases, the tunnel cross section is braced with baked clay collars to control cave-ins (Fig. 3). Another danger is air low in oxygen. Any change in the burning of the illuminating oil lamps is an indication of such danger. And last, but not least, is the hazard during the breakthrough into the mother well, which must be emptied.

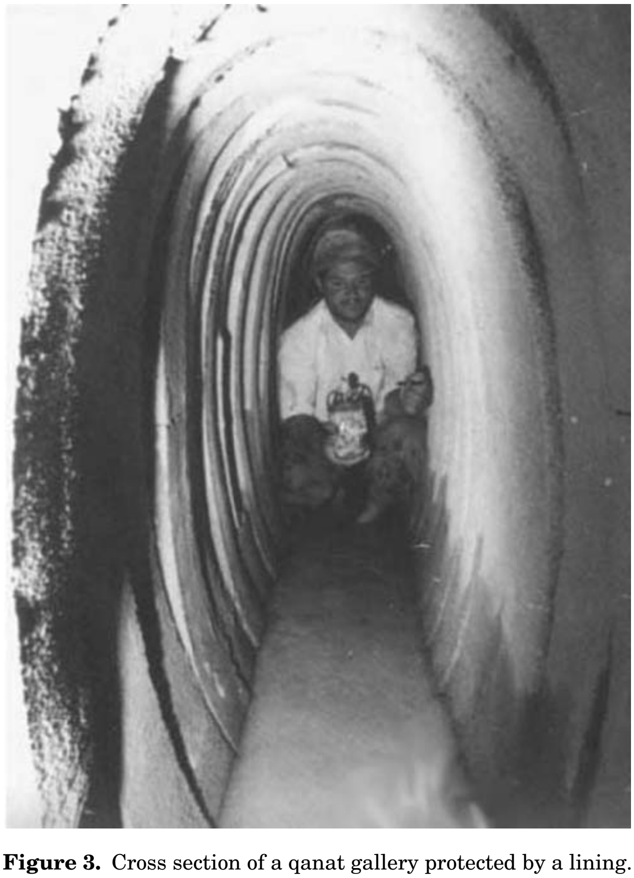

Figure 3. Cross section of a qanat gallery protected by a lining.

Muqannis are highly respected for their courage, hard work, and know-how. They are paid well for their work, and older muqannis are considered blessed or lucky.

QANATS AND WATER REGULATIONS

In Iran, the allotment of water delivered by qanats is regulated by certain laws, which are rooted in a traditional system of water rights. Normally a water master or bailiff, appointed by a qanat owner(s), supervises the water distribution according to each farmer's time share. As Wulff (2) has noted, "the bailiff is guided by an allocation system that has been fixed for hundreds of years. For instance, three hamlets in a region west of Iran, still receive the shares that were allotted to them in the 17th century by the civil engineer in the reign of Shah Abbass. The hamlets of Dastgerd and Parvar in central Iran are entitled to eight shares apiece. These allocations are built into outlets from the qanat distribution basin." English (4) provides a detailed overview of qanat ownership, the complex water distribution system, and, through some examples, how fragmentation of qanat water rights has taken place. He makes a note of strict and unforgiving adherence to communal methods of water rotation and upkeep of the water supply system serving to maintain the social cohesion of qanat-watered villages.

QANATS: COSTLY AND TIME-CONSUMING

Qanats are labor-intensive and time-consuming to build. Both the cost and time to build a new qanat varies with topography, depth of the water table, underground soil type, length of the qanat, type of ownership, availability and experience of muqannis, and local conditions. Thus, reports differ in figures provided for the cost and duration of construction of qanats.

Noting that qanats are long-lasting water resources systems if properly maintained, Wulff (2) believes that the agricultural production sustained by qanat water repays the investment in construction and maintenance by 10% to 25% depending on the size of the qanat, the water yield, and the crop type. Wulff's assessment of the cost in the 1960s showed that a 6-mile long qanat required US$13,500 to US$34,000 to build. The cost runs to about $90,000 for a qanat 10 to 15 miles long.

English (8), on the other hand, reported that it took 27 years to construct a 1-km qanat in Kerman, in central Iran, with a mother well 45 meter deep, due to three changes in ownership. Another 3-km qanat with two mother wells, 50 and 55 m deep, and a bifurcated tunnel took 17 years to build. The costs of these two qanats, respectively, were approximately $10,000 to $11,000 per km in the 1960s. As another example, the cost of constructing a 40-km long qanat near the city of Kerman with a mother well 90 m deep was roughly $213,000 when completed in 1950 (4). Such expenses adjusted for inflation can be raised only through government subsidies or large corporations in modern Iran. Due to high construction investment, qanat owners often try to increase the yield. They may extend branches from the main tunnel to reach additional aquifers or excavate the floor of the existing tunnel to tap water at a deeper level (2).

Note that, although agricultural production cannot repay the investment and maintenance costs of new qanats in some regions, existing qanats are still the second water supply system in volume providing for drinking and domestic use in Iran. Keeping the qanat cost and the enormous building effort in mind, individual farmers are unwilling and unable to fund the construction of new qanats or even maintain old ones. Thus, farmers have turned to drilled wells as the more affordable alternative.

QANAT VERSUS DRILLED WELL

People in arid regions rely on underground aquifers for their water supply. The aquifers can be tapped by a qanat, or alternatively by a drilled well, and the water is directed to an area where it is consumed. The volume of water produced by a qanat depends upon several factors: extent, type, yield, and recharge rate and area of the aquifer. Comparing a drilled well with a qanat system, there are advantages for each. The following compare the two systems:

- As history proves it, qanats are sustainable renewable water resource systems. However, they cannot meet today's increasing demand. Wells are the alternative at the expense of inducing negative water balance in the aquifers they exploit.
- Qanats need no extra energy to harvest water, whereas wells need diesel or electric power to bring water to the surface.
- Qanats can be built and maintained using low-technology tools and material locally available.
- Qanats can be used as a passive cooling system in conjunction with a wind tower (9).
- Qanats reinforce social cooperation, an important issue in traditional societies.
- Wells are dug in a short time, whereas qanat construction is slow, investment-intensive, and quite time-consuming. However, technology can be put to work to accelerate qanat construction by cutting the time and the cost.
- Only a portion of a qanat's water is used during nonirrigation season, unless conserved by other means. During periods of low water use in fall and winter, watertight gates can seal off the qanat outlet damming up the water. In spring and summer, night flow may be stored in small ponds for daytime use (10). A well pump can be switched off when water is not needed.
- A typical qanat's discharge is less than that of pumped wells. The latter are favored to meet growing demands, though, in a nonsustainable manner.

Experts in Iran now suggest an integrated approach of conjunctive use of qanats and wells. The location of a well must be optimized with respect to an existing qanat recharge area.

STATISTICS OF QANATS

No one knows how many qanats were ever built, how many are still in operation, and how much water they deliver. Available reports vary in numbers, albeit they have collected qanat statistics in different times. It is estimated that, as of the 1960s, between 40,000 to 50,000 qanats had been built in Iran during its history, of which some 27,000 running qanats were still used (11). Wulff (2) reported that some 22000 qanats in Iran, totaling 170,000 miles of underground conduits built by manual labor, had a total yield of 19,500 cubic feet of water per second, which amounts to 17 billion cubic meters of water annually. Two recent reports prepared in Iran put the total number of qanats, as of 1995, between 25,000 and 33,000, but it is unclear whether all are currently used. The reports, however, agree on the total volume of water provided by qanats at around 9 billion cubic meters. Having accepted this figure and the figure given by Wulff in 1968, an alarming decline of about 50% in water yield of qanats is inferred, which must be partly due to an excessive number of wells causing underground water tables to drop and affect qanat yield. The declining groundwater tables and increasing number of abandoned qanats have shrunk the share of water supplied by qanats to less than 10% of total use.

The discharge of individual qanats varies widely with the location and, in some cases, time of the year. Qanat discharges of a few liters to as much as 1 cubic meter per second have been reported.

There are some unique qanats in Iran described as follows:

1. Vazvan Qanat in Meimeh, Isfahan province, is 1800 m long. At a distance of 600 meter from its outlet, a stone dam has been built to store the water. A total of six gates have been installed at different elevations to control the flow of water, depending on the time and amount needed. This qanat system is essentially an underground dam.
2. The well-known and unique Moun Qanat in Ardestan, Isfahan province, is a twin-gallery qanat system, the only one of its kind reported in the world. The two galleries are independent conduits, about 3 m apart in elevation. A thin impermeable layer is believed to separate the two qanat conduits. The water in the layers is not mixed, as the upper conduit is bent around the shafts. The qanat is about 2 km long, and its total discharge waters 25 ha.
3. Gonabad region, in Khorasan province northeast of Iran, is known for some of the oldest qanats in Iran. Reports indicate that one qanat has a mother shaft with a depth of 140 meters and a length of about 70 kilometers. Another qanat is reported with a 270-m mother well.

LYSIMETERS

Kristofor R. Brye
University of Arkansas
Fayetteville, Arkansas

Lysimetry is a measurement technique that employs sampling devices called lysimeters to measure the movement of water and solutes through a porous medium. Lysimeters have most commonly been used to quantify water movement (i.e., drainage) through soil and typically consist of a porous plate surface of varying pore sizes through which water moves from the soil into a collection reservoir.

BRIEF HISTORY OF LYSIMETERS

According to Joffe (1), lysimeter studies were initiated in the late eighteenth century to address the fate of precipitation in soil. Many lysimeter studies then shifted to consider leaching of soil and precipitation-deposited constituents, such as ammonium and sulfur (1). Gradually, lysimeters were adopted to investigate fertilizer losses from agricultural and nonagricultural soil (1).

Early lysimeter research involved greatly disturbed soil profiles, unrepresentative of natural soil properties. Lysimeter tanks were dug and refilled with soil after construction was complete (1). For this reason, the validity of drainage and leaching measurements were severely questioned, as they are today. Nonetheless, many technological and methodological advancements have been made since the late 1700s, but the same fundamental question remains today as it did then: how to measure natural water movement through undisturbed soil?

DRAINAGE LYSIMETERS

Two general types of lysimeters exist for monitoring water and solute fluxes through soil, weighing and nonweighing lysimeters. Weighing lysimeters are large-scale sampling devices typically used for measuring evapotranspiration, drainage, and solute leaching. Inputs and losses of moisture are evaluated on the basis of changes in mass in a containerized column of soil within the lysimeter (2). Weighing lysimeters are expensive, labor-intensive to construct, and usually involve filling the lysimeter by reconstructing a disturbed soil profile (3,4), although large weighing lysimeters that have undisturbed soil columns have been constructed, such as the monolith lysimeters near Coshocton, Ohio. However, nonweighing lysimeters are better suited for less burdensome, replicable field measurements of *in situ* water and solute fluxes.

Nonweighing lysimeters are well adapted to monitoring drainage and leaching from soils. Nonweighing lysimeters, also known as drainage or pan lysimeters, are typically much smaller than weighing lysimeters. An advantage of a nonweighing pan lysimeter is that replicable field measurements can be obtained below undisturbed soil profiles. As a result, site-specific information can be gathered relative to the mass flux of water and leachate concentrations of soluble organic and inorganic chemical species (3). Coupling drainage measurements with solute concentrations provides a means of estimating solute mass fluxes through an undisturbed soil profile.

DRAINAGE MEASUREMENTS USING NONWEIGHING LYSIMETERS

The collection of leachate through the porous surface of a lysimeter depends on two conditions: (a) minimal discontinuities in the flow path of moving water and (b) a driving force for water movement. Maintaining a capillary connection between the soil and the porous surface of the lysimeter is imperative for high-quality results. Neglecting to minimize potential sources of error may cause ponding, preferential, and bypass flow around the lysimeter (3).

Drainage lysimeters have been designed to operate where a variety of forces act on soil water. Drainage and solute fluxes are measured and replicated in the field by some variation of a nonweighing pan lysimeter operating under tension (i.e., tension lysimeters) or tensionless (i.e., zero-tension lysimeters). In soil or any other porous material, the bulk of the water moves in response to gradients in gravitational and/or matric potentials. Zero-tension lysimeters rely on the force of gravity for water movement through the lysimeter's porous plate surface. The effect of a matric potential gradient is created by applying suction to a tension lysimeter to quantify drainage and leaching.

Both types of nonweighing lysimeters have several significant disadvantages. Nonweighing lysimeters are commonly operated after the lysimeter has been filled with soil, similar to weighing lysimeters. As a result, soil horizonation, structure, pore size distributions, and many other physical properties no longer reflect natural soil conditions. Therefore, using a disturbed profile technique for general lysimeter installation may generate biased and uninterpretable results (4).

Kung (6) described another disadvantage of nonweighing lysimeters, in which funnel flow may divert percolating water based on the angle of inclination of coarse textured soil lenses. Lenses, or soil textural discontinuities, may cause water to bypass the lysimeter or channel water directly to it. In either case, results may be erroneous.

Tension or tensionless column lysimeters that have sidewalls extending above the soil surface pose additional challenges (7–9). Impeding runoff, as the design of extended-walled column lysimeters do, unnaturally alters the water status of the contained soil column by permitting ponding during winter months and following intense rainfall. Furthermore, crop management becomes more difficult as the extended sidewalls act as obstacles to plowing, seeding, and cultivating (9).

Zero-tension lysimeters rely on the formation of a saturated soil zone above the porous plate before drainage occurs by gravitational flow, which is an unlikely natural condition in most deep, well-drained and moderately well-drained soils and alters the water content and soil water potential of the rooting zone (7). The prerequisite of saturation above these sampling devices may cause drainage water to bypass the lysimeter (3) and create unnatural matric potential gradients that cause water movement from the saturated zone to the surrounding unsaturated soil matrix (10). Zero-tension lysimeters that have upwardly extended sidewalls (7,8,11) may promote preferential flow down the side of the soil column upon drying (11). In addition, lateral flow that normally occurs under field conditions would be restricted in containerized, column lysimeters with fine textured, clayey horizons (12).

Fixed-tension lysimeters improve the flow patterns around and through the lysimeter's porous plate surface. Stored water often moves through soil under some tension. Applying tension (i.e., suction or vacuum) to a porous surface produces more natural flow patterns through a soil profile than relying on gravity to generate drainage. However, fixed-tension lysimeters typically experience vacuum depletion shortly after vacuum application unless constant vacuum is maintained. Fixed-tension lysimeters do not reproduce natural soil water potential variations that can occur during a relatively short period of time. The transient nature of soil water potentials influences unsaturated hydraulic conductivity and thus alters drainage fluxes.

RECENT USAGE OF NONWEIGHING DRAINAGE LYSIMETERS

Drainage lysimeters, both tension and tensionless, have been frequently employed in numerous studies to accomplish a variety of research goals. Zero-tension lysimeters have been used to study salt and water movement and leaching losses under conventional and no-tillage maize [*Zea mays*; (13)]; collect mobile colloids transporting organic and heavy metal compounds (11); investigate nitrate (NO_3^-) and pesticide leaching from removed, but intact, soil columns (12,14); monitor the fate and cycling of ^{15}N on revegetated mine spoils in containerized, soil mini-columns (7); determine the effect of irrigation on the nitrate leaching potential of agroecosystems (4); measure nitrate leaching from maize agroecosystems under zero, intermediate, and high fertilizer N rates (3); and elucidate the effect of various cropping systems on solute leaching and ^{15}N migration (8,9).

Jemison and Fox (10) evaluated the collection efficiency of zero-tension lysimeters. A bromide (Br^-) tracer method was used to determine an overall mean collection efficiency, based on lysimeter recovery of applied Br^-, of 52%, ranging from 13–92%, and high plot-to-plot variability of volumes were collected. Cumulative observed drainage, uncorrected for Br^- collection efficiency, measured from zero-tension lysimeters for 3 years, was consistently lower than LEACHM-predicted drainage (10). LEACHM (Leaching Estimation And Chemistry Model) is a complex computer model capable of simulating water infiltration and redistribution, solute transport and distribution in the soil, and tracer ion uptake by plants (15).

The use of fixed-tension drainage lysimeters has been somewhat more limited. Karnok and Kucharski (16) described the use of an underground rhizotron-lysimeter facility constructed to monitor root growth, evapotranspiration, and leaching under turf grass cover. Leaching losses from observation cells were collected under a continuous, fixed tension of −33.3 kpa. Dolan et al. (17) used wedge-shaped, fixed-tension microlysimeters to ascertain the effect of nitrogen placement on nitrate leaching below maize monoculture grown in sandy soil. Adams et al. (18) evaluated nitrate leaching from poultry litter and manure-amended pasture soil using pan lysimeters at a fixed tension of ∼ −10 kpa. Despite several disadvantages, fixed-tension and tensionless nonweighing lysimeters have many potential uses and applications.

EQUILIBRIUM-TENSION LYSIMETERS

Equilibrium-tension lysimetry is an innovative and improved nonweighing drainage lysimeter technique that allows applied-lysimeter suction to mimic the surrounding bulk soil matric potential fluctuations; thus it minimizes the potential for bypass flow and preserves natural drainage patterns (19). A heat dissipation sensor (19,20) is used to monitor the bulk-soil matric potential, and suction applied to the lysimeters is varied as the bulk-soil matric potential varies. Lysimeter suction was originally set manually every several days (19), but a recently developed automated vacuum system maintains equilibrium between applied-lysimeter suction and bulk-soil matric potential fluctuations within seconds (21).

The use of equilibrium-tension lysimeters is relatively new and even more limited compared to the other types of nonweighing drainage lysimeters (Fig. 1). Equilibrium-tension lysimeters have been used to quantify drainage losses for a multiyear period in a water balance study of a restored prairie and maize agroecosystems in southern Wisconsin (22). At the same study site in southern Wisconsin, equilibrium-tension lysimeters have been used to quantify multiple years of nitrogen and carbon (23,24) and soluble phosphorus fluxes (25) in drainage water from below the root zones of a restored prairie and maize agroecosystems. Equilibrium-tension lysimeters have also been used to quantify heavy metal and antibiotic leaching from the root zone of tall fescue (*Festuca arundinacea*) amended with poultry litter in northwest Arkansas (unpublished data).

Figure 3. Rectangular cavity excavated in sidewall of the trench with nearly completed lysimeter installation.

Figure 4. Complete lysimeter installation with cavity protected from damage upon backfilling with treat plywood.

Figure 5. Soil surface following lysimeter installation and trench backfilling.

GENERAL TENSION-LYSIMETER INSTALLATION AND SAMPLING PROCEDURES

For the most representative results in a field setting, nonweighing drainage lysimeters are typically installed below an undisturbed soil column. A trench is dug by hand or with a backhoe, then a small cavity that extends into the plot or measurement area is excavated in the long sidewall of the trench (Fig. 2). The lysimeter is forced upward against the base of the undisturbed soil column. Some apparatus (e.g., a spring plate, shim, or screw jack) is installed below the lysimeter to provide the necessary upward force to maintain the capillary connection between the lysimeter's porous plate surface and the soil above (Fig. 3). Once the cavity is outfitted with the lysimeter, the trench can either be left open and accessible or completely backfilled. If the trench will be backfilled, tube extensions that extend upward out of the soil can be connected to the drain and vacuum tubes attached to the lysimeter. The lysimeter cavity itself is typically left open but protected with plywood from damage during backfilling (Fig. 4). The trench is backfilled by adding soil in the opposite order in which it was removed and is revegetated, if necessary, so that only the tube extensions and heat dissipation sensor wires if used, are visible above the soil surface (Fig. 5).

Water collected in the lysimeter's collection reservoir is typically removed under vacuum. The leachate volume is recorded, and, if necessary, a portion is saved and refrigerated for subsequent chemical analysis.

STEADY-STATE FLOW AQUIFER TESTS

Harendra S. Chauhan
G.B. Pant University of
Agriculture and Technology
Uttar Pradesh, India

Groundwater studies are conducted to evaluate the occurrence, availability, and quality of groundwater. There are numerous practical applications like optimum development of groundwater basins, safe withdrawal, groundwater recharge, seepage from canals and reservoirs, and drainage that require knowledge of the hydraulic characteristics of aquifers. Two basic aquifer properties needed to make a quantitative assessment of such applications are transmissivity and storage coefficient which represent, in a general sense, its abilities to transmit and store water, respectively. The other hydraulic properties of an aquifer are hydraulic resistance, leakage factor, and drainage factor. Performing an aquifer test is an effective way of determining these hydraulic properties of aquifers. Steady-state flow aquifer tests are conducted to determine transmissivity, hydraulic conductivity, and hydraulic resistance; more detailed unsteady-state tests are conducted if other hydraulic properties are also to be evaluated. The objective of this article is to discuss steady-state methods of determining aquifer characteristics.

AQUIFER TESTS

The procedure involves pumping water from a well for a certain time and at a certain rate and measuring its effect on the water table in the well and at a number of piezometers installed in the vicinity. When pumping is carried out in a well, the water level in its vicinity is lowered; the extent of lowering at any point is termed the, drawdown. The drawdown is maximum at the well point and reduces gradually with distance from the well, becoming zero at a certain distance termed the radius of influence. This distance varies with the well and depends on the well discharge, formation constants, and the duration of pumping. The lowering of the water level in the well during pumping creates a head difference or hydraulic gradient from the surroundings which causes the flow of water in the well. The hydraulic gradient increases as flow converges toward the well. The rate of flow is same through all the concentric cylindrical surfaces around the well, and the surface area decreases as one approaches the well. The form of the surface resembles a cone, and therefore it is known as the cone of depression, which is the characteristic feature of every pumped well. Its size and shape depend on the discharge, length of pumping, aquifer characteristic, and other factors.

Steady-State and Unsteady-State Flows

Both steady-state and unsteady-state groundwater flow conditions occur in nature and cannot be very distinctly separated. It is a matter of interpretation and choice as to which concept is used for practical utility. Although every phenomenon in nature is transient, it could be considered a series of successive steady-state events.

Steady-state groundwater movement requires that the boundary conditions of flow and aquifer characteristics remain unchanging with time. Even though the aquifer characteristics do not remain constant, they are assumed so for practical purposes. Thus, if a hydraulic disturbance like well pumping is created, even though the process is initially unsteady, eventually it becomes steady with time.

DEFINITION OF AQUIFER PROPERTIES

The transmissivity (T) of an aquifer is the rate of flow under a unit hydraulic gradient through a vertical strip of the aquifer of unit width and extending through the whole saturated thickness of the aquifer. It has the dimensions of length^2/time and, for example, may be expressed in m^2/day. T is the product of the average hydraulic conductivity (k) and the saturated thickness (b) of the aquifer.

Hydraulic conductivity (k) is the proportionality constant k in Darcy's law $v = ki$, where v is the specific discharge or Darcy's velocity (L T^{-1}) and i is the hydraulic gradient (dimensionless), which is the volume of water that will flow through a porous medium in unit time under a unit hydraulic gradient through a unit area measured at right angles to the direction of flow. k is a parameter that depends on both the properties of the porous medium and of the fluid and has units of length/time, for example, m/day.

Saturated thickness (b) is equal to the physical thickness of the aquifer between two confining layers in a confined aquifer. The saturated thickness for unconfined aquifers, equal to the difference between the free water table and the impervious layer, is not constant but varies with pumping.

Coefficient of storage (S) of an aquifer is the volume of water released from or taken into storage per unit surface area of the aquifer per unit change in head. In unconfined aquifers, S is known as the *specific yield* which represents the volume of water released from storage per unit surface area of aquifer per unit decline of the water table. Specific yield is also sometimes called effective porosity or drainable pore space. S is a dimensionless quantity.

Hydraulic resistance (c) is a property of semiconfined aquifers that characterizes the resistance of a water-bearing layer to vertical flow. It is also known as the reciprocal leakage coefficient and is given by b'/k' where b' and k' are the thickness and the hydraulic conductivity, respectively, of a semipervious layer. The dimension of the hydraulic resistance is time and is, for example, expressed in days.

Leakage factor (L) describes the spatial distribution of leakage through one or more semipervious layers into a leaky aquifer or vice versa. It is defined as $L = \sqrt{kbc}$, has the dimension of length, and it may be expressed in meters.

Of these aquifer parameters, transmissivity (T), hydraulic conductivity (k), and hydraulic resistance (c) are the properties that can be determined from steady-state aquifer tests.

STEADY-STATE METHODS OF DETERMINING AQUIFER PARAMETERS

Different well flow theories have been derived based on the consideration of a continuity equation in cylindrical or spherical coordinates, well depth, the fully or partially penetrating nature of wells; steady-state or unsteady-state flow conditions; gravity, artesian, leaky or nonleaky aquifer; constant or variable discharge conditions; and sinks or source. The methods of determining aquifer constants depend on the solution of the selected continuity equation and the specific boundary conditions. Steady-state solutions can be used to estimate transmissivity; the storage coefficient (S) cannot be determined because it does not appear in the solution. The following methods based on steady-state approaches can be used to determine the transmissivity of an aquifer.

Unconfined Aquifer Flows

Radial Flow to a Fully Penetrating Constant Discharge Well (Fig. 1). The flow is considered assuming that the aquifer is homogeneous, isotropic, of uniform thickness, and has an infinite aerial extent. The differential equation for groundwater flow in an unconfined aquifer may be written in cylindrical coordinates as

$$\frac{d}{dr}\left(\frac{r\,dh}{dr}\right) = 0 \tag{1}$$

In a well that fully penetrates the gravity aquifer, the flow will be axisymmetric. Neglecting the vertical component of the velocity as small, the equipotential surfaces may be considered coaxial cylinders. The flow across these cylinders at a distance r is given by $Q = av = 2\pi rh\left(-k\dfrac{dh}{dr}\right)$. Equation (1) may be integrated twice. The two constants may be obtained from an assumed boundary condition of a piezometric head at the well as $h(r_0) = h_0$ and the relationship of the well flow at a given distance r. The solution of Eq. 1 under the boundary conditions gives the phreatic surface of the flow as

$$h^2 = \frac{Q}{\pi k}\ln\frac{r}{r_0} + h^2 \tag{2}$$

Three methods may be developed from Eq. 2 to determine transmissivity.

Determination of T Using Two Observation Wells: Dupuit–Thiem Method. It can be seen from Eq. 2 that there is no fixed saturated thickness in gravity aquifers and only k appears in the solution describing phreatic surfaces. Thus, only k can be obtained from the solution. To obtain the transmissivity, k has to be multiplied by some average depth. Measuring heads at two distances $r_1, r_2 (r_2 \geq$

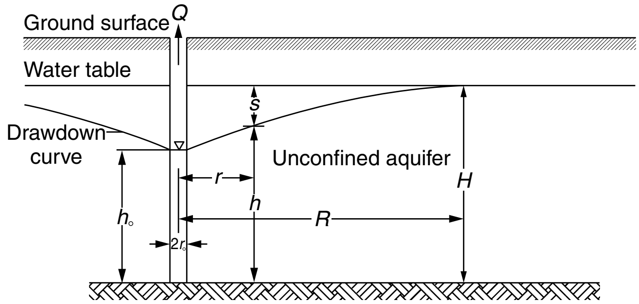

Figure 1. Flow to an unconfined aquifer.

$r_1), h(r_1) = h_1, h(r_2) = h_2$ in Eq. 2, an expression for k may be written as

$$k = \frac{Q}{\pi h(h_2^2 - h_1^2)} \ln \frac{r_2}{r_1} \tag{3}$$

Contrary to Dupuit's assumption, the vertical components of velocity are large in gravity flow and cannot be ignored. Equation 3, consequently, does not give correct results. Setting $h = H - s$, Eq. 3 can be rewritten as

$$kH = \frac{Q}{2\pi\left[\left(s_1 - \dfrac{s_1^2}{2\,H}\right) - \left(s_2 - \dfrac{s_2^2}{2H}\right)\right]} \ln \frac{r_2}{r_1} \tag{4}$$

where H is the saturated thickness of the aquifer, s_1 and s_2 are drawdowns and $s_1 - \dfrac{s_1^2}{2H}$ and $s_2 - \dfrac{s_2^2}{2H}$ are corrected drawdowns s_1' and s_2',

Transmissibility may be written in terms of corrected drawdowns or, neglecting correction terms, it may also be expressed as

$$T = kH = \frac{Q}{2\pi(s_1' - s_2')} \ln \frac{r_2}{r_1} \approx \frac{Q}{2\pi(s_1 - s_2)} \ln \frac{r_2}{r_1} \approx \frac{Q}{2\pi(h_2 - h_1)} \ln \frac{r_2}{r_1} \tag{5}$$

Determination of T Using a Single Observation Well. Due to constraints on funds for pumping tests, it may be possible to construct only one observation well. For such a situation, one may have observations only in a single well. For such conditions, setting $h(r_0) = h_0$ and $h(r_1) = h_1, (r_1 \geq r_0)$, an expression for k may be written as

$$k = \frac{Q}{\pi(h_1^2 - h_0^2)} \ln \frac{r_1}{r_0} \tag{6}$$

In the same way for such boundary conditions, T may be written in terms of corrected drawdowns. Considering that corrections have small values, they may be neglected to give approximate values of transmissivity as

$$kH = \frac{Q}{2\pi\left[\left(s_0 - \dfrac{s_0^2}{2H}\right) - \left(s_1 - \dfrac{s_1^2}{2H}\right)\right]} \ln \frac{r_1}{r_0} \approx \frac{Q}{2\pi(s_0 - s_1)} \ln \frac{r_1}{r_0} \approx \frac{Q}{2\pi(h_1 - h_0)} \ln \frac{r_1}{r_0} \tag{7}$$

Determination of T Using the Head in the Pumped Well. Due to further constraints on funds, one may not be able to make even a single observation well. For such a condition, measuring the head in the pumped well itself, $h(r_0) = h_0$, and considering an arbitrary radius of influence $h(R) = H$, the hydraulic conductivity may be obtained as

$$k = \frac{Q}{\pi(H^2 - h_0^2)} \ln \frac{R}{r_0} \tag{8}$$

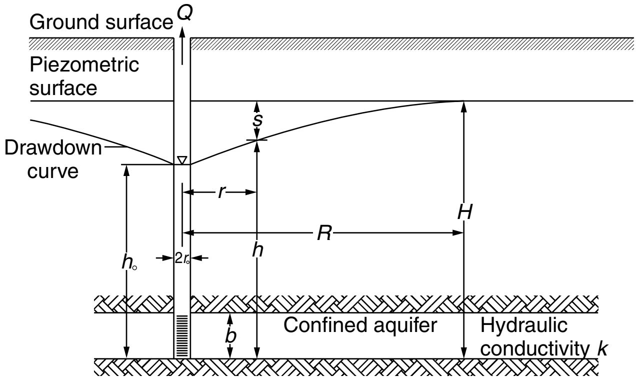

Figure 2. Flow to a confined aquifer.

Writing $h = H - s$, transmissibility may be written as

$$kH = \frac{Q}{2\pi\left(s_0 - \dfrac{s_0^2}{2H}\right)} \ln \frac{R}{r_0} \approx \frac{Q}{2\pi s_0} \ln \frac{R}{r_0} \tag{9}$$

Confined Aquifer Flows (Fig. 2)

Similar to the unconfined aquifer, flow is considered to take place assuming that the aquifer is homogeneous, isotropic, of uniform thickness, and of infinite aerial extent.

Radial Flow to a Fully Penetrating, Constant Discharge Well. Differential equations of the groundwater flow to a fully penetrating well in a confined aquifer may be written in cylindrical coordinates as

$$\frac{d}{dr}\left(r\frac{dh}{dr}\right) = 0 \tag{10}$$

In a fully penetrating aquifer of thickness b, the flow is axisymmetric, and the equipotential surfaces are coaxial circular cylinders. Flow across these cylinders in a fully penetrating artesian aquifer of thickness b at a given distance r from the well center is given as $Q = av = 2\pi rb\left(-k\dfrac{dh}{dr}\right)$. Equation 10 may be integrated twice under the assumed condition of the piezometric head at the well, $h(r_0) = h_0$, and the relationship of the well at a given distance r to give

$$h = \frac{Q}{2\pi kb} \ln \frac{r}{r_0} + h_0 \tag{11}$$

Thiem's (1906) Equilibrium Equation Using Two Observation Wells. To reduce errors because of losses in the well and through the well screen, Thiem (1) proposed measuring piezometric heads h_1, h_2 in two observation wells located at distances r_1, r_2 from a constantly discharging well Q. Thus, setting $h(r_1) = h_1, h(r_2) = h_2$ in Eq. 11 of an expression of transmissivity may be derived as

$$T = kb = \frac{Q}{2\pi(h_2 - h_1)} \ln \frac{r_2}{r_1} \tag{12}$$

Determination of T Using a Single Observation Well. Considering the head as $h(r_1) = h_1$ at a single piezometer installed at distance r_1 from the well, T may be obtained from Eq. 11 as

$$T = kb = \frac{Q}{2\pi(h_1 - h_0)} \ln \frac{r_1}{r_0} \tag{13}$$

Determination of T Using the Piezometric Head in the Pumped Well. By measuring the piezometric head in the pumped well itself and at an arbitrary radius of influence R, $h(R) = H$, T can be obtained from Eq. 11 as

$$T = kb = \frac{Q}{2\pi(H - h_0)} \ln \frac{R}{r_0} = \frac{Q}{2\pi s_0} \ln \frac{R}{r_0} \tag{14}$$

Spherical Flow to a Nonpenetrating, Constant Discharging Well in An Extensively Thick Artesian Aquifer (Fig. 3). The groundwater flow equation for such a flow system is described by a continuity equation in spherical coordinates as

$$\frac{d}{dr}\left(r^2 \frac{dh}{dr}\right) = 0 \tag{15}$$

The isopiestic surfaces to a nonpenetrating well consist of concentric hemispheres. The flow across a hemispherical surface at distance r is given by

$$Q = av = 2\pi r^2(-k dh/dr)$$

Considering the piezometric head at the well, $h(r_0) = h_0$, and the flow equation above, the piezometric surface can be obtained as

$$h = \frac{Q\left(\frac{1}{r_0} - \frac{1}{r}\right)}{4\pi k} + h_0 \tag{16}$$

Determination of k Using Two Observation Wells. It may be observed that from Eq. 16, only hydraulic conductivity can be determined as the thickness of the aquifer is not finite.

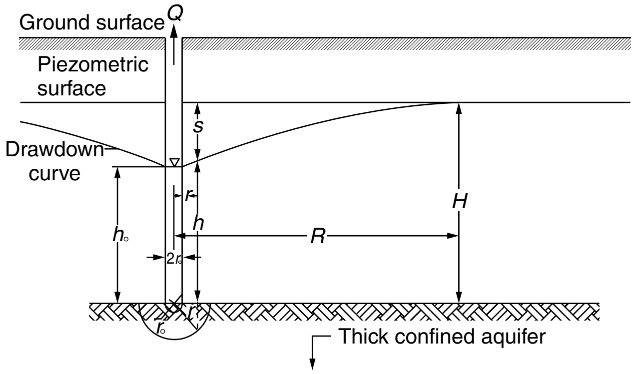

Figure 3. Spherical flow to a thick confined aquifer.

Considering heads at two observation wells located at distances r_1, r_2 as h_1, h_2, an expression for k may be obtained as

$$k = \frac{Q\left(\frac{1}{r_1} - \frac{1}{r_2}\right)}{2\pi(h_2 - h_1)} \tag{17}$$

Determination of k Considering the Head in the Well. Using the measurement of the head in the pumped well itself, $h(r_0) = h_0$, and considering an arbitrary radius of influence R, an expression for k in terms of the head and drawdown $s = H - h$ may be written as

$$k = \frac{Q\left(\frac{1}{r_0} - \frac{1}{R}\right)}{2\pi(H - h_0)} = \frac{Q\left(\frac{1}{r_0} - \frac{1}{R}\right)}{2\pi s_0} \tag{18}$$

Considering that $R > r_0$, 1/R is negligible and can be neglected; this gives

$$k \approx \frac{Q}{2\pi r_0(H - h_0)} \approx \frac{Q}{2\pi r_0 s_0} \tag{19}$$

Semiconfined Aquifer Flows

Aquifer Constants from the Steady-State Flow of a Well in a Semiconfined Aquifer: Hantush and Jacob method (2) (Fig. 4). The solution is based on the assumption that the phreatic surface remains constant, so that the leakage through the semiconfining layer takes place in proportion to the drawdown of the piezometric level. Hantush and Jacob (2) obtained a solution for $L > 3D$, as

$$s_m = \frac{Q}{2\pi kb} K_0\left(\frac{r}{L}\right) \tag{20}$$

where s_m = steady-state drawdown in meters at distance r;
Q = discharge of the pumped well in cubic meters per day;
$L = \sqrt{kbc}$, leakage factor in meters;
$c = \frac{b'}{k'}$, hydraulic resistance of a semipervious layer in meters; and
$K_0(x)$ = modified Bessel's function of the first kind and zero order.

Hantush observed that if r/L is <0.05, Eq. 20 can be approximated as

$$s_m = \frac{2.3Q}{2\pi kb}\left(\log 1.12 \frac{L}{r}\right) \tag{21}$$

A plot of s_m against r on semilog paper, with r on the logarithmic scale, will show a straight line relationship in the range where r/L is small. The slope of the straight line, the drawdown difference per log cycle of r, is expressed as

$$\Delta s_m = \frac{2.3Q}{2\pi kb}$$

$$kb = \frac{2.3Q}{2\pi \Delta s_m} \tag{22}$$

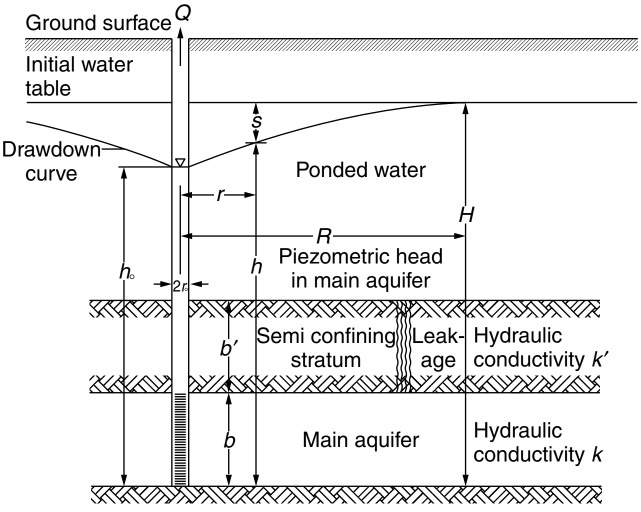

Figure 4. Flow to a semiconfined aquifer.

For any point s_m, r is selected on the straight line. Putting r in Eq. 21 gives $L.c$ can be obtained as

$$\mathrm{c} = \frac{b'}{k'} = \frac{L^2}{kb}$$

Alternatively the extended straight line portion of the curve intercepts the r axis where the drawdown is zero. At the interception point, $s_{\mathrm{m}} = 0, r = r_{\mathrm{o}}$, and Eq. 21 reduces to

$$\left(\log 1.12\frac{L}{r}\right) = 0$$

or

$$1.12\frac{L}{r_0} = 1.12\frac{\sqrt{kbc}}{r_0} = 1$$

or

$$\mathrm{c} = \frac{(r_0/1.12)^2}{kb}$$

Transmissivity from Steady Flow in a Semiconfined Aquifer: Ernst's Modification of the Thiem Method. The relationship is based on assuming that the well discharge is corrected by subtracting, from the total discharge, the amount of phreatic water obtained from the semipervious layer. The determination requires two piezometers installed in semipervious layers at distances r_1, r_2. The coaxial phreatic water from a circular area may be written approximately as $r_0 = r_1 + 1/3(r_2 - r_1)$.

The phreatic water delivered from a circular area is

$$Q' = \pi r_0^2 \Delta s' S' \times 24$$

where $\Delta s'$ = average drop of phreatic level in the semipervious layer during the last hour (m) and S' = specific yield of the semiconfined aquifer (to be estimated from well logs). The transmissivity may be found from

$$kb = \frac{(Q - Q')\ln\dfrac{r_2}{r_1}}{2\pi(s_1 - s_2)} \tag{23}$$

Approximate Methods

Logan's (3) Method for confined aquifers. Equation 14 using the observation in the pumped well itself is also known as Logan's method. According to Logan (3), the accuracy of the calculation depends on the accuracy in measuring the maximum drawdown in the well s_0 and on the accuracy of the ratio R/r_0. The ratio R/r_0 may have a large value, but the ratio of the logarithm may be small. He suggested an approximate value of 3.33 for the log ratio. Putting this value in Eq. 14 gives the transmissivity as

$$kb = \frac{2.3Q}{2\pi s_0}\log\frac{R}{r_0} \approx \frac{1.22Q}{s_0} \tag{24}$$

Logan's (3) Method for Unconfined Aquifers. Using a similar approach and considering observation in the pumped well itself, the transmissivity in an unconfined aquifer may be obtained from Eq. 9 as

$$kH = \frac{2,3Q}{2\pi s_0'}\log\frac{R}{r_0} \approx \frac{1.22Q}{s_0'} \tag{25}$$

where $s_0' \equiv s_0 - \dfrac{s_0^2}{2H}$.

Transmissivity from Other Analytical Solutions

In principle, any analytical solution of a boundary value problem of groundwater flow can be used to estimate aquifer parameters, if other variables can be measured or estimated. A few steady-state solutions for estimating transmissivity are presented.

Two Equal, Constant Discharge, Mutually Interfering Wells. The relationships between two equal and constant discharge interfering wells distance B apart may be written as

$$Q_1 = Q_2 = \frac{2\pi kb(h_a - h_0)}{\ln\dfrac{R^2}{r_0 B}} \tag{26}$$

where r_0 = well radius, h_a = average piezometric head at the external boundary, h_0 = piezometric head at the well, and R = radius of influence ($R > B$).

Thus if the values of the constant equal discharges. Q, h_0, h_a, R, and B are known, the transmissivity may be determined from the relationship

$$kb = \frac{Q\ln\dfrac{R^2}{r_0 B}}{2\pi(h_a - h_0)} \tag{27}$$

Steady-State Flow to a Partially Penetrating Well. A relationship was obtained for such a flow system by De Glee (4) as

$$h_{2b} - h_0 = \frac{Q_p}{4\pi k}\left(\frac{2}{h_s}\ln\frac{\pi h_s}{2r_0} + \frac{0.20}{b}\right)$$

where h_s is the depth of the partially penetrating well, b is the aquifer thickness, h_{2b} is the initial piezometric head at distance 2b, and h_0 is the piezometric head in the well.

$$\text{Also} \quad 1.3\,h_s \le b; \frac{h_s}{2r_w} \ge 5$$

From this relationship and measuring other parameters, the transmissivity may be found as

$$kb = \frac{Q_p b}{4\pi(h_{2b} - h_0)} \left[\frac{2}{h_s} \ln \frac{\pi h_s}{2r_0} + \frac{0.20}{b}\right] \tag{28}$$

For a partially penetrating well in an unconfined aquifer where the drawdown is also small in relation to the saturated thickness, Eq. 28 can be used by replacing b by H.

Kozeny (5) proposed a relationship, by which transmissivity may be determined from

$$T = \frac{2.3 Q_p \log \dfrac{r}{r_0}}{2\pi(h - h_0)\, G} \tag{29}$$

where

$$G = \alpha \left(1 + 7\sqrt{\frac{r_0}{2h_s}} \cos \frac{\pi\alpha}{2}\right)$$

Q_p is the discharge of a partially penetrating well, Q_f is the discharge of a fully penetrating well, $G = Q_p/Qf$ is a correction factor giving the ratio of the two discharges, α is the fractional penetration of the well screen h_s/b, and h_s is the depth of penetration of the aquifer.

PRACTICAL ASPECTS OF PUMPING TESTS (after Ref. 6)

Observation Well Size, Location, and Numbers

An observation well should be just large enough to allow accurate and rapid measurement of water levels. Small wells provide a fast response. Five-cm observation wells are usually effective when hand methods of measuring water levels are used. Larger pipes may be used with automatic recorders. Observation wells are commonly installed with 1–2 m long screens at the bottom embedded in the aquifer to measure the pressure head. Observation wells should be installed at about the same depth as the middle of the well screen in the pumped well.

Observation wells should be located at a reasonably large distance and not too close to the pumped well. Setting observation wells at distances of 30–100 m from the pumped well may work out best in most cases. When observation wells are too close to the pumped well, correct drawdown readings may be difficult. The cone of depression in a water table spreads at a slower rate than in an artesian formation, so the observation wells for a water table aquifer should be relatively closer to the pumped well.

The number of observation wells depend upon the amount of information required and the funds available for the test program. Drawdown data from the well itself or from a single observation well permit estimating the average hydraulic conductivity, transmissibility, and coefficient of storage of the aquifer. If two or more observation wells are placed at different distances, the test data can be analyzed both in terms of the time–drawdown and the distance–drawdown relationships. It is always better to have as many observation wells as conditions may allow. A minimum of three placed at varying distances and radially at equal angles around the well is desirable.

Measurement of Water Levels. The depth to water may be measured many times during the course of a pumping test. Observations should be taken at close intervals during the first 2 hours, and the time between readings should gradually increase as the test continues. The water level measurement may be recorded to the nearest 0.5 cm in the observation wells. Measurements may be made every half-minute during the first 5 minutes after starting the pump, then every 5 minutes for an hour, then every 20 minutes for about two hours. From this point on, readings at hourly intervals should be sufficient.

Water-level measurements can be taken in various ways, the wetted-tape method, mechanical sounder, electric water-level indicator, pressure gauge, or pressure logger. For detailed information on these devices, see Kruisman and De Ridder (7). Fairly accurate measurements of water levels can be made manually.

Measurements of Discharges. The other parameter that needs to be measured is the discharge from wells during pumping tests. To avoid complicated calculations later, the discharge rate should preferably be kept constant throughout the test. The discharge rate can be measured using various devices like commercial water meters, flumes, orifice weirs, containers or the jet-stream method. The procedures for installation and measurements using these devices are available in standard texts.

SUMMARY

An overview of steady-state approaches for determining the transmissivity of confined, unconfined, and semiconfined aquifers has been presented. Detailed procedures for determining transmissivity using drawdown data in a pumped well and one or two observation wells are discussed in the context of two most common methods of Thiem and Dupuit–Thiem. A few approximate methods and analytical solutions for determining aquifer constants have been briefly introduced. General guidelines for conducting pumping tests including measurement of discharge and groundwater levels and numbers and locations of observation wells have been furnished.

TIDAL EFFICIENCY

Todd Rasmussen
The University of Georgia
Athens, Georgia

Ocean tides often cause water levels in coastal aquifers to fluctuate. These fluctuations result from two different causes. In confined aquifers, the additional weight of the water on the surface increases the pressure on the water at depth, which causes an increase in water levels in observation wells located near the coast. In this case, no movement of water between the ocean and the aquifer may have occurred. In unconfined aquifers, however, the loading effect does not occur. Instead, water that has moved directly through the pores within the aquifer has caused the water level response. Regardless of the mechanism, both processes can be described with the phase lag, or delay, between the tidal peak and the aquifer response peak, as well as the amplitude ratio between the magnitudes of the response and the tides

Water levels in wells located near the coast often fluctuate with a rhythm that mimics the rise and fall of the ocean. The tidal efficiency, TE, is the ratio of the change in water levels in wells, ΔW, to the change in tidal levels, ΔT:

$$TE = \frac{\Delta W}{\Delta T}$$

where both water levels are measured with the same type of units (e.g., feet, meters, psi). Tidal efficiencies can range from a maximum of one in poorly consolidated geologic media to a minimum of zero in rigid aquifers (1,2).

The tidal response in an aquifer can result from two types of phenomena, one in confined and a second in unconfined aquifers. As described in greater detail below, the confined aquifer response is caused by the increased load placed on the surface, whereas the unconfined aquifer response is caused by the movement of water in response to changing tidal water levels.

CONFINED AQUIFERS

In confined aquifers, coastal tides affect water levels because the surface load changes as ocean levels fluctuate. The weight of the ocean compresses the underlying aquifer, which causes a change in the fluid pressure. In this situation, no water moves between the ocean and the aquifer, which is similar to the effect that trains have as they pass a well in some confined aquifers—water levels rise and then fall as a train passes by (3).

The loading effect is greater in poorly consolidated aquifers where a greater proportion of the overlying load is borne by the fluid. Pore fluids in consolidated aquifers are less likely to carry the load, and so these aquifers have lower tidal efficiencies.

Coastal aquifers are not the only type of aquifer that shows a response to surface loads. The loading effect on confined aquifers can be observed in response to the placement or removal of any type of mass on the ground surface. Components of the water budget (such as precipitation, evaporatranspiration, and soil moisture) can immediately affect water levels in confined aquifers—even when no direct hydraulic communication is present (4).

An increase in water levels in a confined aquifer under a waste lagoon may be mistakenly attributed to contamination from the lagoon. The cause could be from downward leakage of water from above, or it could also be from the increased surface load causing a rapid increase in fluid pressure.

Another example of surface loading develops when barometric pressure changes cause water levels in wells to fluctuate. In these cases, the response is somewhat complicated because the barometric pressure also exerts a force on water levels in open wells. The tidal efficiency in confined aquifers is related to the barometric efficiency, BE, in that the two efficiencies must sum to unity, $TE + BE = 1$. Thus, aquifers with low tidal efficiencies have large barometric efficiencies, and vice versa. The reader is referred to Barometric Efficiency for additional discussion of this topic.

UNCONFINED AQUIFERS

A second tidal influence occurs in unconfined, surficial coastal aquifers. In these aquifers, water levels change as the hydraulic perturbation created by changing ocean levels moves horizontally through the saturated zone toward the well. Unlike the confined case in which the load is transmitted without concomitant fluid movement, water is free to move through the unconfined aquifer.

For a simple, one-dimensional flow geometry (i.e., a well placed at some distance from a linear shoreline), the response is a function of the distance of the well from the shoreline, L, and the aquifer *hydraulic diffusivity*, $D = T/S$, where T and S are the aquifer transmissivity and storativity, repsectively. Nearby wells in more diffusive aquifers respond more rapidly than do more distant wells in aquifers with lower diffusivity. The response is a function of a dimensionless variable, $\kappa = D\tau/L^2$, where τ is the response time.

This type of response is not limited to coastal areas, however. A similar type of response is found in surficial aquifers next to streams. In this case, changing water levels during floods cause a loss of water from the stream into the adjacent aquifer, with a reversal of flow later in the flood hydrograph. This type of response is also referred to as *bank storage* (5).

SINUSOIDAL OSCILLATIONS

Many types of loading phenomena display periodic variation, tides being a common example. In addition to the gravitational affects of the sun and moon on the oceans, gravitational forces also cause changes in atmospheric pressure, called *atmospheric tides*, and even in the solid earth, called *earth tides*.

These periodic variations can be characterized with the *period* of the oscillation (e.g., 24 hours for solar tides) and the *amplitude*, or *magnitude*, of the oscillation. When observing the tidal response in confined aquifers, the tidal efficiency is equal to the ratio of the magnitude of the water level fluctuation in the well to the magnitude of the ocean tides. For example, if peak daily ocean levels vary by 1 m and the peak daily groundwater levels vary by 10 cm, then the tidal efficiency is 0.10, or 10%.

Another influence is the *phase lag*, which is the delay between when the ocean tide and the aquifer water levels peak. Normally, an insignificant delay occurs between the ocean tide and a confined aquifer response; yet this delay can be large in cases in which significant borehole storage exists.

The tidal efficiency and phase lag in unconfined aquifers can determine the aquifer diffusivity. The transmissivity and storativity can be only determined, however, if the flow of water can be determined, which requires measurements of the flow rate between the ocean (or stream) and the aquifer.

COMBINED FREE AND POROUS FLOW IN THE SUBSURFACE

Diganta Bhusan Das
Oxford University
Oxford, United Kingdom

Vahid Nassehi
Loughborough University
Loughborough, United Kingdom

INTRODUCTION

The presence of a fluid layer adjacent to a porous medium is common in many environmental, chemical, mechanical and petroleum engineering problems. The flow behavior in the fluid layer is determined by the properties of the fluid (e.g., viscosity and density), and surface (e.g., pressure and shear) and body (e.g., gravity and electric field) forces. However, flow in the porous medium depends additionally on the properties of the medium which include, among others, porosity and permeability.

In fluid dynamic analysis of groundwater systems, it is commonly found that water flows through combined free (nonporous) and porous pathways between surface and subsurface systems. Such coupled regimes may also be present due to construction of industrial utilities and structures in the ground. Important engineering processes that may involve combined free and porous flow domains are, for example, fluid losses/leaks from underground pipes and storage tanks in old gas works sites; dig-and-treat, pump-and-treat, and permeable reactive barrier technologies for groundwater treatment; and drilling/extraction of oil from underground reservoirs. However, in most cases, the associated transport phenomena are determined by natural hydroenvironmental conditions, which include, for example, combined surface and subsurface flow, lake–groundwater interactions, seepage through preferential flow channels and macropores, circulatory flows and rise and fall of groundwater, glaciology, and multiple karstic regions interfaced with granular porous sections. The subdomains in coupled flow systems are generally distinguished by an interfacial surface, which represents the transitional zone for contaminants/fluid mobility from free to porous sections or vice versa. To gain on understanding of the combined flow behavior, it is necessary to develop realistic methodologies for evaluating mass and momentum transfer across the free/porous flow interfaces.

The construction of well-posed mathematical formulations for combining different flow regimes can present difficulties. Two general approaches have evolved for this purpose: (1) methodologies based on treating the combined flow domain as a single continuum and (2) formulations in which the flow domain is considered as a combination of discrete sections corresponding to different flow regimes. In the former, the porous section is effectively regarded as a pseudofluid layer, and the whole domain is analyzed as a whole. As such, a suitably formulated momentum equation for the entire domain in conjunction with mass conservation equations is solved. The mathematical model identifies fluid and porous domains based on spatially varying permeability. Such a single-domain approach is usually applied where the flow transition from free to porous flow zones is not distinct and properties of the porous domain change progressively (e.g., metal solidification problems involving mushy zones). However, if the permeability of the porous medium is constant and remains above a relatively high level, then at defined interfaces between adjacent zones, transitions between free/porous regimes occur. Under these conditions, the domain should be viewed as a combination of adjacent flow fields rather than a geometric continuum. In these situations, the second approach should be used where appropriate equations of motion describing the flow in different subdomains are solved. In general, a groundwater system corresponds to this case.

GOVERNING MODEL EQUATION

The main aim of this article is to present a general methodology that can be used to simulate hydrodynamic behavior in combined free (nonporous sections) and porous flow zones in the subsurface based on the assumption of discrete flow domains, which involves selecting governing model equations for each subdomain and the matching conditions at the interface for linking them. Although fluid mobility in combined free and porous flow on the surface has been the focus of intense research for more than two decades, analyses of subsurface flow have not treated the possible interactions between free and porous flow regimes efficiently. Addressing these issues, the hydrodynamic conditions in underground zones of coupled fluid and porous domains have been analyzed on a 3-D spatial scale by Das et al. (1). This methodology is based on the principles of mass and momentum conservation and primitive variable formulations (i.e., the equations are expressed in terms of the pressure and velocity). Conservative forms of the equations have also been adopted to enhance the accuracy of the numerical calculations. The model equations are presented below.

Free Flow Region

The momentum transfer for constant density and viscosity of a fluid at a reference temperature in a free flow region can be represented by the well known Navier–Stokes (N-S) equation,

$$\nabla P_f = -\rho \frac{dv_f}{dt} + \mu \nabla^2 v_f \qquad (1)$$

where the subscript f refers to the free flowing fluid. P and v are the pressure and velocity terms, and ρ and μ are the constant density and viscosity of the fluid, respectively. In Eq. 1, the body forces are automatically incorporated in the pressure term as the resultant flow potential. The following continuity equation that describes the mass conservation for an incompressible fluid can be used for a free flow regime:

$$\nabla \cdot v_f = 0 \qquad (2)$$

Porous Flow Region

The corresponding macroscopic equations representing the flow field in the porous section are more uncertain. The momentum equations have received considerable attention in the past. The two most suitable are the Darcy (2) and Brinkman (3) equations shown below in the transient form for anisotropic porous media where the body forces have been incorporated in the pressure terms to represent the driving flow potential:

$$\text{Darcy equation: } \nabla P_p = -\rho \frac{\partial v_p}{\partial t} - \mu K^{-1} \bullet v_p \qquad (3)$$

$$\text{Brinkman equation: } \nabla P_p = -\rho \frac{\partial v_p}{\partial t} - \mu K^{-1} \bullet v_p \mu' \nabla^2 v_p \qquad (4)$$

In these equations, the subscript p refers to the porous section; P is the interstitial averaged pressure, v is the volume averaged seepage velocity; and ρ and μ are the constant density and viscosity of the fluid, respectively. μ' is the effective viscosity which depends on the fluid viscosity, μ, and the porosity. For flow of an incompressible fluid in a continuum porous medium, the equation of continuity is

$$\nabla \cdot v_p = 0 \qquad (5)$$

where v is the volume averaged seepage velocity of fluid.

Matching Boundary Condition for the Darcy Equation as a Porous Flow Equation. To couple the equations representing the two domains, it is necessary to specify the matching hydrodynamic conditions at the interfacial region separating the two subdomains. Keeping the three-dimensional (3-D) subsurface problem in mind, the matching conditions for pressure (continuous or discontinuous) and velocity components (normal and tangential) must be specified at the interface. The Darcy equation is a first-order differential equation with respect to velocity and pressure, so it is not possible to describe the velocity components fully at the free/porous domain interface, which makes it impossible to link the Darcy and the N-S equations directly because the latter requires specifying all velocity components to solve them. Special techniques have been invoked, henceforth, for this purpose. Addressing this issue, Beavers and Joseph (4) performed their well-known experiment on the measurement of mass efflux of a Poiseulle fluid flowing over a permeable block. They hypothesized the existence of a slip velocity, commonly known as the Darcy slip phenomenon, at the interface and a shear velocity in the porous boundary layer. Consequently, an ad hoc boundary condition was proposed based on the assumption that the slip velocity is proportional to the shear effects. It allowed jumps in the tangential velocities and gave a much-needed relationship between the flow within and outside porous media. The Beavers and Joseph (4) formulation was represented as

$$\left(\frac{\partial u}{\partial y}\right)_f = \frac{\gamma}{\sqrt{K}}(u_f - u_p) \qquad (6)$$

where the x direction was taken as parallel and the y direction as perpendicular to the interface. K is the direction-independent geometric permeability of the porous medium (isotropic), and γ is a slip coefficient that depends only on the properties of the porous medium and is independent of the fluid. The Beavers and Joseph condition has now been modified for cases where the flow and the interface are perpendicular rather than parallel, as in the original formulation. Jones (5) derived the following expression for the interfacial condition, assuming that the Darcy slip phenomenon is due to shear stress at the interface rather than a simple shear velocity:

$$\left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}\right)_f = \frac{\gamma}{\sqrt{K}}(u_f - u_p) \qquad (7)$$

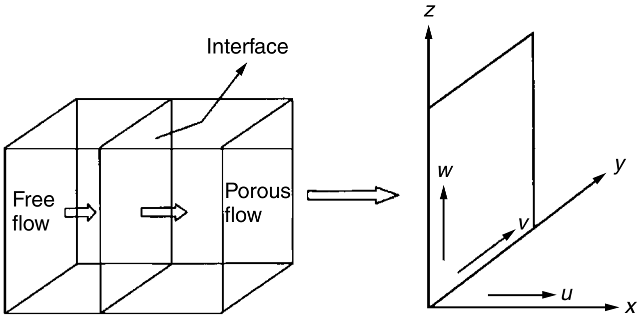

Figure 1. Model of combined free and porous flow domain for extending the Beavers and Joseph (1967) formulation to the 3-D subsurface region.

Direct extension of the above formulations to 3-D cases poses further challenges. However, by resolving the 3-D framework into two planes (x–y and x–z), it is possible to use the Beavers and Joseph formulation for three-dimensional modeling of combined flow in the subsurface (1,2). The extension can be done based on Fig. 1 where the x component of the velocity is normal to the interfacial plane and the y and z components are tangential (parallel). For the 3-D situation in Fig. 1, postulating that the Darcy slip phenomenon takes place at both x–y and x–z planes, the following relationships can be obtained heuristically based on the Jones (5) modification of Beavers and Joseph's original formulation (1,2). The velocity components that are parallel to the interface can be calculated by using these expressions:

$$\text{Velocity slip at } x\text{–}y \text{ plane: } \left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial y}\right)_f = \frac{\gamma}{\sqrt{K_{yy}}}(v_f - v_p) \tag{8}$$

$$\text{Velocity slip at } x\text{–}z \text{ plane: } \left(\frac{\partial w}{\partial x}+\frac{\partial u}{\partial z}\right)_f = \frac{\gamma}{\sqrt{K_{zz}}}(w_f - w_p) \tag{9}$$

The slip coefficient is represented in Eqs. 8 and 9 by γ_{yz} to indicate the plane on which it is active. Equation 8 is used to simulate the jump in the transverse (y) velocity component across the interface, and Eq. 9 is used for the vertical (z) velocity component. K_{yy} and K_{zz} are the permeability in the y and z directions, respectively. The above equations, therefore, represent the slip-flow phenomena at the permeable interface with respect to directional geometric permeability. Also, the velocity component normal to the interface, the longitudinal component, can be taken as continuous across the interface:

$$u_f = u_p \tag{10}$$

However, the pressure does not necessarily remain continuous across the interface and only under static conditions, can it be said to be strictly continuous. If the pressure is to be modeled as discontinuous at the y–z interfacial plane during flow, the following relationship is used:

$$\left(-P + 2\mu\frac{\partial u}{\partial x}\right)_f = -P_p \tag{12}$$

This interfacial condition for pressure jump arises from the fact that stress in the porous side is carried by the porous materials, whereas in the free flow domain, the stress is borne by the fluid medium, which causes a discontinuity in stress, and hence fluid pressure, across the fluid/porous interface.

Matching Boundary Condition for the Brinkman Equation as a Porous Flow Equation. The use of the Brinkman equation for mathematically describing the flow in porous flow zones apparently does not cause any mathematical difficulty. The second-order derivatives of the N-S equations and the Brinkman equation with respect to velocity enable specifying all flow properties as continuous across the interface, which facilitates the task of coupling the equations of motion for the free and permeable domains. The continuity of the flow variables across the interface yields the following matching boundary conditions:

$$u_f = u_p \tag{13a}$$

$$v_f = v_p \tag{13b}$$

$$w_f = w_p \tag{13c}$$

$$P_f = P_p \tag{13d}$$

DISCUSSION AND CONCLUSIONS

Although there are superficial similarities in mathematical formulations of different coupled free and porous flow problems, Das et al. (1) clearly demonstrated that combined flow behavior in the subsurface may differ significantly from other combined flow processes encountered in chemical, petroleum and mechanical engineering applications. Therefore, models to represent specific scenarios need to be developed. In the above studies by Das et al., natural flow behavior has been defined at the exit of the domain by imposing stress-free boundary conditions. Das et al. demonstrated that at the open end (exit) of the domain, coexisting inflow and outflow might take place. In other words, fluid from the surrounding media might come inside the domain through the open end in addition to the defined inlet. For the particular domain investigated, Das et al. observed that although flow in the fluid domain is mostly unidirectional toward the free/porous interface and appears similar to pipe flow, it might become circulatory on the porous side and reverse its direction. Evidence of flow circulation, consistent with the simulated results of Das et al., can also be found in the literature dealing with various scenarios of subsurface flow (6). However, fluid circulation is a complex transient process often involving a moving center of circulation and shifts of the flow reversal front to or from the interface. After a certain time interval, the circulation may disappear, and the porous flow may become unidirectional toward the exit of the porous section. The main cause of such flow behavior has been attributed to complex/variable pressure distributions within the porous domain. The effects of a partially impermeable interface between the free and porous domains has been explored by Das and Nassehi (7). It has been demonstrated that due to the impermeable interface, there is a possibility of buildup of fluid in the free flow region. The influence of having a the multiple number of fluid/porous interfaces in a flow domain has been demonstrated by Das and Nassehi (8). This study showed that, in general, the presence of a multiple number of interfaces in the free flow domain has a minimal effect on flow behavior. However, the flow patterns on the porous side may vary depending on the direction of the free/porous interfaces. Das and Nassehi (8) also examined concentration profiles of a conservative pollutant in associated free flow and porous domains. The effects of different aspect ratios of the subdomains on the hydrodynamic behavior of free/porous regimes have been investigated by Das and Nassehi (9). This study shows the influence of the extent of free and porous domains, which govern the entire flow behavior.

The study of combined free and porous flow in the subsurface using different methodologies is still relatively new in scientific literature. Although a number of issues have been studied, future research aimed at better understanding of combined flow behavior must be continued. For example, investigations into the effects of heterogeneity in porous media and multiphase flow (e.g., oil and water) in combined domains should be carried out. A general methodology, which is not restricted to systems where free/porous interfaces are aligned to coordinate axes, also needs to be developed.

GROUNDWATER TRACING

Hamid Jahani R.
Water Research Institute
Hakimieh, Tehran, Iran

INTRODUCTION

Groundwater tracing is now a major field in groundwater hydrology aiming mainly at demonstrating the direction of groundwater flow and secondly, at giving as much information on the hydrologic setting as possible. It has been used for several decades to study flow conditions, for groundwater reconnaissance, and for managing water resources. During the last decades, water protection has been one of the main issues due to strong pollution of the environment. A groundwater tracer is a substance or a sort of energy conveyed by water to be detected at a sampling point and to be used in analyzing the temporal and spatial distribution of water and the pollutant. Artificial and natural tracers can help in various ways to assess and to predict contaminant transport in surface and groundwater.

Groundwater tracing can be a component of a large hydrogeological program, or it can be a hydrogeological program by itself. Nowadays, new field methods, new tracers, and new measurement techniques are being developed to make hydrogeologists more satisfied with results.

The advantage of groundwater tracing is that it provides the possibility of a direct view of a groundwater system, so the results can be relied on with assurance. In a groundwater tracing program, depending on the question and technical problem, both “natural” (those existing in the water cycle) and “artificial” (those to be introduced into groundwater system) tracers can be selected. The main group of artificial tracers, is soluble tracers, such as fluorescent dyes that are highly detectable, as well as different salts. Another group of artificial tracers includes drift bodies, such as spores, bacteria, or phages. The applicability of each tracer depends on its properties and on the condition of the flow environment. The use of certain tracers, especially for groundwater flow, is strongly restricted due to hydrogeologic conditions and aquifer properties.

For artificial tracers, the methodology comprises introducing the tracer into the groundwater system, letting it travel together with the water, sampling, and finally analyzing the water samples. For natural tracers, the natural physical, chemical, or biological composition of water is traced. For example, the natural temperature of cold water from a spring could be a guide to identifying snowmelt as the main water source and differentiating it from local groundwater.

THE HISTORICAL BACKGROUND

The groundwater tracing method is as old as the interest of humans in nature. It was used while people were curious about finding the source of undiscovered or unknown caves or springs and used chaff, wood bits, or other drifts to reveal the route of the water. The way to perform the test is now almost as simple as it was in the past, at least in most cases. But the way to analyze samples and the results evolved into complicated analytical methods. The development of new tracers and new analytical methods during the last 10 years has led to more accuracy in the results and also more ability to cover longer distances in tracing tests. While using the method during the last decades, it was aimed to find the direction of groundwater flow and its velocity; now, its major application is in studying groundwater pollution problems and protecting the environment.

GOALS OF GROUNDWATER TRACING

The most important goals to be achieved in a tracing program can be categorized into two groups:

Quantitative goals: To determine

- groundwater recharge amount
- groundwater discharge amount
- components of groundwater recharge
- age of groundwater
- elevation of recharge
- groundwater velocity
- volume of aquifer dynamic storage
- dispersion coefficient
- travel time

Quantitative goals: To determine

- origin of water
- hydraulic connection between different surface water and groundwater bodies
- hydraulic connection between different basins
- spring catchment area
- aquifer recharge areas
- aquifer discharge areas
- aquifer boundaries
- groundwater flow direction and path
- flow regime
- role of structural features in groundwater flow
- saline water–freshwater interface
- source of pollution
- pollution distribution pattern
- degree of karstification
- seepage/leakage zones in dams and reservoirs

CHARACTERISTICS OF IDEAL TRACERS

Among the characteristics for selecting a tracer as an ideal applicable tracer are the following:

The tracer

1. should be detectable in low concentrations. In most cases, the tracer material is to be diluted in a big volume of groundwater storage, so it must be easily detectable at low concentrations in water samples. The tracer concentration should be easily differentiated from background values in sampled water.
2. should be applicable as a nontoxic additive to water. It is compulsory for the tracer material not to harm flora and fauna.
3. should not be an absorptive material. The tracer substance should not be easily adsorbed to aquifer material; otherwise, it is possible that a considerable portion of the injected tracer is lost during the test, and it may be a major source of error in interpreting the results. The tracer should move in the same manner as water, and should not interact with aquifer material.
4. should be economically available. In some tracing experiments, the cost of tracer is a decisive factor.
5. should not change the hydraulic conductivity of the medium under investigation.
6. should be stable enough during the test period from injection until detection.

It is obvious that one could not find an ideal tracer that meets all of these specifications. Although there are some tracers developed specifically for groundwater tracing, selecting a suitable tracer, as well as applying a suitable amount of the tracer, is a state-of-the-art task and cannot be done without sufficient experience, favorable expertise, and knowledge about the medium under study.

GROUNDWATER TRACER TYPES

Groundwater tracers can be categorized into two main groups of artificial (to be introduced into the system) and natural (environmental or preexisting in the system) tracers (Fig. 1). Natural tracers are those present in water molecules or accompany water molecules naturally along their path, such as deuterium (^{2}H), carbon-13, or water temperature. Discharge pulses are often good tracers for water especially in the response of springs to flash rainfalls. Artificial tracers are much more diverse in type, and there are many more tracers not mentioned.

Natural (Environmental) Tracers

Natural or environmental tracers are those that already exist in the natural environment, the hydrologic cycle. They could be substances or some kinds of energy.

Environmental Isotopes. Environmental isotopes used as groundwater tracers are isotopes of hydrogen, oxygen, and carbon. They could be part of a water molecule (^{2}H or deuterium, ^{18}O, and ^{3}H or tritium), or they might enter the hydrologic cycle and move together with water molecules (^{13}C, ^{14}C, ^{14}N, ^{15}N, ^{32}S, ^{34}S, ^{36}S ...).

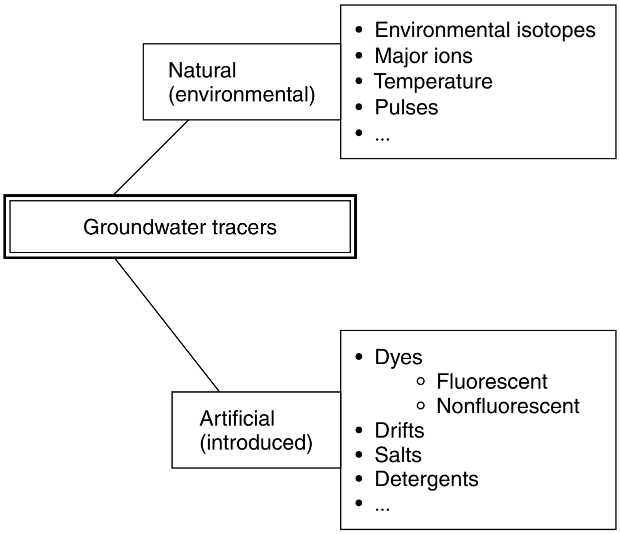

Figure 1. Groundwater tracer types.

Stable Isotopes

Hydrogen and Oxygen Isotopes. Analysis of the natural concentration of these isotopes in water has helped in understanding groundwater flow. Because of the large differences in mass between the two hydrogen isotopes, they tend to fractionate whenever evaporation or condensation takes place. Other factors being equal, waters of higher deuterium content are found near coastlines, at low elevations, in warm rains, and where partial evaporation occurs, as in saline lakes. The variations in oxygen isotope almost follow those of deuterium. The most common use of studies of ^2H and ^{18}O has been to trace the regional movement of groundwater and to locate recharge areas.

Nitrogen. The two abundant isotopes of nitrogen (^{14}N and ^{15}N) can vary significantly in nature. Ammonia escaping as vapor from decomposing animal wastes, for example, tends to remove the lighter nitrogen (^{14}N) and leaves behind a residue rich in nitrogen. In contrast, many fertilizers that have an ammonia base are isotopically light. Natural soil nitrate is somewhat between these two extremes. As a consequence, nitrogen isotopes have been useful in helping to determine the origin of unusually high amounts of nitrate in groundwater.

Most nitrogen in groundwater is in the form of nitrate anion (NO_3^-) or dissolved nitrogen gas (N_2) from the atmosphere. Locally, in zones devoid of dissolved oxygen, the chemically reduced form (NH_4^+) may predominate. In general, nitrate moves as a conservative tracer and is an important indicator of pollution. If nitrate concentrations exceed about 10 mg/L, the health of infant mammals including humans may be adversely affected. Also the presence of more than about 5 mg/L of nitrate commonly is an indirect indication of other forms of contamination, including those from fertilizers and sewage.

Sulfur. Most dissolved sulfur within shallow groundwater is bound within the sulfate ion (SO_4^{2-}). The stable sulfur isotopes (^{32}S, ^{34}S and ^{36}S) found in the sulfate ion vary quite widely and, under certain circumstances, can be useful indicators of the origin of the sulfate, which is particularly true if, for example, one wishes to distinguish sulfate originating from natural dissolution of gypsum ($CaSO_4 : 2H_2O$) from sulfate originating from an industrial spill of sulfuric acid.

Active Isotopes

Tritium. Tritium (^3H) is an unstable isotope of hydrogen whose half-life is 12.32 years. It enters the hydrologic cycle in the same manner as stable hydrogen in the H_2O molecule. This isotope is naturally produced at low levels in the atmosphere. During and after the nuclear tests in the Northern Hemisphere in the 1960s, the tritium concentration (referred to as TU: Tritium Unit) in the atmosphere increased from a level of 5–15 TU to up to 4000 TU. ^3H can be used qualitatively to date groundwater groundwater that has less than 2 to 4 TU is dated prior to 1953; if the amount is significantly greater than 10 to 20 TU, it has been in contact with the atmosphere since 1953. Tritium analysis in groundwater studies is mainly for absolute groundwater dating for ages up to 40 years.

Carbon-14. ^{14}C is the radioactive isotope of carbon. It has a half-life of 5730 years and is mainly used to date groundwaters up to 30,000 years of age. Most ^{14}C in potable groundwater is contained in the HCO_3^- ion in water. As a first approximation, the initial number of ^{14}C nuclei per total carbon nuclei, or X_0 in Eq. 1, in a water sample is considered to have been constant prior to 1950 due to the almost constant natural production of ^{14}C in the atmosphere by cosmic radiation interacting with the atmosphere.

$$X_t = X_0 e^{-\lambda t} \tag{1}$$

where λ = decay constant
t = time
X_0 = number of nuclei at zero time
X_t = number of nuclei at time t

If the only source of ^{14}C in water is originally from the active biosphere, then the ^{14}C that is measured in carbon from a water sample can be considered X_t in the equation because λ is known from experimental work, the age of the sample (t) can be determined directly. Due to some complexities, the use of ^{14}C in age determination is not so simple. The existence of carbon from carbonate formations, or formation of CH_4 gas, are factors that affect the results of age determination. But despite that, ^{14}C dating is highly useful in determining the approximate residence time of old groundwater.

Major ions. The chemical composition of groundwater is in most cases a good indicator of the environment through which the water has passed. In almost all groundwater tracing and isotopic hydrologic programs, water is analyzed for calcium, sodium, magnesium, potassium (major cations), chloride, sulfur, carbonate, bicarbonate, and nitrate (major anions).

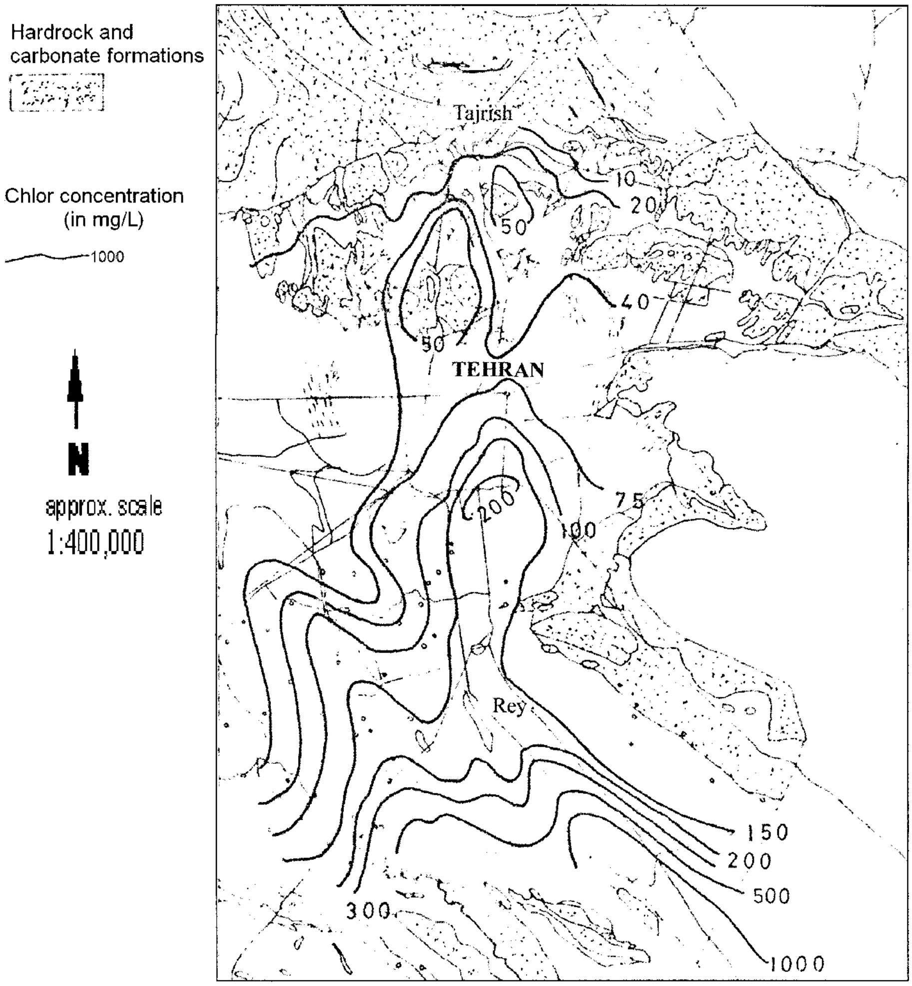

Figure 2. Isochlor map for Tehran plain, 1977, Tehran, Iran. The general groundwater flow direction is southward. As can be seen, groundwater gets richer in ions (specifically in chlor) as it flows downstream.

Typically, if we follow a recharge event and track the water down-gradient in the flow path, it can be seen that the ionic concentration in the water increases as it migrates down-gradient (Fig. 2). Generally, groundwater is the bicarbonate type in recharge areas the sulfate type midway, and the chloride type in terminal zones (e.g., basin outlet). The chemical composition of groundwater would finally be demonstrated on specific presentation charts such as Piper, Durov, Schuler, ... and different groundwater types could be easily recognized.

Temperature. Water temperature is almost a good indicator or tracer where there is an abrupt difference in the physical properties of the aquifer (e.g., a change in hydraulic conductivity, fracture properties ...) or where there is a significant temperature gradient (Fig. 3) Thermometry is a study tool for investigating changes in rock properties in a borehole column. It comprises a heat sensor that goes down through the borehole and records the water temperature along the borehole column. The record is called a temperature log.

Pulses. Pulses are sudden changes in the amount of a specific parameter that can be easily seen as a peak in a graph of the parameter versus time. It could be the graph of a spring discharge, electrical conductivity, turbidity, etc. A pulse is normally an indicator of a hydrologic event upstream. For example, a sudden rise in the amount of turbidity in a spring could be an indication of a storm in a spring recharge area. It could also be a sign of a hydraulic connection between the storm area and the spring.

Artificial Tracers

Artificial tracers are those that are introduced intentionally into groundwater. So an "injection point" is necessary in artificial tracing in addition to a sampling network.[1] While in environmental tracing, the study is performed only through a sampling network. Normally, artificial tracing and natural tracing are complementary, and sometimes both methods are applied to the same area to achieve more reliable results. Among all artificial tracers, the most applicable are fluorescent dye tracers which are discussed at the end for more emphasis.

Drifts. In areas such as karstified limestone terrains or highly faulted volcanic rocks where groundwater flow follows a turbulent pattern, drifts usually are good choices to be selected as tracers. Signal-emitting floats, yeasts,

---

[1] Sometimes the injection point and sampling point are the same. This is the case in the so-called single-well tracing method.

bacteria, viruses, and spores have reportedly been used as tracers in many cases.

Salts. Most tracers that have already been used extensively are common salts. This category of tracers includes those compounds that ionize in water, resulting in separation into charged elements possessing a positive charge (cations) or a negative charge (anions). The most common ionic tracers are chloride (Cl^-), bromide (Br^-), lithium (Li^+), and potassium (K^+). These tracers have been successfully used to determine flow paths, residence time, and aquifer properties. The most important factors that should be considered before applying such tracers are aquifer material texture and natural background concentrations in the aquifer.

The advantages of salt tracers are their availability, low cost, and stability, but they must be injected in large amounts, hundreds of kilograms or tons, and this causes problems in handling and transportation. As they are injected in huge amounts, they make water denser around the injection point, and it may affect the hydrodynamic behavior of the water.

Fluorescent Dyes. For many reasons, fluorescent dyes have become very important as tracers in hydrology and hydrogeology. They can be used in hydrology to measure transit times in streams and rivers, to measure discharge in open channels by the tracer dilution method, and to investigate dispersion processes in rivers, lakes, and seas. Of course their main application is in hydrogeologic studies for estimating hydrodynamic parameters as well as studying sources of pollution.

Application of fluorescent tracers has some great advantages and a few disadvantages:

- They are visible without the use of any instrument at higher concentrations (say more than 10 ppb). This property can be useful for qualitative experiments.
- The limit of detection for the dyes is in the sub-ppb range and therefore much better (up to a factor of 1000 to 10000) than salt tracers. So a small amount of tracer is enough.
- Instrument detection is quick and easy without time-consuming sample preparation.
- The chemical properties of the dyes are in some cases better because salts (particularly the cationic part) are influenced by ion exchange in clayey sediments.
- Fluorescent dyes do not influence the density of water near the injection point.
- Depending on the type of analytical instrumentation, the costs to determine fluorescent dyes are cheaper (using an ordinary photometer) or comparable to a flame photometer which can be used to analyze salt tracers. The detection of salts by electrical conductivity measurement is obviously cheaper but cannot distinguish between different types of salt tracers.
- A disadvantage is the relatively high cost of fluorescent dyes, but, on the other hand, up to 1000 times less dye than salt is necessary for a tracing experiment.

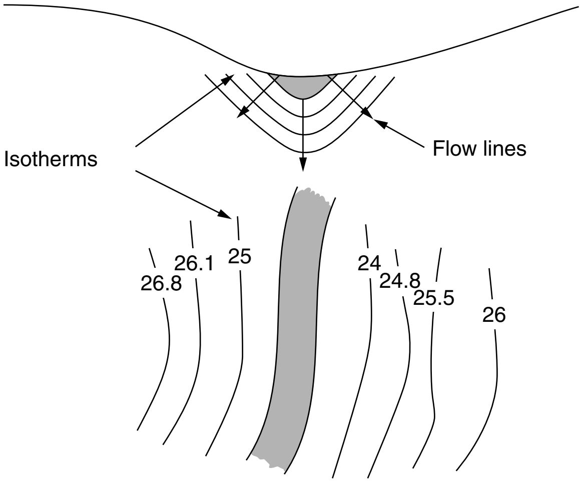

Figure 3. Sketch showing a section of a temperature gradient due to freshwater recharged from the river (up) and the plan of isotherms at both sides of the river (down).

These are the most commonly used fluorescent dyes:

Uranine. For hydrologic or hydrogeologic purposes, uranine ($C_{20}H_{10}O_5Na_2$, Color index name: Acid Yellow 73) is the most important tracer (Fig. 4). It is also the most sensitive of all. The dye is supplied as a hygroscopic orange-red powder: it is very soluble in water and has a yellowish-red color and an intense yellowish green fluorescence. In solutions at concentrations higher than 1 g/m^3 (equal to 1 ppm), the color is orange-red. The fluorescence is visible without any instrument above concentrations of 50 mg/m^3 (50 ppb) and approximately above 10 mg/m^3 (10 ppb) using a UV lamp, depending on the quality of the dye. It has no specific odor. At high concentrations, the fluorescent light is absorbed by the sample itself. The intensity of the fluorescence can be measured exactly only if the concentration is much lower (less than 100 ppb); otherwise, the solution has to be diluted.

The solubility of Uranine is 500 mg/L, and its detection limit is 0.001 mg/m^3. Its fluorescence intensity in solution is very much dependent on the pH. At pH lower than 6, the intensity tends to zero. Uranine is an anionic tracer, and it is adsorbed by clay minerals only to a minor extent. It has also good temperature stability which is important for analytics (a temperature increase in the instrument) and for injection, for example, into thermal systems. From

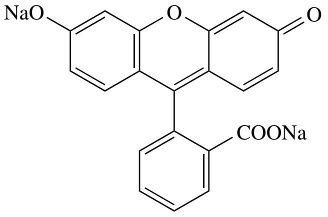

Figure 4. Molecular structure of uranine.

the view point of toxicity, it is not dangerous to humans or animals, in particular, at concentrations normally used in tracing experiments.

Eosin. Eosin ($C_{20}H_6Br_4Na_2O_5$, Acid Red 87) (Fig. 5) is a powder made of red crystals of a bluish tinge. A concentrated aqueous solution is deep brownish-red, dilute solutions are yellowish-red with a greenish fluorescence. The fluorescence is visible in more concentrated solutions (above 10 ppb).

It is very soluble in water, less in alcohol, and insoluble in ether. At high concentrations, fluorescent light is absorbed by the sample itself. For an exact analysis, the concentration should not be higher than 100 ppb, otherwise, dilution is recommended. Its solubility is 300 g/L and the detection limit is 0.01 mg/m^3. The pH effect for eosin is not as significant as that for uranine. Eosin is an anionic tracer and is generally little adsorbed by clay minerals. It can be used in karstic systems as well as in porous groundwater aquifers. It is not dangerous to humans or animals.

Among other fluorescent dyes, sulforhodamine G, Sulforhodamine B, rhodamine WT, rhodamine B, and pyranine are used most groundwater tracing.

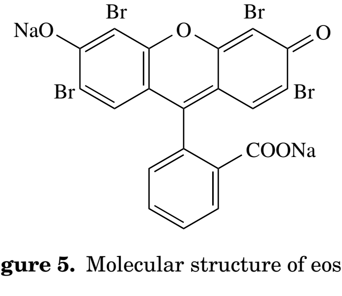

Figure 5. Molecular structure of eosin.

Tracing Experiment

While planning a tracing test, there are some factors that must be considered. First, the objectives of the study should be defined well because they affect other study components such as selecting the tracer. Then all available resources (labor, money, time,) should be considered to facilitate formatting the program. Third, all relevant information and data (maps, reports, well logs) should be available so that a good idea of the geology and hydrogeology of the site is gained.

The general direction of groundwater flow and also its velocity should be estimated before starting the test, which will allow configuring the injection and sampling network effectively.

Different Phases of the Test

Planning and General Assessment. Before starting a tracing test, the test site should be visited and examined carefully, which is to schedule the program activities and other components of the work such as selecting the injection and sampling points, selecting the tracer (which is among the most important and critical components of the work), designing the sampling program, transportation (equipment, tracers, personnel, etc.

Tracer Injection. By injecting the tracer into the aquifer, it will enter the hydrologic cycle and (it is assumed that) will travel in the same manner as water. The injection method varies with the type of tracer, study purpose, site conditions, etc.

Sampling. Sampling is done for the purpose of analyzing water to find if there is tracer in it. Actually the sampling work starts before injecting the tracer because there might be some background concentration of the tracer in the water; this is called background sampling.

Because of the very high dissemination potential of fluorescent tracers, it is very important to avoid any contact between injecting personnel/equipment and sampling. The sampling time interval for each sampling point should be scheduled according to the hydrogeologic factors and distance to the injection point.

Analysis. All samples should be carefully packed and sent to the lab to be analyzed as soon as possible. The analytical method and the instrumentation for measuring the fluorescence of the samples are discussed following. As mentioned before, concentrations higher than 10 ppb of most fluorescent dyes may be visible and can be detected without any instrument.

Detection with a Two Monochromator Spectrofluorometer. To analyze for tracers, the best method is to use a spectrofluorometer with monochromators for excitation and emission (Fig 6). The light of the excitation source is transmitted through a filter of maximum transmittance near or at the absorption maximum of the dye. The dye molecules in the solution will be excited, and the fluorescence can then be dispersed by a secondary filter or a monochromator (prism or grating). Table 1 is a summary of spectral data of some fluorescent dyes, and Table 2 is a summary of their approximate detection limits in water. The final result of an analysis is a time–concentration (or breakthrough) curve, which presents the temporal evolution of the sampling point tracer concentration (Fig. 7).

Interpretation of Results. With regard to the breakthrough curve plotted for each sampling point, one should

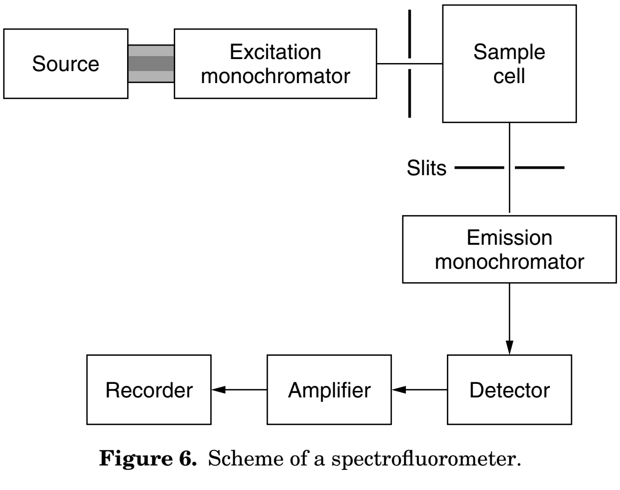

Figure 6. Scheme of a spectrofluorometer.

Table 1. Summary of Spectral Data of Some Fluorescent Dyes

Dye	Fluorescent Excitation	Fluorescent Emission	Wavelength Difference (nm)
Uranine	491.0	512.5	21.5
Eosin	515.5	536.0	20.5
RhodamineB	553.5	576.0	22.5
Pyranine	463.5	512.5	49.0

Table 2. Summary of Approximate Detection Limits for some Fluorescent Dyes

Dye	Limit of Detection (mg/m^3)
Uranine	0.001–0.025
Eosin	0.050–0.5
Rhodamine B	0.010–0.5
Pyranine	0.008–0.5

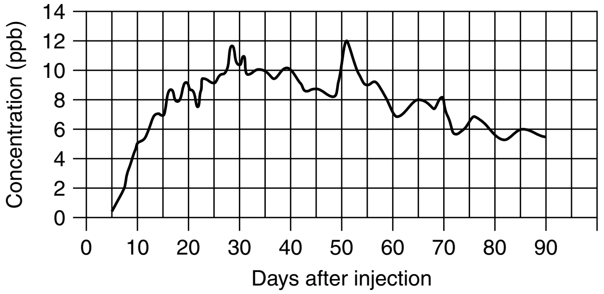

Figure 7. The breakthrough curve for a spring in the Tang-e Shemiran area, western Iran.

first of all focus on the first arrival time of the tracer. It reveals first, that there is an underground hydraulic connection between the injection point and the sampling point and, second, the maximum groundwater flow velocity in that zone. The peak concentration also leads to the average transit time. The shape of the curve is a guide to the approximate volume of water in which the tracer has been diluted. The area under the curve is equivalent to the total mass of tracer recovered from the sampling point (e.g., a spring). The summation of this figure for all sampling points should be close to the injected amount. Otherwise, there is another outlet for the aquifer which was unknown during planning.

HYDRAULIC CONDUCTIVITY/ TRANSMISSIBILITY

Steven A. Dielman
ENVIRON International
Corporation
Arlington, Virginia

Hydraulic conductivity is a fundamental parameter that governs the flow of liquids such as groundwater through aquifers and other porous media. Specifically, hydraulic conductivity is a quantitative measure of the capacity of a geologic formation or other porous media to transmit a specific fluid. It is determined by the characteristics of both the porous medium and the fluid of interest.

Transmissibility (or transmissivity) is a property closely related to hydraulic conductivity that describes the capacity of a specific water-bearing unit of a given thickness, such as an aquifer, to transmit water. Transmissibility is most simply defined as the effective hydraulic conductivity of an aquifer or other water-bearing unit multiplied by the thickness of that unit.

ORIGINS IN DARCY'S LAW

The concept of hydraulic conductivity dates back to Henry Darcy's famous 1856 paper regarding the water supply for the city of Dijon, France. In that paper, Darcy described the results of laboratory experiments that he had conducted to investigate the flow of water through sand. From the results of those experiments came the relationship now referred to as Darcy's law, it is valid for laminar flow conditions that occur in most groundwater systems and can be expressed as

$$Q = -K\frac{\partial h}{\partial l}A \tag{1}$$

where Q = volumetric flow rate (L^3/t)
K = hydraulic conductivity (L/t)
$\frac{\partial h}{\partial l}$ = hydraulic gradient (L/L)
A = Cross-sectional area perpendicular to the flow direction (L^2)

As evident from Eq. 1, the volumetric flow of a fluid through a porous medium is directly proportional to the coefficient K; Darcy recognized that it is dependent on the type of soil through which water flows. For this reason, the coefficient K has historically been referred to as Darcy's coefficient of proportionality. Today, the coefficient K is more commonly called hydraulic conductivity.

RELATIONSHIP TO PERMEABILITY

It is intuitive that the flow of a liquid through soil also depends on the characteristics of the liquid. For example, if all other factors are equal, the volumetric flow rate (Q in Darcy's equation above), and hence the hydraulic conductivity, will be greater for water than for a more viscous liquid such as a heavy oil.

The relationship of hydraulic conductivity (K) to permeability (k)[1] is useful in distinguishing the effects of the porous medium from the effects of the fluid:

$$K = \frac{k\rho g}{\mu} \tag{2}$$

where ρ = density of fluid;
μ = dynamic viscosity of fluid; and
g = gravitational acceleration constant.

Permeability k is a function only of the medium and is commonly used in petroleum studies where various fluids of differing characteristics such as oil, water, and natural gas may be present together in multiphase flow systems.

From Eq. 2, it is clear that hydraulic conductivity is a function of the characteristics of the fluid as well as the permeability of the medium (k).[2] Specifically, a soil with a given permeability will exhibit relatively greater hydraulic conductivity to fluids of lower viscosities and/or greater densities.

Rearranging Eq. 2 also allows determining the hydraulic conductivity to one fluid if the hydraulic conductivity to another is known:

$$K_1 = K_2 \frac{\mu_2}{\mu_1}\frac{\rho_1}{\rho_2} \tag{3}$$

where K_1, μ_1, and ρ_1 are properties of fluid 1 and K_2, μ_2, and ρ_2 are properties of fluid 2.

UNITS OF MEASUREMENT

The units of hydraulic conductivity are (L/t), and the units of permeability are (L^2). In the context of groundwater flow, the units of permeability are sometimes expressed as "darcys"; one darcy approximately equals 1×10^8 cm^2. Conversion factors for commonly used units of hydraulic conductivity and permeability are provided in Table 1. For most applications, the viscosity and density of water vary over a narrow range, and permeability values can be converted to hydraulic conductivity (of water), assuming standard temperature and pressure, without introducing significant error.

Because transmissibility is defined as hydraulic conductivity multiplied by aquifer thickness, its units are (L^2/t), often expressed as volume per unit width of the aquifer per unit time (e.g., gallons per day per foot or gpd/ft).

REPRESENTATIVE HYDRAULIC CONDUCTIVITY VALUES

Local hydraulic conductivity values can vary over an extremely wide range. Ranges in representative values of hydraulic conductivity for various geologic media are summarized below.

Figure 1 illustrates that hydraulic conductivity values may range over approximately 12 orders of magnitude, depending on the type of soil or rock. Even for specific types of geologic deposits, variations over several orders of magnitude are not uncommon.

In general, geologic deposits that exhibit the lowest hydraulic conductivity values are fine-grained unconsolidated materials (e.g., clays) and unfractured sedimentary and crystalline rocks. The presence of fractures in either consolidated or unconsolidated materials of otherwise low permeability can significantly increase the hydraulic conductivity of these materials.

Geologic deposits that exhibit the highest hydraulic conductivity values are typically coarse-grained unconsolidated materials (e.g., coarse sands and gravels) and rocks that are highly fractured or otherwise exhibit significant secondary permeability (e.g., solution-enhanced void space in carbonate formations or basalt shrinkage cracks).

GEOLOGIC FACTORS INFLUENCING HYDRAULIC CONDUCTIVITY

For unconsolidated materials, the factors that have the greatest influence on hydraulic conductivity are generally particle size and particle sorting. It can be theoretically shown that hydraulic conductivity is proportional to the square of the particle diameter for a uniform, porous medium, that is, doubling the particle diameter results in quadrupling hydraulic conductivity. In practice, however, geologic formations are not uniform but contain particles of varying sizes, and the definition of a representative particle diameter is not clear-cut. In general, poorly sorted deposits (i.e., those with greater variation in particle sizes) will exhibit lesser relative hydraulic conductivity compared to that of well-sorted deposits, due to infilling of pore space by finer grained particles.

In consolidated crystalline and sedimentary rocks, the hydraulic conductivity of the rock matrix tends to be low to extremely low. Transmission of water through these rocks is generally via interconnected voids such as fractures, solution channels, shrinkage cracks or metamorphic (e.g., schist) foliations. Transmission of water through such voids is said to occur via "secondary permeability."

HETEROGENEITY AND ANISOTROPY

Geologic depositional environments typically exhibit significant variability across very short distances. As a result, hydraulic conductivity values generally exhibit

---

[1] In older publications, K was sometimes referred to as the coefficient of permeability and, therefore, k become known as "specific" permeability or "intrinsic" permeability to differentiate it from K. More recently, it has become conventional to refer to K as hydraulic conductivity, allowing k to be referred to simply as permeability.

[2] It is common practice in groundwater hydrology publications to use the term hydraulic conductivity as it relates to water, unless a different fluid is specified.

Table 1. Hydraulic Conductivity and Permeability Conversion Factors[a]

	Multiply To obtain	Hydraulic Conductivity					Permeability	
		cm/s by	m/s by	ft/s by	ft/day by	US gal/day/ft^2 by	cm^2 by	Darcy by

[a] Conversions between units of hydraulic conductivity (K) and permeability (k) assume the properties of water at approximately 15 °C.

spatial variation across several orders of magnitude within an area of hydrogeologic interest.

The terms *heterogeneity* and *anisotropy* are often employed to describe variability in hydraulic conductivity. Heterogeneity refers to variability in space, and anisotropy refers to variability in direction from a given point. Figure 2 illustrates the relationship between heterogeneity and anisotropy.

The distinction between anisotropy and heterogeneity often depends on scale and context. For example, on one scale, layered heterogeneity (see Fig. 4) may require consideration as a series of distinct geologic formations that have different representative hydraulic conductivity values. On another scale, it may be more convenient and appropriate to describe this system as one anisotropic layer.

Heterogeneity

A porous medium of uniform characteristics is said to be homogenous. In reality, no geologic system is truly homogenous with respect to hydraulic conductivity. Each system exhibits varying types and degrees of heterogeneity. An illustration of actual heterogeneity is shown in Fig. 3. This two-dimensional cross-section was created from more than 700 measurements within an area approximately 2 meters deep by 20 meters long within the intensely studied Borden aquifer, which is generally recognized as “mildly” heterogenous compared to most groundwater systems. Even in this small area of a relatively uniform aquifer, measured hydraulic conductivity values range across approximately three orders of magnitude.

In some cases, heterogeneity in hydraulic conductivity values may exhibit one or more measurable trends due to geologic conditions. Freeze and Cherry (2) identified three types of common heterogeneity patterns: trending, discontinuous, and layered.

Trending heterogeneity refers to spatial trends resulting from, for example, gradational coarsening or fining depositional sequences such as those that typically result from encroaching or receding seas. Trending heterogeneity may also result from postdepositional processes such as vertical trends in rock fracture frequency.

Discontinuous heterogeneity refers to an abrupt change in local hydraulic conductivity values, such as those across a geologic discontinuity, fault, or other sharp stratigraphic contact.

Layered heterogeneity is a commonly encountered type of heterogeneity, particularly for unconsolidated or consolidated sedimentary sequences formed in time-varying depositional environments. An idealized example of layered heterogeneity is illustrated in Fig. 4. A more realistic depiction of layered heterogeneity is illustrated in the Borden aquifer hydraulic conductivity plot depicted in Fig. 3.

In reality, distinguishing between types of heterogeneities is often difficult. For example, layered heterogeneity may be considered a series of discontinuous heterogeneities. In addition, multiple patterns in heterogeneity may be present at any given location.

Anisotropy

If hydraulic conductivity is independent of the direction of measurement, the medium is described as isotropic; if, however, the hydraulic conductivity value depends on the direction of measurement, it is considered anisotropic. Mathematically, hydraulic conductivity is represented as

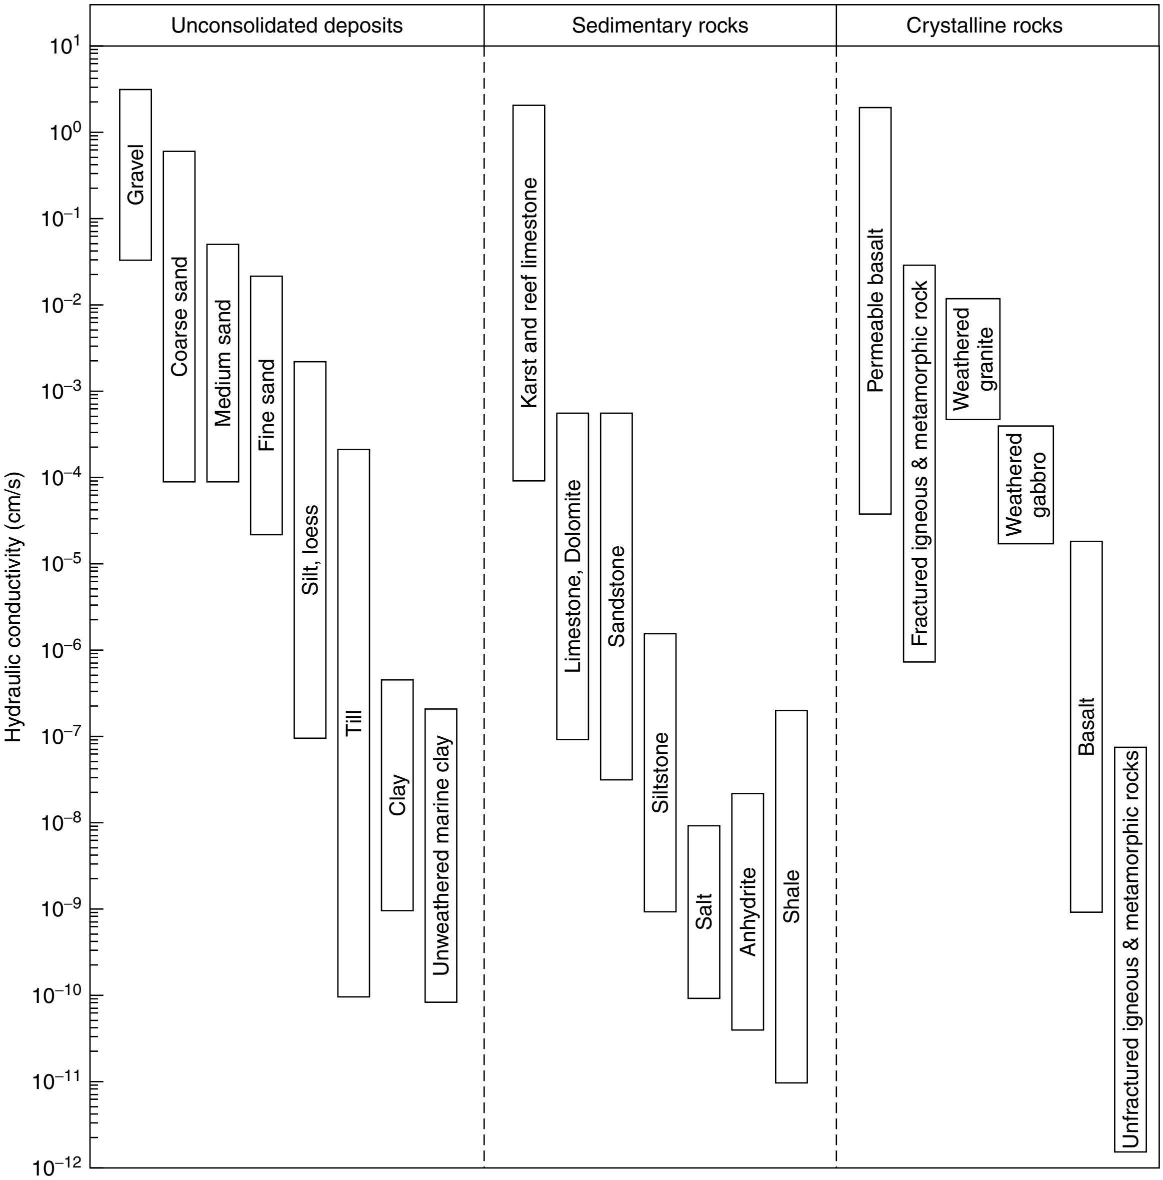

Figure 1. Representative values of hydraulic conductivity for various rock types (adapted from: Ref. 1).

a scalar (direction-independent) variable in the form of Darcy's law presented in Eq. 1 In anisotropic settings, hydraulic conductivity must be considered a tensor variable, leading to more complex forms of Darcy's law and other equations that describe the flow of groundwater and other fluids through porous media.

On a small scale, anisotropy can result from mineral grain orientation. On a larger scale, anisotropy can result from sedimentary bedding planes, metamorphic structure (e.g., shistocity) or directional fracturing of crystalline rocks resulting from postdepositional stresses.

In sedimentary deposits of horizontal or near-horizontal orientation, hydraulic conductivity is frequently greater in the lateral directions compared to the vertical direction. On a small scale, such anisotropy may be relatively modest. Freeze and Cherry (2) report ratios of horizontal hydraulic conductivity (K_{h}) to vertical hydraulic conductivity (K_{v}) between 3:1 and 10:1 for clays and shales due to mineral grain orientation. On a larger scale, however, K_{h}:K_{v} anisotropic ratios for sedimentary deposits may be extremely high due to stratified deposits of greatly different characteristics. High K_{h}:K_{v} anisotropic ratios for stratified deposits are not surprising, considering the large differences in typical hydraulic conductivities of coarse-grained and fine-grained deposits, which may differ by several orders of magnitude.

EFFECTIVE HYDRAULIC CONDUCTIVITY: STATISTICAL TREATMENT OF HYDRAULIC CONDUCTIVITY VALUES

Groundwater hydrologists have used a variety of techniques to characterize the spatial variability of hydraulic conductivity values and to assess groundwater flow in

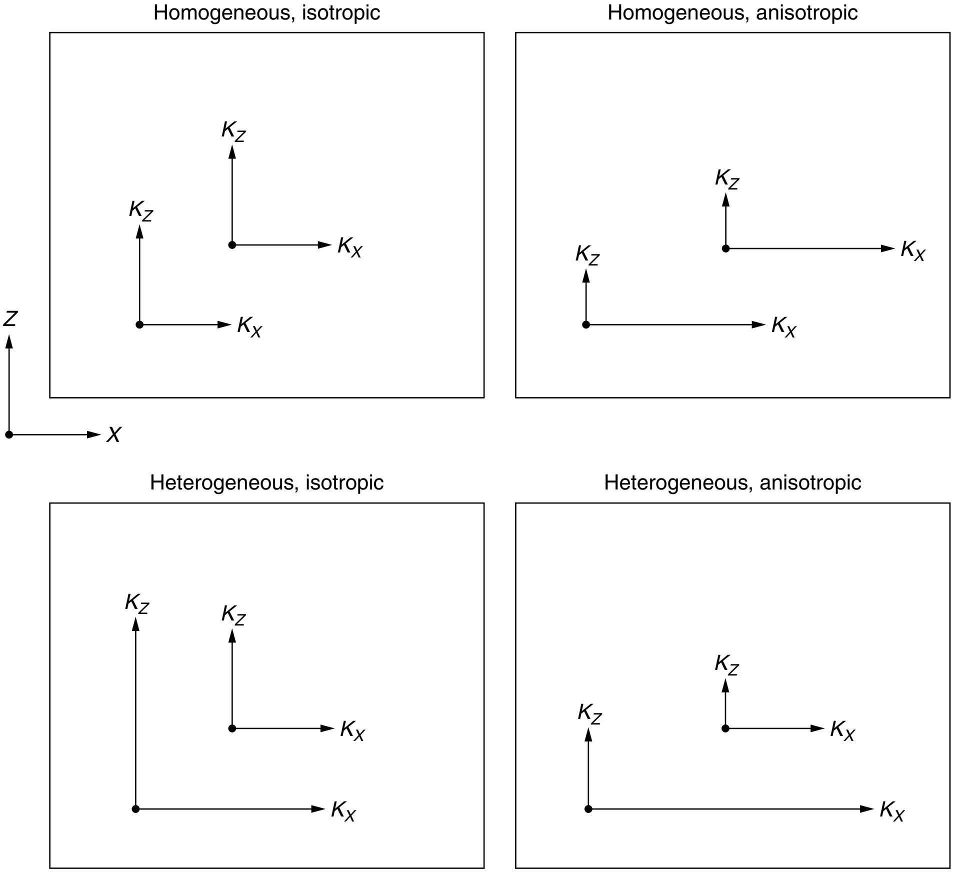

Figure 2. Four possible combinations of heterogeneity and anisotropy (adapted from Ref. 2).

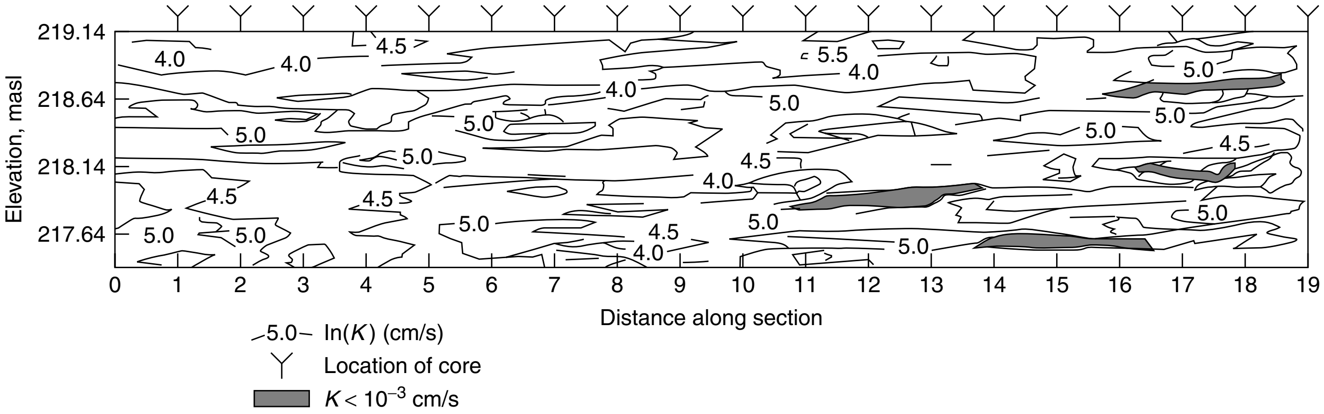

Figure 3. Hydraulic conductivity distribution at Canadian Forces Base Borden (from Ref. 3, v. 22, p. 2069–2082).

heterogenous geologic settings. One such approach is to identify an "effective" hydraulic conductivity that, applied to a heterogenous water-bearing geologic unit, will allow an accurate representation of its ability to transmit water as a whole.

Consider horizontal groundwater flow through an idealized layered geologic system such as that shown in Fig. 4 where the a number of layers equals n. The total flow through the system (Q) is equal to the sum of the flow in all layers (ΣQ_i). From Darcy's law, this can be expressed as

$$Q = \sum Q_i = \sum K_i \frac{dh}{dx} D_i W \tag{4}$$

where

K_i = hydraulic conductivity of layer i,
dh/dx = horizontal hydraulic gradient (assumed uniform in all layers),
D_i = thickness of layer i, and
W = unit width.

For combined flow through the layered system, an effective horizontal hydraulic conductivity ($K_{\text{H-EFF}}$) can be defined for groundwater flow such that

$$Q = K_{\text{H-EFF}} \frac{dh}{dx} DW \tag{5}$$

From Eqs. 4 and 5, the following relationship for $K_{\text{H-EFF}}$ is obtained:

$$K_{\text{H-EFF}} = \frac{\sum K_i D_i}{D} \tag{6}$$

This shows that, for flow parallel to the idealized layered system shown in Fig. 4, $K_{\text{H-EFF}}$ is equivalent to the arithmetic mean of K_i weighted by the thickness of each layer D_i. If all layers are of the same thickness (or all K values are uniformly distributed), $K_{\text{H-EFF}}$ is equal to the arithmetic mean of the individual K_i values.

Consider, however, vertical groundwater flow through the same system. Using a similar analysis, it can be shown that the effective horizontal conductivity in the vertical direction ($K_{\text{V-EFF}}$) is equal to

$$K_{\text{V-EFF}} = \frac{D}{\sum D_i/K_i} \tag{7}$$

If all layers are of equal thickness (or are uniformly distributed), $K_{\text{V-EFF}}$ for the idealized layered system is equivalent to the harmonic mean of K_i values, which is always lower than or equal to the arithmetic mean.

These two simplified conceptual models represent two extreme possibilities of flow uniformly parallel to or perpendicular to geologic layers, respectively. Therefore, the arithmetic and harmonic means of a population of hydraulic conductivity values are generally considered to be upper and lower bounding values, respectively, for the effective hydraulic conductivity of a heterogenous geologic system with respect to groundwater flow through that system.

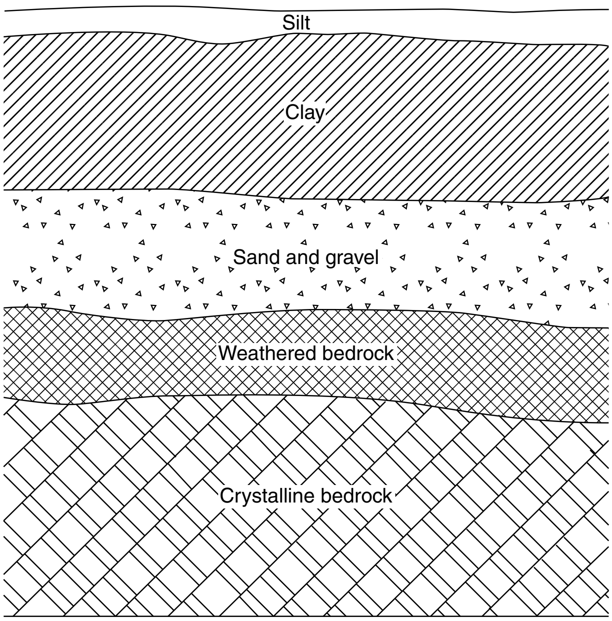

Figure 4. Example of layered heterogeneity.

Frequently, hydraulic conductivity values and well yields within a specific geologic setting are best characterized by a log-normal distribution. As such, the geometric mean is often preferred as a descriptive statistic for the central tendency (e.g., median and mode) of a population of log-normally distributed hydraulic conductivity values. Further, several studies have concluded that the geometric mean provides a better estimate of the effective hydraulic conductivity of a heterogenous groundwater system than the harmonic mean or arithmetic means, which are less than and greater than the geometric mean, respectively.

The preceding provides a simplified discussion of common statistical treatments for hydraulic conductivity values. In recent decades, much work has been conducted to apply more complex statistical models and stochastic techniques to characterize groundwater flow through heterogenous systems.

METHODS OF ESTIMATION AND MEASUREMENT

Empirical Relationships

Several efforts have been made over the years to correlate hydraulic conductivity and/or permeability empirically with characteristics of porous media through which water flows. Some of the more commonly used relationships are provided in Table 2.

Although such empirical relationships correlate hydraulic conductivity with various factors, nearly all can be simplified to the form

$$K = Cd^x \tag{8}$$

where C is a constant or shape factor that is a function of the fluid density and viscosity and may be correlated with properties of the porous medium such as porosity and d is some representative grain size (L). It has been mathematically shown (e.g., by Ref. 5) that for idealized systems of uniform grain size, $x = 2$. For all the empirical relationships shown in Table 2, x ranges between 1.5 and 2, which indicates a disproportionate increase in hydraulic conductivity as grain size increases, but suggests an exponent value of something less than 2 for many real-world situations.

Laboratory Testing

The hydraulic conductivity of geologic deposits can be measured in the laboratory by using a permeameter, a device similar to that originally devised by Darcy. Various configurations of permeameters have been used; the most common are the constant-head permeameter and the falling-head permeameter shown in Fig. 5.

Permeameters consist of a chamber to contain a sample of soil or rock and allow the application of a hydraulic gradient across the sample. Flow through the sample is measured, and hydraulic conductivity is calculated based on principles founded by Darcy. Careful consideration must be used in evaluating permeameter test data. For example, when testing unconsolidated material, was the test conducted on an intact core or on a repacked sample? If the former, the test likely represents the vertical hydraulic conductivity, which may be much lower than the horizontal hydraulic conductivity. If the latter, the disturbance of the sample during repacking may result in a value that is neither representative of the horizontal nor the vertical hydraulic conductivity.

Field Measurements—Aquifer Tests

Hydraulic conductivity and transmissibility on a larger scale are estimated by evaluating data from aquifer tests. There are many different types of aquifer tests and methods for evaluating the test results, but the most common types of tests employed in groundwater studies are pumping tests and slug tests.

Pumping tests involve pumping water from a well at a known rate and measuring the changes in water level through time at the pumping well and/or nearby observation points. Slug tests involve rapid introduction or removal of a volume of water or other material into or out of a well and measuring the changes in water level through time at the well being tested.

Table 2. Examples of Empirical and Semiempirical Relationships for Estimating Hydraulic Conductivity and Permeability[a]

Source	Equation		Parameters
Hazen (1911)	$K = Cd_{10}{}^2$		K = hydraulic conductivity (cm/s) C = constant; 100 to 150 $(\text{cm/s})^{-1}$ for loose sand d_{10} = effective grain size (cm) (10% particles are finer, 90% coarser)
Harleman et al. (1963)	$k = (6.54 \times 10^{-4})\, d_{10}{}^2$		k = permeability, cm^2 d_{10} = effective grain size, cm (10% particles are finer, 90% coarser)
Krumbein and Monk (1943)	$k = 760\, d^2 e^{-1.31\sigma}$		k = permeability (Darcys) d = geometric mean grain diameter, mm σ = log standard deviation of the size distribution
Kozeny-Carmen Bear (1972)	$K = (\rho_w g/\mu) n^3/(1-n)^2 (d_m{}^2/180)$		K = hydraulic conductivity ρ_w = fluid density μ = fluid viscosity g = gravitational constant d_m = representative grain size n = porosity
Shepard (1989)	$K = 40{,}000\, d^2$ $K = 1{,}600\, d^{1.75}$ $K = 450\, d^{1.65}$ $K = 100\, d^{1.5}$	glass spheres beach deposits channel deposits texturally immature consolidated sediments	K = hydraulic conductivity, ft/day d = mean grain size, mm

Constant-head permeameter apparatus

Falling-head permeameter apparatus

Figure 5. Permeameters (adapted from Ref. 4).

In general, pumping tests affect a significantly larger volume of the aquifer than slug tests, and the resulting hydraulic conductivity and transmissibility estimates are considered more representative of conditions across a broad area. Slug tests can be used to target specific zones and points within the aquifer but are generally considered "point estimates" of hydraulic conductivity and transmissibility.

INTRODUCTION

Groundwater is an important source of water for agriculture and domestic drinking water. Two-thirds of the world's freshwater is found in underground aquifers. Groundwater occurs mainly in the tiny spaces between soil particles that are called voids or pores. In its natural state, groundwater is perpetually moving. This movement is governed by conventional hydraulic principles such as Darcy's law, the concept of hydraulic gradient, and the permeability of the medium (1). With the increasing water demand due to population growth, management of water resources is becoming a challenging task. Management of groundwater resources must consider both sustainable development and prevention and control of groundwater contamination. Groundwater contamination is a critical issue because of the importance of groundwater supply and quality in sustainable development. In general, contaminants found in groundwater are associated with adverse health, social, environmental, and economic impacts (2). Exposure to contaminated groundwater may occur accidentally because contaminated water might be colorless, odorless, and tasteless. It is essential to understand groundwater flow and transport processes for the best management of groundwater resources, appraisal of the sustainable yield of aquifers, reliable evaluation of the extent of groundwater contamination, assessment of the corresponding hazards and risks, and design of effective remediation systems and protective alternatives.

This chapter provides an overview of the main principles of groundwater flow and transport processes, including the basic concepts, definitions and terms, physical governing equations, and mathematical modeling.

VERTICAL DISTRIBUTION OF SUBSURFACE WATER

The subsurface occurrence of water may be divided into zones of aeration and saturation (see Fig. 1). The zone of aeration is partially occupied by water and partially by air. In the zone of saturation, all pores are filled with water. The zone of aeration may be further subdivided into the soil–water zone, the intermediate vadose zone, and the capillary zone (see Fig. 1).

The saturated zone extends from the upper surface of saturation down to underlying impermeable rock. In the absence of an overlying impermeable formation, the water table forms the upper surface of the zone of saturation, which is defined as the surface of atmospheric pressure. Water in the soil–water zone exists at less than saturation except temporarily when excessive water reaches the ground surface from rainfall or irrigation. The zone extends from the ground surface down through the major root zone. The water content and distribution within this zone depends on soil texture, vegetation, and atmospheric conditions. The intermediate vadose zone extends from the lower edge of the soil–water zone to the upper limit of the capillary zone. The capillary zone extends from the

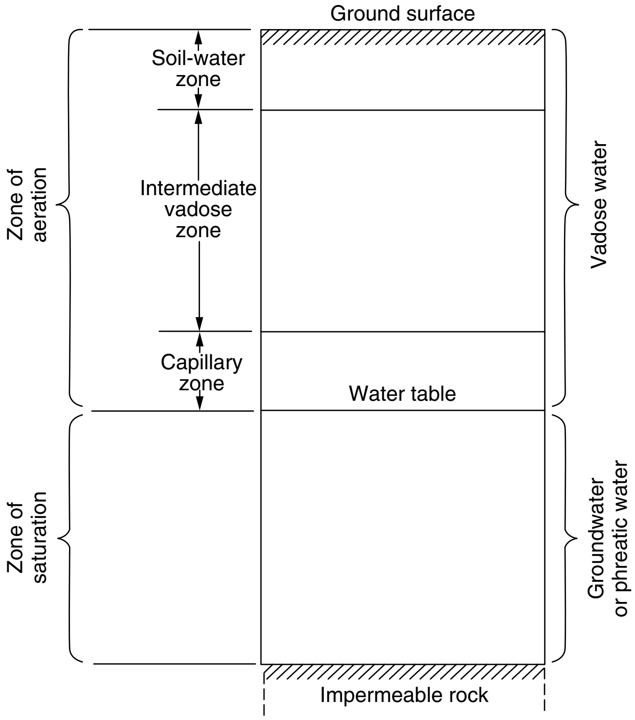

Figure 1. Illustration of saturated and unsaturated zones (1).

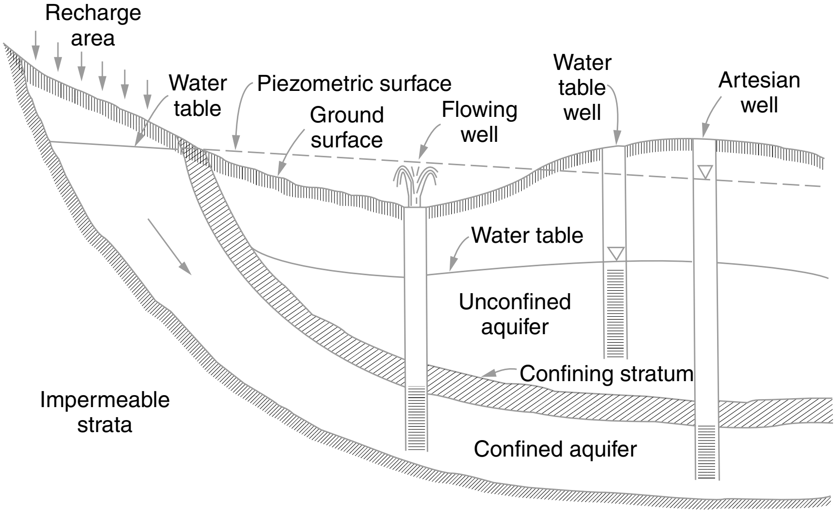

Figure 2. Schematic cross section of unconfined and confined aquifers (1).

water table up to the limit of capillary rise of water. The thickness of the capillary zone varies inversely with the pore size of a soil.

AQUIFER TYPES

An aquifer is a formation that contains sufficient saturated permeable material to yield significant quantities of water to wells and springs (3). Therefore, aquifers have the ability to store and transmit water. Aquifers might be bounded by confining beds that are relatively impermeable materials located adjacent to the aquifers. Confined aquifers occur where groundwater is confined under pressure greater than atmospheric by overlying relatively impermeable formations. In a well penetrating such an aquifer, the water level will rise above the bottom of the confining bed, as shown by the artesian and flowing wells of Fig. 2. Unconfined aquifers do not have confining beds above and the aquifer can be directly recharged by rainfall (see Fig. 2). An unconfined aquifer is one in which the water table varies in a rising and falling form.

DARCY'S LAW

In 1856, the French engineer, Henry Darcy, developed the principal equation in groundwater hydrology based on laboratory experiments he had carried out to analyze the flow of water through sand. Darcy's law can be written as

$$Q = -KA\frac{dh}{dl} \tag{1}$$

Q is the quantity of water per unit of time (L^3/T), A is the area perpendicular to flow (L^2), K is a constant of proportionality called the hydraulic conductivity (L/T), h is the hydraulic head (L), and dh/dl is the hydraulic gradient. The hydraulic conductivity expresses the ease by which water can pass through soil pores and openings and serves as a measure of the permeability of the porous medium. The hydraulic conductivity of a soil is a function of the properties of the porous medium and the fluid passing through it. In addition to hydraulic conductivity, the term transmissivity T (L^2T^{-1}) is widely employed in groundwater hydraulics. Transmissivity equals the hydraulic conductivity multiplied by the saturated thickness of the aquifer.

Darcy flux or specific discharge is given by the following relationship:

$$q = \frac{Q}{A} = -K\frac{dh}{dl} \tag{2}$$

The specific discharge q has the dimensions of velocity (L/T). Finally, the cross-sectional area of flow for a porous medium is actually much smaller than the dimensions of the aquifer. To find the velocity at which water is actually moving, the specific discharge is divided by the effective porosity to account for the actual open space available for flow. The result is the average velocity at which water moves between two points as in the following equation:

$$v = \frac{q}{n_e} = \frac{Q}{n_e A} = -\frac{Kdh}{n_e dl} \tag{3}$$

STORAGE IN CONFINED AND UNCONFINED AQUIFERS

Storage in confined aquifers is associated with the compressibility of water and the porous matrix. The change in the potentiometric head affects the arrangement of mineral grains as well as the density of water in the voids. If the water pressure increases, the mineral skeleton will expand; if it drops, the mineral skeleton will contract. Likewise, water will contract with an increase in pressure and expand if the pressure drops. The specific storage (S_s) is the amount of water per unit volume of a saturated formation that is stored or expelled from storage owing to compressibility of the mineral skeleton and the pore water per unit change in head. The value of specific storage is very small, generally 0.0001 ft^{-1} or less. In unconfined aquifers, pumpage causes drawdown in the water table itself, and the induced hydraulic gradient causes both a horizontal and vertical flow component. Thus, the drop in the water table creates a vertical hydraulic gradient which causes drainage of the porous medium (3–7).

The storativity (S) of a confined aquifer is the product of the specific storage S_s and the aquifer thickness. The value of the storativity of confined aquifers is of the order 0.005 or less. Storativity under unconfined conditions is referred to as the specific yield, defined as the ratio of the volume of water an unconfined aquifer drains by gravity due to the unit decline in the water table to the total volume of the aquifer. The coarser the material, the more closely the specific yield approaches the porosity. The volume of water drained from an aquifer as the head is lowered may be found from the formula,

$$V_w = S\,A\,\Delta h \tag{4}$$

where V_w is the volume of water drained or released (L^3), S is the storativity (L^0), A is the surface area overlying the drained aquifer (L^2), and Δh is the average decline in head (L). Note that Δh for a confined aquifer is the decline in the potentiometric head and for unconfined aquifers is the decline in the water table.

MATHEMATICAL MODEL OF GROUNDWATER FLOW

Groundwater flow is described using Darcy's law and the mass conservation equation. The governing equation, describing transient groundwater flow in a three-dimensional flow domain, is given as

$$\frac{\partial}{\partial x}\left(K_x\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial y}\left(K_y\frac{\partial h}{\partial y}\right)+\frac{\partial}{\partial z}\left(K_z\frac{\partial h}{\partial z}\right)+W' = S_s\frac{\partial h}{\partial t} \tag{5}$$

where K_x, K_y, K_z are the hydraulic conductivity values in the x, y, and z coordinates, respectively; S_s is the specific storage; t is time; h is the hydraulic head; and W' is the source or sink strength in units of volume/time/area. To solve Eq. 5, initial and boundary conditions should be specified for the study area. Solving this equation yields the head distribution in time and space. Computer codes can be used to solve Eq. 5 numerically. MODFLOW developed by the U.S. Geological Survey (8), is one of the most commonly used groundwater softwares for solving one-, two-, or three-dimensional groundwater flow problems. MODFLOW is divided into packages that deal with single simulation aspects. For example, the Well Package simulates the effects of injection and abstraction wells and the River Package simulates the effect of rivers, etc. The WWW address for MODFLOW model and documentation is: http://water.usgs.gov/sofware/ground_water.htm. A brief description of MODFLOW can also be found in Charbeneau (7).

SOURCES OF GROUNDWATER CONTAMINATION

There are three key features that differentiate groundwater contamination sources: (1) degree of localization, (2) loading history, and (3) types of contaminants. Sources of groundwater contamination can be classified into point and nonpoint sources. Point sources include leaking underground pipelines or tanks, wastewater lagoons, septic systems, and leaking barrels of chemical wastes. These sources are identifiable, located at single locations, and have local impacts on groundwater quality. Conversely, nonpoint sources are diffuse, originating from many smaller sources, largely distributed, lack a well-defined single point of origin, and have a regional influence on groundwater quality. Examples of nonpoint sources are agricultural activities such as fertilizer and manure applications; and polluted atmospheric deposition, including dry fallout, precipitation, and runoff from roads and parking lots. The loading history defines how the concentration of a contaminant or its rate of application changed with time at the source location.

TRANSPORT PROCESSES

The physical processes that control contaminant flux into and out of a groundwater system are advection, mechanical dispersion, and molecular diffusion. In the following subsections, the basic concepts related to these physical processes are illustrated.

Advection

Transport by advection or convection entails movement and carrying contaminants with flowing groundwater (6). In advective transport, contaminants travel at a rate equal to the average linear velocity of the groundwater (5). Mathematically, advective flux is expressed by the following equation (6):

$$J = v_x n_e C \tag{6}$$

where J_x is the advective mass flux (ML^2T^{-1}) per unit area per unit time, v_x is the average linear velocity of groundwater(LT^{-1}), n_e is the effective porosity through which flow occurs, and C is the contaminant concentration (ML^{-3}). The average linear velocity can be determined from Eq. 3. The product of the average linear velocity and time since contaminants were introduced into the groundwater system defines the position of the advective front, as depicted in Fig. 3, where the vertical line represents the advective front without considering the effects of dispersion and diffusion (6).

Diffusion

The movement of contaminants from an area of high concentration to an area of lower concentration is called molecular diffusion or diffusion. This diffusive flux is

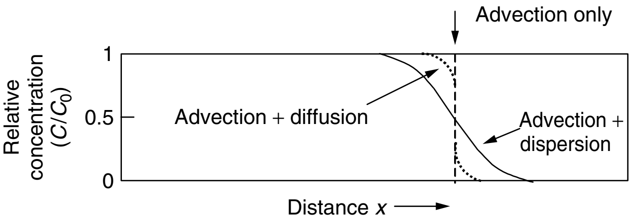

Figure 3. Advective transport and the influence of longitudinal dispersion and diffusion on the transport of a solute in one-dimensional flow.

directly proportional to the diffusion coefficient and the concentration gradient (9). This is known as Fick's first law and can be expressed in a one-dimensional system as in the following:

$$F_x = -D_{\mathrm{d}} \frac{dC}{dx} \tag{7}$$

where F_x is the diffusive mass flux ($\mathrm{ML^2T^{-1}}$), D_{d} is the diffusion coefficient for open water ($\mathrm{L^2T^{-1}}$), C is the contaminant concentration ($\mathrm{ML^{-3}}$); and dC/dx is the concentration gradient ($\mathrm{ML^{-4}}$). The negative sign signifies that the diffusive flux is in the direction of decreasing contaminant concentration.

Mechanical Dispersion

Dispersion describes the gradual spreading of contaminants beyond the region they are expected to occupy when considering advection alone. The phenomenon of dispersion is attributed mainly to the discrepancy between contaminant velocities and the average linear velocity caused by subsurface heterogeneity (5,10,11). According to Fetter (3), this discrepancy is attributed to three key factors: (1) the velocity of groundwater flow is higher in the center of pores than at the edges, (2) the contaminants can pass through different flow paths to reach the same location, and (3) groundwater moves faster in large pores. Therefore, contaminants will dilute due to mixing with noncontaminated water. Mixing, called mechanical dispersion, may occur along the flow path, is called longitudinal dispersion, and is attributed to the aforementioned key factors. The groundwater flow path may diverge at the pore scale, so the contaminant will spread in directions normal to the flow path. This mixing is called *lateral* or *transverse dispersion* (3). The difference between the straight dashed line and the solid line in Fig. 3 depicts the influence of longitudinal dispersion on the transport of a contaminant. Molecular diffusion and mechanical dispersion contribute jointly to the dispersive process of contaminant transport. They are combined to define a coefficient called *hydrodynamic dispersion* as given in the following equations (6):

$$D_{\mathrm{L}} = \alpha_{\mathrm{L}} v_{\mathrm{i}} + D^* \tag{8}$$

$$D_T = \alpha_T v_{\mathrm{i}} + D^* \tag{9}$$

where D_{L} and D_{T} are the longitudinal and transverse hydrodynamic dispersion coefficients, respectively; and α_{L} and α_{T} are the longitudinal and transverse dispersivities, respectively.

Figure 4 illustrates the process of hydrodynamic dispersion in two-dimensional groundwater flow at a constant uniform velocity, V. A tracer was instantaneously injected into the aquifer at $t = 0$. The groundwater flow carries the tracer with it. Due to the effect of dispersion, the solute spreads out such that the maximum concentration decreases with time, as shown for times t_1 and t_2 when $t_2 > t_1$. The spread of the tracer results in an elliptically shaped concentration distribution that is normally distributed in both the longitudinal and transverse directions.

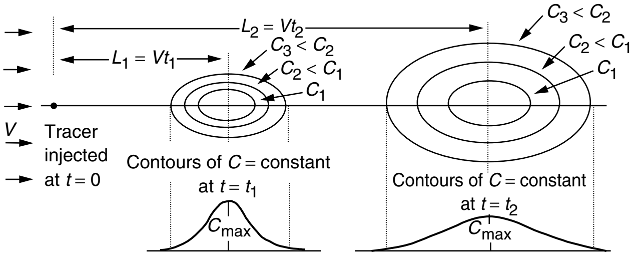

Figure 4. Longitudinal and transversal spreading of a tracer from an instantaneous point injection at $t = 0$.

As mentioned earlier, longitudinal dispersivity or more specifically, dispersivity, is a scale-dependent property that increases with the characteristic transport length distance of measurement. This phenomenon is attributed to the macroscale effects resulting from the heterogeneity of the subsurface on the field scale. Many researchers have developed relationships between longitudinal dispersivity and flow length (6,12–14). The ratio of longitudinal to transverse dispersivity ($\alpha_{\mathrm{L}}/\alpha_{\mathrm{T}}$) controls the shape of the contaminant plume. As the ratio decreases, the wider the plume will be (6). Bear (10) provided a range from 5 to 24 for $\alpha_{\mathrm{L}}/\alpha_{\mathrm{T}}$.

MATHEMATICAL MODEL OF CONTAMINANT TRANSPORT

The advection–dispersion–reaction partial differential equation that governs three-dimensional transport of a single chemical constituent in groundwater, considering advection, dispersion, fluid sinks/sources, equilibrium-controlled sorption, and first-order irreversible rate reactions, is given in the following (11):

$$R\frac{\partial C}{\partial t} = \frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial C}{\partial x_j}\right) - \frac{\partial}{\partial x_i}(v_i C) + \frac{q_{\mathrm{s}}}{n}C_{\mathrm{s}} - \lambda\left(C + \frac{\rho_{\mathrm{b}}}{n}S\right) \tag{10}$$

where the retardation factor is defined as

$$R = 1 + \frac{\rho_{\mathrm{b}}}{n}\frac{\partial S}{\partial C} \tag{11}$$

and C is the dissolved concentration ($\mathrm{ML^{-3}}$); S is the sorbed concentration ($\mathrm{MM^{-1}}$) which is a function of the dissolved concentration, C, as defined by a sorption isotherm; t is time (T); D_{ij} is the dispersion coefficient tensor ($\mathrm{L^2T^{-1}}$); v_i is the average linear groundwater velocity ($\mathrm{LT^{-1}}$); q_{s} is the volumetric flow rate per unit volume of aquifer and represents fluid sources and sinks ($\mathrm{T^{-1}}$); C_{s} is the concentration of the fluid source or sink flux ($\mathrm{ML^{-3}}$); λ is the reaction rate constant ($\mathrm{T^{-1}}$); R is the retardation factor ($\mathrm{L^0}$); ρ_{b} is the bulk density of the porous medium ($\mathrm{ML^{-3}}$); and n is the porosity ($\mathrm{L^0}$). A complete derivation of this equation is provided in Freeze and Cherry (4) and Zheng and Bennett (11).

Solving time-dependent partial differential equations governing contaminant transport requires identification of the initial and boundary conditions. The initial condition describes the distribution of the contaminant in the groundwater within the domain at the beginning of simulation. The boundary conditions can be classified into three categories: (1) specified concentration boundary, called the Dirichlet condition; (2) a specified concentration gradient boundary, called the Neuman condition; and (3) a variable flux boundary, called the Cauchy condition (5).

Solving the mathematical model yields the contaminant concentration as a function of space and time. The approach used in formulating and solving the mathematical model can be classified generally into numerical and analytical approaches. Analytical solutions of the advection–dispersion equations in one-, two-, and three-dimensional space can be found in Baetslé (14), Bear (10), Domenico (15), Domenico and Schwartz (5), and Fetter (6) among others.

Numerical methods provide an approximate solution of the mathematical model by solving a set of algebraic equations that replace the original partial differential equations. Numerical solutions are widely used and preferred because they have the capability to handle more general conditions. Numerical methods for solving the advection–dispersion–reaction equation divide the model domain into small cells, approximate the governing equation over each cell at time t, and then predict a new value at time $t + \Delta t$. This process continues forward in time for small Δt values. The most common numerical methods for solving the advection–dispersion–reaction equation include the finite-difference method, the finite-element method, and the random walk method. A detailed illustration of these methods can be found in Zheng and Bennett (11) and Sun (16). Bedient et al. (17) cited many references that provide detailed descriptions of these numerical methods. One of the common computer codes used in simulating the fate and transport of contaminants in groundwater is MT3D (18). MT3D is a three-dimensional contaminant transport model for the simulation of advection, dispersion, and chemical reactions of dissolved constituents in groundwater systems. MT3D is based on a modular structure to permit simulation of transport components independently or jointly with finite-difference groundwater flow models, such as MODFLOW. MT3D can be downloaded from http://hydro.geo.ua.edu. Further information on MT3D can be found in Zheng (18), Zheng and Bennett (11), and Zheng and Wang (19).

REACTIVE TRANSPORT IN THE SATURATED ZONE: CASE HISTORIES FOR PERMEABLE REACTIVE BARRIERS

LEN LI
CRAIG H. BENSON
University of
Wisconsin-Madison
Madison, Wisconsin

INTRODUCTION

The permeable reactive barrier (PRB) is an *in situ* remediation technology where contaminated groundwater is treated passively as it flows through a reactive medium. Most PRBs use granular zero valent iron (ZVI) to create redox conditions that result in degradation or immobilization of groundwater contaminants, such as chlorinated solvents and herbicides, heavy metals, and radionuclides (1–5). These redox conditions promote precipitation of secondary minerals from ions typically in groundwater as well as some groundwater contaminants (2,6,7). The most common minerals formed in PRBs are magnetite, hematite, goethite, lepidocrocite, calcite, aragonite, siderite, green rust, ferrous hydroxide, ferrous sulfide, and marcasite (8). Calcium carbonates and siderite typically are found near the entrance face of a PRB, whereas magnetite, ferrous hydroxide, green rust, and iron oxyhydroxides form throughout a PRB (6,7). Accumulation of secondary minerals causes loss of pore space and reactive surface area of the medium in PRBs, which can alter flow paths, residence times, and the treatment effectiveness of a PRB (2,7,9).

Developing a general assessment of mineral precipitation in PRBs with field and/or laboratory data is complicated by site-specific geochemical and hydrogeological conditions (7), and the relatively long period over which mineral deposition occurs (9). An alternative approach is to conduct analyses with a reactive transport simulator that predicts mineral deposition and its effects on hydraulics (10–12). Li (12) developed a reactive transport simulator specifically for this purpose. This chapter describes a comparison between ion concentrations predicted with this model and concentrations measured in the field at three PRBs.

REACTIVE TRANSPORT SIMULATOR

Equilibrium and Kinetic Reactive Transport Models

Equilibrium and kinetic models have simulated geochemical processes and mineral formation in PRBs (10,11,13,14). Equilibrium models can estimate the aqueous species and solid phases that exist in a state of thermodynamic equilibrium, but they do not account for the rate at which reactions occur and generally do not involve the movement of groundwater. In contrast, kinetic models describe the rate at which geochemical reactions occur and predict aqueous and solid phase concentrations as a function of time. In kinetic models, the geochemical reactions usually are specified by the user along with reaction rate expressions and the rate coefficients. Thus, when a kinetic model is developed, an equilibrium model often defines the most important reactions to be included in the kinetic model (e.g., see Yabusaki et al. (10)).

Equilibrium models are appropriate when the reaction rate is fast compared with the flow rate, whereas kinetic models are appropriate when flow rates are not negligible relative to reaction rates. For most PRBs, flow rates are fast enough such that reaction kinetics must be considered when evaluating mineral precipitation (10). Reactive transport codes incorporating kinetic geochemical algorithms have been developed by Mayer et al. (11) and Yabusaki et al. (10) for simulating contaminant degradation and mineral precipitation in PRBs. The code developed by Li et al. (8) is similar to those developed by Mayer et al. (11) and Yabusaki et al. (10), but it focuses solely on geochemical reactions that result in mineral precipitation.

Conceptual Model

The conceptual model used by Li et al. (8) consists of a continuous-wall PRB containing ZVI that is placed orthogonal to the groundwater flow. Groundwater flowing into the PRB is assumed to contain dissolved oxygen, Fe^{2+}, Ca^{2+}, Mg^{2+}, $SO_4{}^{2-}$, $CO_3{}^{2-}$, OH^-, $HCO_3{}^-$, and $NO_3{}^-$. These dissolved species are assumed to form $CaCO_3$, $CaMg(CO_3)_2$, $FeCO_3$, $Fe(OH)_2$ (am), FeS (am), and $Mg(OH)_2$ in response to the redox conditions induced by corrosion of the ZVI. In an actual PRB, additional ions may be present and minerals other than those included in the model may also form. However, the reactions in the model include the most common minerals observed in laboratory and field studies of PRBs (6,7,10,11). Contaminant transformation reactions were not included in the model because the volume of mineral precipitates formed as a consequence of contaminant treatment generally is negligible, even though the contaminant transformations are intrinsic to the remediation process (2,11).

Codes

The reactive transport simulator is created with the public domain codes MODFLOW and RT3D (15,16). MODFLOW simulated steady-state flow in the aquifer and PRB. Geochemical processes within the PRB were simulated with RT3D, a three-dimensional multicomponent model that describes advective–dispersive-reactive transport (16). Heads from MODLOW are input to RT3D. A detailed description of the codes that comprise the simulator can be found in Li (12) and Li et al. (8).

Li et al. (8) developed a geochemical module for RT3D that simulated the mineral-forming reactions. Geochemical reactions included in the module are summarized in Table 1. Three redox reactions are related to iron corrosion, along with six mineral precipitation reactions and one reaction for microbial sulfate reduction. A pseudo-first-order reaction rate was assumed for iron corrosion by oxygen or nitrate with the reaction rate proportional to the iron surface area and the concentration of oxygen or nitrate (11). For iron corrosion by water, the reaction rate was assumed to be proportional only to the iron surface area (10,11,17). The rate of degradation of sulfate to HS^- by sulfate-reducing bacteria was assumed to follow the Monod equation (11), and the kinetics of mineral precipitation were assumed to follow transition state theory (18). The kinetic rate expressions and solubility constants for the mineral reactions are summarized in Table 1. All geochemical reactions are assumed to occur in parallel and are solved simultaneously.

FIELD DATA SOURCES AND MODEL SETUP

Field data from three PRBs verified that the MODFLOW-RT3D simulator produces reasonable predictions of major ion concentrations. Comparisons were not made between measured and predicted solid phase concentrations at any of the sites because of a lack of field data. The selected PRBs are located at Moffett Federal Airfield in

Table 1. Geochemical Reactions and Solubility Constants

Reaction	Mineral Formed	Kinetic Rate Expression[a]	Solubility Constant Log(K_{eq})[b]
Iron Corrosion:			
$Fe^0 + H_2O + 0.5O_2(aq) \rightarrow Fe^{2+} + 2OH^-$	—	$k_{an,Fe}\ Sa_{DO}$	—
$Fe^0 + 2H_2O \rightarrow Fe^{2+} + H_2(aq) + 2OH^-$	—	$k_{an,Fe}\ S$	—
$4Fe^0 + 7H_2O + NO_3^- \rightarrow 4Fe^{2+} + 10OH^- + NH_4^+$	—	$k_{NO3}Sa_{NO_3^-}$	—
Microbial Sulfate-Reduction:			
$SO_4^{2-} + 4H_2(aq) \rightarrow HS^- + OH^- + 3H_2O$	—	$k\left(\frac{[SO_4^{2-}]}{K_{SO_4^{2-}} + [SO_4^{2-}]}\right)\left(\frac{[H_2]}{K_{H_2} + [H_2]}\right)$	—
Secondary Mineral Precipitation-Dissolution:			
$CaCO_3(s) \leftrightarrow Ca^{2+} + CO_3^{2-}$	Aragonite/Calcite	$-k_{Ca}(1 - a_{Ca^{2+}}a_{CO_3^{2-}}/K_{eq})$	−8.1
$CaMg(CO_3)_2(s) \leftrightarrow Ca^{2+} + Mg^{2+} + 2CO_3^{2-}$	Dolomite	$-k_{CaMg}(1 - a_{Ca^{2+}}a_{Mg^{2+}}a^2_{CO_3^{2-}}/K_{eq})$	−17.7
$Mg(OH)_2(s) \leftrightarrow Mg^{2+} + 2OH^-$	Brucite	$-k_{Mg2}(1 - a_{Mg^{2+}}a^2_{OH^-}/K_{eq})$	−11.2
$FeCO_3(s) \leftrightarrow Fe^{2+} + CO_3^{2-}$	Siderite	$-k_{Fe1}(1 - a_{Fe^{2+}}a_{CO_3^{2-}}/K_{eq})$	−10.5
$Fe(OH)_2(am) \leftrightarrow Fe^{2+} + 2OH^-$	Ferrous hydroxide	$-k_{Fe}(1 - a_{Fe^{2+}}a^2_{OH^-}/K_{eq})$	−15.2
$FeS(am) + H_2O \leftrightarrow Fe^{2+} + HS^- + OH^-$	Ferrous sulfide	$-k_{FeS}(1 - a_{Fe^{2+}}a_{HS^-}a_{OH^-}/K_{eq})$	−18.4

[a] *k* is rate coefficient, S is reactive surface area of ZVI, a is activity of aqueous species, and K_{eq} is solubility constant. Activity coefficients were calculated with the extended Debye—Huckel equation.

[b] At 15 °C and 101 kPa.

Mountain View, CA; Monticello, UT; and Copenhagen, Denmark. These PRBs were selected because hydrological and geochemical data were sufficiently well defined for each PRB to permit an assessment of the simulator.

For all sites, the simulations were set up assuming homogeneous hydraulic conductivity in each medium (i.e., aquifer, reactive zone, etc.). Constant-head boundaries were applied along the upstream and downstream faces of the domain to establish a hydraulic gradient orthogonal to the PRB. No flow conditions were imposed at the other boundaries. Each species in the PRBs was assumed to have an initial concentration of zero. A constant concentration boundary was applied at the upstream face of the PRBs, and other boundaries were assigned the Cauchy boundary condition with no dispersive flux. Influent groundwater concentrations entering the PRB were set at values measured in the field.

Moffett Federal Airfield

A pilot-scale funnel-and-gate PRB consisting of ZVI was installed in 1996 at Moffett Federal Airfield to remove TCE and DCE from groundwater (10). The gate is 3.0 m long (orthogonal to flow direction), 3.0 m wide (along the flow direction), and 5.5 m deep. The gate consists of a 1.8-m-thick barrier of granular ZVI sandwiched between two 0.6-m-thick layers of pea gravel (up gradient and down gradient). Groundwater samples collected within the PRB between April 1996 (installation) and October 1997 were analyzed for target contaminants, pH, major cations and anions, and indicator parameters (10). Analysis of core samples showed that magnetite, hematite, aragonite, and marcasite formed in the iron media. No direct measurements were made of siderite, FeS, $Fe(OH)_2$ (am), $Fe(OH)_3$, brucite, or green rust.

The MODFLOW-RT3D simulator simulated the nearly one-dimensional conditions in the gate at the Moffett Federal Airfield site. The input was based on data provided in Yabusaki et al. (10). MODFLOW simulated steady-state flow in the pea gravel zones and iron media zone. The initial hydraulic conductivity in the PRB was 186 m/d, and the porosity was 0.66. The hydraulic conductivity in the pea gravel zones was 86.4 m/d. A hydraulic gradient of 0.0003 was applied across the PRB to yield the Darcy velocity (0.04 m/d) reported in Yabusaki et al. (10). Five minerals reported by Yabusaki et al. (10) were included in the model: $CaCO_3$, $FeCO_3$, $Fe(OH)_2$ (am), $Mg(OH)_2$, and FeS (am). Composition of groundwater entering the PRB was based on information provided in Yabusaki et al. (10) (Table 2).

Monticello

A full-scale funnel and gate PRB containing granular iron was installed in 1999 to treat uranium in groundwater at a former uranium mill site near Monticello, UT (14). The gate is 30.0 m long, 2.4 m wide (along flow direction), and 4.5~6.0 m deep. A 1.2-m-thick reactive zone consisting of 100% granular ZVI was sandwiched between two 0.6-m-thick layers of pea gravel (up gradient and down gradient) in the gate. Samples of groundwater were collected from June 1999 (installation) to September 1999 and analyzed for target contaminants, pH, major cations and anions, and indicator parameters. Core samples showed that magnetite and $CaCO_3$ formed within the PRB.

Reactive transport in the gate at the Monticello PRB was simulated with the MODFLOW-RT3D simulator using a one-dimensional model similar to that employed for the PRB at Moffett Federal Airfield (see previous section). A one-dimensional model was selected because flow through the pea gravel zones and ZVI was nearly one-dimensional and steady state. Hydraulic conductivities of the ZVI and pea gravel zones were set at 30.9 m/d and 8.64 m/d. Based on data in Morrison et al. (14), the porosity was set at 0.50 in the ZVI and 0.30 in the pea gravel and the hydraulic gradient was set at 0.142 to yield a

Table 2. Concentrations of Aqueous Species in Influent Ground Water

Aqueous Species in Influent Ground Water	Aqueous Species Concentrations (M)		
	Moffett Federal Airfield, Mountain View, California[a]	Former Mill Site, Monticello, Utah[b]	Copenhagen Freight Yard, Copenhagen, Denmark[c]
Fe^{2+}	1.0×10^{-10}	1.0×10^{-10}	1.0×10^{-10}
Ca^{2+}	3.9×10^{-3}	8.5×10^{-3}	3.3×10^{-3}
Mg^{2+}	2.7×10^{-3}	3.6×10^{-3}	1.2×10^{-3}
OH^-	1.3×10^{-7}	5.2×10^{-8}	5.0×10^{-7}

groundwater velocity of 3 m/d. Five minerals were included in the geochemical model: $CaCO_3$, $FeCO_3$, $Fe(OH)_2$ (am), $CaMg(CO_3)_2$, and FeS. Composition of the groundwater entering the PRB was defined based on data reported in Morrison et al. (14), as summarized in Table 2.

Copenhagen

A full-scale PRB containing granular ZVI was installed in 1998 at the Copenhagen Freight Yard in Copenhagen, Denmark to treat chlorinated solvents in ground water (19). The PRB is a continuous trench 15.0 m long, 1.3 m wide (along flow direction), and 6.0 m deep and consists of a 0.9-m-thick zone of 100% granular ZVI sandwiched between 0.2-m-thick layers of pea gravel. Samples of groundwater were collected from July 1998 (installation) to September 1999 and were analyzed for target contaminants, pH, and major cations and anions (19). No direct measurements were made of minerals forming within the PRB (19).

The MODFLOW-RT3D simulator was set up to simulate one-dimensional flow and reactive transport along the centerline of the Copenhagen PRB. The model predicted steady-state flow in the surrounding aquifer, pea gravel zones, and ZVI. Hydraulic conductivity of the ZVI, pea gravel, and aquifer were set at 6.1, 2.1, and 0.6 m/d, respectively, based on site conditions (19). The porosity was set at 0.60 for the ZVI, 0.40 for the pea gravel zones, and 0.3 in the aquifer (19). A hydraulic gradient of 0.011 was applied across the aquifer based on data reported in Killerich et al. (19). Five minerals were included in the model: $CaCO_3$, $FeCO_3$, $Fe(OH)_2$(am), $CaMg(CO_3)_2$, and FeS. Composition of the groundwater entering the PRB was defined based on data reported in Killerich et al. (19), as summarized in Table 2.

COMPARISON OF PREDICTED AND MEASURED CONCENTRATIONS

Moffett Federal Airfield

Comparisons of the predicted and measured pH and concentration profiles are shown in Fig. 1 for the PRB at Moffett Field after 12 months of operation. The reaction rate coefficients initially were estimated from data in the literature, but ultimately they were adjusted by trial-and-error to reproduce the measured pH, alkalinity, and concentrations of ${SO_4}^{2-}$, Ca^{2+}, and Mg^{2+}. A similar calibration procedure was used at the other two sites. The calibrated reaction rate coefficients are summarized in Table 3 along with typical ranges based on data reported in the literature.

The predicted pH is in general agreement with the observed pH [Fig. 1(a)], including the rapid jump near the entrance face and the leveling out in the interior. The drop in alkalinity just up gradient of the PRB is not captured [Fig. 1(b)], but the alkalinity predicted by RT3D inside the PRB is similar to that measured in the field. The sulfate concentration predicted by RT3D also is in general agreement with the trends observed in the field [Fig. 1(b)], as are the Ca^{2+} and Mg^{2+} concentrations [Fig. 1(c)]. However, the predicted Ca^{2+} concentrations in the PRB are near the upper bound of the measured concentrations [Fig. 1(c)]. The field data are also too sparse to evaluate whether the simulator accurately predicts the rapid changes in geochemical conditions occurring at the entrance face.

Monticello Mill Site

Comparisons of measured and predicted pH, alkalinity, and concentrations of Ca^{2+}, Mg^{2+}, and ${SO_4}^{2-}$ for conditions at 3 months of operation are shown in Fig. 2. Calibrated rate coefficients for the PRB at Monticello are summarized in Table 3. As with the PRB at Moffett Field, insufficient data exist to determine whether the rapid changes predicted at the entrance face accurately replicate the conditions occurring in the PRB at Monticello.

The measured and predicted pH, ${HCO_3}^-$, Mg^{2+}, and ${SO_4}^{2-}$ concentrations in the Monticello PRB are in close agreement (Fig. 2). However, the predicted Ca^{2+} concentrations in the PRB are higher than are the measured concentrations [Fig. 2(b)]. One reason for this discrepancy may be that minerals other than $CaCO_3$ and $CaMg(CO_3)_2$ are precipitating (these minerals only account for 15%

Table 3. Calibrated Rate Coefficients in PRB Case Studies

Geochemical Reactions Terms	Units	Moffett Federal Airfield[c]	Former Mill Site[c]	Copenhagen Freight Yard[c]	Rate Coefficients Reported in Literature[d]
Oxygen Corrosion[a]	m^3/m^2-d	2.8×10^{-2}	2.8×10^{-2}	2.8×10^{-2}	$< 2.8 \times 10^{4}$
Water Corrosion[a]	mole/m^2-d	7.0×10^{-7}	1.5×10^{-5}	1.9×10^{-7}	$3.0 \times 10^{-8} - 5.4 \times 10^{-3}$
Nitrate Corrosion[a]	m^3/m^2-d	2.6×10^{-5}	—	2.8×10^{-5}	$1.8 \times 10^{-8} - 2.8 \times 10^{-5}$
Microbial sulfate reduction[b]	M/d	1.0×10^{-3}	1.0×10^{-3}	4.0×10^{-3}	$5.0 \times 10^{-6} - 5.0 \times 10^{-3}$
$CaCO_3$	M/d	1.0×10^{-4}	4.0×10^{-4}	1.0×10^{-5}	$2.7 \times 10^{-9} - 1.4 \times 10^{-4}$
$FeCO_3$	M/d	1.1×10^{-5}	2.1×10^{-5}	1.0×10^{-5}	$1.1 \times 10^{-5} - 2.7 \times 10^{-4}$
$Fe(OH)_2$ (am)	M/d	5.1×10^{-5}	5.1×10^{-5}	5.0×10^{-5}	$<2.2 \times 10^{-4}$
FeS (am)	M/d	1.0×10^{-6}	1.0×10^{-6}	1.0×10^{-6}	$1.1 \times 10^{-8} - 2.2 \times 10^{-5}$
$CaMg(CO_3)_2$	M/d	—	1.0×10^{-6}	1.0×10^{-9}	6.9×10^{-6}
$Mg(OH)_2$	M/d	2.0×10^{-3}	NA	NA	3.4×10^{-6}

[a] Reactive surface area of ZVI set at 3.9×10^6 m^2/m^3.

[b] Half-saturation constants for $SO_4{}^{2-}$ and H_2 (aq) were $K_{SO4} = 1.0 \times 10^{-4}$ M, and $K_{H2} = 1.0 \times 10^{-7}$ M, respectively.

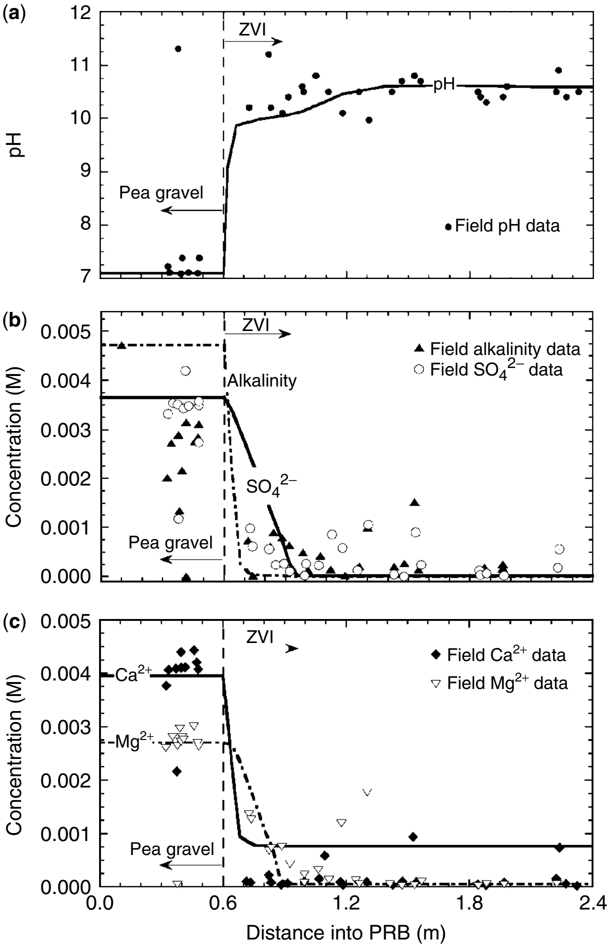

Figure 1. Measured and predicted concentrations for the PRB at Moffett Federal Airfield, Mountain View, CA, after 12 months of operation: (**a**) pH, (**b**) alkalinity and $SO_4{}^{2-}$, and (**c**) Ca^{2+} and Mg^{2+}.

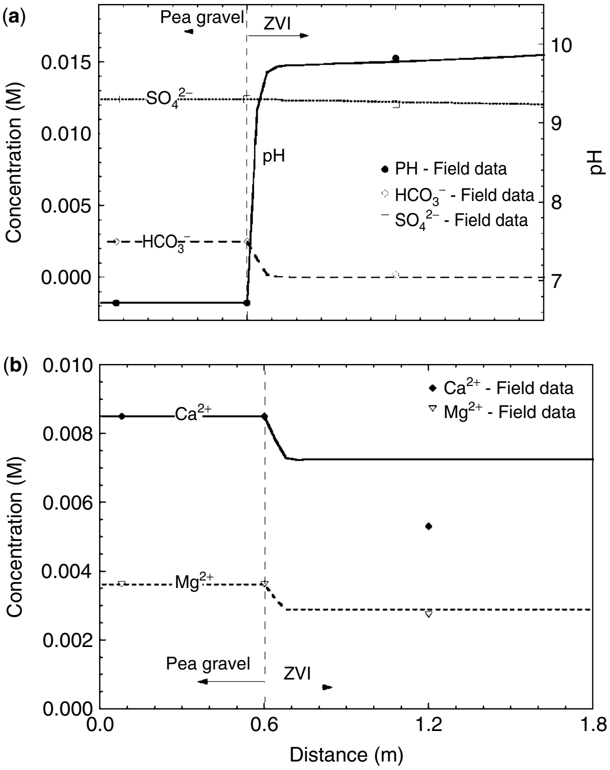

Figure 2. Measured and predicted concentrations for the PRB at the former Uranium Mill Site in Monticello, UT, after 3 months of operation: (**a**) pH, $HCO_3{}^-$, and $SO_4{}^{2-}$ and (**b**) Ca^{2+} and Mg^{2+}.

of aqueous calcium). For example, Morrison et al. (14) included iron-rich calcite ($Fe_{0.4}Ca_{0.6}CO_3$) and gypsum ($CaSO_4$) in their equilibrium model to account for calcium removal in the ZVI. However, neither of these minerals has been observed in the core samples from the PRB at Monticello. The surface complexation of calcium on the ZVI and secondary minerals surfaces, neither of which are considered in the simulator, may also be removing calcium from the solution (10).

Copenhagen Site

Comparisons of measured and predicted pH and Ca^{2+}, Mg^{2+}, $SO_4{}^{2-}$, and $HCO_3{}^-$ concentrations after 15 month of operation of the Copenhagen PRB are shown in Fig. 3. The calibrated rate coefficients corresponding to these predictions are summarized in Table 3.

Close agreement exists between the measured and predicted pH and the HCO_3^-, SO_4^{2-}, Ca^{2+}, and Mg^{2+} concentrations in the ZVI of the Copenhagen PRB [Figs. 3(a) and (b)], but the field data are too sparse to evaluate whether the trends in geochemistry predicted by the model are accurate. In contrast to the PRBs at Moffett Field and Monticello, the predicted pH climbs gradually at the Copenhagen site. This more graduate change in pH may be caused by a lower rate of iron corrosion by water (1.9×10^{-7} mole/m^2-d, Table 3), which results in less OH^- released into solution.

Comparison of Calibrated Rate Coefficients and Literature Values

The calibrated rates coefficients for the three PRB case studies are summarized in Table 3. Most of the calibrated rate coefficients fall within the range of rate coefficients from the literature (Table 3). The exceptions are the rate coefficient for $Mg(OH)_2$ at the Moffett PRB and the rate coefficient for $CaCO_3$ at the Monticello PRB. Both rate coefficients are higher than are the maximum values reported in the literature. However, the rate coefficient for $CaCO_3$ is only slightly above the upper bound from the literature, and only one rate coefficient was available in the literature for $Mg(OH)_2$. Thus, these exceptions are not considered unusual.

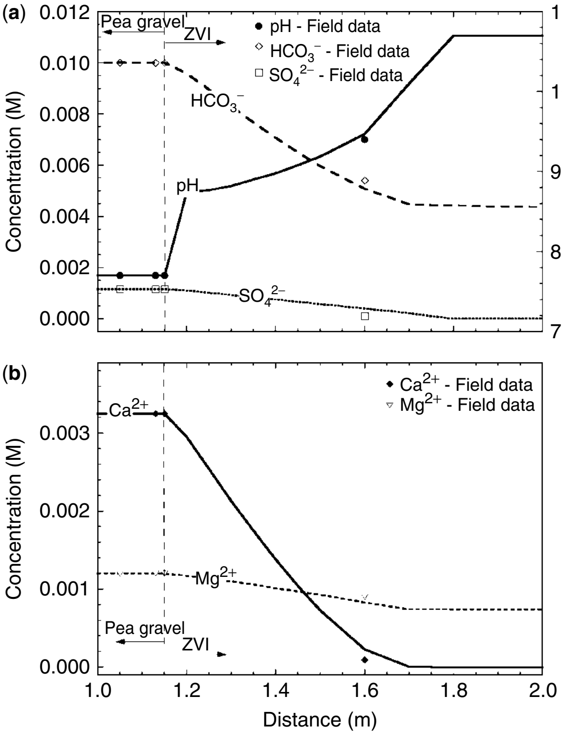

Figure 3. Measured and predicted concentrations at the centerline of the PRB at the Copenhagen Freight Yard, Copenhagen, Denmark, after 15 months of operation: (**a**) pH, HCO_3^-, and SO_4^{2-} and (**b**) Ca^{2+} and Mg^{2+}.

Although good agreement between measured and predicted concentrations has been shown in Figs. 1–3, the accuracy of the simulator when applied to other problems will depend greatly on the rate coefficients used as input. For example, the effect of varying the rate coefficient for iron corrosion by water (Table 1) within a reasonable range (1.0×10^{-7} to 1.0×10^{-5} mole/m^2-d) on pH is illustrated in Fig. 4 with the model for the PRB at Moffett Field. The influent concentrations used for the simulation are shown in Table 2, and the rate coefficients for the reactions other than iron corrosion by water are shown in Table 3. When the rate coefficient for iron corrosion by water is 10^{-7} mole/m^2-d, the predicted pH is much lower than the pH observed in the field, especially near the entrance. In contrast, when the rate coefficient for iron corrosion by water is 10^{-5} mole/m^2-d, the predicted pH increases too rapidly near the entrance and levels out approximately one pH unit higher than observed in the field.

In situ rate coefficients can vary considerably and depend on a variety of factors, and no method currently is available to predict rate coefficients accurately *a priori*. Thus, at the current time, simulators must be calibrated with field data if reliable predictions of mineral precipitation are to be obtained. Alternatively, parametric analyses can be conducted to evaluate the potential range of conditions that may be realized in the field.

SUMMARY

Comparisons between predicted and measured concentrations of common groundwater ions in PRBs have been described in this article. The simulator used for the predictions is based on the public domain codes MODFLOW and RT3D, the latter being augmented with a geochemical algorithm specifically for simulating geochemical reactions in PRBs. Field data from three PRBs were used for the comparison.

The comparisons showed that pH profiles and anion and cation concentrations in PRBs can be predicted accurately. The ability to predict solid phase concentrations has not been evaluated because of lack of field data. However,

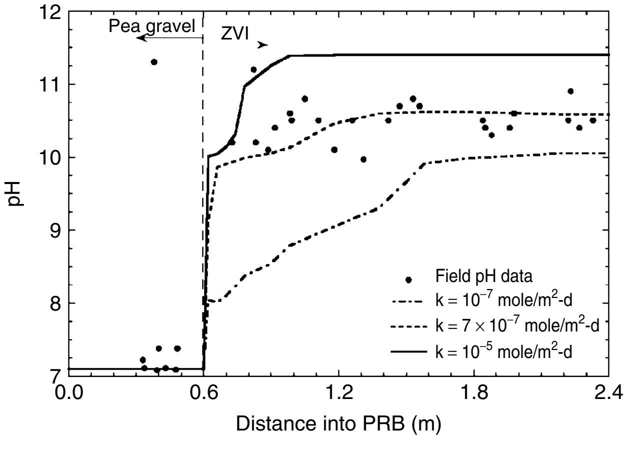

Figure 4. Measured and predicted pH for the PRB at Moffett Federal Airfield, Mountain View, CA, after 12 months of operation using various rate coefficients (k) for iron corrosion by water.

the accuracy of the predictions depends to a great extent on the reaction rate coefficients used as input. In this study, the rate coefficients were obtained by calibration because the actual *in situ* rate coefficients were unknown. Thus, predictions made *a priori* are prone to considerable uncertainty until methods are developed to accurately define reaction rate coefficients.

In many cases, the simulator predicted that the greatest changes in geochemistry generally occur at the entrance face of the PRB. However, the current field data sets contain insufficient detail to confirm that these changes in geochemistry are being predicted accurately. More detailed field observations are needed at the entrance face of the PRBs to more fully evaluate whether the simulator can accurately capture these rapid changes in geochemistry.

TRANSPORT OF REACTIVE SOLUTE IN SOIL AND GROUNDWATER

Natalie L. Capiro
Philip B. Bedient
Rice University
Houston, Texas

INTRODUCTION

Remediation of contaminated aquifers, both vadose zone (unsaturated portion of an aquifer) soils and groundwater, has proven to be a challenging environmental endeavor. Groundwater is the source of about 60% of the United States' water usage and, with contaminant plumes impacting many states, associated human health concerns of great importance exist. Groundwater can become polluted both directly by leaking underground storage tanks and indirectly by leakage of contaminants on the soil surface that leach to the groundwater. Common pollutants include agricultural chemicals applied to crops, industrial spills, landfill leachate, disposal sites, and waste ponds. Subsurface remediation is complicated by not only the behavior of the contaminants themselves but by the heterogeneities found in typical aquifer formations. The processes that govern the fate and transport of solute in aquifer systems generally fall into the categories of hydrodynamic, abiotic, and biotic.

The universal process that impacts all forms of solute include the hydrodynamic processes, which affect contaminant transport by impacting the flow paths of groundwater in the subsurface, including both the vadose zone and the saturated aquifer. Abiotic processes affect contaminant transport physically by causing interactions between the contaminant and the stationary subsurface materials (i.e., sorption) or by affecting the form of the contaminant (i.e., through hydrolysis and redox reactions). Biotic processes are driven by microbial activities and can affect contaminant transport by metabolizing or mineralizing the contaminant (i.e., organic contaminants), or possibly by using the contaminant in the metabolic process (i.e., nitrate under denitrifying conditions).

PHYSICAL MECHANISMS OF SOLUTE TRANSPORT

The three basic hydrodynamic processes affecting contaminant transport in saturated and unsaturated porous media are advection, diffusion, and hydrodynamic dispersion. Advection represents the movement of a contaminant with the flowing groundwater according to the seepage velocity in the pore space. Advection is the most important process driving the down gradient migration of dissolved contaminants in the saturated subsurface (1). If advection was the only process acting on a tracer, a sharp interface would exist continuously as the tracer flushes out the solute-free water. In essence, the tracer would behave as a plug. A breakthrough curve, illustrating the relative effluent concentration (C/Co) vs. time in a continuous tracer input, would appear as a step function (Fig. 1a). The average velocity of advective transport is described by the amended Darcy equation:

$$v_x = -\frac{K}{n}\frac{dh}{dL} \tag{1}$$

where v_{x} is the average linear groundwater velocity [L/t], K is the hydraulic conductivity (a measure of a porous media's ability to transmit water) [L/t], n is the effective porosity [unit less], and dh/dL is the hydraulic gradient [L/L].

The average linear velocity or seepage velocity, v_x, equals the Darcy velocity divided by effective porosity, n, associated with the pore space through which water can actually flow. The average linear velocity is less than the microscopic velocities of water molecules moving along individual flowpaths, because of tortuosity. The one-dimensional (1-D) mass flux (F_x) because of advection equals the product of water flow and concentration (C) of solute, or $F_x = v_x nC$.

Darcy's law is also still valid for the macroscopic view (through the entire pore body) of unsaturated flow, except that hydraulic conductivity is now a function of moisture content. Darcy's law is then used with the unsaturated value for K and can be written as

$$v = -K(\theta)dh/dz \tag{2}$$

where v is Darcy velocity, z is depth below surface [L], $K(\theta)$ is unsaturated hydraulic conductivity [L/T], θ is volumetric moisture content, h is potential or head ($h = z + \psi$) [L/T], and ψ is tension or suction [L]. For saturated soils, the hydraulic conductivity was assumed to be constant; however, in unsaturated soil, it decreases sharply with decreasing water content, because as water drains from pores, the flow decreases (2).

Although advection is associated with bulk macroscopic groundwater movement, diffusion is a molecular-based phenomenon. The process involves spreading because of concentration gradients and random motion. Diffusion causes a solute in water to move from an area of higher concentration to an area of lower concentration. Diffusive transport can occur in the absence of velocity. Mass transport in the subsurface because of diffusion in one dimension can be described by Fick's first law of diffusion,

$$f_x = -D_d\frac{dC}{dx} \tag{3}$$

where f_x is the mass flux [M/L^2/T], D_d is the diffusion coefficient [L^2/T], and dC/dx is the concentration gradient [M/L^3/L].

Typical values of D_d are relatively constant and range from 10^{-4} to 10^{-5} cm^2/sec (3). In cases of very low velocities, such as in a tight soil or clay liner, or in the case of mass transport involving very long time periods, diffusion is the dominant hydrodynamic process. On the other hand, in areas of high groundwater velocity, molecular diffusion can actually be ignored compared with advection and other dispersion mechanisms.

Freeze and Cherry (4) defined hydrodynamic dispersion as the process in which solutes spread out and are diluted compared with simple advection alone. It is defined as the sum of molecular diffusion and mechanical dispersion, where diffusion is caused by concentration gradients alone and dispersion is generally caused by local variations in velocity around some mean velocity of flow. The net effect of the dispersive phenomena is to decrease the concentration gradient between two different solutions of the same solute. In essence, dispersion reduces the sharp interface between the two solutions. Mass transport because of dispersion can also occur normal to the direction of flow. This transverse dispersion, D_y, is caused by diverging flowpaths in the porous media and concentration gradients that cause mass to spread laterally from the main direction of flow. In most cases involving a two-dimensional plume of contamination, D_y is much less than D_x, and the shape of the plume tends to be elongated in the direction of flow (5). Many typical contaminant plumes in groundwater are represented by 2-D advective-dispersive mechanisms.

One-Dimensional Transport Equations

The governing mass transport equation is difficult to solve in field cases of practical interest because of boundary irregularities and variations in aquifer characteristics, so numerical methods must generally be employed (6). However, a limited number of relatively simple, 1-D analytical solutions exist. The simplifying assumptions include the following: (a) the tracer is ideal, with constant density and viscosity; (b) the fluid is incompressible; (c) the medium is homogeneous and isotropic; and (d) only saturated flow is considered. Initial conditions ($t = 0$) in a soil column are usually set to zero ($C(x, 0) = 0$) or to some constant background concentration. Boundary conditions must be specified at the two ends of the 1-D column. For a continuous source load at $x = 0$, the concentration is set to $C(0, t) = C_0$ for $t > 0$. The concentration at the other boundary, $x = \infty$ is set to zero $C(x, \infty) = 0$ for $t > 0$.

For an infinite 1-D column with background concentration of zero and a continuous input tracer concentration C_0 at $-\infty \leq x \leq 0$ for $t \geq 0$, Bear (7) solves the problem using the Laplace transform at $x = L$, length of the column

$$\frac{C(x,t)}{C_0} = \frac{1}{2}\left(\mathrm{erfc}\left[\frac{L - v_x t}{2\sqrt{D_x t}}\right] + \exp\left(\frac{v_x L}{D_x}\right)\mathrm{erfc}\left[\frac{L + v_x t}{2\sqrt{D_x t}}\right]\right) \tag{4}$$

where erfc is the complementary error function, $\mathrm{erfc}(x) = 1 - \mathrm{erf}(x) = 1 - (2/\sqrt{\pi})\int_0^x e^{-u^2}du$, D_x is the coefficient of hydrodynamic dispersion, and v_x is the average seepage velocity. The center of mass $(C/C_0 = 0.5)$ of the breakthrough curve travels with the average linear velocity, v_x, and corresponds to the point where $x = v_x t$. Note that the second term on the right-hand side of Eq. (4) can generally be neglected for most practical problems. The error functions erf (β) and erfc(β) are tabulated in Domenico and Schawartz (3).

The corresponding solution can be derived for the injection of a tracer pulse (instantaneous input) at $x = 0$ with background concentration equal to zero in the 1-D column. As the slug moves downstream with v_x in the $+x$ direction, it spreads out according to

$$C(x,t) = \frac{M}{(4\pi D_x t)^{1/2}}\exp\left[-\frac{(x - v_x t)^2}{4D_x t}\right] \tag{5}$$

where M is the injected mass per unit cross-sectional area. Figure 1b shows the resulting Gaussian distribution of concentration for the instantaneous pulse source in one dimension.

Plots comparing the shapes of Eqs. (4) and (5) are shown in Figs. 1a and 1b, respectively, at $x = L$ at the end of a soil column. The differences between instantaneous (spike) source and continuous source transport problems are obvious in one dimension. The continuous source produces a response or breakthrough curve, which starts at a low concentration and eventually levels off to the initial input concentration C_0 as a function of time. The spike source produces a normal or Gaussian distribution, which continues to decrease in maximum concentration because of spreading out with time in the direction of flow. For the spike source, the amount of mass under each curve is identical if the tracer is conservative.

Additional information can be found on transport equations in several sources (3–6,8), including three-dimensional derivations and those incorporating degradation.

Techniques for Determining Hydrodynamic Parameters

Tracers and tracer tests are valuable methods for estimating dispersion and advection below the water table. In a tracer test, a chemical species is introduced to the subsurface and monitored as it is carried by groundwater through the subsurface in the direction of flow. Average seepage velocity can be determined by analyzing the resulting curves in time and space, and hydraulic conductivity (K) values can be computed from Darcy's Law (Eq. 1). One of the most successful field sites for tracer studies has been the Borden landfill site in Canada, which resulted in a series of classic papers on dispersion and adsorption processes measured during a multiyear field experiment (9,10).

Other methods of determining hydraulic conductivity exist. Permeameters may be used in a laboratory setting to determine K, whereas slug tests and pump tests are recommended for field sites. A slug test involves suddenly adding or removing a volume of water (called a slug) from a well and monitoring the time it takes for the water level to return to normal. This test is convenient, but not as accurate as a tracer test to determine the speed with which a contaminant moves through an aquifer. The pump test involves the constant removal of water from a single well and the subsequent observation of drawdown in adjacent wells. This test gives the K value for a large part of an aquifer, but may produce a large volume of water that requires proper handling and treatment (if performed in a contaminated area) (3).

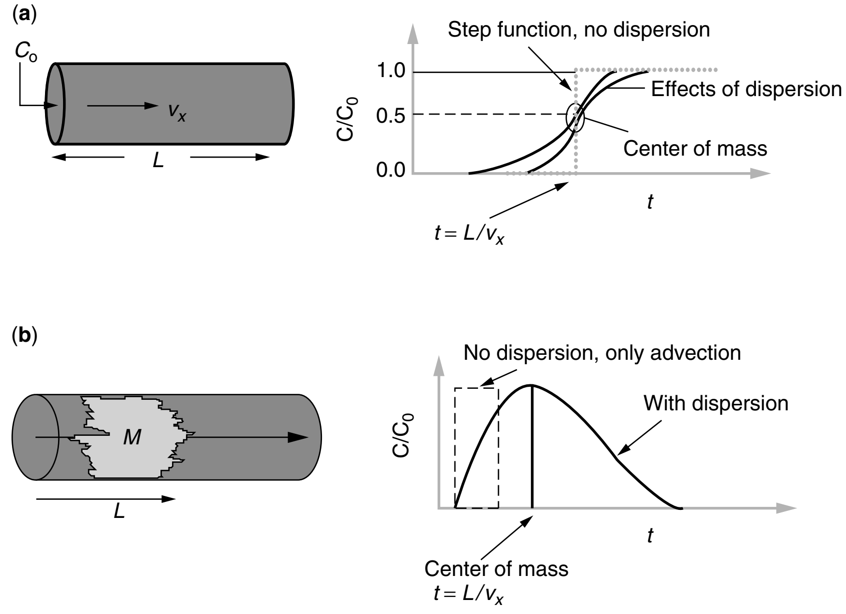

Figure 1. Breakthrough curves in one dimension for: (**a**) continuous and (**b**) instantaneous tracer inputs.

ABIOTIC SOLUTE TRANSPORT

Abiotic processes affect contaminant transport by causing interactions between the contaminant and the aquifer media or by changing the form of the contaminant that may subsequently interact with the subsurface material. The interfaces of most interest in subsurface fate and transport are liquid/solid interfaces and gas/solid interfaces. The processes that detail these interactions are discussed in this section.

Sorption

Sorption includes the phenomena of adsorption, absorption, and ion exchange. Weber (11) defines adsorption as the accumulation occurring at the interface, absorption as the partitioning between two phases (accumulation from groundwater into organic carbon), and sorption as including both adsorption and absorption. Often, the terms adsorption and sorption are interchangeable.

Many organic contaminants are removed from solution by sorption onto the aquifer matrix. Sorption of dissolved contaminants onto the aquifer matrix results in slowing (retardation) of the contaminant relative to the average groundwater seepage velocity and a reduction of dissolved organic concentrations in groundwater. In some cases, sorption is a reversible process; at a given solute concentration (steady state), some portion of the contaminant is partitioning out of solution onto the aquifer matrix and some portion is desorbing from the matrix back to solution; this process is called desorption.

The ability of chemicals to completely desorb from a solid is an area of current study (12–15). At high contaminant concentration, desorption patterns are generally predictable through equilibrium analysis. However, the phenomena of solid phase contaminant concentrations exceeding the predicted concentration, based on the surrounding aqueous phase concentrations, is observed in materials that have been contaminated for long time periods and contain low solid-phase contaminant concentrations (nominally less than 20 mg/kg). The importance of this observation is potentially enormous, because site remediation requirements include the removal of sorbed contamination. If a contaminant does not desorb as readily as it sorbed, the ability to meet cleanup levels may be seriously threatened (16).

Ion exchange is a specific category of sorption that occurs when the absorbent charge deficiency of a surface can be neutralized more efficiently by ions in solution than those ions currently absorbed (17). An example of ion exchange that is familiar is a home water softener. Home water softeners operate by accumulating the divalent cations from the groundwater onto the absorbent (ion exchange resin) while releasing monovalent ions, which reduces water hardness. In the subsurface, the resin would be natural minerals such as those found in clays. The most common ions occurring naturally are as follows (listed in order of occurrence from high to low): cations, Ca^{2+}, Mg^{2+}, Na^+, and K^+; anions, $SO_4{}^{2-}$, Cl^-, $PO_4{}^{3-}$, and $NO_3{}^-$ (18).

Cosolvation and Ionization

Cosolvation and ionization are two examples of processes that act to increase the chemical solubility, by altering the solvent phase or by altering the chemical form, respectively. Cosolvation is the process by which the mobility of one contaminant is enhanced by the presence of a solvent (19), whereas ionization refers to the gaining or losing of protons as a function of pH and thus going from a neutral form to an ionic form. These processes are solvent motivated; when a contaminant is in the presence of a solvent, it will have decreased sorption and an increased solubility leading to elevated concentrations in the surrounding solute. Based on these assumptions, it would be expected that as the fraction of cosolvent increases in solution, the level of sorption will decrease.

These attributes of cosolvents lead to increased mobility of originally slow dissolving hydrophobic (lacking affinity for water) contaminants. An example of this is the affect of ethanol on petroleum hydrocarbons. The issue concerning an ethanol releases' potential to cosolubilize benzene and other aromatic compounds in groundwater (20) has been addressed in recent groundwater modeling studies (21,22) and in laboratory studies (23,24). The reason that tremendous efforts are being employed to understand this phenomenon is that benzene, which is known to increase cancer risks, has a maximum contaminant level of only 0.005 mg/L in drinking water as set by the U.S. EPA and ethanol is now being used as a fuel additive (an oxygenate).

Oxidation and Reduction

Oxidation and reduction (or redox) refer to the transfer of electrons and contaminant species change of ions or compounds. Oxidation refers to the loss of electrons and reduction refers to the gain of electrons in a reaction. The two processes often occur in tandem; electrons given by one compound must be gained by another compound. Inorganic compounds, such as reduced metals and reduced sulfur, are possible mediators of oxidation-reduction reactions (25–27). The presence or absence of inorganic species is often dependent on aquifer conditions. A common condition is that many anaerobic environments will contain elevated levels of Fe(II) or Fe^{2+}, H_2S/HS^-, and other reduced species that are capable of donating electrons and reducing certain contaminants. For example, the two half reaction equations for the oxidation-reduction of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}) are:

$$4\,Fe^{2+} \Leftrightarrow 4\,Fe^{3+} + 4e^-[\text{oxidation}]$$

$$O_2 + 4H^+ + 4e^- \Leftrightarrow 2H_2O[\text{reduction}]$$

Biologically mediated oxidation-reduction reactions are often more rapid than abiotic reactions for many contaminants of interest in groundwater systems, and thus abiotic oxidation-reduction are often neglected in transport calculations. In cases where they become important, oxidation-reduction processes are generally introduced as a first-order reaction (rate $= k^1X$) with respect to contaminant concentration, analogous to hydrolysis.

Hydrolysis

Hydrolysis refers to a chemical reaction between a contaminant molecule and water. Hydrolysis may function when direct biodegradation (microbially driven) of the contaminant cannot, and hydrolysis may produce a product that is susceptible to biodegradation, which can be significant in affecting fate and transport (17). With respect to organics, this process frequently results in the formation of alcohols and alkenes (28).

The rate that a chemical undergoes hydrolysis is strongly influenced by the temperature and pH of the system (27). As temperature increases, hydrolysis rates increase. As pH becomes either acidic or alkaline (e.g., greater than or less than 7.0), rates of acid-catalyzed or base-catalyzed hydrolysis can increase. Typically, hydrolysis is described with a first-order rate expression as shown in Eq. 6

$$\frac{C}{C_0} = e^{-k_{hyd}t} \tag{6}$$

where C is the concentration of the chemical species and k_{hyd} is a first-order hydrolysis rate coefficient. Knowing factors, such as pH and temperature, is important in determining the appropriate rate coefficient for a particular contaminant.

Volatilization

The transfer of a contaminant from the aqueous phase, nonaqueous phase liquid (NAPL), or sorbed phase directly to the gas phase is a process referred to as volatilization. The rate and extent to which volatilization occurs is strongly influenced by a number of parameters including the contaminant phase, the contaminant's vapor pressure, environmental factors (e.g., temperature and others), proximity in respect to the vadose zone, and other site-specific parameters (29,30). As a result of the range of factors, that play an important role in vapor transport, which include the physical transport processes of advection and dispersion, it is difficult to calculate the contribution of volatilization to the fate of chemicals in groundwater.

For the evaluation of volatilization, however, consider a closed bottle that contains water and air. If a contaminant is introduced to the bottle and allowed to equilibrate, some fraction of the contaminant added will reside in the gas phase. The distribution of a chemical between the water and the gas at equilibrium is described by the Henry's law coefficient (31,32). Mathematically, Henry's law is presented in Eq. (7), where P_c is the partial pressure of the contaminant, $[C]_{aq}$ is the aqueous phase concentration of the contaminant, and H_c is the Henry's constant.

$$H_c = \frac{P_c}{[C]_{aq}} \tag{7}$$

In groundwater systems that are isolated from the vadose zone, Henry's law can be applied to estimate the distribution of contaminants between the aqueous phase and the gas phase. If direct exchange is possible with the vadose zone, equilibrium may not be achieved and the calculation of gas phase concentrations is more difficult. Additionally, volatilization from NAPLs in the vadose zone or floating on the water table can yield high concentrations of contaminants in the gas phase (16).

BIOTIC PROCESSES AFFECTING SOLUTE TRANSPORT

Biotic processes include those biological phenomena that affect the transport and/or fate of compounds (organics, inorganics, or the microbes themselves) in the subsurface. Biodegradation of organics is one process that is of particular interest to minimize human health risks associated with the widespread contamination of chlorinated ethenes and hydrocarbons in the environment, because this process is able to achieve mineralization (endproducts CO_2,H_2O, etc.) and effectively render the contaminant innocuous (harmless). It has only been in the last two decades that the variety and magnitude of micro-organisms present in aquifers, and thus the ability of aquifers to support biodegradation, has been realized (33). Laboratory column studies (34) and improved field sampling methods are chiefly responsible for these advances.

Energy Flow and Metabolism

All living organisms require energy to survive, and the capture of usable energy through the process of catabolism is a significant part of an organism's overall metabolism. Bacteria that obtain energy from chemical forms are classified as chemotrophs. Chemotrophic organisms are further differentiated as either lithotrophs, which use inorganic sources of energy, or organotrophs, which use organic compounds. Examples of lithotrophic substrates include ammonia (NH_3), hydrogen (H_2), ferrous iron (Fe^{2+}), and sulfide (HS^-). Examples of common groundwater contaminants that serve as organotrophic substrates include fuel components and chlorinated solvents (35).

Biodegradation involves the process of extracting energy from organic chemicals via oxidation of the organic chemicals during catabolism. As a chemical is oxidized, it loses electrons. For this reason, chemotrophic substrates are often referred to as primary electron donors. Electrons lost during oxidation are coupled with the reduction of electron acceptors. Eventually, the complex sequence of oxidation-reduction reactions that occur during catabolism results in the reduction of a terminal electron acceptor. Common terminal electron acceptors in groundwater systems include oxygen (O_2), nitrate ($NO_3{}^-$), ferric iron (Fe^{3+}), sulfate ($SO_4{}^{2-}$), and carbon dioxide (CO_2). Aerobic catabolism occurs when oxygen is the terminal electron acceptor, and anaerobic conditions are in place when all other terminal electron acceptors are used. Typically, an individual bacterial strain is capable of using only one terminal electron acceptor. Facultative aerobes are the exception to this rule; these organisms can use nitrate as a terminal electron acceptor in the absence of the preferred oxygen. An important evaluation of contaminant biodegradation potential involves an analysis of the availability of primary electron donors and terminal electron acceptors, as their presence is required for organisms to obtain energy for survival and selects the types of organisms that will be present (16).

The metabolism of organic contaminants can be broadly differentiated by the ability of organisms to use the contaminant for catabolic processes. If the compound is a primary electron donor and provides the bacterium with energy for cell growth, the contaminant is referred to as a primary substrate, whereas secondary substrates are contaminants that provide the cell with energy, but are present at concentrations that are not sufficient to support the energy requirements of the organism. If a compound is metabolized fortuitously as the cell is obtaining energy from another primary electron donor, the transformation is referred to as cometabolic (36,37). However, cometabolism is generally a slow process and not all chlorinated solvents are susceptible (e.g., PCE and carbon tetrachloride). In the case of chlorinated ethenes, the contaminant serves as an anaerobic terminal electron acceptor in a process referred to as dehalorespiration, which is faster than cometabolism.

Metabolic Pathways of Common Contaminants

An overview of how bacteria are capable of metabolizing two of the primary groundwater contaminants (hydrocarbons and chlorinated solvents) is presented in this section. It is important to note that this continues to be an area of extensive research. Theoretical frameworks continue to change and it is difficult to assert definitive analysis regarding the totality of metabolic processes that may impact an individual contaminant's fate.

As a result of accidental spills and leaking underground storage tanks, hydrocarbon compounds consisting of gasoline, diesel, and jet fuels are common groundwater contaminants. Of particular concern are benzene, toluene, ethylbenzene, and xylene isomers (BTEX), which, under aerobic conditions, are rapidly biodegraded as primary substrates (38). Unfortunately, the oxygen demand resulting from the aerobic oxidation of these compounds can exceed the solubility of oxygen in water. Dissolved oxygen concentrations are rapidly depleted because of the biodegradation of these and other fuel constituents, yielding anaerobic conditions in contaminated aquifers (39).

Only recently have laboratory studies confirmed that the biodegradation of all BTEX compounds occurs under all anaerobic electron acceptor conditions (listed above). From these studies, it appears that toluene is the most degradable under all electron acceptor conditions and benzene is the least degradable. Certain modeling studies of certain well-characterized contaminated field sites infer that anaerobic benzene degradation may occur *in situ*. Only several recent laboratory studies conducted under anaerobic conditions have demonstrated that benzene may degrade in the absence of oxygen (40). Despite the possibility of anaerobic degradation of BTEX compounds, it is still generally slower than rates that are observed through aerobic processes.

Chlorinated methanes, ethanes, and ethenes comprise a group of compounds commonly referred to as chlorinated solvents. Chlorinated ethenes, particularly tetrachloroethene (PCE) and 1,1,2-trichloroethene (TCE), are commonly used as degreasers and cleaning solvents in the dry cleaning, aviation, and computer industries. Through accidental spills, improper storage, and disposal techniques, these chemicals have become major subsurface contaminants (41). The extensive impacts observed are primarily because of their widespread usage by industry, their general mobility and persistence in the environment, and the health risks associated with compound exposure.

The metabolism of chlorinated solvents is perhaps more diverse than any other group of environmental contaminants. Depending on the compound of interest, the electron acceptor condition, and the presence of inducing substrates, the metabolism of chlorinated solvents may occur through primary metabolism, secondary metabolism, cometabolism, or through terminal electron acceptor processes (16). Laboratory studies (34,36,37,42–44) have shown that, in the presence of a suitable substrate, certain microbes are capable of anaerobically metabolizing PCE by using it as an electron acceptor. In this process, known as reductive dechlorination, PCE may be dechlorinated to 1,1,2-trichloroethene (TCE), to typically cis-1,2 dichloroethene (DCE), to vinyl chloride, and eventually to ethene and ethane, an innocuous compound (45).

SUMMARY OF SOLUTE TRANSPORT PHENOMENA

Fate and transport of solutes in subsurface soils and groundwater is impacted by a combination of many processes that are difficult to quantify. No two field sites or aquifers have the exact same characteristics. Soil type, pH, temperature, groundwater flow velocity, the availability of electron donors for microbes, and the contaminant itself (among other parameters) all influence the path and lifetime of the pollution source. However, measurement techniques are improving, and understanding these processes is an area of on going research.

In summary, nonreactive (conservative) chemicals tend to move unimpeded through the subsurface and are subject to only hydrodynamic processes such as advection, dispersion, and diffusion. On the other hand, many actual contaminants (organic solvent and fuels, and inorganic metals) can be affected during groundwater transport by a number of subsurface mechanisms and chemical reactions. The processes that have the largest impact on contaminant fate and transport include advection, dispersion, sorption, cosolvation, volatilization, biological oxidation-reduction reactions, and cometabolism/mineralization. These processes are reviewed in Table 1, and Fig. 2 provides an illustration of these processes acting on a typical contaminant spill.

Table 1. Subsurface Processes Affecting Solute Transport

Category	Process	Contaminant (Solute) Behavior
Hydrodynamic Solute Transport	Advection	Plug flow; movement with bulk fluid
	Diffusion	Movement from high to low concentration
	Dispersion	Spreads out and dilutes
Abiotic Solute Transport	Sorption	Decreased solubility
	Ion exchange	Neutralizes the charge and sorbs
	Cosolvation	Increased solubility by solvent
	Oxidation-Reduction	Transfer of electrons
	Hydrolysis	More susceptible to biodegradation
	Volatilization	Phase transfer from aqueous or sorbed to gas
Biotic Transport Influences	Cometabolism	Metabolized as cell obtains energy
	Mineralization	Broken down to benign products
	Oxidation-Reduction	Microbial driven transfer of electrons

WATER IN THE UNSATURATED ZONE

Mukand Singh Babel
Asian Institute of Technology
Parthumthani, Thailand

The soil profile immediately below the land surface and above the water table is called the unsaturated zone, where the pores contain both water and air. Figure 1 shows a schematic diagram of the unsaturated zone. This zone differs from the saturated zone, where the pores are saturated with water. The unsaturated zone is sometimes called the vadose zone.

The thickness of an unsaturated zone can range from zero (e.g., when a lake or marsh is at the surface) to hundreds of meters, as is common in arid regions. It is a zone of natural and human-induced activity. It experiences physical phenomena such as thermodynamic interactions, transport processes of various kinds, and chemical reactions involving both natural and artificial substances. Several biological activities involving plant roots, rodents, worms, microbiota, and other organisms also take place in this zone. The zone is used for cultivating plants, constructing structures, and disposal of waste.

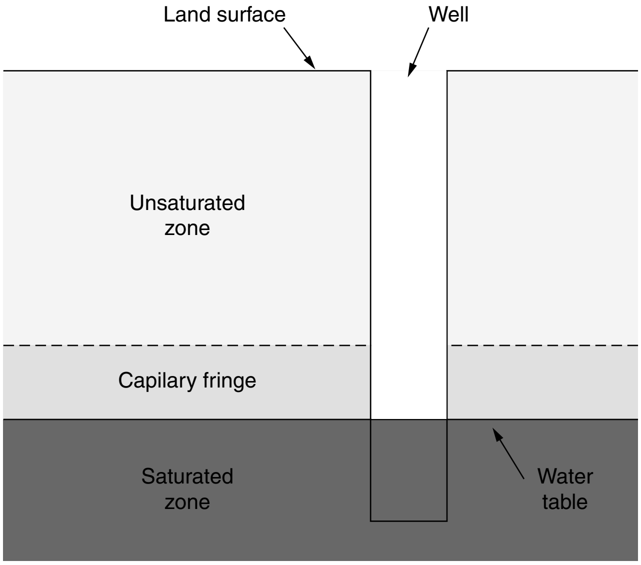

Figure 1. A schematic diagram of the unsaturated zone.

To a large degree, the unsaturated zone controls the transmission of water to aquifers (water bearing strata), as well as to the land surface, to water on the surface, and to the atmosphere. It also acts as a filter as it removes undesirable substances before they reach and affect aquifers. Figure 2 gives a pictorial representation of the unsaturated zone.

Though the unsaturated zone stores water, plant nutrients, and other substances, it is not always considered a major storage component of the hydrologic cycle because it holds only a tiny fraction of the earth's fresh water and this water is usually difficult to extract. But it is of great importance for storing water and nutrients in ways that are vital to the biosphere.

SOIL WATER

Soil water is normally considered to include both the water contained in the soil profile and the subsurface water in the unsaturated subsoil layers. Soil water may be present as gravity water in transit in larger pores, as capillary water in smaller pores, as hygroscopic water adhering

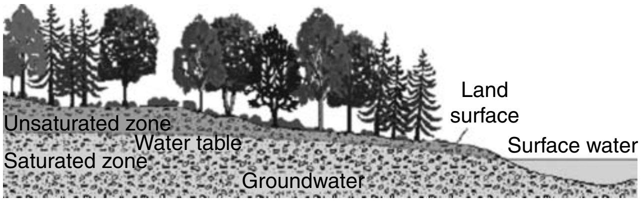

Figure 2. Unsaturated zone.

in a thin film to soil grains, and as water vapor. After a rain, gravitational water moves downward in larger pores, but it is dispersed into capillary pores or passes through the unsaturated zone to the groundwater or to a stream channel. Hygroscopic water is held very tightly to the soil surface by molecular attraction and is not normally removed from soil. Capillary water, therefore, is the important variable element of soil water.

SOIL WATER POTENTIAL

The most basic measure of the water in an unsaturated soil is water content or wetness, defined as the volume of water per bulk volume of the soil. Water is held in unsaturated soil by forces whose effect is expressed in terms of the energy state or pressure of the water. Like all matter, water can possess both kinetic and potential energy. However, in general, the flow of water in soils is too small to consider kinetic energy. Therefore, the energy state of soil water is represented by its equivalent potential energy. Potential energy is defined as the ability to do work. Work is done whenever an object is accelerated through a distance or heat is produced or transferred. Soil water potential thus measures the ability of soil water to move and/or produce heat. Water potential is important to any process in which soil water moves, such as infiltration and redistribution within the soil or removal of water from the soil by evaporation or plant uptake.

To define the soil water potential parameter, a reference body of water is defined, and the soil water potential of any other body of water is defined as the difference in potential energy concentration (potential energy per unit quantity of water) between the soil water and the reference body of water. The reference body of water is usually called the reference state, which is defined as "*pure* (no dissolved solutes), *free* (free of adsorptive forces) water at a specified temperature and *specified elevation* exposed to *atmospheric pressure*." The water potential of water in the reference state is zero.

Total soil water potential may formally be defined as the amount of work per unit quantity of pure water that must be done by external forces to transfer an infinitesimal amount of water reversibly and isothermally from the reference state to the soil at the point under consideration (1).

FACTORS AFFECTING WATER POTENTIAL

A change in the potential energy of the soil water brings about a change in the soil water potential. There are several factors that affect the potential energy of soil water, including adsorption of water onto soil particles, solutes dissolved in the soil water, the elevation of the soil water in the earth's gravitational field, and applied pressure (both positive and negative).

WATER POTENTIAL COMPONENTS

The total soil water potential can be broken into several components. A complete list of soil water potential components consists of gravitational potential, osmotic potential (also sometimes called solute potential), matric potential, vapor potential, hydrostatic pressure potential, and overburden pressure potential. The major potential components of interest in the unsaturated zone are gravitational potential, osmotic potential, and matric potential that give rise to the total potential as follows:

$$\Psi_{\mathrm{t}} = \Psi_{\mathrm{g}} + \Psi_{\mathrm{o}} + \Psi_{\mathrm{p}} + \dots \tag{1}$$

where Ψ_{t} is the total potential, Ψ_{g} is the gravitational potential, Ψ_{o} is the osmotic potential, and Ψ_{p} is the matric potential.

Gravitational potential is defined as the energy of water per unit volume that is required to move a specific amount of pure, free water from an arbitrary reference point to the soil-water elevation. It is independent of soil properties and solely dependent on the vertical distance between the arbitrary reference point and the interest point. Often, the soil surface is chosen as the point of reference, whereby the distance z (m) to each point of interest is negative by convention. Gravitational potential is given as

$$\Psi_{\mathrm{g}} = \rho_{\mathrm{l}} g z \tag{2}$$

where ρ_{l} is the density of the soil water, g is the acceleration due to gravity (m/s^2) and Ψ_{g} is the gravitational potential (J/m^3).

The osmotic potential component arises due to the salts in the soil water. It may be thought of more a suction than a pressure. In a dynamic soil–water–plant system, in the presence of a selective permeable membrane as found in the roots of plants, the pressure or energy potential (a suction) on the solution side is less than that of pure, free water. Water will pass through the membrane to the solution side until equilibrium is reached. The osmotic potential, Ψ_{o}, is given by

$$\Psi_{\mathrm{o}} = -\frac{\Pi}{\rho_{\mathrm{w}}} \tag{3}$$

where Π is the osmotic pressure and ρ_{w} is the density of water.

Soil is porous, so it acts as a semipermeable barrier to salt solutions. An individual particle has an electric field that causes a decrease in the concentration of the soil solution near the particle surface, which results in an increased cross-sectional area for water transport compared to the area available for transport of dissolved salts, causing water to move due to the osmotic difference. The amount of flow depends on the particle size of the soil and the gradient of the osmotic pressure. In coarse, saturated sand, soil pores are relatively larger than those in clays, and consequently, the thickness of fluid layer with decreased salt concentration is small compared to the total area available for transport. Thus, the semipermeability is small, and the transport of soil solution due to osmotic potential is negligible. In clays, with many more pores, the solutes in the soil solution can be completely repelled from the soil and restricted from flow. In such soils, water movement in response to an osmotic pressure gradient is significant.

The matric potential component results from the soil matrix. Water molecules can form hydrogen bonds with the surface of soil minerals that give rise to adsorption and with other water molecules that result in cohesion. In unsaturated soil, these forces of attraction between the soil mineral surfaces and the soil water exert a "pull" on the soil water reducing the free energy of the water. It is usual to deal with the combined effect of both capillary and adsorptive forces in the way in which water is held in the soil matrix. The matric potential is the potential of the water in a pore of the medium relative to the potential of the air that results primarily from the adsorptive and capillary forces of the soil matrix. When a medium is unsaturated, the water generally is at lower pressure than the air, so the matric potential is negative.

Moisture content increases as the matric potential increases. Zero matric potential is associated with high (saturated or nearly saturated) water content. As the matric potential decreases, the water content decreases. Figure 3 shows the relation between matric potential and water content, called a retention curve. It is a characteristic of a porous medium that depends on the nature of its pores. This relation strongly influences the movement of water and other substances in unsaturated media.

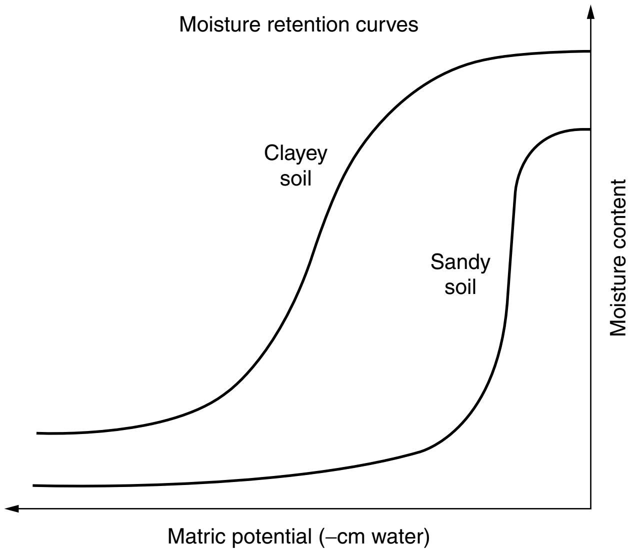

Figure 3. Moisture retention curves.

MEASUREMENT OF SOIL WATER

Soil water can be measured as either soil water content or soil water potential; conversion from one to the other uses the moisture retention curve. Their combined use provides a powerful approach to the study of soil fluxes in unsaturated soil.

The most commonly used method for measuring the water content of soil directly is the gravimetric method, which involves taking a number of soil samples of known volume and determining their weight loss when dried in an oven at 105 °C. The neutron probe is the most widely used indirect way of measuring soil water. In this method, a source of high-energy neutrons is used that is lowered into an aluminum access tube in the soil. Fast neutrons lose energy through collision with atoms of low atomic weight, such as the hydrogen in water, and are converted to slow neutrons. These slow neutrons are counted with a high count indicating high moisture content. Time-domain reflectometry (TDR) determines soil water content by measuring the dielectric constant of the soil. TDR has two significant advantages over the neutron probe method; it is nonradioactive and can be set up for an automatic, nonmanual operation. The satellite-mounted synthetic aperture radar (SAR) method has the potential for measuring soil moisture content on a drainage basin scale. It determines soil water content by monitoring changes in soil dielectric properties.

Tensiometers are the oldest and most widely used technique for measuring matric potential. They comprise a liquid-filled porous cup connected to a pressure-measuring device such as a mercury manometer or a pressure transducer. The cup is embedded in the soil, and water can flow between the soil and cup until the pressure potential inside the cup equalizes with that of the soil water. In fine-textured soils, the resistance block method may be useful. In this method, two electrodes are embedded in a porous block, which is buried in the soil. The matric potential in the block comes into equilibrium with that of the soil water, and the resistance across the electrodes varies with the resulting water content of the block. Gypsum resistance blocks can be used for measuring potentials as low as −15,000 cm (1500 kPa).

GROUNDWATER AND VADOSE ZONE HYDROLOGY

Uwe Dannwolf
URS Australia Pty Ltd.
Turner, Australia

The vadose zone is the geologic media between the land surface and the regional water table.

The vadose zone

- is the foundation for most man-made structures;
- provides nutrients and water to all plant and animal life;
- protects drinking water reservoirs (aquifers);
- governs how much groundwater is replenished;
- provides the pathway for contaminants to penetrate into groundwater, and
- is one of the least understood media.

The latter point becomes evident when a definition for the vadose zone is needed. All publications include the unsaturated soil zone, but some publications include the capillary fringe; others do not. The term “vadose” is derived from the Latin noun *vadosu*s, which translates to “shallow”.

The vadose zone includes the weathered soil horizon and the unconsolidated sediments and rocks below. The capillary fringe separates the water saturated zone from the unsaturated zone. The water saturated zone is often referred to as an aquifer if it allows significant amounts of water to be transmitted. Several processes take place in the vadose zone.

PROCESSES IN THE VADOSE ZONE

The processes, which influence the vadose zone and the recharge to groundwater include

- precipitation,
- evapotranspiration,
- surface water runoff, and
- infiltration and groundwater recharge.

Precipitation

Precipitation is the water that falls on the land surface as rain, snow, and other forms such as dew, frost, and irrigation water. It is measured as volume per time period (e.g., mm/a) or as volume per area and time (e.g., L/km^2 s), which is a relatively simple parameter to measure and is often available from meteorological stations. However, care should be exercised when using this parameter for climatic water balancing because there is great variability even between neighboring stations, due to the precipitation and wind characteristics as well as the various measuring devices.

Evapotranspiration

Evapotranspiration, the reverse of precipitation, represents the transport of water from the earth back to the atmosphere through evaporation and plant transpiration. This process depends on the microclimatic conditions at a given site. This parameter depends on many factors (air temperature and humidity, solar irradiation, vegetation, wind speed, etc.). It is more difficult to measure and therefore not available from all meteorological stations. Simple (1) and complex calculations (2–5) can estimate its range. Its units are generally reported as millimeter per time period. The vegetation type and cover greatly influence this parameter and are often neglected in standard formulas, which can lead to significant variations.

Surface Water Runoff

Surface water runoff is the amount of precipitation that does not immediately enter the subsurface and contributes to surface water discharge (e.g., into local creeks). A portion of this surface water runoff appears on the surface again after a short underground passage (interflow). The amount of surface water runoff depends on the size of the catchment, vegetative cover, relief [(slope or gradient) and depressions (pond formation)], soil cover and soil type, initial soil moisture content, and rainfall intensity. For instance, if the supply rate of water to the soil surface is greater than the soil’s ability to allow the water to enter, excess water either accumulates on the soil surface or becomes runoff. Steep slopes cause greater runoff rates, allowing the water a shorter time to infiltrate. In contrast, gentle slopes have less impact on infiltration due to decreased runoff.

Surface water runoff is even more difficult to measure than any of the above parameters. Hydrological models aid in estimating it.

Effective Recharge or Infiltration

Both evapotranspiration and surface water runoff limit the amount of total precipitation that enters the subsurface, the effective recharge or infiltration into the vadose zone. The term infiltrability is generally used in soil physics and hydrology to define the maximum rate at which rain or irrigation water can be transmitted through a soil under a given condition.

As a general rule of thumb, a total of four water relevant zones exist in the vadose zone (after Reference 6):

1. a near-surface zone to shallow (<1 m) depths affected by episodic rain;
2. a zone below which shows signs of seasonal water infiltration;
3. a zone of virtually constant moisture content, in which the hydraulic gradient is unity (i.e., 1), and there is a predominantly downward flow toward the water table; and
4. a capillary zone above the water table, in which the water moves in the groundwater flow direction.

This simplified zoning is complicated by the fact that irregularities (heterogeneities) in the soil profile such as root channels, earthworm burrows, soil fissures or cracks, spatially varying sediment size therefore exhibiting variable hydraulic and physical characteristics

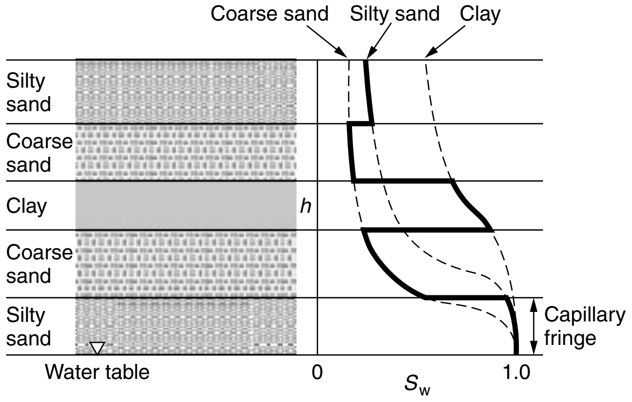

Figure 1. Saturated water content (S_w) above the water table for a layered sequence. Dashed lines represent water content for homogeneous sediments (from Reference 7, altered).

(see Fig. 1), and distinct layering allow preferential (i.e., faster) flow of water in selected areas. For instance, clay layers generally impede flow due to their lower saturated hydraulic conductivity, whereas sand layers have a lower tendency to retard the movement of infiltrating water. This process, which is also referred to as "fingering," can occur in less than a few percent and to up to 70% of the soil profile. Such layers generally retard water movement during infiltration. For the remainder of the soil profile, the entering moisture results in a semicontinuous wetting front, a zone of increased moisture content and a zone below of significantly lower moisture content. Beyond the wetting front, there is no visible penetration of water.

Infiltrating precipitation can appear as

1. retarded interflow discharging as surface runoff after a brief underground passage,
2. increased soil moisture, and
3. effective recharge.

The effective recharge can be measured by using lysimeters, but this requires a substantial effort. It is furthermore dynamic, changing constantly over time and space.

The measuring units are volume or m per time period. Infiltrating water also changes the moisture content of the soil. If rain infiltrates a previously dry soil (typical moisture content of less than 10% saturation), then the rainwater is first absorbed into the soil pores, increasing the moisture content. The soil gas in the soil profile needs to be replaced, and as a result the infiltration velocity is reduced initially. Later in the process when the soil gas dissolves gradually in the infiltrating water, the infiltration rate increases again before a renewed reduction occurs. This reduction is from increased solid particles washed into the soil profile from the rain and the growth of organisms near the soil surface. Additionally, the increase in soil moisture leads to a reduction in capillary pressure.

Snow and frost also impact the infiltration rate. In frost periods, soils of low initial water content may become porous, and the infiltration rate is increased. Soils of high initial water content may freeze and become nearly impermeable.

In detail, infiltration depends on material properties, such as

- grain size,
- porosity,
- capillary forces and soil suction,
- permeability, and
- fluid densities and viscosities.

MATERIAL DEPENDENCIES

Grain Size and Porosity

Unconsolidated materials are distinguished by their grain sizes. Various classifications exist, the grain sizes commonly decrease in the order block, cobble, gravel, sand, silt, clay, colloid, and ion. Clays are smaller than 2 μm, whereas colloids consist of particles less than 0.1 μm in size. On the other hand, gravels start at 2 mm. The distribution of soil grain size and bulk densities (often referred to as ρ) of soil and rock are commonly measured during geotechnical investigations.

With regard to water and contaminant transport, a critical parameter of vadose zone materials is the type and distribution of void spaces (pores). Loose materials contain widely distributed void spaces that typically are interconnected. These pores are usually individually very small, but numerous, and the total volume of pores usually varies from 30–50% of the total volume. However, not all of these pores are available for water circulation. A clay may exhibit a total porosity of >50%, however, only less than a few percent are available for water circulation. In contrast, in gravel sediments, almost all of the pore space (roughly 20% of the total volume) allows water transport.

As can be seen from Fig. 2, classifications exist for pore spaces. The largest pores are obviously present in the coarsest materials. Pores of the order of 60–1000 μm are present in sandy sediments. Small and smallest pores are present in clay grain size and below.

Also depicted in Fig. 2b is the approximate rate of water movement in meters per year. The coarser the sediments, the higher the rate of vertical water movement. It is, however, important to note that even in silts, the vertical water movement under unit gradient can be as high as 2 m per year.

Capillary Rise and Capillary Pressure

When water evaporates near the surface, it generates a low hydraulic potential, which is equilibrated by the capillary rise at the groundwater table. The rate at which this supply is determined is governed by the permeability (and size, respectively) of the sediments. Consequently, the height of the capillary fringe depends on the sediment's permeability, as Fig. 2a outlines. The water in the capillary fringe is held by capillary forces against gravity induced flow.

The capillary pressure (C_p, also named matrix or soil suction) for sands and silts can be estimated roughly from

$$C_p(\text{kPa}) = 0.3/\text{grain size (mm)} \quad (1)$$

The higher the soil suction, the higher the residual saturation of a sediment.

Soil–Water Characteristic Curve

The soil–water characteristic curve (also referred to as the water retention curve) for a soil is defined as the relationship between the water content and the capillary pressure. This curve is characteristic for each soil, it governs the rate at which water is taken up or released by the soil.

As can be seen from Fig. 3, when the water content decreases (i.e., the soil suction increases), the permeability of a sediment (here, a silty soil) decreases. The order of decrease depends on pore sizes. Sands have a much slighter decrease in permeability. Tight soils stay wet

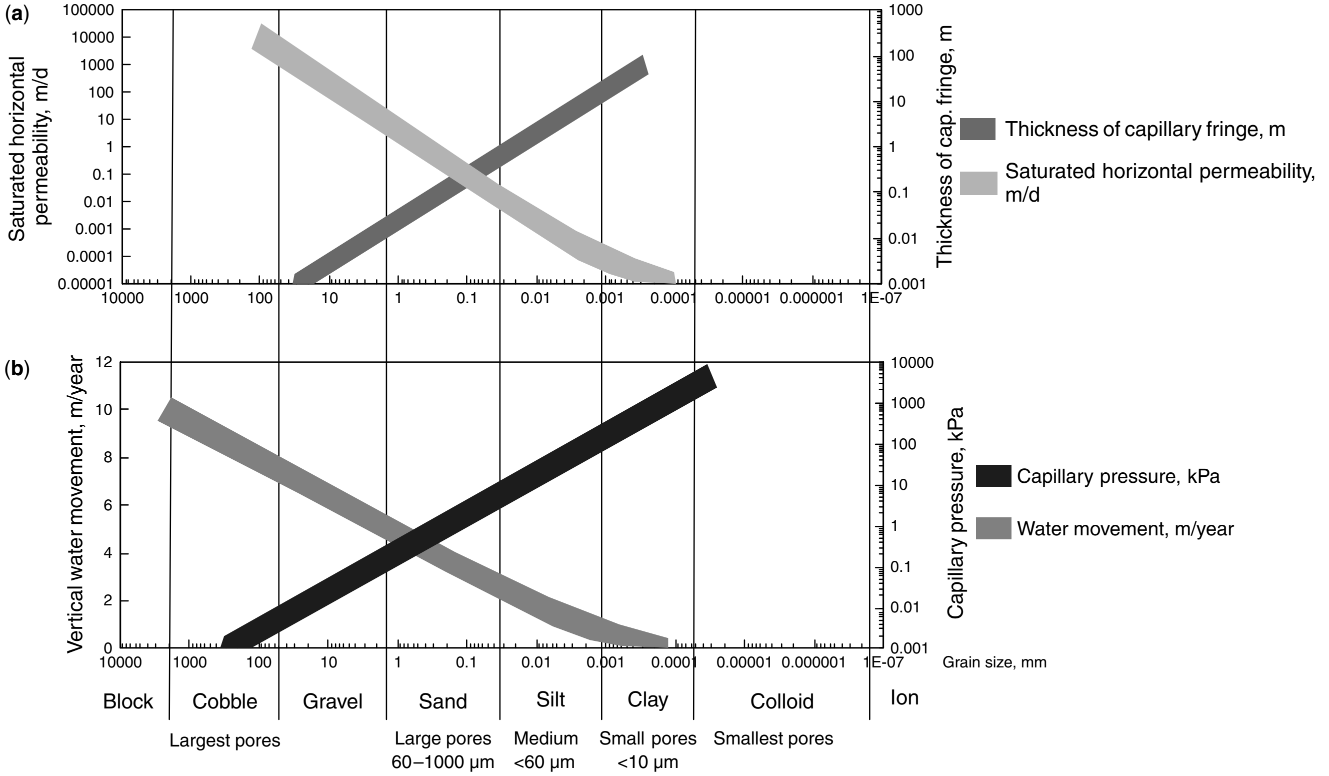

Figure 2. (**a**) Generalized diagram depicting the thickness of the capillary fringe and saturated horizontal permeability. (**b**) Generalized diagram depicting pore sizes, capillary pressure, and the vertical annual water movement rate of sediments.

for much longer, however, suffer much more from evaporative losses.

Figure 3 also introduces terms often used by soil scientists to describe the wetting and drying behavior of a soil. The term field capacity is used when the water content of a soil has reached a maximum (often referred to as Θ sat). Any further increase in soil moisture results in a water release (i.e., gravity induced flow). When the water content nearly equals its minimum, then the wilting point is reached. By definition, the wilting point equals a soil suction between 500 and 6000 kPa. A soil is referred to as "air dry" at or above a capillary pressure of 70,000 kPa. Furthermore, two terms are defined through this water retention curve: the air entry value and the residual water content. The air entry value is the meeting point of the two tangents shown in Fig. 3. The residual water content (referred to as Θ res) is defined similarly by using the lower tangent. Figure 3 further introduces a fundamental feature soils display when drying out or becoming wet (the hysteresis effect).

Hysteresis describes the effect of retardation of forces acting on a body to change (as if from viscosity or internal friction in magnetic induction and other physical phenomena). In soil science, when a soil is dried and then rewetted, the drying and wetting soil–water characteristic curves are not identical. The wetting curve is drier than the drying curve over a wide range of soil–water potentials. This hysteresis is caused by:

1. the drainage of an individual pore, which is controlled by the smallest radius. When the meniscus retreats under increasing tension, the pore's radius is decreasing. Rewetting (imbibition), on the other hand, is controlled by the pore's largest radius.
2. contact angle hysteresis. This is a well-recognized phenomenon, but it is only significant at relatively high flow rates. The slower the process, the less contact angle hysteresis. Because drainage and rewetting curves are generally measured at slow ("quasi-equilibrium") rates, this is not likely to be an important contributor.
3. Air entrapment effects. During imbibition, air can become trapped inside the larger soil pores. Given sufficient time, the entrapped air bubbles slowly dissolve in the water and cause hysteresis

Determining the Soil–Water Characteristic Curve. The most commonly used direct way to measure the soil–water potential is with a tensiometer. A body of pure water is hydraulically connected to the soil water via a permeable ceramic cup. If the soil water is under tension, then a small fraction of water in the tensiometer is pulled out, lowering the pressure inside. This negative pressure can then be measured by a gauge or pressure transducer.

Alternatively, mathematical models can help in determining the soil–water characteristics of a soil.

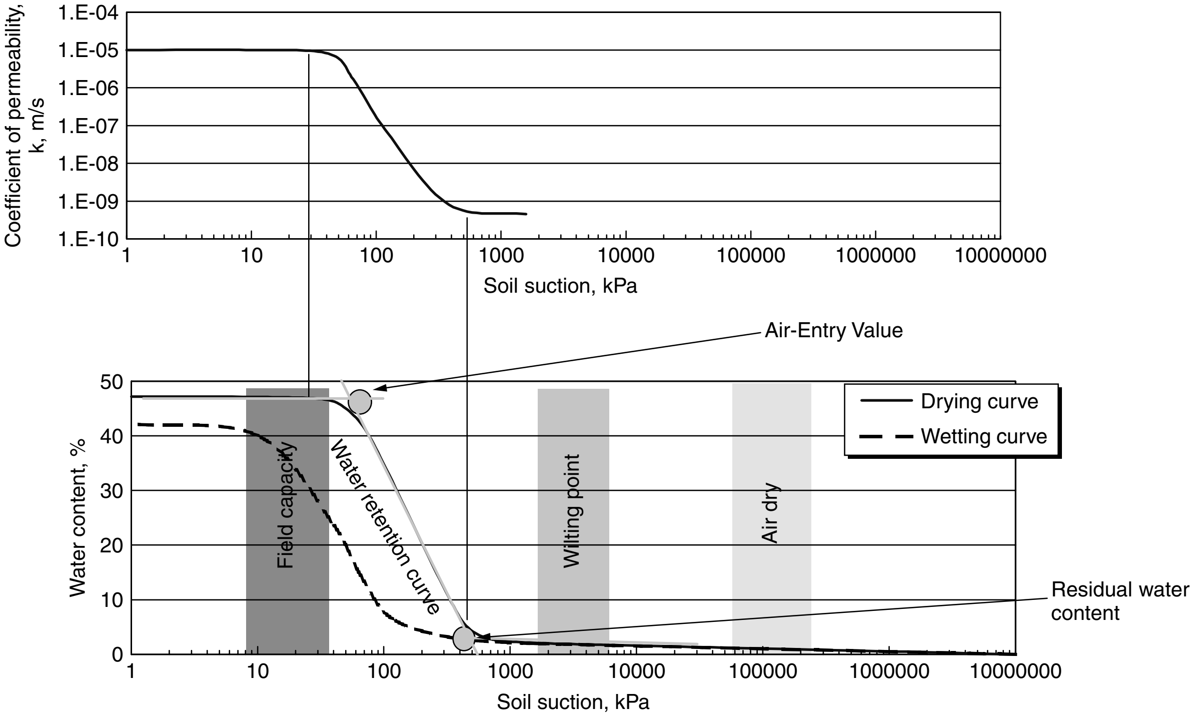

Figure 3. Visualization of the relationship between the permeability function and the soil water characteristic curve (from Reference 8, altered).

Hydraulic Conductivity

The basic formula to determine hydraulic conductivity was first developed by Henry Darcy in 1856 when he determined that the flux of water in sand columns depends on hydraulic conductivity and the hydraulic gradient. It can further be shown that hydraulic conductivity depends on both the water and the porous media properties according to

$$K = \frac{k\varphi g}{\mu} \tag{2}$$

where μ = viscosity,
ϕ = density
g = acceleration of gravity
k = intrinsic permeability of the soil (independent of fluid).

The intrinsic permeability is generally a function of the porous media, and it is proportional to the square of the grain diameter, $k \sim d^2$. Consequently, capillary pressure depends on the soil's conductivity:

$$Cp \sim 1/\sqrt{K} \tag{3}$$

This relationship is commonly used in numerical modeling studies to scale the magnitude of the capillary pressure curves in the absence of direct measurements of capillary pressure.

Measurements of Hydraulic Conductivity. The hydraulic conductivity of an aquifer with respect to water can be determined by a variety of field tests, including pumping tests from groundwater monitoring wells, slug tests, and other indirect measurements like grain-size distribution. In vadose zone studies, tensiometers are used for determining the field capacity of a soil.

FLOW PROCESSES IN THE VADOSE ZONE

Two processes control water in the vadose zone. The first is gravity, which moves water downward. The second is a capillary process that, similar to water dripped slowly on a sponge, moves water in all directions and stores and releases it. The capillary process is controlled by the nature of the sediment and rock and the pores and fractures within it. In most cases, capillary processes are dominant in fine-grained sediments (clay, silt, and the like), whereas gravity is dominant in coarse-grained sediment and large fractures. Pores and fractures can be completely filled with water in places within the vadose zone. These saturated portions of the vadose zone are typically referred to as "perched water" or "capillary fringe," depending on where they occur. At most sites, the water content is changing over time throughout the system representing a dynamic system.

Once saturation is continuous, this groundwater moves through the system from the highest potential to the lowest. Numerical modeling studies show that a range of infiltration patterns occur, which can be related to the ratio of infiltration rate to unsaturated hydraulic conductivity. A high value of this ratio reflects a prevailing hydraulic conductivity, which cannot readily redistribute the newly infiltrated moisture. Moisture accumulates in the near-surface region before advancing down through the soil as a distinct wetting front. In contrast, low values of the ratio of rainfall to unsaturated hydraulic conductivity show minimal moisture accumulation, as the relatively small volumes of infiltrating moisture are readily redistributed through the soil profile.

MODELS

Accurate *in situ* measurement of unsaturated hydraulic conductivity is cumbersome and time-consuming. One alternative to direct measurement of unsaturated hydraulic conductivity is to use theoretical methods, which predict the conductivity from more easily measured soil water retention data. Methods of this type are generally based on statistical pore-size distribution models, a large number of which have appeared in the soil science and petroleum engineering literature during the past several decades (see Reference 9 for a review). Implementation of these predictive conductivity models still requires independently measured soil–water retention data. Measured input retention data may be given either in tabular form or by closed-form analytical expressions, which contain parameters that are fitted to the observed data.

Water flow in variably saturated soils is traditionally described by the Richards equation:

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z}\left\{K(\theta)\frac{\partial h}{\partial z}\right\} + \frac{\partial K(\theta)}{\partial z} \qquad (4)$$

where h is the soil water pressure head (or fluid pressure with dimension L), θ is the moisture content [−], t is time (T), z is soil depth (L), and K is the hydraulic conductivity [LT−1]. The solution of the Richards equation requires knowledge of the unsaturated soil hydraulic functions $\theta(h)$ and $K(h)$ or $K(\theta)$.

Several equations have been proposed to describe the soil–water retention curve near saturation. Most of these functions are mathematically too complicated to be easily incorporated into predictive pore-size distribution models for hydraulic conductivity. A smooth function with attractive properties is the equation of van Genuchten (10):

$$S_{\mathrm{eff}}(h) = [1 + (ah)^{n}]^{-m} \qquad (5)$$

where a, n, and m are empirical constants affecting the shape of the retention curve (i.e., curve fitting parameters). Another mathematical solution is provided by Brooks and Corey (11).

Various computer programs exist to model unsaturated soil properties, including (but not limited to)

William J. Blanford
Louisiana State University
Baton Rouge, Louisiana

INTRODUCTION

Monitoring fluids of the vadose zone has multiple motives, including detecting contaminants, measuring soil properties and water conditions for construction or monitoring geologic hazards, and determinations of water saturation that may be used for optimizing irrigation. Because fluids must move through the vadose zone to reach the water table, monitoring of the vadose zone allows predicting possible sources and processes of groundwater contamination. Geologic hazards such as landslides, rising water tables, or land subsidence can be partially predetermined by monitoring the vadose zone. And in agriculture, monitoring soil water content to irrigate most efficiently has a long history.

Monitoring the temporal and spatial variance in the vadose zone is vitally important to engineers, geologists, meteorologists and other environmental scientists interested in studying water and contaminants. There are many techniques that directly or indirectly assess water content, sorbed mass, gaseous and liquid contaminants, flow direction, and other parameters that may be monitored. The methods discussed here are divided into two categories, direct and indirect monitoring techniques. Direct monitoring techniques require a degree of sampling or large-scale soil disturbances. Conversely, indirect techniques are analogous to remote sensing in which no disturbance to the soil or water is required, although a well may be required in some techniques. This section discusses in short detail some of the attributes and shortfalls of most of the currently used techniques for monitoring the three phases of the vadose zone: liquid, soil, and gas. For a more in-depth understanding, readers are directed to the references listed after each entry.

INDIRECT MONITORING METHODS

Indirect methods for monitoring the vadose zone commonly have links to geophysical tools, principles, and techniques. Many vadose zone characteristics such as water content, the presence of contamination, and flow direction, among others may be determined without soil sampling. These techniques may also be used to determine the nature and extent of soil stratification for site delineation.

In practice, these methods are generally nonintrusive and do not require disturbing the soil, but some require well installation. When drilling or augering is necessitated, proper techniques must be ensured so that mud linings, drilling fluids, or other drilling by-products do not affect hydraulic conductivity, which may then affect measurements. It is also important to clean any grease or oil from drilling tools to avoid contamination and to clean tools between use.

Tension Infiltrometers

Tension infiltrometers are used to characterize hydraulic properties of saturated and partially saturated porous media, including saturated and unsaturated hydraulic conductivities. Infiltrometers are commonly used to measure hydraulic conductivity as a function of matrix potential in partially saturated porous media, sorptivity, steady-state volumetric flow rate (Q), and water content (Fig. 1).

There are variations of the disk infiltrometer and multiple methods of measuring hydraulic properties using infiltrometers, but all consist of three basic parts: the bubble tower, the reservoir, and a porous baseplate. The porous base plate lies flat on a wetted soil surface, and both the bubble tower and reservoir are connected perpendicularly to it. The purpose of the baseplate is to establish hydraulic contact between the soil and the reservoir. A thin layer of moist sand may be placed under the baseplate to ensure better hydraulic conductivity between it and the soil. The reservoir supplies water to the baseplate and the bubble tower; the latter consists of a series of tubes that relieve the vacuum in the reservoir when water infiltrates into the soil. Tension measurements correspond to the level of the water in the reservoir. An important point to note is that hydraulic conductivity must exist between the baseplate and the wet porous media for the device to operate.

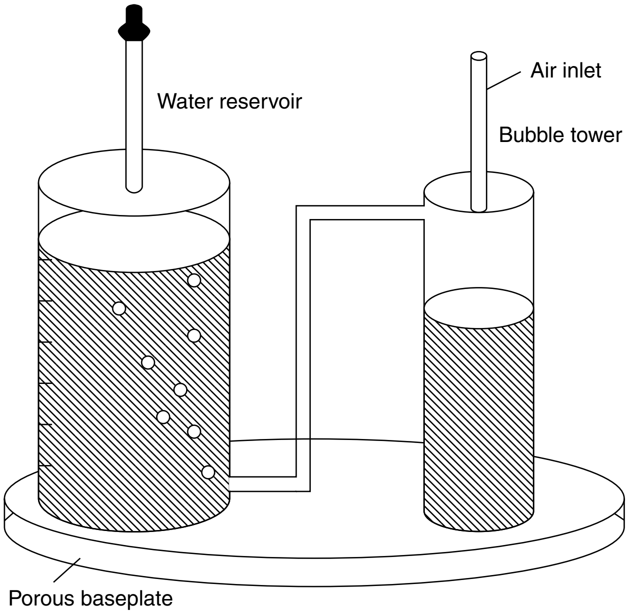

Figure 1. Tension infiltrometer. Tension measurements may be made using a handheld tensiometer on nongraduated models or on the side of graduated models (pictured).

The main advantage of disk infiltrometers is that *in situ* measurements of vadose zone hydraulic properties are rapid, reliable, and replicable and the devices are inexpensive and easy to operate. There exists, however, a limited range of tensions (generally 0 to 25 cm below the ground surface (BGS) in which the infiltrometers can operate, and measurements can be made only at the soil surface unless trenches are dug to the desired measurement level and the device used (1–3). Ideal soil properties are also assumed (soil is uniform, homogenous, and nonswelling), and pore closure may result from the weight of the device if used on freshly cultivated soils. There are other limitations that may be observed in Hussen and Warrick (4).

Neutron Moisture Probe

Initially designed for the agricultural industry, the neutron moisture probe has been adapted to environmental monitoring to obtain soil moisture levels. It is a nondestructive method of obtaining soil moisture levels when the probe is inserted in a well. The only restriction to depth of use is the length of the well used and the probe cord length.

Once lowered down a well, the probe begins to emit neutrons. The velocity at which neutrons return to the probe is correlative to the substance by which they were reflected. Neutrons reflected by heavy atoms of the soil matrix return with higher velocities compared to those of neutrons reflected by lighter hydrogen atoms. Hydrogen may be found in organic matter or in mineral lattices, but water is the greatest source of hydrogen in the subsurface. Due to this, the counts of reflected low-velocity neutrons are correlative to soil moisture content. A complete moisture stratification along the length of a well may be obtained, given a well-calibrated instrument.

Attributes of the neutron probe include ease of use and high accuracy, given a well-calibrated probe. It may be operated by one person, and soil moisture changes of the order of 1–5 volume % may be measured. Water flow pathways may also be located with the instrument. The largest drawback of the neutron moisture probes lies with calibration difficulties that may be extreme. Improper neutron probe calibration nearly renders the probe useless. Ideally, the probe is calibrated using soils collected in a drum with a known quantity of water from the field site of interest. Another drawback is that neutron probes cannot distinguish between water and other substances with similar hydrogen densities in the subsurface, such as gasoline. Problems of applying single calibrations to multiple media types also arise, which is the case in heterogeneous soils. Inaccuracies may also be result from improper well packing and the presence of certain elements, such as migrating boron or chlorine. Finally, care should be taken to mitigate exposure to the neutron source (5–8).

Psychrometers

Psychrometers represent another tool adapted from the agricultural industry for environmental monitoring. Estimation of the hydraulic gradient using the matric suction, osmotic potential, and water vapor potential are possible.

The generic class of instruments used to measure relative humidity using both wet and dry bulb thermometers are called psychrometers; they may be used for both surface (agriculture) and subsurface (environmental) applications. For the latter, they are placed in a small diameter well and surrounded by silica flour or air-filled packers. A dry bulb thermometer is employed to measure the ambient temperature, and a wet bulb thermometer is then used to measure the temperature decrease resulting from fluid evaporation in the subsurface (evaporative cooling). Liquid-filled thermometers are not accurate enough for the precision required, however, and thus more precise thermocouple thermometers are employed. The junction of two wires, a thermocouple, generates an electrical current that is a function of the junction temperature. The temperature of the thermocouple determines the activity of the water surrounding it, which is then correlated with the evaporation rate.

The direction and magnitude of water and contaminant migration may be observed easily and inexpensively with psychrometers, but regular calibration and monitoring of the thermocouple are necessary as temperature deviations of $\pm 0.001\,^\circ\mathrm{C}$ between the thermocouple and the liquid phase can introduce significant errors. Regular calibration is necessary due to corrosion of metals and the accumulation of salts on the thermocouple junction. Also, psychrometer equations assume that water is the first liquid to condense, and, at a site containing volatile liquids, this may not always be true (9,10).

Tensiometry

Tensiometers measure the force which holds water to the soil, or the soil–water potential, at shallow depths (0 to 8 m BGS). Because water moves from areas of high potential energy to low, evaluation of water's energy may be used to estimate the direction of water flow and the direction of contaminant plume migration. Rapid measurements at different locations may be obtained with tensiometers, which may then be plotted to obtain a spatial distribution of water and an estimation of the water flow direction.

A tensiometer measures matric potential using a porous ceramic cup placed in the soil, a connecting tube, and a vacuum gauge. The cup and tube are filled with water to provide hydraulic contact from the tensiometer to the water in the soil. Once placed in the ground, water flows out of the cup and into the soil until equilibrium is reached. Because the device is sealed from the atmosphere, the drop of the water level in the tube creates a vacuum which is measured by a vacuum gauge or pressure transducer from the surface.

Tensiomenters represent a low-cost, simple, and accurate measurement of matric potential (11–13). It is one of the most widely used devices for monitoring soil moisture levels in the vadose zone, though tensiometry values are limited to tension values below 0.85 bar at atmospheric pressures near 1 bar. For field applications, air coming out of solution from water or air trapped in the tube are the major shortcomings. During installation, care must be taken to ensure good hydraulic contact between the cup and the soil.

Time-Domain Reflectometry

Time-domain reflectometry (TDR) allows shallow, rapid, *in situ* measurements of water content and electrical conductivity in porous media (14–17). It is commonly used to locate underground cables. It is a relatively new development in vadose zone monitoring that was first described by Topp et al. (18). Accuracy within 1–2% of volumetric water content is feasible with TDR.

TDR uses a probe that is inserted into the soil equipped with 2 or 3 metallic rods that transmit electromagnetic pulses. The travel time of these pulses across the rods through the soil is used to compute the soil's bulk dielectric constant from which the water content is inferred, which provides an average soil water content over the depth of probe insertion.

The main advantage of TDR is that simple and rapid accumulation of shallow soil moisture content with high volumetric accuracy is possible. Calibration requirements are minimal compared to other indirect monitoring methods, and measurements for spatial and temporal analyses are easily obtained. The drawbacks associated with TDR include temperature-dependent readings and probe insertion in rocky or hard substrates because readings are limited to depth of insertion. Additionally, water molecules bound by interfacial forces in high surface area substances, for example, clays, result in lowered bulk dielectric constant compared to other soils at similar water content.

Ground-Penetrating Radar

Ground-penetrating radar (GPR) is an adaptation of seismic reflection for shallow use that images subsurface features by deploying radar waves. It may be used to image any homogeneity in the vadose zone, including contaminant plumes and soil stratification.

GPR is used to observe the electromagnetic impedance of soils using high-frequency radar waves to measure subsurface properties. It consists of an enclosed wave emitter and antenna unit that is dragged across the ground, generally in a grid pattern. Wave pulses are emitted and when an inhomogeneity is encountered, part of the incident energy is reflected back to the radar antenna within the unit. The reflected signal is amplified and transformed into a viewable image. The data are in visual form, not a quantified form, so results must be interpreted.

Any inhomogeneity in the vadose zone can be imaged with GPR. For vadose zone monitoring, contaminant plumes of both light nonaqueous phase liquids (LNAPLs) and dense nonaqueous phase liquids (DNAPLs), as well as buried utility lines and pipes may be imaged with GPR. Additionally, both underground storage tanks (UST) and leaking underground storage tanks (LUST) may be imaged and discerned. The most obvious drawback to GPR, however, is the fact that all data must be interpreted from visual images. Heterogeneities are viewed as anomalies in imaged data, which must be deciphered according to available information on subsurface conditions. Due to this fact, GPR benefits from use in combination with other vadose zone monitoring techniques to avoid misinterpretations (19,20).

Electrical Resistance Blocks

Electrical resistance blocks have been used in agriculture for more than 50 years to measure soil moisture in dry areas. In the environmental field, they are employed where other methods, including tensiometers, lysimeters, and manometers, are not operable due to low soil–water tension, generally between 0.5 and 15 bars.

The method consists of two or more electrodes that are placed in a porous block, commonly made of gypsum. The block is buried in the soil and allowed to remain until moisture equilibrium with the native soil is achieved. Changes in the electrical properties of the block, measured with the electrodes, reflect changes in the water content, which are measured with a wheatstone bridge resistance meter.

The benefits of this technique include low-cost, extensive historical use in agriculture research, and simplicity of use. It is generally useful for approximate soil moisture level changes. The disadvantages include limited historical use in the environmental industry and measurement and calibration difficulties at wet soil moisture potentials. Standard calibration curves exist, but as in many indirect techniques, soil-specific calibration of the instrument is recommended. Other limitations are associated with dissolution of the gypsum block and salinity changes in vadose zone water.

DIRECT MONITORING METHODS

Direct monitoring methods, in contrast to indirect monitoring methods, employ sampling of the vadose zone for liquid, soil, or gas. Obtaining liquid samples is fairly straightforward, using the most widely practiced method, suction lysimeters, but techniques for soil and gas sample acquisition are generally more complicated. Soil sampling commonly involves trenching or digging of some sort, which may be subject to Occupational Safety and Health Administration (OSHA) guidelines (24). Trenches deeper than 5 feet are subject to OSHA regulations and diggings deeper than 20 feet require the approval of a professional engineer. Soils are also subject to maximum allowable slope protocol, depending on their nature. In addition, certain cases may require confined space, heavy machinery, or decontamination permits. Readers are referred to OSHA literature for proper digging protocol. In gas sampling, problems stem from the nature of the phase being sampled, and, to a lesser extent, safety concerns. Vadose zone gas readily exchanges with any other gas with which it comes in contact, and thus samplers must be fully enclosed. Special safety procedures are required when considering volatile substances, such as methane.

Additionally, direct monitoring methods have a much higher risk of introducing contamination into the aquifer or exposing workers to contamination, and thus proper field procedures are absolutely necessary. In contaminated areas, all equipment must be constructed of nonreactive and low sorbing materials and be decontaminated between each use (25–27).

Direct Liquid Monitoring Techniques

Directly monitoring the liquid phase of the vadose zone involves obtaining a representative sample, whether in the form of water or NAPL. These may be important for soil–water chemistry analyses or contaminant plume delineation, among others. The primary method of collection is by using suction lysimeters placed into unconsolidated soil. As a suction device, lysimeters rely on applying a vacuum greater than the soil–water tension to draw a water sample up to the surface. A porous cup is inserted into the soil or in a shallow well, and a vacuum tube connects it to the surface. Once the vacuum is applied, water is drawn to the surface and a sample is obtained. Outside of lysimeters, other methods involve driving devices into unconsolidated sediment or lowering devices down wells above the water table to acquire liquid samples. Lysimeters have the advantage of being relatively cheap and simple to install. Virtually no maintenance is required, although sample volumes may be small.

Described by Gardner (28), wavelengths of light from gamma to X ray may be used to monitor the water content of the vadose zone by direct soil sampling. In practice, however, only gamma rays are employed. In this method, a sample is collected and a narrow beam of gamma radiation is sent through it. A recorder on the opposite side of the sample records only those rays that passed freely through the sample with no reflection along the way. By this method, the volumetric water content can be measured (29).

Direct Soil Monitoring Techniques

Due to the sorbing nature of many contaminants, soil samples are used to monitor the spatial and temporal distributions of contaminants in the soil. For certain applications, undisturbed samples are desired, in which case special precautions must be taken, and certain sampling tools and techniques must be employed. Generally, soil sampling involves inserting a device into the ground to recover a soil sample, although more intensive methods may be necessary in certain situations. Hand-operated samplers are typically used for shallow sampling and mechanically powered devices for deeper sampling. There are five basic hand-operated samplers, as described by Dorrance et al. (30), that include screw augers, barrel augers, tube samplers, hand-powered augers, and bulk samplers (shovels, etc). Each type has its own pros and cons depending on cost, ease of use, availability, size of matrix grains, degree of sediment cohesiveness, and other factors. Due to these, sampler choice is often site specific. For deeper monitoring applications, mechanically powered tools such as a drill rig must be employed.

Direct Vadose Zone Gas Monitoring

Monitoring the gas phase of the vadose zone is important because many contaminants volatilize to a significant degree. Unlike liquid and soil phases, the gaseous component of the vadose zone is problematic because atmospheric air and foreign vadose zone gases readily exchange and react upon exposure. When sampling, all gaseous vadose zone samples must avoid exposure to foreign air, and all sampling methods must be designed to avoid it. *In situ* sampling and devices with internal liners designed to seal samples from the atmosphere are preferred (31).

Monitoring through sampling the gas phase typically involves hydraulically ramming a specially designed device into the soil where it collects samples via a vacuum and pumps them to the surface for collection. Passive gas sampling by an *in situ* absorbent, such as an activated carbon trap placed in the vadose zone, may be used, but less information is provided by this method. Direct sampling of gases is more desirable, but it is more difficult and costly. An alternative is monitoring gas advection by using groundwater tracers. A tracer that partitions to the gas phase is injected, samples are taken at other sites, typically at wells, and analyzed for the tracer concentration (32–35).

VAPOR TRANSPORT IN THE UNSATURATED ZONE

Fred D. Tillman
U.S. Environmental Protection Agency
Athens, Georgia

James A. Smith
University of Virginia
Charlottesville, Virginia

INTRODUCTION

The term "vapor" describes the gaseous phase of a substance that is normally a liquid or solid at standard atmospheric pressure and temperature. Examples of vapors that are important in environmental systems include humidity (water vapor), gasoline vapor, and solvent vapor. Soil and groundwater that are contaminated by organic solvents and fuel hydrocarbons may emit vapors that can move through the subsurface and reach the land surface. Human exposure to these harmful vapors has become an increasingly important topic in the evaluation and remediation of contaminated soil and groundwater. The potential for inhalation of vapors transported from a groundwater plume to the interior of buildings often controls the outcome of a risk based corrective action (RBCA) analysis (1). Additionally, vapors emanating from subsurface contamination contribute to the reduction of contaminant mass and may provide a beneficial mechanism of natural attenuation at sites where there are no human receptors. Subsurface processes affecting the transport of organic vapors through the soil above the water table (here defined as the unsaturated zone) may slow, reduce, or enhance the release of these vapors to potential receptors at the land surface. A careful investigation of organic vapor transport in the unsaturated zone is therefore important in assessing the potential for natural attenuation and the impact of even deep contamination on receptors at the land surface. This article describes potential sources, fate and transport, and measurement of organic vapors in the unsaturated zone. Although this article deals exclusively with organic vapors, many of the fate and transport properties discussed are also applicable to other vapors, including metals and moisture.

SOURCES OF ORGANIC VAPORS

Contaminants of concern in vapor transport in the unsaturated zone are typically volatile organic compounds (VOCs), although vapors emanating from inorganic sources such as mercury vapor may be of concern as well. A chemical is considered volatile if its Henry's law constant is 1×10^{-5} atm-m^3/mol or greater (2). Examples of VOCs that are important in impacted environmental systems include chlorinated solvents such as carbon tetrachloride, tetrachloroethylene, and trichloroethylene (and their degradation compounds), fuel hydrocarbons such as benzene, toluene, ethylbenzene, and *o*,*m*,*p*-xylenes as well as volatile pesticides such as chlordane, aldrin, and lindane. The U.S. Environmental Protection Agency lists 107 compounds whose toxicity and volatility produce a potentially unacceptable inhalation risk to receptors (2). These VOCs can be released into the subsurface environment from leaking landfill liners, improper disposal, accidental spillage, or leaking storage tanks (LSTs). Once in the subsurface, these compounds can become bound to the soil matrix, dissolved in groundwater (or soil water), and/or exist as a separate, residual phase known as a nonaqueous phase liquid (NAPL). Soil, aqueous, and NAPL-phase organics may all be sources of organic vapors in the subsurface. Therefore, organic vapor transport in the unsaturated zone requires understanding of interphase mass-transfer processes because the contaminant can be distributed among soil gas, water, soil, and NAPL phases. In modeling organic vapor transport, the equilibrium vapor concentration at the source of contamination is often estimated from the following relationships (3):

Soil contamination:

$$C_{\text{source}} = \frac{H_{\text{TS}} C_{\text{R}} \rho_{\text{b}}}{\theta_{\text{w}} + K_{\text{d}} \rho_{\text{b}} + H_{\text{TS}} \theta_{\text{a}}} \quad (4) \qquad (1)$$

Groundwater contamination:

$$C_{\text{source}} = H_{\text{TS}} C_{\text{w}} \qquad \text{Henry's Law} \qquad (2)$$

NAPL contamination:

$$C_{\text{source}} = \frac{x_i p_i \text{MW}_i}{RT} \qquad \text{Raoult's Law} \qquad (3)$$

where C_{source} is the vapor concentration at the source of contamination (ML^{-3}), H_{TS} is the dimensionless Henry's law constant at the system temperature (unitless), C_{R} is the soil concentration (MM^{-1}), ρ_{b} is the soil dry bulk density (ML^{-3}), θ_{w} is the soil water-filled porosity (L^3L^{-3}), θ_{a} is the soil air-filled porosity (L^3L^{-3}), K_{d} is the soil–water partition coefficient (L^3M^{-1}), C_{w} is concentration of the contaminant in the groundwater (ML^{-3}), x_i is the mole fraction of component i in the NAPL mixture (unitless), p_i is the vapor pressure of component i at the soil temperature ($\text{ML}^{-1}\text{T}^{-2}$), MW_i is the molecular weight of component i (M), R is the ideal gas constant ($\text{ML}^2\text{T}^{-2}\text{T}^{-1}\text{M}^{-1}$, e.g., 8.314570 $\text{J}^{\circ}\text{K}^{-1}\ \text{mol}^{-1}$), and T is the soil temperature (T). Both Henry's law constant and vapor pressure rise with temperature for organic compounds of interest, so a higher source vapor concentration is expected from higher soil and groundwater temperature.

TRANSPORT AND FATE OF ORGANIC VAPORS IN THE UNSATURATED ZONE

Organic vapors emanating from contaminated soil or groundwater or from a residual phase such as gasoline floating on the water table may move through unsaturated zone soil gas by diffusion or soil-gas advection due to pressure or density gradients or a combination of these processes.

Diffusion

Molecular diffusion is the spreading out of compounds from random collisions resulting from thermal motion of atoms. These collisions may be between molecules themselves or between molecules and their surroundings. Under most environmental conditions, molecular diffusion in natural systems proceeds from locations of higher concentration toward locations of lower concentrations. In a typical scenario, organic vapors above a contaminated water table (high concentration) diffuse toward the land surface (lower concentration). The well-known relation describing the diffusion of a compound across a unit of cross-sectional area is Fick's first law:

$$F_{\text{x}} = -D^{\text{eff}} \frac{dC}{dx} \qquad (4)$$

where F_{x} is the mass flux [$\text{ML}^{-2}\text{T}^{-1}$], D^{eff} is the effective diffusion coefficient of the compound in the gas phase [L^2T^{-1}], and dC/dx is the concentration gradient of the compound in one dimension [$\text{ML}^{-3}\text{L}^{-1}$]. From this equation, it is apparent that the rate of molecular diffusion in the gas phase depends on the concentration gradient and the effective diffusion coefficient of the compound of interest. Several relations relate the effective diffusion coefficient to the free-air diffusion coefficient of the compound and the total and air-filled porosities of the diffusing media (5–14). An increase in diffusive flux is seen in soils with greater air passageways (i.e., greater porosities and air-filled porosities). Therefore, in a layered unsaturated zone, vapor diffusion from depth to the land surface is limited by the wettest, least porous soil layer. Because free-air diffusion coefficients are compound dependent, ranging from $2.5 \times 10^{-3}\ \text{cm}^2\ \text{s}^{-1}$ for hexachloroethane to $2.71 \times 10^{-1}\ \text{cm}^2\ \text{s}^{-1}$ for chloroethane among the 107 volatile compounds of concern to the U.S.EPA (2), different chemicals diffuse at different rates under the same concentration gradients. Increased temperature also produces an increased free-air diffusion coefficient, leading to a greater rate of diffusion relative to the same system at lower temperatures. Fick's First Law may not sufficiently describe vapor diffusion in systems where pore sizes are very small (Knudsen diffusion) and when volatile species constitute a substantial fraction of the total soil-gas concentration (nonequimolar diffusion) (15–17). In these situations, it may be necessary to employ the Stefan–Maxwell equation.

Advection

The flow of soil gas (advection) in the subsurface may be caused by gas-pressure gradients or, in certain cases, gas density gradients. Pressure-driven advection is produced when differences in soil-gas pressure form, causing soil gas to flow and carrying any vapors present with it. Air pressure gradients in the subsurface of natural systems may result from several phenomena. As diurnal or weather related atmospheric pressure cycles occur at the land surface, pressure waves are transmitted into the unsaturated zone and air may flow in response—a process known as "barometric pumping." Barometric pumping may cause soil gas to flow either toward the land surface carrying soil vapor or away from the land surface bringing in fresh atmospheric air (13,15,18–25). The underpressurization of an overlying building will produce gas pressure differences in subsurface soils. This underpressurization may be caused by thermal differences between indoor and outdoor air (stack effects), wind loading on the building superstructure, and unbalanced building ventilation (26,27). Soil-gas pressure gradients may also be produced by a rapidly rising or falling water table, as in coastal zones (28), or through the buildup of gas pressure from decomposing organic matter inside a landfill (29). Finally, natural temperature differences between warmer deep and cooler shallow soil gas will cause soil gas to rise (30,31). Density-driven flow of organic vapors may occur in the vicinity of residual-phase organic compounds whose saturation gas densities are greater than that of air. As organic liquids with high vapor pressures and molecular weights volatilize, the density of the soil gas surrounding the liquid changes. In almost all cases, organic liquids have molecular weights that are greater than air, so the resulting density-driven flow is in a downward direction and is proportional to soil permeability and density differences between the vapor and air (32–34). Organic compounds for which density-driven advection may be significant include methylene chloride, 1,2-dichloroethylene, 1,1,1-trichloroethane, carbon tetrachloride, and 1,1-dichloroethane, among others (32–34).

Sorption

As organic vapors move through the unsaturated zone by diffusion and advection, they come in contact with soil moisture, infiltrating rainwater, and the soil matrix itself. Each of these interactions may affect the concentration of the contaminant in the soil gas. Depending on the compound, organic vapors may adsorb to soil grain surfaces or partition into soil organic matter (35–40). Adsorption of relatively nonpolar organic vapors is suppressed by high humidity in the subsurface because as polar water molecules can effectively out-compete organic vapors for mineral-surface adsorption sites (41,42). For these high-humidity conditions, sorption may be limited to organic vapor partition into soil organic matter (41,42). Soil moisture trapped in unsaturated-zone pore space or infiltrating rain water may also sorb organic vapors to varying degrees (43,44). Finally, gas-phase organic compounds may adsorb to the air–water interface in unsaturated zones (45,46). Each of these sorption processes may act as both a source and a sink of organic vapors in the unsaturated zone.

Biodegradation

Under favorable conditions, organic vapors in the unsaturated zone that partition into soil moisture may be biodegraded by indigenous bacteria in oxidation/reduction reactions. The aerobic biodegradation of petroleum hydrocarbons requires an abundant oxygen supply as well as necessary nutrients of nitrogen and phosphorus (47–51). When oxygen is depleted, other possible electron acceptors for biodegradation of petroleum hydrocarbons include nitrate (NO_3^-), iron oxides (e.g., $Fe(OH)_3$), sulfate (SO_4^{2-}), and carbon dioxide (CO_2) (48). Lightly chlorinated compounds (e.g., chlorobenzene, dichlorobenzene) may be biodegraded under aerobic conditions. The more highly chlorinated hydrocarbons are recalcitrant to aerobic biodegradation but may undergo direct or cometabolic anaerobic reductive dechlorination. Reductive dechlorination has been observed to be most effective under sulfate-reducing and methanogenic conditions (52). In direct reductive dechlorination, the chlorinated hydrocarbon is used as an electron acceptor and the bacteria gain energy and grow as a result of the reaction (53). In cometabolic reductive dechlorination, enzymes produced during microbial metabolism of another hydrocarbon fortuitously reduce and dehalogenate the chlorinated contaminant. For either reductive dechlorination process to be successful, a primary substrate (electron donor) such as soil organic matter, lactate, acetate, methanol, or glucose is necessary (54).

VAPOR SAMPLING AND FLUX MEASUREMENT

Organic vapors in the unsaturated zone above contaminated soil or groundwater are typically sampled to provide evidence of biodegradation (49,55), calibrate vapor flow and transport models for estimating natural attenuation (23), or to estimate the region of contaminated groundwater (42,56,57). Soil gas is often sampled through low volume, inert pipe or tubing penetrating the subsurface to the desired sampling depth (42,44,49,56,58,59). This tubing can be installed with the help of a Geoprobe®-type device or inserted in a previously drilled borehole. The sampling portion of the tubing must be sealed from the atmosphere and other sampling depths to prevent preferential flow down the borehole during sampling. Samples may be collected from these vapor probes in various ways, including direct syringe withdrawal (49), pumping of soil gas into Tedlar® bags (57,60,61), or pumping of soil gas through adsorbent traps (58,62,63). Analyses of samples collected by syringe withdrawal require on-site analysis. Samples collected in Tedlar® bags or onto adsorbent traps may be transported to an off-site laboratory for analysis. Alternatively, there are field-portable gas detectors and gas chromatographs with flame-ionization and photoionization detectors capable of measuring real time hydrocarbon concentrations (47,57,64).

Efforts to measure the flux of VOCs from the unsaturated zone to the atmosphere at the land surface have included using the aerodynamic method, which necessitates the measurement of trace concentrations and atmospheric conditions such as wind speed, temperature and pressure (65); using groundsheets sampled through a nylon sampling tube (66); and several chamber designs (58,59,67–71). Surface measurements of vapor flux are important because they provide a direct measurement of total natural flux that can be used to estimate volatilization rates for a field site. This natural attenuation process for contaminants in soil and groundwater may be significant, and, at times, approach the removal rate of active remediation systems (58). Complexities involved in the measurement of vapor transport from the subsurface to the atmosphere include possible preferential flow paths (e.g., underground utilities, macropores, etc.) and spatial and temporal variability in vapor concentrations. Spatial variability may be produced by subsurface heterogeneities that are geologic as well as constructed barriers (e.g., storm drains, basement foundations). Temporal variability in vapor concentrations is produced by changing soil moisture content, temperature, and gas-pressure gradients.

SUMMARY

Analysis of the transport of organic vapors in the unsaturated zone is fundamental in evaluating potential human exposure to harmful compounds from a contaminated subsurface as well as determining a site's potential for natural attenuation. Analysis of soil gas vapors may also aid in estimating the areal extent of a contaminated plume. Soil, aqueous, and NAPL-phase organics may all be sources of organic vapors in the subsurface, and interphase mass transfer to and from soil, soil moisture, groundwater, and soil gas all play a role in vapor transport in the unsaturated zone. Diffusion of the vapor phase contaminant proceeds from higher concentrations near the source toward lower concentrations at the land surface. Advection of soil gas results from pressure gradients in the subsurface and from density-driven flow for certain high molecular weight compounds. Under favorable conditions, organic vapors in the unsaturated zone may be biodegraded by indigenous bacteria in oxidation/reduction reactions. All biodegradation reactions of organic compounds require nutrients and electron acceptors in sufficient, usable quantities. Soil-gas concentrations may be quantified through the use of vapor probes, adsorbent traps, Tedlar® bags, direct syringe withdrawal with field-portable analytical equipment, and the use of gas chromatography. The total flux of contaminants from the subsurface to the land surface may be estimated by the aerodynamic method, through the use of ground sheets, or with flux chambers. Surface flux measurement is useful for estimating the total volatilization of contaminants from a site, but all vapor-phase measurements are complicated by spatial and temporal variability.

APPLICATIONS OF SOIL VAPOR DATA TO GROUNDWATER INVESTIGATIONS

Blayne Hartman
H&P Mobile Geochemistry
Solana Beach, California

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

This article describes the uses and interpretation of soil vapor data for a variety of common applications related primarily to groundwater. It begins with an overview of the applications of soil vapor surveys, a brief discussion of the various soil vapor methods, and then focuses on a number of specific issues relating to soil vapor surveys for groundwater investigations. The intent of this article is to guide professionals on when, why, and how soil vapor data can be useful for groundwater-related investigations and how to interpret the results.

BACKGROUND AND APPLICATIONS

Soil vapor in the pore spaces, also called soil gas, soil air, pore gas, and interstitial gas refers to the vapor that lies among the soil grains in the soil column lying between the ground surface and the water table (vadose zone). Soil vapor data are collected in a variety of ways, and the data can be used for various purposes. Soil vapor samples are most commonly analyzed for volatile organic compounds (VOCs). VOCs include simple hydrocarbons such as methane; lighter hydrocarbons such as gasoline; gasoline constituents such as benzene and methyl tert-butyl ether (MtBE); and chlorinated solvents such as trichloroethylene (TCE), trichloroethane (TCA), and tetrachlorethylene (PCE).

Soil vapor is surveyed for a variety of reasons. Historically, soil vapor surveys have been used primarily for site assessment to identify soil and groundwater contamination (1–4). More recent applications include evaluation of upward and downward vapor transport to monitor site remediation (natural and engineered) and to monitor landfills and migrating VOCs (5–7).

Soil vapor surveys are quick, relatively nondisruptive, and generally inexpensive. The surveys are frequently performed early in the site investigation, when investigation for numerous VOCs is performed. The data obtained are often used to focus subsequent soil and groundwater investigatory sampling programs.

Regulatory agencies across the country are increasingly concerned with human health risk due to the upward migration of contaminant vapors through the vadose zone into buildings. Vertical soil vapor profiles enable measuring actual soil vapor concentrations that give a more accurate calculation of the upward vapor migration than values calculated from soil or groundwater data. These data are used in risk based corrective action (RBCA) computer models (8).

Use of soil vapor data for monitoring site remediation takes many forms. Most commonly, concentrations of vapor contaminants are monitored to measure the progress of a vapor extraction system. Remediation of groundwater or soil by natural attenuation requires monitoring the concentrations of contaminants, by-products, and oxygen in the soil vapor to measure the progress of the degradation of the contaminant plume.

Soil vapor is frequently measured at the fringes of landfills to ensure that harmful compounds such as methane, chlorinated compounds (primarily vinyl chloride), and petroleum related carcinogens such as benzene are not migrating from landfills to neighboring developments.

SOIL VAPOR METHODS

Collection of Soil Vapor Samples

Three methods exist for collecting soil vapor data: (1) active, (2) passive, and (3) flux chambers. A brief overview of these methods follows. More comprehensive descriptions of soil vapor collection methods and protocols are given in documents written by Hartman (9,10), Hartman and Jacobs (5,11), EPA (1), ASTM (12), and Devitt et al. (4).

The *active* approach is quantitative and consists of the withdrawal of a volume of vapor from the subsurface, typically using a steel sampling rod driven into the ground from 0.9 to 6 meters below ground surface, and subsequent analysis of the withdrawn vapor. Originally, surveys were limited to shallow depths of 3 meters because the sampling

[1] Some of this material is excerpted from previous work, appearing in "Petroleum Hydrocarbon Contamination-Legal and Technical Issues" and "Chlorinated Solvent Contamination-Legal and Technical Issues" Copyright © 1998, 1999, Argent Communications Group. rods were driven and extracted using hand techniques. Currently, active surveys can routinely achieve depths exceeding 30.5 meters due to the use of direct-push probe rigs, cone penetrometer (CPT) sampling rigs, and full-size drill rigs to collect soil vapor using newly developed sampling tools.

Sample containers for active vapor sampling include syringes, gas sampling Tedlar® bags, preevacuated stainless steel canisters (e.g., SUMMA canisters), and gastight vials (e.g., 40 mL preevacuated volatile organic analysis (VOAs) vials or headspace vials). Analysis can be performed on-site or off-site, usually within 48 hours of collection. The quantitative results are typically presented in concentration units (e.g., ppmv, μg/L vapor). The active method requires actively withdrawing soil vapor and is best suited to sites that have higher vadose zone permeabilities and higher contaminant concentrations (>0.1 μg/L vapor). The active method can be used for investigating groundwater contamination, and as discussed later in this chapter, the active method is also useful for groundwater issues relating to contaminant fate and transport because it gives concentration data.

The *passive* approach consists of emplacing a natural or synthetic absorbent into the subsurface (typically 0.15 to 0.9 meters) for an extended time, and subsequently removing and analysing the absorbent. The absorbent is typically placed in the upper end of an inverted container or sleeve that has openings for migrating vapors to enter and collect. Unlike the active method, which requires one visit to the site, the passive method requires one visit to the site to deploy the absorbents and a second trip to retrieve them.

The passive method is qualitative and does not allow for real-time data. Measured values are reported as total absorbed mass (e.g., μg) or relative units because the amount of vapor meeting the absorbent is unknown. The passive method offers more sensitivity than the active method; hence it offers advantages in sites of low vadose zone permeability and lower contaminant concentrations (>0.01 μg/L vapor). Contaminants must have an appreciable vapor pressure to be detected by this method, regardless of the deployment time or contaminant concentration in the soil or water. As a rule of thumb, one should not expect compounds whose vapor pressures are less than 10^{-6} atmospheres to be detectable by passive soil vapor methodology in a reasonable time frame (<50 days of exposure) for reasonable contaminant concentrations in the water.

Flux chambers consist of an enclosed chamber that is placed on the surface for a specific period of time. Vapor concentrations are measured in the chamber through time or after a period of time. This method is also quantitative and yields both concentration data in the chamber and flux data (mass/area-time). Flux chambers are the least common soil vapor method and are seldom used for groundwater assessment. Their most useful application is for sites where volatilization of contaminants from groundwater is of concern and direct fluxes are desired Hartman (9).

Analysis of Soil Vapor Samples

The type of analytical instrumentation employed depends upon the goals of the project and the type of soil vapor method used. For screening-level active soil vapor surveys, in which the primary goal is simply to find contamination qualitatively, simple handheld or portable instruments, such as organic vapor analyzer (OVAs), organic vapor meter (OVMs), gas-monitoring meters (e.g., IR detectors), and gas detector tubes, can be used. For applications where quantitative results are desired, the analytical methodology employed is typically gas chromatography (GC) or gas chromatography-mass spectrometry (GC-MS). These latter techniques differentiate a wide variety of compounds. These latter methods are also used to analyze passive soil vapor samples and flux chamber samples.

More comprehensive treatments of the available analytical options for soil vapor samples are given by Hartman & Jacobs (5) and the EPA (1).

APPLICATIONS OF SOIL VAPOR DATA TO GROUNDWATER ISSUES

This section discusses how to use and interpret soil vapor data for applications specifically related to groundwater.

Assessing and Defining Groundwater Contamination

Soil vapor surveys have frequently been used for initial site assessment to identify groundwater contamination, and the data are used to focus subsequent groundwater investigatory sampling programs (1,3,4). The soil vapor data are typically plotted as contours or as a raised surface. More sophisticated approaches, including three-dimensional visualizations of the soil column, cross sections, normalization, and statistical analysis, are sometimes used depending on the project goals.

The applicability of a soil vapor survey to detect potential groundwater contamination depends upon a number of factors, including the local geology, contaminant properties, and the concentration of the contaminant in the groundwater (11). The maximum concentration of a contaminant in the soil vapor due to volatilization from the groundwater can be estimated from Henry's law:

$$C_{\mathrm{sg}} = HC_{\mathrm{w}} \tag{1}$$

where C_{sg} is the soil gas concentration in equilibrium with the groundwater,
C_{w} is the groundwater concentration, and
H is the dimensionless Henry constant.

As an example, consider groundwater that has a benzene concentration of 10 μg/L. The dimensionless Henry constant for benzene is 0.22, giving an equilibrium soil vapor concentration of 2.2 μg/L vapor at the groundwater interface. Hence, a soil vapor survey conducted near groundwater could at best be expected to detect only a maximum value of 2.2 μg/L in the vapor if groundwater were the only source.

Equilibrium phase partitioning is rarely achieved in the subsurface, so measured soil vapor values from groundwater volatilization will be significantly lower (generally one to two orders of magnitude) than predicted from Henry's constants. In addition, soil vapor concentrations decrease as distance increases from the groundwater due to other processes active in the vadose zone, such as biodegradation and sorption onto soils (13). For these reasons, the chances of detecting groundwater contamination from soil vapor data increases the closer the samples are collected to groundwater.

Due to its increased sensitivity for some compounds, the passive soil vapor method can offer advantages over the active method for this application. Similar to the active method, the ability of passive methods to detect groundwater contamination increases the closer the samples are collected to groundwater. However, regardless of sampling depth, the capability of passive methods to detect contaminants is still limited by the vapor pressure of the compound of concern (5).

Transport of Contaminant Vapors in the Subsurface

To understand the source of soil vapor and groundwater contamination, it is necessary to understand how contaminants move in the vapor phase. A condensed version of this topic is addressed in this section beginning with a discussion of the processes by which vapors move through the vadose zone. A more detailed presentation can be found in Hartman (6,7,14).

There are two types of physical processes by which contaminants are transported in the vapor phase. The first is advection, the bulk movement of the vapor itself. In advective transport, any contaminants in the vapor are carried along with the moving vapor. Advective transport processes can be important in soil vapor, for example, near the surface due to atmospheric pressure differences (15), near buildings that can create pressure gradients (16), and movement of vapor by density-induced flow (17).

The second type of transport process is gaseous diffusion, the motion of contaminants by molecular processes through a nonmoving vapor column, which is the primary mechanism for contaminant transport in the vapor phase through the vadose zone (18).

Contaminant transport by gaseous diffusion is described by Fick's first law as

$$\text{FLUX} = \frac{D_e\, C_{sg}}{X} \tag{2}$$

where Flux is the rate of movement of a compound per unit area,
D_e is the effective diffusion coefficient in the vadose zone,
C_{sg} is the contaminant concentration gradient in the soil vapor, and
X is depth in the vadose zone

Similar to momentum transfer (e.g., water running downhill) and heat transfer (movement from hot areas to cold areas), contaminant transfer by gaseous diffusion moves from areas of high concentration to areas of low concentration. The flux is always down the concentration gradient, regardless of the orientation of the concentration gradient with respect to the depth below the surface. Diffusional transport is a three-dimensional process, so contaminants move away from a source in all directions, similar to an expanding balloon.

Differentiating the Source of Soil Vapor/Groundwater Contamination

A common problem confronted by environmental geologists is determining the source of contamination at a site that has both soil vapor and groundwater contamination. Is the soil vapor responsible for the groundwater contamination, or is the groundwater responsible for the soil vapor concentration? Contaminant transfer by gaseous diffusion moves from areas of high concentration to areas of low concentration, so vertical profiles of the soil vapor through the vadose zone down to groundwater can provide this answer. Figure 1 shows the expected shape of soil vapor profiles in the vadose zone for three common conditions. Processes active in the vadose zone such as sorption, biodegradation, and advection may alter these ideal profiles, but the source of contamination must still be in the area of highest concentration, as dictated by Ficks law.

Vertical soil vapor is profiled by installing vapor monitoring wells at multiple depths through the vadose zone to the groundwater. For soil vapor, vapor wells are often constructed of small diameter 0.5 to 1.0 cm (1/8 in. to 1/4 in. OD) flexible tubing and "nested" in the same borehole (Fig. 2).

Repeated sampling of the vapor wells allows averaging any temporal effects. Thomson (19) describes two case histories of vertical profiling using nested vapor wells.

Contaminant Vapor Transport Rates

The distance that contaminant vapors can move by gaseous diffusion can be approximated from

$$\text{Distance} = (2 \times D_e \times t)^{1/2} \tag{3}$$

where D_e is the effective diffusivity and t is time.

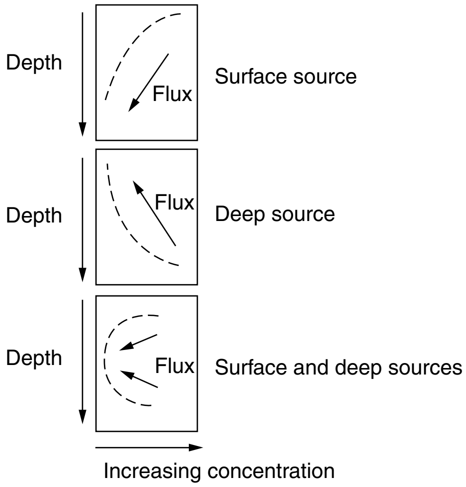

Figure 1. Common soil vapor profiles in the vadose zone for several one-dimensional situations (8).

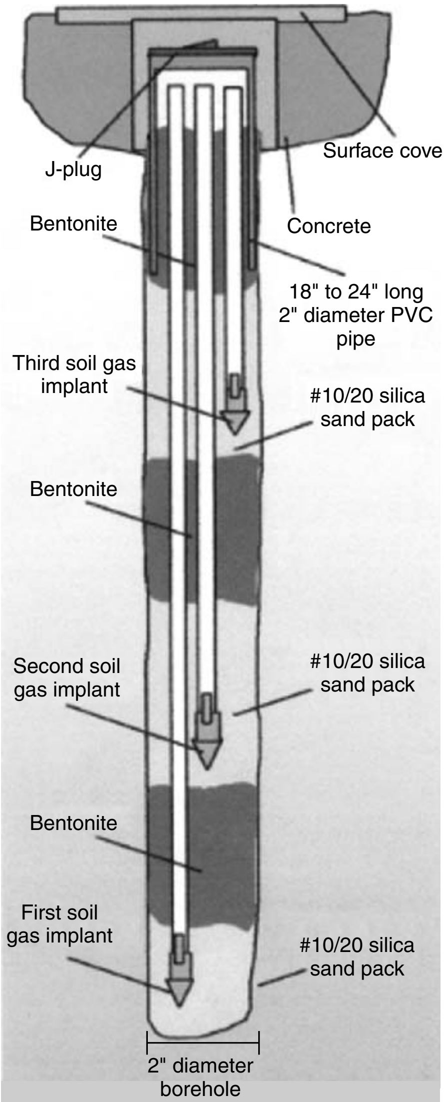

Figure 2. Schematic diagram of a multidepth, nested vapor monitoring well (19).

Through the Vadose Zone. For contaminant vapor transport through the vadose zone, the effective diffusion coefficient is the gaseous diffusion coefficient corrected for soil porosity. For many vapors, the gaseous diffusion coefficient is approximately 0.1 cm^2/s. The effect of soil porosity varies depending upon the type of soil, and several equations are available to calculate the effect of porosity on diffusivity. A general approximation is that the porosity reduces the gaseous diffusivity by a factor of 10. Thus, for vapors, D_e can be approximated as 0.01 cm^2/s.

The distance that contaminant vapors can move through the vadose zone in a year can be estimated as

$$\text{Distance} = (2 \times 0.01\ \mathrm{cm}^2/\mathrm{s} \times 31{,}536{,}000\ \mathrm{s})^{1/2}$$

$$\sim 800\ \mathrm{cm}$$

This calculation shows that contaminant vapors can move long distances through the vadoze zone in a short period of time. Within a few years, vapor contamination can move laterally underneath a neighboring room or building or downward to the groundwater surface.

Into or out of Groundwater. In contrast to movement through the vadose zone where contaminant vapors move through the soil vapor, the movement of contaminant vapors into or out of groundwater is controlled by the rate at which vapors partition into and move through the liquid. Because groundwater movement is so slow, the water interface remains relatively undisturbed (laminar flow), and vertical mixing of the water is minimal. The primary exchange process is again molecular diffusion, but in this case, the exchange rate is controlled by liquid diffusion, not gaseous diffusion. A general value for the liquid diffusion coefficient for compounds is approximately 0.00001 cm^2/s. Using the same factor of 10 reduction due to soil porosity, D_e for most liquids can be approximated as 0.000001 cm^2/s.

The distance that contaminants can move into and through groundwater in a year can be estimated as

$$\text{Distance} = (2 \times 0.000001\ \mathrm{cm}^2/\mathrm{s} \times 31{,}536{,}000\ \mathrm{s})^{1/2}$$

$$\sim 8\ \mathrm{cm}$$

These calculations show that although contaminant vapors can move through the vadose zone relatively quickly, they partition into and move through groundwater extremely slowly. The reverse situation is also true; the movement and partitioning of contaminants through groundwater and into soil vapor is also extremely slow.

Estimation of the Downward Transport of Contaminant Vapors into Groundwater

The calculations summarized in the preceding sections indicate that although contaminant vapors can move quickly down to groundwater, they do not partition into groundwater very quickly because phase partitioning across a liquid laminar interface is kinetically controlled. For this reason, phase partitioning rarely reaches equilibrium, and the use of Henry's constants to estimate groundwater concentrations from soil vapor data (or the reverse) often gives estimated values one to two orders of magnitude from measured values.

Using a modification of Fick's first law, the transfer rate of a contaminant from soil vapor into groundwater can be estimated, and in turn, reasonable estimates of the expected contaminant concentration in groundwater due to contamination in the overlying soil vapor can be estimated.

The flux is calculated as

$$\text{Flux} = K_\mathrm{L}\ (C_\mathrm{sg}/H - C_\mathrm{w}) \tag{4}$$

where K_L is the gas exchange coefficient (length/time),
C_sg is the soil gas concentration time (mass/volume),
H is the dimensionless Henry's law constant, and
C_w is the groundwater concentration (mass/volume).

The ratio C_{sg}/H represents the groundwater concentration in equilibrium with the overlying soil vapor at the interface between the soil vapor and groundwater.

The gas exchange coefficient has units of velocity and represents the distance that contaminants move through the groundwater per unit time. This coefficient is highly dependent on a compound's effective diffusivity and advective mixing of the groundwater interface. For groundwater velocities less than 30.5 meters per year and soil grain sizes less than 0.5 mm, diffusional transport dominates over dispersion, and K_L can be approximated as:

$$K_L = 1.1\,(D_e\,v/d)^{1/2} \tag{5}$$

where D_e is the effective diffusivity,
d is the horizontal distance (downgradient) over which the soil vapor plume and groundwater are in contact, and
v is the horizontal groundwater flow velocity.

For the groundwater conditions described above, the interface remains laminar (i.e., no turbulent mixing), and the gas transfer coefficient is approximately 8 cm/yr. Using this value for the gas exchange rate, estimates of the expected contaminant concentration in groundwater due to contamination in the overlying soil vapor for various soil vapor concentrations are summarized in Table 1. These calculations assume equilibrium partitioning at the soil vapor/groundwater interface, transfer into groundwater by molecular diffusion only, and uniform mixing of the contaminant into the groundwater over the well screen length.

Table 1 shows that for equilibrium concentrations (C_{sg}/H) up to 100 μg/L, the resulting ground water concentration after 5 years will be low (<10 μg/L) if liquid molecular diffusion is the only exchange process.

Table 1. Expected Contaminant Concentration in Groundwater for Various Soil Vapor Concentrations at the Groundwater Interface[a,b]

C_{sg}, μg/L	C_{sg}/H, μg/L	Flux, μg/cm^2-yr	Water conc at 1 yr, μg/L	Water conc at 5 yrs, μg/L
10	40	315	0.63	3.2
20	80	631	1.3	6.3
30	120	946	1.9	9.5
40	160	1261	2.5	13
50	200	1577	3.2	16
100	400	3154	6.3	32
500	2000	15,768	31	158
1000	4000	31,536	63	315

[b] Assumptions used to compute the tabulated values:

Henry's law constant:	0.25 (dimensionless)
Gas transfer coefficient:	8 cm/yr
Well screen interval:	5 m

Importance of Downward Vapor Transport for Several Common Contaminants

The potential importance of downward vapor migration for several of the more common compounds encountered by environmental consultants are given special consideration in this section.

Leaking Vapors from Chlorinated Solvents (Dry Cleaners and Vapor Degreasers). Many compounds, primarily chlorinated solvents, have relatively high vapor pressures and vapor densities three to six times greater than air. Because of these physiochemical properties, vapors may emanate from containers or pipes holding gaseous or liquid products. If air flow is restricted, such as in a closed room containing a washer unit, degreaser, or tank, leaking dense vapors can penetrate the floor and enter the upper vadose zone. Density-driven advection can continue to drive vapor downward through the vadose zone until the vapor is diluted to low enough concentrations (<1%) that density-driven advection is no longer an important factor in vapor transport and molecular diffusion takes over. Vapor clouds reaching tens of feet into the uppermost vadose zone have been documented in thousands of cases. Businesses and commercial operations that are most susceptible to this situation are those that deal with chlorinated solvents (dry cleaners, vapor degreasers, spray facilities, etc.).

The soil vapor concentration to yield an equilibrium water concentration of 100 μg/L is 35 μg/L vapor for TCA, 60 μg/L vapor for PCE, and 100 μg/L vapor for vinyl chloride. In areas of groundwater deeper than 9.1 meters, soil vapor concentrations for these compounds are generally less than these values at groundwater, unless in the presence of contaminated soil, suggesting that surface vapor leaks are not a significant contaminant pathway to groundwater in most cases. In areas of groundwater shallower than 6 meters, soil vapor concentrations exceeding these values are found, even in the presence of clean soil, suggesting that leaking dense vapors from the surface may be a significant contaminant pathway.

Leaking, Hydrocarbon Fuel Vapors. In contrast to chlorinated solvents, aboveground vapor releases are not common for petroleum hydrocarbons because they rarely are stored in confined spaces (due to their flammability). However, subsurface vapor leaks from petroleum hydrocarbons are possible from USTs and piping associated with them (vent pipes, pipe joints, and tank bungs. Gasoline vapor contains approximately 8000 μg/L vapor of benzene and lower, although still high concentrations (>1000 μg/L vapor) of toluene and xylene. Reformulated gasolines have very high concentrations of MtBE or ethanol, and their vapors contain approximately 130,000 μg/L vapor of MtBE and 11,500 μg/L vapor of ethanol. Due to these high concentrations, leaking vapors must be considered a potential source of groundwater contamination, as further described below.

Benzene and Light Aromatics (BTEX). For light aromatics, the soil vapor concentration to yield an equilibrium water concentration of 100 μg/L is approximately 25 μg/L vapor. In areas of groundwater deeper than 9.1 meters, soil vapor concentrations of aromatics are generally less than 25 μg/L vapor at the groundwater, unless in the presence of contaminated soil from a leaking UST, suggesting that vapor leaks are not a contaminant pathway in most cases.

In areas of groundwater shallower than 3 meters, soil vapor concentrations exceeding 25 μg/L vapor have been found even in the presence of clean soil, suggesting that leaking gasoline vapors from the UST are a possible contaminant pathway. In areas where the groundwater is near or above the UST, vapor leaks could be very significant in groundwater contamination.

MtBE and Ethanol. Due to extremely low Henry constants, the soil vapor concentration to yield an equilibrium water concentration of 100 μg/L is only 2 μg/L vapor for MtBE and approximately 0.02 μg/L vapor for ethanol. Hence, leaking gasoline vapors from a UST are a likely contaminant pathway to groundwater for both compounds in shallow and deep groundwater. The likelihood is even more acute in locations where the water table is near or above the UST and/or in areas that have significant amounts of rainwater infiltration.

Summary. In areas of deeper groundwater (>10 m), slow groundwater flow rates less than 30.5 meters per year and low recharge, soil vapor concentrations for most contaminants at the groundwater surface are typically well below equilibrium values (C_{sg}/H) of 100 μg/L. Hence contamination of groundwater by downward vapor transport is not likely to be significant. For compounds with very low Henry constants (MtBE, ethanol), downward vapor transport could be important, even under these groundwater conditions.

In areas where groundwater is shallower than 10 meters or higher groundwater flow rates and high recharge, soil vapor concentrations for many contaminants at the groundwater surface may approach high enough values that contamination of the groundwater by downward vapor transport may be significant. This potential will be enhanced for compounds with low Henry constants and when vapor leaks occur directly into the groundwater.

Additional discussion of the downward migration of vapors can be found in Hartman (7,14).

The Upward Migration of Vapors from Groundwater Devolatilization

Attention has been raised in the past several years to the risk to human health by the upward migration of contaminant vapors into buildings and other enclosed spaces (20–22). In cases of contaminated groundwater, it is common to assess this risk pathway before site closure is obtained.

Simplified, the upward contaminant vapor flux into a building is computed by Fick's first law, requiring the soil vapor concentration at some depth underlying the structure. Soil vapor data may be measured directly, or alternatively, in the absence of actual soil vapor data, soil vapor concentrations can be calculated from groundwater data assuming equilibrium conditions using Henry's constants (23). As discussed in the preceding sections, soil vapor values calculated from groundwater using Henry's constants are likely to be overestimated by amounts as large as 10 to 100 times; hence the resulting risk will also be overestimated. The potential error in the calculated risk introduced by the incorrect vapor concentration can be orders of magnitude greater than errors introduced using default values for other parameters, such as porosity. Thus, if a site fails the upward risk calculation using calculated soil vapor values from groundwater data, direct measurement of actual soil vapor concentrations will yield more representative soil vapor values to be used in the calculation (13).

When groundwater is extremely shallow (1.5 meters) and representative soil vapor data are unobtainable, the use of surface flux chambers may yield the best estimate of the vapor flux (24).

A more detailed discussion of the upward vapor migration risk pathway, including a recommended protocol for determining the upward vapor flux, can be found in Hartman (8).

GROUNDWATER VELOCITIES

MUKAND SINGH BABEL
Asian Institute of Technology
Pathumthani, Thailand

Groundwater flows through interconnected pore spaces in subsurface soil in response to differences in fluid pressure and elevation. Groundwater flow rates are extremely slow, compared to surface water, and they are also highly variable. For example, in clayey soils, groundwater moves as slowly as a fraction of a millimeter per day; however, in sandy soils, it moves faster, even up to more than a meter per day. Hydrology is concerned with both the speed and the direction of groundwater movement. Groundwater velocity is very important in dealing with contaminant migration and arrival time, mass flux, site characterization, reactive barrier design, and calibration of transport processes.

Hydraulic head drives flow through porous media. Two main components contributing to the hydraulic head at a given point in a groundwater flow system are pressure head and elevation head, as shown in Fig. 1. The pressure head is due to the porewater pressure at that point, which can be measured by a piezometer. The elevation head is due to gravitational energy. The higher the elevation of a fluid from sea level or some selected datum, the more gravitation potential energy it has. The third component, kinetic energy, can be ignored, as groundwater flow velocities are usually very small in magnitude. Thus, the hydraulic head (h) is the sum of the pressure head (Ψ) and the elevation head (z), expressed usually in the units of length (meters).

Henry Darcy, a French engineer who studied the movement of water through sand in 1856, found that the rate of water flow through a pipe filled with sand is proportional to the difference in the height of the water between the two ends of the tube, and inversely proportional to the length of the tube (Fig. 2). The constant of proportionality, K, is called hydraulic conductivity. This law, universally known as Darcy's law, is given as

$$Q = -KA[(h_A - h_B)/L]$$

or

$$Q = -KA(dh/dL) \tag{1}$$

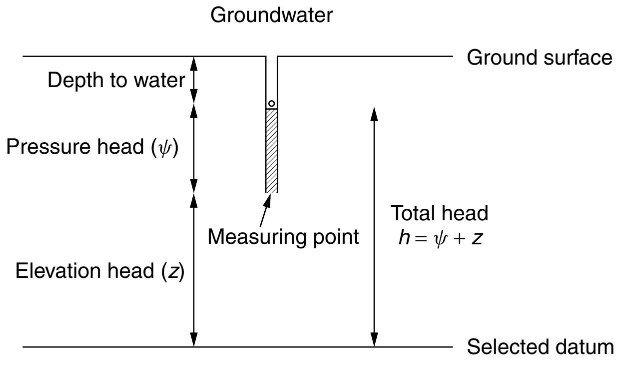

Figure 1. Elevation head, pressure head, and total head (adapted from Reference 1).

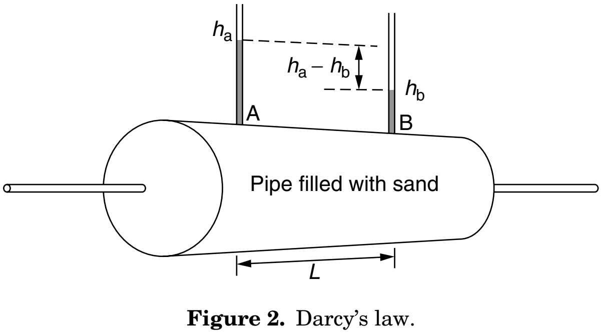

Figure 2. Darcy's law.

or

$$q = Q/A = -K\ (dh/dL) \tag{2}$$

where Q is the quantity of flow per unit of time (m^3/day); $K =$ hydraulic conductivity (m/day); $A =$ cross-sectional area (m^2); h_A and h_B are the hydraulic head at points A and B, respectively; and $dh/dL =$ hydraulic gradient. The term Q/A in Eq. 2 is also known as the specific discharge (q), which is the flow per unit area [LT^{-1}]. The specific discharge is sometimes referred to as Darcy flux, Darcy velocity, or bulk velocity.

The negative sign in Eq. 2 indicates that the fluid moves in the direction of decreasing hydraulic head. Darcy's law assumes that the flow is laminar, that is, the water follows distinct flow lines rather than mixing with other flow lines, which is the case for most groundwater flow in porous media. Most groundwater movements occur in small interstices, so that there is considerable resistance to flow imposed by the aquifer material, making the flow laminar. When the flow velocity increases, especially in media having large pores, the occurrence of turbulent eddies dissipates kinetic energy, rendering the hydraulic gradient less effective in inducing flow. In very large interstices, such as those in many limestone and volcanic areas, groundwater flow is almost identical to the turbulent flow of surface water. Darcy's law is not valid for turbulent flow, for unusually high velocity that may be found in fractures or in granular aquifers.

Equation 2 yields only an apparent velocity value, the macroscopic velocity, through the cross-sectional area of a solid matrix and interstices, which, however, is not the true velocity of water moving through the pores. Clearly, flow velocities through interstices alone will be much higher than the macroscopic value. The interstices themselves vary in shape, width, and direction, so the actual velocity in the soil or rock is highly variable. Furthermore, the flow path of a water particle around and between the grains in an aquifer is tortuous, so water particles must travel longer than the apparent distance given by the measured length of the porous medium in the direction of flow, as shown schematically in Fig. 3.

To calculate the true linear velocity, one must take into account the fact that water travels only through the pores of the sediment. The fraction of the area covered by open space is equal to the effective porosity (n_e). Thus, the effective velocity (v), also known as the porewater velocity, is obtained by dividing the macroscopic velocity by the effective porosity:

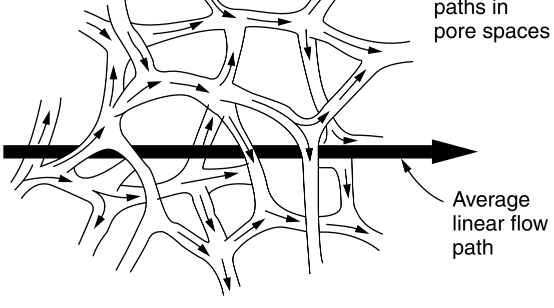

Figure 3. Concept of average linear velocity (2).

$$v = -(K/n_\mathrm{e})dh/dL \tag{3}$$

or

$$v = Q/n_\mathrm{e}/A$$

or

$$v = q/n_\mathrm{e}$$

From Eq. 3, it can be seen that, for sand with an effective porosity of 33%, the actual velocity is three times the Darcy velocity. Therefore, to define the actual velocity, one must consider the microstructure of the material. Usually, actual velocities tend to decrease with depth as porosities and hydraulic conductivities also decrease.

INTRODUCTION

This text describes the elementary concepts of viscous fluid flow. The principal laws that govern the motion of fluids are also discussed. From our common experience, we know that fluids deform under the action of external forces. The deforming forces and rate of deformation are related to each other through a proportionality constant known as the coefficient of viscosity. The value of this constant depends upon the chemical identity, material properties, and thermodynamic state of a given fluid. To develop a theory that shows how viscosity affects fluid dynamics, one must understand the relationships between stress and the rate of strain. The outlines given in this article provide basic concepts of viscous flow. For more detailed analysis, the reader should consult specialized texts on this topic. Some of these texts are listed in the references at the end of this article.

VISCOSITY AND NEWTON'S LAW OF VISCOSITY

The physical property by which the resistance to fluid flow can be characterized is known as viscosity. A more fundamental approach to viscosity shows that it is the property of a fluid that relates applied stress to a resulting strain rate. By experience, we come across many different types of fluids. For example, consider water and lubricating oil such as that used in automobiles. Water can flow more freely compared to lubricating oil under isothermal conditions. Hence, we say that the viscosity of water is less than that of oil.

When we deform a solid, so that it is strained, we know that the solid will exert a restoring force that opposes the strain; for small strains, the restoring force is proportional to the strain, the familiar Hooke's law. Real fluids also oppose strains; however, in a fluid it is not the amount of strain that is important but the rate at which the strain is produced.

Consider simple fluid flow between the two plates shown in Fig. 1. If the force per unit area of the top plate is F, we find that

$$\frac{F}{A} = \mu \frac{v}{d} \qquad (1)$$

where d is the separation between the plates, which defines the viscosity μ (sometimes called the absolute or dynamic viscosity). Equation 1 can be written in a more generalized form given by Eq. 2. The shear stress exerted in the x direction on a fluid surface of constant y by the fluid in the region of lesser y is designated as τ_{yx}, and the x component of the fluid velocity vector is designated as v_x:

$$\tau_{yx} = -\mu \frac{dv_x}{dy} = \mu \dot{\gamma} \qquad (2)$$

This equation is commonly known as *Newton's law of viscosity*. It states that the shear force per unit area is proportional to the negative of the local velocity gradient. The left-hand side of Eq. 2 represents the shear stress, and the right-hand side represents the rate of strain $\dot{\gamma} \cdot \tau_{yx}$ from Eq. 2 can also be interpreted as the viscous flux of the x momentum in the y direction. It can be seen that the viscous momentum flux is in the direction of the negative velocity gradient, that is, the momentum tends to go in the direction of decreasing velocity. A velocity gradient can thus be considered a driving force for momentum transport.

Fluids in which shear stress is directly proportional to the rate of deformation are termed *Newtonian fluids*. The viscosity of such fluids is independent of the rate of shear and rate of strain and always remains constant under given conditions. Examples of Newtonian fluids are air, water, and gasoline. In SI units, the units of viscosity are kg/m · s or Pa · s. In the cgs system, the unit of viscosity is g/cm · s, also called the poise (after Poiseuille) and equals 0.1 Pa · s. In fluid mechanics, the ratio of absolute viscosity to density is also termed kinematic viscosity which is often denoted by η. Generally, the viscosity of liquids decreases as temperature increases. Gases, on the other hand, have viscosities which generally increase with increasing temperature. More detailed explanations are based on the kinetic theory of gases and can be found in (1).

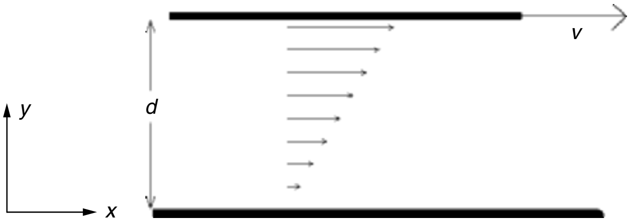

Figure 1. Viscous drag between two plates, which the bottom plate is held fixed.

NON-NEWTONIAN FLUIDS

There are fluids that do not obey the simple relationship between shear stress and shear strain rate given by Eq. 2 for a Newtonian fluid. These fluids are known as *non-Newtonian* fluids. Examples are paints, solutions of various polymers, food products such as applesauce and ketchup, emulsions and suspensions of various solids, and coal slurries. The subject of non-Newtonian flow is actually a subdivision of the science of *rheology*, which is also known as the "science of deformation and flow."

We categorize non-Newtonian fluids and discuss them under three general classifications:

1. The first is the time independent non-Newtonian fluid in which the shear rate is a unique but nonlinear function of shear stress.
2. In the second category are the time dependent non-Newtonian fluids that have more complicated shear stress and shear strain relationships. In these fluids, the shearing rate is not a single valued function of the shear stress. The shear rate depends on shearing time or on the previous shear stress rate history of that fluid.
3. In the third category are viscoelastic fluids. Unlike a truly viscous fluid in which all its energy of deformation is dissipated, some of the energy of deformation of a viscoelastic fluid may be recoverable as in the deformation of an elastic fluid.

Time-Independent Fluids

For time-independent non-Newtonian fluids,

$$\dot{\gamma} = f(\tau) \qquad (3)$$

A Newtonian fluid is a special case of this category where the function $f(\tau)$ is linear.

Time-independent non-Newtonian fluids can be commonly represented by three distinct rheograms shown in Fig. 2:

1. Bingham plastics
2. pseudoplastics
3. dilatant fluids

Bingham Plastics. Bingham plastics exhibit yield stress at zero shear rate, followed by a straight-line relationship between shear stress and shear rate. The characteristics

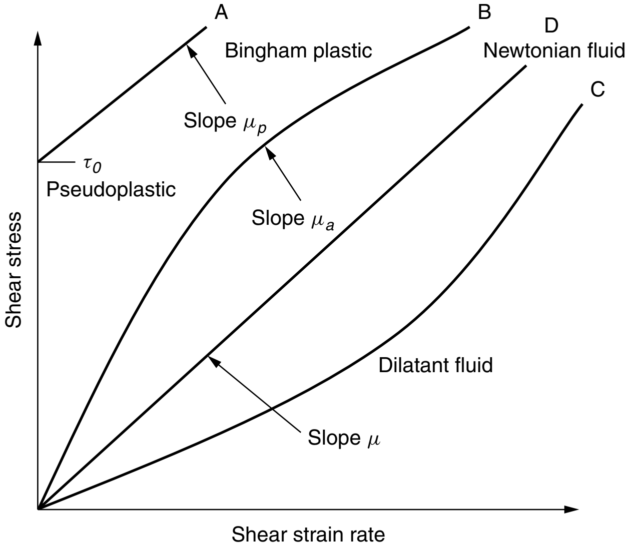

Figure 2. Shear stress–strain rate relationships for non-Newtonian fluids.

of such fluids are defined by two constants. The first is the yield stress denoted by τ_0; this is the stress that must be exceeded for the flow to begin. The second is the plastic viscosity μ_p which is the slope of the straight-line portion on curve A, Fig. 2. The model for Bingham plastics can be represented by Eq. 4:

$$\tau_{yx} = \mu_p \dot{\gamma} + \tau_0 \qquad \mathit{if}\ \tau_{yx} > \tau_0 \tag{4}$$

This model closely approximates the behavior of many real fluids such as slurries, plastics, emulsions such as paints, and suspensions of finely divided solids in a liquid. However, different constitutive models representing this type of fluids have been proposed by Herschel and Bulkley (2), Oldyroyd (3), and Casson (4).

Pseudoplastic fluids. Pseudoplastics (curve B, Fig. 2) do not have any yield stress. A pseudoplastic fluid is characterized by a progressively decreasing slope of shear stress versus strain rate. The slope has been defined as apparent viscosity,

$$\mu_a = \tau_{yx}/\dot{\gamma} \tag{5}$$

At very high shear rates, the apparent viscosity becomes constant, and the shear stress versus shear strain becomes linear. A number of empirical relations have been used to describe the behavior of pseudoplastic fluids. The simplest of these is the power law model proposed by Ostwald in 1923 [refer to (5)] and expressed in the form of Equation 6.

$$\tau_{yx} = k\dot{\gamma}$$

where $n < 1$ and k and n are constants for a particular fluid. k is known as the consistency coefficient for a given fluid, and n is the power law index. n also represents the deviation of a particular fluid from a Newtonian fluid. For a Newtonian fluid, $n = 1$, and $k = \mu$, the viscosity of the fluid. Combining Eqs. 5 and 6,

$$\mu_a = k\dot{\gamma}^{(n-1)} \tag{7}$$

The value of n is greater than unity for pseudoplastic fluids.

Dilatant Fluids. Dilatant fluids (curve C, Fig. 2) are similar to pseudoplastics in having no yield stress. They differ from pseudoplastics in a fashion such that the apparent viscosity increases as shear rate increases. The power law model given by Eq. 7 is also applicable to dilatant fluids, and so are Eqs. 6 and 7. The only difference here is that the power law index n is greater than unity. Pseudoplastic and dilatant fluids are also known as shear thinning and shear thickening fluids.

Time-Dependent fluids. Some fluids are more complex than those just described, and the apparent viscosity depends not only on the shear rate but also on the time for which the shear has been applied. Such fluids can be classified in two categories;

1. thixotropic fluids
2. rheopectic fluids

The shear stress decreases with time for a thixotropic fluid, whereas the shear stress increases with time for a rheopectic fluid. Rheopexy and thixotropy are complex phenomena resulting from transient changes of the molecular structure of time-dependent fluids under an applied shear stress. The proposed models for such fluids are hence based on many simplifying assumptions (6).

Thixotropic Fluids. The apparent viscosity of thixotropic fluids depends on the length of time of shearing as well as on the shear rate. As the fluid is sheared from the state of rest, it breaks down (on a molecular scale), but then the structural reformation increases with time. An equilibrium state is achieved when the breakdown rate is equal to the build up rate. If allowed to rest, the fluid builds up slowly and eventually regains its original consistency. As the shear is decreased, the apparent viscosity is less than that for increasing shear. For more detailed discussions, refer to (7).

Rheopectic Fluids. Molecular structure in rheopectic fluids, is formed by shear, and the behavior is opposite to that of thixotropy. A simple example of the formation of shear structure is the beating and thickening of egg whites. Many substances lose their rheopectic properties at extremely high shear rates and behave as thixotropic fluids.

Viscoelastic Fluids. A viscoelastic fluid exhibits both viscous and elastic properties. The simplest type of such a material is one which is Newtonian and obeys Hooke's law for the elastic part. The shear rate for such fluids can hence be written as

$$\dot{\gamma} = \tau_{yx}/\mu_0 + \dot{\tau}_{yx}/\lambda \tag{8}$$

where λ is the rigidity modulus. Under steady-state flow, $\dot{\gamma} = \tau_{yx}/\mu_0$ and the fluid behaves like a simple Newtonian fluid. However, if the shear is changed, an elastic effect is added. Maxwell first proposed Eq. 8 in the form

$$\tau_{yx} + \dot{\tau}_{yx}\ (\mu_0/\lambda) = \mu_0\dot{\gamma} \tag{9}$$

Liquids that obey Eq. 9 are known as Maxwell liquids. The constant $(\mu_0/\lambda)^{-1}$ is known as the relaxation time, which is the time constant for the exponential decay of stress at constant strain. If the motion is stopped, the stress relaxes at $e^{-t\lambda/\mu_0}$. Rather complex models of viscoelastic materials have been developed in which higher time derivatives of τ_{yx} and $\dot{\gamma}$ appear. A very readable text for these models is (8).

MICROSCOPIC BALANCES OF MASS, MOMENTUM, AND ENERGY

We define the control volume as a region in space within which our fluid flow system is present. Laws of conservation (or change) of mass, momentum, and energy desribe the behavior of fluid flow within this system. To yield the detailed descriptions of variables of interest, the control volume must be of infinitesimal dimensions that can shrink to zero, yielding a point volume. This approach reduces the quantities to point variables. The application of conservation principles to this infinitesimal system produces microscopic or differential conservation equations.

Shell Momentum Balances

Shell momentum balances are written to represent a fluid flow problem mathematically. The momentum balance for any fluid flow system can be written as

$$\begin{aligned}&(\text{Rate of momentum in}) - (\text{rate of momentum out})\\&\quad + (\text{sum of forces acting on the system})\\&\quad = (\text{rate of momentum accumulation})\end{aligned} \tag{10}$$

Momentum can enter the system by momentum transfer according to Newtonian (or non-Newtonian) expressions for momentum flux. Momentum can also enter from overall fluid motion, bulk transfer. The forces acting on a system in fluid flow problems are pressure forces (acting on surfaces) and gravity forces (acting on the entire volume as a whole). The general procedure for solving any viscous flow problem is

1. Write a momentum balance in form of Equation 10 for a shell of finite thickness, a microscopic shell momentum balance.
2. Let this thickness approach zero, and use the mathematical definition of the first derivative to obtain the corresponding differential equation describing the momentum flux distribution.
3. Insert the appropriate Newtonian or non-Newtonian expression for momentum flux to obtain a differential equation for the velocity distribution.
4. Integrate these differential equations which yields the momentum flux and velocity distributions for the system under consideration.

Refer to (1) to get more acquainted with shell momentum balance concepts, where this approach has been applied to simple flow problems.

EULERIAN AND LAGRANGIAN COORDINATE SYSTEMS

Conservation equations and the constitutive equation are expressed in terms of relative kinematics, velocities, gradients of velocities, strains, and rates of strain, so it is very important to quantify these variables.

Flow kinematics, the relative motion of fluid particles, can be described by using either a *Lagrangian* or a *Eulerian* description. In the Lagrangian system, the motion of an individual particle is tracked where the coordinates locate the position of a particle and are functions of time. In the Eulerian system, dependent variables such as the velocity vector and pressure are considered functions of fixed spatial coordinates and of time.

The Lagrangian framework is considered a more natural choice to represent the actual kinematics and stresses experienced by fluid particles. However, to solve complex flow problems, this approach is limited (e.g., due to the necessity of tracking particles along unknown streamlines). This system is particularly convenient in flows of viscoelastic fluids with memory that require particle tracking and calculation of deformation and stresses along streamlines. The Eulerian formulation is, in general, more convenient to use because it deals only with local or present kinematics. In most cases, all variables of interest, such as strain, rate of strain, stress, and streamlines, can be obtained from the velocity field. An additional advantage of the Eulerian system is that it involves only time as a variable in unsteady-state flow, whereas the Lagrangian system uses traveling time as a variable, even in steady-state flow. All equations described in subsequent sections have been represented in the Eulerian coordinate system.

EQUATIONS OF CHANGE

The shell balance approach was used to acquaint the beginner with the application of the principle of conservation of momentum to viscous flow problems. It is, however, not always necessary to formulate a momentum balance. It is quicker and easier to start with the equations of continuity and motion in general form and then to simplify them to fit the problem in hand. These two equations describe all problems of the viscous flow of a pure isothermal fluid.

EQUATION OF CONTINUITY

The equation of continuity is developed by applying the law of conservation of mass to a small 3-D volume element within a flowing fluid, as shown in Fig. 3.

$$\begin{aligned}&(\text{Rate of mass accumulation})\\&\quad = (\text{rate of mass in}) - (\text{Rate of mass out})\end{aligned} \tag{11}$$

We consider each of the six faces of this volume element and evaluate the mass entering and exiting the system:

$$\text{Rate of mass in} = \Delta y \Delta z \rho v_x \Big|_x + \Delta x \Delta z \rho v_y \Big|_y + \Delta x \Delta y \rho v_z \Big|_z \qquad (12)$$

$$\text{Rate of mass out} = \Delta y \Delta z \rho v_x \Big|_{x+\Delta x} + \Delta x \Delta z \rho v_y \Big|_{y+\Delta y} + \Delta x \Delta y \rho v_z \Big|_{z+\Delta z} \qquad (13)$$

$$\text{Rate of mass accumulation} = \Delta x \Delta y \Delta z \frac{\partial \rho}{\partial t} \qquad (14)$$

After inserting, Eqs. 12–14 in Eq. 11, dividing the entire equation by $\Delta x \Delta y \Delta z$, and taking the limit of dimensions approaching zero, we get the equation of continuity.

For generality, we have expressed the equation of continuity in vector form:

$$\frac{\partial \rho}{\partial t} = -(\nabla \cdot \rho v) \qquad (15)$$

Here $(\nabla \cdot \rho v)$ is called the "divergence" of $\rho \mathbf{v}$. Vector $\rho \mathbf{v}$ is the mass flux and is the net rate of mass efflux per unit volume. Equation 15 states that the rate of increase of density within a small volume element fixed in space is equal to the net rate of mass influx to the element divided by its volume. Note that the derivation can be performed for a volume element of any shape.

A very special form of the equation of continuity is Eq. 16, which is applicable to fluids of constant density, *incompressible fluids*.

$$(\nabla \cdot \mathbf{v}) = 0 \qquad (16)$$

EQUATION OF MOTION

Using the shell momentum balance approach for the 3-D volume element shown in Fig. 5, an equation of motion is developed. It should be emphasized that momentum is a vector quantity, and hence the equation of motion has components in each of the three coordinate directions x, y, and z, respectively. For simplicity, we consider only the x component here; y and z components can then be handled analogously. Momentum flows in and out of the control volume by two mechanisms; convection, which is a result of the bulk fluid flow and molecular transfer (i.e., viscous transfer), that is, by virtue of velocity gradients.

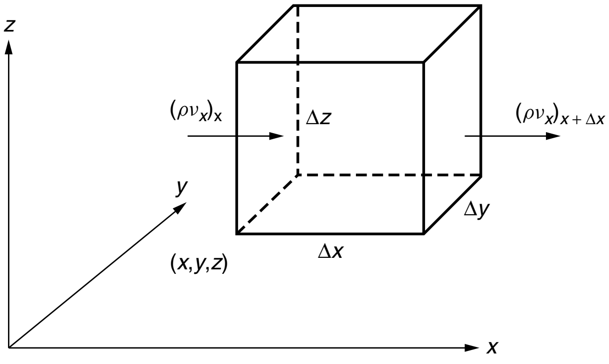

Figure 3. Region of volume in $\Delta x \Delta y \Delta z$ through which fluid is flowing.

The important forces acting on the cubic element in Fig. 4 are the fluid pressure p and the gravitational force g_x. Hence, to write Eq. 10 in mathematical form,

$$\begin{aligned} \text{Rate of momentum in} &= \text{Rate of momentum in by (convection + viscous transfer)} \\ &= \Delta y \Delta z \rho v_x v_x \Big|_x + \Delta x \Delta z \rho v_y v_x \Big|_y + \Delta x \Delta y \rho v_z v_x \Big|_z + \Delta y \Delta z \tau_{xx} \Big|_x \\ &\quad + \Delta x \Delta z \tau_{yx} \Big|_y + \Delta x \Delta y \tau_{zx} \Big|_z \end{aligned} \qquad (17)$$

$$\begin{aligned} \text{Rate of momentum out} &= \text{Rate of momentum out by (convection + viscous transfer)} \\ &= \Delta y \Delta z \rho v_x v_x \Big|_{x+\Delta x} + \Delta x \Delta z \rho v_y v_x \Big|_{y+\Delta y} + \Delta x \Delta y \rho v_z v_x \Big|_{z+\Delta z} + \Delta y \Delta z \tau_{xx} \Big|_{x+\Delta x} \\ &\quad + \Delta x \Delta z \tau_{yx} \Big|_{y+\Delta y} + \Delta x \Delta y \tau_{zx} \Big|_{z+\Delta z} \end{aligned} \qquad (18)$$

$$\begin{aligned} \text{Sum of forces acting} &= \text{body forces} + \text{pressure} \\ &= \Delta y \Delta z \left(p \Big|_x - p \Big|_{x+\Delta x} \right) + \rho g_x \Delta x \Delta y \Delta z \end{aligned} \qquad (19)$$

$$\text{Rate of accumulation of } x \text{ component of momentum} = \Delta x \Delta y \Delta z \frac{\partial \rho v_x}{\partial t} \qquad (20)$$

These stresses developing in viscous transfer can be divided into normal and shear stresses. For example, τ_{xx} is the normal stress, whereas τ_{yx} is the shear stress resulting from viscous forces. At each point in a continuous medium, whether it is solid or fluid, we need six components; each represents a component of force per unit area to define

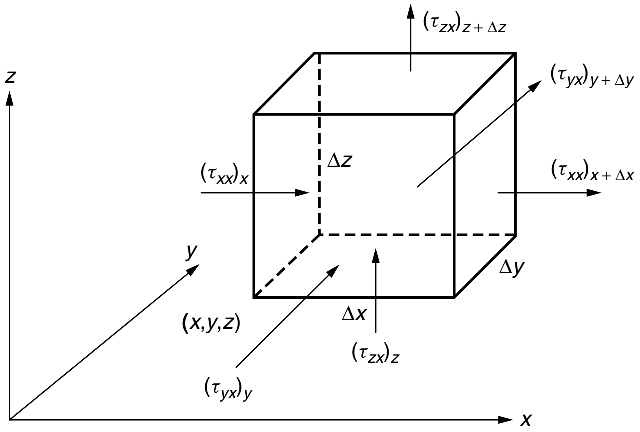

Figure 4. Direction of transfer of x component of momentum through the surfaces.

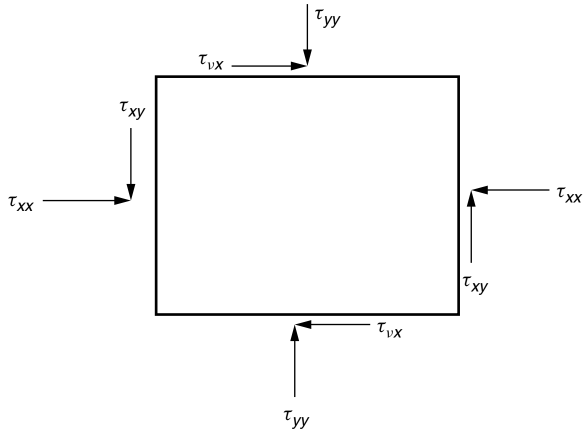

Figure 5. Local stresses acting on a cubic element in an x–y plane.

the local stress completely. The local stresses acting in the x–y plane are shown in Fig. 5.

Using Eqs. 17–20, dividing the entire equation by $\Delta x \Delta y \Delta z$, and taking the limit of the dimensions approaching zero, we get the x component of the equation of motion. Analogously, we can find the components for the y and z components. Adding the three components of equation of motion, the equation of motion can be expressed in vector notation as

$$\frac{\partial}{\partial t}\rho\mathbf{v} = [\nabla\cdot\rho\mathbf{vv}] \quad -[\nabla p] \quad -[\nabla\cdot\boldsymbol{\tau}] \quad +\rho\mathbf{g} \tag{21}$$

$\frac{\partial}{\partial t}\rho\mathbf{v}$	$[\nabla\cdot\rho\mathbf{vv}]$	$-[\nabla p]$	$-[\nabla\cdot\boldsymbol{\tau}]$	$+\rho\mathbf{g}$
Rate of increase of momentum per unit volume	Rate of momentum gain by convection per unit volume	Pressure on element per unit volume	Rate of momentum gain by viscous transfer per unit volume	Gravitational force on element per unit volume

$\boldsymbol{\tau}$ is known as the "stress tensor", $[\nabla\cdot\rho vv]$ represents the rate of loss of momentum per unit volume by fluid flow, and $(\nabla\cdot\rho v)$ represents the rate of loss of mass per unit volume. To use Eq. 21 to determine the velocity distribution, we must insert expressions for various stresses in terms of velocity gradients and fluid properties. For Newtonian fluids, these expressions can be written as

$$\tau_{xx} = -2\mu\frac{\partial v_x}{\partial x} + \frac{2}{3}\mu(\nabla\cdot\mathbf{v}) \tag{22}$$

$$\tau_{yy} = -2\mu\frac{\partial v_y}{\partial y} + \frac{2}{3}\mu(\nabla\cdot\mathbf{v}) \tag{23}$$

$$\tau_{zz} = -2\mu\frac{\partial v_z}{\partial z} + \frac{2}{3}\mu(\nabla\cdot\mathbf{v}) \tag{24}$$

$$\tau_{xy} = \tau_{yx} = -\mu\left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x}\right) \tag{25}$$

$$\tau_{yz} = \tau_{zy} = -\mu\left(\frac{\partial v_y}{\partial z} + \frac{\partial v_z}{\partial y}\right) \tag{26}$$

$$\tau_{zx} = \tau_{xz} = -\mu\left(\frac{\partial v_z}{\partial x} + \frac{\partial v_x}{\partial z}\right) \tag{27}$$

Equations 22–27 have been presented with proof in (9) and can be applied to various complex situations. Equations 22–24 are normal stresses and should contain an additional term. For example, Eq. 22 should be written as

$$\tau_{xx} = -2\mu\frac{\partial v_x}{\partial x} + \left(\frac{2}{3}\mu - \kappa\right)(\nabla\cdot v) \tag{28}$$

Similarly, Eqs. 23 and 24 are also written as

$$\tau_{xx} = -2\mu\frac{\partial v_x}{\partial x} + \left(\frac{2}{3}\mu - \kappa\right)(\nabla\cdot v) \tag{29}$$

$$\tau_{xx} = -2\mu\frac{\partial v_x}{\partial x} + \left(\frac{2}{3}\mu - \kappa\right)(\nabla\cdot v) \tag{30}$$

κ is known as "bulk viscosity." The bulk viscosity is zero for low-density monoatomic gases and not too important for dense gases and liquids which are almost incompressible. Experimental measurements to estimate the value of "bulk viscosity" have been discussed by Karim and Rosenhead (10). Formulas to estimate the value of bulk density can be found in (11). When the fluid flows in the x direction between two parallel plates perpendicular to the y direction and v_x is only a function of y, then this set of six equations reduces to Eq. 2 described previously. Equations 22–27 inserted in Eq. 21 yield the equations of motion for a Newtonian fluid with varying density and viscosity.

1. For constant ρ and μ, the equation of motion can be written as

$$\rho\left(\frac{\partial v}{\partial t} + v\cdot\nabla v\right) = -\nabla p + \mu\nabla^2 v + \rho g \tag{28}$$

Equation 28 is the well-known **Navier–Stokes** equations, first developed by Navier in France in 1822.

2. When viscous effects are ignored, Eq. 28 reduces to

$$\rho\left(\frac{\partial v}{\partial t} + v\cdot\nabla v\right) = -\nabla p + \rho g \tag{29}$$

Equation 29 model laminar flow when viscous effects are negligible. These flows are termed Euler, potential, or inviscid flows. Equation 29 is the well-known **Euler** equation.

3. When the motion of a fluid is "very slow," the flow is said to be creeping or Stokes flow. Viscous forces dominate creeping flows and hence, the nonlinear inertia term in Eq. 28 is neglected. Then,

$$\rho\frac{\partial v}{\partial t} = -\nabla p + \mu\nabla^2 v + \rho g \tag{30}$$

Equation 30 is the well-known **Stokes** equations.

The equations of motion together with the equation of continuity, the equation of state $p = p(\rho)$, viscosity models illustrated in previous sections, and the intial and the boundary conditions, complete the problem specification for any viscous flow problem. These equations, when solved mathematically, determine completely the density, pressure, and velocity components in a flowing isothermal fluid.

Boundary Conditions

Boundary conditions are constraints imposed on conservation equations to describe how flow behavior conforms to the surroundings. Boundary conditions come from nature and are mathematical descriptions of the physics at the boundary. These may describe conditions along the boundary dealing with motion, external stresses, rate of mass and momentum flux, boundary values of field variables as well as the relations among them. When the solution involves the time evolution of flow fields, initial conditions are also needed. The number of boundary conditions required to solve a particular problem is determined by the nature of the governing partial differential equation. In general, elliptical equations require boundary conditions on each portion of the boundary; hyperbolic equations require boundary conditions at upstream but not at downstream boundaries; parabolic equations require initial conditions and boundary conditions everywhere except downstream. The Navier–Stokes equations are hyperbolic at high Reynolds numbers and elliptical at low Reynolds numbers. The Euler equation is the upper limit of hyperbolicity, whereas Stokes equations are the lower limit of ellipticity. Different types of boundary conditions in mathematical form have been described by Papanastasiou (12) and are applicable to a wide range of viscous flow problems.

In general, there are three types of boundary conditions:

1. First kind or *Dirichlet* boundary conditions: The value of the dependent variable along the boundary is imposed as the condition. Typical Dirichlet boundary conditions are no-slip boundary conditions for velocity and the specification of inlet/outlet velocities.
2. Second kind or *Neumann* boundary conditions: The normal derivative of the dependent variable is specified along the boundary. Examples are symmetry conditions and free surface and interface stress conditions.
3. Third kind or *Robin's* boundary condition: The dependent variable and its normal derivative are related. Slip wall conditions are typical Robin conditions.

Nomenclature

A	Area
F	Force
$\mathbf{g}$	Gravity force vector
n	Power law index
p	Pressure
$\mathbf{v}$	Velocity vector
t	Time variable
Greek Symbols	
$\dot{\gamma}$	Rate of strain
κ	Bulk viscosity
μ	Viscosity of a fluid
τ	Stress
$\dot{\tau}$	Rate of shear
λ	Elasticity modulus
ρ	Density of a fluid
Subscripts	
a	Stands for apparent
p	Stands for plastic
o	Stands for yield stress
x	Stands for x component
y	Stands for y component
z	Stands for z component

VULNERABILITY MAPPING OF GROUNDWATER RESOURCES

Thomas Harter
University of California
Davis, California

WHAT IS GROUNDWATER VULNERABILITY?

Groundwater vulnerability is a measure of the likelihood that pollution or contamination at the land surface reaches a production aquifer. It is a measure of the "degree of insulation" that natural and man-made factors provide to keep pollution away from groundwater. The term was first used in Europe in the 1960s. In defining groundwater vulnerability, a number of issues must be examined and clarified; all refer to these two questions: vulnerability *of what?* and vulnerability *to what*? Exact definitions of groundwater vulnerability have therefore varied (1).

In principle, all groundwater is vulnerable to human activity; no groundwater is completely isolated from the aboveground environment. The degree of vulnerability depends on environmental conditions, on how we define groundwater and the part of groundwater in which we are interested in (hence the question, "vulnerability *of what*?"), and on the timescale of interest. In addition, it depends on whether or not a vulnerability measure is intended to account also for the presence and type of pollutants (hence, "vulnerability *to what*?").

Vulnerability of What?

Groundwater is produced from a wide variety of hydrogeologic environments. When defining vulnerability, therefore, we need to define the portion of groundwater to be assessed. Because the shallowest groundwater zone is typically the most vulnerable, vulnerability assessments are mostly concerned with the vulnerability of the uppermost aquifer (in a multiaquifer system) or with the water table (in an unconfined aquifer system). Deep groundwater is considered less vulnerable than shallow groundwater because of the longer travel times necessary for a pollutant to reach these deeper aquifers.

Some methods of assessing vulnerability therefore account, directly or indirectly, for the travel time between the water table and a well by considering aquifer permeability or travel-time zones (e.g., 2). Timescales are important in defining vulnerability. The practical question is, should we consider groundwater vulnerable to today's activities only if the recharge time is a few years or also if recharge timescales are tens, hundreds, thousands, or tens of thousands of years? The potential travel time between contaminant source and groundwater or groundwater wells is an important consideration for protection, monitoring, and assessment. Timescales are also important when mapping vulnerability to specific pollutants that become less harmful over time and with travel distance due to radioactive decay, degradation, inactivation (in the case of pathogens), filtration, or strong sorption to soils and aquifer materials.

Vulnerability to What?

An assessment of groundwater vulnerability may or may not include consideration of the presence of pollutants. Vulnerability that is independent of whether or not contaminants (pollutants) are present and focuses primarily on a description of natural environmental conditions is often (though not always) referred to as "susceptibility," "natural vulnerability," "aquifer sensitivity," or "intrinsic vulnerability." Pollution-type-dependent vulnerability, or vulnerability to specific land uses, is sometimes referred to as "specific vulnerability" or "integrated vulnerability" (1).

WHY ASSESS GROUNDWATER VULNERABILITY?

The purpose of vulnerability assessments is to provide a decision-making tool based on the best available data and good scientific judgment. It is generally not intended to be a scientifically rigorous analysis of groundwater resources. The National Research Council (3) identified four general objectives typically achieved by groundwater vulnerability assessments: (1) to facilitate policy analysis and development at the local and regional level, (2) to provide program management, (3) to inform land use decisions, and (4) to provide general education and awareness of a region's hydrogeologic resources.

The usefulness of vulnerability maps is limited (some would say, arguable). The scientific literature lists pros and cons to vulnerability assessments (1). The facts that speak for implementing assessments are that land use decisions have to be made, land management practices need to be sensitive to the risk for groundwater contamination, and not all anthropogenic activities can be carried out isolated from groundwater. Timescales and distinctions based on travel time are important, at least with respect to some pollutants. Timescales are also important in placing groundwater monitoring wells and in scheduling and providing for planning and action–response time if pollution does occur. So a need exists to provide at least some general guidance to land use planners, decision makers, and water users. Carefully prepared vulnerability assessments allow them to make decisions that are economically sensible and at the same time hydrogeologically reasonable.

On the other hand, some may argue against the use of vulnerability maps for land use planning because groundwater flow conditions and the transport properties of the subsurface are too complex to be appropriately captured by any vulnerability tool. A second group of arguments against vulnerability zoning arises from the fact that all groundwater is vulnerable to land pollution. The only geographically differing factor is the timescale for the pollution to reach groundwater.

WHAT FACTORS DETERMINE VULNERABILITY?

We distinguish between intrinsic factors (natural conditions) and extrinsic factors (anthropogenic activities). Among intrinsic factors, the thickness and hydraulic properties of the geologic formations above the aquifer—the unsaturated zone and confining layers above the aquifer—are key factors in determining the vulnerability of an aquifer system. They are the principal natural controls that determine the recharge rate and recharge time to the aquifer. The unsaturated zone also provides key groundwater protection by

- intercepting, sorbing, and eliminating pathogenic viruses and bacteria;
- sorbing and degrading many synthetic organic chemicals; and
- attenuating heavy metals and other inorganic chemicals through sorption and complexation with mineral surfaces within the unsaturated zone and through uptake into plants and crops (e.g., fertilizer).

The potential of the soil and the unsaturated zone to sorb, degrade, or eliminate substances depends on the type of pollutant and therefore is considered only in vulnerability studies that are specific to certain land uses.

The amount of recharge at the land surface is another important factor that determines vulnerability. The higher the recharge, the higher the vulnerability of the aquifer. If climatic conditions are such that little or no recharge occurs at the land surface, downward movement of moisture through the unsaturated zone is very limited, regardless of the hydraulic properties of the unsaturated zone.

In vulnerability assessments that encompass more than just aquifer susceptibility (see above), the presence of contamination sources or possible contaminating activities is considered an important factor. The amount, spatial distribution, and chemical properties of the contaminants (possibly) released into the subsurface are highly specific to individual sources and regions.

CHARACTERIZATION OF GROUNDWATER VULNERABILITY

Numerous schemes have been developed for assessing and mapping vulnerability. These methods can be grouped into three major categories:

- index-and-overlay methods
- process-based computer simulations
- statistical analyses

Index-and-Overlay Methods

Index-and-overlay methods are based on assembling information on the most relevant factors affecting aquifer vulnerability (soil type, geologic formation type, recharge, etc.), which then is interpreted by scoring, integrating, or classifying the information to produce an index, rank, or class of "vulnerability." The scoring, ranking, and integration methods are based on expert opinion rather than processes and are inherently subjective to some degree. In the United States, the most prominent vulnerability assessment method in this category is "DRASTIC" (2). Others include the vulnerability analysis specified by California's Drinking Water Source Assessment Program (4) and the British "GOD" method (1). A brief overview of DRASTIC and GOD is given below.

The advantage of index-and-overlay methods is that they provide relatively simple algorithms or decision trees to integrate a large amount of spatial information into maps of simple vulnerability classes or indexes. The methods are designed to rely on data that are readily available from local, state, or federal agencies, such as information on soils, water level depth, precipitation, and geology. These methods are particularly suitable for use with computerized geographic information systems (GIS), which is a digital form of mapmaking, because they usually involve overlaying and aggregating multiple maps showing soil properties, depth to water table, recharge, and so on.

DRASTIC Vulnerability Mapping (2). DRASTIC is the most popular vulnerability mapping tool in the United States. Put together by a group of experts and the EPA in the mid-1980s, it has been applied to a number of groundwater basins, regions, even states.

The name stands for *d*epth to groundwater, *r*echarge rate, *a*quifer media, *s*oil media, *t*opography, *i*mpact of vadose zone media, and hydraulic *c*onductivity of the aquifer. In DRASTIC, scores of 0 to 10 are assigned to each parameter, 0 means low risk of groundwater contamination; 10 means high risk of contamination. The scores are multiplied by a parameter-specific weight. The weighted scores of all seven parameters are then added for the final DRASTIC score. Two sets of weights can be used: one for general (intrinsic) vulnerability analysis, one for specific vulnerability to pesticides.

GOD (1). GOD is a vulnerability assessment method developed in Great Britain, where most groundwater resources are in hardrock aquifers, primarily sandstone and limestone aquifers. Unconsolidated overburden or soil layers cover the fractured hardrock in many places. Like DRASTIC, GOD is an index-and-overlay method designed to map groundwater vulnerability across large regions based on a few important parameters; GOD stands for *g*roundwater occurrence, *o*verall lithology of the unsaturated zone or overlying aquitard, and *d*epth to the groundwater table. Scores are assigned to each of the three categories and then multiplied to yield a final score. In developing GOD, the method's authors have given particular consideration to the likelihood of fractures or fracture systems to develop in the soils, overburden, or overlying geologic units of the aquifer.

Process-Based Computer Simulations

Process-based computer simulations afford a great amount of realistic complexity and detail to be built into the vulnerability assessment. Computer models can account for complex physical and chemical processes on a very detailed scale. Unlike the two-dimensional maps and map layers used with other methods, computer modeling allows for complete three-dimensional resolution. Geologic and hydrogeologic variations with depth can therefore be reproduced to evaluate their effect on vulnerability. Process-based computer models focus on re-creating the flow and transport patterns within the unsaturated zone or in an actual aquifer and can be used to compute travel times or concentrations of a contaminant in the unsaturated zone or in the aquifer. Computer models do not compute vulnerability directly. Rather, vulnerability is defined as a function of what the computer models simulate. For example, high vulnerability may be defined as any region in the aquifer for which the computer model shows a travel time of less than 5 years.

The most advanced computer models also allow the analyst to compute the uncertainty that is inevitably associated with the computer model predictions due to shortcomings in the database fed into the computer and due to our limited knowledge of the "underground world". These methods use statistical methods to quantify uncertainty. However, even simple computer models can include a sensitivity analysis, that is, an investigation of the sensitivity of the model predictions to the input provided.

Computer models are not commonly used for vulnerability assessment due to their considerable data requirements and the expertise required to implement models. In other words, computer simulation models are rarely an economical alternative for vulnerability mapping. However, computer modeling is an excellent and economical tool for vulnerability mapping if

- a more localized analysis of specific vulnerability to particular land uses (particular contaminants) is required and sufficient data are available or can be collected to prepare the computer model, and
- a number of "what-if" scenarios involving complex processes need to be evaluated for making important land use planning decisions.

Four computer model codes are particularly popular for computing the fate and transport of contaminants as those contaminants travel downward through the unsaturated zone to the water table: VLEACH (EPA), PRZM (EPA), LEACH (Cornell University), and HYDRUS (U.S. Department of Agriculture/Agricultural Research Service Salinity Laboratory, Riverside, California) (for up-to-date information on these codes, see the web pages of these agencies). All four codes (listed here roughly in order of complexity and user expertise required; VLEACH is least complex and HYDRUS the most complex) compute the downward movement of water (flow) and contaminants (transport). These codes are designed specifically to determine the amounts of sorption and degradation that occur in soils and in the unsaturated zone and are typically used to compute the residual, nondegraded mass of a contaminant that arrives, over time, at the water table. For vulnerability assessments, subregions or smaller sections of land with similar unsaturated zone properties are selected and grouped. One simulation is performed for each group or section, and the results are mapped in various ways; a map of the travel time to the water table (perhaps specific to a contaminant), a map of the percent removal of a contaminant within the vadose zone, and so on.

The most common computer code used for groundwater modeling (in all three dimensions) is MODFLOW (U.S. Geological Survey). This model and other 3-D computer models can be used for highly specific site studies of groundwater contamination that are far beyond the purpose of a typical vulnerability assessment. The data requirements for running these models are tremendous and require careful data preparation and data processing, particularly in a fully three-dimensional simulation. Sometimes, groundwater models are used to compute explicitly the complex source area of the water reaching a well. In that case, the same computer model can also be used to compute specific vulnerability for particular contaminants of concern within the source area of the well. If a well-calibrated and well-documented groundwater model exists, it may be preferrable to use the groundwater model to address specific vulnerability issues rather than using a basic index or a scoring-based vulnerability assessment.

Statistical Methods

Statistical methods are used to quantify the risk of groundwater pollution by determining the statistical dependence or relationship between observed contamination, observed environmental conditions that may or may not characterize vulnerability (e.g., unsaturated zone properties, recharge), and observed land uses that are potential sources of contamination (e.g., fertilizer applications, septic tank occurrence). Once a model of this dependence or relationship has been developed from the statistical analysis, it can be used to predict—in a similar area elsewhere—the chance or risk of contamination. Such an application requires, of course, knowledge of significant environmental conditions for that area. When statistical methods are used, the risk of contamination is essentially a quantitative measure of "vulnerability." The higher the contamination risk, the higher the vulnerability.

In principle, statistical methods are not much different from index-and-overlay methods. Both establish a relationship between inherent natural conditions and groundwater vulnerability (which the statisticians refer to as groundwater contamination risk). In overlay methods, the relationship is established by a team of experts. In statistical methods, the relationship is established by statistical analysis. The advantage of the statistical method is that the statistical significance can be explicitly calculated, which provides a measure of uncertainty or certainty of the model. The disadvantage is that statistical methods are difficult to develop and, once established, can be applied only to regions that have environmental conditions similar to those of the region for which the statistical model was developed.

Few statistical methods have been developed for vulnerability assessment, primarily because they rely on large data sets from regions already contaminated. The key to the development of a statistical method is a large, high quality data set of a specific contaminant or several specific contaminants commonly found in a region. That data set is then correlated in one fashion or another to specific properties of the subsurface (depth to water, soil permeability, slope, hydraulic conductivity, etc.) to create a statistical predictive model that can be used to make a quantitative statement about the contamination risk, such as, "if this kind of unsaturated zone, aquifer, and land use properties exist in a location, then the risk for groundwater contamination is X%, with a confidence interval of plus or minus Y%." Some examples follow.

CALVUL. In California, a statistical method has been developed by the California Department of Pesticide Regulations (DPR) to determine the specific vulnerability of groundwater to pesticide residues. The method is nicknamed CALVUL (California Vulnerability approach; (5)). DPR uses the vulnerability analysis to determine, for each section of agricultural land in California, whether groundwater in that section of land is vulnerable or not. If it is vulnerable, the land section (square mile) becomes part of a groundwater protection area with restricted pesticide use. The DPR method distinguishes two types of vulnerability: (1) vulnerability to pesticide leaching in coarse soils with a shallow water table and (2) vulnerability to pesticide runoff over hardpan soils (and subsequent leaching in dry wells). Pesticide management practices depend on whether pesticide leaching or pesticide runoff is of concern.

A pesticide database for the San Joaquin Valley was used to determine the statistical relationship between pesticide residue in groundwater and a large number of soil (unsaturated zone) properties, including water holding capacity, texture, organic matter content, permeability, shrink-swell potential, slope, and infiltration. By determining which soil and geographic properties are good predictors of pesticide residue in groundwater, the statistical model can be used to identify sections of land that have similarly "vulnerable" soil and geographic conditions but no past or current pesticide residue detections (5). Presumably, the most vulnerable areas are identified and can be targeted for implementation of mitigation management practices.

Texas Case Study. In Texas, a statistical analysis similar to DPR's San Joaquin study, albeit based on a different set of statistical tools, was developed by Evans and Maidment (6). Instead of pesticide residues in groundwater, this method uses an analysis of nitrate in groundwater as the basis for delineating vulnerable groundwater areas. As in CALVUL, the assumption made by the developers of the method was that where high contamination exists, the aquifer is more vulnerable than elsewhere. Nitrate was used as the target variable because a large amount of data was available throughout Texas and because nitrate is neither sorbed nor significantly degraded in groundwater (except under anaerobic conditions). The analysis was done by using data from the entire state. From a 30-year statewide database, the probability (risk) that a well would have nitrate levels in excess of some threshold value (1, 2, 5, or 10 mg/L NO_3-N) was computed separately for each analysis unit. The exceedance probability is used as a quantifiable measure of vulnerability; the higher the chances that nitrate is found in wells within an analysis unit (area), the higher the vulnerability. The study illustrates that overall results of the statistical analysis follow the general patterns laid out by the index-and-overlay methods, albeit at considerably higher expense.

National Groundwater Nitrate Vulnerability Assessment. The U.S. Geological Survey recently published a national assessment of the probability of nitrate contamination in recently recharged groundwater (7). The assessment relied on a specialized statistical regression analysis among major factors affecting the specific vulnerability of groundwater to nitrate and the measured occurrence of elevated nitrate levels in wells. The data set used to develop the regression model included wells from 20 major groundwater basins across the United States; each contained 20–30 test wells. Nitrogen fertilizer loading and percent cropland were significant extrinsic (nitrogen use related) factors. The presence of well-drained soils, depth to a seasonally high water table, and the presence of unconsolidated sand and gravel aquifers were the key intrinsic factors that determine groundwater nitrate vulnerability.

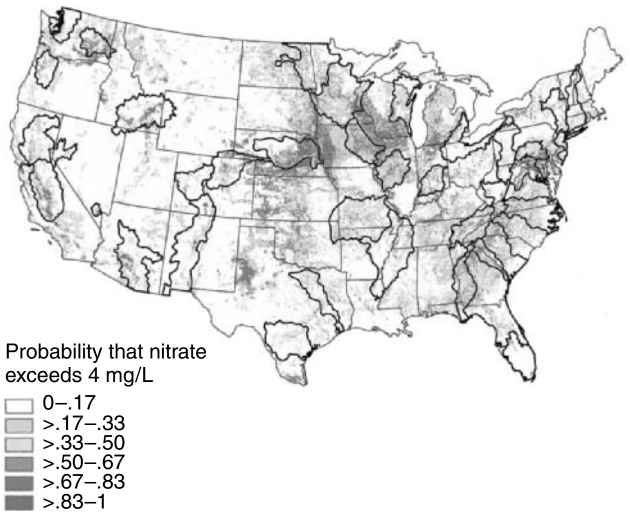

Figure 1. Groundwater vulnerability map for the United States, where vulnerability is here defined as the probability that nitrate concentration in groundwater exceeds 4 mg/l. (reprint from (7), also published at http://water.usgs.gov/nawqa/nutrients/pubs/est_v36_no10/fig3.html).

The regression model was validated (tested) on a large set of well records not used in developing the regression model and then applied to predict the probability of elevated nitrate (a measure of nitrate vulnerability) in groundwater throughout the United States at a resolution of 1 km^2 (Fig. 1, from Reference 7). The study demonstrates the advantage of the statistical method over index-and-overlay methods. The statistical assessment model uses objective, quantifiable measures to assess vulnerability. Its predictive capability has been quantified as well (through the validation test).

WHAT ARE THE LIMITATIONS OF VULNERABILITY ASSESSMENTS?

Because of the implied imprecise nature of vulnerability assessments and the inevitable subjectiveness of the underlying interpretive scheme, the National Research Council (3) issued "three rules of groundwater vulnerability." These rules, or limitations, should be spelled out explicitly with every vulnerability assessment:

- All groundwater is vulnerable to some degree.
- Uncertainty is inherent in all vulnerability assessments.
- There is a risk that the obvious may be obscured and the subtle may become indistinguishable.

The last refers to the danger, especially when using complex vulnerability assessment tools, that in light of the final vulnerability index or ranking, one may lose sight of the data used for the analysis and of the assumptions underlying vulnerability assessment schemes. The results of vulnerability assessments may mask real differences between specific sites or aquifer conditions.

AFTER THE ASSESSMENT: VERIFICATION AND POSTAUDIT

Verification refers to some independent procedure that can verify the results of the vulnerability analysis. *Postaudit* is essentially the same as verification but typically occurs years later, when additional data have been sampled that can be compared with the predictions made by the vulnerability analysis.

Verification and postaudits of vulnerability assessments can be done in many different ways. The most common approach, particularly for verifying assessments done with index-and-overlay methods, is to compare the vulnerability map with the actual occurrence of some common pollutant in groundwater. Typical pollutants used are nitrate and pesticides. However, such verification works well only where the appropriate pollution source is actually present and has been present for some time.

WATER/ROCKS INTERACTION

Henry Teng
The George Washington University
Washington, DC

Water–rock interaction is a process whereby solid earth materials and aqueous phases in the Earth system exchange matter and, ultimately, energy through chemical and biochemical reactions. The extent of reactions is determined by how far the system is away from equilibrium, and the rate of reactions is controlled largely by the kinetics of mineral-water interfacial processes. In a broad sense, these reactions can be classified into two categories based on the reactants involved: (1) those between H_2O and the mineralogical components of rocks and (2) those between solutes dissolved in natural waters and the minerals. Water–rock interactions participate in many geological processes such as ore deposit formation, weathering, and pedogenesis. The outcome of these interactions plays an important role in regulating geochemical cycling of elements, the atmospheric CO_2 level, and the chemistry and nutrient availability of surface/near-surface waters at both local and global scales.

Water–rock interactions are heterogeneous reactions because of the involvement of multiple phases (that is, solid and liquid phases in most cases). Despite the complexity associated with the heterogeneity and variations in mineral assemblages, water chemistry, and environmental conditions, reactions between aqueous phase and rocks at the fundamental level can be regarded as consisting of only two types of mechanistic movement (1), chemical species attachment to and detachment from mineral surfaces. Individual or combined development of the two basic actions over time yields three primary types of water–rock interactions: adsorption (including ion exchange), dissolution, and precipitation. Following is a detailed discussion of the three types of reactions.

ADSORPTION

Chemical sorption results directly from the occurrence of undercoordinated sites and associated charges on mineral surfaces. Development of surface charge in aqueous environments can be understood as a consequence of surface complexation, by which water molecules form chemical bonds with the undercoordinated surface atoms (2). These surface-bound water molecules are then subject to a proton transfer process that shifts hydrogen ions onto neighboring surface anions. This dissociative sorption of water molecules results in one or more types of surface species, depending on the chemical composition of the minerals in question. For (hydr)oxide materials, hydroxylated surface cation centers $>X(\mathrm{OH})^0$, where $>$ symbolizes lattice bonds and X represents the cationic component, seem to be the only concern. For salt-type minerals X_mA_n, an additional, second-type nonhydroxylated surface anion site $>A\mathrm{H}^0$ has to be taken into consideration.

When present in solution environments, the surface hydroxyl groups can undergo protonation or deprotonation to form charged surface species. The relative abundance of protonated and deprotonated species thus governs the surface electric properties. Consider an oxide mineral XO. The sign and quantity of surface charges incurred in pure water will be controlled by the following reactions

$$\equiv X\mathrm{OH_2}^+ \Leftrightarrow \equiv X(\mathrm{OH})^0 + \mathrm{H}^+ \qquad K_{\mathrm{a1}}^{\mathrm{app}} \tag{1a}$$

and

$$\equiv X(\mathrm{OH})^0 \Leftrightarrow \equiv X\mathrm{O}^- + \mathrm{H}^+ \qquad K_{\mathrm{a2}}^{\mathrm{app}} \tag{1b}$$

where $K_{\mathrm{a1}}^{\mathrm{app}}$ and $K_{\mathrm{a2}}^{\mathrm{app}}$ are the apparent equilibrium constants of reactions 1a and 1b. The participation of hydrogen ions in the above reactions indicates that the relative concentrations of the protonated and deprotonated surface species, and hence the amount of surface charges, are controlled by the pH of the aqueous environment. The pH at which there are equal amounts of $>X\mathrm{OH_2}^+$ and $>X\mathrm{O}^-$ (i.e., an uncharged surface) is defined as the pH of zero net proton charge, below which the surface is positively charged for $>X\mathrm{OH_2}^+$ is more abundant than $>X\mathrm{O}^-$ and above which the surface is negatively charged because of the excess of $>X\mathrm{O}^-$.

In the presence of other sorbing ions, say $M^{(\mathrm{n}+1)+}$ and $L^{(\mathrm{n}+1)-}$, in solutions, competitive complexation becomes operative as M can exchange for H and L for OH at the $>X(\mathrm{OH})^0$ sites to result in the formation of surface complexes such as $>X\mathrm{O}M^{\mathrm{n}+}$ and $>XL^{\mathrm{n}-}$. Surface complexation under this condition becomes adsorption where both chemical bonding and electrostatic interaction take place between solute particles and surface atoms (3). Empirical approaches to adsorption employ simple equations to describe the adsorption isotherm (relationship between the solution concentration or activity and the surface concentration of an adsorbate), without concerning the specific interfacial interactions between adsorbate and adsorbent. For example, the Langmuir isotherm, one of the most common empirical models, simply treats adsorption as a free surface site $>S$ occupied by an adsorbate A to form a sorbed site $>SA$:

$$>S + A \Leftrightarrow >SA \tag{1c}$$

The adsorption constant K_{ad} given by the mass law is

$$K_{\mathrm{ad}} = \frac{[>SA]}{[>S][A]} \tag{1d}$$

Because the total amount of surface sites is $[>S]_{\mathrm{tot}} = [>S] + [>SA]$, Eq. 1d can be rewritten as

$$[>SA] = [>S]_{\mathrm{tot}} \frac{K_{\mathrm{ad}}[A]}{K_{\mathrm{ad}}[A] + 1} \tag{1e}$$

High concentrations of $[A]$ lead to $[>SA] \cong [>S]_{\mathrm{tot}}$, whereas low values of $[A]$ reduces Eq. 1e to a linear form of $[>SA] \cong K_{\mathrm{d}}[A]$. Another common empirical adsorption model, the Freundlich isotherm, uses a logarithmic relationship between $[>SA]$ and $[A]$ so that

$$[>SA] = k_f[A]^n \tag{1f}$$

where both k_f and n are constants. The Freundlich model can be thought of as the Langmuir isotherm integrated over many types of surface sites (4).

In the surface complexation model, adsorption is treated as a chemical reaction

$$>X(\mathrm{OH})^0 + M^{(\mathrm{n}+1)+} \Leftrightarrow >X\mathrm{O}M^{\mathrm{n}+} + \mathrm{H}^+ \tag{1g}$$

The equilibrium constant K^{app}

$$K^{\mathrm{app}} = \frac{[>X\mathrm{O}M^{\mathrm{n}+}][\mathrm{H}^+]}{[>X\mathrm{OH}^0][M^{(\mathrm{n}+1)+}]} = K^{\mathrm{int}}K^{\mathrm{coul}} \tag{1h}$$

now has contributions from chemical (intrinsic) as well as electrostatic (coulombic) interactions between the reactants. Quantitatively, $K^{\mathrm{coul}} = \exp(F\Delta\mathrm{Z}\Psi)$, where $\Delta\mathrm{Z}$ is the change of charges in surface species because of adsorption. The surface potential Ψ is a function of surface charge σ, and the charge-potential relationship can be derived from electrochemistry theories. A common one

$$\sigma = (8RT\varepsilon\varepsilon_0 I)^{1/2}\sinh(z\Psi F/2RT) \tag{1i}$$

is given by the Gouy–Chapmen theory (diffuse double-layer model). Here ε is the relative dielectric constant of water, ε_0 is the permittivity of vacuum, I is the ionic strength of the bulk solution, and z is the valence of the symmetrical background electrolyte. The quantity of surface charge can be computed from the concentration of charged surface species. For Eq. 1g,

$$\sigma = F[\equiv X\mathrm{O}M^{(\mathrm{n}-1)+}]/AS \tag{1j}$$

where A and S are the specific area (m^2/g) and solid concentration (g/l) of the adsorbent material, respectively. Overall, assuming the total amount of surface sites in Eq. 1g is approximated by $[>X\mathrm{O}]_{\mathrm{tot}} = [>X(\mathrm{OH})^0] + [>X\mathrm{O}M^{\mathrm{n}+}]$, one can rearrange Eq. 1h into

$$[>X\mathrm{O}M^{\mathrm{n}+}] = [>X\mathrm{O}]_{\mathrm{tot}}\left[\frac{\exp(\mathrm{nF}\Psi)K^{\mathrm{int}}[M^{(\mathrm{n}+1)+}]}{\exp(\mathrm{nF}\Psi)K^{\mathrm{int}}[M^{(\mathrm{n}+1)+}] + [\mathrm{H}^+]}\right] \tag{1k}$$

It becomes apparent that, after inspecting Eqs. 1e, 1f, and 1h, the surface complexation approach is advantageous over the empirical isotherms in that the formal provides additional insight into the dependence of adsorption upon pH and ionic strength (through Eq. 1i). Moreover, the use of K^{int} in surface complexation models makes it possible to compare results from different experiments because, unlike empirical parameters such as K_{ad} (Eq. 1d) and K_{f} (Eq. 1f), the intrinsic surface complex formation constant is not experimental condition dependent.

It is noteworthy to point out that although surface complexation reactions can occur on any mineral crystals, effective adsorption requires small grain sizes. Because of the inverse relationship between particle size and specific surface area (defined as the ratio of surface area to volume of a particles), small grains (<1 μm) tend to have a significant percentage of surface-bound atoms. Consequently, small particles have large numbers of active surface sites available to undergo complexation reactions. Micron-scale suspended particles and sub-micron-scale colloids of minerals are a common occurrence in surface waters and groundwaters (Ref. 5). It is estimated that 80% of the materials transported by rivers and discharged into the oceans is in the form of suspended particles. Although the exogenic cycle of the major cations and anions is controlled by solution process, in most cases the geochemistry of trace elements in natural waters is governed by adsorption on separate mineral grains (6).

DISSOLUTION

Minerals dissolve because the chemical potential of solute in solid and liquid phases has not reached equality, which indicates that the driving force of any dissolution reaction may be estimated by the free energy difference, ΔG, between reactants and products. As the reaction approaches equilibrium conditions where ΔG becomes zero, dissolution should cease to proceed.

Consider the dissolution of a solid compound ML,

$$ML \Leftrightarrow M^{n+} + L^{n-} \tag{2a}$$

The free energy change in this system is described by

$$\Delta G = \Delta G^{\mathrm{o}} + RT\ln(a_{\mathrm{M}}a_{\mathrm{L}}) \tag{2b}$$

where ΔG^{o} is the standard free energy change, R is the gas constant, and T is the temperature; a_{M} and a_{L} are the activity of aqueous species M^{n+} and L^{n-}, respectively. At equilibrium conditions, $\Delta G = 0$ and Eq. 2b can be rewritten as

$$a_{\mathrm{M}}a_{\mathrm{L}} = \exp(-\Delta G^{\mathrm{o}}/RT) \tag{2c}$$

Because ΔG^{o} can be computed as the difference between the standard free energy of formation for the dissolved species and the solid phase, Eq. 2c yields a numerical value defined as the standard equilibrium constant or solubility constant, K_{sp}, of the compound ML.

When the solid–fluid interface is concerned, surface energies and grain sizes have to be taken into account to define the equilibrium conditions. Consider a mineral crystal of any geometry with any number of faces that are not related by any symmetry operations. At constant temperature and pressure, the free energy change in a system containing the crystal in contact with an undersaturated solution can be described by

$$dG = -\sum_i \nu_i\mu_i dn + \sum_j \gamma_j dA_j \tag{3a}$$

where μ_i is the chemical potential of the ith species in the liquid phase; ν_i is the stoichiometric coefficient of the ith species in the solid phase; n is the number of moles of solute that are involved in the dissolution reaction; and γ_j and A_j are the surface free energy and the surface area of the jth type of faces, respectively. Using the definition of chemical potential,

$$\mu_i = \mu_i^{\mathrm{o}} + RT\ln\alpha_i \tag{3b}$$

one can rewrite Eq. 3a as

$$\frac{dG}{dn} = -\sum_i \nu_i\mu_i^{\mathrm{o}} - RT\ln\prod_i \alpha_i^{\nu_i} + \sum_j \gamma_j(dA_j/dn) \tag{3c}$$

where μ_i^{o} and α_i are the standard chemical potential and the activity of the ith species, respectively. At equilibrium conditions, $dG/dn = 0$, $\sum_i \nu_i\mu_i^{\mathrm{o}} = -RT\ln K_{\mathrm{sp}}$, it then follows that the crystal solubility $K_b = \prod_i \alpha_i^{\nu_i}$ can be expressed as

$$\ln K_b = \ln K_{\mathrm{sp}} + \frac{1}{RT}\sum_j \gamma_j(dA_j/dn) \tag{3d}$$

Equation 3d states that the solubility of a crystal is always greater than the standard solubility product of the solute. Rewrite Eq. 3d using the volume v and density ρ of the crystal and the molecular weight W of the solute, one gets

$$\ln K_b = \ln K_{\mathrm{sp}} + \frac{W/\rho}{RT}\sum_j \gamma_j(dA_j/dv) \tag{3e}$$

For isotropic crystals with any characteristic dimension l (i.e., length, width, or height), $\Sigma\gamma_j(dA_j/dv)$ can be approximated by $(2\gamma)/(3l)$ and Eq. 3e can be simplified to

$$\ln K_b = \ln K_{\mathrm{sp}} + \frac{2W/\rho}{3RT}(\gamma/l) \tag{3f}$$

Equation 3f is the statement of the classic Gibbs–Thomson relationship, which predicts that the difference between crystal solubility and K_{sp} is size-dependent, and the solubility of any crystals can only be approximated by the standard solubility product of the solute when the crystal is infinitely large. In a practical sense, the "infinite" size is usually no larger than a few micrometers. For anisotropic minerals, each crystal face has to be considered individually because the surface energy is face-specific and Eq. 3e cannot be easily simplified. Nonetheless, the conclusions drawn from Eq. 3f are just as well applicable.

Dissolution not only takes place in the form of dissociation reactions (Eq. 2a), but it can also result from reduction–oxidation reactions where the number of valence electrons changes on one or more reactant elements. Redox reactions particularly affect water–rock interactions involving minerals that contain multivalence state elements such as S and Fe. However, because of the relatively few minerals concerned, the contribution of redox chemistry to the exogenic cycle of elements is considered auxiliary (7). Most natural redox reactions are mediated by microbial communities or induced by solar radiation. In the formal scenario, oxidized mineral species are often used as electron acceptors for metabolism, whereas in the latter situation, electrons in the reactants' molecular orbital are excited photochemically to pair up with more electrons or to be released to lower the energy state of the system.

Traditionally, geochemists treat redox reactions as reactants' gaining or losing oxygens. The more modern approaches, on the other hand, choose to use electron as a basic component. In this convention, reductants are electron donors that release e^- and oxidants electron acceptors that receive e^-. The activity of electron can be expressed as a potential (Eh, in volts) or as an activity unit ($\mathrm{p}e = -\log a_{e^-}$). Quantitatively, Eh and pe can be converted to each other through

$$\mathrm{p}e = \frac{F}{2.303RT}Eh \tag{4a}$$

where F is the Faraday constant. In addition, Gibbs free energy and the activity of electrons are related by

$$\Delta G = -nFEh \tag{4b}$$

where n is the number of electrons in the reaction. If a redox dissolution reaction can be written as

$$\text{Ox (solid)} + ne^- \Leftrightarrow \text{Rd (aqueous)} \tag{4c}$$

the standard free energy expression (Eq. 2b) becomes

$$Eh = E^{\mathrm{o}} - \frac{RT}{nF}\ln a_{\mathrm{Rd}} \tag{4d}$$

or

$$\mathrm{p}e = \mathrm{p}e^{\mathrm{o}} - \frac{1}{n}\log a_{\mathrm{Rd}} = \frac{1}{n}\log K^{\mathrm{o}} - \frac{1}{n}\log a_{\mathrm{Rd}} \tag{4e}$$

where E^{o} and pe^{o} are the activity of electrons under standard conditions. Notice that the equilibrium constant of redox reaction K^{o} can still be calculated from the difference between the standard free energy of formation for the dissolved species and the solid phase (i.e., Eq. 2c).

In general, the rate R of dissolution reactions can be related to ΔG by (8)

$$R = k(1 - e^{\Delta G/RT}) \tag{5a}$$

where k is the rate constant. When the reaction is sufficiently close to equilibrium (i.e., $|\Delta G| \ll RT$), Eq. 5a reduces to

$$R = -(k/RT)\Delta G \tag{5b}$$

This expression depicts a linear relationship between the driving force and the kinetics of dissolution reactions at near-equilibrium conditions. When applying Eq. 5b to water–rock interactions, however, caution has to be used because the dissolution of many minerals in aqueous environments is initiated by the formation of etch pits on crystal surfaces. Etch pit nucleation usually requires one to overcome an energy barrier that decreases with descending saturation state (9,10). At very close to equilibrium conditions, the saturation state may be too high to bring down the barrier to the extent that allows pit formation, which indicates that dissolution kinetics may change discretely, rather than in a linear fashion, with decreasing saturation state (11,12).

A unique characteristic of mineral dissolution is that some (alimino)silicate minerals may dissolve in an incongruent or nonstoichiometric manner. This type of reaction is best exemplified by the dissolution process of Na- and K-feldspars in acidic environments. It is generally agreed that the dissolution starts with an initial fast ion exchange of hydrogen ions for alkali and alkaline earth metals, followed by a slow process that disrupt the Si-O-Al-O framework. The disruption seems to proceed by preferential release of aluminum (i.e., nonstoichiometric surface leaching) so SiO_2 accumulates *in situ*. Observations by numerous workers indeed reveal the presence of a Si-rich surface coating on feldspar crystal faces when the minerals are exposed to solutions with pH <3–5 (Ref. 13). What researchers are not in complete agreement on is to what extent the Si-rich layer is originated from surface alteration. Although results from investigations up to the end of the last century imply that most coating (up to several thousand angstroms in depth) forms through nonstoichiometric leaching of the underlying minerals (Ref. 13), recent studies using more modern experimental techniques suggest otherwise. Synchrotron radiation and high-resolution transmission electron microscopy show that the incongruent dissolution may be operative only for, at most, the first few unit cells at the mineral-water interface, and the thick surface alteration thus forms largely by interfacial dissolution–reprecipitation (14,15).

PRECIPITATION

Much of the discussion on reaction driving forces in dissolution section is directly transferable to precipitation reactions. However, precipitation is not a pure mirror image of dissolution in that the former is a combination of two separate but sequentially occurring processes, nucleation and growth. Nucleation refers to the atomic process in which solute components congregate to form a thermodynamically stable cluster, whereas the following accretion of the cluster is termed growth. Both nucleation and growth require the occurrence of supersaturation, but each of the two processes has its unique physiochemical controls.

Homogeneous nucleation occurs when a thermodynamically stable 3-D cluster is born directly from solution. On the other hand, solute particles can assemble onto an existing surface, and hence through heterogeneous nucleation, to form a stable 2-D cluster. No matter how nucleation takes place, the classic nucleation theory requires the sizes of the clusters to satisfy the following energetics for the atomic assemblage to become stable nuclei: A surface energy increase associated with the emergence of the solid phase precisely offsets the chemical potential decrease in the solution because of losing solute. Mathematically, free energy change upon formation of a spherical cluster of radius r can be expressed as

$$\Delta G = 4\pi r^2\overline{\gamma} - (4/3\pi r^3/\overline{\mathrm{v}})\Delta\mu \tag{6a}$$

where $\overline{\gamma}$ is the average surface free energy and $\overline{\mathrm{v}}$ is the specific molecular volume of the solid. The minimal size of a stable cluster

$$r_\mathrm{c} = 2\overline{\mathrm{v}}\overline{\gamma}/\Delta\mu \tag{6b}$$

can be found by solving the equation $d(\Delta G)/dr = 0$. Any cluster with $r < r_\mathrm{c}$ is unstable and will be dissolved, whereas the ones with $r > r_\mathrm{c}$ will move on to the growth stage. Inserting Eq. 6b into 6a, one has an expression that estimates the energy barrier, ΔG^*, for nucleation:

$$\Delta G^* = \frac{16\pi\overline{\gamma}^3\overline{\mathrm{v}}^2}{3\Delta\mu} \tag{6c}$$

The nucleation rate R_n, according to the conventional rate theory, is then available through

$$R_\mathrm{n} = \overline{A}\exp\Big(\frac{-\Delta G^*}{k_BT}\Big) \tag{6d}$$

where k_B is the Boltzmann constant and $\overline{A}$ is a constant related to the efficiency of particle collision (16). All implications from Eqs. 6a–6d apply to heterogeneous nucleation, except that, quantitatively, ΔG^* is usually smaller when nucleation occurs on a substrate surface. This result leads to a general conclusion that heterogeneous nucleation often occurs at a lower supersaturation than does homogeneous nucleation.

Precipitation enters the growth stage with the onset of enlargement of the minimal sized clusters. Nuclei increase their size through attachment of individual solute particles onto the cluster surfaces. During growth, crystallographic control becomes strongly operative. That is, faces that are more closely packed will prevail, whereas the ones with smaller packing density will be phased out. The more closely packed faces usually are the flat face (F-face) on the ideal Kossel crystals (17); the growth of flat surfaces is commonly recognized as following a layer-by-layer mechanism where solute particles attach to kink sites along steps (i.e., the edges of individual layers) generated either by crystal imperfection or surface nucleation. The net rate of step advance, v_s, is determined by the difference between solute fluxes attaching to and detaching from the step kinks. This relationship can be described mathematically by (18,19)

$$v_s = (d^2/\lambda_\mathrm{o})\upsilon\{\exp[(\mu_\mathrm{S} - \overline{\mathrm{E}})/k_BT] - \exp[(\mu_\mathrm{L} - \overline{\mathrm{E}})/k_BT]\} \tag{6e}$$

Here, d is the size of the attaching species in the lattice, λ_o is the interlink distance, and υ is the fundamental frequency (20) that can be approximated by k_BT/h_p where h_p is the Planck constants; μ_L and μ_S are the chemical potentials of solute in liquid (solution) and solid (crystal), respectively, and $\overline{\mathrm{E}}$ is the free energy of an intermediate activated complex.

Equation 6e can be further rearranged into

$$v_s = (d^2/\lambda_\mathrm{o})\upsilon\exp[(\mu_\mathrm{L} - \overline{\mathrm{E}})/k_BT]\{\exp[(\mu_\mathrm{S} - \mu_\mathrm{L})/k_BT] - 1\} \tag{6f}$$

Considering that the term $\exp(\mu_\mathrm{L} - \overline{\mathrm{E}})$ has an entropy factor, $\exp(\Delta\overline{\mathrm{S}}/k_B)$, and an energy factor, $\exp(-\Delta E/k_BT)$, and that $(\mu_\mathrm{S} - \mu_\mathrm{L})$ is essentially the driving force for growth and is quantitatively related to supersaturation, σ, by

$$\Delta\mu = k_BT\ln(a/a_e) = k_BT\sigma \tag{6g}$$

one can rewrite Eq. 6f as

$$v_s = \{(d^2/\lambda_\mathrm{o})\upsilon\exp(-\Delta\overline{S}/k_B)\exp(-\Delta E/k_BT)\}/ k_BT]\}\{(a - a_e)/a_e\} \tag{6h}$$

Notice that step velocity has a linear dependence on the difference between solute activity and its equilibrium value $(a - a_e)$. By convention, the quantity between the first two curly parentheses in Eq. 6h is termed the kinetic coefficient, β, of step growth. This parameter, as shown here, is characterized by the activation energy barriers, ΔE, and the corresponding entropic changes for the formation of activated intermediate complexes.

Complementary to the classic approach of atom-by-atom growth, recent findings suggest that crystals can also grow by oriented aggregation of nano-sized clusters (21,22). In this growth mode, adjacent nanocrystallites coagulate after spontaneous self-organization that situates the two parties to a common crystallographic orientation. The new, larger particles gain thermodynamic stability by forming chemical bonding between the original clusters to eliminate the interface between them. It is entirely possible that different growth mechanisms operate at different conditions. When nucleation rates are low and nuclei are far apart in the media, growth may only be accomplished by atom-by-atom attachment on growing surfaces. When sufficient nuclei are present, they can coalesce, through orientated coagulation, to form larger crystals, as long as the system is shifting toward a lower energy state.

It is important to be informed that the kinetics of interfacial reactions such as dissolution and growth can be controlled either by the pace of the actual chemical reactions or the speed at which the reactants and products are delivered to and removed from the reaction sites, or both. To date, it is generally agreed that surface reactions, rather than transport, play a predominant role in controlling the rate of mineral-water interactions. This point of view is supported by the nearly ubiquitous occurrence of etching features on both laboratory dissolved and naturally weathered grains of many minerals. The significance of this understanding is directly reflected by the intensive interests in mineral surface geochemistry that has been growing for more than two decades.

GROUND WATER: WELLS

Roger M. Waller
U.S. Geological Survey

There's a good chance that the average Joe who had to dig a well in ancient Egypt probably did the work with his hands, a shovel, and a bucket. He would have kept digging until he reached the water table and water filled the bottom of the hole. Some wells are still dug by hand today, but more modern methods are available. It's still a dirty job, though!

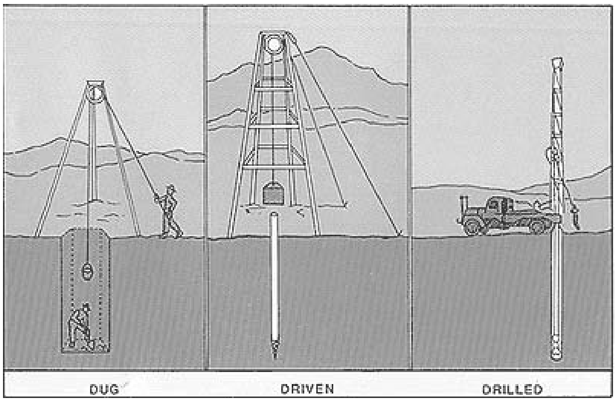
Wells are extremely important to all societies. In many places wells provide a reliable and ample supply of water for home uses, irrigation, and industries. Where surface water is scarce, such as in deserts, people couldn't survive and thrive without ground water.

TYPES OF WELLS

Digging a well by hand is becoming outdated today (would YOU want to do it?). Modern wells are more often drilled by a truck-mounted drill rig. Still, there are many ways to put in a well—here are some of the common methods.

Dug Wells

Hacking at the ground with a pick and shovel is one way to dig a well. If the ground is soft and the water table is shallow, then dug wells can work. They are often lined with stones to prevent them from collapsing. They cannot be dug much deeper than the water table—just as you



---

cannot dig a hole very deep when you are at the beach... it keeps filling up with water!

Driven Wells

Driven wells are still common today. They are built by driving a small-diameter pipe into soft earth, such as sand or gravel. A screen is usually attached to the bottom of the pipe to filter out sand and other particles. Problems? They can only tap shallow water, and because the source of the water is so close to the surface, contamination from surface pollutants can occur.

Drilled Wells

Most modern wells are drilled, which requires a fairly complicated and expensive drill rig. Drill rigs are often mounted on big trucks. They use rotary drill bits that chew away at the rock, percussion bits that smash the rock, or, if the ground is soft, large auger bits. Drilled wells can be drilled more than 1,000 feet deep. Often a pump is placed at the bottom to push water up to the surface.

WATER LEVELS IN WELLS

Ground-water users would find life easier if the water level in the aquifer that supplied their well always stayed the same. Seasonal variations in rainfall and the occasional drought affect the “height” of the underground water level. If a well is pumped at a faster rate than the aquifer around it is recharged by precipitation or other underground flow, then water levels around the well can be lowered. The water level in a well can also be lowered if other wells near it are withdrawing too much water. When water levels drop below the levels of the pump intakes, then wells will begin to pump air—they will “go dry.”

WELL SCREENS

Dennis E. Williams
Geoscience Support Services
Claremont, California

A well screen is a fairly generic term that denotes the component of a well that provides (1) an opening for water to enter the well casing from the aquifer; and (2) stabilizes material in the “near-well zone” (i.e., materials immediately adjacent to the well) and prevents it from entering the well.

Proper design of well screens therefore is paramount in successful water wells. Most modern wells are constructed using a filter pack placed between the well screen and the aquifer. In a proper well screen/filter pack design (i.e., gravel envelope well), the fundamental principle is: *The purpose of the filter pack is to stabilize the aquifer; the purpose of the well screen is to stabilize the filter pack*.

A properly designed well screen therefore allows sand-free water to flow into the well with minimum drawdown. Features of a properly designed well screen include:

1. Adequate open area (typically greater than 3–5%) to maximize well efficiency[1]
2. Strong pipe-based well screen (e.g., horizontal louver shutter screen) to provide maximum collapse strength.
3. Constant diameter throughout the entire length of the well screen.
4. Single material type (e.g., all copper-bearing or all stainless steel) to avoid galvanic corrosion from two different metals coming in contact with one another.

Well screens may be constructed with a variety of different materials and designs. The screen material can be different steels, such as carbon, copper-bearing, high strength low-alloy, and stainless, or PVC materials. The type of material used is dependent on the purpose of the well, strength requirements, groundwater quality (corrosion potential), the expected well life, and cost factor. There are many different types of well screens; however, the most commonly used are discussed below.

HORIZONTAL LOUVER SCREENS

Horizontal louver screens are a pipe-based well screen manufactured by punch-formed downward facing horizontal louver-shaped openings (Fig. 1). This type of screen is particularly suited for use in large diameter, deep, gravel envelope wells. The horizontal louver screen can be manufactured in a variety of patterns, with various percentages of open areas. Percentage open areas range from approximately 3.4% to 7.4% for Ful Flo to Super Flo patterns (2). The smooth, unobstructed interior of the horizontal louver screen allows for efficient use of highly effective development techniques such as swabbing and also facilitates employment of efficient maintenance and repair methods. Disadvantages of horizontal louver screen include

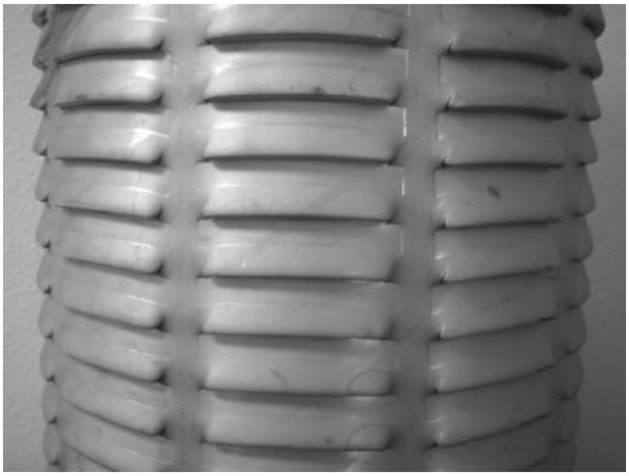


Figure 1. Horizontal louver screen.

---

[1] [It has been demonstrated (1,2) that if the percentage open area is above 3–5%, well efficiencies do not significantly increase. It has also been demonstrated that entrance velocity is not a critical design factor and only needs to be below 0.5 m/s (1.5 ft/s).]

unavailability of slot size smaller than 1 mm (0.040 in.), and difficulty in perforating though thick walled pipe [i.e., greater than 9.5 mm (0.375 in.)]. However, the superior strength capabilities and long-life characteristics have made horizontal louver screens an industry standard in deep high capacity water supply wells.

CONTINUOUS WIRE WRAP SCREEN

Wire wrap screen is manufactured by wrapping a shaped wire (steel or plastic) around an internal array of longitudinal rods (Fig. 2). The wire and rod are joined by resistance welding, which produces a cage-shaped cylindrical configuration. Continuous slot screens are very effective in naturally developed wells in uniform fine-grained sands in relatively shallow, thin aquifers since they are able to be manufactured with very small slot sizes and yet still maintain the necessary open area to minimize frictional head loss. Continuous wire wrap screens typically have open areas greater than 25%. Additionally, the design allows small particles to pass completely through the screen without becoming wedged in and causing clogging of the screen. Disadvantages of the continuous slot screen are associated with its relatively low strength, which necessitates special handling during installation and development, and also restricts the extent of future well maintenance and repair efforts. As the interior is obstructed by rods, the use of highly effective well development techniques such as swabbing is precluded. Should the screen be damaged, repair by swedging is impractical.

Figure 2. Continuous wire wrap screen.

BRIDGE SLOT SCREENS

Bridge slot screens are manufactured on a press from flat sheets or plates. The slot opening is usually vertical and provides two orifices, longitudinally aligned to the axis. The perforated steel sheets or plates are then rolled into cylinders and the seam is welded (Fig. 3). A bridge slot screen is usually installed in gravel envelope wells. Its chief advantages are reasonably high area of opening (approximately 4.8%) and minimum frictional head losses at relatively low cost. One important disadvantage is its low collapse strength due to the large number of vertically oriented slots. The manufacturing process is restricted with respect to wall thickness, which is limited to a maximum of 6.35 mm (0.250 in.).

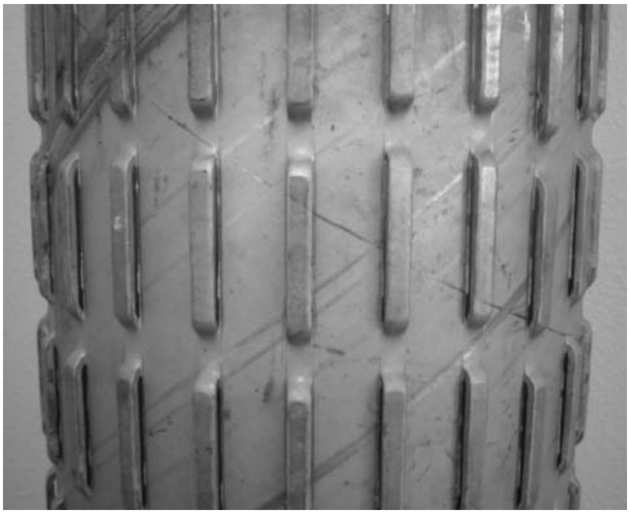

Figure 3. Bridge slot screen.

MACHINE-SLOTTED (MILLED) SCREENS

Horizontal and vertical machine-slotted screens are manufactured from casing in which openings are milled with axially oriented precision cutters (Fig. 4). Vertical slotted screens are also manufactured by prepunching flat sheets of steel prior to fabrication into cylinders. Machine-slotted screens have disadvantages that include clogging due to the parallel surfaces within the opening. As slot

Figure 4. Horizontal machine-slotted screen.

clogging is directly related to wall thickness, thicker material encourages greater plugging. Some vertical machine-slotted casings are machined with an undercut to reduce this tendency. A second drawback is the low area of openings (less than 1%), although this can be overcome at higher cost by increasing the number of slots. Collapse strength of vertically machine-slotted casings, however, is substantially reduced when the number of openings is increased. The main positive characteristics of machine-slotted screens are low cost, uniform openings, and availability in a fairly wide range of apertures and patterns.

WELL CASING PERFORATED IN PLACE

Well casing perforated in place has historically been used with cable tool wells drilled in unconsolidated alluvium. Once the casing has been driven or jacked to its total depth, a mills knife (vertical slots) or hydraulic louver-type perforator (horizontal slots) is used down the hole to perforate the casing at specific intervals. The hydraulic louver-type perforator is superior to the mills knife in producing slots due to better physical casing characteristics and more control over the aperture size; in addition, the louver-shaped openings provide greater stabilization of particles in relative fine-grained sand formations. The hydraulic louver-type perforator is limited to a slot size of 3.2–4.0 mm (0.125–0.156 in.). Typically, a well casing perforated in place would have a percentage open area of less than 1%.

The design of the screen slot or aperture size for gravel envelope wells requires the filter pack to be designed first. The screen slot size must result in 90% retention of filter pack material outside the screen.

WELL TEST

Dennis E. Williams
Geoscience Support Services
Claremont, California

A well test is a test conducted in a completed and developed well from which data can be collected to calculate certain hydraulic parameters of the well and surrounding aquifer. Hydraulic parameters may then be used, for example, to design the maximum safe pumping rate of the well, determine well field spacing, calculate aquifer storage, or determine the rate of movement of contaminants in the groundwater. Well tests include pumping tests, recovery tests, and slug tests. Essential measurements and data collected during well tests include time, depth to water, and discharge rate. Obtaining accurate data from a pumping test involves a carefully planned test program, including consideration of continuous operation and execution of the necessary steps.

Step-drawdown tests are generally the first type of test performed on a newly completed production well following final well development. A step-drawdown test involves pumping the well at several discharge rates and measuring the change in depth to pumping level in the well as time progresses (Fig. 1). At least three "discharge steps" are required for the test with subsequent discharge rates increasing over the previous steps. Data obtained from step-drawdown tests are used to determine well production and drawdown characteristics, from which the permanent production pump can be designed. The discharge step rates are determined based on results from the final development pumping. For example, if during final development, the maximum discharge rate reached 2500 gpm with good groundwater level stabilization, then the three rates for the step-drawdown test might be 750, 1500, and 2200 gpm. The discharge rates for a step-drawdown test should be reasonably spread out over the maximum range available for the well (as determined during development).

Following the step-drawdown test, a constant-rate pumping test is usually performed. The purpose of the constant-rate test is to verify the design discharge rate estimated from the step-drawdown test and also to measure longer-term (usually greater than 24 h) drawdown effects on the pumping well and any nearby wells. Data obtained from both the pumping well and nearby wells can be used to calculate aquifer parameters, which can then be used to design spacing between wells, calculate groundwater storage volumes, or determine the rate of movement of groundwater. The discharge rate during the constant-rate test should be kept constant for the entire duration of the test and should be at the design discharge rate for the well (Fig. 2). The design discharge rate may be based on both development pumping and results from the step-drawdown test. The step-drawdown test is seldom performed for a duration sufficient to design the permanent pump and should always be verified with a longer-term constant-rate test. However, the final design pumping rate is still subject to "sound engineering

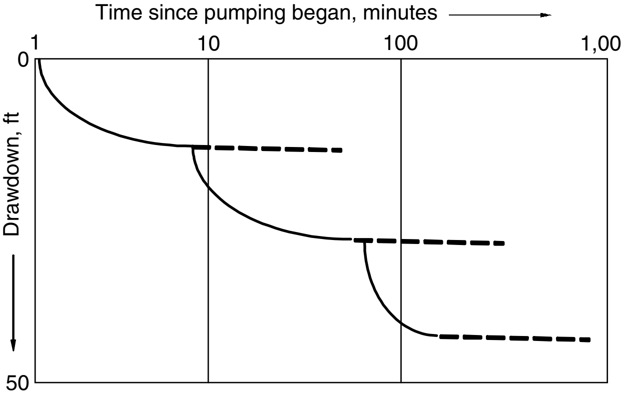

Figure 1. Step-drawdown test data.

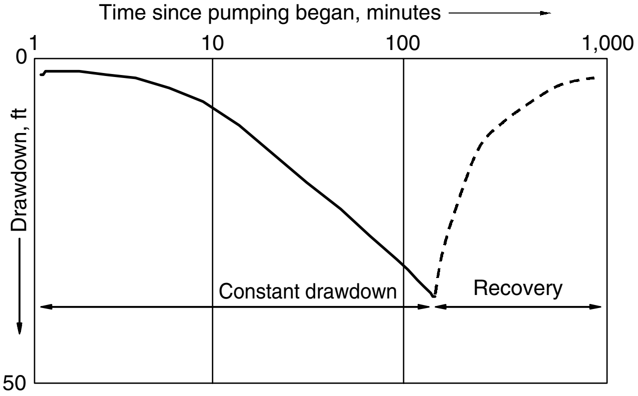

Figure 2. Constant-rate test with recovery data.

judgment" and should consider both demand requirements and pumping test results.

Recovery tests are carried out after pumping tests. The test involves measuring the rate at which the groundwater level recovers to its initial level after pumping has stopped. In general, water level data from recovery tests are more reliable due to the lack of water level fluctuations caused by discharge variations.

A slug test is a popular and inexpensive method of estimating the hydraulic properties of aquifers in small diameter wells when the hydraulic conductivity of the aquifer materials is too low to conduct a pumping test. Slug testing involves either rapidly adding or removing a "slug of water" from a well and measuring the rate at which the water level recovers (either falling-head or rising-head). Disadvantages with this method are that it can only be used to determine the aquifer's hydraulic conductivity in the immediate vicinity of the well, and results can be influenced by filter pack material adjacent to the well screen.

The type of test to be performed depends on the test purpose, available resources, and site-specific limitations. For example, in an area containing only a single well, it is not possible to calculate aquifer storage parameters from a pumping test without an observation well (i.e., nonpumping well). Similarly, observation wells not screened in the same aquifer as the pumping well cannot provide reliable interference data.

Once groundwater level data from the well tests have been collected, compiled, and graphically plotted, the data are evaluated using various methods to determine hydraulic parameters of the aquifer and well. In many cases, the calculation of parameters requires only solving simple equations or a set of equations. For each method there are basic underlying assumptions from which the method equation was derived. These assumptions need to be carefully considered with respect to the test data and specific aquifer conditions when a method is used. In addition to the basic assumptions, each of the analysis methods has other assumptions specific to the method. Many of the analytical solutions are based on the basic differential equation of groundwater flow, which can be derived from fundamental laws of physics.

SAFE YIELD OF AN AQUIFER

Eric S. Wilson
E. L. Montgomery & Associates, Inc.
Tucson, Arizona

Safe yield is a controversial term and concept that may be defined for common usage as the amount of water an aquifer system can yield over a long period without producing unacceptable effects. Unacceptable effects may include an excessive decline in groundwater level, sometimes described as groundwater mining; reduction or elimination of riparian vegetation; reduction or elimination of water in streams, lakes, springs, and wetlands; aquifer compaction and land subsidence; reduction in groundwater underflow to downgradient aquifer systems; a change in groundwater temperature; an undesirable change in the chemical quality of groundwater; and salt water intrusion into aquifer systems adjacent to oceans or saline lakes.

The definition of safe yield has evolved for nearly a century; initially, it was defined by Lee (1) as "...the limit and quantity of water which can be withdrawn regularly and permanently without dangerous depletion of the storage reserve." The definition was modified and expanded by Meinzer (2), Conkling (3), and Todd (4). Due to ambiguity and lack of agreement on the definition, many authors have suggested abandoning the term (5–7) for an alternate term such as "sustainable yield."

Incorrect concepts, regulations, or laws may indicate that safe yield is equal to recharge. This incorrect concept has been described by Bredehoeft et al. (8) as the "water-budget myth" because the concept oversimplifies the necessary information needed to understand the effects of groundwater development on an aquifer system.

It is a great deal more difficult to define safe yield of an aquifer based on analyzing the unacceptable effects of overpumping than to assume simply that safe yield is equal to recharge. When water is pumped from an aquifer, even in amounts equal to recharge, natural groundwater discharge continues. The initial result of pumping is the decline of groundwater levels near the pumping well, and with time, across larger areas of the aquifer. This water level decline increases the hydraulic gradient and assists in drawing groundwater from marginal parts of the aquifer system into the central part of the aquifer system, but eventually water levels drop sufficiently that natural groundwater discharge becomes smaller. As a result, even by pumping groundwater at rates equal to recharge, a decline in groundwater discharge may occur. This decline in discharge could possibly be defined as unacceptable, and the aquifer may not be in a state of safe yield.

When considering the pragmatic aspects of safe yield, it is important to address the principal elements of the water budget expressed by the law of conservation of mass and the water budget equation:

$$\text{Inflow} = \text{outflow} \pm \text{change in storage}$$

Pumping from an aquifer system over time changes the amount of water in storage and subsequently changes values of inflow and outflow, thus changing values in the water budget equation. Theis (9) stated that groundwater withdrawals are balanced, over time, by a loss of water somewhere. Groundwater withdrawals by pumping result in one or more of the following: (1) a decrease in the amount of groundwater in storage; (2) capture of previously rejected recharge, if available; (3) an increase in water entering the aquifer system through increased underflow, if available; (4) decreased outflows by way of underflow to downgradient aquifers; or (5) decreased outflow by reduction of discharge to streamflow or to evapotranspiration. The hydraulics of an aquifer system evolve toward, and eventually may approach, a new dynamic equilibrium under increased pumping. An exception may occur in hydraulically isolated, arid environments where little recharge is available. Under these conditions, if pumping exceeds the meager natural recharge, no subsequent equilibrium will be reached and groundwater mining is expected.

Groundwater withdrawal or development of water resources of an aquifer system occurs in stages. These stages include the predevelopment stage, partially developed stage, and fully developed stage. Under natural or predevelopment conditions, an aquifer system is in dynamic equilibrium among change in aquifer storage, groundwater underflow, and interaction between groundwater and surface water. As additional development occurs, water budget values change as a result of an extended period of groundwater pumping. A partially developed aquifer system will see moderate declines in groundwater level and decreases in groundwater in storage; an increase in recharge may occur, and a decrease in natural discharge is expected. Full development of an aquifer system results in a large magnitude of groundwater level decline, additional depletion of groundwater in storage, maximization of recharge, elimination of discharge to surface waters, and underflow to downgradient aquifers may cease.

Safe yield cannot be defined solely on the basis of hydrologic conditions. Hydrologists may describe and quantify the effect of groundwater withdrawals on an aquifer system, but safe yield is properly a determination by a team of natural resource managers, and the results must be acceptable to concerned citizens. It is often difficult to reach consensus on the true safe yield of an aquifer system. Although difficult, the term and concept are the basis of many water management programs and groundwater laws and therefore must be given careful attention.

Wood (10) states, "...scientists and engineers must avoid the trap of blurring the boundary between scientific investigations and management decisions. Neither I nor any other scientist or engineer can say whether any given volume of water or delivery rate meets the needs of anyone beyond the minimum personal requirement of two or three liters per day necessary for long-term survival. 'Meeting the needs' requires many value judgments, and their assessment lies outside the realm of science or engineering. In many ways, sustainability appears to be analogous to the management concept of aquifer 'safe yield' that has been extensively used and misused in the last 85 years."

SPECIFIC YIELD STORAGE EQUATION

THOMAS HARTER
University of California
Davis, California

The specific yield, S_y, is the ratio of the volume of water that can be drained by gravity from a mass of porous rock (unconsolidated or consolidated) and the volume of that mass:

$$S_y = \frac{V_W}{V_T},$$

where V_W is the volume of drainable water and V_T is the total volume of porous rock or sediments (Fig. 1). Specific yield, S_y, is typically expressed as a percentage.

Specific yield is part of the total porosity of a porous rock or sediment. The total porosity (total pore space) of a rock or sediment formation is much larger than the specific yield. Total porosity includes the fraction of pore space that is interconnected (called "effective porosity") and porosity due to isolated pores. The effective porosity itself includes specific retention and specific yield. Specific retention is that volume fraction of water that is held back by adhesion and capillary forces, when an aquifer is drained. Specific yield is the amount of water that is actually available for groundwater pumping, when sediments or rocks are drained due to lowering of the water table.

Specific yield depends on the distribution of pores, their shape, and grain size (Table 1). The larger the surface area of the rocks or sediment particles per unit volume values of inflow and outflow, thus changing values in the water budget equation. Theis (9) stated that groundwater withdrawals are balanced, over time, by a loss of water somewhere. Groundwater withdrawals by pumping result in one or more of the following: (1) a decrease in the amount of groundwater in storage; (2) capture of previously rejected recharge, if available; (3) an increase in water entering the aquifer system through increased underflow, if available; (4) decreased outflows by way of underflow to downgradient aquifers; or (5) decreased outflow by reduction of discharge to streamflow or to evapotranspiration. The hydraulics of an aquifer system evolve toward, and eventually may approach, a new dynamic equilibrium under increased pumping. An exception may occur in hydraulically isolated, arid environments where little recharge is available. Under these conditions, if pumping exceeds the meager natural recharge, no subsequent equilibrium will be reached and groundwater mining is expected.

Groundwater withdrawal or development of water resources of an aquifer system occurs in stages. These stages include the predevelopment stage, partially developed stage, and fully developed stage. Under natural or predevelopment conditions, an aquifer system is in dynamic equilibrium among change in aquifer storage, groundwater underflow, and interaction between groundwater and surface water. As additional development occurs, water budget values change as a result of an extended period of groundwater pumping. A partially developed aquifer system will see moderate declines in groundwater level and decreases in groundwater in storage; an increase in recharge may occur, and a decrease in natural discharge is expected. Full development of an aquifer system results in a large magnitude of groundwater level decline, additional depletion of groundwater in storage, maximization of recharge, elimination of discharge to surface waters, and underflow to downgradient aquifers may cease.

Safe yield cannot be defined solely on the basis of hydrologic conditions. Hydrologists may describe and quantify the effect of groundwater withdrawals on an aquifer system, but safe yield is properly a determination by a team of natural resource managers, and the results must be acceptable to concerned citizens. It is often difficult to reach consensus on the true safe yield of an aquifer system. Although difficult, the term and concept are the basis of many water management programs and groundwater laws and therefore must be given careful attention.

Wood (10) states, "...scientists and engineers must avoid the trap of blurring the boundary between scientific investigations and management decisions. Neither I nor any other scientist or engineer can say whether any given volume of water or delivery rate meets the needs of anyone beyond the minimum personal requirement of two or three liters per day necessary for long-term survival. 'Meeting the needs' requires many value judgments, and their assessment lies outside the realm of science or engineering. In many ways, sustainability appears to be analogous to the management concept of aquifer 'safe yield' that has been extensively used and misused in the last 85 years."

SPECIFIC YIELD STORAGE EQUATION

Thomas Harter
University of California
Davis, California

The specific yield, S_y, is the ratio of the volume of water that can be drained by gravity from a mass of porous rock (unconsolidated or consolidated) and the volume of that mass:

$$S_y = \frac{V_W}{V_T},$$

where V_W is the volume of drainable water and V_T is the total volume of porous rock or sediments (Fig. 1). Specific yield, S_y, is typically expressed as a percentage.

Specific yield is part of the total porosity of a porous rock or sediment. The total porosity (total pore space) of a rock or sediment formation is much larger than the specific yield. Total porosity includes the fraction of pore space that is interconnected (called "effective porosity") and porosity due to isolated pores. The effective porosity itself includes specific retention and specific yield. Specific retention is that volume fraction of water that is held back by adhesion and capillary forces, when an aquifer is drained. Specific yield is the amount of water that is actually available for groundwater pumping, when sediments or rocks are drained due to lowering of the water table.

Specific yield depends on the distribution of pores, their shape, and grain size (Table 1). The larger the surface area of the rocks or sediment particles per unit volume

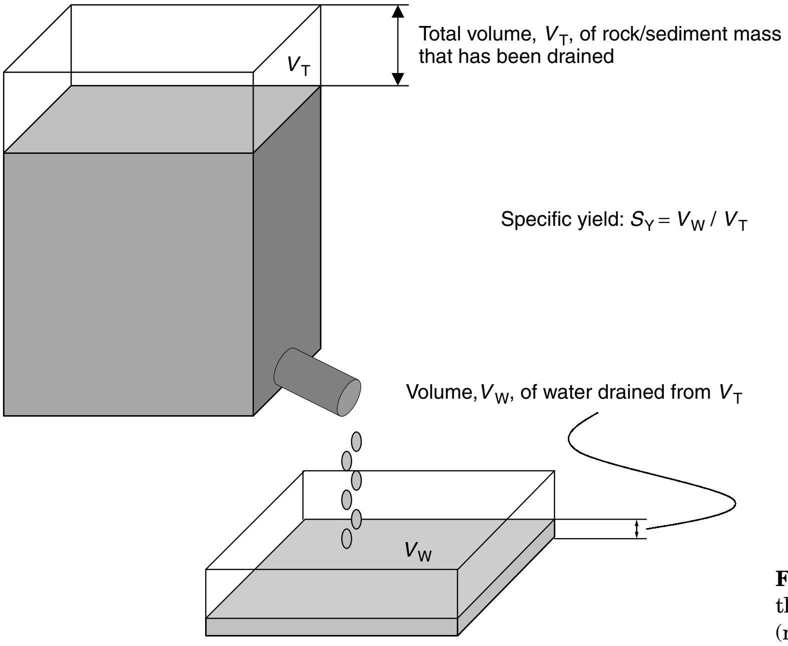

Figure 1. Illustration of the concept of specific yield. Note that the drained volume V_T contains sediment particles (not shown here). The volume V_W is much less then V_T.

("specific surface area"), the more water adheres to these surfaces. This decreases the specific yield in favor of specific retention. Fine-grained sediments have the largest specific surface area, the highest specific retention, and the lowest specific yield. Coarse-grained sediments have a very small specific surface area; hence, the specific retention is small, and the specific yield is large. Specific yield typically decreases with depth due to compaction of sediments.

Clay, silt, and fine sand have relatively high effective porosities, but their specific yields vary widely. The specific yield of clay is often 2% or less, due to its extremely small grain size. In contrast, the specific yield of fine sand can be over 20%. The highest specific yield is obtained in coarse sands and gravels (20–30%), where little water is held back by retention (large pores have only small capillary forces). This makes sand and gravel aquifers good storage reservoirs for groundwater. Peat stands out for its large effective porosity: 90% of its total volume consists of pores, half of which is drainable (specific yield: ~ 45%). These properties (high specific retention and high specific yield) make it a good amendment for garden and potting soil.

Table 1. Specific Yield of Various Sediments and Rocks

Sediment or Porous Rock	Specific Yield, in %,[a]
Gravel, coarse	10–25
Gravel, medium	15–25
Gravel, fine	20–35
Sand, gravelly	20–35
Sand, coarse	20–35
Sand, medium	15–30
Sand, fine	10–30
Silt	1–30
Clay, sandy	3–20
Clay	1–20
Sandstone	10–40
Limestone	1–25
Dune sand	30–40
Loess	15–35
Peat	30–50
Siltstone	1–35
Till	5–20
Tuff	2–35

[a] Compiled by Reference 1.

The specific yield is used to determine how much water can be produced from an unconfined aquifer per a unit (foot, meter) decline in the water table (Fig. 1). An example may illustrate this. A shallow, unconfined sand and gravel aquifer in a small montane basin has an extent of 10 km^2, an average thickness of 10 m, and a specific yield of 20%. Let us assume that there is a drought and the aquifer does not receive any recharge. How much water has been produced from the aquifer, if the water table across the entire aquifer drops by 1 m? The answer: The total volume of aquifer drained is 10 km^2 × 1 m. Then the volume of water obtained is 20% of that volume, or 10 km^2 × 0.2 m.

The same example can be turned around. Let us assume there is no pumping from the aquifer during a 6-month rainy period. During this time, recharge from a river and from precipitation amounts to a total volume of 10 km^2 × 0.1 m or an average of 100 liters/m^2. How much will this raise the water level? With specific yield at 20%, the 100 liters/m^2 recharge will fill an aquifer volume of 100 liters/0.2 = 500 liters/m^2 (0.5 m^3/m^2) in each empty cubic meter of aquifer. Hence, the water level rises by 0.5 m.

Specific yield is measured by a variety of laboratory and field methods, or by estimation from computer models (for recent reviews and applications, see references). The most common field technique is evaluation of well-pumping test data (2,3).

INTRODUCTION

The EPA Regional Ground Water Forum is a group of EPA professionals representing Regional Superfund and Resource Conservation and Recovery Act (RCRA) Offices, committed to the identification and resolution of ground-water issues impacting the remediation of Superfund and RCRA sites. Innovative technologies for subsurface remediation are being evaluated more often for specific sites, as the limitations to conventional technologies are recognized. The purpose of this Issue Paper is to provide those involved in assessing remediation technologies with some basic information regarding monitored natural attenuation (MNA) processes, specifically in determining overall contribution of microbial processes.

On April 21, 1999, the Office of Solid Waste and Emergency Response (OSWER) issued Directive 9200.4-17P, titled "Use of Monitored Natural Attenuation at Superfund, RCRA Corrective Action, and Underground Storage Tank Sites." It specifies the current EPA policy regarding the use of MNA for the remediation of contaminated soil and ground water at OSWER sites. The Directive's aim is to promote consistency in the manner in which MNA remedies are proposed, evaluated, and approved. Accordingly, "EPA does not consider MNA to be a presumptive or default remedy—it is merely one option that should be considered with other applicable remedies." Thus, during the process of selecting a site remedy, MNA may be evaluated and compared with other remedial technologies and chosen upon attainment of each relevant remedy selection criteria, including the full protection of human health and the environment, and achieving the intended site remedial objectives within a time frame that is comparable to the other remedial techniques. The Directive expects that "source control and long-term performance monitoring will be fundamental components of any MNA remedy" (U.S. EPA, 1999).

It should be emphasized that this document is not intended to be used in establishing protocol involved in natural attenuation investigations or policies leading to the interpretation of the results of those investigations. To that end, the reader is referred to the EPA Protocol for chlorinated solvents (U.S. EPA, 1998a), and ASTM for petroleum hydrocarbons (ASTM, 1998). EPA is also preparing a guidance for long term monitoring (LTM) for MNA.

BACKGROUND

Interest in the natural attenuation of ground-water contaminants has increased in recent years as the result of dealing with complexities of subsurface systems and the inherent problems and costs associated with more conventional remedial technologies, such as pump-and-treat systems. There is a growing perception in the environmental community that, under favorable conditions, the selection of natural attenuation as a remedy will result in significant savings in cost over more intrusive remedial alternatives which are exacerbated by the complex geochemical, biochemical, and hydrogeological uncertainties which are dominant

---

at most sites. While this perception may or may not be true, depending upon site specific characteristics, like all relatively new technologies, actual cost and performance data will be required as the remediation alternative matures. Natural attenuation, which is also referred to as natural assimilation, intrinsic remediation, intrinsic bioremediation, natural recovery, or passive remediation, is the use of natural processes to remove contaminants from soil or ground water. While the mechanisms of chemical transformation, dispersion, dilution, sorption and volatilization have been identified, aerobic and anaerobic degradation comprise the major processes for the reduction of contaminant mass in the subsurface. Some considerations needed for the evaluation of these processes are depicted in Table 1.

There is little question that naturally occurring biodegradation processes are taking place at many sites where sediments have been contaminated (Davis et al., 1994; Lee, 1988). To those who have examined subsurface sediment, the reduced mineralogy (darkening) and unpleasant odors (anaerobic metabolic products) are indicators of microbial degradation processes. While there are limitations to natural attenuation due to factors such as complex hydrogeology, microbial toxicity of contaminants, and other physical, biological, chemical and environmental factors, many of the organic compounds introduced into the subsurface can be transformed by indigenous microorganisms. The primary challenge in evaluating natural attenuation is not in demonstrating that biodegradation is occurring. This can be a relatively easy task accomplished by determining that the production of metabolites and the loss or electron acceptors are concomitant with the distribution of contaminants. As with any other remedial technology, the appropriate evaluation of natural attenuation as a remedial alternative is to make the determination that the transformation processes are taking place at a rate that is protective of human health and the environment. The evaluation should include a reasonable expectation that these processes will continue at an acceptable rate for an acceptable period of time.

Chlorinated aliphatics are among the most widespread contaminants in ground water (Fig. 1) and soil due to their use for degreasing, dry cleaning, and as solvents (Westrick et al., 1984). At the same time, the impact of petroleum hydrocarbons among the various environmental media is ubiquitous (Tiedje and Stephens, 1988; Sharples, 1992; Kennedy and Hutchins, 1992). Because of their prominence as environmental contaminants, these two groups of chemicals will be used as case examples in this issue paper.

MONITORED NATURAL ATTENUATION MODEL

Contaminants in the subsurface partition into four phases including sorption to the soil and aquifer solids, a free phase which displaces water from the pore spaces, dissolved in the water, and vapor (Fig. 2). The degree to which contaminants partition into these phases is determined by their physical/chemical properties or notably the sorption coefficient, Henry's Law Constant (gas partition coefficient), octanol-water coefficient, and solubility (water partition coefficient). The mass in each phase will therefore depend on the preference of the contaminants of concern for each phase.

Plume movement is dependent on the same partition coefficients, in addition to the hydrology of the site itself. In most instances, chemicals will prefer to partition to organic

matter within sediments, to oily or free-phase material that may completely fill pore spaces, or be dissolved in water at solubility levels. The mass of the contaminants in the aqueous phase is usually lower than that in the other phases.

As water moves through pore spaces, chemicals are desorbed from sediments or dissolved from free-phase liquids. Once in solution, these chemicals move with the aqueous phase. Their movement downgradient is impeded by further sorption to sediments and biodegradation. The basis of natural attenuation is that the partition of chemicals into the aqueous phase reaches equilibrium with the processes of biological transformation at an acceptable time and distance from the source. To understand these biological processes, some knowledge of microbiology is required.

MICROBIAL PHYSIOLOGY

Bacteria, although unicellular, share characteristics with most living things. Information is encoded in DNA (deoxyribonucleic acid) and transferred through RNA (ribonucleic acid) to ribosomes to make proteins or enzymes which are used to operate systems within the organism. In regard to this discussion, enzymes are responsible for the degradation of organic carbon, which is used by the bacterial cell to produce both the building blocks of life and energy. The degradation of any organic molecule, including contaminants, requires the production and efficient utilization of enzymes. In most instances, degradation is merely a complex oxidation/reduction reaction. The electrons or reducing equivalents (hydrogen or electron-transferring molecules) produced must be transferred to a terminal electron acceptor (TEA). During the transfer process, energy is produced which is utilized by the cell.

In regard to TEAs, bacteria are generally grouped into three categories:

1. *Aerobic bacteria*—Bacteria which can only utilize molecular oxygen as a TEA. Without molecular oxygen, these bacteria are not capable of degradation.
2. *Facultative aerobes/anaerobes*—Bacteria which can utilize molecular oxygen or when oxygen concentrations are low or nonexistent, may switch to nitrate, manganese oxides or iron oxides as electron acceptors.
3. *Anaerobes*—Bacteria which cannot utilize oxygen as an electron acceptor and for which oxygen is toxic. Though members may utilize nitrate or other electron acceptors, it can be said that they generally utilize sulfate or carbon dioxide as electron acceptors.

In this discussion, three modes of contaminant degradation are addressed including aerobic, cometabolic, and anaerobic. The first is the case in which the contaminants, for example, petroleum hydrocarbons, are utilized by bacteria as a sole source of carbon. Petroleum hydrocarbons are degraded through a series of enzymatic reactions to produce needed cellular constituents. Electrons or reducing equivalents must be regenerated. If a contaminant serves as a sole source of carbon and energy, conditions must be within acceptable pH, Eh, and temperature limits and the appropriate TEA must be present. In this case, the rate of degradation will be determined by the rate of dissolution of toxic end products away from the microbial population and the rate at which the TEA is replenished. Some of the lesser chlorinated solvents, such as dichloroethene (DCE), may also serve as sole sources of carbon; however, tetrachloroethene (PCE) and trichloroethene (TCE) are not thought to serve as sole sources of carbon.

In the case of TCE (and lesser chlorinated solvents), degradation may occur through cometabolic processes. Under aerobic conditions, the enzymes necessary for the degradation, however, must be induced. Inducible enzymes are those that are not produced unless an inducer compound is present within the bacterial cell. Pertinent to this discussion are the inducers for methane monooxygenase and various mono- and dioxygenase enzymes produced by aromatic degrading bacteria.

In the presence of oxygen and methane, methanotrophic bacteria are known to produce the enzyme methane monooxygenase (Hanson and Hanson, 1996; Patel et al., 1982). The substrate for this enzyme is methane, but it has been shown to have a broad substrate specificity including chlorinated solvents (Mayer et al., 1988). Methanotrophs downgradient from a chlorinated solvent event may feed on methane produced within the anaerobic portion of the plume and cometabolically degrade some chlorinated solvents.

Numerous authors have shown that oxygenase enzymes produced by bacteria capable of degrading aromatic hydrocarbons are capable of degrading chlorinated solvents. Aromatic compounds, such as toluene and phenol, have been shown to induce the responsible enzymes. In contaminated aquifers which contain both aromatic hydrocarbons and chlorinated solvents, degradation of both may occur.

It should be noted that reports on the degradation of PCE under aerobic conditions do not exist in the peer-reviewed literature. The structure and oxidative state of PCE may preclude its aerobic degradation (Chen et al., 1996). The anaerobic process for degradation of chlorinated solvents is known as reductive dechlorination (Bouwer et al., 1981; Bouwer, 1994). Chlorinated solvents are not utilized as a carbon source, rather as an acceptor for electrons produced during the metabolism of other oxidizable carbon (electron donor). Thus, this process cannot be termed cometabolism. Electrons or reducing equivalents formed during metabolism are accepted by the chlorinated solvent. As an example, PCE will accept electrons or reducing equivalents formed during metabolism. This results in the reduction of PCE, the concomitant release of a chloride ion and the formation of TCE. While almost any degradable carbon appears capable of driving reductive dechlorination, in most instances, a low percentage of the electrons or reducing equivalents are utilized in the reductive process. This is a function of other metabolic requirements for reducing equivalents (substrate specific) and the presence or absence of more suitable TEAs.

The behavior of the chlorinated solvent plumes can be classified into three types based on their primary substrate source (U.S. EPA, 1998a).

- *Type 1 Behavior*—Primary substrate is adequate amount of anthropogenic organic carbon, solvent plume degrades
- *Type 2 Behavior*—Primary substrate is adequate amount of native organic carbon, solvent plume degrades
- *Type 3 Behavior*—Low native organic carbon concentrations or low anthropogenic organic carbon concentrations, PCE, TCE, and DCE do not degrade

For complete detoxification, the parent chlorinated solvent must be dechlorinated in a stepwise fashion to the environmentally benign ethene. This is illustrated in Fig. 3. While PCE and TCE are readily reduced as a result of their oxidative states, the more reduced daughter products (DCE and VC) are less prone to reductive processes. These intermediates tend to accumulate in anaerobic aquifers where contaminants are allowed to naturally attenuate (Lesage et al., 1990). While this may indeed be a function of the oxidative state of the lesser-chlorinated compounds, it may also be a function of the concentration of degradable organic matter within the contaminated system.

The efficacy of an anaerobic microbial population for natural degradation of chlorinated solvents is determined by the same environmental factors as for the other systems (i.e., pH, Eh, temperature, osmotic potential), the presence of a carbon source which can be readily degraded (electron donor), and a TEA other than chlorinated solvents (Vogel et al., 1987). In addition to organic carbon and a TEA, bacteria require macro- and micronutrients, most notably nitrogen and phosphorous, for the production of DNA, RNA

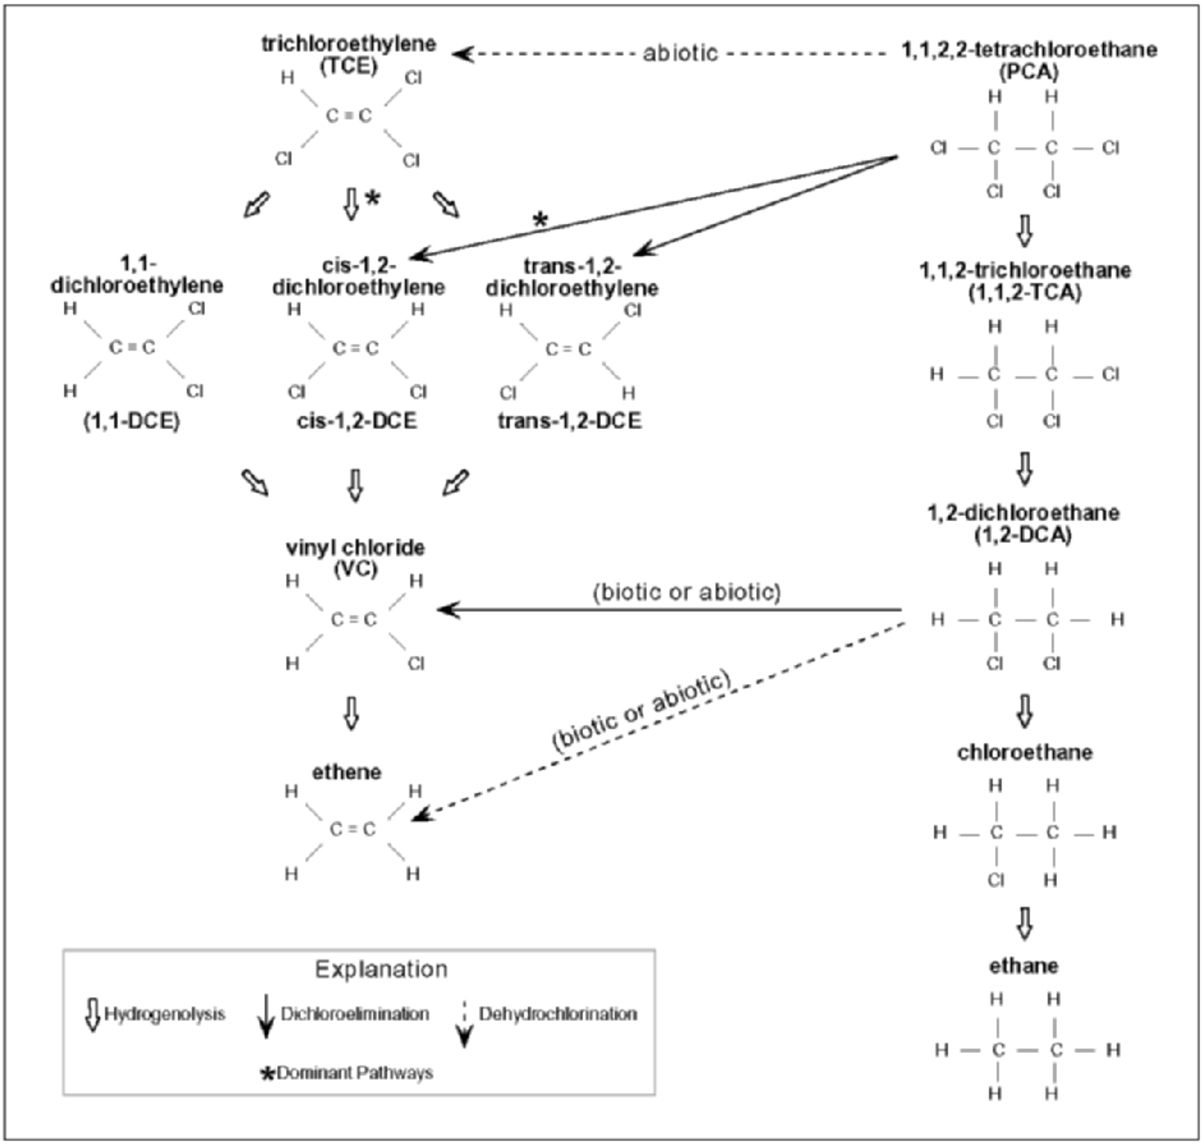

Figure 3. Anaerobic degradation pathways for trichloroethylene and 1,1,2,2-tetrachloroethane. (Modified from Chen et al., 1996; McCarty, 1996; Nyer and Duffin, 1997; and Vogel et al., 1987.).

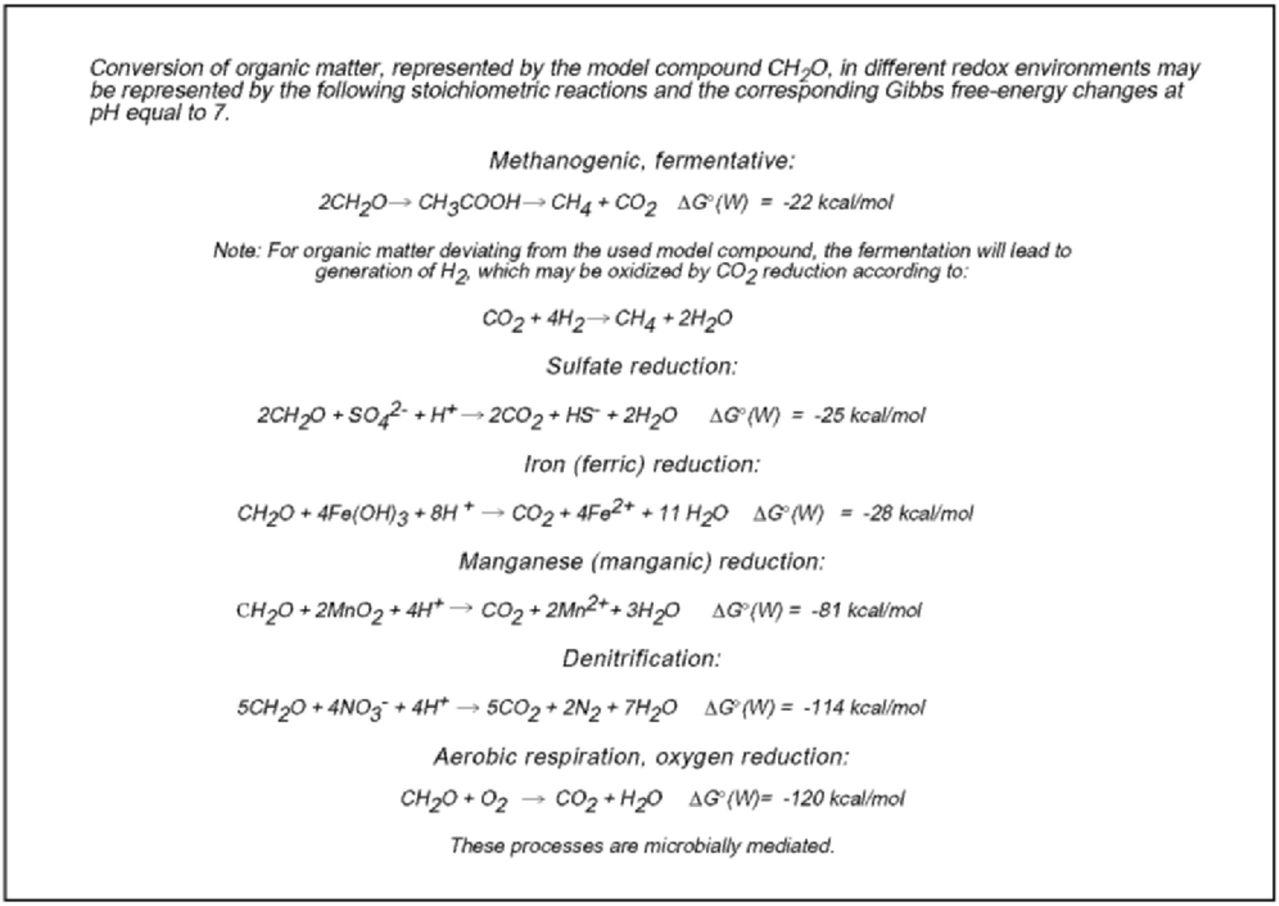
and other needed cellular constituents. In most instances within an aquifer, sufficient macro- and micronutrients will be available for microbial processes. On the other hand, the availability of organic carbon can often be the limiting factor in the continuance of these processes. For example, during the reductive dechlorination of chlorinated solvents, the ratio of the mass of the electron donor to that of the contaminant ranges between 100/1 and 1000/1 (Bouwer, 1994).

MECHANISMS OF BIODEGRADATION

In theory, in any environment in which microbial activity occurs, there is a progression from aerobic to anaerobic (methanogenic) conditions. There is a definite sequence of electron acceptors used in this progression through distinctly different redox states (Fig. 4).

The rate, type of active microbial population, and level of activity under each of these environments are controlled by several factors. These include the concentration of the electron acceptors, substrates which can be utilized by the bacteria, and specific microbial populations leading to the progression of an aquifer from aerobic to methanogenic conditions (Salanitro, 1993). This results in a loss of organic carbon and various electron acceptors from the system as well as a progression in the types and physiological activity of the indigenous bacteria.

If microbial activity is high, the aquifer environment would be expected to progress rapidly through these conditions. The following scenario outlines a general sequence of events in which aerobic metabolism of preferential carbon sources would occur first. The carbon source may be contaminants of interest or other more readily degradable carbon which has entered



Conversion of organic matter, represented by the model compound CH_2O, in different redox environments may be represented by the following stoichiometric reactions and the corresponding Gibbs free-energy changes at pH equal to 7.

Methanogenic, fermentative:

$$2CH_2O \rightarrow CH_3COOH \rightarrow CH_4 + CO_2 \quad \Delta G^\circ(W) = -22\ \text{kcal/mol}$$

Note: For organic matter deviating from the used model compound, the fermentation will lead to generation of H_2, which may be oxidized by CO_2 reduction according to:

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O$$

Sulfate reduction:

$$2CH_2O + SO_4^{2-} + H^+ \rightarrow 2CO_2 + HS^- + 2H_2O \quad \Delta G^\circ(W) = -25\ \text{kcal/mol}$$

Iron (ferric) reduction:

$$CH_2O + 4Fe(OH)_3 + 8H^+ \rightarrow CO_2 + 4Fe^{2+} + 11\,H_2O \quad \Delta G^\circ(W) = -28\ \text{kcal/mol}$$

Manganese (manganic) reduction:

$$CH_2O + 2MnO_2 + 4H^+ \rightarrow CO_2 + 2Mn^{2+} + 3H_2O \quad \Delta G^\circ(W) = -81\ \text{kcal/mol}$$

Denitrification:

$$5CH_2O + 4NO_3^- + 4H^+ \rightarrow 5CO_2 + 2N_2 + 7H_2O \quad \Delta G^\circ(W) = -114\ \text{kcal/mol}$$

Aerobic respiration, oxygen reduction:

$$CH_2O + O_2 \rightarrow CO_2 + H_2O \quad \Delta G^\circ(W) = -120\ \text{kcal/mol}$$

These processes are microbially mediated.

Figure 4. Examples of redox reactions involved in degradation of organic matter (expressed as the model compound CH_2O) in different redox environments. (Reprinted from *Attenuation of Landfill Leachate Pollutants in Aquifers*, box 1, p. 138, 1994, by Christensen, T.H., P. Kieldsen. H-J. Albrechtsen, G. Heron, P.H. Nielsen, P.L. Bjerg, and P.E. Holm, with permission of CRC Press, Inc., Boca Raton, FL.).

the system previously or simultaneously with the contamination event.

Oxygen-Reducing to Nitrate-Reducing Conditions

Once available oxygen is consumed, active aerobic populations begin to shift to nitrate respiration. Denitrification will continue until available nitrate is depleted, or usable carbon sources become limiting.

Nitrate-Reducing to Manganese-Reducing Conditions

Once nitrate is depleted, populations which reduce manganese may become active. Bacterial metabolism of substrates utilized by manganese-reducing populations will continue until the concentration of manganese oxide becomes limiting.

Manganese-Reducing to Iron-Reducing Conditions

When manganese oxide becomes limiting, iron reduction becomes the predominant reaction mechanism. Available evidence suggests that iron reduction does not occur until all manganese IV oxides are depleted. In addition, bacterial Mn(IV) respiration appears to be restricted to areas where sulfate is nearly or completely absent.

Iron-Reducing to Sulfate-Reducing Conditions

Iron reduction continues until substrate or carbon limitations allow sulfate-reducing bacteria to become active. Sulfate-reducing bacteria then dominate until usable carbon or sulfate limitations impede their activity.

Sulfate-Reducing to Methanogenic Conditions

Once usable carbon or sulfate limitations occur, methanogenic bacteria are able to dominate.

The ambient redox condition of the aquifer is important when determining the contribution of microbial degradation to MNA mechanisms. In the case of petroleum hydrocarbons, because of their highly reduced condition, the preferred TEA for microbial processes would be oxygen (Brown et al., 1996; Clark et al., 1997). From a thermodynamic standpoint, this is the most favorable reaction mechanism. When the soluble portion of petroleum hydrocarbons, BTEX (benzene, toluene, ethylbenzene, xylenes), are the contaminants of concern, an inverse relationship between BTEX and dissolved oxygen concentrations within a plume is indicative of the microbial metabolism of these compounds as well as other hydrocarbons in the mixture (Donaldson et al., 1992; Huesemann and Truex, 1996). Data available from various sites indicate that the natural attenuation of BTEX proceeds at higher rates under oxic conditions than normally achieved in anoxic environments (Fig. 5), with rate constants ranging from 0.3 to 1.3 percent per day when modeled as a first-order process (Chiang et al., 1989; Kemblowski et al., 1987; Salanitro, 1992; and McAllister and Chiang, 1994). Although anaerobic biodegradation of toluene and xylene under nitrate-reducing (Barbaro et al., 1992; Schocher et al., 1991), iron-reducing (Lovley et al., 1989; Lovley and Lonergan, 1990), sulfate-reducing (Beller et al., 1992a and b; Edwards and Grbić-Galić, 1992; Rabus et al., 1993), and methanogenic (Vogel and Grbić-Galić, 1986; Bouwer and McCarty, 1983; Edwards and Grbić-Galić, 1994) conditions have been extensively reported. Until recently, unequivocal biodegradation of benzene under strict anaerobiosis was not demonstrated (Edwards and Grbić-Galić, 1992; Lovley et al., 1994). According to Borden et al. (1997), even though accurate description of anaerobic biodegradation of individual BTEX constituents may not follow a simple first-order decay function, biodegradation of total BTEX seems to more closely approximate a first-order decay function.

Biodegradation of chlorinated solvents, depending on the degree of halogenation (Fig. 6), is fundamentally different from that of petroleum hydrocarbons and other oxidized chemicals (Wiedemeier et al., 1995). The preferred redox conditions for the effective degradation of these chemicals is anaerobic (exception is vinyl chloride, VC). Effective degradation of these compounds may occur only when redox conditions are below nitrate reducing.

Although under aerobic conditions, cometabolism of TCE by autotrophic bacterial populations, obtained from soil and ground water, have been demonstrated, it is generally accepted that this route of removal is limited only to low concentrations of TCE. The cometabolism of TCE proceeds in the presence of methane (Fogel et al., 1986; Henson et al., 1988; Wilson and Wilson, 1985), ammonia (Arciero et al., 1989), or toluene (Ensley, 1991; Mu and Scow, 1994; McCarty and Semprini, 1994) as cosubstrate. Due to the inherent toxicity of TCE to microorganisms responsible for degradative process (Alvarez-Cohen and McCarty, 1991a; Broholm et al., 1990), and because of the competitive inhibition between a cosubstrate and the secondary substrate for oxygenase enzymes (Alvarez-Cohen and McCarty, 1991b; Hopkins et al., 1993), special attention to concentrations of TCE and its cosubstrate is warranted. Toxic or inhibitory effects of TCE are more serious than those of 1,1,1-TCA (Broholm et al., 1990).

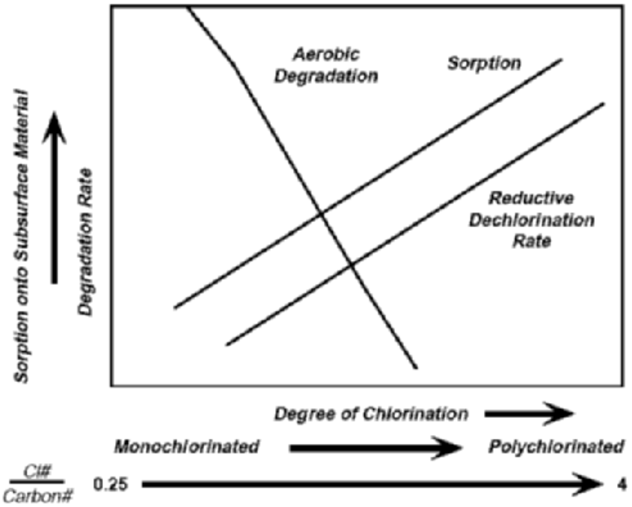

Figure 6. Relationships between degree of chlorination and anaerobic reductive dechlorination, aerobic degradation and sorption onto subsurface material. (Reprinted from *In-Situ Bioremediation of Ground Water and Geological Material: A Review of Technologies*, p. 10–19, 1993, by Norris et al., EPA/600/R-93/124.).

Microcosm studies involving anaerobic biotransformation of PCE/TCE from environmental samples including sediments (Parsons et al., 1984), ground water (Wilson et al., 1983; Sewell and Gibson, 1991), and soil (Kleopfer et al., 1985) have been documented. Also, the reductive dechlorination of PCE and other chlorinated compounds under methanogenic conditions has been reported (Vogel and McCarty, 1985 and 1987b; Vogel et al., 1987; Freedman and Gossett, 1989; McCarty, 1988). Bagley and Gossett (1990) suggested that the ability of sulfate-reducing enrichment cultures for PCE dechlorination is apparently less than that of mixed methanogenic cultures. The main by-product of anaerobic biodegradation of chlorinated ethene is VC which is more toxic than the parent compounds PCE, TCE, and DCE (Chu and Jewell, 1993). It is noted that anaerobic reduction of VC to ethylene is a slow and inefficient process (Freedman and Gossett, 1989). Gantzer and Wackett (1991) determined that dechlorination of chlorinated ethenes proceed via first-order rate constants.

The oxidation-reduction (redox) potential is a relatively simple and inexpensive indicator of the redox state of an aquifer. If the redox is positive, one can assume that dissolved oxygen is present and the system has not been stressed by biological activity (Borden et al., 1995). If the redox potential is significantly negative, it can be assumed that processes favored under aerobic conditions, such as BTEX degradation, are occurring at a substantially reduced rate. Figure 7 suggests that the redox should be -400 mV or less and the dissolved oxygen should be below

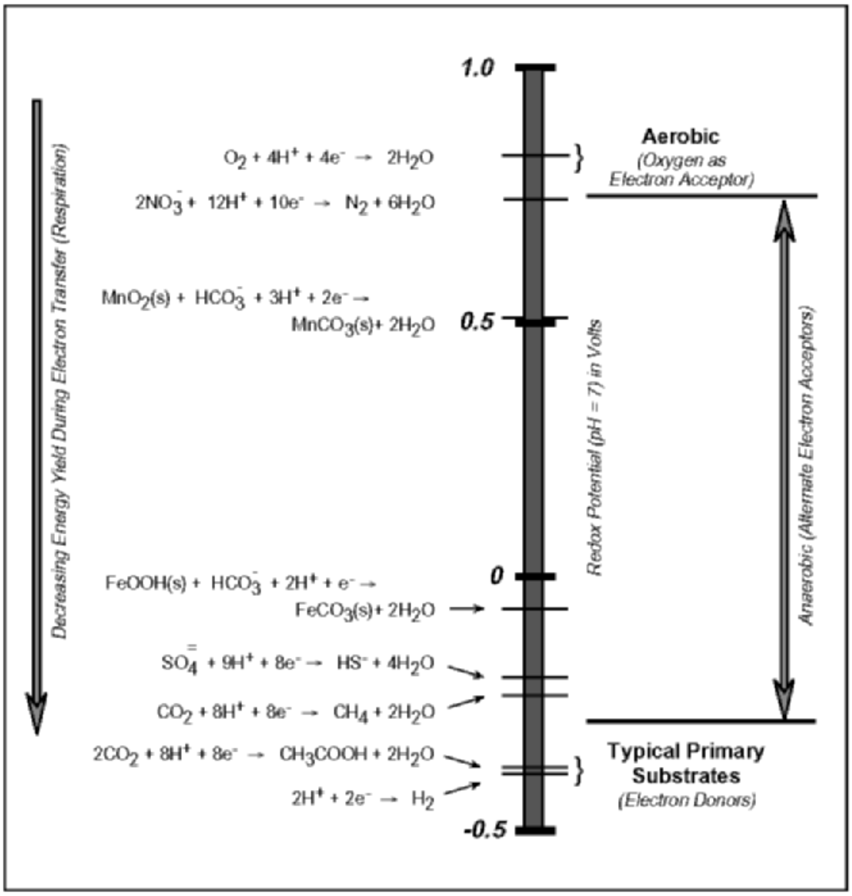

Figure 7. Important electron donors and acceptors in biotransformation processes. Redox potentials data were obtained from Stumm and Morgan (1981). (Modified from *In-Situ Bioremediation of Ground Water and Geological Material: A Review of Technologies*, p. 8-3, 1993, by Norris et al., EPA/600/R-93/124.).

0.25 mg/l before anaerobic microbial reactions could take place for the more highly chlorinated compounds (i.e., PCE, PCA). It should be stressed that one normally does not attempt to determine the actual redox conditions for comparison between different sites, rather the differences between points within a plume. Furthermore, due to the lack of internal equilibrium (Morris and Stumm, 1967) and the mixed Eh potentials of natural aqueous systems, the use of any measured master Eh as an input in equilibrium hydrogeochemical model for predicting the equilibrium chemistry of redox reactions is misleading. Instead, measuring certain sensitive species such as oxygen, Fe(II), hydrogen sulfide, or methane as qualitative guides to the redox status of the water may generate better results (Lindberg and Runnells, 1984).

In anoxic waters, where low pH and Eh exist, the reduced form of manganese, Mn(II) is favored (Stumm and Morgan, 1981). Reduction of Fe(III) and Mn(IV), due to chemical processes or microbial metabolic reactions that couple the oxidation of organic matters to the reduction of these chemical species, has a major influence on the distribution of Fe(II) and Mn(IV) in aquatic sediments, submerged soil, and ground waters (Stone and Morgan, 1984; Burdige and Nealson, 1986; Ehrlich, 1987; DiRuggiero and Gounot, 1990; Lovley, 1991). Thus, measurable Fe(II) or Mn(II) may indicate suboxic conditions in the absence of detectable oxygen concentration (Higgo et al., 1996).

In addition to establishing background conditions away from the plume, dissolved oxygen, nitrate, manganese, iron, sulfate, and sulfide should be measured along the axis of the plume, as well as transverse to it, in order to characterize biological activity with respect to the redox state at those locations. This information will allow an estimation of the current redox state at various parts of the contaminated plume, thereby defining the types of reactions that may take place.

The rate of change in the concentration of these parameters can be useful as input to predictive models. This set of data will also characterize the abundance of the principal electron acceptors, oxygen, nitrate, and sulfate, to allow an estimate of how long natural attenuation will remain a viable remedial alternative.

Another approach that may be used to indicate the terminal electron acceptor process (TEAP) predominant in the areas of contamination is the hydrogen (H_2) concentration (Lovley and Goodwin, 1988). Hydrogen concentrations for the various terminal electron acceptors are shown in Table 2 (Chapelle et al., 1995).

Parameters that investigators should analyze for petroleum hydrocarbons include dissolved oxygen, nitrate, Fe(II), sulfate, redox potential, pH, Mn(IV), dissolved methane, and total petroleum hydrocarbons (ASTM, 1998). The majority of these parameters can be determined using field measurements, Hach™ kits, and/or CHEMetrics™ test kits. Since methane is produced after other TEAs

Table 2. Range of Hydrogen Concentrations for a Given Terminal Electron-Accepting Process. (Data from Chapelle et al., 1995)

Terminal Electron Accepting Process	Hydrogen (H_2) Concentration (nanomoles per liter)
Denitrification	<0.1
Iron (III) Reduction	0.2 to 0.8
Sulfate Reduction	1 to 4
Methanogenesis	5–20

(nitrate, iron, sulfate) are depleted, dissolved methane data is superior to contaminant data (Underground Storage Tank Technology Update, 1998). The parameters for chlorinated solvents may include: temperature, redox potential, DO, sulfide, Fe(II), methane, ethane/ethene, alkalinity, pH, sulfate, nitrate, chloride, dissolved organic carbon, and hydrogen. Since Fe(III) may be dissolved from aquifer matrix, Fe(II) is measured as proxy for biodegradation due to iron reduction. Although there may be a correlation between sediment redness and the hematite content of soil, when a soil sample represents a mixture of several iron species, the color is not a useful indicator (Heron et al., 1994).

The microbial activities of a site are thus determined by the dissolved organic carbon, presence of macro- and micronutrients and the TEA (Semprini et al., 1995). The presence and concentration of each will determine not only the activity, but the predominant population.

Different levels of QA/QC may be required for those analyses determined in the field versus those performed under laboratory conditions (U.S. EPA, 1996; Klusman, 1980; Shampine et al., 1992; Koterba et al., 1996). For example, dissolved iron and oxygen, redox, and temperature must be determined on-site (Shelton, 1994; Wood, 1981) using field test kits because of the deterioration that would normally occur between the time of sample collection and that of arrival at the laboratory. On the other hand, parameters such as metals, organics (Shelton and Capel, 1994; Fishman and Friedman, 1985), and bacteria can be properly preserved by cooling, capping, or chemical fixation, and thereby subjected to a higher level of QA/QC.

FACTORS AFFECTING THE DEMONSTRATION OF NATURAL ATTENUATION

Hydrogeology

State and federal agencies are increasingly relying on risk based corrective action (RBCA) and/or MNA for cleanup of contaminated sites (Brady et al., 1998). The American Society for Testing and Materials released on RBCA protocol two years ago (ASTM, 1998) and recently finalized an MNA protocol. The U.S. EPA has recently published a directive on MNA (U.S. EPA, 1999) and a protocol for chlorinated solvents (U.S. EPA, 1998a). Since RBCA and MNA incorporate no safety factors to reduce contaminant concentrations compared to active remediation technologies, these strategies rely solely on accurate and high quality hydrogeological site characterizations (Boulding, 1993a and b; U.S. EPA, 1997a) to demonstrate adequate public protection.

Adequate monitoring is one of the most important facets of proving that natural bioremediation is occurring in the subsurface. Many factors other than natural attenuation or bioremediation can have an effect on the observed concentration of contaminants at a monitoring well (Black and Hall, 1984). The infiltrating precipitation into a system may have a profound effect on contaminant concentrations, especially if the contaminants are light nonaqueous phase liquids (LNAPLs) such as petroleum hydrocarbons (Kemblowski and Chiang, 1990; Lenhard and Parker, 1990). High rates of infiltration may lower the apparent concentration of contaminants due to dilution. Pettyjohn (1982) has shown that there are actually two time periods after a precipitation event when dilution may have an effect on monitoring. The first is a few hours after a precipitation event where flow is through macropores or "wormholes" to the water table, and the second is a few days after with flow through the vadose zone. The time required for both of these events to occur will be a function of the number and size of the macropores, overall permeability of the unsaturated zone and depth to the water table. Monitoring during these events can result in an apparent decrease in the concentration of contaminants by dilution, or if contaminants are present in the vadose zone, an increase in concentrations due to their infiltration. Seasonal variations may also occur in flow paths within an aquifer (Schmidt, 1977). These variations may cause an apparent increase or decrease in concentration of contaminants due to dilution or plume movement. Although dilution is considered to be a part of natural attenuation, this reduction in concentration should not be attributed to degradation.

A major problem with monitoring wells is that a sample from the uncontaminated portion of the aquifer may be a composite of contaminated water from the plume drawn into the cone of depression along with clean water from the aquifer. This will result in an apparent increase in contamination. The reverse is also often possible if the monitoring well is pumped for an extended period prior to sampling, the amount of clean water coming into the well in relation to contaminated water will result in an apparent decrease in the concentration of the contaminants of interest. These problems are often exacerbated by using well screens that are too long (greater than 2 meters), inconsistent screened intervals, and inappropriate sampling methods (Church and Granato, 1996).

Pumping wells other than those designed for monitoring (such as those in an interdiction field, or water supply wells for municipalities or irrigation) may influence the movement of a plume as well as flow lines within an aquifer. Depending on when these wells were designed and constructed, how they are pumped, and how they affect plume movement, apparent decreases in concentration may be observed in monitoring wells (Martin-Hayden and Robbins, 1997; Martin-Hayden et al., 1991; Robbins, 1989; Robbins and Martin-Hayden, 1991).

Monitoring programs should be designed such that these concerns are taken into account (Zeeb et al., 1999).

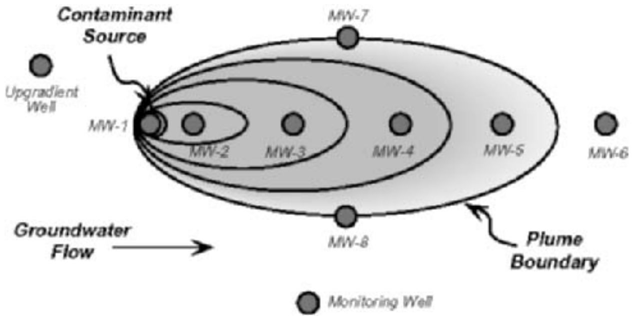

Figure 8. Recommended groundwater monitoring well network for demonstrating natural attenuation. (Reprinted from *A Practical Approach to Evaluating Natural Attenuation of Contaminants in Ground Water*, p. 166, 1994, by P.M. McAllister and C.Y. Chlang. Reprinted by permission of *Ground Water Monitoring & Remediation*, Westerville, OH, Copyright 1994. All rights reserved.).

A good monitoring program will require sampling (Puls and Barcelona, 1996) of not only monitoring wells which are completed into the plume, but also monitoring wells outside of the contaminated zone in order to establish background conditions (Fig. 8). Data from monitoring wells in the contaminated portion are then compared to background wells. The number and location of monitoring wells are not only determined by plume geometry and ground-water flow (ASTM, 1991), but by the degree of confidence required to statistically demonstrate that natural attenuation is taking place, to estimate the rate of attenuation processes, and to predict the time required to meet established remediation goals. These issues will be addressed in detail in the EPA guidance for long term monitoring (LTM) for MNA which is in preparation.

MNA Monitoring Well Network Considerations

RBCA and MNA both rely on sentinel wells for early warning signals of plume migration. The installation of monitoring wells (Aller et al., 1991) to adequately identify contaminant concentrations is of paramount importance in determining the overall contribution of biological processes to a reduction in either concentration or mass of contamination. Monitoring wells which are to be used to determine the contribution of natural bioremediation to site cleanup cannot be located until sufficient knowledge of the aquifer system is obtained (Zeeb et al., 1999). Information that must be obtained before installation include depth to water table, hydraulic conductivity (Molz et al., 1994) and gradient, direction of ground-water flow, storage coefficient or specific yield, vertical and horizontal conductivity distribution, direction of plume movement and the effects of any man-made or natural influences (i.e., lagoons or seeps) on the aquifer system. It is also important to determine if the hydraulic gradient is affected seasonally. Also, sentinel well screen depth and length are important. Often it is advantageous to use short screens to minimize averaging of vertical water quality differences (Martin-Hayden and Robbins, 1997).

The location, number (ASTM, 1995) and other pertinent data regarding monitoring wells (U.S. EPA, 1998b) for the evaluation of MNA should be determined on a site-specific basis. The design of the monitoring network will be determined by the size of the plume, site complexity, source strength, ground-water/subsurface water interactions, distance to receptors and the confidence limits each party involved wishes to place in the data obtained. By necessity, the denser the monitoring network, the greater the degree of confidence one may place in the data. The wells should be capable of monitoring singular flow paths within a plume's course and subsequent movement of contaminants along these flow paths. One way to determine natural attenuation is to determine the concentration of appropriate parameters at one location and sample the same volume of water for the same parameters at some distance downgradient. It is generally impractical to monitor flow paths within a plume with the exception of the plume axis which is the only flow line that can be located with any reasonable level of certainty.

A second way to monitor for natural attenuation assumes that the plume is in equilibrium. While less costly and less time-consuming than monitoring single flow paths for contaminants where a mass balance cannot be performed, the confidence level for data obtained is significantly less when plume equilibrium is assumed. Problems arise because plumes are never in complete equilibrium. Monitoring wells even a few feet apart differ significantly in observed concentrations of contaminants. It has been suggested that internal tracers such as trimethylbenzene (TMB), a biologically recalcitrant compound, can increase the confidence one might place in this method. One simply uses the difference between TMB concentrations at the upgradient and downgradient points to measure the observed loss which can be attributed to other factors such as dispersion. One must be cautioned, however, when using TMB as a conservative tracer due to its degradation under anaerobic conditions and the resulting production of aromatic acid intermediates (Fang et al., 1997).

To monitor the anaerobic degradation of chlorinated solvents, monitoring of singular flow paths may not be necessary, if a pseudo-mass balance can be performed. This method assumes that at each monitoring point either the parent chlorinated solvent or daughter product should be observed. Using PCE as an example at each monitoring point, samples are analyzed for PCE, TCE, DCE, VC, and ethene. The total concentration of analytes is compared on a molar basis. Changes in total molar concentrations are assumed to be losses due to flaws in the monitoring system. The pseudo-mass balance method does not account for physical loses due to dispersion, sorption, or dilution, therefore, one would also have to utilize some method, such as a conservative tracer, to account for these other processes. To place even greater confidence in data, the time frame for analysis must be sufficient to allow for differences in subsurface mobility of the various chlorinated solvents. They will not arrive at the downgradient monitoring point at the same time.

Often hazardous waste sites are monitored for natural attenuation using monitoring wells which have previously been installed, especially if plume equilibrium is assumed. This in itself presents a number of problems, especially if the wells were installed without adequate knowledge of the subsurface and plume movement. If it can be demonstrated that contamination exists between these wells, by using tracer study for example, they can be used as appropriate monitoring points for assessing natural attenuation. Reinhard and Goodman (1984) used chloride as a reference to investigate the behavior of the trace organic compounds in leachate plumes of two sanitary landfills. Kampbell et al. (1995) and Wiedemeier et al. (1996) described the use of TMB to normalize for changes in BTEX concentration due to abiotic processes of dispersion, dilution, sorption, and volatilization.

It is also necessary to determine what contribution physical processes between sequential monitoring wells have on apparent reduction of chemicals. It may also be necessary to construct new monitoring wells which are offset to present wells or to perform borings near existing wells.

Statistical Validity of Data for MNA

Adequate monitoring is critical (Reinhard and Goodman, 1984), especially when considering natural attenuation as a remedial alternative. The number of sampling points (Barcelona et al., 1994 and 1985) and sampling rounds are often insufficient to establish statistically valid trends, given the natural variability in ground water quality, the variability due to pumping and sampling, and differences between analytical laboratories. Schmidt (1977) lists a number of conditions in which large fluctuations in water quality may be noted, indicating that minor changes in water chemistry may be related to sampling procedures. In order to minimize the effects of natural seasonal variations, sampling, and subsurface heterogeneity on ground water quality, any natural attenuation monitoring program (Gibbons, 1994; Gilbert, 1987) should be based on a detailed statistical evaluation of pertinent data (Hardin and Gilbert, 1993; McDonald and Erickson, 1994; O'Brien et al., 1991; O'Brien, 1997). Although it is recognized that intensive monitoring is expensive, increasing sampling points and frequencies, along with acceptable QA/QC procedures, will give more statistically reliable information. Caution should be exercised when drawing conclusions from limited data sets, especially when attempting to model complex situations.

The number of samples required for evaluating natural attenuation is intrinsically a function of a preselected confidence error and the variance of the data. Quarterly samples collected for a year or two, for example, may not be adequate for evaluating an overall reduction in the mass of contaminants from a particular monitoring well. Sampling frequencies such as this offer small windows for viewing contaminant reduction rates. Contaminant fronts may or may not have reached the monitoring points at the time of sampling, or as stated previously, any number of processes such as infiltration, dilution, and sorption may bias results when addressing only the bioremediation component of natural attenuation.

If the reduction of contaminant mass is to be determined by temporal trends (least squares analysis), for example, the statistical confidence is based on the variance of the data and the square root of the number of samples. In a least square analysis, the correlation coefficient (r) is a function of the degrees of freedom (df) which, in this case, is the number of observations minus two (n − 2). For example, if a well were sampled quarterly for two years, the degrees of freedom would be 6 (8 − 2) which requires a correlation coefficient of about 0.8 to demonstrate statistical significance at a 95 percent level of confidence (an r of 1.0 denotes a perfect correlation). The point is that one must sample with enough frequency, over a protracted period in order to obtain a statistically meaningful correlation between the reduction of contaminant mass and time.

MNA Degradation Rate Constant Considerations

Precision and accuracy in estimation of rate constants are essential to conclude how quickly the ground-water plume will be cleaned up following the source control (McNabb and Dooher, 1998). Reviews by Vogel et al. (1987a) and Howard et al. (1991) contain a compilation of chlorinated solvents rate constants. Experimental data on the neutral and base-catalyzed abiotic hydrolysis rates of chlorinated ethanes and ethenes was determined by Jeffers et al. (1989). Chapelle et al. (1996) integrated field and laboratory data to estimate rates of petroleum hydrocarbon biodegradation.

In the derivation of the rate constants, it is of considerable significance to calculate concentrations at the point of compliance, compare rates at the site to those in the literature to determine if the site is behaving like other sites, and predict changes caused by fluctuations in flow (Weaver et al., 1996). Although microcosms are used as an effective tool to determine the biodegradation potentials, the use of the microbiological laboratory data for calculation of rate constants may be inappropriate since they are not always representative of the degradative rate(s) under the field conditions (U.S. EPA, 1997b). Results from laboratory studies may significantly over- or underestimate biodegradation rates if environmental conditions in the laboratory differ from conditions in the field (Borden, 1994). Rifai (1997) also points out that, although useful in evaluating the biodegradation potential, microcosms can disrupt the normal structure of ecosystems and prevent the direct extrapolation of microcosm-determined biodegradation rates to field scale. If rate constants for attenuation of chlorinated contaminants are to be used for exposure assessments, it is necessary to estimate the residence time of the contaminants in the aquifer as accurately as possible (Molz and Boman, 1997). One should also be cautioned to not substitute literature biodegradation rates in the place of site specific values.

Often, first-order kinetics obtained from field studies are used to approximate the degradation mechanism. Wiedemeier et al. (1996) described two methods to estimate first-order rate constants: (1) the use of a conservative tracer, a biologically recalcitrant compound found in the dissolved contaminant plume; and (2) the interpretation of a steady state contaminant plume as proposed by Buscheck and Alcantar (1995). The later method is founded on a one-dimensional steady state analytical solution to the advection-dispersion equation presented by Bear (1979).

Modeling as a Predictive Tool for MNA

MNA requires two types of models: (1) conceptual and (2) fate and transport. In order to understand ground water-flow and contaminant movement (Bear et al., 1992), the construction of a three-dimensional conceptual model of the site must be an integral part of any MNA Work Plan. A comprehensive conceptual model should be used as a clear and concise aid for the general understanding of the nature of the site, the acquired sampling results, and to indicate where additional sampling efforts should be directed. Once a conceptual model has been accepted, a period of monitoring is required to verify that the forecast of the conceptual model is adequate. Only when sufficient quantitative site characterization data are generated and the conceptual model is well developed, can an appropriate analytical or numerical fate and transport model be chosen for the site.

Care should be exercised when choosing the models to predict the fate and transport of contaminants in the subsurface. This may also include the use of screening models such as BIOSCREEN and BIOCHLOR (Newell et al., 1996 and 1998). Appropriateness of the model to the actual hydrogeologic situation, assumptions, limitations, and manner of application are all considerations (Corapcioglu and Baehr, 1987; Carey et al., 1988). The overall effectiveness of the model for predicting fate and transport of contaminants at a particular site depends on all of these factors. Caution should also be exercised when drawing conclusions from limited data sets, especially when modeling complex situations. The validity of the input data is critical in determining the accuracy of predictions made with the model.

Once a model is chosen, it may be applied using the site data (Hunt et al., 1988) and calibrated. Calibration is a process of careful modification of site hydrogeologic or contaminant transport parameters over numerous simulations to identify a set of parameters which generate simulation results which closely match field measured values of hydraulic head for the flow model and contaminant concentrations for the transport model. Calibration of the model results to observed values requires that an acceptable range of error be identified for each calibration target. This range will depend on the model purpose and also on the amount and reliability of the field data (Kresec, 1997). Once calibrated, the fate and transport model can then be used to predict the future extent and concentration of a dissolved contaminant plume by simulating the combined effects of advection, dispersion, sorption, and biodegradation (Rifai et al., 1989).

Many times during calibration, if a model does not fit observed concentrations, it is assumed that the biodegradation coefficient is the proper parameter to be adjusted. Using biodegradation to adjust a model without supporting field data should not be done until all abiotic mechanisms for reduction are explored. When using a model which incorporates a biodegradation term, care should be taken to verify that assumptions made about degradation rates and the amount and activity of biomass are valid for the site in question. Degradation rates are sensitive to a wide array of field conditions which have been discussed previously. Extrapolation of laboratory derived rates to a site can also lead to significant errors. Likewise, using models to derive degradation rates from limited field data where abiotic variables are not well defined can be misleading. Models can be useful tools in determining plume movement (Mercer, 1998) and the contribution of natural attenuation (Rifai et al., 1995) to reductions in contaminant mass provided that all model inputs are correct, particularly those associated with biodegradation rates. Kinetic constants derived from laboratory microcosms or other sites are generally not useful on a wide scale to predict overall removal rates. Site specific degradation rates should be developed and incorporated into a model.

SUMMARY

The behavior of a contamination plume, whether stable, shrinking, or expanding, is the primary evidence for the occurrence of natural attenuation. In the majority of the cases, historical data to indicate the status of a plume are not available. In these events, there are at least four basic conditions which must be present to confirm that natural attenuation processes are taking place. These include, but are probably not limited to:

1. The points of sampling must be on flow lines from the source of contamination or an upgradient point of observation. It must be demonstrated that the downgradient observations accurately reflect the abiotic and biotic processes which have occurred between the two points. Ideally, one would sample the same volume of water at the downstream point that was sampled earlier at the source or upgradient observation well. Since this is rarely practical, it must be assumed that the plume is in equilibrium with respect to natural attenuation processes between the two points of observation. If these conditions are not satisfied, any downgradient measurement of contaminant concentration must be lower than the true value, and therefore, exaggerate the effectiveness of natural attenuation. Confidence levels may be enhanced by 1) increasing the number of observation points and times at fixed frequencies, and 2) use of a conservative tracer.
2. There must be a reduction in contaminant mass or concentration. One could argue that natural attenuation results in a reduction in contaminant concentration by sorption, volatilization, or dilution, with the only loss of mass being that of volatilization to the atmosphere. Natural bioremediation, on the other hand, must result in a reduction of mass of the contaminants of concern by the eventual conversion to environmentally acceptable compounds.
3. Site geochemistry must assure that conditions are right for reduction of contaminant concentration,

such as the presence of mineral nutrients and electron acceptors, the state of redox, temperature, and pH.

4. Daughter products of contaminants must be present, perhaps with indicators of mineralization. For example, claims of intrinsic or natural bioremediation need to be supported by data including the relationship between the mass loss and the loss of oxygen. In addition to the biological utilization of oxygen, nitrate, and sulfate, these natural attenuation processes often result in the creation of by-products such as dissolved Fe(II), Mn(II), HCO_{3^-}, $CO_{3^=}$ and methane.

The use of MNA or passive remediation at contaminated ground-water sites is gaining attention both within the scientific and regulatory communities. The OSWER directive recommends that MNA be applied concurrently with or subsequently to active measures such as source control or active remedial technologies. Selection of MNA as a remedy or part of a remedy can be advantageous since it may minimize the transfer of contaminants to other media, is less intrusive to the environment, may be applied to all or part of a site, and overall remedial costs may be lower than for an active remedy. There are several factors which may limit the application of natural attenuation as a remedial alternative. They are: (1) the longer time frame that may be required to achieve remedial goals, (2) site characterization investigations that may be more extensive and costly, (3) the added responsibility for long-term monitoring and costs, (4) toxicity of byproducts, (5) potential for continued contaminant migration, and (6) required alternatives if natural attenuation fails to meet established goals.

Under proper conditions, MNA along with source removal, long-term monitoring, and land use restrictions might be selected over more expensive conventional technologies. There will be other sites where natural attenuation will not be acceptable as a remedial alternative because of regulatory constraints or the site conditions are not favorable for its application. In the end, the selection of a remedial technology at a specific site will be determined by time constraints in obtaining remediation objectives, the hydrogeology and geochemistry at the site, the contaminants of concern, regulatory constraints, and considerations of environmental exposure and cost.

DISCLAIMER

The U.S. Environmental Protection Agency through its Office of Research and Development partially funded and collaborated in the research described here under Contract No. 68-C4-0031 to Dynamac Corporation. It has been subjected to the Agency's peer and administrative review and has been approved for publication as an EPA document. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

QUALITY ASSURANCE STATEMENT

All research projects making conclusions or recommendations based on environmentally related measurements and funded by the Environmental Protection Agency are required to participate in the Agency Quality Assurance Program. This project did not involve physical measurements and as such did not require a QA plan.

Groundwater vulnerability to pesticides is the potential for contamination of groundwater by pesticides from a nonpoint source or aerially distributed point sources. Due to widespread pesticide use and detection in groundwater, assessments that evaluate and estimate pesticide vulnerability have increasingly proven valuable during decisions regarding groundwater management, conservation, and remediation because of the significant costs of such actions. To predict groundwater vulnerability and understand factors that affect the transport of pesticides to groundwater resources, a variety of approaches have been developed that are broadly classified into three general categories: (1) overlay and index, (2) statistically based, and (3) process based. Often the selection of an appropriate approach for assessing groundwater vulnerability to pesticides is determined by the type and scale of the problem and by the available resources. This article provides an overview of the approaches and methods of evaluation for assessing groundwater vulnerability to pesticides.

BACKGROUND

Pesticide vulnerability assessments have become increasingly important in managing groundwater resources because of widespread pollution of groundwater by various pesticides. Pesticides are synthetic organic chemicals used to destroy insects or other organisms harmful to agriculture or animals. A comprehensive review by Barbash and Resek (1) of the published information on the distribution and behavior of pesticides in groundwater suggests that the greatest potential for unintended adverse effects from pesticides is through contamination of the earth's hydrologic system. Pesticides from every chemical class have been detected in groundwater (1), including samples collected from major aquifers of the United States, as part of the U.S. Geological Survey's National Water-Quality Assessment (NAWQA) Program. The samples collected from 1992 to 1998 by NAWQA revealed that pesticides were found most frequently in shallow groundwater in urban (54% of wells) and agricultural areas (61%), where pesticide use is greatest (2).

Knowledge of pesticide vulnerability for specific groundwater resources can be of great value for preserving and sustaining water quality. A variety of approaches have been developed to predict groundwater vulnerability and understand factors that affect the transport of pesticides to groundwater resources. Many of these approaches have been used by water-resource managers to make informed decisions regarding the potential risk of groundwater contamination by pesticides. This article provides an overview of the approaches and methods of evaluation for assessing groundwater vulnerability to pesticides.

Vulnerability is the potential for [pesticide] contamination of groundwater from a nonpoint source or aerially distributed point sources. The National Research Council (3) defined groundwater vulnerability to contamination as "the tendency or likelihood for contamination to reach a specified position in the groundwater system after introduction at some location above the uppermost aquifer." Similarly, the U.S. Environmental Protection Agency (4) defined groundwater vulnerability as "the relative ease with which a contaminant applied on or near the land surface can migrate to the aquifer of interest under a given set of agronomic management practices, pesticide characteristics, and hydrogeologic sensitivity conditions." Many definitions conceptualize two distinct components of groundwater vulnerability (5): (1) *intrinsic susceptibility*, which is defined by the inherent properties of the hydrogeologic system (hydraulic conductivity, porosity, depth to water, and soil type) and the associated sources of water and stresses for the system (rates and sources of recharge and discharge); and (2) *specific vulnerability*, or simply *vulnerability*, which is defined by the proximity of contaminant sources, fate and transport properties of the contaminant, and other factors that could increase loads of specified contaminants to the aquifer, their eventual delivery to a groundwater resource, or both. As Rupert (6) noted, although multiple definitions have been used for the term "vulnerability," they all address the same underlying question: What is the potential for groundwater contamination?

To assess the vulnerability of a groundwater resource to pesticide contamination, the physical and chemical mechanisms that control pesticide movement into groundwater must be addressed. A complete discussion of all processes and factors responsible for the behavior and fate of pesticides from land surface to groundwater is beyond the scope of this article. For additional details on pesticide fate and transport, refer to Barbash and Resek (1), a literature review of pesticide transport and leaching to groundwater by Flury (7); and Hornsby et al. (8), which is a comprehensive database that lists the properties of pesticides in the environment.

APPROACHES TO GROUNDWATER VULNERABILITY ASSESSMENTS OF PESTICIDES

A variety of approaches are presently used for assessing groundwater vulnerability to pesticides, ranging from subjective, qualitative, and opinion-based to objective, quantitative, and scientifically defensible methods. The approaches for assessing groundwater vulnerability can be classified into three general categories: (1) overlay and index, (2) statistically based, and (3) process based. Note that selection of the appropriate approach for assessing groundwater vulnerability is primarily driven by the type and scale of the problem and by the available resources.

Overlay and Index Approach

The overlay and index, one of the earliest approaches, generates vulnerability indexes based on the aggregation, or overlay, of many variables or factors deemed important in a given hydrologic setting, such as well location, geology, soil, and depth to water. This approach often is used as an initial screening tool and has an advantage over other methods because the data needed for implementation are generally available on the appropriate scale of study. The most widely used overlay and index method is DRASTIC (9), which incorporates professional judgment to weigh factors and create an aggregate point rating of groundwater vulnerability. DRASTIC is defined by seven factors: depth to water, net recharge, aquifer media, soil media, topography, impact of vadose zone media, and hydraulic conductivity of the aquifer. DRASTIC and other approaches that are based on best professional judgment are subjective and thus inherently result in less scientifically defensible groundwater vulnerability assessments. Overlay and index methods are not usually calibrated to measured pesticide concentrations in the groundwater and can result in poor correlation with actual pesticide concentration measurements (10). In addition, the seven factors considered by DRASTIC may not be the most appropriate for all groundwater systems.

Statistical Approach

Statistical approaches rely on empirical observation of measured pesticide concentration or detection in groundwater to establish relations with independent, or explanatory, variables. Explanatory variables represent the physical and chemical system of the land surface and subsurface, such as land use, soil taxonomy, lithology, depth to water, and pesticide application rates. The results of statistical models often express vulnerability as the probability of detecting pesticide concentrations within the groundwater of a specific area from which the empirical data were drawn. Although statistical models do not explicitly define underlying processes of pesticide fate and transport, important processes can be inferred based on proper selection of explanatory variables. An important assumption of statistical vulnerability models is that the area to which they are applied must be comparable to that in which they were developed (3). To address this assumption, statistical models rely on groundwater monitoring networks that are spatially representative of the area of interest.

The following sections outline two common statistical approaches used to assess groundwater vulnerability to pesticides: logistic regression and posterior probability distribution. Other statistically based approaches include cluster analysis (11), principal component analysis (11), and linear regression.

Logistic Regression. Logistic regression is a multivariate statistical approach that has been used extensively in the health sciences to predict a binary response in the dependent variable from measured explanatory variables, but recently, it has been used to estimate the probability of detecting pesticide concentrations in groundwater resources (6,12–17). Logistic regression is conceptually similar to multiple linear regressions because the relation between one dependent (response) variable and several independent (explanatory) variables is evaluated (18). However, logistic regression has an advantage over other generalized linear regression models because is does not require a normal sample distribution and censored (nondetect) values can be used. The concentrations of pesticides in groundwater generally are low; therefore, laboratory detection levels serve as a convenient threshold for establishing the binary response (i.e., detection of pesticides in groundwater samples versus nondetection of pesticides). The underlying assumption of logistic regression is that the natural logarithm of the odds ratio, which is the probability of being in a response category, is linearly related to the explanatory variables. The odds ratio is defined by the probability of exceeding the established threshold, expressed as

$$\text{Odds ratio} = \frac{p}{1-p} \tag{1}$$

where p is the probability of exceeding the threshold value.

The log of the odds ratio, or logit, transforms a variable constrained between 0 and 1 into a continuous variable that is a linear function of the explanatory variables (19). The logit transformation is

$$\log\left(\frac{p}{1-p}\right) = b_o + b_x \tag{2}$$

where b_o is the logistic regression constant and b_x is the vector of slope coefficients and explanatory variables. Predicted values of the response variable are converted back into probability units by using the logistic transformation; the logistic regression model takes the form

$$P = \frac{e^{(b_o+bX)}}{1+e^{(b_o+bX)}} \tag{3}$$

where P is the probability of the binary response event, often defined as detecting the pesticide of interest in groundwater, and e is the base of the natural logarithm.

An additional advantage of logistic regression is the user's ability for model validation using an independent set of pesticide concentration data. However, logistic regression, like other statistical approaches, has received criticism because the models do not represent the physical, chemical, and biological processes that affect groundwater vulnerability and process-based approaches. A detailed description of logistic regression analysis is presented by Hosmer and Lemeshow (18).

Posterior Probability Distribution. Using the posterior probability distribution method, Worrall and Kolpin (20) developed an approach for the direct assessment of groundwater vulnerability to pesticides based on a single observation of multiple contaminants. This method of direct assessment is independent of the compounds examined, and it has a direct probabilistic interpretation making it ideal for risk assessment. In addition, this method has the advantage that the measures of vulnerability are based on observation rather than expert opinion, indexes, or physical models (20). Furthermore, errors of the probabilistic interpretation can be easily quantified.

The posterior probability distribution method is a measure of the difference between two proportions (the proportion of detections in the region and the proportions of detections observed in a single observation well) (20). Because vulnerability is always calculated relative to the region as a whole, compounds that are either always detected or never detected add no discriminating information to the assessment. The proportion of detections of each compound is calculated for the entire data set, and the probability distribution for each of the proportions is determined based on the observed data. The posterior probability distribution can help identify differences between the proportions of detections in the well compared to that in the region and provides estimates of vulnerability of the area of the aquifer contributing to the well. Worrall and Kolpin (20) provide in-depth details regarding the posterior probability distribution methodology.

Although the posterior probability distribution method is advantageous because it can be used to determine a probabilistic measure of vulnerability based on empirical observation rather than expert opinion, this method relies on a number of significant assumptions that may not be reasonable for all groundwater systems (20).

Process-Based Approach

Process-based pesticide vulnerability models include a wide range of methods and depend primarily on the extent to which they simulate subsurface solute-transport processes (21). These deterministic models require analytical or numerical solutions of mathematical equations that represent processes governing pesticide fate and transport. Although process-based models incorporate a more complete description of the physical, chemical, and biological processes that affect groundwater vulnerability, they may not necessarily provide more reliable estimates of pesticide vulnerability because of extensive data requirements needed to define the subsurface hydrogeology (3). Often, detailed data sets of the subsurface are not available or may result in predictions that are of little value if the parameters describing the system are ill-defined or if they vary significantly in time and space (22).

Process-based pesticide vulnerability assessments include complex and simple models. Complex pesticide vulnerability models can range from analytical solutions for one-dimensional transport through the unsaturated zone to coupled, unsaturated–saturated, two- or three-dimensional models (3). The Pesticide Root Zone Model (PRZM) (23) is one of the most commonly used complex models for pesticide vulnerability modeling. PRZM is a one-dimensional, deterministic-empirical/conceptual model that simulates soil–water movement by using an empirical drainage algorithm and solute transport with the advection-dispersion equation. PRZM has two distinct advantages over simple index models for estimating pesticide leaching: (1) concentrations are estimated with reference to depth and time, and (2) heterogeneity in the soil column and variability in recharge can be accounted for (24). Other complex process-based models include the Type Transfer Function (TTF), outlined by Stewart and Loague (25); the Leaching Estimation and Chemistry Model (LEACHM) (26); and Monte-Carlo simulations of deterministic models (27).

Advantages gained by using complex pesticide vulnerability models can be minimized by extensive data requirements, which have limited their use to local or field-scale evaluations. If data are unavailable, estimates are used that may introduce additional model uncertainty. Therefore, uncertainty can be reduced when using a simple method (28). Simple index-based process models have been used more routinely for large-scale and regional pesticide vulnerability modeling. Process-based index models are first-order approximations of pesticide vulnerability that describe the relation between how fast the pesticide leaches and how fast it can be degraded. The net result of these two processes determines what fraction of soil-applied pesticides potentially reaches groundwater (29).

Index models are conceptually simplified and are valid only under steady-state flow within a uniform homogeneous ideal medium. The models represent the important transport processes for pesticides, are most appropriately used as screening tools, and are intended for evaluation and comparison of pesticide behavior under constrained and limited conditions with the advantage of requiring few input data (21). The following sections describe index process models that have routinely been used to evaluate pesticide vulnerability of groundwater.

Attenuation Factor. The attenuation factor (AF) (30) is a simple index of residence time and degradation rate of a pesticide that is equivalent to the fraction of applied pesticide mass likely to leach past a reference depth. This index is a simple solution of the one-dimensional, advection-dominated transport equation and is defined as

$$\mathrm{AF} = e\left(\frac{-0.693\ d\mathrm{RF}\theta_{\mathrm{FC}}}{\mathrm{q}t_{1/2}}\right) \tag{4}$$

where d is the distance from the land surface to groundwater; RF is the retardation factor, which accounts for pesticide sorption effects; θ_{FC} is the volumetric water content at field capacity; q is the net groundwater recharge rate; and $t_{1/2}$ is the half-life of pesticide degradation. RF is defined as

$$\mathrm{RF} = \left(1 + \frac{\rho_{\mathrm{b}} f_{\mathrm{oc}} K_{\mathrm{oc}}}{\theta_{\mathrm{FC}}} + \frac{\theta_{\mathrm{g}} K_{\mathrm{H}}}{\theta_{\mathrm{FC}}}\right) \tag{5}$$

where ρ_{b} is the soil bulk density (g/cm^3), f_{oc} is the fraction of soil organic carbon on a mass basis, K_{oc} is the organic carbon sorption coefficient (mL/g), θ_{g} is the gas constant (unitless), and K_{H} is Henry's constant for the pesticide of interest (unitless).

The AF ranges from zero to one, where zero corresponds to a minimal threat of applied pesticide leaching and a value of one corresponds to all the applied pesticide mass reaching the groundwater.

Leaching Potential Index. The Leaching Potential Index (LPI) was developed by Meeks and Dean (31) and, similar to the AF, is derived from the advection-dispersion equation. The LPI is compound specific and includes information regarding adsorption and degradation parameters. The LPI is defined as

$$\mathrm{LPI} = \frac{1000\ t_{1/2} V}{0.693\ RFd} \tag{6}$$

where V is the average linear vertical soil–water velocity (L/t).

Increases in LPI values reflect a direct relation between increases in pesticide vulnerability. It should be noted that the LPI is simply the inverse of the exponent in Equation 5 of the AF, and a factor of 1000 is arbitrarily included to increase the numerical values of the LPI (32).

Schlosser and McCray (28) conducted a sensitivity analysis by using the LPI to evaluate the relative importance of input-parameter variability on model-predicted vulnerability. Results indicated that the calculated vulnerabilities were most sensitive to organic carbon content, depth to groundwater, and vertical soil–water velocity.

Vulnerability Index. The Vulnerability Index (VI) (32) is a modified version of the LPI equation, defined as

$$\mathrm{VI} = \frac{200\ k\theta_{\mathrm{FC}}}{d\rho_{\mathrm{b}}(\mathrm{OM})}\left(\frac{t_{1/2}}{K_{\mathrm{oc}}}\right) F_{\mathrm{DGW}} \tag{7}$$

where k is the decay constant (day^{-1}); OM is the percentage of organic matter present in the soil; $(t_{1/2}/K_{\mathrm{oc}})$

is the leachability ratio, which is the measure of the pesticide's propensity to biodegrade ($t_{1/2}$) and to sorb to organic matter in the soil (K_{oc}); and F_{DGW} is a factor that accounts for the depth to groundwater.

The VI model is a practical approach to assessing many pesticides simultaneously by incorporating the leaching potential. The VI uses the leachability ratio to account for the leaching potential of multiple pesticides that have similar chemical properties. This method has a significant advantage over other index methods; by grouping pesticides according to their leachability ratio, vulnerability assessments are made for each group, rather than for each individual pesticide.

PESTICIDE VULNERABILITY MAPS

Pesticide vulnerability maps are spatial representations of models (i.e., overlay and index, statistical, or process-based) that identify areas of the aquifer that have a potential for pesticide contamination in the groundwater. Often, pesticide vulnerability maps are used to predict pesticide vulnerability of groundwater that has not been previously sampled. Many pesticide vulnerability assessments have incorporated the use of geographic information systems (GIS) for calculating pesticide vulnerability and visualizing the model over the study area. GIS is a modeling framework and tool designed for the analysis and display of spatial data. Many vulnerability studies use GIS because (1) a GIS can display and analyze the spatial variability of georeferenced variables important for the assessment, (2) a GIS can incorporate georeferenced measurements of pesticide concentration data, and (3) the digital display and data-manipulation ability of a GIS provides numerous advantages for creating maps of groundwater vulnerability to pesticide contamination.

UNCERTAINTY OF PESTICIDE VULNERABILITY ASSESSMENT

Uncertainty is unavoidable during estimation of pesticide vulnerability because of limitations in knowledge of contaminant behavior in the subsurface and significant limitations in the spatial databases used for assessments (3). Uncertainty in predictions reflect limitations due to (1) accurate spatial delineations of data and its transfer from real-world to digital data or maps; (2) spatial averaging and uncertainties of soil properties and other explanatory variables; (3) assumptions related to individual pesticide vulnerability approaches that often assume steady-state conditions or homogeneous conditions in the soil or unsaturated zone; (4) uncertainties from spatial interpolation from point estimates, if kriging or other interpolation methods are used; and (5) temporal variability of explanatory variables, such as land-use practices, may limit predictions of future vulnerability estimates for a given groundwater resource.

Increasingly, studies of pesticide vulnerability have acknowledged the inherent uncertainty in the assessment and have made attempts to quantify this uncertainty. Refer to the work of Freissinet et al. (33), Loague et al. (24), and Loague (34) for specific approaches to estimate and quantify uncertainty during pesticide vulnerability assessments.

GROUNDWATER—NATURE'S HIDDEN TREASURE

Environment Canada

Groundwater is an essential and vital resource for about a quarter of all Canadians. It is their sole source of water for drinking and washing, for farming and manufacturing, indeed, for all their daily water needs. Yet for the majority of Canadians—those who do not depend on it—groundwater is a hidden resource whose value is not well understood or appreciated.

Our image of Canada is of a land of sparkling lakes, rivers and glaciers. Groundwater, which exists everywhere under the surface of the land, is not part of this picture. Not surprisingly, therefore, concerns of Canadians about water quality focus primarily on surface waters—our lakes and rivers. The less visible, but equally important, groundwater resources have received less public attention, except in regions of Canada where people depend on them.

GROUNDWATER NEEDS PROTECTION

In recent years, however, a number of events affecting groundwater quality have contributed to a heightened public awareness and concern about the importance and vulnerability of the resource. Media reports about the contamination of wells from leaking gasoline storage tanks or dry cleaning solvents, and about the effects on groundwater of chemical leakage from landfill or industrial waste disposal sites have raised public concerns about

groundwater quality. Early in 1990, chemical seepage, caused by the tire fire at Hagersville, Ontario, threatened to pollute groundwater supplies in that region. Newspaper reports alerted area residents and helped focus attention on the problem of groundwater pollution.

Even where we might not use it directly as a drinking water supply we must still protect groundwater, since it will carry contaminants and pollutants from the land into the lakes and rivers from which other people get a large percentage of their freshwater supply.

Groundwater and Geology

Groundwater is also important quite apart from its value as a resource or its close connection with surface water supplies. Engineers must consider groundwater when planning almost any kind of structure, either above or below the ground. Ignoring the effect of groundwater on slope stability can be both costly and dangerous. Geologists see groundwater as a major force in geological change. The fluid pressures exerted by groundwater, for example, play an important role in the occurrence of earthquakes. Geologists also know that the movement of water through underground geologic formations controls the migration and the accumulation of petroleum and the formation of some ore deposits.

WHAT IS GROUNDWATER?

It is sometimes thought that water flows through underground rivers or that it collects in underground lakes. Groundwater is not confined to only a few channels or depressions in the same way that surface water is concentrated in streams and lakes. Rather, it exists almost everywhere underground. It is found underground in the spaces between particles of rock and soil, or in crevices and cracks in rock. The water filling these openings is usually within 100 metres of the surface. Much of the earth's fresh water is found in these spaces. At greater depths, because of the weight of overlying rock, these openings are much smaller, and therefore hold considerably smaller quantities of water.

Groundwater flows slowly through water-bearing formations (aquifers) at different rates. In some places, where groundwater has dissolved limestone to form caverns and large openings, its rate of flow can be relatively fast but this is exceptional.

Many terms are used to describe the nature and extent of the groundwater resource. The level below which all the spaces are filled with water is called the *water table*. Above the water table lies the *unsaturated zone*. Here the spaces in the rock and soil contain both air and water. Water in this zone is called *soil moisture*. The entire region below the water table is called the *saturated zone*, and water in this saturated zone is called *groundwater*.

WHAT IS AN AQUIFER?

Although groundwater exists everywhere under the ground, some parts of the saturated zone contain more water than others. An *aquifer* is an underground formation of permeable rock or loose material which can produce useful quantities of water when tapped by a well. Aquifers come in all sizes. They may be small, only a few hectares in area, or very large, underlying thousands of square kilometres of the earth's surface. They may be only a few metres thick, or they may measure hundreds of metres from top to bottom.

GROUNDWATER—ALWAYS ON THE MOVE

Permeable material contains interconnected cracks or spaces that are both numerous enough and large enough to allow water to move freely. In some permeable materials groundwater may move several metres in a day; in other places, it moves only a few centimetres in a century. Groundwater moves very slowly through relatively *impermeable* materials such as clay and shale.

Groundwater scientists generally distinguish between two types of aquifers in terms of the physical attributes of the aquifer: porous media and fractured aquifers.

Porous media are those aquifers consisting of aggregates of individual particles such as sand or gravel. The groundwater occurs in and moves through the openings between the individual grains. Porous media where the grains are not connected to each other are considered *unconsolidated*. If the grains are cemented together, such aquifers are called *consolidated*. Sandstones are examples of consolidated porous media.

Fractured aquifers are rocks in which the groundwater moves through cracks, joints or fractures in otherwise solid rock. Examples of fractured aquifers include granite and basalt. Limestones are often fractured aquifers, but here the cracks and fractures may be enlarged by solution, forming large channels or even caverns. Limestone terrain where solution has been very active is termed *karst*. Porous media such as sandstone may become so highly cemented or recrystallized that all of the original space is filled. In this case, the rock is no longer a porous medium. However, if it contains cracks it can still act as a fractured aquifer.

Most of the aquifers of importance to us are unconsolidated porous media such as sand and gravel. Some very porous materials are not permeable. Clay, for instance, has many spaces between its grains, but the spaces are not large enough to permit free movement of water.

Groundwater usually flows downhill with the slope of the water table. Like surface water, groundwater flows toward, and eventually drains into streams, rivers, lakes and the oceans. Groundwater flow in the aquifers underlying surface drainage basins, however, does not always mirror the flow of water on the surface. Therefore, groundwater may move in different directions below the ground than the water flowing on the surface.

Unconfined aquifers are those that are bounded by the water table. Some aquifers, however, lie beneath layers of impermeable materials. These are called *confined aquifers*, or sometimes *artesian aquifers*. A well in such an aquifer is called an *artesian well*. The water in these wells rises higher than the top of the aquifer because of confining pressure. If the water level rises above the ground surface a *flowing artesian well* occurs. The *piezometric surface* is the level to which the water in an artesian aquifer will rise.

Groundwater As a Source of Energy

Groundwater may be used as a source of heat. Ground source heat pumps are receiving increased attention as energy efficient commercial and residential heating/cooling systems. Although initial costs are higher than air source systems—due to the additional costs of the underground installations—the much greater energy efficiency of ground source systems makes them increasingly attractive.

Research into the use of geothermal water has been carried out in a number of institutions across Canada. The City of Moose Jaw has developed a geothermal heating system for a public swimming pool and recreational facility. Carleton University in Ottawa already uses groundwater to heat and cool its buildings. The Health Centre complex in Sussex, New Brunswick, has been utilizing an aquifer for thermal energy storage since 1995.

GROUNDWATER—A MAJOR LINK IN THE HYDROLOGIC CYCLE

Groundwater circulates as part of the hydrologic cycle. As precipitation and other surface water sources recharge the groundwater it drains steadily, and sometimes very slowly, towards its discharge point.

Groundwater does not stay underground forever, and it does not lie still waiting for us to draw it from a well. The *hydrologic cycle* is the series of transformations that occur in the circulation of water from the atmosphere onto the surface and into the subsurface regions of the earth, and then back from the surface to the atmosphere. Precipitation becomes surface water, soil moisture, and groundwater. Groundwater circulates back to the surface, and from the surface all water returns to the atmosphere through evaporation and transpiration.

When precipitation falls on the land surface, part of the water runs off into the lakes and rivers. Some of the water from melting snow and from rainfall seeps into the soil and percolates into the saturated zone. This process is called recharge (Fig. 2). Places where recharge occurs are referred to as *recharge areas*.

Eventually, this water reappears above the ground. This is called *discharge*. Groundwater may flow into streams, rivers, marshes, lakes and oceans, or it may discharge in the form of *springs* and flowing wells.

Groundwater discharge can contribute significantly to surface water flow. In dry periods, the flow of some streams may be supplied entirely by groundwater. At all times of the year, in fact, the nature of underground formations has a profound effect on the volume of surface runoff. While the rate of discharge determines the volume of water moving from the saturated zone into streams, the rate of recharge determines the volume of water running over the surface. When it rains, for instance, the volume of water running into streams and rivers depends on how much rainfall the underground materials can absorb. When there is more water on the surface than can be absorbed into the groundwater zone, it runs off into streams and lakes.

The *residence time* of groundwater, i.e., the length of time water spends in the groundwater portion of the hydrologic cycle, varies enormously. Water may spend as little as days or weeks underground, or as much as 10 000 or more years. Residence times of tens, hundreds, or even thousands of years are not unusual. By comparison, the average turnover time of river water, or the time it takes the water in rivers to completely replace itself, is about two weeks.

Groundwater and Permafrost

Most of the Northwest Territories is covered by either the Canadian Shield or permafrost (permanently frozen ground), both of which inhibit the flow of groundwater. The major exceptions include the Mackenzie Mountains in the western Northwest Territories and Yukon, and the limestone terrain southwest of Great Slave Lake, where soils, fractured rock, and glacial debris provide material that can store and release groundwater.

On a local scale, the seasonal development of a thawed "active layer" above the permafrost can provide permeable pathways for the subsurface movement of water and contaminants.

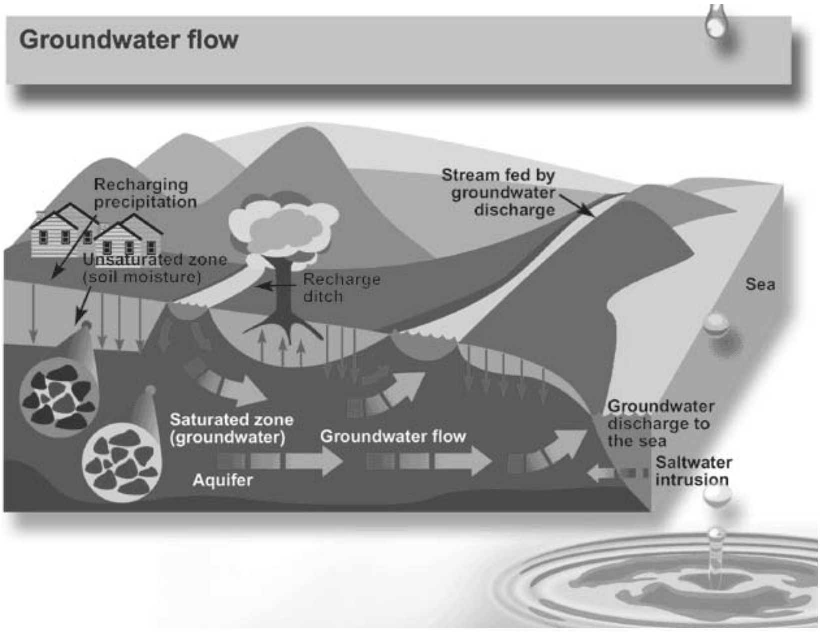
ALMOST NINE MILLION CANADIANS DEPEND ON GROUNDWATER

In Canada, 8.9 million people, or 30.3% of the population, rely on groundwater for domestic use. Approximately two thirds of these users live in rural areas. In many areas, wells produce more reliable and less expensive water supplies than those obtained from nearby lakes, rivers and streams. The remaining users are located primarily in smaller municipalities where groundwater provides the primary source for their water supply systems. For instance, 100% of Prince Edward Island's population and over 60% of the population of New Brunswick rely on groundwater to meet their domestic needs.

Furthermore, the predominant use of groundwater varies by province. In Ontario, Prince Edward Island, New Brunswick, and the Yukon, the largest users of groundwater are municipalities; in Alberta, Saskatchewan, and Manitoba, the agricultural industry for livestock watering; in British Columbia, Quebec and the Northwest Territories, industry; and in Newfoundland and Nova Scotia, rural domestic use. Prince Edward Island is almost totally dependent on groundwater for all its uses.

According to some estimates, the quantity of groundwater in the earth would cover the entire surface of the globe to a depth of 120 metres. By contrast, the volume of surface water in lakes, rivers, reservoirs and swamps could be contained in a depth of about one quarter of a metre.

It is extremely difficult to estimate the volume of groundwater on the entire planet. For example, a recent review of the literature revealed estimated figures ranging from 7 000 000 to 330 000 000 cubic kilometres. However,



all the estimates imply that if we do not include the water frozen in ice caps, glaciers and permanent snow, groundwater makes up almost the entire volume of the earth's usable *fresh* water. Yet, this supply is often not easily accessible, and it may be difficult and expensive to develop these water supplies in some regions. The quality of the groundwater source is also a significant determining factor when identifying its use.

GROUNDWATER QUALITY

We often think of water quality as a matter of taste, clarity and odour, and in terms of other properties which determine whether water is fit for drinking. For other uses different properties may be important. Most of these properties depend on the kinds of substances that are dissolved or suspended in the water. Water for most industrial uses, for instance, must not be corrosive and must not contain dissolved solids that might precipitate on the surfaces of machinery and equipment.

Pure water is tasteless and odourless. A molecule of water contains only hydrogen and oxygen atoms. Water is never found in a pure state in nature. Both groundwater and surface water may contain many constituents, including microorganisms, gases, inorganic and organic materials.

The chemical nature of water continually evolves as it moves through the hydrologic cycle. The kinds of chemical constituents found in groundwater depend, in part, on the chemistry of the precipitation and recharge water. Near coastlines, precipitation contains higher concentrations of sodium chloride, and downwind of industrial areas, airborne sulphur and nitrogen compounds make precipitation acidic.

One of the most important natural changes in groundwater chemistry occurs in the soil. Soils contain high concentrations of carbon dioxide which dissolves in the groundwater, creating a weak acid capable of dissolving many silicate minerals. In its passage from recharge to discharge area, groundwater may dissolve substances it encounters or it may deposit some of its constituents along the way. The eventual quality of the groundwater depends on temperature and pressure conditions, on the kinds of rock and soil formations through which the groundwater flows, and possibly on the residence time. In general, faster flowing water dissolves less material. Groundwater, of course, carries with it any soluble contaminants which it encounters.

Saltwater Intrusion

Saltwater intrusion can be a problem in coastal areas where rates of groundwater pumping are high enough to cause sea water to invade freshwater aquifers (Fig. 2). The problem can be avoided by appropriate well field design and by drilling relief wells to keep the salt water away from the fresh groundwater source. Some wells pumping saltwater in Prince Edward Island, are used as convenient water supplies for shellfish farms.

Scientists assess *water quality* by measuring the amounts of the various constituents contained in the water. These amounts are often expressed as milligrams per litre (mg/L), which is equivalent to the number of grams of a substance per million grams of water.

The suitability of water for a given use depends on many factors such as hardness, salinity and pH. Acceptable values for each of these parameters for any given use depend on the use, not on the source of the water, so that the considerations important for surface water (as mentioned in Freshwater Series No. A-3, entitled "Clean Water—Life Depends on It!") are equally applicable to groundwater.

The natural quality of groundwater differs from surface water in that:

a. for any given source, its quality, temperature and other parameters are less variable over the course of time; and,
b. in nature, the range of groundwater parameters encountered is much larger than for surface water, e.g., total dissolved solids can range from 25 mg/L in some places in the Canadian Shield to 300 000 mg/L in some deep saline waters in the Interior Plains.

At any given location, groundwater tends to be harder and more saline than surface water, but this is by no means a universal rule. It is also generally the case that groundwater becomes more saline with increasing depth, but again, there are many exceptions.

Leaking Underground Storage Tanks and Piping

Leaks of petroleum products have been increasing over the last two decades because underground steel tanks installed in large numbers in the 1950s and 1960s have become corroded. Before 1980, most underground tanks were made of steel. Without adequate corrosion protection, up to half of them leak by the time they are 15 years old.

Groundwater dissolves many different compounds, and most of these substances have the potential to contaminate large quantities of water. For example, one litre of gasoline can contaminate 1 000 000 litres of groundwater. This problem is particularly severe in the Atlantic provinces where there is a high usage of groundwater. In many cases, the problem is noticed long after the aquifer is contaminated, for example, when consumers start tasting or smelling gasoline.

As groundwater flows through an aquifer it is naturally filtered. This filtering, combined with the long residence time underground, means that groundwater is usually free from disease-causing microorganisms. A source of contamination close to a well, however, can defeat these natural safeguards. Natural filtering also means that groundwater usually contains less suspended material and undissolved solids than surface water.

DNAPLs

A type of contaminant that is especially troublesome is the group of chemicals known as *dense non-aqueous phase liquids*, or *DNAPL*s. These include chemicals used in dry cleaning, wood preservation, asphalt operations, machining, and in the production and repair of automobiles, aviation equipment, munitions, and electrical equipment. They can also be generated and released in accidents, e.g., the Hagersville "tire fire." These substances are heavier than water and they sink quickly into the ground. This makes spills of DNAPLs more difficult to handle than spills of petroleum products. As with petroleum products, the problems are caused by groundwater dissolving some of the compounds in these volatile substances. These compounds can then move with the groundwater flow. Except in large cities, drinking water is rarely tested for these contaminants.

HOW WE CONTAMINATE GROUNDWATER

Any addition of undesirable substances to groundwater caused by human activities is considered to be *contamination*. It has often been assumed that contaminants left on or under the ground will stay there. This has been shown to be wishful thinking. Groundwater often spreads the effects of dumps and spills far beyond the site of the original contamination. Groundwater contamination is extremely difficult, and sometimes impossible, to clean up.

Sources of Contamination That Can Cause Groundwater Contamination

Point sources

- On-site septic systems
- Leaky tanks or pipelines containing petroleum products
- Leaks or spills of industrial chemicals at manufacturing facilities
- Underground injection wells (industrial waste)
- Municipal landfills
- Livestock wastes
- Leaky sewer lines
- Chemicals used at wood preservation facilities
- Mill tailings in mining areas
- Fly ash from coal-fired power plants
- Sludge disposal areas at petroleum refineries
- Land spreading of sewage or sewage sludge
- Graveyards
- Road salt storage areas
- Wells for disposal of liquid wastes
- Runoff of salt and other chemicals from roads and highways
- Spills related to highway or railway accidents
- Coal tar at old coal gasification sites
- Asphalt production and equipment cleaning sites

Non-point (distributed) sources

- Fertilizers on agricultural land
- Pesticides on agricultural land and forests
- Contaminants in rain, snow, and dry atmospheric fallout

Source: Adapted from Cherry, p. 395.

Groundwater contaminants come from two categories of sources: *point sources* and distributed, or *non-point sources*. Landfills, leaking gasoline storage tanks, leaking septic tanks, and accidental spills are examples of point sources. Infiltration from farm land treated with pesticides and fertilizers is an example of a non-point source.

Among the more significant point sources are municipal landfills and industrial waste disposal sites. When either of these occur in or near sand and gravel aquifers, the potential for widespread contamination is the greatest.

In Ville Mercier, Quebec, for example, the disposal of industrial wastes into lagoons in an old gravel pit over many years rendered the water supplies of thousands of residents in the region unusable. Water had to be pumped from a well 10 kilometres away to replace the area's supply.

Other point sources are individually less significant, but they occur in large numbers all across the country. Some of these dangerous and widespread sources of contamination are septic tanks, leaks and spills of petroleum products and of dense industrial organic liquids.

Septic systems are designed so that some of the sewage is degraded in the tank and some is degraded and absorbed by the surrounding sand and subsoil. Contaminants that may enter groundwater from septic systems include bacteria, viruses, detergents, and household cleaners. These can create serious contamination problems. Despite the fact that septic tanks and cesspools are known sources of contaminants, they are poorly monitored and very little studied.

Contamination can render groundwater unsuitable for use. Although the overall extent of the problem across Canada is unknown, many individual cases of contamination have been investigated such as Ville Mercier in Quebec; the highway de-icing salt problem in Nova Scotia; industrial effluents in Elmira, Ontario; various pesticides in the Prairie provinces; industrial contamination in Vancouver, British Columbia; and so on. In many cases, contamination is recognized only after groundwater users have been exposed to potential health risks. The cost of cleaning up contaminated water supplies is usually extremely high.

Contamination problems are increasing in Canada primarily because of the large and growing number of toxic compounds used in industry and agriculture. In rural Canada, scientists suspect that many household wells are contaminated by substances from such common sources as septic systems, underground tanks, used motor oil, road salt, fertilizer, pesticides, and livestock wastes. Scientists also predict that in the next few decades more contaminated aquifers will be discovered, new contaminants will be identified, and more contaminated groundwater will be discharged into wetlands, streams and lakes.

Once an aquifer is contaminated, it may be unusable for decades. The residence time, as noted earlier, can be anywhere from two weeks or 10 000 years.

Furthermore, the effects of groundwater contamination do not end with the loss of well-water supplies. Several studies have documented the migration of contaminants from disposal or spill sites to nearby lakes and rivers as this groundwater passes through the hydrologic cycle, but the processes are not as yet well understood. In Canada, pollution of surface water by groundwater is probably at least as serious as the contamination of groundwater supplies. Preventing contamination in the first place is by far the most practical solution to the problem. This can be accomplished by the adoption of effective groundwater management practices by governments, industries and all Canadians. Although progress is being made in this direction, efforts are hampered by a serious shortage of groundwater experts and a general lack of knowledge about how groundwater behaves.

GROUNDWATER AND ENGINEERING

Groundwater can also have dramatic implications for engineering and geotechnical studies. The study of groundwater is essential for engineers who construct dams, tunnels, water conveyance channels, mines, and other structures. Groundwater must be considered whenever the stability of slopes is important, whether the slope is natural or constructed. Groundwater must also be taken into account when devising measures to control flooding. In all of these situations, groundwater flow and fluid pressure can create serious *geotechnical problems*.

Groundwater, for example, may create structural weaknesses in dams, or it may flow underground right around the structure as it did at the Jerome Dam in Idaho. Water flowed so efficiently through the rock formations surrounding the reservoir that the dam would hold no water, even though it was structurally sound.

In another case, when geological exploration was being carried out in preparation for the construction of the Revelstoke Dam in British Columbia, geologists and engineers were concerned about an old landslide on the bank of the proposed reservoir. They suspected that the water held in the reservoir could increase groundwater pressures enough to make the slide unstable. The solution was to increase drainage around the slide to ensure that groundwater pressures did not increase. In 1963, these same conditions at the Vaiont reservoir in Italy caused a slide which killed 2500 people.

Other problems result from the excessive use of groundwater. *Overdrafting* occurs when people draw water out of an aquifer faster than nature can replenish it. The most obvious problem created is a shortage of water. Overdrafting, however, can also create significant geotechnical problems. Although not an issue in Canada, at many locations around the world overdrafting has caused *land subsidence*. This can produce severe engineering difficulties. Parts of Mexico City, for instance, have subsided as much as 10 metres in the past 70 years, resulting in a host of problems in its water supply and sewerage system. Land subsidence may also occur when the water table is lowered by drainage. In the early 1970s, for example, an entire residential subdivision in Ottawa subsided when a collector sewer was constructed nearby. The subsidence seriously damaged the residents' property.

Groundwater and Wetlands

Wetlands, which provide a summer home to nearly all of North America's 45 million ducks and other waterfowl, often have very close connections with the groundwater system. Some wetlands, e.g., potholes in higher ground, may serve as important groundwater recharge areas. Others, especially those in low-lying areas, may be the receptors for significant amounts of groundwater discharge. Therefore, if the underlying groundwater is contaminated, detrimental consequences will be felt by the wildlife and all other resources dependent on that wetland.

SAFEGUARDING OUR GROUNDWATER SUPPLY

Groundwater is an essential resource. It exists everywhere under the Canadian landscape and is vitally connected to our rich surface water resources.

Contamination of groundwater is a serious problem in Canada. Industrial and agricultural activities are major sources of contaminants, but Canadian households are equally important sources.

Groundwater moves so slowly that problems take a long time to appear. Because of this, and because it is so expensive to clean up a contaminated aquifer (if it can be done at all), it is preferable by far to prevent contamination from happening in the first place. For example, leaking underground storage tanks can be replaced by tanks that will not corrode; landfills can be sited in locations where leachates will not contaminate underlying groundwater; and the impacts of spills of hazardous materials reduced by restricting access to recharge areas.

All levels of government in Canada are starting to take some of the actions necessary to protect our groundwater supplies, but there is a long way to go before these measures are fully effective. At the same time, universities and government research institutes are investigating what happens to water underground and what can be done to preserve it and even improve its availability to us. Both as a society and as individuals, we must keep in mind groundwater's susceptibility to contamination.

Groundwater is just as important as the sparkling lakes and rivers of our postcard image of Canada. This national treasure may be "hidden," but it must not be forgotten.

PHARMACEUTICALS, HORMONES, AND OTHER ORGANIC WASTEWATER CONTAMINANTS IN U.S. STREAMS

Herbert T. Buxton
Dana W. Kolpin
United States Geological Survey

A recent study by the Toxic Substances Hydrology Program of the U.S. Geological Survey (USGS) shows that a broad range of chemicals found in residential,

---

industrial, and agricultural wastewaters commonly occurs in mixtures at low concentrations downstream from areas of intense urbanization and animal production. The chemicals include human and veterinary drugs (including antibiotics), natural and synthetic hormones, detergent metabolites, plasticizers, insecticides, and fire retardants. One or more of these chemicals were found in 80 percent of the streams sampled. Half of the streams contained 7 or more of these chemicals, and about one-third of the streams contained 10 or more of these chemicals. This study is the first national-scale examination of these organic wastewater contaminants in streams and supports the USGS mission to assess the quantity and quality of the Nation's water resources. A more complete analysis of these and other emerging water-quality issues is ongoing.

BACKGROUND

Chemicals, used everyday in homes, industry and agriculture, can enter the environment in wastewater. These chemicals include human and veterinary drugs (including antibiotics), hormones, detergents, disinfectants, plasticizers, fire retardants, insecticides, and antioxidants. To assess whether these chemicals are entering our Nation's streams, the Toxic Substances Hydrology Program of the U.S. Geological Survey (USGS) collected and analyzed water samples from 139 streams in 30 states during 1999 and 2000. Streams were sampled that were considered susceptible to contamination from various wastewater sources, such as those downstream from intense urbanization or livestock production. Thus, the results of this study are not considered representative of all streams.

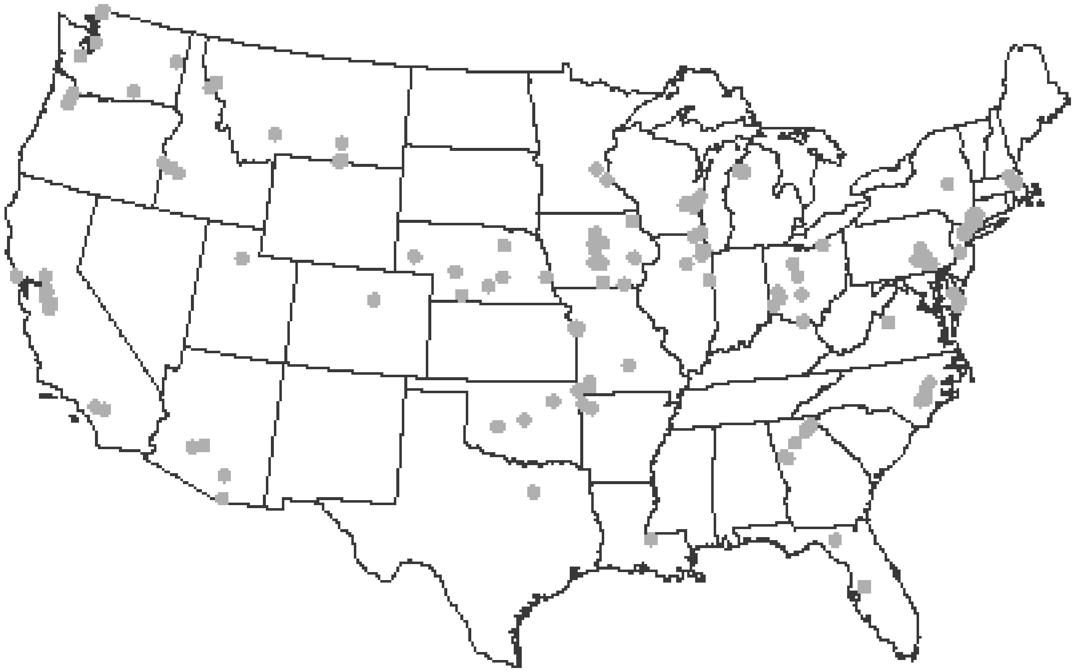
Although each of the 95 chemicals is used extensively, there is little information about the extent or occurrence of many of these compounds in the environment. Some may be indicators of certain classes of contamination sources, such as livestock or human waste, and some have human or environmental health implications. The results of this study are a starting point for investigation of the transport of a wide range of organic wastewater contaminants in the Nation's waters.

New laboratory methods were developed in several USGS research laboratories to provide the analytical capability to measure concentrations of 95 wastewater-related organic chemicals in water. Uniform sample-collection protocols and field and laboratory quality-assurance programs were followed to ensure that results are comparable and representative of actual stream conditions.

FINDINGS

One or more chemicals were detected in 80 percent of the streams sampled, and 82 of the 95 chemicals were detected at least once. Generally, these chemicals were found at very low concentrations (in most cases, less than 1 part per billion). Mixtures of the chemicals were common; 75 percent of the streams had more than one, 50 percent had 7 or more, and 34 percent had 10 or more.

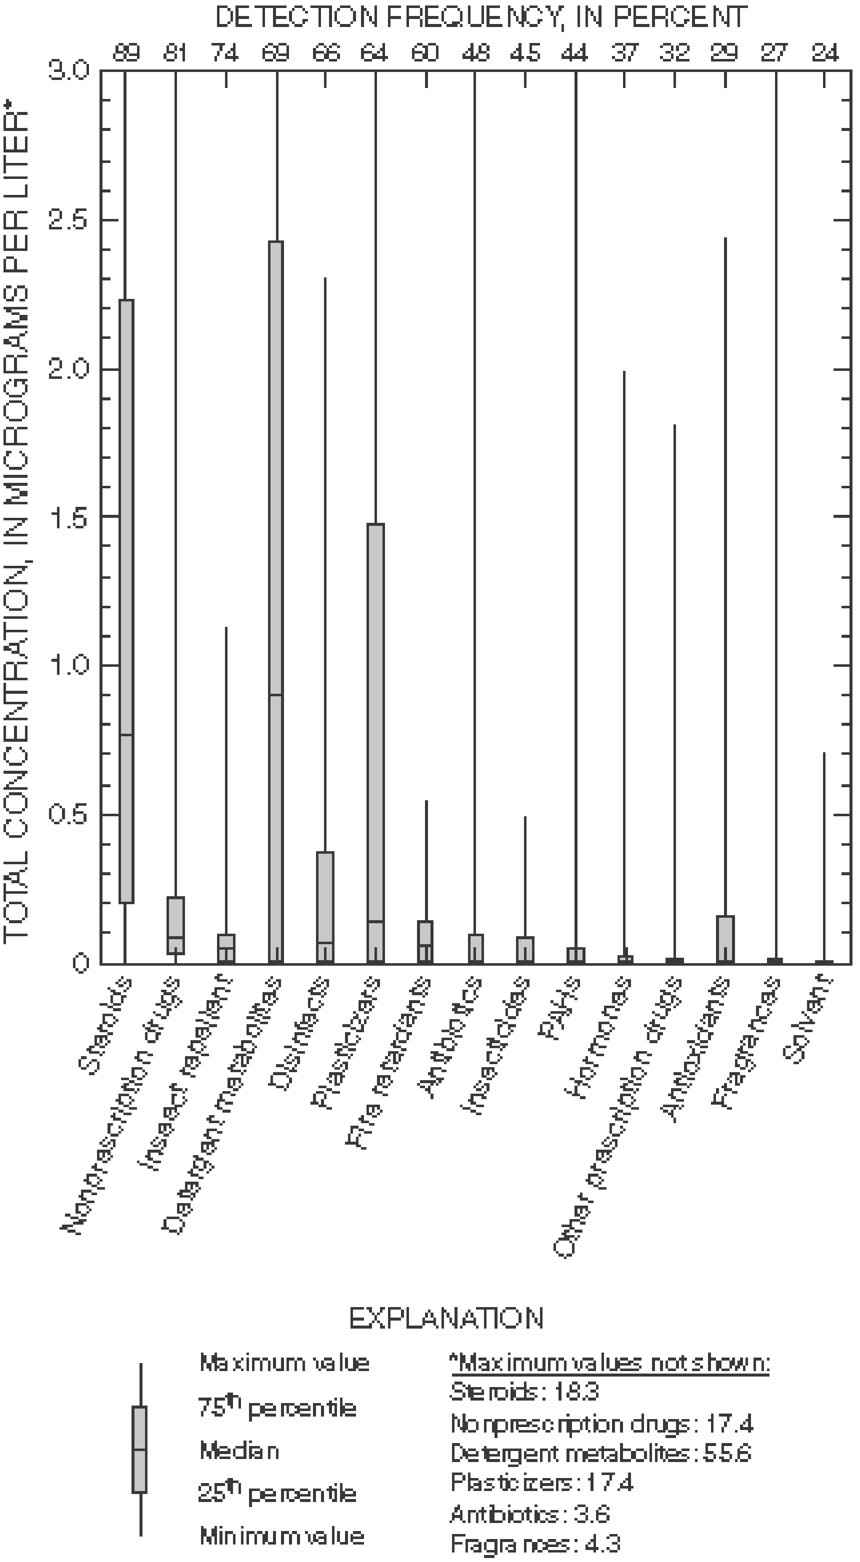
The most frequently detected chemicals (found in more than half of the streams) were coprostanol (fecal steroid), cholesterol (plant and animal steroid), N-N-diethyltoluamide (insect repellent), caffeine (stimulant), triclosan (antimicrobial disinfectant), tri (2-chloroethyl) phosphate (fire retardant), and 4-nonylphenol (nonionic detergent metabolite). Steroids, nonprescription drugs, and insect repellent were the chemical groups most frequently detected. Detergent metabolites, steroids, and plasticizers generally were measured at the highest concentrations.



Pharmaceuticals, hormones, and other organic wastewater contaminants were measured in 139 streams during 1999 and 2000.

HUMAN AND ENVIRONMENTAL EFFECTS

Knowledge of the potential human and environmental health effects of these 95 chemicals is highly varied; drinking-water standards or other human or ecological health criteria have been established for 14. Measured concentrations rarely exceeded any of the standards or criteria. Thirty-three are known or suspected to be



Steroids, nonprescription drugs, and an insect repellent were the three chemical groups most commonly detected in susceptible streams. Detergent metabolites, steroids, and plasticizers generally were found at the highest concentrations.

hormonally active; 46 are pharmaceutically active. Little is known about the potential health effects to humans or aquatic organisms exposed to the low levels of most of these chemicals or the mixtures commonly found in this study.

SIGNIFICANCE OF FINDINGS

This study suggests that mixtures of pharmaceuticals, hormones, and other wastewater contaminants can occur at low concentrations in streams that are susceptible to various wastewater sources. It provides methodology and guidance for future monitoring and assessment of these types of environmental contaminants, and establishes the needed foundation for setting priorities for further study of sources, pathways and effects.

Household chemicals can enter streams through wastewater discharges. A wastewater treatment facility near Atlanta, Georgia, is shown above. (Photograph by Daniel J. Hippe, U.S. Geological Survey).

Veterinary pharmaceuticals used in animal agriculture can enter streams through runoff or infiltration. A swine facility near the South Fork Iowa River, Iowa, is shown above. (Photograph by Doug Schnoebelen, U.S. Geological Survey).

FUTURE DIRECTIONS

Further analyses of these data, including relationships to specific source types, are ongoing. The Toxic Substances Hydrology Program is conducting research on the occurrence of organic wastewater chemicals in susceptible wells and drinking-water sources across the nation; assessments of antibiotics and antibiotic-resistant bacteria; the identification of wastewater indicators; and the development of new laboratory analytical capabilities, including sediment and fish tissue.

ADDITIONAL INFORMATION

These findings are based on “Pharmaceuticals, hormones, and other organic wastewater contaminants in U.S. streams, 1999–2000: A national reconnaissance,” an article published in the March 15, 2002 issue of Environmental Science & Technology, v. 36, no. 6, pages 1202–1211. Data are presented in a companion USGS report, “Water-quality data for pharmaceuticals, hormones, and other organic wastewater contaminants in U.S. streams, 1999–2000” (USGS Open-File Report 02-94). These and other reports, data, and maps can be accessed on the Internet at http://toxics.usgs.gov.

THE ENVIRONMENTAL IMPACT OF IRON IN GROUNDWATER

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Iron is a common constituent in soils and groundwater. It readily participates in subsurface redox reactions and under some conditions can cause taste, odor, and flow problems with drinking water wells and can precipitate and plug up *in situ* groundwater remediation systems. In other geochemical conditions, iron can aid in the remediation of certain chemicals undergoing chemical transformations associated with Redox reactions. Ferrous iron is used as a terminal electron acceptor for anaerobic bioremediation processes that play a dominant role in the natural attenuation process.

BACKGROUND

The average crustal abundance of iron is 5% by weight. The iron content of soils is typically in the range of 0.5% to 5% and is dependent on the source rocks from which the soil was derived, transport mechanisms, and overall geochemical history. Not only is iron common, but it is also reactive and readily reflects changes in surrounding Eh/pH conditions. This is particularly true in soil and groundwater systems that have been environmentally impacted with hydrocarbons. In groundwater systems, iron occurs in one of two oxidation states: reduced soluble divalent ferrous iron (Fe^{+2}) or oxidized insoluble trivalent ferric iron (Fe^{+3}). The modern atmosphere has 21% oxygen, which causes most iron in shallow subsurface soils to be in the oxidized ferric state. Ferric hydroxide ($Fe(OH)_3$) is the direct result of ferrous iron oxidation and precipitation. With time, ferric hydroxide is mineralized. The principal forms of mineralized ferric iron found in soils are follows:

- Amorphous hydrous ferric oxide ($Fe_2O_3 \cdot XH_2O$)
- Maghemite (gamma-Fe_2O_3)
- Lepidocrocite (gamma-FeOOH)
- Hematite (alpha-Fe_2O_3)
- Goethite (alpha-FeOOH)

The above iron oxides are listed in order of decreasing solubility, which also reflects increasing crystallinity. Amorphous hydrous ferric oxide at neutral pH and oxidizing Eh conditions has a solubility of 0.6 μg/L, which is three orders of magnitude greater than that of goethite. However, a high concentration of iron in groundwater is not rare. Obviously, other processes are at work.

IRON COMPLEXING

Ferrous iron is soluble as a cation, and ferric iron is not. However, ferric iron can form soluble complexes with many inorganic and organic ligands, including compounds that are the byproducts of the biodegradation of aromatic petroleum hydrocarbons (catechols, which are organic acids resulting from aromatic ring cleavage). The yellow/orange coloration of groundwater at some sites contaminated with petroleum hydrocarbons is caused by these ferric-catechol complexes.

It is important to remember that complexed ions typically react more slowly than do uncomplexed ions, which impacts the behavior of ferrous iron. Ferrous iron normally can be oxidized to ferric iron in minutes (see below for more details). Complexed ferrous iron may take months to complete the same reaction, which has profound implications for the fouling of groundwater injection systems. Humic acid, fulvic acid, and tannic acid are examples of noncontaminant organic complexes. Phosphate also serves as an effective complexing agent for iron.

IRON OXIDATION

The time required for uncomplexed ferrous iron to undergo oxidation to the ferric state is dependent on many factors, the dominant ones being: pH, temperature, dissolved oxygen level, and the presence of other soluble ions. The lower the pH and temperature, the longer the time required for completion of the oxidation reaction. Increasing dissolved oxygen decreases the time required for oxidation. For example:

At pH 7.0, 90% Fe^{+2} oxidation requires 1 hour at 21 °C and 10 hours at 5 °C.

At pH 8.0, 90% Fe^{+2} oxidation occurs in 30 seconds; at pH 6.0, it requires 100 hours.

The critical dissolved oxygen concentration is 2 mg/L. Below that ferrous iron oxidation occurs slowly.

The above reactions are often responsible for the iron fouling of air strippers treating iron-rich groundwater. These reactions can also foul screens in poorly designed recovery wells pumping that groundwater.

MICROBIOLOGY AND IRON

Iron readily undergoes reduction or oxidation, depending on surrounding conditions. As a consequence, many microbiological metabolic pathways use redox couples between ferrous and ferric iron. Organic material can be biodegraded with ferric iron as the terminal electron acceptor, which results in the production of reduced soluble ferrous iron. Anaerobic conditions are required as is the presence of ferric iron in a suitable form. As the crystallinity of the ferric iron mineral increases (as discussed above), the microbiological availability decreases. Or contrarily, iron fixing bacteria can oxidize ferrous iron to ferric iron, even under oxygen poor conditions, by many methods, including the extraction of carbon dioxide (for microbial energy systems) from ferrous bicarbonate leaving insoluble ferric hydroxide and the utilization of iron bearing organic acid complexes as a carbon source, leaving precipitated ferric hydroxide. Bacteria also reduce nitrate and oxidize ferrous iron to ferric iron. It is now thought that the Precambrian banded iron formations were the consequence of the mass utilization of ferrous iron in the ancient oceans shortly before oxygenation because photosynthesis took place. These are the reactions that are typically responsible for iron fouling of well screens, piping systems, and air strippers that remediate iron-rich groundwater.

IRON OXIDES AND *IN SITU* METAL/ORGANIC ADSORPTION

Amorphous hydrous ferric oxide can be described as an amphoteric ion exchange media, which means that as pH conditions change, it has the capacity to offer hydrogen ions (H^+) or hydroxyl ions (OH^-) for cation or anion exchange, respectively. As a rough rule of thumb, amorphous ferric oxide is capable of adsorbing 0.5 millimoles of ionic material per gram. Ionic material includes oxyanions of chrome, arsenic, or selenium; heavy metal cations; or ionized organic compounds. The dominant mechanism of interaction between iron oxides and soluble organic compounds is through carboxyl and hydroxyl functional groups on the organic, which is particularly true for the organic acids that are the intermediate product of the biodegradation of petroleum hydrocarbons.

Sorption behavior is primarily related to pH (within the typical range of 5.0 to 8.0), and each ion has its optimum pH range for adsorption. Given the average concentration in soil, the iron in a cubic yard of soil is capable of adsorbing from 0.5 to 5 pounds of soluble metals as cations, anionic complexes, or a similar amount of organic biodegradation products.

SUMMARY

The reactions described above are complex. At any given location, it is difficult to determine the specific processes taking place. However, the overall effect is as follows: Impacting hydrocarbons provide a carbon source to stimulate aerobic microbial degradation, which consumes the readily available oxygen driving the system anoxic. In the anoxic state, soluble ferrous ions are generated by the action of iron reducing bactgeria and soluble ferrous and ferric complexes are formed. High levels of soluble iron is an indicative side effect of hydrocarbon contamination in groundwater.

The mobilized iron is then drawn into any installed groundwater recovery and treatment systems. There, oxygenation takes place changing redox conditions, and the elevated levels of soluble iron react and which causes fouling in the recovery and treatment systems. Adsorption and attenuation of contaminant transport is concurrently taking place on the residual solid iron oxide phases remaining in the soil matrix, which can extend the duration of a pump and treat effort. Or it can be exploited in a passive “funnel and gate” groundwater barrier remediation system.

The presence and form of naturally occurring iron in groundwater are indicators of complex reactions in the subsurface. Iron in high concentrations does affect drinking water quality. It can also be an important element in aiding or lowering the efficiency of *in situ* remediation of contaminants, depending on specific geochemical conditions. It is also a key element in the natual attenuation process. Therefore, iron data are valuable information that may greatly affect everything from groundwater quality to remedial operations.

GROUNDWATER AND COBALT: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs

Mill Valley, California

HISTORY OF COBALT

Cobalt has been used as a pigment since 3000 B.C. The name “Kobald” may have come from the Erzgebirge region of Saxony, a silver mining region. Kobalds are mythical creatures like gnomes who frequented the mines causing trouble. The problems were due to interference of cobalt with silver smelting and causing respiratory illnesses in the miners. Before 1914 only oxides of cobalt were used; since then the metal has been used in a variety of ways, particularly as alloys and in the electronic component industry.

MINERAL COMMODITY

Cobalt, identified by Co in the periodic table, has an atomic weight of 58.9322. There are seven radioisotopes of cobalt. It is a solid at room temperature and has been classified as a transition metal. It is magnetic, hard, and brittle and has a metallic gray color. Cobalt will also exist as cobalt(II) and cobalt(III) and will form a number of organic and inorganic salts. Cobalt is not found as a discrete metal but as a solid solution with other elements in minerals. The similarity in ionic radii allows cobalt to substitute for iron, manganese, copper, and chromium. Cobalt metal is produced as a by-product of copper, nickel, and lead production, as it is not economically feasible to isolate cobalt on its own.

Worldwide, the background concentration range of cobalt in soil is 1–40 mg/kg and the average background concentration of cobalt in soil is 8 mg/kg (1). Many mineral species contain cobalt as an integral structural component. Cobalt salts are important for biological processes such as production of vitamin B_{12} and providing the blue-green color in broccoli and other vegetation. On average, humans contain 20 parts per billion (ppb) by mass of cobalt. Cobalt is also an important commercial, industrial, and military metal. Its uses are as follows:

- Cobalt salts are used for the production of brilliant and permanent blue colors in porcelain, glass, pottery, tiles, and enamels.
- For magnet, stainless, and high speed steel production.
- For electroplating, cemented carbides, and diamond tools.
- In the petroleum and chemical industry as catalysts.
- Cobalt compounds are used as paint pigments.
- Cobalt is combined with iron, nickel, and other metals to make corrosion- and wear-resistant alloys.
- Cobalt-60 is an artificial radioactive isotope used as a tracer and radiotherapy agent for cancer treatment and as a food preservation method, also called the food irradiation process.
- Cobalt is used in batteries, car tires, recording media, semiconductor ceramics, and most importantly in superalloys in jet turbines and gas turbine generators.

SOURCES OF COBALT

Mining of cobalt occurs primarily in twelve countries, most notably Canada, Russia, Democratic Republic of Congo, Zambia, and Australia, which also refine the cobalt ore.

The main countries that only refine cobalt include Finland, Norway, and Brazil.

PHYSICAL PROPERTIES

Cobalt is a shiny, gray, brittle metal with a close packed hexagonal (CPH) crystal structure at room temperature but which changes at 421 °C to a face centered cubic form. The metal is rarely used as a structural material in the pure form but almost always as an alloy or a component of another system. The density is 8.85 g/cm^3, the melting point is 1493 °C (2719 °F), the Curie point is 1121 °C, and the atomic number for cobalt is 27. Cobalt comes in two valence states: +2 and +3. For more information on physical and chemical properties, see Reference 2.

CHEMICAL REACTIONS

Cobalt is not particularly reactive with air. However, on heating the oxide Co_3O_4 is formed. If the reaction is carried out above 900 °C, the result is cobalt(II) oxide, CoO. Cobalt does not react directly with nitrogen (N_2).

$$3Co(s) + 4O_2(g) \rightarrow 2Co_3O_4(s),$$

$$2Co(s) + O_2(g) \rightarrow 2CoO(s).$$

Water has little effect on cobalt metal. The reaction between red hot cobalt metal and steam produces cobalt(II) oxide, CoO. Simple inorganic salts of cobalt are generally very soluble in water.

$$2Co(s) + O_2(g) \rightarrow 2CoO(s).$$

Cobalt metal reacts directly with halogens, producing cobalt(II) salts.

$$Co(s) + Br_2(l) \rightarrow CoBr_2(s) \quad [\text{green}],$$

$$Co(s) + Cl_2(g) \rightarrow CoCl_2(s) \quad [\text{blue}],$$

$$Co(s) + I_2(s) \rightarrow CoI_2(s) \quad [\text{blue-black}].$$

Cobalt metal dissolves slowly in dilute sulfuric acid to form solutions containing the aqueous Co(II) ion together with hydrogen gas, H_2. In practice, Co(II) is present as the complex ion $[Co(OH_2)_6]^{2+}$ (see Reference 3).

$$Co(s) + H_2SO_4(aq) \rightarrow Co^{2+}(aq) + SO_4^{2-}(aq) + H_2(g),$$

COBALT ISOLATION

Numerous ores contain cobalt, but not many of these are of economic importance. These include the sulfides and arsenides linnaeite (Co_3S_4), cobaltite, (CoAsS), and smaltite, ($CoAs_2$). Normally the cobalt ore is "roasted" to form a mixture of metals and metal oxides. Treatment with sulfuric acid leaves metallic copper as a residue and dissolves out iron, cobalt, and nickel as the sulfates. Iron is obtained by precipitation with lime (CaO) while cobalt is produced as the hydroxide by precipitation with sodium hypochlorite (NaOCl):

$$2Co^{2+}(aq) + NaOCl(aq) + 4OH^{-}(aq) + H_2O \rightarrow 2Co(OH)_3(s) + NaCl(aq).$$

The trihydroxide $Co(OH)_3$ is heated to form the cobalt oxide and then reduced with carbon (as charcoal) to form cobalt metal (3).

$$2Co(OH)_3(\text{heat}) \rightarrow Co_2O_3 + 3H_2O,$$

$$2Co_2O_3 + 3C \rightarrow Co + 3CO_2.$$

FATE AND TRANSPORT

The geochemical behavior of cobalt generally follows the iron–manganese system. The cobalt concentration in soils is controlled by adsorption and coprecipitation reactions with manganese and iron oxide minerals. Cobalt-60 (^{60}Co) is an activation product of stable cobalt (^{59}Co). It is the isotope of primary importance to waste disposal and site remediation. ^{60}Co has a half-life of about 5.3 yr, relatively short compared to other radionuclides of environmental concern. It readily adsorbs to minerals and as such its mobility should be limited to soil and water systems near to the area in which it was released (2).

Co(II) is the stable valence state in water under most geochemical conditions. Co(III) is a strong oxidizing agent; hence it is not thermodynamically stable and will decompose under the conditions typical of natural water. Cobalt(III) will form strong complexes with organic ligands such as ethylenediamine-tetraacetic acid (EDTA) and NH_3 and exist in aqueous solution. These complexes affect cobalt's environmental mobility by increasing its solubility in aqueous solutions, decreasing its adsorption in soil, and stabilizing Co(III) in some sediment systems. Co(III) can be mobilized and reduced to Co(II) as a result of bacterial iron reduction. The solubility of Co(III) is a function of the composition of the media and buffers (see Fig. 1).

The migration and sorption of cobalt depends strongly on the pH of the medium. In acidic media, cobalt occurs in solution; an increase in pH will cause it to sorb to soil, sediments, and other precipitates such as manganese and iron oxides and clay minerals. Adsorption is minimal below a pH of 4. In the absence of organic complexants cobalt will adsorb (moderate to high) to minerals at near neutral and basic pH values. Humic acid will increase the adsorption of cobalt on all mineral sorbents by 10–60%. The highest cobalt adsorption due to humic acid will occur between pH 4.5 and 6.5. K_d for dissolved Co(II) ranges from 10^3 to 10^5 mL/g. Inorganic ligands such as cyanide in low concentrations can decrease cobalt adsorption on sediment significantly ($K_d < 2$ mL/g). The presence of other cations (K^+, Ca^{2+}, Mg^{2+}, Na^+) in solution can decrease cobalt adsorption.

Adsorption on manganese minerals results in the surface-mediated oxidation of Co(II) to Co(III) by the reduction of surface Mn(IV) sites. This will occur at pH values of 4, 6, and 7. At pH 8 and 10, Co(II) adsorption resulted in the precipitation of something similar to cobalt

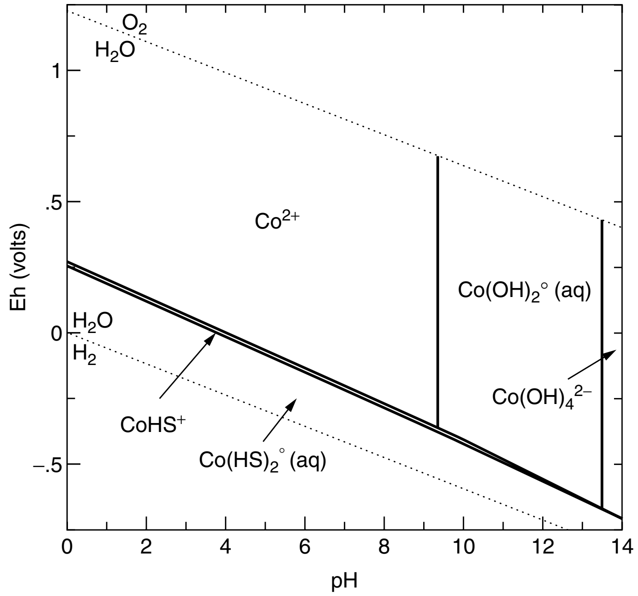

Figure 1. Eh−pH diagram showing the dominant aqueous complexes of cobalt (2). (Diagram was calculated at 25 °C and a concentration of 10−14.8 mol/L total dissolved cobalt in the presence of dissolved chloride, nitrate, sulfate, and carbonate).

hydroxide; this could explain the large range of K_d values reported in the literature (2).

HEALTH AND SAFETY

Exposure to very high levels of cobalt can cause serious health problems to the respiratory system and skin of humans and animals. Most typically, persons breathing air with high cobalt levels are at risk for lung problems, wheezing, asthma, and pneumonia. Cobalt has been found to be a sensitizer and as such dermatitis can occur on contact. Three cobalt compounds are classified as a human carcinogen on the PHS Category 1 Chemical Table maintained by the Los Alamos National Laboratory (2000). The three carcinogenic compounds include cobalt(II) arsenate, cobalt−chromium alloy (as Cr^{6+}), and beryllium−copper−cobalt alloy.

Research has shown that a high cobalt level is harmful to fetus development in pregnant animals. It is known to cause cancer in animals when placed under the skin or in the muscle. The lowest published lethal dose by oral application in rats is 1500 mg/kg, 250 mg/kg for intraperitoneal doses, and 25 mg/kg for intratracheal doses. Inhalation is the most hazardous exposure pathway of cobalt. When working with cobalt, goggles and gloves are recommended for personal protection. If cobalt powder is present, the area should be well ventilated and inert, as the powder can ignite spontaneously.

Several countries have determined different toxicity levels for cobalt.

In Ontario, the cobalt toxicity limit in soil is 40 parts per million (ppm) (4). In Sweden the limit is 30 ppm (5) and in Quebec the agricultural soil standard is 15 ppm.

PERSISTENCE IN GROUNDWATER

Cobalt will exist in groundwater as Co(II) or Co(III) depending on the pH. Under most geochemical conditions, Co(II) is the stable valence state in water. Co(III) is not thermodynamically stable and decomposes under Eh−pH conditions common for most natural waters. However, the presence of certain complexing ligands can stabilize Co(III) relative to reduction and allow it to persist in aqueous solutions. Cobalt will be retarded in groundwater due to its large K_d values (2).

COBALT CONTAMINATION

Cobalt is naturally occurring in the environment and is found in a variety of places, including plants, soil, dust, and seawater. Anthropogenic releases are by way of burning coal and oil and fuel exhaust from cars, trucks, airplanes, and many industrial processes that use any of the numerous cobalt compounds. Most sites with cobalt contamination have occurred due to mining operations. Cobalt contamination is generally greatest in the soil around mine sites due to the leaching acids in the tailings. Cobalt contamination is usually coupled with high arsenic and nickel contaminations and is rarely the contaminant of major concern due to its low toxicity. Cobalt-60 contamination does occur when storage tanks leak or disposal practices are inadequate. Contamination by ^{60}Co is generally of less concern than other radionuclides based on its short half-life. ^{60}Co is highly sorbed on sandy soils and relatively immobile. When ^{60}Co is complexed with EDTA, the cobalt mobility increases.

COBALT REMEDIATION TECHNIQUES

Remediation of cobalt-contaminated sites can be carried out via removal of the soil and groundwater. Cobalt is most hazardous to the human respiratory system. Cobalt fumes can be generated when cutting or torching cobalt-containing metals. Cobalt mists occur when groundwater or process water containing dissolved cobalt is sprayed through a nozzle, such as a process washing system or a bathroom shower.

To reduce the mobility of cobalt dust from contaminated soil, the stockpiles are usually covered with clean soil, plastic sheeting, sod, or pavement. Because cobalt is mobile in an acidic medium, the upper layers of contaminated soil can be tilled with lime to reduce the pH and prevent toxicity to plants. The soil can also be covered with a thick layer of crushed limestone. The limestone layer will raise the pH in the vadose zone and prevent further leaching of the soluble cobalt.

Phytoaccumulation is one of the biological techniques used to remediate soils close to the surface contaminated by cobalt. Phytoaccumulation is done using nonfood crops to absorb metals from the soil into the stems and leaves. There are several plants that are hyperaccumulators; they can absorb large amounts of metals in their root structures (comparative to other plants and the concentration of metal in the ground). The cobalt is transported to the leaf and stalk biomass. Ultimately, the plant containing the cobalt is harvested for disposal or reclamation of the cobalt. There are 26 known plants that are hyperaccumulators of cobalt. There are also high accumulator plants that will take metal out of the soil in larger quantities than normal plants. Cobalt will exist as an oxalate compound in leaves, and as such it is readily extracted using accumulator plants. Accumulator plants are metal specific and will contain about 100 times more of a toxic element than normal plants. Phytoaccumulation can be enhanced using EDTA, citric, or oxalic acids on the soil (1).

For conventional remediation of cobalt in the groundwater, pump and treat or natural attenuation is used. At low pH, the cobalt is mobile. The contaminated water can be removed and treated with a strong base to reduce its solubility. Treatment with sodium hypochlorite (NaOCl) will cause precipitation of cobalt trihydroxide. The movement of cobalt-containing acidic plume within an aquifer matrix causes the pH to rise due to the presence of carbonate materials, which allows cobalt to be sorbed to the soil. High dissolved oxygen content will cause manganese oxides in the soil to precipitate and increase cobalt sorption, thus reducing the amount of soluble cobalt in the aquifer. Where monitored natural attenuation is the chosen remediation method, the down-gradient surface water body will be the location at which remediation is complete as the adsorbed cobalt will be remobilized with the migration of the plume. Only when the plume has traveled to a source with adequate dissolved oxygen will the iron and manganese oxides precipitate with sorbed cobalt.

Cobalt-contaminated groundwater can be treated *in situ* with a combination of methods that will allow the pH to be raised sufficiently to immobilize the cobalt and by providing enough dissolved oxygen to allow manganese oxides to precipitate and enhance cobalt sorption. Geochemical fixation using calcium polysulfide (pH 11.3–11.5) would significantly raise the pH in an aquifer. Extraction wells can be placed down-gradient to remove the acidic plume or in the middle.

GROUNDWATER AND CADMIUM: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Craig Foreman
Environmental Bio-Systems, Inc.
Mill Valley, California

Cadmium occurs naturally in ores containing other elements such as oxygen (cadmium oxide), sulfur (cadmium sulfate, cadmium sulfide), and chlorine (cadmium chloride) or compounds (cadmium carbonate). Cadmium is usually extracted during the production of other metals such as zinc, lead, and copper. A primary use for cadmium is in rechargeable nickel–cadmium and solar batteries, which are sold worldwide. Cadmium does not corrode easily and is also used in metal plating and coating operations including transportation equipment and various industrial machinery as well as plastics manufacturing. It is used in numerous pigments, in baking enamels, and in photographic processes as well as in television and monitor screen phosphors. Cadmium is released into the environment through industrial waste streams and landfills. Cadmium is relatively mobile in surface and groundwater and has a United States Environmental Protection Agency (U.S. EPA) Maximum Contaminant Level Goal (MCLG) of 5 parts per billion (ppb) in drinking water (1). The World Health Organization has set the provisional tolerable daily intake of cadmium at 60–70 μg/day (2).

PHYSICAL AND CHEMICAL CHARACTERISTICS

In ancient times cadmium was known as “calamine” and was often confused with zinc carbonate. In 1817, cadmium was discovered by the German chemist Friedrich Strohmeyer from an impurity in zinc carbonate ($ZnCO_3$), also called calamine. The impurity glowed with a yellow color and was identified as a new element, cadmium. Cadmium most often occurs in small quantities associated with zinc ores, such as sphalerite (ZnS). Greenockite (CdS) is the only mineral of any consequence bearing cadmium. Cadmium is a poisonous metal. The oxidation state of cadmium is +2.

The most common forms of cadmium are Cd^{2+}, cadmium–cyanide complexes, or cadmium hydroxide solid sludge (3). Cadmium hydroxide [$Cd(OH)_2$] and cadmium carbonate ($CdCo_3$) solids are most common at high pH, whereas the cadmium ion (Cd^{2+}) and aqueous cadmium sulfate species are the dominant forms at lower pH (<8). Under reducing conditions when sulfur is present, the stable solid cadmium sulfate [CdS(s)] is formed. Cadmium will also precipitate in the presence of phosphate, arsenate, chromate, and other anions, although solubility will vary with pH and other geochemical factors (4).

Naturally occurring cadmium is composed of 6 stable isotopes; 27 radioisotopes have been characterized with the most stable being Cd-113 with a half-life of 7.7 quadrillion years, Cd-109 with a half-life of 462.6 d, and Cd-115 with a half-life of 53.46 h. All of the remaining radioactive isotopes have half-lives that are less than 2.5 h and the majority of these have half-lives that are less than 5 min. This element also has 8 metastates with the most stable being Cdm-113 ($t_{1/2}$ 14.1 y), Cdm-115 ($t_{1/2}$ 44.6 d), and Cdm-117 ($t_{1/2}$ 3.36 h). The isotopes of cadmium range in atomic weight from 96.935 amu (Cd-97) to 129.934 amu (Cd-138).

Almost all cadmium is obtained as a by-product in the treatment of zinc, copper, and lead ores. It is a soft, bluish-white metal that is easily cut with a knife and is similar in many respects to zinc. It is a component of some of the lowest melting alloys and therefore is used in bearing alloys with low coefficients of friction and great resistance to fatigue. It is also used extensively in electroplating and in many types of solder, for standard EMF cells, for Ni–Cd rechargeable batteries, and as a barrier to control nuclear fission. Cadmium compounds are used in black and white television phosphorus and in blue and green phosphorus for color television and computer monitor tubes. It forms a number of salts, of which the sulfate is most common with the sulfide being used as a yellow pigment.

SOURCES OF CADMIUM

Environmental Exposure

Numerous human activities result in the release of significant quantities of cadmium to the environment. The relative importance of individual sources varies considerably from country to country. The major sources of anthropogenic cadmium release can be divided into three categories. The first is made up of those activities involved in the mining, production, and consumption of cadmium and other nonferrous metals. The second category consists of inadvertent sources where the metal is a natural constituent of the material being processed or consumed. Sources associated with the disposal of materials that had earlier received cadmium discharges or discarded cadmium products make up the third category. As a minor impurity in a variety of phosphate fertilizers, cadmium is introduced into the environment through direct application onto agricultural lands. The amount of cadmium impurities that are contained within phosphate fertilizers varies with the mining district.

Atmospheric Cadmium

The average global total emission of the metal from human sources in 1983 was 7570 tons (5) and represented about half the total quantity of cadmium produced in that year. In comparison, the worldwide emission of lead from human activities was about 10% of the total lead produced in 1983 (5). In both the European Economic Community (EEC) and on a worldwide scale (6), about 10–15% of total airborne cadmium emissions arise from natural processes, the major source being volcanic action. Nonferrous metal production, which accounts for about 75% of the total anthropogenic cadmium emissions worldwide, accounts for only 25% in the EEC. This is primarily a result of the extensive emission controls due to legislation and regulation in developed countries.

In addition, of the two basic methods of zinc production—thermal smelting and electrolyte refining—only the former releases significant atmospheric cadmium emissions. In recent years, electrolytic refining has assumed the major share of the world's production of zinc and cadmium and has largely replaced thermal processes in Europe. The once important vertical and horizontal retort smelters, which emit large quantities of atmospheric cadmium, have been phased out in most developed countries but are still in operation in several developing countries (7).

Other industries that employ thermal processes, for example, iron production, fossil fuel combustion, and cement manufacture, all release airborne cadmium, the metal being a natural component of the raw materials. The cadmium content of these materials is generally relatively low but due to the significant consumption of the raw material, significant cadmium is released into the environment. In addition, the elevated temperatures employed result in the volatilization of cadmium and release into the atmosphere. Municipal refuse is a common cadmium waste-related source, the cadmium being derived from discarded nickel–cadmium batteries and plastics that contain cadmium pigments and stabilizers. The incineration of refuse is also a major source of atmospheric cadmium release worldwide.

Sewage sludge receives cadmium from industrial sources, particularly from the discharges of plating operations and pigment works. One disposal option, the incineration of sewage sludge, is a relatively minor source of airborne cadmium, reflecting the small quantities of sludge disposed of in this manner.

Steel production can also be considered as a waste-related source, as large quantities of cadmium-plated steel scrap are recycled by this industry, at least in developed countries. As a result, steel production is responsible for considerable emissions of atmospheric cadmium.

Aquatic Cadmium

Nonferrous metal mines represent a major source of cadmium release to the aquatic environment. Contamination can arise from mine drainage water, wastewater from the processing of ores, overflow from the tailings pond, and rainwater runoff from the general mine area. The release of these effluents to local water sources can lead to extensive contamination of aquatic environments. The cadmium content of the ore body and climatic and geographical conditions, as well as mine management policies, all influence the quantities of cadmium released from individual sites. Aquatic inputs of cadmium are not restricted to active mine sites, and abandoned mining operations are also sources of continuing contamination of aquatic environments.

Cadmium is a natural constituent of rock phosphates and deposits from some regions of the world contain markedly elevated levels of the metal. The manufacture of phosphate fertilizer results in a redistribution of the cadmium in the rock phosphate between the phosphoric acid product and the gypsum waste. In many cases, the gypsum is disposed of by dumping in coastal waters, which leads to considerable cadmium inputs. Some countries, however, recover the gypsum for use as a construction material and thus have negligible cadmium discharges.

Acidification of soils and lakes may result in enhanced mobilization of cadmium from soils and sediments and lead to increased levels in surface and groundwaters (2). The corrosion of soldered joints or zinc-galvanized plumbing by acidic waters can dissolve cadmium and produce increased levels of the metal in drinking water.

Terrestrial Cadmium

Solid wastes from a variety of human activities are disposed of in landfill sites, resulting in large cadmium inputs at the national and regional levels when expressed as a total tonnage (8,9). Of greater potential environmental significance are the solid wastes from both nonferrous metal production and from the manufacture of cadmium-containing articles, as well as the ash residues from refuse incineration. All three waste materials are characterized by elevated cadmium levels and as such require disposal to controlled sites to prevent the mobilization of the cadmium in groundwater.

Cadmium soil contamination is a characteristic feature around nonferrous metal mines and smelters, particularly in the case of those handling zinc ores. Contamination from mining is generally local but may be widespread in areas of high mineral content. Shipham, England, in the United Kingdom, is a site of extreme soil cadmium contamination. Between 1650 and 1850 the village of Shipham was the site of a major zinc mine. Once the mining stopped, the area was flattened and developed for agriculture and housing. Cadmium levels in agricultural and garden soils are some of the highest ever reported worldwide (10).

The application of municipal sewage sludge to agricultural soil as a fertilizer can also be a significant source of cadmium. Large increases in soil cadmium concentration have resulted in the past from the application of contaminated sludge in both North America and Europe. Even today, the high application rates used for sewage sludge result in relatively large cadmium inputs, a value of 80 g/ha having been estimated for the United Kingdom (9). On a national or regional basis, however, these inputs are much smaller than those from either phosphate fertilizers or atmospheric deposition.

TERRESTRIAL IMPACTS

Large cadmium concentrations in terrestrial environments are commonly a result of solid wastes disposed of in landfill sites, ashes from fossil fuel combustion, waste from cement manufacture, and the disposal of municipal refuse and sewage sludge. The solid wastes from both nonferrous metal production and the manufacture of cadmium-containing articles, as well as the ash residues from refuse incineration, are the main contributors to cadmium contamination in terrestrial environments. These three waste materials are characterized by elevated cadmium levels and as such require disposal to controlled sites to prevent the contamination of the groundwater.

The agricultural application of phosphate fertilizers represents a direct input of cadmium to arable soils. The cadmium content of phosphate fertilizers varies widely and depends on the origin of the rock phosphate that is the main component in fertilizers, particularly in third world countries. The application of municipal sewage sludge to agricultural soils as a fertilizer can also be a significant source of cadmium.

Impact on Water Bodies

Rivers contaminated with cadmium can contaminate surrounding land, either through irrigation for agricultural purposes, by the dumping of dredged sediments, or through flooding. Cadmium compounds are able to leach through soils to groundwater. When cadmium compounds do bind to the sediments of rivers, they can be more easily bioaccumulated or redissolved when sediments are disturbed, such as during flooding. Its tendency to accumulate in aquatic life is great in some species. Much of the cadmium entering fresh waters from industrial sources is rapidly adsorbed by particulate matter, where it may settle out or remain suspended, depending on local conditions. This can result in low concentrations of dissolved cadmium even in rivers that receive and transport large quantities of the metal.

Health Risks

Cadmium and solutions of its compounds are toxic. In comparing the various standards available, exposure to cadmium dust is most common in workplaces, such as battery manufacturing plants, industrial facilities and metal fabricators having metal soldering and welding fumes, and coal plants. The cadmium dust levels should not exceed 0.01 mg/m^3 (8-h time-weighted average, 40-h week). The ceiling concentration (maximum), for a period of 15 min, should not exceed 0.14 mg/m^3. Cadmium oxide fume exposure (8-h day, 40-h week) should not exceed 0.05 mg/m^3, and the maximum concentration should not exceed 0.05 mg/m^3. Cadmium stays in the body for a very long time and concentrations in the body can build from years of low exposure (1).

Effects on Humans/Mammals. The United States Department of Health and Human Services (DHHS) has determined that cadmium and cadmium compounds may reasonably be anticipated to be carcinogens (1). Apart from the gastrointestinal tract and the lungs, the organ most susceptible to chronic cadmium exposure is the kidney. Cadmium is a cumulative poison; its ready solubility in weak acids is an important precondition for its absorption in the organism: 5% of cadmium is resorbed via the gastrointestinal tract and accumulated in liver and kidneys. In Asia, “Itai-Itai” disease is caused by high cadmium concentrations in rice.

Lung cancer is one potential result of chronic inhalation of fine-particle cadmium compounds, particularly cadmium oxide, which readily dissolves in the body. Ingestion of the compounds in food results from the fact that plants and fish absorb and retain cadmium, and hazardous levels can be reached when consuming food from areas where cadmium contamination has been generated at industrial sites or by the use of phosphate fertilizers. Adverse health

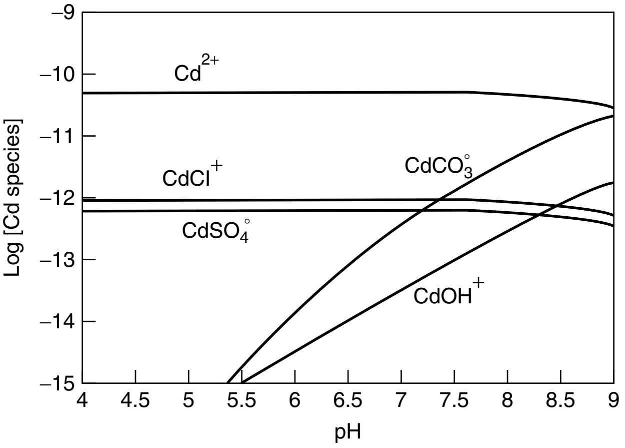

Figure 1. Inorganic cadmium speciation in soil water.

results from long-term, high level ingestion of cadmium include kidney damage and kidney stones, and debilitating effects on bones and the skeletal structure (1).

Effects on Plants. Cadmium reduces the photosynthesis and transpiration rate while increasing the respiratory rate. Small cadmium concentrations in the soil are sufficient to produce marked damage such as shortening of the shoot axis and intensive yellowing of older leaves. Absorption not only takes place via the roots but also through shoots and leaves. In addition to yield shortfalls, the main hazard results from the contamination of (accumulation in) crop plants since this is how cadmium as a cumulative poison enters the food chain.

GEOCHEMISTRY OF CADMIUM

In nature cadmium exists in the +2 oxidation state and forms a number of aqueous complexes, particularly with dissolved carbonate. The concentration of cadmium in the environment may be controlled by either adsorption or precipitation/coprecipitation processes. The concentration and extent to which cadmium is present in soils vary greatly with type of minerals, oxidation state of the system, and presence of competing cations in solution. Cadmium concentrations in uncontaminated soils are usually less than 1 mg/kg. However, higher concentrations may be present as a result of human activities or by the weathering of parent materials with high cadmium concentrations (i.e., cadmium-rich igneous rocks).

CADMIUM SPECIES AND CONDITIONS

Cadmium forms soluble complexes with inorganic and organic ligands resulting in an increase of cadmium mobility in soils. As the pH increases between 6 and 8.2, cadmium carbonate species [$CdHCO_3$ and $CdCO_3$ (aq)] assume greater significance. At pH values between 8.2 and 10, most of the cadmium in solution is expected to exist as the neutral complex $CdCO_3$(aq). The species $CdSO_4$(aq), $CdHCO_3$, $CdCl^{2+}$, and $CdOH^{+}$ are also present, but at much lower concentrations (Fig. 1).

CONDITIONS FOR THE DISSOLUTION AND PRECIPITATION OF CADMIUM

At pH values less than 7.5, most cadmium minerals are more soluble than cadmium concentrations found in oxic soils (10^{-7} M), indicating that cadmium at these concentrations is not likely to precipitate. At pH levels greater than 7.5, the solubilities of $Cd_3(PO_4)^2$ or $CdCO_3$ may control the concentrations of cadmium in soils. $CdCO_3$ precipitates in calcareous soils (pH $>$ 7.8), whereas in neutral or acidic soils, adsorption is the predominate process for removal of cadmium from solution. The activity of dissolved cadmium in cadmium-amended soils was lowest in calcareous soils. Cadmium may coprecipitate with calcium to form carbonate solid solutions, $(Ca,Cd)CO_3$. This may be an important mechanism in controlling cadmium concentrations in calcareous soils. Although cadmium itself is not sensitive to oxidation/reduction conditions, its concentration in the dissolved phase is generally very sensitive to redox state. The concentrations of dissolved cadmium greatly increase when reduced systems are oxidized, such as when dredged river sediments are land filled or rice paddies are drained.

The following mechanisms appear to be responsible for this increase in dissolved cadmium concentrations:

1. Very insoluble cadmium species in rocks or soils (e.g., greenockite) dissolve as sulfide [S(II)] that is oxidized to sulfate [S(VI)].
2. Organic materials binding cadmium are decomposed through oxidation, releasing cadmium into the environment. This mechanism appears to be important only in environments in which moderate to high organic matter concentrations are present. Dissolved cadmium concentrations greatly increased when the sediments were incubated under oxidizing conditions (Eh $>$ 350 mV).
3. Pyrites that may be present in soils or sediments get oxidized when exposed to air. The pyrite oxidizes to form $FeSO_4$, which generates high amounts of acidity when reacted with water. The decrease in the pH results in the dissolution of cadmium minerals and increase in the dissolved concentration of cadmium.

SORPTION AND DESORPTION OF CADMIUM IN SOILS

At high solution concentrations of cadmium ($>$10 mg/L), the adsorption of cadmium often correlates with the cation exchange capacity of the soil. During cation exchange, cadmium generally exchanges with adsorbed calcium and magnesium. At low solution concentrations of cadmium, surface complexation to calcite (11) and hydrous oxides of aluminum and iron (12) may be the most important adsorption mechanism. Both Cd^{2+} and possibly $CdOH^{+}$ may adsorb to aluminum and iron oxide minerals.

As with other cationic metals, cadmium adsorption exhibits pH dependency. The effect of pH on cadmium adsorption by soils, sediment, and iron oxides is influenced by the solution concentration of cadmium and the presence of competing cations or complexing ligands. In lower pH environments, these metals, based on their propensity to adsorb, would rank as follows: Pb > Cr > Zn > Cd. This order is inversely related to the pH at which hydrolysis of these metals occurs.

Competition between cations for adsorption sites strongly influences the adsorption behavior of cadmium. The presence of calcium, magnesium, and trace metal cations reduces cadmium adsorption by soils and manganese oxides and aluminum oxides. The extent of competition between cadmium and other ions depends on the relative energies of interaction between the ions and the adsorbing surface, the concentrations of the competing ions, and solution pH (12,13). The addition of copper or lead, which are more strongly adsorbed, slightly reduces cadmium adsorption by iron and aluminum oxides, suggesting that copper and lead are preferentially adsorbed by different surface sites (14). In contrast, zinc almost completely displaces cadmium.

FATE AND TRANSPORT

Cadmium can enter the environment in several ways. It can enter the air from the burning of coal and household waste and from metal mining and refining processes. It can enter water from disposal of wastewater from households or industries. Fertilizers often contain some cadmium, which results in cadmium entering the soil. Spills and leaks from hazardous waste sites can also result in excessive amounts of cadmium entering the soil or water. Cadmium may attach to small particles, which may be transported in the air as a result of an industrial process (i.e., metallurgy, zinc/lead smelting). Cadmium does not break down in the environment but may form complexes, ligands, and compounds that facilitate transportation of cadmium ions. Most cadmium stays where it enters the environment for a long time. Some of the cadmium that enters water will bind to soil but some will remain in the water. Cadmium in soil can enter water or be taken up by plants. Fish, plants, and animals take up cadmium from the environment.

Cadmium in Water

About 67–75% of the cadmium in surface water and groundwater is adsorbed on suspended matter. It can be remobilized from sediment by complexing agents. Aquatic life tends to be vulnerable to increases in cadmium concentration. Fish toxicity is dependent among other things on the calcium content of the water. Generally, high calcium content in water reduces the toxic effect of cadmium on fish. It has been noted that biological self-purification of surface water and groundwater is impaired when cadmium concentrations are in excess of 0.1 mg/L.

Cadmium in Air

Cadmium is stable in air since it forms an oxide layer.

Cadmium in the Soil

The cadmium retention capacity is a function of the number of exchangeable alkalis. There is hardly any dilution because of the adsorption on organic soil components. The accumulation horizon for cadmium is in the rhizosphere (roots). The minimum availability is at pH 6.5. Cadmium absorption by plants increases with a decreasing pH of the soil.

Cadmium in Organisms

Excessive cadmium concentrations in the environment will affect all organisms. In humans, 50% of the accumulated amount of cadmium is found in the liver and the kidneys. Cadmium is primarily excreted in urine [2 mg/d on average (0.2–3.1 mg/L)]. The biological half-life of cadmium in the human body is between 15 and 25 years (measured in the kidneys) (15). Humans consume roughly one-third of the cadmium to which they are exposed in animal foodstuffs and two-thirds in vegetable foodstuffs. Smoking significantly increases the cadmium impact.

METHODS OF REMEDIATION

There are several ways to deal with soil contaminated with toxic heavy metals such as cadmium. The following sections detail some of the more common remediation options for cadmium-contaminated soil and water.

Capping

Capping systems are used to provide an impermeable barrier to surface water infiltration to contaminated soil for prevention of further release of contaminants to the surrounding surface water or groundwater. A variety of materials are available for use in capping systems and choice of materials is site specific because local soils are often incorporated into parts of the cap. Synthetic membranes such as high density polyethylene are also available for incorporation into capping systems. Surface water controls, such as ditches and dikes, are usually included to help control drainage from the cap. Multilayered capping systems may also include a hard cover and/or a layer of topsoil to separate the underlying layers from the ground surface. Revegetation is promoted in order to reinforce the topsoil, to reduce soil erosion and runoff velocity, and to help remove water from the soil by evapotranspiration.

Subsurface Barriers: Pump and Treat

Subsurface barriers may be used to isolate contaminated soil and water by controlling the movement of groundwater at a contaminated site. These barriers are designed to reduce the movement of contaminated groundwater from the site, or to restrict the flow of uncontaminated groundwater through the contaminated site. Vertical barriers are commonly used to restrict the lateral flow of groundwater. For effective isolation of the contaminated matrix, the barrier should extend and key into a continuous, low permeability layer, such as clay or competent bedrock, below the contaminated area. If an impermeable layer is not available, a groundwater extraction system must be used to prevent transport of contaminants under the barrier and this contaminated water must be treated after extraction. Subsurface barriers are often implemented in conjunction with a capping system to control surface water infiltration. The use of circumferential barriers can prevent the escape of contamination from the site by using an infiltration barrier and collection system to create a hydraulic gradient in the inward direction.

Solidification, Stabilization, and Removal

The usual methods of dealing with soils contaminated with heavy metals are solidification, stabilization, and removal. The most commonly used method is solidification. Solidification involves a process in which the contaminated matrix is stabilized and fixated or encapsulated into a solid material by the addition of a chemical compound such as cement. The metal contaminants are chemically and/or physically bound to the matrix and are not obliterated but are contained in such a way that leaching into the environment is prevented or reduced. Removal is the process of physically removing the metal-contaminated soil from the current site and discarding the waste into a designated contaminated site. Stabilization, also referred to as fixation, usually uses a chemical reaction to convert the waste to a less mobile form. The general approach for solidification/stabilization treatment processes involves mixing or injecting treatment agents into the contaminated soils. Inorganic binders, such as cement, fly ash, or blast furnace slag, are commonly used. The dominant mechanism by which cadmium is immobilized is by precipitation of hydroxides or sulfides within the solid matrix.

ex situ Vitrification

The mobility of metal contaminants, particularly cadmium, can be decreased by high temperature treatment of the contaminated area, which results in the formation of vitreous material, usually an oxide solid. Most soils can be treated by vitrification with cadmium commonly being treated with *ex situ* vitrification. Typical stages in *ex situ* vitrification processes may include excavation, pretreatment, mixing, feeding, melting and vitrification, off-gas collection and treatment, and forming or casting of the melted product.

Bioremediation

Bioremediation is the use of microorganisms to control, precipitate, or destroy contaminants. Enhanced bioremediation of soil involves the delivery of oxygen for aerobic bioremediation or a carbon source (molasses, corn syrup, milk, cheese whey, lactic acid, propane, etc.) for anaerobic bioremediation. For cadmium, anaerobic and reducing conditions are more likely to contribute toward precipitating the cadmium as a sulfide or hydroxide than are oxidizing conditions. More information about metals stabilization and phytoremediation are described in Reference 16. For enhanced bioremediation, cadmium concentrations must be carefully evaluated so as not to be toxic to the microbial populations. Bench testing with the appropriate treatment chemicals can optimize pH, Eh, and other factors in the laboratory.

Phytoremediation

Phytoremediation is defined as the use of green plants to remove heavy metals and contaminants from the soil (16). The plants take up the toxic metals or isotopes through their roots and transport them to the stems or leaves. There are plants that tolerate excessive concentrations of metals in soils by absorbing, translocating, and storing the metals in a nontoxic way. Many of these plants have evolved on metal-rich soils. Research over the last two decades has shown that certain specialized plants have the ability to accumulate up to 3% (by dry weight) of heavy metals and up to 25% (by dry weight) in sap/latex with no apparent damage to the plant. Alpine pennycress (*Thlaspi caerulescens*) can be used for the removal of zinc and cadmium. Research has indicated that the pennycress plant typically absorbed 3–4% of the cadmium contamination from the soil (in some cases as much as 9%). Willow is another plant that proved able to absorb cadmium but never more than 1% of the soil content. Consequently, soil could advantageously be cleaned of cadmium by pennycress, possibly in combination with willow.

In Situ Electrokinetic Remediation

An emerging remediation technology, which in laboratory experiments has indicated substantial results in the removal of heavy metal contaminants particularly cadmium, is electrokinetic remediation (4). While bench tests conducted at the Naval Air Weapons Station at Pt. Mugu, California did not give statifactory results in the removal of cadmium and chromium contamination from the site, the technology holds some promise. Electrokinetic remediation is an *in situ* process in which an electrical field is created in a soil matrix by applying a low voltage direct current (DC) to electrodes placed in the soil.

The current density is generally on the order of milliamperes per square centimeter (mA/cm^2) or an electric potential difference on the order of a few volts per centimeter across electrodes placed in the ground. The electrodes can be placed in either a vertical or horizontal array. When direct current is applied to the electrodes, an electrical field develops between the anodes and cathodes. The application of the electric field has several effects on the soil, water, and contaminants. These effects include electromigration, electroosmosis, changes in pH, and electrophoresis. Electromigration refers to the movement of cations and anions under the influence of the electrical field. Cations (positively charged ions) tend to migrate toward the negatively charged cathode, and anions (negatively charged ions) migrate toward the positively charged anode. These ions concentrate in the solutions near the electrodes or may undergo reactions at the electrodes, which may plate the metals onto the electrodes or liberate gaseous compounds. The electrokinetic remediation system was designed to extract the metal contaminants via electromigration of the contaminant ions and concentration of the ions in the electrode wells. The majority of these contaminants were expected to remain in solution with only minimal plating occurring on the electrodes. Once metal contaminant concentrations had built up in the electrode well, processing of the electrolyte fluid would be conducted to extract the metal contaminants and return the processed electrolyte fluid back to the wells for continued use. This would have minimized the volume of waste generated by the process.

Precipitation/Flocculation/Sedimentation

Cadmium precipitation has been described in the literature (4). This process is the most common method of removing cadmium from soils. In precipitation reactions chemicals are added to transform dissolved cadmium constituents to form insoluble cadmium precipitates. Metals are precipitated as hydroxides, sulfides, and carbonates by adding appropriate precipitant and adjusting the pH to favor insolubility. Precipitation can be used to remove most metals and many anionic species (phosphates, sulfates, fluorides). Better removal efficiencies can be achieved with sulfite precipitation, but hydroxide precipitation, using lime or caustic, is more practiced, due to lower cost and better availability of the materials such as lime. This may change with newer chemicals such as calcium polysulfide (CaS_5). Precipitation reactions require rapid mixing, while flocculation reactions require slow, gentle mixing to encourage particle contact. After the contaminated product has reacted in the precipitation tank, it flows into the flocculation tank. In a flocculation reaction, alum, lime, ferric chloride, or polyelectrolytes are added to the inflow to reduce the repulsive forces between the precipitated particles. These particles aggregate, forming large flocs of material, which can be settled out in a sedimentation tank. For *in situ* methods, sulfur-based reducing chemicals such as calcium polysulfide, sodium metabisulfate, and ferrous sulfate can be used to precipitate cadmium and other metals. The resultant precipitate is cadmium sulfide (CdS).

CONCLUSIONS

Cadmium usage will continue to grow, especially in the area of rechargeable batteries and solar cells. The health effects of cadmium are well understood, so exposures are minimized through regulations. With recycling programs handling more spent batteries than in the past, cadmium emissions into the air and land should decline over time.

GROUNDWATER MODELING

Ekkehard Holzbecher
Humboldt Universität Berlin
Berlin, Germany

INTRODUCTION

Since the early beginnings with applications for the oil industry (1), computer models have become an indispensable tool to study aquifers, to understand the interaction of different processes affecting the biogeochemistry and/or the heat distribution, to predict the effect of changes, and to solve practical groundwater problems. Examples are aquifer characterization, capture zone delineation, pumping and recharge well design and management, watershed simulation, groundwater pollution, potential hazards and remediation, acid mine drainage, natural attenuation, geo- and hydrothermics, and saltwater intrusion.

Computer software codes are available today for the modeler to set up groundwater models. Some codes are equipped with user-friendly interfaces and can be used for simulations of flow, as well as mass and heat transport. Some are even capable of including reactions between various chemical or biochemical species. Only a few specific programs can be mentioned here in detail. An extended description of codes is given elsewhere (2,3). Some topics have to be left out also. Multiphase flow is not considered, and modeling of sorption and biogeochemistry could only be mentioned in the context of reactive transport, just to list some topics.

DIFFERENTIAL EQUATIONS

A quantitative description of groundwater flow, transport, and reaction processes is obtained via differential equations. In three dimensions flow equations can be formulated as

$$S\frac{\partial h}{\partial t} = \left\{ \begin{array}{ll} \nabla \cdot T\,\nabla h & \text{for the confined aquifer} \\ \nabla \cdot \mathbf{K}h\,\nabla h & \text{for the unconfined aquifer} \end{array} \right\} + Q \tag{1}$$

with storativity S, transmissivity T, and the tensor of hydraulic conductivities $\mathbf{K}$. The tensor $\mathbf{K}$ allows us to take into account the direction-dependent conductivity. In the case of an isotropic porous medium, the tensor reduces to a scalar conductivity value K, which may change from one location to the other in order to consider different hydrogeological strata or inhomogeneities. In the term Q all types of sinks and sources are gathered. The value of Q is positive for sources of fluid and negative for sinks. Unknown is the variable of piezometric head h. Sometimes pressure p is used as an unknown variable, which is the more appropriate variable in cases in which water density changes (4).

The flow differential equations are derived from the principle of water mass conservation and from Darcy's law (2). The differential equations for the steady state are obtained when the storage term on the left side of differential equation 1 is omitted. More details are given elsewhere (5–7).

The general differential equation for mass transport in three-dimensional space is

$$\frac{\partial}{\partial t}(\phi c) = \nabla\phi\,\mathbf{D}\cdot\nabla c - \nabla(\mathbf{v}c) + q \tag{2}$$

with porosity ϕ, the vector of Darcy velocity $\mathbf{v}$, and the dispersion tensor $\mathbf{D}$. With the dispersion tensor $\mathbf{D}$ it is possible to account for direction-dependent dispersive processes, as they are mostly observed in porous media. The dispersion tensor depends on the parameters of molecular diffusivity D_m and longitudinal as well as transversal dispersivity, α_L and α_T. The term on the left side of the equation represents storage, the first two terms on the right side dispersion and advection. In the term q different additional processes can be taken into account, like decay, degradation, or production. Unknown is the concentration c of a chemical species. For more details see References 4, 8, and 9. In order to describe multispecies systems, the transport equations for the different species are combined by reaction terms:

$$\frac{\partial}{\partial t}(\phi\mathbf{c}) = \nabla\phi\,\mathbf{D}\cdot\nabla\mathbf{c} - \nabla(\mathbf{v}\mathbf{c}) + \mathbf{S}^T\mathbf{c} + q \tag{3}$$

$\mathbf{S}$ denotes the reaction matrix, in which all equilibrium reactions are gathered. In the given notation all unknown concentrations are gathered in a vector $\mathbf{c}$. In order to handle the system described by Equation 3, the equations are rearranged by linear operations, which makes the reaction term $\mathbf{S}^T\mathbf{c}$ vanish. In addition to the remaining transport equations, the equilibrium conditions for the reaction have to be taken into account (10,11). Sorption can be treated similarly, but instead of solving the equilibrium state equation directly, often a retardation parameter R is used as an additional coefficient on the left side of the transport equation (see References 2 and 3).

The heat transport equation is given by

$$(\rho c)^*\frac{\partial}{\partial t}T = \nabla\cdot\lambda\,\nabla T - (\rho c)_f\mathbf{v}\cdot\nabla T + H \tag{4}$$

with heat capacity $(\rho c)_f$ of the fluid as well as thermal conductivity λ and heat capacity $(\rho c)^*$ of the saturated porous medium (2,4,12). In the term H, all types of heat sources can be gathered. Sometimes direction-dependent dispersion processes are taken into account in heat transport; then a tensor has to be used, as in the mass transport equation 2. Unknown in Equation 4 is the temperature T.

Table 1 provides an overview of the types of processes and equations, their unknown variables, and parameters. While in the simplest case a model can be related uniquely to one of the three given types, some model concepts are complex. Transport models are often based on a flow model, which calculates the necessary velocity field $\mathbf{v}$. Even more complex is the coupled situation, when one of the transport variables has an influence on flow. The most prominent example is density-driven flow, in which the effect of salinity and/or temperature on the density is taken into account; see Reference 4. The complexity increases further when, for example, the effect of temperature on kinetic reaction rates in mass transport is to be considered.

BOUNDARY AND INITIAL CONDITIONS

Before the computer is engaged, the first task of the modeler is to specify the *model region*. The model region can be one, two, or three dimensional, depending on the situation to be modeled. The extent of the model region, more specifically its boundaries, has to be chosen appropriately, in order to formulate *boundary conditions*.

Table 1. Overview of Types of Models, Unknown Variables, and Parameters

Type	Unknown Variable	Parameters[a]
Flow	Head, h, or pressure, p	S, T, K, Q, ρ
Mass transport	Concentration(s), c	$\phi, D_m, \alpha_L, \alpha_T, q, R$
Heat transport	Temperature, T	$(\rho c)^*$, $(\rho c)_f$, λ, H

[a] See text for description of parameters. The list of parameters is not complete; neither are all of them necessary in all cases.

The boundary of a one-dimensional model consist of two points, the boundary of a two-dimensional area consists of closed lines, and the boundary of a three-dimensional volume is given by surfaces.

In order to complete the mathematical formulation of the problem, boundary conditions have to be formulated. At the boundaries additional information about the behavior of the system is necessary, as the variation of the unknown variable is free outside the model region, while in the interior it is fixed in all directions by the differential equation. There are three major types of boundary conditions, which are listed in Table 2.

Some typical examples for boundary conditions in field situations are given as illustration. When a river or a lake is perfectly connected to groundwater (no clogging layer), the water table of the surface water body is taken as a first-type boundary condition for flow (see Fig. 1); the concentration or temperature of the surface water can be used as first-type boundary conditions for mass or heat transport. Interfaces to nearly impermeable strata in the subsurface are also appropriate boundaries: Neumann conditions are specified for both flow and mass transport, representing no-flow for water and solute. For transport the Neumann conditions represent no dispersive flux, but in combination with a no-flow condition for water there is no advective flux across that boundary either. More complex types of boundary conditions, in which heads and fluxes are combined, are described elsewhere (7,13).

In transient simulations, that is, when the system changes with time, *initial conditions* for the unknown variable have to be specified by the modeler additionally. The task, in mathematical terms, is to solve the *initial and boundary problem* for the differential equation. For this task analytical solutions are sought or numerical models are applied.

Analytical solutions are mostly given by an explicit equation, which is valid for all locations in the model region and all time instants (6). For the evaluation and illustration of such solutions usually a computer is used. Finally, the analytical methods also depend on discretization, that is, the use of discrete time and space values instead of a continuum. But in *numerical methods* the discretization is already applied in the solution process.

Table 2. Overview of Types of Boundary Conditions

Type	Name	Known Value, to be Specified as Condition
First	Dirichlet	Unknown variable
Second	Neumann	Derivative of unknown variable normal to the boundary
Third	Cauchy or Robin	Combination of unknown variable and its derivative

DISCRETIZATION

The major step in groundwater modeling by numerical methods is discretization. The term discretization means that an aquifer or a part of it is divided into a *grid* of small pieces, which are called blocks, volumes, elements, or cells, depending on the *method of discretization*; see below. In one-dimensional models a grid size of 1000 is already a fine model; in two-dimensional cases such a grid size is still small. In three-dimensional models grids containing more than a million unknowns are not uncommon nowadays.

Grids may look very different. A grid may consist of regular rows and columns of blocks: such a regular grid is shown in Fig. 1. It may consist of irregularly shaped triangles as shown in the upper left part of Fig. 3. In fact, these are the major types of grids, connected to the methods of finite differences (FD) and finite elements (FE), but other forms are possible also: irregular rectangular grids, regular triangular grids, grids containing triangles, and other forms of geometries (14). The term grid is not only valid in two dimensions: it consists of intervals in one dimension and prisms or tetrahedrons in three dimensions.

All discretization methods are constructed to calculate approximate solutions for the initial and boundary value problem. Finer grids usually guarantee better approximations. On the other hand, finer grids require more computer space and much longer execution time on the computer. Based on available computer facilities and experience, the modeler usually decides on the grid resolution. Only advanced software tools provide the user with the ability to check the model accuracy by adaptive grids (15).

There are different numerical discretization methods, by which computer algorithms are derived from differential equations. Most important are *finite differences* (FD), *finite elements* (FE), and *finite volumes* (FV).

Using the FD method, derivatives (differential quotients) in the differential equations are approximated by difference quotients. For first and second order derivatives in the x-direction, the simplest central stencils are given by

$$\frac{\partial f}{\partial x} \approx \frac{f_{i+1} - f_{i-1}}{2\Delta x} \quad \text{and} \quad \frac{\partial^2 f}{\partial x^2} \approx \frac{f_{i+1} - 2f_i + f_{i-1}}{\Delta x^2} \tag{5}$$

where the f-values denote function values at the grid nodes: that is, f_i is the approximate value of the function at node i, f_{i-1} at the previous node, and f_{i+1} at the following node. In that way, the differential equation delivers a condition for each block or node of the grid; altogether a system of equations is obtained for the values of unknown functions at the nodes.

Using the FE technique, the solution of the differential equation is approximated by a combination of shape

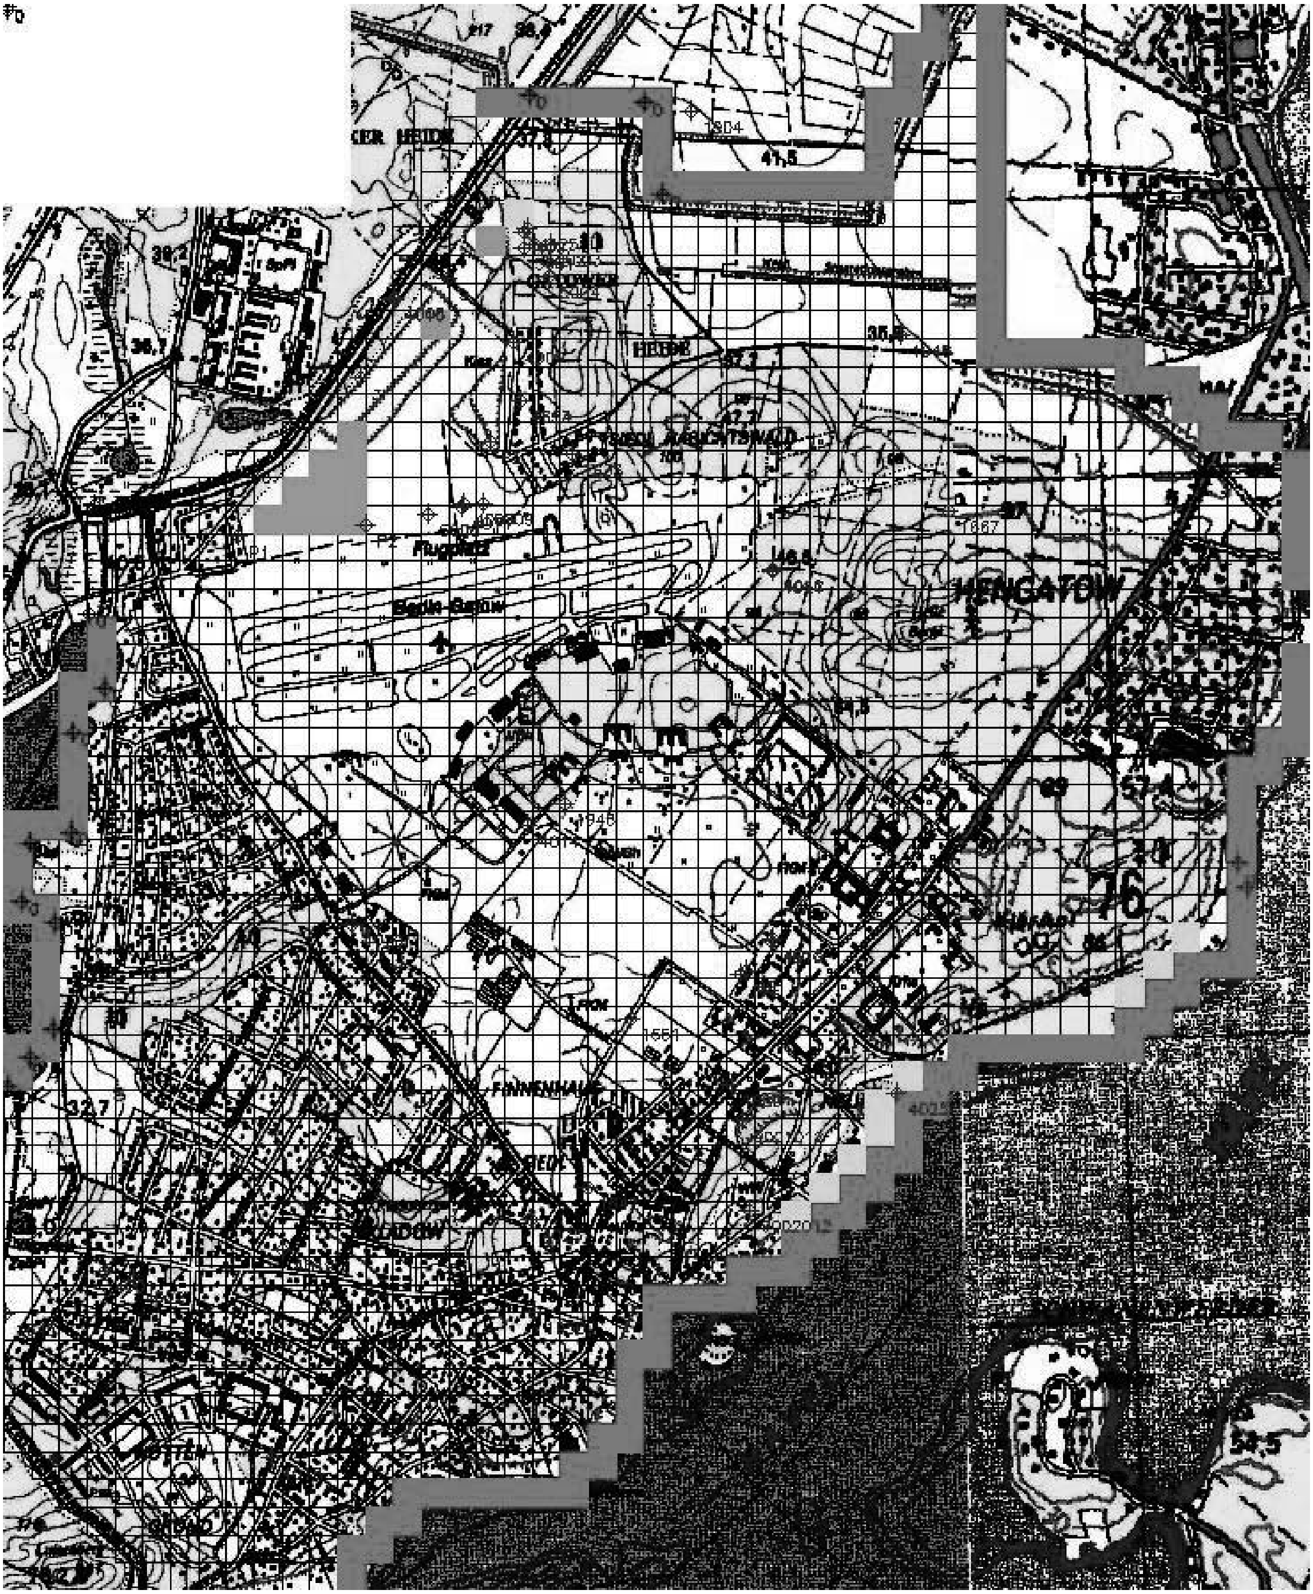

Figure 1. Regular finite volume grid for a horizontal model region. A map is depicted, underlying a regular FV grid, from which only active blocks are shown; boundaries of the model region are shorelines of lakes (west and east) and creeks (north), a water divide (northwest), and a streamline (southwest). Blocks with first-type boundary condition are dark colored pumping wells are light colored, and abandoned landfills as sources of contaminants are gray.

functions, which depend on the element type. For the most common triangular elements, the prescribed shape functions are linear within each element: in the two-dimensional situation the unknown function $f(x, y)$ is approximated by

$$f(x, y) = a_{\alpha 0} + a_{\alpha 1}x + a_{\alpha 2}y \quad \text{within element } \alpha \tag{6}$$

The so-called weak form of the differential equation delivers conditions for the coefficients $a_{\alpha j}$ for all elements in the form of a linear or nonlinear system (14). FEFLOW (16) is a popular FE groundwater code, using prisms for single layers, while in the mathematical FEMLAB code (14) more general tetrahedrons can be used.

The method of finite volumes (FV) is derived from a mass or energy balance for all volumes of the grid. In the two-dimensional rectangular volume *ij*, for example, the balance can be noted as

$$\frac{\partial V}{\partial t} = Q_{i-} + Q_{i+} + Q_{j-} + Q_{j+} + Q \tag{7}$$

where V denotes the volume or mass in the block, Q_{i-}, Q_{i+}, Q_{j-}, Q_{j+} the fluxes across the block edges, and Q other sources or sinks for water volume, mass, or energy in the volume. For further illustration of the technique, the flow equation 1 is considered: replacing the four flux terms in Equation 7 by using Darcy's law leads to a system of equations for the heads at the block centers. The popular MODFLOW code (13) is implemented following this strategy. Under certain conditions the FV technique delivers the same algorithm as the FD method.

The discretization of time is mostly implemented by a time-stepping approach; that is, starting from the initial condition the numerical simulation proceeds in time steps. For each time step, the discretized form of the left side of the differential equation is solved.

Concerning specific modeling situations, the basic techniques may deliver poor results; that is, they may produce bad approximations or results that do not resemble the solution at all, or they may even not converge. A very prominent example problem is transport in advection-dominated flow, for which standard methods deliver unrealistic oscillations or numerical diffusion (3,14). For this specific problem *operator splitting*, using different discretization methods for the different terms on the right side of the transport equation 2, has turned out to be a successful strategy to obtain accurate results even for small time steps (see References 2, 3, and 11).

Independent of the discretization method, a system of equations for the values of the unknown functions at the grid nodes is obtained. The task to find an approximation for the solution of the differential equation is thus transformed to the task of solving a linear or nonlinear system of equations. For the latter task, various solution techniques have been developed in numerical mathematics, which are included in modeling software tools.

PREPROCESSING, SOFTWARE, AND SOLUTION

The entire task of modeling can be divided into three steps: preprocessing, processing, and postprocessing. Processing means the execution of the mathematical solution algorithm for the system of equations (the *solver*), for which different alternatives are available. Taking into account several input parameters, in a model run the solver delivers values for the unknown variable in question on the grid. Depending on the discretization method, values are calculated at the nodes of the grid or at block centers.

Input parameters are prepared during preprocessing. Common software tools allow different preprocessing tasks, concerning the specification of input data. Data fields of distributed parameters can be calculated. For these calculations the user interfaces are equipped with interpolation tools, varying from simple nearest neighbor to complex krigging schemes.

The solvers are special numerical algorithms for the solution of large systems of linear or nonlinear equations. Several solvers and variants are included in most modeling codes. The default values for these solvers (often of conjugate gradient type) are usually appropriate for a wide range of model setups, but sometimes it may be necessary to change a solver parameter or switch to another solver type, in order to obtain a correct and fast solution.

User-friendly shells often not only offer the alternative to use different solvers of one processing program, but allow the user to choose different programs, for which the input data are prepared automatically. Visual MODFLOW (17), GMS (18), and PMWIN (19) are such shells, which are currently used. Operations with the values, which have been delivered by the solver, are gathered under postprocessing, which is dealt with next.

POSTPROCESSING: RESULTS AND VISUALIZATION

There are various ways to visualize large numerical data sets, delivered by a solver, in a form that provides direct insight to the hydrogeological situation. The most common output are head contours, shown as a surface plot, as a pattern of contours with or without fill pattern (see Fig. 2). When several layers of aquifers are modeled, contour plots are generally different from one layer to the other. In three-dimensional models, contour plots can be shown for layers and also for cross sections.

Very informative are flowpaths or flowlines, that is, the travelpaths of particles in the calculated flow field. Start positions have to be chosen by the modeler, and the trace of the particles is followed by a numerical algorithm (2,20). The direction can be either forward or backward in time: the path is traced forward to future positions or back to its origin. Traveltimes can be visualized as so-called isochrones, lines of equal traveltime. In transient simulations, the flowpath usually changes with time, while in steady-state flow the flowpaths are constant. In the latter case, one may speak of streamlines. In three-dimensional models it may be sufficient to depict flowpaths in one picture, in which crossovers are allowed (Fig. 2). Some modeling software delivers the very instructive three-in-one plots with one view from the top and two views in vertical cross sections, as in PMPATH (19).

With streamline plots, it is possible to visualize not only flow direction but also velocities. When streamline

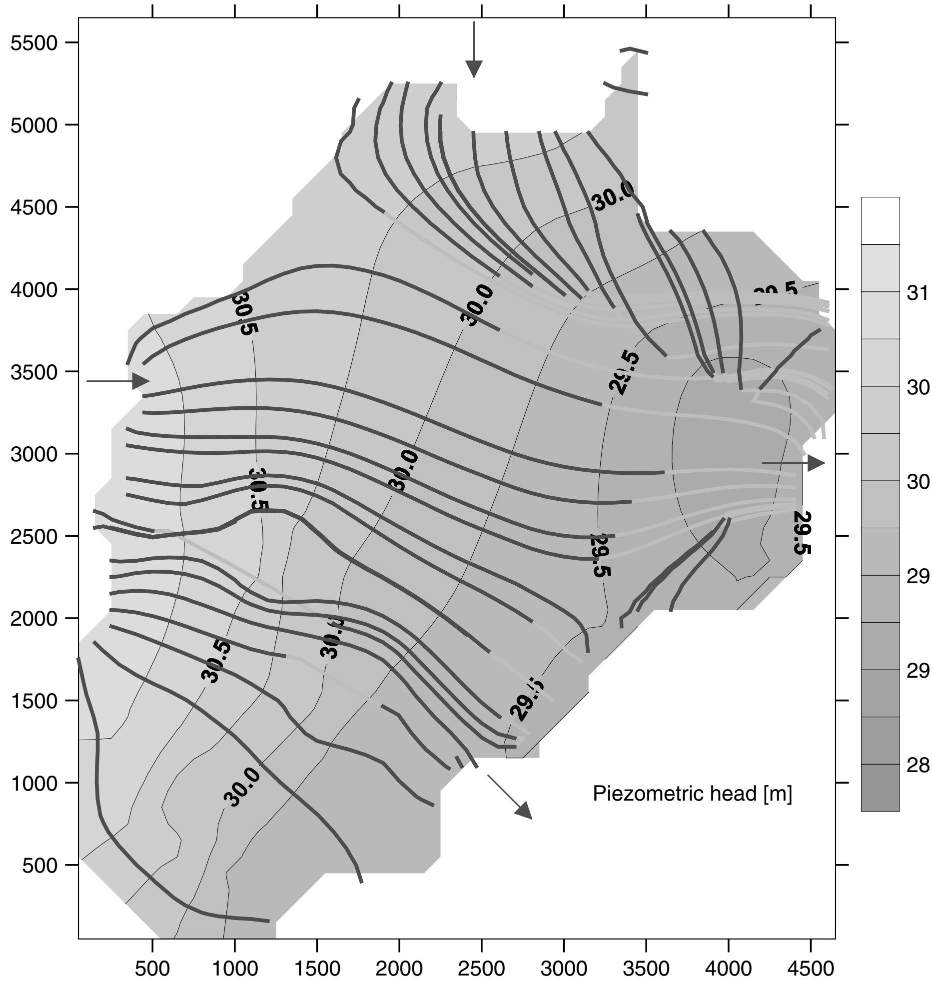

Figure 2. Head contour and flow-path plot, calculated using MODFLOW (13) and PMWIN (19).

levels are equidistant, streamlines become dense, where velocities are high; as the distance widens, the velocities are low. See the bottom left of Fig. 3 as an example.

Vector plots of velocities are also informative, as depicted in the top right of Fig. 3. Not only is the direction shown by the vectors, but the velocity can also be visualized by scaling the length of the vector with the size of the velocity. A problem with such a representation is that in most groundwater problems velocities change by several orders of magnitude within the model region; that is, some vectors become very large, while others are hard to recognize. The alternative is to scale the length of the vectors with the logarithm of the velocity.

In transport models, distributions of concentration or heat are depicted by plots of filled or unfilled contours, representing isohalines in the case of salt and isotherms in the case of temperature. An example for a steady-state concentration is given in the bottom right of Fig. 3. The transient behavior at certain locations of interest within the model region can be captured by breakthrough curves, as implemented in PMWIN (19).

Another important postprocessing tool is the calculation of a budget, for example, of fluid mass for flow models, of component mass in the case of mass transport, and of energy in the case of heat transport. Such budgets are extremely useful for the entire model region or for parts of it. Some programs allow a graphical representation of the different budget terms in a histogram (16).

PARAMETER ESTIMATION

There is an increasing demand for and use of parameter estimation in groundwater models. While the usual modeling task, as described so far, is termed *direct modeling*, parameter estimation is performed by *inverse modeling*. While in direct modeling of groundwater flow (for example) hydraulic conductivity (for example) is an input variable and piezometric head is the unknown variable, their role is exchanged in inverse modeling. However, direct modeling is part of the inverse modeling task.

After each direct modeling run, the performance of the model is evaluated. The performance measure usually is the mean deviation between measured and modeled values. Special algorithms are applied to change the input data set in a way that is likely to increase the performance. Levenberg-Marquard and Gauss-Newton are algorithms of that type, which are applied in all fields of parameter estimation. Various programs offer different types of assistance to the modeler to perform inverse

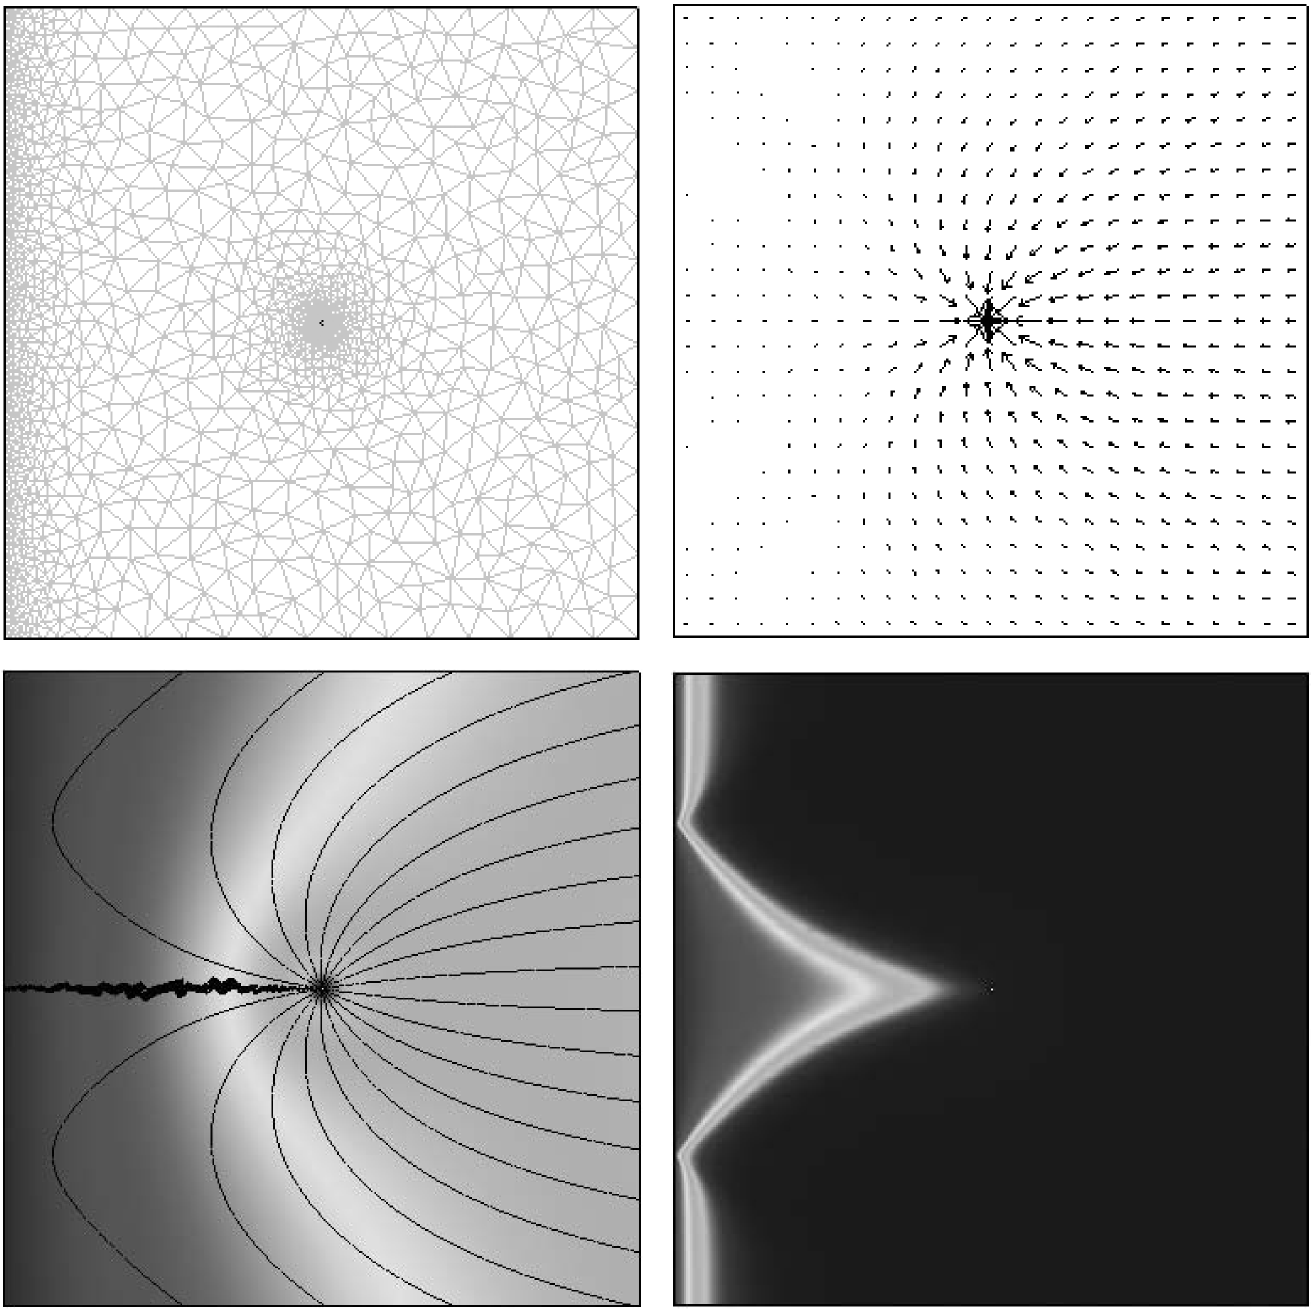

Figure 3. Finite element grid (top left), velocity vector plot (top right), head and streamline plot (bottom left), and concentration plot (bottom right) for bank filtration. The bank is located on the left boundary, the well in the middle of the depicted model region; water pumped at the well is a mixture of bank filtrate and groundwater. Simulated and visualized by FEMLAB (15).

modeling (16,19). In most cases the groundwater models are connected with general-purpose parameter estimation codes, like PEST (21) or UCODE (22).

CONCLUSION

Groundwater modeling has become a broad field in the few decades since its early beginnings. Only major features could be mentioned in a short introduction. Available software tools vary in many aspects and are in permanent development. The treated topics can thus be only a guideline for users searching for appropriate tools for specific applications. The reader may consult References 2 and 3 for more details.

GROUNDWATER AND BENZENE: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Keith Villiers
Environmental Bio-Systems, Inc.
Mill Valley, California

Benzene (C_6H_6) is a clear, colorless, highly flammable aromatic hydrocarbon liquid. As an important ingredient for making plastics, rubber, resins, and synthetic fabrics like nylon and polyester, benzene is one of the most commonly used industrial chemicals in the world. It is also used as a solvent in printing, paints, and dry cleaning. It is also a major component of gasoline. The wide ranging industrial applications of benzene make it widely distributed, particularly in the case of petroleum products, of which it is a primary constituent. Benzene is highly toxic to humans and the environment. Because of its severe toxic effects, both in the short and long term, benzene use has been under strict regulations for many years. Nonetheless, widespread contamination of benzene has occurred in the environment, and, therefore, significant regulatory efforts in the United States and other nations are being enacted to limit or eliminate potential impacts.

HISTORY

In 1825, Michael Faraday began a number of experiments in distillation. Among the products he worked on was crude oil, from which he extracted a colorless gas-phase compound. Faraday lit the gas compound and it burned. For decades the benefits of what Faraday called "bicarburet of hydrogen" were unknown. In 1834 Eilhard Mitscherlich isolated the same gas-phase compound by heating benzene carboxylic acid ($C_6H_5CO_2H$), also called benzoic acid, with lime (CaO). He derived the chemical formula C_6H_6 and named the compound "benzin." In 1846, A. W. Hoffman isolated the same product, later called benzene, in large quantities by distilling coal (1).

CHEMICAL STRUCTURE

The molecular structure of benzene baffled scientists for many years, although the empirical formula was known. None of the proposed molecular structures at the time supported the chemical properties observed. In 1865, Friedrich August Kelule proposed a ring structure. It is now known that benzene, like all aromatic hydrocarbons, contains a cyclohexane type of ring structure that has alternating single and double bonds.

This unique molecular structure of benzene (C_6H_6), a volatile, colorless, and flammable hydrocarbon, made it incompatible or reactive with strong oxidizers, many fluorides, perchlorate, and nitric acid. It is slightly soluble in water [580–1780 ppm (∼0.06–0.17%)] and has a boiling point of 80 °C and a freezing point of 5.5 °C. Benzene has a characteristic sweet odor, with an odor threshold of 2.7–12 ppm in air.

PRODUCTION AND USES

For a long time, benzene could only be extracted from coal; however, with the rise of crude oil use, its importance increased significantly. From the start of the twentieth century, benzene saw extraordinary growth in its applications in an abundance of industrial areas, including chemical, petroleum, agricultural, and pharmaceutical manufacturing. Benzene has been given a list of trade names by product producers, including Benzol 90, Pyrobenzol, Polystream, Coal naptha, and Phene (2).

Benzene first saw major industrial production during World War I, where it was produced specifically for the rubber industry as well as for the production of toluene, a major component of explosives. Eventually, benzene began finding uses in other industrial processes such as the manufacture of artificial leather, rubber goods, and rotogravure printing industries, and as a starting material in organic synthesis.

Benzene has been released into the air primarily from fumes and exhaust through incomplete vehicular combustion. Other air sources of benzene include the release of fumes from the production and use in manufacturing of other chemicals (2). Vapor emissions of benzene can be detected from carpet glue, textured carpet, and furniture wax (3).

Benzene is also an important component of gasoline. Benzene has been released into the subsurface through leaking fuel tanks, primarily gasoline. Discharges into water come from industrial effluents and losses during spills (2).

HAZARDOUS EFFECTS

Benzene has been recognized since 1900 as a toxic substance capable of producing acute and chronic nonmalignant effects in humans. When benzene vapors are inhaled, the benzene diffuses rapidly through the lungs and is quickly absorbed into the blood. Acute circulatory failure resulting in death within minutes often accompanies exposure to benzene concentrations as high as 20,000 ppm. Other acute effects of exposure to milder, though still high (250–500 ppm), concentrations of benzene include vertigo, nervous excitation, headache, nausea, and breathlessness. As a result of its toxicity, benzene's history has been one of regulation. In 1946, the American Conference of Governmental Industrial Hygienists recommended a threshold limit value for benzene exposure of 100 ppm. This value was reduced to 50 ppm in 1947, to 35 ppm in 1948, to 25 ppm in 1963, and to 10 ppm in 1974. The American National Standards Institute adopted a threshold limit value of 10 ppm in 1969, which OSHA adopted in 1971 without rulemaking under the authority of 29 U.S.C.A. § 655(a). This standard, codified in 29 C.F.R. § 1910.1000 Table Z-2, was based on the nonmalignant toxic effects of benzene exposure and not on any possible leukemia hazard (4).

The U.S. Congress passed the Safe Drinking Water Act (SDWA) in 1974. The law requires the U.S. EPA to determine safe levels of chemicals in drinking water, which do or do not cause health problems. These nonenforceable levels are based on possible health risks and exposures are called Maximum Contaminant Level Goals (MCLG). The MCLG for benzene is zero, as this level would not cause any harm to humans. The EPA set the enforceable Maximum Contaminant Level (MCL) for benzene at 5 μg/L or 5 parts per billion (ppb). This is the lowest level to which water systems can be reasonably required to remove benzene prior to serving the water. All community or public water supplies in the United States must abide by these regulations (2).

The carcinogenic nature of benzene was known from as early as the 1920s (5) and since then numerous medical studies have confirmed linkages between human exposure to benzene and the occurrence of leukemia. Since then, a number of U.S. health authorities [e.g., the Occupational Safety and Health Association (OSHA), the National Institute of Occupational Safety and Health (NIOSH), and the American Conference of Governmental Industrial Hygienists (ACGIH)] have set benzene exposure risk standards (at levels not exceeding 0.1 ppm per day) (6). Short-term exposure above the MCL could cause temporary nervous system disorders, immune system depression, and anemia. Long-term lifetime benzene exposure at levels above the MCL has the potential to cause chromosome aberrations and cancer (2).

CONTAMINATION AND EXPOSURE

Benzene has been found in at least 813 of the 1430 National Priorities List sites identified by the U.S. EPA. Industrial sites and gasoline service stations are the main sites of benzene contamination (7). Human exposure to benzene may result from such factors as industrial and motor vehicle emissions, tobacco smoke, industrial factories working environments, and hazardous waste disposal sites. Benzene is capable of passing into the air from soil and water sources. The largest issue is benzene contamination from leaking underground storage tanks (LUSTs) into groundwater, which may impact drinking water sources.

Remedial Measures

Environmental contamination of pure benzene is unlikely since benzene is often used as an ingredient with other compounds. Most benzene contamination occurs when other more common chemicals, such as gasoline, having benzene as a main constituent, are released into the environment. Examples of such products include petroleum fuel hydrocarbons (gasoline, diesel, and kerosene), industrial solvents, detergents, and pesticides, among others compounds (7). At present, there are a number of major contamination sites containing elevated levels of benzene and benzene-based products. In many of these cases, the contamination poses a threat to sources of groundwater utilized for human consumption.

Benzene does not readily sorb to soil and therefore may be transported large distances from its source depending on groundwater velocity and hydraulic conductivity. The potential environmental impact of subsurface benzene contamination is dependent on many factors. Under optimal subsurface conditions, benzene is biodegradable. Benzene is relatively easy to oxidize with chemical oxidants such as ozone, potassium permanganate, sodium persulfate, and hydrogen peroxide. Benzene has been extracted from the subsurface using soil vapor extraction in the vadose zone and groundwater pump and treat systems. Common aboveground treatment methods for benzene include thermal and catalytic oxidizers, granular activated carbon, biofilters, and advanced oxidation processes. Aerobic bioremediation and enhanced natural attenuation work well with benzene. Suthersan (8) describes various gasoline and benzene bioremediation methods.

Extraction technologies such as soil vapor extraction (SVE) for the vadose zone and groundwater extraction with pumps and aboveground treatment of benzene have been used for decades. A good summary of various technologies for benzene vadose zone and groundwater treatment is Reference 9.

GROUNDWATER AND NITRATE: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Lorraine Geddes-McDonald
Environmental Bio-Systems, Inc.
Mill Valley, California

Nitrate is a naturally occurring substance, which is an essential ingredient for the growth of plants. Human activities can contribute to higher levels of nitrate in the ground and surface waters. The major source of excess nitrogen is nitrate fertilizers for agricultural, lawn, and other garden uses. Nitrates are sourced from nitrates in nitrate fertilizers, the storage or use of animal manure, leaky septic systems, leaky sanitary sewer pipelines, and improper disposal of treated wastewater containing high nitrate levels. Through storm runoff and leaching processes, nitrates have become dissolved in stormwater runoff or infiltration waters. These sources of dissolved nitrates have created significant impacts on worldwide surface water and groundwater resources.

INTRODUCTION

Besides nitrate-based fertilizers, other sources of nitrates include animal manure from feedlots, dairies, and poultry farms; septic tanks; rainwater (acid rain); and sewage sludge. Human exposure to nitrates can occur through certain foods, such as cured meats and vegetables, and through tobacco smoke (1).

HISTORY

Daniel Rutherford in Scotland discovered nitrogen in 1772. In 1905 the world's first production of nitrogen fertilizer [Nrgessalpeter (calcium nitrate)] was done at a test facility in Nottodon, Norway. Production was based on the Birkeland Eyde invention using hydroelectric power to extract nitrogen from the air.

The German physical chemist Fritz Haber invented a process in 1909 that directly combines nitrogen from the air with hydrogen from a hydrocarbon source under extremely high pressure (200–400 atm) and moderately high temperatures (400–650 °C) to make ammonia (NH_3). The process initially used coal and later natural gas as a source of hydrogen and as a source for the considerable energy required. For his efforts, Haber received the Nobel Prize in Chemistry in 1918. It was an industrial chemist, Carl Bosch, who took the Haber method and designed a large scale process using a catalyst and high pressure methods. Those efforts were rewarded with a jointly shared Nobel Prize in 1931 with Friedrich Bergius for high pressure studies. The discovery and feasibility of the Haber–Bosch process (also called the Haber Ammonia Process and the Synthetic Ammonia Process) were dependent on the newly discovered sources of energy from coal and petroleum, which made the production of ammonia economically feasible. In 1928, ammonia-based production replaced the Birkeland Eyde technology both at the Nottodon and Rjukan facilities. Calcium nitrate based on ammonia from Rjukan nitrogen–phosphorus–potassium (NPK) production using a newer nitrophosphate process, started in the mid-1930s and gained importance in the mid-1960s.

PROPERTIES OF NITRATES

Nitrates, chemical compounds containing the nitrate (NO_3) radical, are salts or esters of nitric acid (HNO_3)

formed by replacing the hydrogen with a metal (e.g., sodium or potassium) or a radical (e.g., ammonia or ethyl). Some important inorganic nitrates are potassium nitrate (KNO_3), sodium nitrate ($NaNO_3$), silver nitrate ($AgNO_3$), and ammonium nitrate (NH_4NO_3). Calcium nitrate is also used in fertilizers. The presence of nitrate in the soil is of great importance, since it is from these compounds that plants obtain the nitrogen necessary for their growth. Nitrogen-fixing bacteria are important in keeping soil supplied with nitrates.

Nitrate is present in various compounds: nitrate (NO_3), nitrate-nitrogen (NO_3-N), nitrite (NO_2), nitrate plus nitrite (NO_3+ NO_2). Each represents a different measurement of nitrogen's impact on health.

Persistence in Groundwater

Nitrate occurs naturally in the subsurface in small quantities. Due to large inputs of agricultural fertilizers and runoff from manure, the level of nitrate in groundwater has in risen significantly in some locations. Nitrate in groundwater can be reduced by denitrification, resulting in nitrogen gas (2). Commonly available activated carbon, filtration, and standard water softeners do not remove nitrate-nitrogen from water.

Taste and Odor

Nitrate is odorless and colorless, so it can be detected only through a water test.

Health Risk

The main health threat from nitrate is methemoglobinemia, or blue baby syndrome. Infants less than six months old do not have the enzyme needed to break down nitrates. Excess nitrogen in the system interferes with the blood's ability to carry oxygen, resulting in a bluish tint to the skin. This condition is rare but can be fatal.

There is no conclusive evidence that nitrates can cause cancer in adults. However, there is some evidence that high levels of nitrate consumed over a long period may be toxic. Maximum contaminant levels (MCLs) are standards that provide a minimal level of risk to health from consuming a contaminant over the course of a lifetime. Lifetime exposure to nitrate levels above MCL can cause diureses, increased starchy deposits, and hemorrhaging of the spleen (3).

A water test for nitrate is suggested for households with infants, pregnant women, nursing mothers, or elderly people. It is recommended that new water supplies should be tested to determine the baseline nitrate concentration. In addition, if a water supply has never been tested for nitrate, it should be tested. If excess nitrate is found in a water supply, then the water should be treated, or an alternative source of potable water should be secured (4).

REGULATORY ISSUES

In 1974 the U.S. congress passed the Safe Drinking Water Act. This law requires the Environmental Protection Agency (EPA) to determine safe levels of chemicals in drinking water, which do or may cause health problems. The MCL for nitrate has been set at 10 ppm and 1 ppm for nitrite (3).

FATE AND TRANSPORT

Nitrate is a highly soluble anion that readily transports in groundwater, resulting in contamination of large subsurface areas. Many sites are affected by nitrate contamination. Nitrate is easily transported in oxygen-rich water with no transformation and little or no retardation. Nitrate is not removed by filtration and the compound is stable over a considerable range of conditions. Large numbers of activities contribute to the problem: farming, fertilization, animal feedlots, dairy; manufacturing of explosives and chemicals; nuclear industry, large amounts of nitric acid, dissolved metals and actinides; mining industry.

Use of agricultural fertilizers is the major source of contamination. Nitrate contamination depends on factors such as the amount of excess nitrate not used by plants, the soil type, and the underlying geology. Areas with soils that are sandy, gravelly, or shallow over porous limestone bedrock and areas with karsts topography (cave areas) have the greatest risk of nitrate contamination of groundwater sources.

The primary inorganic nitrates that may contaminate drinking water are KNO_3 and NH_4, both of which are widely used as fertilizers. Nitrates are highly soluble in water and do not bind to soils. They have a high potential to migrate to groundwater. Because they do not evaporate, nitrates are likely to remain in H_2O until consumed by plants or other organisms (3).

Nitrate is often the dominant source of nitrogen in the soil since it generally occurs in high concentrations and is free to move to the roots by mass flow and diffusion. In addition to KNO_3 and NH_4, other nitrate-containing fertilizers including $NaNO_3$ and $Ca(NO_3)$ are quite soluble and thus very mobile in soil solution. They are quickly available to crops because of their mobility. They are susceptible to leaching under conditions of high rainfall. Nitrate supplied in commercial fertilizer is subject to leaching. The $NO_3{}^-$ form of nitrogen is completely mobile and within limits moves largely with soil water. Under conditions of excessive precipitation or irrigation, it is leached out of the vadose zone.

Immobility of nitrate occurs when large quantities of low nitrogen crop residues begin decomposing in the soil. The high amounts of carbohydrate in such residues cause the population of microflora to build up quickly. As new cells are formed, nitrogen is used to build up protoplasm. Almost invariably this leads to a decrease in levels of nitrates. Biodegradation of nitrates occurs through processes such as denitrification (5).

A study by the United States Geological Survey for point and nonpoint sources in major U.S. watersheds indicated that agricultural nitrate accounted for over 80% of the nitrogen input into the environment: (53%) fertilizers, (27%) animal manure, (14%) atmospheric, and (6%) point sources (6).

GROUNDWATER INVESTIGATION

Nitrate is highly soluble in water and poorly retained in the soil; therefore, it can move through the soil and into groundwater sources. The likelihood and seriousness of leaching is of concern as the public cost of groundwater contamination is high. Studies have shown that more public supply wells have been impacted by nitrate contamination than all other contaminants combined. Frequent sampling for nitrate contamination should be conducted.

REMEDIATION

Several approaches for actively treating nitrate contamination have been proposed. The duration, success, and cost of treatment are dependent on the method used.

Phytoremediation using shrubs and specific types of plants to remediate a nitrate-contaminated aquifer is a passive but cost effective method to remove contaminants. However, it is a slow process and could take decades to clean up nitrate contamination.

Active pump and treat remediation is also used successfully in depleting nitrate contaminant. Nitrate reduction by denitrification where nitrate is sequentially reduced to nitrite, nitric oxide, and nitrogen gas is also effective.

Nitrate can be removed in anaerobic groundwater systems, such as may occur in natural or contaminated environments with elevated concentrations of dissolved organic matter, by bacterial action through the process of denitrification (7). It is the major microbial process that destroys nitrate by reducing it into nitrogen gas (N_2):

$$\begin{array}{ccccccccc} (1) & & (2) & & (3) & & (4) & & \\ NO_3^- & \rightarrow & NO_2^- & \rightarrow & [NO] & \rightarrow & N_2O & \rightarrow & N_2 \end{array}$$

Oxidation state:

$$\begin{array}{ccccc} +5 & +3 & +2 & +1 & 0 \end{array}$$

where (1) is nitrate reductase, (2) is nitrite reductase, (3) is nitric oxide reductase, and (4) is nitrous oxide reductase.

Bacteria use nitrate as a terminal electron acceptor when oxygen is not available. Denitrification has developed over millions of years and can occur readily in an oxygen-depleted environment (anaerobic) with abundant carbon and electron acceptors.

Electron acceptors include oxygen (O_2), nitrate (NO_3^-), nitrite (NO_2^-), manganese [Mn(IV)], ferric iron [Fe(III)], sulfate (SO_4^{2-}), and carbon dioxide (CO_2) (2). Usually by the time the sulfate and carbon dioxide are used as the electron acceptor or oxidant, the nitrate is already completely reduced to nitrogen gas (N_2). More information on denitrification can be found in References 2 and 8. The half-cell reaction for denitrification produces -16.9 kcal/mole $\cdot\, e^-$ of usable energy, also called the Gibbs free energy of reaction (9):

$$5e^- + 6H^+ + NO_3^- \rightarrow 0.5N_2 + 3H_2O$$

An injection of a carbon source into wells, well points, probe rods, trenches, or other delivery systems can move a nitrate-contaminated groundwater plume into the denitrification process, which will produce nitrogen gas as the end product. Laboratory bench testing is recommended prior to pilot scale field testing to optimize the site-specific geochemistry. Adjustments of pH or additions of nutrients may be required to optimize nitrate reduction rates.

Short-term solutions to high nitrate concentrations include bottled water and blending nitrate-impacted water with clean water to deliver water that is within the safe range for human consumption. Nitrate can be removed from drinking water by several physical/chemical methods, including distillation, reverse osmosis, electrodialysis or electrodialysis reversal, and ion exchange (4).

Distillation involves heating the water to boiling and collecting and condensing the steam generated as the water boils. Merely boiling water will increase rather than decrease the nitrate concentration. In the reverse osmosis process, pressure is applied to water to force it through a semipermeable membrane. As the water passes through the membrane, dissolved salts, including nitrate, are removed. Electrodialysis uses a driving force of direct current (DC) power to transfer ionic species (e.g., nitrate, sodium) from the feed water through cation and anion transfer membranes to a concentrated stream, creating a more dilute stream as the product water. Electrodialysis reversal is a variation on the electrodialysis process, in that it uses electrode polarity reversal to automatically clean membrane surfaces. Nitrate removal by ion exchange operates on the same principle as a household water softener. In a standard water softener, calcium and magnesium ions are exchanged for sodium ions. For nitrate removal, special anion exchange resins are used that exchange chloride ions for nitrate and sulfate ions in the water as it passes through the resin (4).

CONCLUSION

Nitrate is highly soluble and is subject to leaching. Therefore, it will migrate readily to groundwater sources. High levels of rainfall or frequent irrigating make groundwater sources more susceptible to nitrate contamination from agricultural fertilizers. Enhanced natural attenuation using a carbon source (such as propane gas, molasses, corn syrup, or lactic acid) can lead to denitrification of nitrates, producing nitrogen gas as the end product.

GROUNDWATER AND PERCHLORATE: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Shonel Dwyer
Environmental Bio-Systems, Inc.
Mill Valley, California

Large-scale perchlorate production began in the 1940s. Perchlorate leakage has been ongoing in some cases for decades. The majority of perchlorate spills are related to the use of explosive propellant as a solid rocket fuel for missiles and for the NASA space shuttle. It has only been since the late 1990s, when laboratory methods improved detection of perchlorate in the groundwater, that the full impact of the groundwater contamination became evident. A variety of point of use treatments for perchlorate are available, at varying efficiencies and costs. Of the various *in situ* technologies, anaerobic bioremediation is the most promising for widespread subsurface perchlorate treatment.

INTRODUCTION

The environmental impact/toxicity of perchlorate is an active area of research, critical to the protection of groundwater resources. Perchlorate ($ClO_4{}^-$) is the soluble anion associated with the solid salts of ammonium, magnesium, potassium, and sodium perchlorate. Perchlorate is used in the United States to make rocket fuel, fireworks, road flares, and similar products. It remains one of the key ingredients in numerous national defense weapons systems. The occurrence of perchlorate in public drinking water supplies over the years may be inextricably linked with inadequate maintenance, storage, and disposal practices followed in the past. Consequently, varying quantities of the compound leached into the soil and groundwater, especially at or near sites that developed or manufactured aerospace materials or armaments for U.S. national defense programs.

Contamination of numerous sites is highest in California, where cities like Rialto, already affected by drought and increasing population, are continuing to lose water capacity to perchlorate contamination and its spreading plume. Perchlorate is an unregulated contaminant in the United States, meaning it does not have a set maximum concentration level (MCL). A good overview of perchlorate issues is summarized by Motzer (1).

Perchlorate

Perchlorate has the following uses:

- As a solid propellant in rockets, missiles, and fireworks (primarily ammonium perchlorate)
- In road flares
- As a component of airbag inflators
- In munitions for smokeless powder
- In nuclear reactors and electronic tubes
- As additive in lubricating oils
- In tanning and finishing leather
- As a mordant for fabrics and dyes
- In electroplating, aluminum refining, and rubber manufacture
- In the production of paints and enamels
- As a component of certain imported Chilean fertilizers

About 90% of the 20 million pounds of perchlorate produced each year goes into solid rocket fuel for Air Force missiles and the NASA space shuttle (2). Although the vast majority of locations where perchlorate has been detected in the groundwater are influenced by anthropogenic activity, perchlorate has been found to occur naturally in Chilean caliche. Perchlorate is reported to be present in some caliche formations in Chile that are used to produce nitrate fertilizers (3).

Ammonium Perchlorate (ClH_4NO_4)

Ammonium perchlorate is used as an energetics booster or oxidant in solid propellant for rockets and missiles. It is therefore a national technical asset integral to the nation's strategic defense system and space exploration. Ammonium perchlorate is also used in certain fireworks, the manufacture of matches, as a component of airbag inflators, and in analytical chemistry to preserve ionic strength. Large-scale production of ammonium perchlorate began in the United States in the mid-1940s. Ammonium perchlorate has a limited shelf life and must be periodically replaced in munitions and rockets or in inventory. This has led to the disposal of large volumes of the compound since the 1940s in Nevada, California, Utah, and other states.

Potassium Perchlorate ($KClO_4$)

Potassium perchlorate until recently was used to treat hyperthyroidism resulting from Graves' disease and is still used diagnostically to test thyroid hormone production in some clinical settings (medicinal use). In addition, potassium perchlorate is used in protective breathing equipment on Air National Guard (ANG) aircraft for use in the event of depressurization, and in naval emergency escape breathing devices (4).

Sodium Perchlorate (NaClO4:H_2O)

Sodium perchlorate is mainly used in the manufacture of perchloric acid, also used in the gun-powder industry.

HISTORY OF OCCURRENCE

Several hundred drinking water wells were sampled by the California Department of Health Services (CDHS) for perchlorate beginning February 1997. Perchlorate was first detected in drinking water wells (up to 260 μg/L) near the Aerojet site in Sacramento County. Groundwater treated to remove volatile organic chemicals (such as trichloroethylene) was reinjected into the groundwater. Perchlorate, also in the contaminated shallow groundwater, has been present in the reinjected water at concentrations up to 8000 μg/L (5).

Characteristics of Perchlorate

Perchlorate is a highly soluble inorganic anion (2.09 kg/L for $NaClO_4{}^-$) that adsorbs poorly to mineral surfaces and activated carbon and is not retarded during groundwater transport.

Persistence of Perchlorate in Groundwater

Perchlorate is very stable/inert in groundwater. It does not biodegrade unless there is an absence of available, dissolved oxygen (oxygen acts as an alternate electron acceptor). Groundwater has naturally occurring dissolved oxygen, which microbes will use first before turning to other sources, so natural biodegradation of perchlorate is unlikely.

Plumes may be nearly 8 miles (which is large). Perchlorate may disperse in the aquifer as it flows downgradient in the subsurface, to the extent that it may not be detectable using available analytical methods.

Taste and Odor

There is no perceptible odor or taste that perchlorate imparts to water.

Fate and Transport

Fate and transport of the chemical essentially depend on its physical characteristics and natural attenuation. Perchlorate is highly soluble in groundwater. Volatilization is not expected to be one of the predominant pathways of transport. Perchlorate and concentrated solutions of perchlorate are denser than water (ammonium perchlorate at 1.95 g/mL), which allows it to sink. Perchlorate is kinetically stable and adsorbs poorly to mineral surfaces and activated carbon and is not retarded during groundwater transport.

HEALTH RISKS

At present, there is a large amount of information available on the health effects from exposure to perchlorate; however, there is still widespread debate on the potential toxicity of perchlorate, the ecological receptors, and the long-term effects on humans. Health studies using data from patients who were given perchlorate to treat thyroid conditions indicate that high doses can affect metabolism, growth, and development of the body. Long-term exposure to high levels of perchlorate taken as medication has been linked to a potentially serious blood disorder. However, it is impossible for the levels of perchlorate in drinking water to cause such conditions. Perchlorate slows the uptake of iodide into the thyroid. Because iodide is an essential component of thyroid hormones, at high doses perchlorate can affect how the thyroid functions. In adults, the thyroid helps to regulate metabolism; in children, the thyroid also plays a role in proper development (6).

A clinical study using human volunteers was performed to determine whether levels of perchlorate similar to the low levels that are currently being found in the groundwater are safe for people. This human study was performed in the same way that pharmaceutical studies look at the effect that soon-to-be-approved medicines have on people. At the low levels used in the study, no health effects were observed (7). In Chile, an epidemiological study was performed on pregnant women who drank water that contained naturally occurring perchlorate, at levels at least 10 times higher than what we've detected in our drinking water. There were no health effects observed (8).

The maximum contaminant level (MCL) has not been established by the U.S. Environmental Protection Agency and review and evaluation are ongoing. California has more perchlorate sites than any other state or country. Until the MCL is in place, the California Department of Health Services (CDHS) will continue to use a 6-μg/L perchlorate level as a notification level or public health goal with which to protect water consumers (5).

Perchlorate is easily absorbed into the bloodstream after ingestion but leaves the body very quickly. Infants and small children may be more sensitive to perchlorate than adults. The U.S. Environmental Protection Agency (EPA) is focusing on those most sensitive in its ongoing evaluation. Perchlorate does not appear to cause cancer at low levels that are currently being measured in drinking water. Perchlorate does not cause Graves' disease. Perchlorate does not cause changes in thyroid hormones at the levels that are currently being measured in drinking water (6).

GROUNDWATER INVESTIGATION

Widespread perchlorate contamination of groundwater only became known when a new ion chromatography (IC) method lowered the anion's detection limit in water from 400 parts per billion (ppb) to 100 ppb. After more refinement in the spring of 1997, a method was developed (EPA Method 314 using IC-MS or LC-MS-MS) that could quantify perchlorate concentrations to a limit of 4 ppb (9,10).

REMEDIATION

Treatment of perchlorate contamination in water is essentially complex. The perchlorate anion does not respond to typical water treatment techniques due to its fundamental physical and chemical nature. Chemical oxidation, granular activated carbon, and air sparging technologies have been evaluated as being relatively ineffective for perchlorate treatment. Tailored granular activated carbon impregnated with special amine coatings are being used with success for point of use applications. Fluidized bed bioreactors are being used at the Kerr McGhee, Henderson, Nevada Site. At that site, perchlorate influent is approximately 180 ppm; after 45 min of contact time, the effluent is less than 4 ppb (A. Eaton, personal communication, 2004).

The ideal treatment technology for a given perchlorate occurrence may depend on a number of factors, including perchlorate concentration, the presence and concentration of cocontaminants, pH, alkalinity, presence of natural organic matter (NOM), amount of total dissolved solids (TDS), presence of metals, and geochemical parameters (nitrate, sulfate, chloride, dissolved oxygen, redox potential, etc.). The presence of indigenous perchlorate-reducing microbes and substances inhibitory to microbial activity will also influence perchlorate treatment technology effectiveness. For *in situ* treatment of perchlorate contamination, variables related to the site hydrogeological setting, such as depth to and distribution of contaminants, soil permeability, and groundwater flow velocity, are also important.

PHYSICAL REMOVAL TECHNOLOGIES

Ion Exchange

This is a process with two similar applications of the same technology:

- Water softening removes ions from the water and replaces them with sodium (Na^+) and chloride (Cl^-) ions. This technique is employed at Aerojet, Sacramento, California.
- Deionization removes ions and replaces them with hydrogen (H^+) and hydroxyl (OH^-) ions, which combine to form water.

Ion exchange treatment has been successful in reducing perchlorate concentrations in water from 75 ppb to less than detectable levels at the San Gabriel Valley Superfund sites. Resulting brines from the ion exchange process can be problematic because the perchlorate is concentrated and not destroyed. Ion exchange is the preferred large-scale treatment method used by utilities for aboveground treatment of perchlorate.

Single Pass Adsorption Resins

This technology uses nonregenerative single-pass adsorption resins, which are tailored for perchlorate. This technology is currently being used by municipalities for large-scale water treatment.

Membrane Techniques

- *Reverse Osmosis and Nanofiltration*. This technology uses semipermeable membranes, allowing the water to pass through it, while retaining perchlorate. RO and NF can be costly due to the energy use and perchlorate disposal. They are typically used on small-scale systems.
- *Electrodialysis*. This is an electrically driven membrane separation process that separates ions from water. The process is based on the property of ion exchange membranes to selectively reject anions or cations.

In Situ Biological Treatment

In situ anaerobic biological remediation of perchlorate-contaminated waters is promising. The anaerobic conversion of chlorine in perchlorate to chloride requires the overall transfer of eight electrons (11):

$$\text{perchlorate}(ClO_4{}^-) \longrightarrow \text{chlorate}(ClO_3{}^-) \longrightarrow \text{chlorite}\ (ClO_2{}^-) \longrightarrow \text{oxygen}\ (O_2) + \text{chloride}\ (Cl^-)$$

The perchlorate and chlorate are used as electron acceptors (11). An *in situ* treatment zone or wall could be emplaced with a biodegradable carbon source, such as propane (gas infusion), molasses, corn syrup, or lactic acid.

CONCLUSION

Perchlorate plumes have been developing for decades. New technologies are being developed for aboveground and *in situ* treatment for perchlorate.

GROUNDWATER AND VINYL CHLORIDE: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Angela Munroe
Environmental Bio-Systems, Inc.
Mill Valley, California

Vinyl chloride is a colorless, flammable gas at normal temperatures with a mild, sweet odor. It exists in liquid form if it is kept under high pressure or at low temperatures (less than −13.4 °C). Vinyl chloride is also known as chloroethene, chloroethylene, and ethylene monochloride (1). All vinyl chloride is manufactured or results from the breakdown of other manufactured substances, such as trichloroethane (TCA), tetrachloroethylene (PCE), and trichloroethylene (TCE). Vinyl chloride was first produced commercially in the 1920s and is now one of the highest volume chemicals produced in the United States (2). Of the vinyl chloride produced, 96–98% is used to make poly(vinyl chloride) (PVC) with the remaining 2–4% being utilized in the manufacture of specific chlorinated hydrocarbons such as 1,1,1-TCA, 1,1,2-TCA, and vinylidene chloride (3). PVC is used to make a variety of plastic products including pipes, wire, cable coatings, and packaging materials. Other uses include furniture and automobile upholstery, wall coverings, housewares, and auto parts. Vinyl chloride has been used in the past as a refrigerant, an extraction solvent for heat-sensitive materials, and in the production of chloroacetaldehyde and methyl chloroform (4). Also, limited quantities of vinyl chloride were used as an aerosol propellant and as an ingredient in drug and cosmetic products (4). However, these practices were banned by the United States Environmental Protection Agency (U.S. EPA) in 1974.

CHARACTERISTICS

Vinyl chloride is a colorless, flammable gas with a faintly sweet odor. It is slightly soluble in water, soluble in ethanol, and very soluble in ether, carbon tetrachloride, and benzene. It is extremely flammable and is easily ignited by heat, sparks, or flames. Explosive mixtures will form with air, and it tends to self-polymerize explosively if peroxidation occurs. It reacts vigorously with oxidizers and, in the presence of moisture, corrodes iron and steel. Fires may release irritating and toxic gases including carbon dioxide, carbon monoxide, hydrogen chloride, and traces of phosgene (2). A good overview of chlorinated solvents and vinyl chloride is included in Reference 5.

PRODUCTION

Vinyl chloride was first produced commercially in the 1920s (2). In the Unites States, production of vinyl chloride steadily increased from approximately 6 to 9 billion pounds per year in the late 1970s through the 1980s to approximately 15 billion pounds per year in the mid-1990s (2). The projected demand for 2001 was 16.8 billion pounds (2). There are at least 11 current chemical suppliers of vinyl chloride in the United States. Imports reached a peak of 302 million pounds in 1989. In 2000, the United States imported more than 231 million pounds compared to 29 million pounds in 1994 and 164 million pounds in 1991 (1). Exports fluctuated from approximately 685 million pounds per year to 2.2 billion pounds per year from the late 1970s to the mid-1990s (1). In 2000, U.S. exports were approximately 1.03 billion pounds (2).

Commercial Production of Vinyl Chloride

Vinyl chloride is produced commercially by the chlorination of ethylene through one of two processes, direct chlorination or oxychlorination. Direct chlorination reacts ethylene with chlorine to produce 1,2-dichloroethane. Similarly, oxychlorination produces 1,2-dichloroethane, but this is accomplished by reacting ethylene with dry hydrogen chloride and oxygen:

$$\mathrm{HCl} + \mathrm{H_2C{=}CH_2} + 0.5\ \mathrm{O_2} \longrightarrow \mathrm{Y\ H_2C{=}CHCl} + \mathrm{H_2O}$$

After both processes, the 1,2-dichloroethane is subjected to high pressures (2.5–3.0 MPa) and temperatures (550–550 °C) (1). This causes the 1,2-dichloroethane to undergo pyrolysis, or thermal cracking, which forms the vinyl chloride monomer and hydrogen chloride. The vinyl chloride monomer is then isolated. The technical-grade product is available in 99.9% purity (1).

Production of Vinyl Chloride in Groundwater

Vinyl chloride is produced in groundwater through the biodegradation of chlorinated solvents such as PCE and TCE. Biodegradation is a process in which naturally occurring microorganisms, such as yeast, fungi, and bacteria, break down target substances, such as fuels and chlorinated solvents (6). In the absence of oxygen, microorganisms often use chlorinated compounds to aid in respiration. This is done through an electron transfer process called dehalorespiration (7). In the case where the carbon in the contaminant is the food source, the contaminant is an electron donor. In the case where food is obtained from another source, the contaminant sometimes aids this transfer by accepting electrons that are shed through respiration (6). The most common anaerobic process for degrading chlorinated compounds is an electron transfer process called reductive dechlorination. In this process, hydrogen atoms are sequentially substituted for a chlorine atom in the contaminant molecules. PCE is reductively chlorinated stepwise through TCE, DCE, vinyl chloride, and then to ethene (ethylene). However, vinyl chloride resists reductive dechlorination once it is formed. The major requirement for reductive dechlorination is the presence of other organic compounds, such as fuels, that can serve as the food source (7).

FATE AND TRANSPORT

Anthropogenic sources are responsible for all of the vinyl chloride found in the environment. Most of the vinyl chloride released to the environment is eventually transported to the atmosphere. Lesser amounts are transported to groundwater. Vinyl chloride has been detected in the ambient air near vinyl chloride and PVC manufacturing plants and hazardous waste sites. It has been found in tobacco smoke, perhaps as a result of the manufacturing process (8). When vinyl chloride is released to the ground, it is not adsorbed onto soil; it migrates readily to groundwater, where it degrades to carbon dioxide and the chloride ion. It may also remain unchanged for several months to years. Vinyl chloride has been reported in groundwater as a degradation product of chlorinated solvents TCE and PCE (9).

Effluents and emissions from vinyl chloride and PVC manufacturers are responsible for most of the vinyl chloride released to the environment. It has entered the environment at hazardous waste sites as a result of its improper disposal or leakage from storage containers or from spills. When released to the atmosphere, vinyl chloride is expected to be removed by reaction with photochemically generated hydroxyl radicals (half-life = 1–2 days). When vinyl chloride breaks down in air, it can form other harmful chemicals. Reaction products include hydrochloric acid, formaldehyde, formyl chloride, acetylene, chloroacetaldehyde, chloroacetylchloranil, and chloroethylene epoxide. In photochemical smog, the half-life of vinyl chloride is reduced to a few hours. When released to water, volatilization is expected to be the primary fate process. In waters containing photosensitizers, such as humic materials, sensitized photodegradation may also be important. When released to soil, vinyl chloride either volatilizes rapidly from soil surfaces or leaches readily through soil, ultimately entering groundwater (1).

DISPOSAL

The recommended method of disposal is total destruction by incineration. The temperature of the incinerator must be sufficient to ensure the complete combustion of the vinyl chloride in order to prevent the formation of phosgene. The recommended temperature range for incineration is 450–1600 °C, with residence times of seconds for gases and liquids, and hours for solids (1). If in solution, the vinyl chloride product may need to be adsorbed onto a combustible material prior to incineration. Recommended materials include vermiculite, sawdust, or a sand–soda ash mixture (90/10) covered with wood and paper (1). The vinyl chloride can also be dissolved in a flammable solvent prior to incineration. An acid scrubber should be used in conjunction with the incinerator in order to remove any hydrogen chloride that is produced by the combustion process (1). Alternatively, chemical destruction may be used, especially with small quantities. From 1 to 2 days is generally sufficient for complete destruction. Aqueous by-product solutions from the production of vinyl chloride are usually steam-stripped to remove volatile organic compounds, neutralized, and then treated in an activated sludge system to remove nonvolatile organic compounds remaining in the wastewater (1).

EXPOSURE

Historically, exposure to vinyl chloride has been in the industrial workplace, in particular, from inhalation of factory air. As industry has made efforts to better protect workers from vinyl chloride exposure, attention has also been drawn to other avenues of exposure, such as environmental and commercial (10).

Since vinyl chloride commonly exists in a gaseous state, one is most likely to be exposed to it by breathing it in. Vinyl chloride is not normally found in urban, suburban, or rural air in amounts that are detectable by the usual methods of analysis. However, vinyl chloride has been found in the air near plastics industries, hazardous waste sites, and landfills. The amount of vinyl chloride in the air near these places ranges from trace amounts to 0.041 mg/L of air, but may exceed 1 mg/L. Levels as high as 44 mg/L have been found at some landfills. One can also be exposed to vinyl chloride in the air through tobacco smoke from cigarettes or cigars (10). Workers who produce or use vinyl chloride and PVC are at a high risk of exposure by breathing vapors in the workplace air, or if the chemical comes into contact with their skin or eyes (4)

Exposure to vinyl chloride may also occur by drinking water from contaminated wells, but how often this occurs is not known. Most drinking water supplies do not contain vinyl chloride. In a 1982 survey, vinyl chloride was found in less than 1% of the 945 groundwater supplies tested in the United States. The concentrations found in groundwater were up to 0.008 mg/L, with a detection limit of 0.001 mg/L. Other studies have reported groundwater vinyl chloride concentrations at or below 0.38 mg/L (8). High concentrations up to 200,000 μg/L were detected in well water in the vicinity of a PVC plant in Finland ten years after leakages (9).

At one time, the flow of water through PVC pipes added very low amounts of vinyl chloride to water. For example, in one study of newly installed pipes, the drinking water had 0.001 mg/L of vinyl chloride. No current information on the amount of vinyl chloride released from PVC pipes into water is available (8).

Owing to its high volatility, vinyl chloride has rarely been detected in surface waters; the concentrations measured generally do not exceeding 10 μg/L, with a maximum of 570 μg/L from contaminated sites (9). A recent example is the finding of vinyl chloride up to 56 μg/L together with other volatile organic compounds in heavily polluted shallow rivers in Osaka, Japan (11).

Once set, poly(vinyl chloride) by itself is a hard, brittle, and inflexible material. To induce the flexibility needed for products such as food wraps, plasticizers are added. Poly(vinyl chloride) food wrappings, however, pose a potential problem as monomers and oligomers of vinyl chloride as well as some plasticizers can migrate into food from the wrappings (10). The U.S. government now regulates the amount of vinyl chloride in food packaging materials. A model of food systems shows that when levels less than 1 mg/L of vinyl chloride monomer are used in PVC packaging, “essentially zero” vinyl chloride enters food by contact with these products (8).

Estimated Total Exposure and Relative Contribution from Drinking Water

If an ambient air concentration of 0.1–2.0 μg/m^3 and a daily inhalation of 20 m^3 of air are assumed, daily intake by the inhalation route would amount to 2–40 μg. For those living and working in industrial areas, in particular, near vinyl chloride/PVC polymerization plants or near waste sites, this could be at least a factor of ten or more higher (i.e., daily intake 20–400 μg).

At a concentration of 1–2 μg/L in drinking water, daily intake would be about 2–4 μg. Daily intake from food has been estimated to be about 0.02–0.025 μg (9). It appears that inhalation is the most important route of vinyl chloride intake, although drinking water may contribute a substantial portion of daily intake where PVC piping with a high residual content of vinyl chloride monomer is used in the distribution network, in particular, in hot countries or where drinking water is from wells near sites contaminated with chlorinated hydrocarbons. Boiling drinking water reduces the risk of contamination of water with vinyl chloride (9).

HEALTH EFFECTS

A wide variety of deleterious health effects have been attributed to vinyl chloride exposure. However, prior to the 1974 discovery at the B. F. Goodrich plant in Kentucky, where the factory’s doctor linked vinyl chloride exposure to angiosarcoma, most toxicologists believed that vinyl chloride did not pose a serious health risk. In fact, prior to 1974, the “safe” exposure level was set at 200 mg/L, rather than the 5 mg/L and under levels, which are standard for most jurisdictions today. The discovery in 1974 set in motion a series of events that led government, industry, labor, and science to the realization of the hazards of vinyl chloride exposure. Subsequently, industry, labor, and government all supported research into the biological consequences of vinyl chloride exposure (10).

Short-Term Exposure

Breathing high levels of vinyl chloride leads to feelings of dizziness and sleepiness. These effects occur within 5 min at about 10,000 mg/L of vinyl chloride. One can easily smell vinyl chloride at this concentration and one can rapidly recover from these effects by breathing fresh air (8). Limited exposure to vinyl chloride may also induce a feeling of dullness, nausea, and headache; irritate the eyes, mucous membranes, and respiratory tract; and have neurotoxic and dermatological effects. Escaping compressed gas or liquid can cause frostbite or irritation of the skin and eyes (1). It is difficult to clearly define the duration of a short-term or limited exposure, and its effect will almost surely differ from person to person (10).

Long-Term Exposure

There are many possible consequences of long-term exposure to vinyl chloride. These include various forms of liver disease such as liver sarcoma and liver carcinoma, as well as diseases in other tissues such as lung cancer, digestive system cancers, cardiovascular disease, genetic defects, and even melanoma. In the case of angiosarcoma, which appears to be the signature disease of long-term vinyl chloride exposure, the average length of exposure to vinyl chloride necessary to trigger angiosarcoma development has been estimated at 18 years, though a recent study has documented workers with as little as 3.5 and 4 years of exposure contracting angiosarcoma (10). Another condition attributed to prolonged vinyl chloride exposure is a cold-induced pallor of the extremities, referred to as Raynaud’s syndrome. A potentially serious side effect of chronic exposure to vinyl chloride, even at low doses, is associated with the body’s defense mechanisms. More medical information is contained in the ATSDR Medical Management Guidelines report (12).

Many of the health effects listed above are specific to workers in VC and PVC factories. These include sclero dermiform lesions, acroosteolysis, Raynaud’s syndrome, and liver function abnormalities (10). Some men who work with vinyl chloride have complained of a lack of sex drive. Results of studies in animals show that long-term exposure may damage the sperm and testes. Some women who work with vinyl chloride have had irregular menstrual periods. Some have developed high blood pressure during pregnancy. Studies of women who live near vinyl chloride manufacturing plants could not prove that vinyl chloride causes birth defects. Studies using pregnant animals show that breathing vinyl chloride may harm their unborn offspring. Animal studies also show that vinyl chloride may cause increased numbers of miscarriages early in pregnancy. It may also cause decreased weight and delayed skeletal development in fetuses. The same very high levels of vinyl chloride that caused these fetal effects also caused adverse effects in the pregnant animals (8).

Mutation and Cancer

Vinyl chloride has been shown to be mutagenic in almost all assay systems in which it has been tested. Phylogenetically, vinyl chloride has been shown to be mutagenic in all life forms tested including bacteria, yeast, insects, plants, mammalian cells in culture, human cells, and whole animals. In fact, vinyl chloride is currently used as the positive control substance in many studies. Vinyl chloride is known to induce almost a full spectrum of mutations including several types of point mutations and chromosome aberrations. Studies have indicated that certain chromosomes elicit a greater sensitivity to vinyl chloride than most of the chromosomes, suggesting some degree of specificity in the action of vinyl chloride (10).

Results from several studies suggest that breathing air or drinking water containing low levels of vinyl chloride may increase the risk of getting cancer. The monomer of vinyl chloride is a potent human carcinogen while only a weak to moderate animal carcinogen. Unlike many carcinogens, the carcinogenic metabolite(s) of vinyl chloride is considered a complete carcinogen; that is, it does not need a cocarcinogen to produce cancer. In rodents, the mechanism by which vinyl chloride and its metabolites transform normal cells into the neoplastic state appears to initially follow the pathway involved in the development of genotoxic effects (10). The primary cancer produced by vinyl chloride is its signature disease, angiosarcoma. Sarcomas of the liver are extremely rare and have been strongly linked to vinyl chloride exposure. Evidence also exists, however, that links vinyl chloride to hepatocellular carcinoma, cancers of the digestive system, lung cancer, brain cancer, and melanoma. Many cohort and epidemiology studies have attempted to correlate exposure to vinyl chloride with the abovementioned cancers. In almost all cases, the clearest correlation is with angiosarcoma. Studies indicate that induction of angiosarcoma generally requires a fairly extensive exposure (∼18 years) to vinyl chloride. Based on at least one calculation, the latency period, the time from the initial exposure to the onset of the disease, for angiosarcoma is approximately 22.6 years. From this calculation, it has been estimated that by the year 2010 there will be another 500 cancer-related mortalities in North America and approximately 2000 more in Europe due to previous vinyl chloride exposure (10).

DETECTION OF VINYL CHLORIDE

Biological Samples

The analytical method used to analyze for the presence of vinyl chloride in biological samples is separation by gas chromatography (GC) combined with detection by mass spectrometry (MS), flame ionization detector (FID), or electron capture detector (ECD). Vinyl chloride and/or its metabolite, thiodiglycolic acid, have been detected in breath, urine, blood, and tissues. Breath samples can be concentrated by cryogenic trapping. The two methods most commonly used to prepare liquid and solid samples are concentration by a purge-and-trap technique or headspace analysis. Concentration not only increases the sensitivity but also, in certain instances, may decrease the sample separation time prior to quantization (1).

Vinyl chloride can be determined in exhaled air by concentration with a multistage cryogenic trapping system followed by thermal desorption using GC/FID, GC/ECD, and GC/MS (1). Sensitivity is in the low-ppb range. One limitation of this method is its reduced ability to detect vinyl chloride when air concentrations in the workplace are below 50 mg/L (1).

Environmental Samples

Analysis of environmental samples is similar to that of biological samples. The most common methods used to detect vinyl chloride in environmental samples are GC/MS, GC/ECD, and GC/FID. Concentration of samples is usually done by sorption on solid sorbent for air and by the purge-and-trap method for liquid and solid matrices. Alternatively, headspace above liquid and solid samples may be analyzed without preconcentration (1).

Air. The primary method of analyzing vinyl chloride in air is GC combined with MS, ECD, or FID. Air samples are usually pumped through a sample collection column with Tenax-GC, coconut activated charcoal, or spherocarb (a carbon molecular sieve material) as the most common adsorbents. It has been noted that Tenax-GC displays poor retention for vinyl chloride when the compound is present in the very low ppb range (1).

Vinyl chloride is thermally desorbed from the collection column and concentrated on a cryogenic trapping column located on the gas chromatograph. Vapors are heat released from the trapping column directly to the gas chromatograph (1). Grab samples of air can also be obtained and preconcentrated on a cryogenic trapping column. With careful technique, precision is adequate, ranging from 5% to 20% (1).

Water. Vinyl chloride can be detected in drinking water, groundwater, wastewater, and leachate from solid waste. Analysis of vinyl chloride is done by purge-and-trap or headspace GC. The primary analytical method is separation by GC combined with MS, ECD, FID, Hall's electrolytic conductivity detector (HECD), or another type of halogen-specific detector (HSD). In most methods, vinyl chloride is liberated from the liquid matrix by purging with an inert gas and concentrated by trapping on a suitable solid sorbent. Vinyl chloride is thermally desorbed and back flushed onto the column of the gas chromatograph with an inert gas. Detection of vinyl chloride is generally achieved using HECD, HSD, or MS (1). Accuracy is greater than 98% and precision ranges from 11% to 25% for GC/HECD and GC/MS (1).

REGULATIONS

In September 1974, eight months after a correlation between angiosarcoma and vinyl chloride exposure was observed, the U.S. EPA established a national emissions standard for vinyl chloride which came into effect two years later when published as part of the U.S. Clean Air Act (October 1976) (10).

The U.S. EPA requires that the amount of vinyl chloride in drinking water not exceed 0.002 mg/L. It is also required that spills or accidental releases into the environment of 1 lb or more of vinyl chloride be reported to the EPA (1). The Occupational Safety and Health Administration (OSHA) set the maximum allowable level of vinyl chloride in workroom air during an 8-h workday in a 40-h workweek at 1 mg/L (1).

The EPA has set emission standards for vinyl chloride and PVC plants. The amount of vinyl chloride allowed to be emitted varies depending on the type of production and discharge system used. To limit intake of vinyl chloride via foods to levels considered safe, the Food and Drug Administration (FDA) regulates the vinyl chloride content of various plastics. These include plastics that carry liquids and plastics that come into contact with food. The limits for vinyl chloride content vary depending on the nature of the plastics and its use (4). However, the FDA has set the allowable level for vinyl chloride at 0.002 mg/L in bottled water (2).

GROUNDWATER REMEDIATION

A variety of technologies can be used for VC removal and destruction. Selected technologies are described below.

In Situ Biological Treatment

In situ bioremediation techniques are destruction techniques directed toward stimulating the microorganisms to grow and use the contaminants as a food and energy source by creating a favorable environment for the microorganisms. Generally, this means providing some combination of oxygen (electron acceptor), nutrients, and moisture, controlling the temperature and pH for aerobic conditions, providing a carbon source as a food source and nutrients and moisture, and controlling the temperature and pH for anaerobic conditions.

Contaminants are usually destroyed and little to no residual treatment is required. Some compounds break down and the breakdown products are more toxic than the original product: for example, PCE and TCE, which break down to form the more toxic vinyl chloride. For *in situ* applications, the vinyl chloride may be mobilized in groundwater if no control techniques are used.

Enhanced Biodegradation. The rate of bioremediation of organic contaminants by microbes is enhanced by increasing the concentration of electron acceptors and nutrients in groundwater, surface water, and leachate. Oxygen is the main electron acceptor for aerobic bioremediation. Nitrate, manganese (4+), iron (3+), sulfate, and ultimately carbon dioxide serve as an alternative electron acceptor under anaerobic and reducing conditions.

Although vinyl chloride can be released into the environment as a liquid product, vinyl chloride is also a degradation by-product of the anaerobic reductive dechlorination process that starts with tetrachloroethylene (PCE) (4 chlorine atoms) and proceeds to trichloroethylene (TCE) (3 chlorine atoms) and moving through *cis*-1,2-dichloroethene (*cis*-1,2-DCE) (2 chlorine atoms) before creating vinyl chloride (VC) (1 chlorine atom) by primarily biological reactions. Other pathways to VC include limited biological reactions from 1,1-dichloroethene (1,1-DCE) and *trans*-1,2-dichroloethene (*trans*-1,2-DCE) (13). For chlorinated solvents, the carbon source for anaerobic degradation is a food source and the contaminant is the anaerobic electron acceptor.

Once at VC, the aerobic breakdown of VC into ethene and later into ethane is best done using oxygen as the electron acceptor under aerobic conditions. Oxygen enhancement for VC breakdown can be achieved by a variety of methods: air sparging, pure oxygen gas infusion using mass transfer tools in monitoring wells, and injection of peroxide compounds [hydrogen peroxide (H_2O_2), calcium peroxide (CaO_2), and, to a lesser extent, magnesium peroxide (MgO_2)]. Even ozone (O_3) can be used as an oxygen source. Vinyl chloride has been observed to degrade four times faster under aerobic conditions than under anaerobic conditions (14).

In Situ Physical/Chemical Treatment

Physical/chemical treatment uses the physical properties of the contaminants or the contaminated medium to destroy (i.e., chemically convert) or separate the contamination. Available *in situ* physical/chemical treatment technologies include chemical oxidation, air sparging, bioslurping, directional wells, dual phase extraction, thermal treatment, hydrofracturing, in-well air stripping, passive/reactive treatment walls, and soil vapor extraction (SVE).

Chemical Oxidation. The chemical oxidants most commonly employed to date include rapidly reacting hydrogen peroxide, Fenton's reagent, and ozone. Slower oxidizers include potassium permanganate and sodium persulfate. These oxidants have been able to cause the complete chemical destruction of many toxic organic chemicals including vinyl chloride. In general, the oxidants have been capable of achieving high treatment efficiencies (>90%) for chlorinated solvents. Field applications have clearly affirmed that matching the oxidant and *in situ* delivery system to the contaminants of concern and the site conditions is the key to successful implementation and achieving performance goals. Bench testing is recommended prior to performing pilot studies in the field. Oxidant delivery systems often employ vertical or horizontal injection wells and sparge points, probe rods, or lances under pressures from 40 psi up to 5000 psi. Reaction temperatures, pH, DO, and other field variables are used to help monitor progress of the subsurface reactions.

Passive Reactive Treatment Walls. Passive reactive treatment walls are barriers that allow the passage of water while causing the degradation or removal of contaminants. A permeable reaction barrier (PRB) is installed across the flow path of a contaminant plume, allowing the water portion of the plume to passively move through the wall. These barriers allow the passage of water while prohibiting the movement of contaminants by employing such agents as zero-valent metals, chelators (ligands selected for their specificity for a given metal), sorbents, and microbes. The contaminants will either be degraded or retained in a concentrated form by the barrier material. The wall could provide permanent containment for relatively benign residues or provide a decreased volume of the more toxic contaminants for subsequent treatment. An iron treatment wall consists of iron granules or other iron-bearing minerals for the treatment of chlorinated contaminants such as TCE, DCE, and vinyl chloride. As the iron is oxidized, a chlorine atom is removed from the compound by one or more reductive dechlorination mechanisms, using electrons supplied by the oxidation of iron. The iron granules are dissolved by the process, but the metal disappears so slowly that the remediation barriers can be expected to remain effective for many years, possibly even decades.

Soil Vapor Extraction. Soil vapor extraction (SVE) is an *in situ* unsaturated (vadose) zone soil remediation technology in which a vacuum is applied to the soil to induce the controlled flow of air and remove volatile and some semivolatile contaminants from the soil. The gas leaving the vadose zone may be treated to recover or destroy the contaminants, depending on local and state air discharge regulations.

For the soil surface, plastic sheeting or membranes are often placed over the soil surface to prevent short circuiting and to increase the radius of influence of the wells. Groundwater depression pumps may be used to reduce groundwater upwelling induced by the vacuum or to increase the depth of the vadose zone. Air injection is effective for facilitating extraction of deep contamination, contamination in low permeability soils, and contamination in the saturated zone. The duration of operation and maintenance for *in situ* SVE is typically medium to long term. Dual phase extraction is a variation of the SVE–groundwater extraction approach that can be used successfully with VC.

Ex Situ Physical/Chemical Treatment

Once the VC is extracted using SVE or groundwater extraction, the contaminant must be treated and destroyed on the surface.

Advanced Oxidation Processes. Advanced oxidation processes including ultraviolet (UV) radiation, ozone, and/or hydrogen peroxide are used to destroy organic contaminants as water flows into a treatment tank. UV oxidation is a destruction process that oxidizes organic and explosive constituents in wastewater by the addition of strong oxidizers and irradiation with UV light. Oxidation of target contaminants is caused by direct reaction with the oxidizers, UV photolysis, and through the synergistic action of UV light, in combination with ozone and/or hydrogen peroxide. If complete mineralization is achieved, the final products of oxidation are carbon dioxide, water, and occasionally salts. Easily oxidized organic compounds such as those with double bonds (e.g., vinyl chloride) are rapidly destroyed in UV/oxidation processes.

The main advantage of UV oxidation is that it is a destruction process, as opposed to air stripping or carbon adsorption, for which contaminants are extracted and concentrated in a separate phase. UV oxidation processes can be configured in batch or continuous flow modes, depending on the residence treatment time required. The UV oxidation process is generally done with low pressure UV lamps operating at 65 W of electricity for ozone systems and lamps operating at 15–60 kW for hydrogen peroxide systems (15).

Air Stripping. Air stripping is a full-scale technology in which volatile organics are partitioned from groundwater by greatly increasing the surface area of the contaminated water exposed to air. Henry's law constant is used to determine whether air stripping will be effective and organic compounds with constants greater than 0.01 $\text{atm}\cdot\text{m}^3/\text{mol}$ are considered amenable to stripping. Vinyl chloride has a constant of 1.2 $\text{atm}\cdot\text{m}^3/\text{mol}$. Types of aeration methods include packed towers, diffused aeration, tray aeration, and spray aeration. The typical packed tower air stripper includes a spray nozzle at the top of the tower to distribute contaminated water over the packing in the column, a fan to force air countercurrent to the water flow, and a sump at the bottom of the tower to collect decontaminated water. Packed tower air strippers are installed as permanent installations on concrete pads or as temporary units on a skid or a trailer. Aeration tanks strip volatile compounds by bubbling air into a tank through which contaminated water flows. A forced air blower and a distribution manifold are designed to ensure air–water contact without the need for any packing materials. The baffles and multiple units ensure adequate residence time for stripping to occur (15).

Containment

Containment technologies are often performed to prevent, or significantly reduce, the migration of contaminants in soils or groundwater. Containment is necessary whenever contaminated materials are to be buried or left in place at a site, such as at a landfill. Available containment technologies include physical/biological barriers.

Physical Barriers. Physical barriers (or slurry walls) are used to contain contaminated groundwater, divert contaminated groundwater from the drinking water intake, divert uncontaminated groundwater flow, and/or provide a barrier for the groundwater treatment system. Most slurry walls are constructed of a soil, bentonite, and water mixture. Unfortunately, most barriers do not provide complete containment unless active hydraulic control is maintained using a groundwater extraction system.

GROUNDWATER AND URANIUM: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Ricardo Smalling
Environmental Bio-Systems, Inc.
Mill Valley, California

The element uranium, symbol U, is a chemically reactive radioactive metallic element. It is the main fuel used in nuclear reactors. Uranium has atomic number 92, which places it in the actinide series of the periodic table. The German chemist Martin Heinrich Klaproth discovered uranium in 1789 in pitchblende. He named it after the planet Uranus. Uranium was first isolated in the metallic state in 1841and the radioactive properties were first demonstrated in 1896 by the French physicist Antoine Henri Becquerel (1).

Uranium melts at about 1132 °C and boils at about 3818 °C. It has a specific gravity of 19.05 at 25 °C and the atomic weight of the element is 238.03. Uranium has three crystalline forms, of which the one that forms at about 770 °C is malleable and ductile. Uranium is soluble in hydrochloric and nitric acids, and it is insoluble in alkalis. It displaces hydrogen from mineral acids and from the salt solutions of such metals as mercury, silver, copper, tin, platinum, and gold. When finally divided, it burns readily in air at 150–175 °C. At 1000 °C, uranium combines with nitrogen to form a yellow nitride (1).

FATE AND TRANSPORT

Uranium has multiple oxidation states of three, four, five, and six. The hexapositive compounds include uranyl trioxide, UO_3, and uranyl chloride, UO_2Cl_2. Uranium tetrachloride, UCl_4, and uranium dioxide, UO_2, are examples of the tetrapositive, or uranous, compounds. Uranous compounds are usually unstable; they revert to the hexapositive form when exposed to excess air. Uranyl salts, such as uranyl chloride, may decompose in the presence of strong light and organic matter. *In situ* soil moisture pH greatly influences the formation of uranium surface complexes (2). The carbon dioxide (CO_2) partial pressure in soil gas is a dominant factor in controlling the pH of soil moisture.

Uranium never occurs naturally in the free state but is found as an oxide or complex salt in minerals such as pitchblende and carnotite. It has an average concentration in the crust of the earth of about 2 ppm (parts per million) and, among the elements, ranks about 48th in natural abundance in crustal rocks. Pure uranium consists of more than 99% of the isotope uranium-238, 0.72% of the fissile isotope uranium-235, and a trace of uranium-234, formed by radioactive decay of uranium-238. Among the artificially produced isotopes of uranium are uranium-233, uranium-237, and uranium-239. Isotopes ranging from mass number 222 to 242 are known (3).

Uranium has a generally low solubility and will not easily reach groundwater. It is also easily adsorbed to soil particles. Uranium oxide will precipitate from uranium-bearing groundwaters as they enter a reducing environment.

Uranium is unstable and, as it decays, it releases radiation and forms decay products. Uranium-238 decay products include uranium-234, radium-226 (both of which are solids), and radon-222, a gas. Radon is soluble but does not remain in water. It can be released by simple agitation. All the decay products are radioactive as well. The half-life for uranium-238 is about 4.5 billion years; for uranium-235 it is 710 million years, and for uranium-234 it is 250,000 years.

PROCESSING OF URANIUM

There are two major methods of producing uranium. In the classical procedure for extracting uranium, pitchblende is broken up and mixed with sulfuric and nitric acids. Uranium dissolves to form uranyl sulfate, UO_2SO_4; radium and other metals in the pitchblende ore are precipitated as sulfates. With the addition of sodium hydroxide, uranium is precipitated as sodium diuranate, $Na_2U_2O_7 \cdot 6H_2O$, known also as the yellow oxide of uranium. To obtain uranium from carnotite, the ore is finely ground and treated with a hot solution of caustic soda and potash to dissolve out uranium, radium, and vanadium. After the sandy matrix is washed away, the solution is treated with sulfuric acid and barium chloride. A caustic alkali solution added to the remaining clear liquid precipitates the uranium and radium in concentrated form. These classical methods of extracting uranium from its ores have been replaced in current practice by such procedures as solvent extraction, ion exchange, and volatility methods. *In situ* leaching is another method that is used in the United States. The artificial isotope uranium-233 is produced from thorium, another actinide metal (1).

Uranium oxide precipitates from uranium-bearing groundwaters as they enter a reducing environment. It can be mobilized (redissolved) *in situ* by oxygenated leach solution.Uranium ores are widely distributed throughout the world. Deposits of pitchblende, the richest uranium ore, are found chiefly in Canada, the Democratic Republic of the Congo (DRC, formerly Zaire), and the United States. Most of the uranium mined in the United States is obtained from carnotite occurring in Colorado, Utah, New Mexico, Arizona, and Wyoming. A mineral called coffinite, discovered in 1955 in Colorado, is a high grade ore containing nearly 61% uranium. Coffinite deposits were found subsequently in Wyoming and Arizona and in several foreign countries.

USES OF URANIUM

After the discovery of nuclear fission, uranium became a strategic metal, and its uses were at first restricted mainly to the production of nuclear weapons. In 1954 the United States government relaxed controls to permit leasing of uranium enriched in the isotope uranium-235 to various private and foreign agencies for the development of nuclear power. Peacetime applications were discussed at the three International Conferences on the Peaceful Uses of Atomic Energy held in Geneva, Switzerland, in 1955, 1958, and 1964.

The potentiality of uranium as a vast source of industrial power became apparent with the launching in 1954 of the first nuclear-powered submarine, the USS *Nautilus*. By 1989, 112 nuclear power plants in the United States produced more than 101,000 megawatts electric, MW(E). In addition, there are 316 plants in 40 countries outside the United States, which produced more than 213,000 MW(E). The first such U.S. plant, which began operations at Shippingport, Pennsylvania, generates 60,000 kW and requires about 15 lb of uranium-235 per month. Conventional plants producing 60,000 kW consume about 40 million lb of coal per month. Problems of uranium scarcity, plant safety, and storage of radioactive uranium and plutonium waste products, however, have prevented the full realization of nuclear energy's potential.

Uranium-235 is used in nuclear weapons and nuclear reactors. Depleted uranium (natural uranium in which almost all of the uranium-235 has been removed) is used to make ammunition for the military, guidance devices and compasses, radiation shielding material, and X-ray targets. Uranium dioxide is used to extend the lives of incandescent lamps used for photography and motion pictures. Very small amounts of other uranium compounds are used in photography for toning, in the leather and wood industries for stains and dyes, and in the wool industry. Uranium has also been used in the past in ceramics as a coloring agent.

HEALTH EFFECTS AND TOXICITY

Natural uranium releases alpha particles and low levels of gamma rays. The alpha particles can travel only short distances and cannot penetrate human skin. Gamma radiation, however, can penetrate the body. In general, uranium outside the body is less harmful than inside the body.

Uranium can enter the body in several ways. It is inhaled or swallowed or enters through cuts in the skin. About 99% of the uranium ingested in food or water will leave a person's body in the feces; however, a small quantity may enter the bloodstream where it is eventually filtered by the kidney.

Although uranium is radioactive and can cause cancer, its primary toxic effect when consumed in water is that of a heavy metal. Heavy metals, like uranium, lead, cadmium, and arsenic, are deposited in the kidneys and can cause irreparable damage to the chief filtering mechanism of the body (4–6).

METHODS OF REMEDIATION

Several methods of remediation have been tried with sites contaminated with uranium. These include pump and treat systems for groundwater and removal of contaminated soils. In light of the high potential for negative health effects on workers, these methods are not favored. Three *in situ* remedial approaches that do not adversely affect worker health are phytoremediation, chemical precipitation, and bioremediation.

Phytoremediation

More recent methods include phytoremediation. Rhizofiltration technology uses the plant roots to uptake the contaminant. In 1996, a rhizofiltration study was performed using hydroponically grown plants in uranium-impacted groundwater. The original study was performed in a greenhouse under controlled conditions. Sunflower plants were found to have the best uptake of uranium in the laboratory studies. In the study, the uranium-impacted water was introduced into a recirculation loop with inlet concentrations of 80–350 ppb. After treatment, the outlet treatment water was reduced to less than 5 ppb, and most of the concentrations were below 0.5 ppb. The uranium contaminant was recovered from the sunflower plant roots, with no translocation of the uranium to the plant shoots. The roots were disposed of as radioactive waste (7). Additional uranium speciation and plant uptake studies are described in detail in References 8–10.

Chemical Precipitation

Long-term sequestration of uranium by *in situ* U(VI) phosphate mineral precipitation has been documented (11). In one case at Coles Hill, Virginia, uranium remains essentially immobile and mineralized during the oxidation and chemical weathering of the uranium ore. The groundwater at the site is oxic, has a pH of 6, and falls within the uranyl phosphate stability field showing that the Coles Hill U(VI) phosphates may precipitate rapidly (weeks) relative to groundwater flow. In this location, the groundwater contains 15 μg/L or parts per billion (ppb) of dissolved uranium in the groundwater. These levels are well below the EPA maximum contaminant level (MCL) of 30 μg/L (4). In similar hydrologic conditions, phosphate-based remediation of uranium could be considered. Other uranium compounds may also provide long-term stabilization of uranium-impacted groundwater.

Bioremediation

Bioremediation has been used in uranium treatment. Microbial reduction of soluble U(VI) to insoluble U(IV) can immobilize uranium from contamianted groundwater. This remedial method may be added to soil washing for concentrating uranium from contaminated soils. Laboratory studies (12) have demonstrated that U(VI) is reduced concurrently with Fe(III) reduction and molecular studies have suggested that, in most instances, metal reduction can be attributed to the activity of the bacteria Geobacteraceae. Currently, field studies are under way to evaluate *in situ* bioremediation options for uranium.

GROUNDWATER AND MERCURY: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Silvia Johnson
Environmental Bio-Systems, Inc.
Mill Valley, California

INTRODUCTION

Mercury is rarely found as a pure metal. The chief ore of mercury is cinnabar, also called vermilion, a bright red mineral composed of mercury sulfide. Metallic mercury is recovered by heating cinnabar ore in air and condensing the mercury vapor. It was originally found primarily in Spain and Italy. Mercury's chemical symbol comes from the Greek word *hydrargyrum*, which means "liquid silver." Mercury has an atomic number of 80, atomic weight of 200.59, and a density of 13.5336 g/cm^3. It is the only metal element that is a liquid at room temperature. Mercury is not an active element, combining with other elements only with some difficulty. It is therefore a *noble* metal, like gold, silver, and the platinum group, which are all highly resistant to chemical reactions and oxidation. Mercury accumulates most efficiently in the aquatic foodweb and is highly toxic to humans (1).

There are three forms of mercury in the environment: elemental, inorganic, and organic mercury. All forms of mercury are toxic. Elemental mercury occurs naturally in three valence states: elemental (Hg^0), monovalent mercurous (Hg^{1+}), and the divalent mercuric (Hg^{2+}). Elemental mercury is the most stable form and is only slightly water soluble. Both mercuric and mercurous mercury are thermally unstable and readily decompose to elemental mercury. Vapors of elemental mercury can occur at room temperature, presenting a hazard if spills occur.

Inorganic mercury compounds contain ionic mercury usually in a salt formation (e.g., mercuric chloride).

Organic mercury compounds can be chemically synthesized or biologically converted from mercury compounds by bacteria (e.g., methylmercury). Some organic mercury compounds are water soluble and capable of transport in the aquatic food chain through the process of bioaccumulation.

Although mercury does not combine easily with other elements to form compounds, it will, however, dissolve other metals to form a solution with two or more metals. These alloys are called amalgams. Dentists have used silver–mercury amalgams, consisting of silver powder dissolved in mercury, to fill teeth. Mercury is used in mining applications to recover gold from gold ore. In this application, the mercury containing dissolved gold is heated and vaporized to leave behind the gold.

HISTORY AND USES

Spain has mercury mines that have been operating continuously for over 2000 years. Mercury was well known to the ancient Chinese. Samples of the metal have been found in Egyptian tombs dating back to 1500 B.C. Mercury was an important chemical for medieval alchemists and was suspected of being an element from which all matter is made. When a solid, mercury was thought to be gold. It was also called “quicksilver” because it is liquid and silver-white in appearance. Mercury is not usually found free in nature and is primarily obtained from the mineral cinnabar (HgS). Spain and Italy produce about half of the world’s supply of mercury. Mercury has been used in mining for hundreds of years in the separation of valuable metals, such as gold, from placer deposits (1).

Mercury has been used to produce chlorine and caustic soda; in wiring devices and switches; for electric lights; for measuring and control instruments (such as blood pressure gauges, barometers, and thermometers); and in other industrial applications.

HEALTH RISKS

All forms of mercury are highly toxic to humans and animals. Its toxicity was recognized in the nineteenth century when hat makers, who used a mercury compound in making hats, began to exhibit damage to their nervous systems. This is the origin of the phrase “mad as a hatter.” Workers in mercury-battery factories, mercury processing plants, power plant workers, and dentists are in occupations associated with mercury exposure to mercury liquid or dust. The U.S. EPA has performed a detailed assessment of exposure using various computer models (2).

Mercury concentrations in air are usually low and of little direct concern for exposure to humans (3). From the standpoint of public health, when mercury enters the water, it is the most serious problem because of the manner in which mercury accumulates in the living tissue of animals. Mercury combines chemically with enzymes in the body, causing them to lose the ability to act as catalysts for vital body functions (1).

When mercury is deposited into waterways, bacteria and algae in the water convert inorganic mercury into organic methylmercury (CH_3Hg). Fish that eat these bacteria and algae accumulate the mercury in their tissues, and the larger fish up the food chain that feed on fish with mercury in their tissues accumulate even higher levels of mercury (biomagnification) (4).

Elemental Mercury

The major health effect from elemental mercury results from inhalation of mercury vapor. Acute (short-term) inhalation exposure to high levels of elemental mercury in humans results in central nervous system effects such as hallucinations and delirium. Gastrointestinal and respiratory effects have also been noted. Studies are inconclusive regarding elemental mercury and cancer.

The central nervous system is the major organ affected by chronic (long-term) exposure to elemental mercury. Effects noted include increased excitability, irritability, insomnia, severe salivation, loss of teeth, and tremors. Chronic exposure to elemental mercury also affects the kidneys (2).

Inorganic Mercury Compounds

The major risk from inorganic mercury occurs through ingestion. Acute oral exposure to inorganic mercury compounds has been known to produce a metallic taste in the mouth, nausea, vomiting, and severe abdominal pain. The primary effect from chronic exposure to inorganic mercury is kidney damage.

Organic Mercury Compounds

The major risk posed by organic mercury occurs through ingestion. The most important organic mercury compound in terms of human exposure is methylmercury. Acute exposure to high levels of methylmercury can result in damage to the central nervous system, including blindness, deafness, intellectual deterioration, and death. No human studies are available on the carcinogenic effects of methylmercury.

Chronic methylmercury exposure occurs primarily through diet, with fish and fish products as dominant sources. The primary effect from chronic exposure to methylmercury is damage to the central nervous system, which produces malaise, numbness and tingling, blurred vision, deafness, speech difficulties, and constriction of the visual field. Infants born to women who ingest high levels of methylmercury may exhibit blindness, mental retardation, lack of coordination, and cerebral palsy. The U.S Environmental Protection Agency (EPA) currently advises pregnant women not to eat shark, swordfish, king mackerel, tilefish, and tuna.

What is known about the health effects of mercury has come from several accidental exposures, including two high dose episodes that occurred in Japan and Iraq. From 1953 to 1960, manufacturing plants in Japan discharged methylmercury into the local waterways. In 1956, the population living near Minamata Bay in southwestern Japan suffered severe neurotoxic effects from ingesting fish from the bay that had accumulated high levels of mercury because a chemical manufacturing plant had dumped tons of mercury into the water. Levels of mercury in Minamata Bay were found to be as high as 550 ppm (aquatic biota impact level for mercury is 0.000025 ppm or 0.025 μg/L). In the 1970s, over 6000 people were hospitalized in Iraq after eating imported wheat seeds that had been treated with a methylmercury fungicide. Several hundred people died, although because the incident occurred in a rural area the exact magnitude of the accident is not known (2).

FATE AND TRANSPORT

When liquid mercury spills, it forms drops that can accumulate in the smallest of spaces and then emits vapors into the air. Once in surface water, mercury enters a complex cycle in which one form can be converted to another. Mercury can easily be adsorbed onto small particles of matter. Mercury attached to particles can settle on the sediments, where it can diffuse into the water column, be resuspended, be buried by other sediments, or be methylated. Methylmercury can enter the food chain, or it can be released back into the atmosphere by volatilization (3).

The concentration of dissolved organic carbon (DOC) and pH have a strong effect on the ultimate fate of mercury in the ecosystem. Studies have shown that for the same species of fish taken from the same region, increasing the acidity of the water (decreasing pH) and/or the DOC content generally results in higher mercury levels in fish, an indicator of greater net methylation. Higher acidity and DOC levels enhance the mobility of mercury in the environment, thus making it more likely to enter the food chain. More information is given in Reference 2.

Mercury and methylmercury exposure to sunlight (specifically ultraviolet light) has an overall detoxifying effect. Sunlight can break down methylmercury to Hg(II) or Hg(0), which can leave the aquatic environment and enter the atmosphere as a gas. Since mercury is an element, it is not biodegradable. Mercury is converted among its various forms through a range of abiotic and biogeochemical transformations and during atmospheric transportation. Although its form and availability to living organisms may change over time, mercury persists in the environment.

Nearly 8 million pounds of mercury were produced in the United States in 1986. From 1987 to 1993, according to the EPA's Toxic Chemical Release Inventory, releases of mercury to land and water totaled nearly 68,000 lb, primarily from chemical and allied industries (3).

REMEDIATION

Although mercury is a globally dispersed contaminant, it is not a problem everywhere. Pollution prevention controls and equipment to contain airborne mercury and mercury spills would greatly limit future mercury releases into the environment. Aside from grossly polluted environments, mercury is normally a problem only where the rate of natural formation of methylmercury from inorganic mercury is greater than the reverse reaction. Environments that are known to favor the production of methylmercury include certain types of wetlands, dilute low pH lakes in the northeast and north central United States, parts of the Florida Everglades, newly flooded reservoirs, and coastal wetlands, particularly along the Gulf of Mexico, Atlantic Ocean, and San Francisco Bay. The highest concentration of mercury in freshwater sediments in the world is found in a section of Berry's Creek in New Jersey, near the Meadowlands Sports Complex. Several defunct industrial plants, including one mercury plant, are parts of some Superfund environmental cleanup sites (4).

In highly polluted areas where mercury has accumulated through industrial or mining activities, natural processes may bury, dilute, or erode the mercury deposits, resulting in declines in concentration. In many relatively pristine areas, however, mercury concentrations have actually increased because atmospheric deposition has increased.

For instance, concentrations of mercury in feathers of fish-eating seabirds from the northeastern Atlantic Ocean have steadily increased for more than a century. In North American sediment cores, sediments deposited since industrialization have mercury concentrations about 3–5 times those found in older sediments (2). Some sites may have become methylmercury hot spots inadvertently through human activities. Although scientists from the United States Geological Survey (USGS) and elsewhere are beginning to unravel the complex interactions between mercury and the environment, a lack of information on the sources, behavior, and effects of mercury in the environment has impeded identification of effective management responses to the nation's growing mercury problem.

Mercury contamination of shallow soil is commonly remediated by excavation and importation of clean backfill, as in the example of the mercury contamination remediation at gas pipeline sites in Kansas (5). Off-site treatment or transportation to a licensed disposal facility may be part of the remedial action.

Bioremediation is not an option for mercury, as the metal is also toxic to most microbial colonies (6). The following treatment methods have been approved by the U.S. EPA for removing mercury from drinking water: coagulation/filtration, granular activated carbon, lime softening, and reverse osmosis (3).

Remediation of mercury has been treated using capping and containment strategies wherein the mercury is surrounded by low permeability (bentonite) or nonpermeable material (steel shoring, plastic sheeting) to prevent the migration of the mercury. Other techniques include *in situ* vitrification.

Mercury is one of the most difficult wastes to stabilize. Aboveground stabilization techniques employing cement, kiln dust, fly ash, or other materials have been used to treat mercury-contaminated soils (7). Sulfide chemistry has also been used to chemically precipitate mercury into mercury sulfide. Calcium polysulfide (CaS_5) has been used in an aboveground soil washing treatment of mercury-impacted soil and refractory bricks at the Red Devil Mine in Alaska. The project converted toxic mercury and lead compounds into insoluble mercury sulfide and lead sulfide precipitates (B. Graves, personal communication). Mercury with zinc was encapsulated using an alkali-activated slag matrix. The physical encapsulation and chemical fixation mechanisms were responsible for the immobilization of the mercury ions in the alkali-activated slag matrix (8).

SPECIFIC REGULATORY GUIDELINES

The United States Environmental Protection Agency (U.S. EPA) has established a Maximum Contaminant Level of Goal for mercury in drinking water at 2 μg/L or parts per billion (ppb) (3). This is the lowest level that water systems can reasonably attain, given current treatment technologies and health information.

Efforts by manufacturers of mercury-containing products, by government programs, and by solid waste management facilities have significantly reduced mercury entering the environment from products that contain it. For example, Hennepin County programs to keep mercury out of the waste stream, together with pollution control equipment on the county's waste-to-energy plant, have brought mercury emission levels down from 67% of the amount allowed under the Minnesota Pollution Control Agency permit, to under 6% of the permitted amount (9).

The EPA has issued several major studies on mercury to the U.S. Congress, including the *Mercury Study Report to Congress* in 1997 and *Utility Hazardous Air Pollutant Report to Congress* in 1998 (2,4). The agency has also taken steps to reduce human sources of mercury, including issuing regulations for the medical waste combustion, municipal waste combustion, and chloralkali production. The EPA has proposed regulations for industrial boilers, another large source of mercury. On December 15, 2003, the EPA announced a plan to significantly reduce mercury emissions from coal power plants through a cap and trade program, a market-based approach that worked successfully to reduce acidic precipitation from sulfur dioxide. The proposal would require utilities to cut emissions by 70% over the next 15 years. The EPA has also proposed a second option that is a traditional "command and control" regulation. This alternative would require utilities to install what is known as "maximum achievable control technologies" (MACT), as required under the Clean Air Act, to reduce mercury emissions by 29% over the next three years. It is not clear which of these two approaches will become the final regulation.

CONCLUSIONS

Mercury is highly toxic to humans. Significant reduction of mercury in the environment can be attained through better pollution prevention programs and control of both mercury vapors and liquid spills. Mercury waste is difficult to remediate and several treatment methods have been developed.

Acknowledgments
The authors wish to thank Ross B. Jacobs, a student interested in environmental research and issues related to mercury, for his contributions to this entry.

GROUNDWATER AND LEAD: CHEMICAL BEHAVIOR AND TREATMENT

James A. Jacobs
Lisa Kirkland
Environmental Bio-Systems, Inc.
Mill Valley, California

Lead (Pb) occurs naturally in the earth's crust and is reported as being the most abundant among the heavy metals, with the average Pb content of the crust ranging from 13 to 16 parts per million (1). Lead has a crustal abundance of 1.4×10^1 mg/kg, with an estimated oceanic abundance of 3×10^{-5} mg/L (2). Lead makes up 0.013% of the earth's crust. There are more than 200 minerals of Pb. Natural mobilization of Pb into the environment occurs mainly from the erosion of Pb-containing rocks and via gaseous emissions during volcanic activity. Lead is mined and refined easily. On a worldwide basis, most lead is concentrated by roasting galena, also called lead sulfide (PbS), in hot air. Nearly one-third of the consumption in the United States is obtained by recycling efforts (2).

INTRODUCTION

The impact of Pb on the environment has been long and persistent. Approximately 5000 years ago Pb mining waste began the first time a curious human picked at an outcropping of lead, pulled away the dirt and rock, and discarded the unwanted material. The Romans were the first of the ancient people to use Pb on a large scale and they used Pb more than any other people until recent time. In fact, there were laws prohibiting the production of excess amounts, according to *Pliny the Elder's Natural History* (3). The name lead comes from the Anglo-Saxon word for lead. The symbol, Pb comes from the latin word for lead, *plumbus*. Plumbers were lead workers using lead pipes and lead solder.

Lead is a cumulative poison and the ancient Romans were exposed to significant levels of lead in their water system. The blood levels of Pb in the post-Roman Italian population are as high as the Roman population, which is indicative that Pb was obtained in food and drink; this may be the result of continued use of Pb water pipes and cisterns or a result of the use of pewter, poor Pb glazes, and Pb salts (e.g., Pb acetate, "sugar of lead", which was used as a sweetener). Poor wine was improved in the Middle Ages by the addition of Pb even though it was known to be a dangerous practice and outlawed and sometimes punishable by death. There are many records of Pb epidemics, which persist well into the eighteenth century (4).

New centuries brought new uses for Pb, some of which helped change the course of history. In the mid-1400s, Johannes Gutenberg created the printing press by casting letters of molten Pb and tin. Later, Pb made possible electronic circuitry, computer screens, and televisions.

As the uses of lead increased, driven by the growing number of social benefits it provided, there was more lead mining and mining waste. Until a few decades ago, there was little concern about the environmental impact of mining waste. Limited engineering solutions and lack of public concern about the issue meant that, over the years, mining companies have developed their own methods of handling and disposing of these materials. In fact, before engineers spent time deciding how to keep piles of tailings from washing or blowing away and before society understood the need for such controls, tailings were simply left in piles. As the early Pb mines were exhausted of ore and closed, the tailing piles were left behind. In some cases the piles have slumped into streams; in other cases, wind has blown away portions of the piles. In recent years, society's concern about the impact of tailings on the environment and human health has grown. That, along with engineering advancements that help stabilize tailing piles, has led to changes.

PROPERTIES

Lead is a bluish-white metal of bright luster, soft, highly malleable, ductile, and a poor conductor of electricity. Lead is a soft, malleable, and corrosion-resistant metal, belonging to group IV of the periodic table. Lead has an atomic weight of 207.19, a melting point of 327.5 °C, a boiling point of 1744 °C, and specific gravity of 11.342 g/cm^3. Lead is a solid at room temperature. The oxidation states of Pb are II and IV and there are four stable isotopes (204, 206, 207, 208) and two radioactive isotopes (210, 212). A variety of lead oxide compounds exist in nature.

USE

In ancient times the need for silver propelled Pb production. This was coupled with its properties—that is, its low melting point, ductility, malleability, and durability contributed to its use as a construction material. Currently, the construction and automobile industries are the primary users of Pb. It is estimated that 60% of Pb is consumed in the auto industry for solder in the building of cars, buses, trucks, vehicular batteries, and as gasoline additive. The use of Pb as gasoline additive has been declining since the mid-1970s as a result of legislation in many countries, responding to environmental concern about the release of Pb from auto exhausts.

Other important uses of Pb are in the manufacture of cable sheathings, pigments, pipe, foil and tube, and various alloys. Secondary use of Pb includes ammunition and type metal, varnishes, the production of inorganic compounds, protective coating, glassware, ceramics, TV tubes, shield against radioactivity, galvanizing, Pb plating, weights, and ballasts. Lead carbonate ($PbCO_3$), also called cerussite, is a white pigment used in early paints, especially in interior white paints. These paints have caused significant lead-based-paint (LBP) poisoning, especially of infants and children who might chew on the sweet-tasting lead paint chips. Currently, titanium oxide (TiO_2) has replaced the toxic lead in paints. Other lead compounds used in paints include lead sulfate or anglesite ($PbSO_4$) and lead chromate or crocoite ($PbCrO_4$). Other lead compounds include lead nitrate [$Pb(NO_3)_2$] used in fireworks and lead silicate ($PbSiO_3$) used in glass making and in the production of paints and rubber (2).

Lead arsenate [$Pb(AsO_4)_2$] was used as an insecticide and has been banned as an ingredient in pesticides (5). The high density of lead makes it useful to shield against X-ray and gamma-ray radiation in X-ray machines and other scientific instruments. It is used to absorb vibrations, as well as in the manufacture of ammunition. Most lead currently is used in lead-acid storage batteries, the type found in vehicles. Lead has been used in crystal and glass as well as solder (with tin).

The elevated levels are due:

- to the continued use of lead (Pb) pipes in drinking water transport
- chips and dust from leaded paint
- emissions from various industrial combustion processes
- deterioration of leaded paint
- historical fall-out from leaded gasoline (6).

HEALTH RISKS

The health risks associated with Pb include poisoning, with the most common symptoms being insomnia, delirium, hallucinations, tremor, colic, nausea, and vomiting. (Persons at risk would include those handling tetraethyl lead or leaded gasoline.) Symptoms of lead poisoning also include neuropathy, encephalopathy (both adult and children), renal failure, intoxication, and death. Lead anemia is seldom severe unless concomitant with iron deficiency. More importantly, low level Pb exposure can have profound, adverse physiological and cognitive effects that can have long-lasting impacts. In children this could lead to permanent damage to the central nervous system, lower performance I.Q., and impairment of fine motor function. Children are more susceptible due to their greater rates of absorption (an area that needs further examination). Lead poisoning in adults is manifested by a decrease in reaction time, lower memory capacity, weakness in fingers, wrists, or ankles, anemia, insomnia, weight loss, anorexia, malnutrition, nausea, abdominal pain, constipation, and vomiting. Lead in men may increase blood pressure and high levels may damage the male reproductive system (6,7).

Pb is incorporated in the hair, nails, and sweat, but losses from the body by these routes are trivial. Blood Pb levels tend to be higher in city dwellers than in rural dwellers, while within cities those living in areas with the greatest traffic density tend to have the highest blood levels (8). The relative contribution which the various environmental sources of Pb make to the blood Pb concentration is not known with certainty and more study needs to be done in this regard. Currently, the EPA guideline for Pb blood level is 10 Mg/dL.

FATE AND TRANSPORT

Lead released to land, surface water, and groundwater is usually elemental lead, lead oxides, lead hydroxides, and lead–metal oxyanion complexes (9).

Pb naturally is present in small quantities in practically all environmental matrices, which includes air, water, soil, and plants. The distribution of Pb is greatly exacerbated as a result of emission from the combustion of Pb-containing fuel. It must be pointed out that Pb toxicity is inversely proportional to pH in soil. Pb in water originates from a variety of sources: atmosphere, lithosphere, and, for drinking water, the possibility from plumbing fixtures as well as from mines that may percolate into underlying aquifers. In the 1970s Pb from anti-knock additives resulted in approximately 180,000 tons/yr in the United States alone. Lead is the most common metal contaminant found at U.S. Superfund sites (460 sites) (10).

Pb is rarely found in source water, but Pb mining and smelting operations may be sources of significant contamination. Eighty-eight percent of the Pb mined in the United States comes from seven mines in the New Lead Belt in southeastern Missouri. From 1987 to 1993, according to the Toxics Release Inventory, Pb compound releases to land and water totaled nearly 144 million pounds. These releases were primarily from Pb and copper smelting industries. The largest releases occurred in Missouri, Arizona, and Montana. The largest direct releases to water occurred in Ohio. Pb in the form of very small particles may be airborne and disseminated over long distances. Metal-rich mine tailings, metal smelting, electroplating, gas exhausts, energy and fuel production, downwash from power lines, intensive agriculture, and sludge dumping are the human activities that introduce the largest quantities of Pb into soils. When released to land, Pb binds to soils and does not migrate to groundwater. A total of 71,529 tons of lead were released to the land in the United States over a seven-year period. In water, it binds to sediments. A total of 485 tons were released to water in the United States over a seven-year period. The worst industries for releasing lead to water are the steelworks, lead smelting, and refining and iron foundries. The worst industries for releasing lead to land are the lead smelting and refining, copper smelting, and steelworks. Lead does not accumulate in fish but does in some shellfish, such as mussels (11).

Lead (Pb^{2+}) and lead–hydroxy complexes are the most stable forms of lead (9). Lead forms low solubility compounds by complexation with inorganic ions (Cl^-, ${CO_3}^{2-}$, ${SO_4}^{2-}$, ${PO_4}^{3-}$) and organic ligands (humic and fulvic acids, EDTA, amino acids) (12). Lead carbonate solids form above pH 6. Lead sulfide forms with high sulfide concentrations under reducing conditions. Most lead released into the environment is retained in the shallow soil. The main processes affecting the fate of lead in soil generally limits the amount of lead entering the groundwater. The processes include adsorption, ion exchange, precipitation, and complexation with sorbed organic matter in the soil (13). The amount of lead dissolved in groundwater and surface water is heavily pH dependent and to a lesser degree related to the concentration of dissolved salts and types of mineral surfaces present. In surface and groundwater, lead usually occurs as a precipitate (rather than in solution), as $PbCO_3$, PB_2O, $PB(OH)_2$, and $PbSO_4$, as sorbed ions or surface coatings on minerals, or as suspended organic matter (13).

The major pathways of exposure to lead are:

- the inhalation of lead-containing car exhausts or industrial emission
- the ingestion of lead-based paint
- the ingestion of contaminated soil or dust from hand-to-mouth activities of those living in lead-polluted environments
- the inhalation of leaded dust carried on clothing or by the wind

The specific pathways of exposure to lead for children are:

- swallowing lead paint chips
- eating contaminated food
- putting hands, toys, or objects contaminated with lead dust or soil in their mouths

GUIDELINES AND STANDARDS

In 1974, the U.S. Congress passed the Safe Drinking Water Act. This law requires the EPA to determine safe levels of chemicals in drinking water, which do or may cause health problems. These nonenforceable levels, based solely on possible health risks and exposure, are called Maximum Contaminant Level Goals (MCLG).

The MCLG for lead has been set at zero because the EPA believes this level of protection would not cause any of the potential health problems. Since lead contamination generally occurs from corrosion of household lead pipes, it cannot be directly detected or removed by the water system. Instead, the EPA is requiring water systems to control the corrosiveness of their water if the level of lead at home taps exceeds an Action Level.

The Action Level for lead has been set at 15 parts per billion (ppb) because the EPA believes, given present technology and resources, this is the lowest level to which water systems can reasonably be required to control this contaminant should it occur in drinking water at their customers' home taps.

These drinking water standards, and the regulations for ensuring these standards are met, are called National Primary Drinking Water Regulations. All U.S. public water supplies must abide by these regulations.

REMEDIATION

Various remedial methods exist for the treatment of Pb contamination such as excavation, phytoremediation, soil containment, soil washing and flushing, deep tilling, and geochemical fixation. Other remedial approaches include isolation by capping and subsurface barriers including slurry walls. Immobilization includes solidification/stabilization using cement-based binders and stabilizers, organic binders, and vitrification. Permeable treatment walls, *in situ* soil flushing, and electrokinetic extraction are also gaining popularity in the treatment of heavy metals (13). Phytoremediation, soil washing, and geochemical fixation are described below.

Phytoremediation

Phytoremediation is a relatively new technology that has been gaining commercial acceptance as research on the field scale has confirmed greenhouse and pilot scale success. While it has been used mainly in open, industrial settings, phytoremediation has been used in several urban, residential applications for Pb reduction. For example, in Massachusetts phytoremediation significantly reduced high soil lead levels in both an open lot that was revitalized into a community garden and in an urban residential backyard. In the case of the community garden, several plantings of Indian mustard lowered the Pb levels that initially exceeded 1000 ppm to concentrations less than half that amount. While phytoremediation in a full-scale residential application presents a few more challenges than that in an industrial site or an isolated lot, it can be successfully implemented over time through the use of a comprehensive monitoring and planting regime. This method is inexpensive and is particularly suited for developing countries.

Soil Washing

Soil washing is a remediation system that leaches and recovers Pb and other metals from contaminated soil, dust, sludge, or sediment. Soil washing also uses physical and mechanical sorting methods to separate the various fractions of the sediment by size. The Pb compounds are often tightly bound by fine soil constituents such as clay, manganese and iron oxides, and humus. A pretreatment, physical separation stage may involve dry screening to remove gross oversized material. The soil can be separated into oversized (gravel), sand, and fine (silt, clay, and humus) fractions. Soil, including the oversized fraction, is first washed. Most Pb contamination is typically associated with fines fraction, and this fraction is subjected to countercurrent leaching to dissolve the adsorbed Pb and other heavy metal species. The sand fraction may also contain significant Pb, especially if the contamination is due to particulate Pb, such as that found in battery recycling, ammunition burning, and scrap yard activities. In this case, the sand fraction is pretreated to remove dense metallic or magnetic materials before subjecting the sand fraction to countercurrent leaching. Sand and fines can be treated in separate parallel streams.

After dissolution of the Pb and other heavy metal contaminants, the metal ions are recovered from the aqueous leachate by a metal recovery process such as reduction, liquid ion exchange, resin ion exchange, or precipitation. The metal recovery technique depends on the metals to be recovered and the leachate employed. In most cases, a reduction process is used so that the metals are recovered in a compact form suitable for recycling. After the metals are recovered, the leachate can be reused within the soil washing system for continued leaching.

Geochemical Fixation

An *in situ* technology for Pb treatment is geochemical fixation using a chemical reductant such as calcium polysulfide, ferrous sulfate, or sodium metabisulfite. As an example, calcium polysulfide generally produces hydrogen sulfide, thiosulfate, and colloidal sulfur when placed in groundwater. The soluble Pb^{2+} in the groundwater is precipitated as an insoluble lead sulfide by thiosulfate breakdown products and the hydrogen sulfide. Lead sulfide is less soluble than lead hydroxide. The reductants tend to be injected or poured into wells, trenches, or delivery points. Some chemical reductants can remain active in the groundwater for months to years.

Durban, South Africa

INTRODUCTION

The prime objective of this text is to describe the elementary concepts involved in laminar fluid flows. In general, any flow is characterized by the continuous deformation of fluid particles and a corresponding internal state of stress. It has been experimentally established that, under laminar situations, the rate of deformation is directly proportional to local viscous stress. Laminar flows thus fall under the category of viscous flows. The principle laws that govern the motion of fluids are also discussed. We shall take geometrically simple configurations and provide a more specific introduction of laminar fluid dynamics. The outlines given in this article provide basic concepts of laminar flows. For more detailed analysis, the reader should consult specialized texts within this topic. Some of these texts are listed in the references given at the end of this article.

VISCOSITY AND OSTWALD'S EXPERIMENT

Viscosity is a measure of how easily the fluid deforms or flows under an applied stress. Alternatively, viscosity is a measure of the fluid's internal resistance to deformation or internal friction between the fluid layers. Experimentally, under conditions of laminar flow, the force required to move a plate at constant speed against the resistance of a fluid is proportional to the area of the plate and to the velocity gradient perpendicular to the plate. The constant of proportionality is called the viscosity. Consider a simple fluid flow between the two plates shown in Fig. 1.

If the force per unit area of the top plate is measured as F, we can write that as

$$\frac{F}{A} = \mu \frac{v}{d} \tag{1}$$

with d as the separation between the plates, which essentially defines the absolute or dynamic viscosity, μ, which has the units of kg/ms. The ratio of dynamic viscosity to density of the fluid is known as kinematic viscosity and has the units of m^2/s. Experimentally, the viscosity can be measured using specially designed viscometers, whose operation is based on simple flow between one plate fixed and another moving with constant velocity v. If the gap d between the plates is small compared with the length of the plates, the flow with reasonable accuracy can be assumed to be one-dimensional. For such flows, the velocity is constant in the direction of flow but varies in the normal direction. For example, in Fig. 1, the velocity in x-direction is a function of y coordinate, i.e., $v = v(y)$. Equation (1) also represents that the viscous stresses are directly proportional to the velocity gradient, i.e.,

$$\textit{Viscous stresses} = \mu(\textit{Rate of deformation})$$

These stresses developing in the viscous transfer can be divided into normal and shear stresses. For example, τ_{xx} is the normal stress, whereas τ_{yx} is the shear stress resulting from the viscous forces. At each point in a continuous medium, whether it is solid or fluid, we need six components, each of them representing a component of force per unit area, to define the local stress completely. The local stresses acting in the x-y plane have been shown in Fig. 2.

Equation (1) can be cast in a more generalized form as given by Eq. (2). The shear stress exerted in the x-direction on a fluid surface of constant y by the fluid in the region of lesser y is designated as τ_{yx}, and the x-component of the fluid velocity vector is designated as v_x

$$\tau_{\mathrm{yx}} = -\mu \frac{du}{dy} \tag{2}$$

This law is commonly known as Newton's law of viscosity. It states that the shear force per unit area is

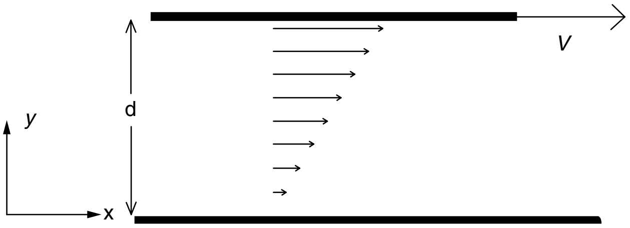

Figure 1. Viscous drag between two plates; the bottom plate is held fixed.

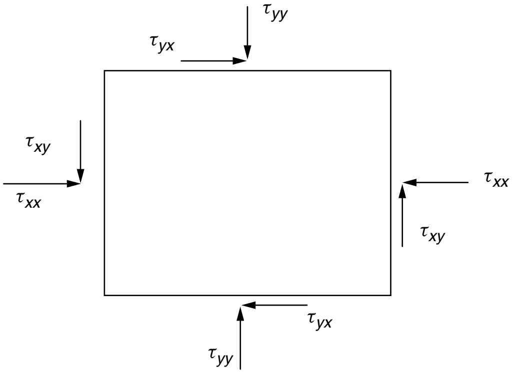

Figure 2. Local stresses acting in a *x-y* plane on a cubic element.

proportional to the negative of the local velocity gradient. In an arbitrary three-dimensional laminar flow, this relation can be generalized as

$$\begin{bmatrix} \tau_{xx} & \tau_{xy} & \tau_{xz} \\ \tau_{xy} & \tau_{yy} & \tau_{yz} \\ \tau_{xz} & \tau_{yz} & \tau_{zz} \end{bmatrix} = \mu \begin{bmatrix} \left(2\dfrac{\partial u}{\partial x}\right) & \left(\dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x}\right) & \left(\dfrac{\partial u}{\partial z} + \dfrac{\partial w}{\partial x}\right) \\ \left(\dfrac{\partial u}{\partial y} + \dfrac{\partial v}{\partial x}\right) & \left(2\dfrac{\partial v}{\partial y}\right) & \left(\dfrac{\partial w}{\partial y} + \dfrac{\partial v}{\partial z}\right) \\ \left(\dfrac{\partial u}{\partial z} + \dfrac{\partial w}{\partial x}\right) & \left(\dfrac{\partial w}{\partial y} + \dfrac{\partial v}{\partial z}\right) & \left(2\dfrac{\partial w}{\partial z}\right) \end{bmatrix} \quad (3)$$

For detailed derivations and discussion of viscous stresses, one should refer to References 1 and 2.

Flows in which fluid viscosity is important can be of two types, namely laminar and turbulent. The basic difference between these flows was demonstrated by Osborne Reynolds in 1883. A thin stream of dye was introduced into the flow of water through the tube. At low flow rates, the dye stream was observed to follow a well-defined straight path, indicating that the fluid moves in parallel layers (*laminas*) with no macroscopic mixing across the layers, which is known as *laminar flow*. As the flow rate was increased beyond certain critical values, the dye streak broke up into an irregular motion and spread throughout the cross section of the tube, indicating the macroscopic mixing motions perpendicular to the direction of flow. Such a chaotic fluid motion is known as *turbulent flow*.

REYNOLDS NUMBER

The Reynolds Number (Re) is a quantity that engineers use to estimate if a fluid flow is laminar or turbulent. Consider the flow of an incompressible fluid through a circular pipe as shown in Fig. 3.

The variables associated with this pipe-flow configuration are the dimensions of the pipe, the rate of flow, and the physical properties of the fluid.

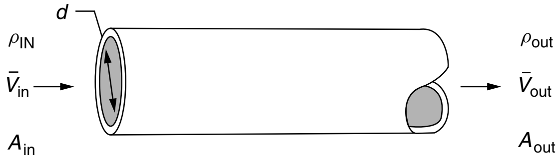

Figure 3. Flow through a pipe.

d = Internal diameter of the pipe

ρ = Density of the fluid and in an incompressible flow $\rho_{\text{in}} = \rho_{\text{out}}$ because it is constant

$\bar{v}$ = Average velocity

Q = Volumetric flow rate

A = Cross-sectional area and is constant, i.e., $(A_{\text{in}} = A_{\text{out}})$

We can then represent the Reynolds Number as a dimensionless entity as

$$\text{Re} = \frac{\rho \bar{v} d}{\mu} = \frac{\rho\left(\dfrac{Q}{A}\right)d}{\mu} = \textbf{Unitless Number} \quad (3)$$

The Reynolds Number also indicates the relative significance of the inertial forces compared with the viscous forces. Laminar flow occurs at low Reynolds Numbers, where viscous forces are dominant, and is characterized by smooth, constant fluid motion, whereas turbulent flow occurs at high Reynolds Numbers and is dominated by inertial forces, producing random eddies, vortices, and other flow fluctuations. Different ranges of Reynolds Numbers determine the nature of different flow regimes, as shown in Fig. 4.

In laminar flow, the particles in the fluid follow streamlines (see Fig. 4), and the motion of particles in the fluid is predictable. If the flow rate is very large, or if objects obstruct the flow, the fluid starts to swirl in an erratic motion. No longer can one predict the exact path a particle on the fluid will follow. This region of constantly changing flow lines (see Fig. 4) is said to consist of turbulent flow.

RANGE 1: laminar flow (see Fig. 4)

Generally, a fluid flow is laminar from $\text{Re} = 0$ to some critical value $\text{Re} = 2100$, at which transition flow begins.

RANGE 2: transition flow (see Fig. 4)

Flows in this range may fluctuate between laminar and turbulent flow. The fluid flow is on the verge of becoming turbulent. In this zone, $2100 < \text{Re} < 4000$.

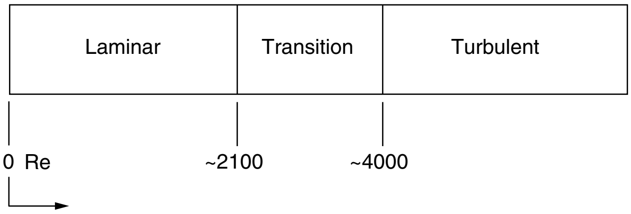

Figure 4. Different flow regimes and Reynolds Number in pipe flow.

RANGE 3: turbulent flow (see Fig. 4)

The fluid flow has become unstable. In turbulent flow, increased mixing exists that results in viscous losses, which are generally much higher than in those in laminar flow. In this zone, the values of Reynolds Number is greater than 4000.

It should be noted that the critical Reynolds Number depends on the flow type and the definition of the Reynolds Number, which varies for different geometries.

CONSERVATION LAWS FOR FLUID FLOW SYSTEMS

The behavior or dynamics of any fluid flow system can be described by laws of conservation of mass, momentum, and energy. In order to yield the detailed descriptions of variables of interest within the flow system, the control volume must be of infinitesimal dimensions that can shrink to zero, yielding a point volume. This approach reduces the quantities to point variables. The application of the conservation principles to this infinitesimal system produces microscopic or differential conservation equations. The governing momentum, energy, and mass balance differential equations for a given flow system can be derived using the shell balance concepts or directly from equations of change, which have been discussed in detail in References 2 and 3. Shell balance concepts are generally valid for simple flow systems, whereas equations of change can describe the flow behavior in complex flow real-life situations.

The governing differential equations for any flow system can be expressed in Lagrangian and Eulerian coordinate systems. In the Lagrangian approach, the fluid is assumed to be composed of particles, and the motion of individual particles is tracked. However, in the Eulerian approach, the attention is instead focused on a fixed coordinate system that defines space. We consider a prime variable of interest in fluid dynamics, that is, velocity. In the Lagrangian approach, this parameter is a function of time, whereas in Eulerian systems, it is a function of both time and spatial coordinates. Therefore, the acceleration of a particle that at time t occupies a fixed location can be calculated either by using the material or substantial derivatives as

$$a = \frac{DV}{Dt} \tag{4}$$

or by chain rule of differentiation as

$$a = \frac{\partial v}{\partial t} + \frac{\partial v}{\partial x}\frac{\partial x}{\partial t} + \frac{\partial v}{\partial y}\frac{\partial y}{\partial t} + \frac{\partial v}{\partial z}\frac{\partial z}{\partial t} \tag{5}$$

Equations (4) and (5) are the same; Eq. (4) represents the Lagrangian approach, whereas Eq. (5) is representative of an Eulerian system.

$$\underset{\substack{\uparrow\\ \textbf{Lagrangian Approach}}}{\frac{DV}{Dt}} = \underset{\substack{\uparrow\\ \textbf{Eulerian Approach}}}{\underline{\frac{\partial v}{\partial t} + \frac{\partial v}{\partial x}\frac{\partial x}{\partial t} + \frac{\partial v}{\partial y}\frac{\partial y}{\partial t} + \frac{\partial v}{\partial z}\frac{\partial z}{\partial t}}} \tag{6}$$

For advanced discussions about Lagrangian and Eulerian coordinate systems, the readers are advised to refer to References 2, 4, and 5.

EQUATIONS OF CHANGE IN LAMINAR FLOW SYSTEMS

The governing differential equations corresponding to mass and momentum conservation are solved to obtain field variables of interest in fluid dynamics (i.e., velocities and pressures), which are also known as the continuity equation and equations of change, which describe the laminar flow of a pure isothermal fluid.

EQUATION OF CONTINUITY

Equation of continuity is derived by applying the law of conservation of mass to a small 3-D volume element (see Fig. 5) within a flowing fluid. In vector notation, this equation can be represented as

$$\frac{\partial \rho}{\partial \mathbf{t}} = -(\nabla.\rho v) \tag{7}$$

Here, $(\nabla.\rho v)$ is called the "divergence" of $\rho\mathbf{v}$. This vector $\rho\mathbf{v}$ is the mass flux and is the net rate of mass efflux per unit volume. Equation (7) states that the rate of increase of the density within a small volume element fixed in space is equal to the net rate of mass influx to the element divided by its volume. A very special form of the equation of continuity is Equation (8), which is applicable for fluids of constant density, that is, incompressible fluids.

$$(\nabla.\mathbf{v}) = 0 \tag{8}$$

EQUATION OF MOTION

The equation of motion is developed by implementing the shell momentum balance concept on a 3-D volume element, as shown in Fig. 5.

It should be noted that momentum is a vector quantity, and hence the equation of motion will have components in each of the three coordinate directions x, y, and z, respectively. For detailed derivation of equation of motion, readers should refer to References 2 and 5. Adding the three components of equation of motion, the equation of

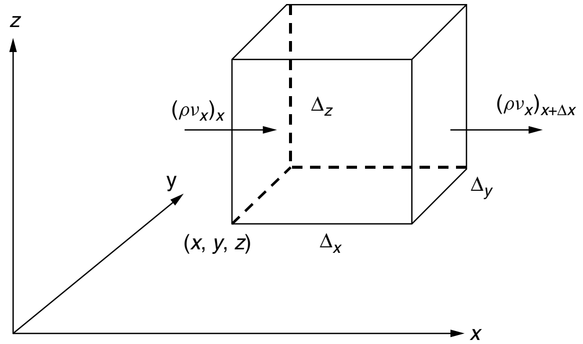

Figure 5. Region of volume in $\Delta x\Delta y\Delta z$ through which the fluid is flowing.

motion can be represented in vector notation as

$$\underset{\substack{\text{Rate of increase of}\\ \text{momentum per unit}\\ \text{volume}}}{\frac{\partial}{\partial t}\rho\mathbf{v}} = \underset{\substack{\text{Rate of momentum}\\ \text{gain by convection}\\ \text{per unit volume}}}{[\nabla.\rho\mathbf{vv}]} - \underset{\substack{\text{Pressure force on}\\ \text{element per unit}\\ \text{volume}}}{[\nabla p]} \underset{\substack{\text{Rate of momentum}\\ \text{gain by viscous}\\ \text{transfer per unit}\\ \text{volume}}}{-[\nabla\cdot\boldsymbol{\tau}]} + \underset{\substack{\text{Gravitational force}\\ \text{on element per unit}\\ \text{volume}}}{\rho\mathbf{g}} \qquad (9)$$

$\boldsymbol{\tau}$ is known as “stress tensor” and has nine components, $[\nabla.\rho vv]$ represents the rate of loss of momentum per unit volume by fluid flow, and $(\nabla.\rho v)$ represents the rate of loss of mass per unit volume. In order to use Equation (9) to determine velocity distribution, appropriate expressions for various stresses in terms of velocity gradients and fluid properties are substituted, which yields the equations of motion for a Newtonian fluid with varying density and viscosity.

For constant ρ and μ, the equation of motion can be written as

$$\rho\left(\frac{\partial v}{\partial t} + v.\nabla v\right) = -\nabla p + \mu\nabla^2 v + \rho\mathbf{g} \qquad (10)$$

Equation (10) is the well-known Navier–Stokes equation, first developed by Navier in France in 1822.

The equations of motion together with equation of continuity, equation of state $p = p(\rho)$, viscosity models for different fluids [see References 4 and 6], and the initial and the boundary conditions [see References 1, 3, 4, and 7], complete the problem specification for any laminar flow problem in hand. These equations, when solved mathematically, determine completely the density, pressure, and velocity components in an isothermal laminar flow situation.

Equation (10) can be written in nondimensional form as

$$\left(\frac{\partial v'}{\partial t} + v'.\nabla v'\right) = -\nabla p' + \frac{1}{\mathrm{Re}}\nabla^2 v' + \mathbf{g} \qquad (11)$$

where the primed quantities are dimensionless. The ratio of second term to the fourth term in Equation (11) is of order *Re*, which indicates the physical representation of Reynolds Number as

$$\mathrm{Re} = \frac{\text{inertia forces}}{\text{viscous forces}} \qquad (12)$$

Detailed derivation of nondimensional form of Navier–Stokes and Stokes equations can be found in References 2 and 8.

Concept of Dynamic Pressure

If the body of fluid is at rest, the pressure is hydrostatic and

$$\rho\mathbf{g} - \nabla p = 0 \qquad (13)$$

Subtracting Eq. (13) from Eq. (10), we get

$$\rho\left(\frac{\partial v}{\partial t} + v\cdot\nabla v\right) = -\nabla p_{\mathrm{d}} + \mu\nabla^2 v \qquad (14)$$

where $p_{\mathrm{d}} = p_{\mathrm{s}} - p$ is the pressure change because of dynamic effects. However, no accepted terminology exists for p_{d}, but we shall call it dynamic pressure. Other common terms are modified pressure (9) and excess pressure (10). For a fluid of uniform density, introduction of p_{d} eliminates gravity from the differential equations in Eq. (10). However, the process may not eliminate gravity from the problem. Gravity reappears in the problem if the boundary conditions are given in terms of total pressure p. Examples are surface gravity waves where the total pressure is fixed at the free surface. Without a free surface, however, gravity has no dynamic role, and its only effect is to add a hydrostatic contribution to the pressure field.

Equations (7)–(14) have been presented in rectangular coordinate systems. However, in real complex flow situations, depending on the geometrical configurations of the flow system, other coordinate systems such as spherical and cylindrical can be used. Hence, in these cases, Equations (7)–(14) can be cast in alternative coordinate systems using coordinate transforms. Detailed literature and methodology for performing coordinate transformations can be found in References 2 and 5.

STEADY-STATE FLOW BETWEEN PARALLEL PLATES

A laminar flow within two parallel plates is considered in Fig. 6.

The term fully developed in the figure signifies that we are considering regions beyond the developing stage near the entrance, where the velocity profile changes in the direction of flow because of the development of boundary layers from the two walls. The discussion of boundary layer theory is beyond the scope of the present text, and we shall only consider the flows under fully developed situations, i.e., far away from the entrance. For advanced discussions on boundary layer theory, readers may consult References 2 and 11.

Consider the fully developed stage of a two-dimensional flow between two infinite parallel plates, as shown in Fig. 7.

The flow is driven by an externally imposed pressure gradient, and the motion of the upper plate is maintained

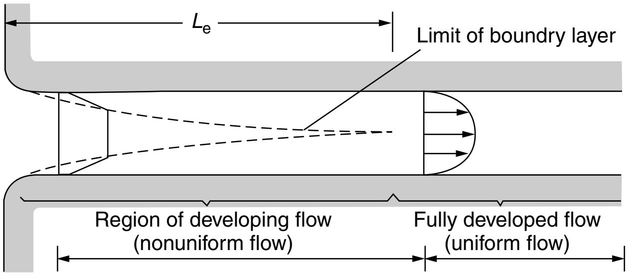

Figure 6. Developing and fully developed flows in a channel. Flow is fully developed after the boundary layers merge.

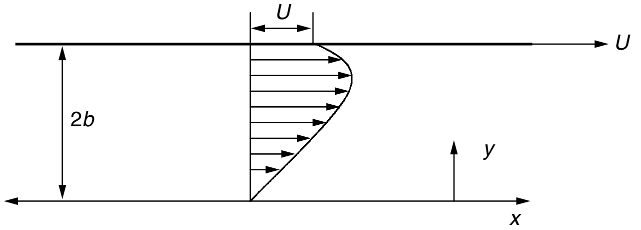

Figure 7. Steady-state flow between two parallel plates.

at velocity U. The x coordinate axis is parallel to the direction of flow. Two-dimensionality of the flow requires that $\frac{\partial}{\partial z} = 0$. Flow characteristics are also invariant in the x-direction, so that continuity requires $\frac{\partial v}{\partial z} = 0$. As $v = 0$ at $y = 0$, it follows that $v = 0$ everywhere, which implies that the flow is parallel to the walls. The momentum balance equations in x and y directions can be written as

$$0 = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \mu\frac{d^2u}{dy^2} \tag{15}$$

$$0 = -\frac{1}{\rho}\frac{\partial p}{\partial y} \tag{16}$$

The y-momentum in Eq. (16) shows that p is not a function of y. In the x-momentum in Eq. (15), the first term can only be a function of x, whereas the second term can only be a function of y. The only way this can be established is that both the terms are constants. The pressure gradient is hence a constant, implying that the pressure varies linearly across the channel. Integrating Eq. (15) twice, we get

$$0 = \frac{y^2}{2}\frac{dp}{dx} + \mu u + Ay + B \tag{17}$$

where p is a function of x only. The constants of integration are determined by using the conditions imposed on lower and upper plates. For the lower boundary, $u = 0$ at $y = 0$ requires that $B = 0$. The upper boundary condition $u = u$ at $y = 2b$, requires that $A = b\frac{dp}{dx} - \mu\frac{u}{2b}$.

The velocity profile from Eq. (17) then becomes

$$u = \frac{yU}{2b} - \frac{y}{\mu}\frac{dp}{dx}\left(b - \frac{y}{2}\right) \tag{18}$$

The volumetric flow rate per unit width of the channel can be calculated using

$$Q = \int_{O}^{2b} u dy = Ub\left[1 - \frac{2b^2}{3\,\mu U}\frac{dp}{dx}\right] \tag{19}$$

The average velocity can further be written as

$$\overline{V} = \frac{Q}{2b} = \frac{u}{2}\left[1 - \frac{2b^2}{3\,\mu U}\frac{dp}{dx}\right] \tag{20}$$

Two special cases of interest have been discussed in the subsequent section,

1. *Plane Couette Flow*. The flow driven by the motion of the upper plate, without the imposition of any external pressure gradient, is called a plane Couette flow.

Equation (18) then reduces to a linear profile represented by Eq. (21) and can be seen in Fig. 8.

$$u = \frac{yU}{2b} \tag{21}$$

The magnitude of shear stress is given by

$$\tau_{\mathrm{yx}} = \mu\frac{dU}{dy} = \frac{\mu u}{2\mathrm{b}} \tag{22}$$

which is uniform across the channel.

2. *Plane Poiseuille Flow*. The flow driven by an externally imposed pressure gradient through two stationary flat walls is called a plane Poiseuille flow. In this case, Eq. (18) reduces to Eq. (23), which represents a parabolic profile, as seen in Fig. 9.

$$u = -\frac{y}{\mu}\frac{dp}{dx}\left(b - \frac{y}{2}\right) \tag{23}$$

The magnitude of shear stress is given by

$$\tau_{\mathrm{yx}} = \mu\frac{du}{dy} = (b - y)\frac{dp}{dx} \tag{24}$$

which shows that the stress distribution is linear with a magnitude of $b(dp/dx)$ at the walls (as seen in Fig. 9).

It should be noted that the constant pressure gradient and the linearity of the shear stress distribution are general results for a fully developed flow and even hold in a turbulent flow situation.

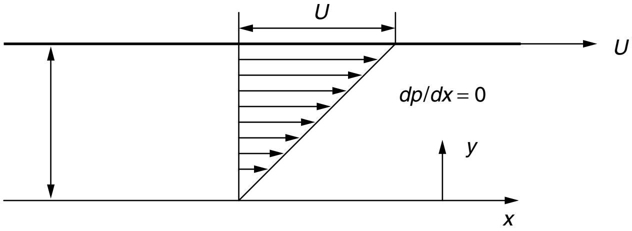

Figure 8. Plane Couette flow between two parallel plates.

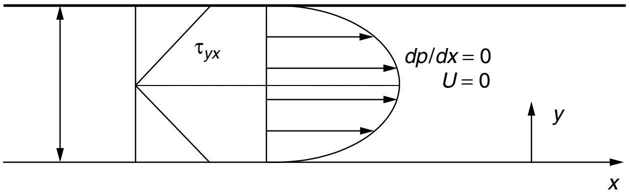

Figure 9. Plane Poiseuille flow between two parallel plates.

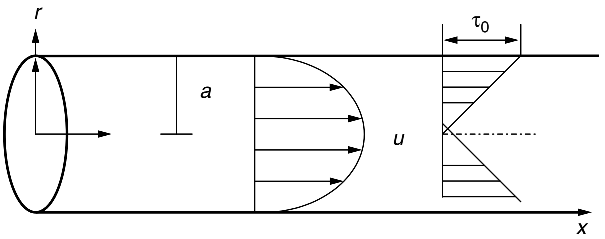

Figure 10. Laminar flow through a circular pipe.

STEADY-STATE FLOW IN A PIPE

Consider the fully developed laminar motion of a fluid through a circular pipe of radius a as shown in Fig. 10.

This type of flow is commonly known as circular Poiseuille flow. In this case, cylindrical coordinates (r, θ, x) have been used, with the x-axis coinciding with the axis of the pipe. The only nonzero component of velocity is the axial velocity u(r), and none of the variables depend on θ. The equations of motion are written in cylindrical coordinates [for detailed derivation, please refer to (2)]. The radial equation of motion gives,

$$0 = \frac{\partial p}{\partial r} \tag{25}$$

showing that p is a function of x only. The x-momentum equations gives

$$0 = \frac{dp}{dx} + \frac{\mu}{r}\frac{d}{dr}\left(r\frac{du}{dr}\right) \tag{26}$$

As the first term can only be a function of x and the second term can only be a function of r, it follows that both terms should be constants. The pressure, therefore, falls linearly along the length of the pipe. Integrating twice, we get

$$0 = \frac{r^2}{4\mu}\frac{dp}{dx} + A\ln r + B \tag{27}$$

As u must be bounded at $r = 0$, we must have $A = 0$. The wall condition, $u = 0$ at $r = a$, gives $B = -\left(\frac{a^2}{4\mu}\right)\left(\frac{dp}{dx}\right)$. The velocity profile is hence parabolic and can be represented as in Eq. (28),

$$u = \frac{r^3 - a^2}{4\mu}\frac{dp}{dx} \tag{28}$$

The shear stress at any point can be expressed using Eq. (29),

$$\tau_{\mathrm{xr}} = \mu\frac{du}{dr} = \frac{r}{2}\frac{dp}{dx} \tag{29}$$

The shear stress distribution is linear with a maximum value of $\frac{a}{2}\frac{dp}{dx}$ at the walls.

The volumetric flow rate is given by

$$Q = \int_{\mathrm{O}}^{\mathrm{a}} u 2\pi r dr = -\frac{\pi a^4}{8\mu}\frac{dp}{dx} \tag{30}$$

Equation (30) is also commonly known as the Hagen–Poiseuille law. It gives the relationship between the volumetric flow rate and the forces causing the flow, that is, the forces associated with the pressure gradient and the viscosity.

The average velocity over the circular cross section can be written as

$$\bar{v} = \frac{Q}{\pi a^2} = \frac{a^2}{8\mu}\frac{dp}{dx} \tag{31}$$

CREEPING FLOW PAST A SPHERE

When the motion of fluid is "very slow" ($\mathrm{Re} \ll 1$), the flow is said to be creeping or Stokes flow. Examples of such flows are the motion of settling of particles near the ocean bottom and the fall of moisture drops in the atmosphere. In creeping motions, viscous forces are dominant and, hence, the nonlinear inertia term present in Eq. (10) is neglected. We then have

$$\rho\frac{\partial v}{\partial t} = -\nabla p + \mu\nabla^2 v + \rho g \tag{32}$$

Equation (32) is the well-known **Stokes** equation, which is used to model creeping flows. The solution of creeping flow around a sphere was first given by Stokes in 1851. The detailed solution of velocity and pressure distributions around a sphere is quite advanced for the present text. Interested readers can refer to (2), (8), and (11) for detailed derivations. The positive pressure difference in front and negative in the rear of the sphere creates pressure drag on the sphere. Consider a fluid flowing with velocity U past a sphere of radius r. The total drag force on a sphere is obtained by calculating the total viscous stress and the normal stress and then multiplying it with the surface area of the sphere, which is found out to be

$$D = 6\pi\mu r U \tag{33}$$

One-third of the total drag comprises pressure drag, whereas two-thirds is the viscous or skin drag. It can be seen from Eq. (33) that the resistance in a creeping flow is proportional to the velocity, and is commonly known as Stokes Law.

Drag coefficient can be defined as the drag force nondimensionalized by $\rho u^2/2$ and the projected area of the sphere, which is πr^2, and stated as follows:

$$C_{\mathrm{D}} = \frac{d}{\frac{1}{2}\rho u^2 \pi r^2} = \frac{24}{\mathrm{Re}} \tag{34}$$

where $\mathrm{Re} = 2rU\rho/\mu$

Most of the problems in fluid dynamics fall under two broad categories, namely flow in channels and flow around submerged objects. Relatively simple geometrical configurations were presented in prior sections. However, real-life examples of flows in channels include pumping oil in pipes, flow of water in channels, extrusion of plastics through dyes, and fluid flows in filters. Examples of flow around submerged objects are the flow of air around an airfoil, an airplane wing, motion of fluid around particles undergoing sedimentation, etc. Flow in channels are mainly concerned with establishing a relationship between the volumetric flow rate and the pressure gradient. However, in flow past submerged objects, one is more interested in determining the relationship between the velocity of the fluid approaching the object and the drag force. As in many flow systems velocity and pressure profiles cannot be determined, the concept of friction factors/drag coefficient is found to be very useful. In other words, standard correlations are used to estimate the flow in geometrically complex systems. For an in-depth analysis, one can refer to Reference 2.

REMARKS

For understanding the physics and making generalizations in laminar flow situations, analytical solutions to simple flow configurations have been presented in the main text. With an advanced knowledge in mathematics, the readers should find it easy to solve any analytically tractable problem in laminar flow situation. Another area of utmost importance these days is Computational Fluid Dynamics, in which the equations of change are solved numerically using computers. Some of the commonly used numerical techniques for fluid flows include finite difference, finite element, and the finite volume methods. It is expected that the current text shall encourage the reader to learn numerical methods in a separate study.

INTRODUCTION

The article discusses the finite element modeling (FEM) of groundwater flow in coupled free and porous domains in natural hydroenvironmental conditions. In general, free flow regime can be viewed as if the flow were in a layer of fluid or a pipe, which needs only the fluid dynamic characterization of the domain, e.g., Reynolds Number. On the other hand, porous flow regime indicates that fluid flow takes place through a porous medium, which needs the characterization for both the fluid dynamics and the medium, e.g., permeability, porosity, pore size distribution, etc. Coupled free and porous flow is observed in many hydroenvironmental conditions. As an example, conjunctive surface and subsurface flow may be cited. The flow on the surface is characterized as free flow. Some of the water from the surface seeps into the underground soil, which is a porous medium. The flow in the underground soil may be called as the subsurface or porous flow. As well as the expected media heterogeneity, e.g., presence of layers, laminations, etc., the subsurface also contains nonporous sections, e.g., conduits, fissures, buried structures that are often damaged, macropores, vugular inclusions and fractures, etc. The hydrodynamics of groundwater flow in the nonporous (e.g., vugs) and porous sections are fundamentally governed by the Navier–Stokes and Darcy equations, respectively (1–3), although simplified forms of Navier–Stokes equations are often used in practice for the nonporous domains. The overall flow behavior in the coupled nonporous and porous region can be modeled with an approach that combines Navier–Stokes and Darcy equations with suitable interfacial, boundary, and initial conditions. However, the complexity of the subsurface regions is such that it is usually not possible to predict the coupled flow behavior with confidence using the traditional analytical methods or experiments. FEM is a powerful method that can be used to validate results from experiments and/or analytical method. In other cases, where such results are not available, FEM modeling can be used independently to predict the flow field in the subsurface. The versatility of FEM lies in its ability to cope with complex and irregular geometries of the flow domain found in subsurface regimes.

In this article, the finite element method will be discussed in the context of solving coupled free and porous flow governed by Navier–Stokes and Darcy equations, respectively. Boundary conditions that may be used for simulating coupled flow problems are also discussed very briefly.

COUPLED FREE AND POROUS FLOW MODEL

The flow in the free flow regime can be mathematically expressed by the well-known Navier–Stokes equations in vector form as

$$\rho \frac{\partial \vec{v}}{\partial t} + \rho \vec{v} \cdot \nabla \vec{v} = -\nabla p \vec{\vec{\delta}} + \nabla \cdot \vec{\vec{\tau}} + \rho \vec{g} \qquad (1)$$

where ρ is the density of the incompressible fluid; $\vec{v}$, p, $\vec{\vec{\tau}}$, and $\vec{g}$ represent velocity, pressure, extra stress, and body force, respectively; and $\vec{\vec{\delta}}$ is the Kronecker delta tensor. Equation (1) expresses the conservation of momentum of free flow for an incompressible viscous fluid. The first term on the left-hand side represents the rate of change of momentum, whereas the second term represents the convective flow. On the right-hand side, the first term represents the hydrostatic pressure gradient; the second term is the deviatoric stress, whereas the last term contributes to the momentum because of the gravitational force.

The porosity of soil in the subsurface is generally low (<0.5). In such a case, the inertia forces seem to be dominated by the viscous forces, although this cannot be generalized because of its heterogeneous nature. Nevertheless, the flow in the subsurface can be mathematically expressed by the Darcy equation as

$$\rho \frac{\partial \vec{v}}{\partial t} = -\nabla p - \frac{\eta}{\vec{\vec{K}}} \cdot \vec{v} \qquad (2)$$

where $\vec{\vec{K}}$ represents the permeability tensor.

According to Newton's first law, the total mass of fluid flowing in the flow regions must be equal to the amount of fluid leaving the domain without any accumulation or consumption. This mass conservation can be represented by the continuity equation for a fluid of constant density as

$$\nabla \cdot \vec{v} = 0 \qquad (3)$$

The governing equations for the groundwater flow system are either solved analytically or numerically. Analytical models contain an analytical solution of the field equations, continuously in space or time. In numerical models, a discrete solution is obtained in both space- and time-domains by using numerical approximations of the governing partial differential equations. In general, a wide variety of numerical techniques are used in groundwater flow modeling. The most commonly used methods are the finite difference, finite element, finite volume, and analytical element methods. However, we will limit this text to discuss the use of finite element method for reasons explained earlier.

PRINCIPLES OF FINITE ELEMENT MODELING

The finite element method (FEM) is based on the principles of variational calculus. In this method, the overall geometrical domain is divided into a number of small discrete regions, termed as finite elements, with each element associated with a fixed number of nodal points. The variables within each element can be approximated by their values at each elemental node multiplied by an appropriate shape function associated with that node. This approximation is substituted in the mathematical statement of a problem, and the residual statement is weighted over the entire elemental domain. The solution is achieved by minimizing the errors introduced by the approximation.

TYPES OF FINITE ELEMENTS

Various finite element families are available, mainly based on the geometrical shapes of the elements, such as triangular or rectangular in 2-D cases or brick or prismatic elements for 3-D situations. In the context of 2-D modeling, we briefly discuss triangular and rectangular elements. Typical triangular elements are shown in Fig. 1(a) and (b).

To define the variations of the dependent variable over the elemental domain, nodal geometrical functions associated with each node, commonly known as shape functions, need to be derived. For a two-dimensional

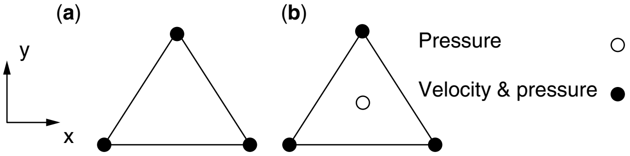

Figure 1. Triangular finite elements.

element, the approximation for the dependent variable in terms of the nodal shape functions can be written as

$$f(x,y) = \tilde{f}(x,y) = \sum_{i=1}^{p} N_i(\overline{x},\overline{y}) f_i \tag{4}$$

where the overbar indicates the values at each node of the element.

Multidimensional elements should also satisfy the following conditions:

$$\sum_{i=1}^{p} N_i(\overline{x},\overline{y}) = 1$$

$$N_i(\overline{x}_j,\overline{y}_j) = 1, \quad i = j$$

$$N_i(\overline{x}_j,\overline{y}_j) = 0, \quad i \neq j$$

In case of a three-noded element, shown in Fig. 1(a), the shape functions are

$$\left.\begin{aligned} N_i &= \frac{1}{2A}[a_i + b_i x + c_i y] \\ N_j &= \frac{1}{2A}[a_j + b_j x + c_j y] \\ N_k &= \frac{1}{2A}[a_k + b_k x + c_k y] \end{aligned}\right\} \tag{5}$$

where

$$\begin{vmatrix} 1 & X_i & Y_i \\ 1 & X_j & Y_j \\ 1 & X_k & Y_k \end{vmatrix} = 2A$$

$$\begin{aligned} a_i &= X_j Y_k - X_k Y_j, & b_i &= Y_j - Y_k & \text{and} \quad c_i &= X_k - X_j \\ a_j &= X_k Y_i - X_i Y_k, & b_j &= Y_k - Y_i & \text{and} \quad c_j &= X_i - X_k \\ a_k &= X_i Y_j - X_j Y_i, & b_k &= Y_i - Y_j & \text{and} \quad c_k &= X_j - X_i \end{aligned}$$

where (X_i, Y_i), (X_j, Y_j), and (X_k, Y_k) are the coordinates corresponding to the nodes i, j, and k, respectively. For detailed derivations, the readers can refer to Nassehi (4) and Segerlind (5). A four-noded rectangular finite element is shown in Fig. 2. The shape functions for this element can be written as

$$\left.\begin{aligned} N_i &= \frac{1}{4}\left(1 - \frac{q}{b}\right)\left(1 - \frac{r}{a}\right) \\ N_j &= \frac{1}{4}\left(1 + \frac{q}{b}\right)\left(1 - \frac{r}{a}\right) \\ N_k &= \frac{1}{4}\left(1 + \frac{q}{b}\right)\left(1 + \frac{r}{a}\right) \\ N_k &= \frac{1}{4}\left(1 - \frac{q}{b}\right)\left(1 + \frac{r}{a}\right) \end{aligned}\right\} \tag{6}$$

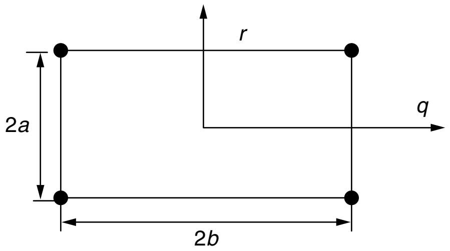

Figure 2. A linear rectangular finite element.

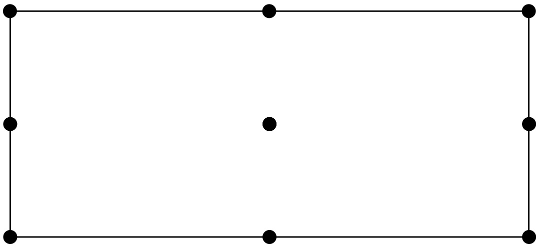

Figure 3. A biquadratic rectangular finite element.

The second member of this group is the nine-noded biquadratic rectangular element with equal order interpolation functions for velocity and pressure, as shown in Fig. 3.

Higher order elements of this family can also be readily generated using the tensor products of the higher order one-dimensional interpolation functions. In addition to all these classes of finite elements, some nonstandard elements exist, such as the Taylor–Hood elements specially designed for the solution of incompressible flow problems. In the Taylor–Hood elements, interpolation of pressure is always based on a lower order polynomial than the velocity interpolation functions.

PARAMETRIC MAPPING

Finite element method can deal with irregular or curved geometries in a straightforward and systematic way using parametric mapping (6). A regular element, known as the master element, is chosen and a local finite element approximation based on this master elemental shape function is selected. The Master element is mapped into the global coordinates to generate required curved irregular element. Two independent elements can be used in the finite element analysis, one for approximating geometry and the other for interpolation of field variable. When a typical element in global coordinate system is transformed to a master element, it is requisite to transform the global coordinate system to local coordinate system of the master element. Depending on the relationship between the degree of approximation used for coordinate transformation and for the field variable, three different types of mapping schemes can be employed.

1. *Subparametric Transformation*: Shape functions used for geometry are of lower order than that used for dependent variable.
2. *Isoparametric Transformation*: Shape functions used for mapping geometry are of the same order as for the dependent field variable.
3. *Superparametric Transformation*: Shape functions for mapping geometry are of higher order than that used for the field variable.

FINITE ELEMENT SCHEMES FOR INCOMPRESSIBLE FLOW PROBLEMS

Application of the weighted residual method to the solution of incompressible flow equations of continuity and momentum conservation is commonly based on two different schemes.

U-V-P Scheme

The name U-V-P implies U as the component of velocity in x-direction, V as a component of velocity in y-direction, and P as pressure with all these variables calculated simultaneously in the solution scheme. Zienkiewiez and Taylor (6) classified the U-V-P scheme to general category of mixed finite element methods. In this technique, both velocity and pressure are termed as primitive variables and are discretised as unknowns. In the U-V-P method, the weighted residual statements for the groundwater flow model can be formulated as

Free Flow Zone

$$\int_{\Omega} N_P \nabla\cdot\bar{v}\,d\Omega = 0$$

$$\int_{\Omega} \rho N_V\left(\frac{\partial\bar{v}}{\partial t} + \bar{v}^0\nabla\bar{v}\right)d\Omega = \int_{\Omega} N_V\left(-\nabla\bar{p}\delta + \nabla\cdot\bar{\tau} + \rho g\right)d\Omega \tag{7}$$

Porous Flow Zone

$$\left.\begin{array}{l} \int_{\Omega} N_P \nabla\cdot\bar{v}\,d\Omega = 0 \\ \int_{\Omega} \rho N_V\left(\dfrac{\partial\bar{v}}{\partial t}\right)d\Omega = \int_{\Omega} N_V\left(-\nabla\bar{p} + \dfrac{\eta}{K}\cdot\bar{v}\right)d\Omega \end{array}\right\} \tag{8}$$

where an over bar indicates interpolated variables over an element. N_v and N_P are the appropriate basis functions or weight functions.

The interpolating functions for the field variables are substituted in the formulations, and the equations are then integrated, which yields a final set of finite element working equations (7).

Penalty Scheme

The penalty method is a standard technique to reduce the number of variables in the flow calculation (4). In the penalty method, the pressure is expressed in terms of the incompressibility condition (4)

$$p = -\lambda(\nabla\cdot v) \tag{9}$$

This relation is then substituted in the momentum balance equation, after which the weighted residual finite element method is applied. λ is the penalty parameter that generally has a very large value. Elimination of pressure as a field variable leads to a compact set of working equations reducing the computational cost. The only problem with the penalty scheme lies in the selection of appropriate value of the penalty parameter to avoid ill conditioning of the solution matrices.

MODELING SCHEMES BASED ON U-V-P FORMULATION

In the modeling of incompressible flows, the Ladyzhenskaya–Babuska–Brezzi (LBB) stability condition must be satisfied (8), which poses a severe restriction on the type of approximating functions that can be used in finite element formulations. Different finite element models based on various strategies have been developed that satisfy the LBB condition. They range from the use of elements generating unequal order interpolation functions (6) for the field unknowns to a perturbed form of continuity equation (9) representing slightly compressible fluids.

Taylor–Hood Scheme

In order to satisfy the LBB condition, unequal order interpolation functions for velocities and pressure can be used. In this scheme, the incompressibility constraint can be used without any modifications (i.e., Eq. (3) remains as $\nabla\cdot\vec{v} = 0$). In addition to the requirement of LBB criterion, it is also known that because of the incompatibility of the operators in the Navier–Stokes and Darcy equations, the approximating function spaces used for the numerical solution of these equations need to be different. In essence, the Darcy equation should be treated as an elliptic Poisson equation, where the degrees of freedom should be kept as low as possible. This scheme is developed using C^0 continuous Taylor–Hood elements (10). This element is a member of the bubble element family (11), and it is expected that all other members of this family will generate stable solutions for incompressible flows with a variety of time-stepping schemes. A typical Taylor–Hood element can be seen in Fig. 4.

Perturbed Continuity Scheme

The perturbed continuity method (12) depends on the inclusion of the term $\dfrac{1}{\rho c^2}\dfrac{\partial p}{\partial t}$ in the continuity equation (i.e., Eq. 3), where ρ is the fluid density and c is the velocity of sound in the fluid. Therefore, this results in the incorporation of the temporal derivative of pressure in the continuity equation, which in physical terms amounts to considering the fluid to be slightly compressible (9). To use the time-dependent continuity equation, transient terms, such as $\dfrac{\partial\vec{v}}{\partial t}$, should also be added into the Navier–Stokes and the Darcy equations, which inherently forces the use of a time-stepping scheme in the numerical solution of the coupled flows. The perturbed continuity scheme allows the use of equal order interpolation functions for velocity and pressure. Steady-state conditions can be obtained iteratively using different time-stepping schemes.

TEMPORAL DISCRETIZATION

The finite element solution of time-dependent flow problems produces a system of linear first-order differential

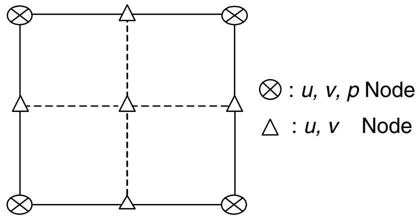

Figure 4. Taylor–Hood element.

equations in the time-domain. The method for solving time-dependent partial differential equations is the Partial Discretization Method. In this method, the space-time domain is not discretized as a whole, but the time derivatives are treated separately.

θ Time-Stepping Method

In this method, the time derivatives are kept unchanged, and the spatial discretization is carried out to form a weighted residual statement, which yields a system of ordinary differential equations in time. Consider a partial differential equation

$$\frac{\partial \phi(x,t)}{\partial t} + f[\phi(x,t)] - c = 0 \tag{10}$$

where f is a linear differential operator with respect to x.

At any time level θ, the temporal derivative is approximated by a forward difference as

$$\left.\frac{\partial \phi}{\partial t}\right|_{\theta} = \frac{\phi|_{n+\theta\Delta t} - \phi|_n}{\theta \Delta t} = \frac{\phi|_{n+1} - \phi|_n}{\Delta t} \tag{11}$$

In general, this differential system can be shown in matrix form as

$$[M]_\theta \left\{\phi^\bullet\right\}_\theta + [K]_\theta\{\phi\}_\theta = \{F_\theta\} \tag{12}$$

where $0 \leq \theta \leq 1$.

The terms, except the differential term, in the equation are approximated using a linear interpolation as

$$[K]_\theta\{\phi\}_\theta = (1-\theta)[K]_n\{\phi\}_n + \theta[K]_{n+1}\{\phi\}_{n+1} \tag{13}$$

$$\{F\}_\theta = (1-\theta)\{F\}_n + \theta\{F\}_{n+1} \tag{14}$$

Substitution of these equations and carrying out algebraic manipulation gives

$$\begin{aligned}([M]_\theta + \theta\Delta t[K]_{n+1})\{\phi\}_{n+1} = {} & ([M]_\theta - (1-\theta)\Delta t[K]_n)\{\phi\}_n \\ & + ((1-\theta)\{F\}_n + \theta\{F\}_{n+1})\Delta t \end{aligned} \tag{15}$$

On the basis of this equation, a global set is derived and solved to obtain unknowns at time level $n+1$ using the known value at time level n.

Taylor–Galerkin Method

The Taylor–Galerkin time-stepping technique is elaborated in detail in the work by Donea (13). Consider the same differential equation. Taylor series expansion of variable ϕ within the time steps n and $n+1$ gives

$$\phi^{n+1} = \phi^n + \Delta t \left.\frac{\partial \phi}{\partial t}\right|^n + \frac{1}{2}(\Delta t)^2 \left.\frac{\partial^2 \phi}{\partial t^2}\right|^n + \ldots.. \tag{16}$$

The temporal derivatives in Eq. (15) can be substituted from the parent differential Eq. (9) evaluated at that time level. Hence, we have

$$\left.\frac{\partial \phi(x,t)}{\partial t}\right|_n = -f[\phi(x,t)]|_n + c \tag{17}$$

Similarly, the second-order derivative at time step n can be replaced as

$$\left.\frac{\partial^2 \phi(x,t)}{\partial t^2}\right|_n = \frac{\partial}{\partial t}\{-f[\phi(x,t)]|_n + c\} \tag{18}$$

All the temporal derivatives in the Taylor series expansion can be substituted principally from the original differential equation. Taylor series expansion of the field variable is truncated, keeping only first few terms. Accuracy of the scheme is solely dependent on the highest order of derivative remaining in the expansion after truncation.

MATHEMATICAL MODELS FOR COUPLED FLOWS

The main challenge is to construct a sound mathematical formulation for the coupled free and porous flow dynamics (14). The selection of appropriate approximating function spaces for the numerical solution of these equations, which guarantee unified stability of both the free flow and porous flow models, is not straightforward (15). In order to circumvent this problem, most of the solution algorithms are based on two approaches.

The first approach employs the Brinkman's equation to describe the flow on a free/porous interface (16). The Brinkman's equation includes the Laplacian of the velocity field and, hence, is of the same order as the Stokes equation. Therefore, its use across a free/porous interface ensures continuity of velocity and pressure fields. The Brinkman's equation is only applicable to media of high permeability (17). In addition, the Brinkman's equation is constructed using a parameter called "effective viscosity." The second approach is based on the imposition of a slip-wall boundary condition at the free/porous interface, as suggested by Beavers and Joseph (18). Using this approach, the interfacial boundary condition is modified to match the free and porous flow conditions by an auxiliary relationship. This approach is empirical and deduced from a simple one-dimensional situation, and its extension to multidimensional cases is not well understood. The value of the slip coefficient depends on many physical parameters such as the geometrical features of the interface.

Discacciati et al. (19) developed a model for coupling of Navier–Stokes and Shallow Water equations for surface flows and Darcy equations for groundwater flows. They applied the boundary conditions similar to that of the Beavers and Joseph (18) at the free/porous interface. They developed an iterative method for the solution, which requires the solution of one problem in the fluid part and one in the porous medium.

Recently, Burman and Hansbo (15) proposed a unified approach for the solution of the coupled Stokes/Darcy problem using an edge stabilization technique in conjunction with the use of mixed P_1/P_0 finite elements. The edge stabilization, as named by these authors, involves the splitting of the viscous stress term into its normal and tangential components at the free/porous interface. The normal stress component is then equated to the pressure differential across the free/porous interface.

NODAL REPLACEMENT SCHEME FOR COUPLED FLOWS

In addition to the schemes described in the previous section, Nassehi et al. (7) have developed a nodal replacement technique based on finite element method, which can be used for modeling coupling the free and the porous flow dynamics in two-dimensional situations.

The scheme is based on the imposition of Darcy equation as a boundary condition for the Navier–Stokes equations at the free/porous interface (and vice-versa at the porous/free interface). The field variable velocities and pressures are forced to be continuous in both the free and porous regions across the interface. In the stiffness matrix corresponding to the elements in the free flow regime, which are also present on the free/porous interface, the Navier–Stokes terms corresponding to the interfacial nodes are replaced by the appropriate form of the discretised Darcy components and vice-versa. This procedure is illustrated in Fig. 5.

BOUNDARY CONDITIONS FOR COUPLED FLOW DOMAINS

For the solution of free flow equations, no-slip-wall boundary conditions (20) are generally specified on the impermeable walls of the domain. A velocity boundary condition is given at the inlet of the flow domain, whereas at the exit, stress-free boundary conditions (21) are used.

For the solution of porous flow equations, a partial slip boundary condition (4) may be specified, and at the flow exit, a pressure datum can be imposed. In the coupled flow situation, the Darcy equation is imposed as the boundary condition for the Navier–Stokes equation at the free/porous interface.

COMMERCIAL GROUNDWATER FLOW MODELS

There are many commercially available groundwater flow models based on a numerical method, which have been developed in the past. They are widely used in industries and academia for carrying out a variety of numerical studies. For example, FEMWATER is commonly used for 3-D modeling of flow and transport in groundwater systems. Salient features of some of the other frequently used groundwater flow tools have been presented in Table 1.

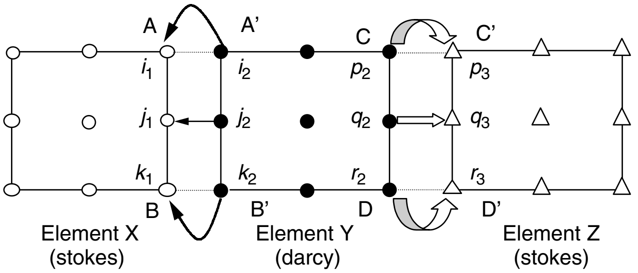

Figure 5. Schematic representation for linking of Navier–Stokes and Darcy regimes.

Table 1. Commercial Finite Element Groundwater Models

S No.	Model	Application
1	**3DFEMFAT**	3-D finite-element model of flow and transport through saturated-unsaturated media.
2	**AQUA3D**	3-D groundwater flow and contaminant transport model.
3	**ChemFlux**	Finite element mass transport model.

13	**FEMWATER**	3-D Finite Element Model for Coupled Groundwater Flow and Contaminant Transport.

BENEFITS OF FINITE ELEMENT MODELING FOR MODELING COUPLED FLOW

The finite element method is generally found to be more robust and reliable toward obtaining stable and convergent solution, which is because it involves the minimization of errors introduced because of variable approximation. The Galerkin weighted residual finite element method is very flexible and can cope with irregular, complex, and curved geometries of the problem domain, which is the normal case in the free surface and subsurface flows. The previously developed mathematical models for the coupled free/porous problems are based on concepts like the use of the Brinkman's equation or the specification of slip-wall boundary condition at the interface. Although both of these methodologies appear to be simple, they seem to be compromising their accuracy and lacking flexibility with suitability only for specific problem domains. The novel nodal replacement technique available in FEM is a simple mathematical concept that links the physics behind the free flow and porous flow phenomena without any simplified assumptions and can be easily extended to three-dimensional flow regimes. The linking of the free and the porous flow regimes is achieved without imposition of any artificial boundary conditions at the free/porous interface. It can be concluded that the FEM schemes are highly robust and reliable for the combined flow without any mathematical problems developing from stability requirements, numerical incompatibility, or time-stepping schemes.

SUMMARY

The coupled free and porous flow phenomenon has been discussed in the context of natural hydroenvironmental conditions. Mathematical statements of free and porous flow models have been represented elaborating physical significance of each flow regime. Various finite element families have been listed and classified mainly according to the geometric shapes of the elements. Finite element formulations for the incompressible flow problems based on two common methods, namely the U-V-P and penalty schemes, have been derived. In the context of unsteady-state studies, time-stepping schemes like θ-method and Taylor–Galerkin methods have been explained for the temporal discretization of the governing equations. The currently available mathematical models for the coupled flow problems have been discussed regarding their conceptual details and related assumptions. A recently developed nodal replacement scheme for the coupled flow situation has been analyzed with the help of a pictorial representation and required boundary conditions.

Nomenclature

v	Fluid velocity
$\vec{v}$	Velocity vector
p	Fluid pressure
$\vec{g}$	Gravitational acceleration vector
$\vec{\vec{K}}$	Permeability tensor
A	Area of the finite element
N	Shape functions
c	Speed of sound in fluid

Subscripts

x	In x-direction
y	in y-direction
v	For velocity
p	For pressure

Greek Symbols

ρ	Fluid Density
η	Fluid viscosity
θ	Time-stepping parameter
Ω	Elemental domain
λ	Penalty parameter
∇	Gradient
$\vec{\vec{\delta}}$	Kronecker delta tensor
$\vec{\vec{\tau}}$	Extra stress tensor

UNCONFINED GROUNDWATER

Aly I. El-Kadi
University of Hawaii at Manoa
Honolulu, Hawaii

INTRODUCTION

An unconfined aquifer is a geologic formation with subterranean water that is not confined by relatively impermeable layers. Part of the precipitation and irrigation water as well as water from recharge basins, reservoirs, and ponds moving downward from the soil layer will reach the saturated groundwater zone. The top of this zone is the water table, which separates the fully saturated zone from a partially saturated zone. The latter zone is simply referred to as the unsaturated zone, but it is also known as the zone of aeration or vadose zone. Generally, the water in the unsaturated zone is under less than atmospheric pressure. The unsaturated zone includes the capillary fringe, directly above the water table, which is near saturation but still under negative pressure relative to the atmospheric pressure.

Often, groundwater flow discharges into or receives water from surface water bodies such as river channels or lakes. An effluent or gaining stream is supplied by groundwater, which is usually the case in humid climates. An influent or losing stream supplies water to the groundwater and is a characteristic of arid climates. In addition to the flow to streams from the saturated zone, there exists throughflow, which is the sporadic horizontal water flow above the water table. Such a flow normally takes place when parts of the soil are completely saturated. Flow rates are usually low, with maximum flow likely occurring on steep slopes and in pervious sediments.

The presence of a low conductivity zone or an impermeable layer (called perching bed) can lead to the formation of a perched water table above the aquifer's main water table. Springs are often formed when a perched water table intersects the ground surface. Perched groundwater can be permanent if recharge is frequent enough to maintain a saturated zone above the perching bed. Intermittent cases occur when recharge is not large or frequent enough to prevent the perched water from disappearing at times due to drainage through the perching bed or over its edges.

Water input to an unconfined aquifer mainly includes recharge due to rainfall and return irrigation, direct injection, and leakage from surface water bodies. Major outflow can include pumping of groundwater, plant usage, evaporation from the soil surface, and leakage onto surface water bodies. Water table elevation will change according to the relative magnitude of groundwater replenishment versus depletion.

When compared to confined aquifers, unconfined aquifers are more susceptible to contamination by dissolved chemicals, such as agricultural chemicals, and nonaqueous phase liquids (NAPLs), such as hydrocarbon products, due to the absence of a confining layer. Light nonaqueous phase liquids (LNAPLs), such as gasoline, can form a floating lens on top of the water table. The lens moves in the direction of groundwater flow. A dissolved phase plume can form in the saturated zone that also moves in the direction of water flow. A plume of dense NAPLs (DNAPLs) can penetrate down through the unsaturated and saturated zones and move by gravity in a direction that is independent of groundwater flow. A dissolved phase plume due to DNAPLs can also exist.

WATER FLOW

Mathematical Formulation

A description of processes involved in saturated/unsaturated flow in unconfined aquifers is covered by Bear (1) and more recently by El-Beshry (2) and Charbeneau (3). Flow in parts of the unconfined aquifer is characterized by the existence of water and air. Various mathematical approaches for flow in unconfined aquifers are described by Brutsaert and El-Kadi (4). The approaches cover various degrees of complexities. The engineering approach includes a two-equation system for the flow of water and air. If the air phase is considered as continuous and at atmospheric pressure, a single equation that describes water flow will result. The equation will include the effects of unsaturation and solid-matrix and water compressibility. If compressibility effects are ignored, the equation will reduce to the well-known Richards equation (5), which can be written in the following form:

$$\nabla \cdot (K \, \nabla h) = \frac{\partial \theta}{\partial t} \tag{1}$$

where K is the hydraulic conductivity, h is the hydraulic head, θ is the water content, and t is time. The hydraulic head is related to pressure head ψ by $h = \psi + z$, in which z is the elevation above an arbitrary datum. Equation 1 is also applicable to the saturated zone, where K equals its saturated value and θ equals porosity. Following solution of Equation 1, the water table would be identified as the surface where the pressure head value equals zero.

Needed for a complete formulation are the relationships $K(\psi)$ and $\theta(\psi)$. Popular forms of these relationships are provided by van Genuchten (6):

$$S_e = [1 + |\alpha\psi|^n]^{-m} \tag{2}$$

in which S_e is defined as

$$S_e = \frac{(\theta - \theta_r)}{(\theta_s - \theta_r)} \tag{3}$$

In Equations 2 and 3, θ_s and θ_r are saturated and residual water content, respectively, and α, n, and m are parameters with n and m related by

$$m = 1 - 1/n \tag{4}$$

The hydraulic conductivity function is given by van Genuchten (6) as

$$K = K_s S_e^{0.5}[1 - (1 - S_e^{1/m})^m]^2 \tag{5}$$

where K_s is the saturated hydraulic conductivity.

Solutions for Equation 1 are complicated by its nonlinearity due to the dependence of the conductivity and saturation on hydraulic head. Analytical solutions are available for simplified conditions, such as those for infiltration and discharges from sources in the unsaturated zone (6,7).

Numerical solutions are suitable for general problems involving more realistic flow conditions and spatially varied parameters, such as hydraulic conductivity. Examples of numerical models include VS2D (8,9), HYDRUS (10; http://www.pc-progress.cz/Fr_Hydrus.htm), and FEMWATER (11). VS2D is in the public domain and can be downloaded from the U.S. Geological Survey web site: http://www.usgs.gov/software/vs2di.html. FEMWATER is included in the commercial package GMS (http://www.ems-icom), which serves as the data pre- and postprocessor for the model. The original version of the model is in the public domain (http://www.epa.gov/ceampubl/gwater/femwater/). FEMWATER is a three-dimensional model, in contrast to HYDRUS and VS2D, which are two-dimensional models.

Care is required in choosing the size of the mesh or grid for numerical models. Small sizes, on the order of centimeters, are needed in some cases for achieving good numerical accuracies, mostly due to the nonlinear nature of Equation 1 (12). Such a restriction puts a severe limitation on the use of numerical models for large-scale three-dimensional aquifers with thick unsaturated zones.

Solutions for Equation 1 also require specification of initial and boundary conditions. The initial condition may include location of the water table and the relevant distribution of pressure head. Boundary conditions may include specified head or water flux rates. Wells are usually treated as sources (injection) or sinks (pumping).

In some applications, flow in the unsaturated zone can be overlooked and only the flow in the saturated zone is considered. In this case, a number of mathematical formulations exist, which include the use of a specific yield parameter that assumes instantaneous flow from the unsaturated zone toward the water table (1). Saturated flow models, such as MODFLOW (13), can be used in this regard. The limitations have to be recognized, however, especially for aquifers with a thick unsaturated zone compared to the saturated thickness of the aquifer.

Infiltration Models

Infiltration is the process of water entry to the subsurface en route to the saturated zone. Infiltration quantification is an important part of estimating runoff needed for watershed assessment. Numerical models can simulate infiltration. However, their use is cumbersome for watershed assessment. Empirical and physically based models are useful in this regard. Such models are reviewed by Philip (14) and El-Kadi (15). Popular models include those developed by Green and Ampt (16), Kostiakov (17), Horton (18), and Philip (19). More recent models include those by Smith and Parlange (20), Parlange et al. (21), and Parlange and Haverkamp (22).

Models for Aquifer Test Analysis

Aquifer test analysis is a popular technique for estimating hydraulic parameters that control an aquifer's capacity to transmit and store water. Both analytical and numerical solutions can be used in the process through an automatized or manual fitting process. The nature of the flow in an unconfined aquifer causes failure of the classic Theis solution (23), which is based on restrictive assumptions relevant to the nature of confined aquifer flow. Most analytical models attempt to account for the water table condition and flow in the unsaturated zone by assigning a certain boundary condition at the water table. Theoretical developments and model assumptions can be found in Freeze and Cherry (24), Kruseman and de Ridder (25,26), Driscoll (27), Dominico and Schwartz (28), Walton (29), and Fetter (30).

Popular aquifer test models include those by Boulton (31), Boulton and Streltsova (32), Boulton and Pontin (33), Dagan (34), Neuman (35–37), Moench (38,39), and Moench et al. (40). The pioneering model of Boulton (31) approximates drainage from the zone above the water table by using an exponential relation containing an empirical parameter considered as a delay index. Moench (38) substituted Boulton's (41) convolution integral for Neuman's (35,36) boundary condition for the free surface. Additional improvements were introduced by Moench (39) and Moench et al. (40).

Available commercial pump-test packages include AquiferTest (42; http://www.waterloohydrogeologic.com). The package includes the solutions of Moench (43) and Neuman (37). The package also includes a solution with a correction term that allows the use of the Theis (23) and Cooper–Jacob (44) solutions for the analysis of pumping test data for an unconfined aquifer.

CONTAMINATION

Mathematical Formulation

As discussed earlier, contamination can be caused by dissolved chemicals or NAPLs. Subsurface solute transport and fate in the unsaturated/saturated zone are described by Charbeneau (3), including degradation due to biological, chemical, and photochemical processes, volatilization, immobilization, sorption, ion exchange, advection, diffusion, dispersion, residual saturation, and preferential flow. Further discussion of these processes is provided by Hughes (45).

For conservative dissolved chemicals, that is, in the absence of chemical and biological transformations, the governing equation can have the following form (3):

$$\nabla \cdot (\theta D \cdot \nabla C) - \nabla(VC) = \frac{\partial \theta C}{\partial t} \tag{6}$$

where C is the solute concentration, D is the dispersion coefficient, and V is the seepage velocity. The seepage velocity is estimated by dividing Darcy's flux by the effective porosity, which is defined as the porosity available for water flow. Darcy's flux is estimated by solving Equation 1. Mathematical formulation for nonconservative chemical transport is covered by Freeze and Cherry (24), Fetter (46), and Charbeneau (3). Equation 6 is applicable to the saturated zone, where θ equals the effective porosity, which is constant with respect to time but can be spatially varied.

Multiphase flow in cases of NAPL contamination requires the use of various phase equations that include water flow, liquid product flow, gas flow, and dissolved phase transport and fate processes. Discussion of concepts involved, as well as practical aspects of addressing NAPL contamination, is covered by Bedient et al. (47) and Charbeneau (3).

A free interactive guide for the fate, transport, and remediation of LNAPLs is available for downloading from the website of the American Petroleum Institute: http://www.groundwater.api.org/lnaplguide/. The guide provides understanding of principles and some tools for evaluating the mobility, stability, and recoverability of LNAPLs. The guide is designed to provide an overall approach for evaluating the LNAPL at a site, assessing its potential risk, quantitatively defining mobility and recoverability, developing remedial strategies, and examining methods to enhance site-closure opportunities.

Saltwater Contamination

In addition to potential contamination by dissolved chemicals and NAPLs, saltwater can be a contamination threat for unconfined aquifers in coastal zones and islands. Classic textbooks, such as those by Bear (1), Todd (48), and Fetter (30), discuss the subject, including theoretical developments and practical aspects of the processes involved. Density effects, which can be justifiably overlooked in the cases for dissolved chemicals, dominate saltwater contamination situations.

For coastal aquifers, fresh groundwater discharges to the ocean and mixes with saltwater. The contact between saltwater and fresh water creates a zone of mixing that is characterized by brackish water with a salinity gradient. Such a transition can be sharp, with a thin mixing zone. However, under freshwater head fluctuations, excessive well pumping, and tidal fluctuations, the mixing zone can be quite large.

For unconfined aquifers, fresh groundwater moves upward to discharge near the shoreline, while cyclic water flow occurs in the salty water near the interface (49). Under ideal conditions that include a sharp interface and hydrostatic condition, the depth to the freshwater extent below sea level, Z, is expressed by the Ghyben–Herzberg equation (50,51):

$$Z = \frac{\rho_f}{\rho_s - \rho_f} H \tag{7}$$

where H is the elevation of the water table above sea level, ρ_f is the density of fresh water, and ρ_s is the density of saltwater. Such a relationship would provide a ratio of 1 to 40 for H to Z.

Equation 7 is also valid under conditions for mainly horizontal flow, which is usually valid away from the shoreline. Todd (48) and Fetter (30) provide other useful analytical expressions, such as that of the depth to the interface between fresh water and saltwater for an oceanic island with groundwater recharge. The U.S. Geological Survey has developed the numerical modes SHARP (52), which can be used in simulating freshwater and saltwater flow under the assumption of a sharp interface. The model is available from the URL site http://water.usgs.gov/software/sharp.html.

AQUIFER VARIABILITY

Variability of soil and aquifer material is common and may cause substantial difficulties in assessing water flow and contaminant transport and fate in unconfined systems. Jury et al. (53,54) summarized results from a number of unsaturated zone field studies regarding variability of hydraulic conductivity, porosity, and infiltration. Properties can be highly heterogeneous due to the nature of geological formations, including the existence of various geological units of contrasting features. Fractures due to structural or other factors can cause preferential flow and transport (55,56). Overlooking preferential flow may lead to unacceptable errors in estimating travel times and the risk of contamination (57).

Estimating parameters under variable conditions is difficult due to the costs involved in physically collecting data and the potential for affecting the integrity of the aquifer. Inverse methods involve the indirect estimation of parameters based on hydraulic head or solute concentration values. An example of available software is PEST (58), which can be used with various models in estimating their parameters. However, questions arise regarding model uniqueness.

Approaches to model systems under variable conditions include both deterministic approaches and stochastic approaches. For deterministic approaches, continuum models are adapted in which it is assumed that a representative control volume exists where aquifer or soil properties are defined. For example, a continuum model for flow in an unconfined aquifer would assume validity of the Richards equation but would use soil hydraulic properties that are modified to reflect a fracture-porous system (59). Examples of soil properties for this system are provided by Durner (60) and Mohanty et al. (61).

Other deterministic approaches include the use of discrete fracture models to account for water flow and solute transport in fractured rocks by taking into consideration the location and aperture of rock fractures (62). Charbeneau (63) and Germann (64) adopted a kinematic wave approach to account for water flow in fracture or macropore domains, which are also known as dual- or double-porosity domains. Two-domain models were developed by Duguid and Lee (65), Gerke and van Genuchten (66), Ray et al. (67), and Vogel et al. (68), while a three-domain model was developed by Gwo et al. (69). Such models simulate mobile water in soils or fractured porous media conceptualized to have two- or three-pore domains. These models are commonly referred to as dual- or multipermeability models, where advective movements of chemicals are considered in the matrix domain. Zyvoloski et al. (70, 71) developed a general purpose finite-element code for the simulation of water, heat, and multisolute species at the Yucca Mountain nuclear waste repository site.

Stochastic models assume that parameters are described as statistical variables derived from certain distributions and may include spatial correlation structures. The simplest approach involves the use of the Monte Carlo method, which is based on the repetitive solution of the governing equation with different sets of parameters derived from their statistical distributions, followed by a statistical analysis of results to quantify uncertainties (72). Other stochastic methods include the spectral approach (73) and the similar-media approach (74). For solute transport in unsaturated media, available approaches include the models of Dagan and Bresler (75), Simmons (76), and Jury et al. (77).

A CASE STUDY

Extensive studies of an unconfined aquifer at a Cape Cod site in Massachusetts have been completed. The hydrogeology of the site is described in Moench et al. (40), Hess et al. (78), LeBlanc et al. (79), Garabedian et al. (80), and Rudolf et al. (81). The unconfined aquifer is composed of unconsolidated glacial outwash sediments, which overlie crystalline bedrock at a depth of about 100 m. Clean, medium-to-course-grained, high permeability deposits cover fine-grained, relatively low permeability material at about 50 m below the water table.

Moench et al. (40) analyzed data for an aquifer test conducted at the Cape Cod site. After the aquifer was pumped at a rate of 0.02 m^3/s for 72 h, drawdown measurements were made in the pumped well and in 20 piezometers located at various distances from the pumped well and various depths below the land surface. The estimated hydraulic parameter values were consistent with estimates from prior studies (78). The results indicated that effects of heterogeneity at the site were small. The estimated parameter values were as follows: specific yield, 0.26; saturated thickness, 52 m; horizontal hydraulic conductivity, 11.68×10^{-4} m/s; vertical hydraulic conductivity, 7.11×10^{-4} m/s; and specific storage, 4.3×10^{-3} m^{-1}.

El-Kadi (82) used the same aquifer test data to examine the validity of the generalized Richards equation (GRE), which includes unsaturation and compressibility effects. The solution of the GRE closely matched the field-measured drawdowns, with some parameters close to their independently measured values, including conductivity and storage coefficient. However, the model was not fully validated due to the need for calibrated soil-hydraulic parameters that represent a finer soil than the coarse-grained highly permeable material characteristic of the site (83). Good accuracy was obtained using a physically based value for the storage coefficient when well-pore storage was considered. Saturated flow models did not provide results as accurate as those provided by the GRE model. Classifying the aquifer material as coarse can be misleading, considering that its effective soil properties are that of a finer-textured material. As such, unsaturated flow effects should not be overlooked.

Hess et al. (78) assessed the variability of hydraulic conductivity in the Cape Cod aquifer and used stochastic transport theories to estimate macrodispersivities. About 1500 estimates were obtained from borehole flowmeter tests and permeameter analyses of cores. The geometric mean for the flowmeter tests (0.11 cm/s) were larger than the mean for the permeameter tests (0.035 cm/s), possibly because of compaction of the cores. Geostatistical analyses estimated correlation scales that ranged from 2.9 to 8.0 m in the horizontal direction and from 0.18 to 0.38 m in the vertical direction. Estimates of asymptotic longitudinal dispersivity were in the range of 0.35–0.78 m.

McCobb and LeBlanc (84) studied a plume of contaminated groundwater that migrated from a former landfill on the Massachusetts Military Reservation to Red Brook Harbor, a small coastal embayment along the Cape Cod coast of Buzzards Bay. The primary contaminants were trichloroethene (TCE) and tetrachloroethene (PCE). The landfill was capped in December 1995, and a groundwater remediation system was established in 1999. The study identified the location of maximum concentrations of the contaminants. Fresh groundwater was present beneath the harbor at locations within 76 m of the shoreline. TCE was detected at several locations in fresh groundwater obtained from the sandy aquifer materials beneath the harbor.

LeBlanc et al. (79) analyzed data from a three-dimensional large-scale natural gradient experiment in the Cape Cod aquifer. Bromide (a conservative tracer) and lithium and molybdate (reactive tracers) injected in July 1985 were monitored for distances up to 280 m. The bromide cloud moved at a rate of 0.42 m/d, while the reactive chemicals moved at a reduced rate of about 50% of that for bromide. The dispersive characteristics of the aquifer were analyzed in the follow-up paper by Garabedian et al. (80). The asymptotic value for longitudinal dispersivity was 0.96 m, while the respective values for transverse-horizontal and transverse-vertical dispersivities were 1.5 cm and 1.55 mm, respectively.

INTRODUCTION

Nonaqueous phase liquids (NAPLs) such as the homogenate hydrocarbons used in dry cleaning and industrial degreasing (DNAPLs), hydrocarbon fuels and aromatic solvents (LNAPLs), and neutrally buoyant coal tars and creosotes are widespread in our environment. Because of their low solubility, NAPL sources can emit toxic contaminants to groundwater for many decades if not managed properly. The migration of dense nonaqueous phase liquids (DNAPLs), which are immiscible with water, through the saturated porous media is an important part of contaminant hydrology and in petroleum engineering. Protection and remediation of groundwater resources require an understanding of processes that affect the fate and transport of such contaminants in the subsurface environment. To implement appropriate remedial schemes in the contaminated area, it is necessary to evaluate the extent of the contaminated area. This information can be obtained by extensive field investigation, which generally is expensive and time consuming. Field investigation can be reduced or made more cost effective, if the migration pattern of the DNAPLs can be evaluated by using numerical models accurately.

The movement of DNAPLs through an initially saturated porous medium is represented as the two-phase flow of water and DNAPLs simultaneously in the porous medium (1). One of the fluids may wet the porous medium more than the other. A large number of experiments for multiphase processes have been carried out (2–4) and these have shown that Darcy's velocity for each phase in the porous medium can be described by the generalized Darcy's law. Darcy's law is extended to multiphase flow by postulating that the gradient in phase pressure of each phase is causing that fluid phase to flow in the porous medium and the effective premeability of each phase is a function of saturation of that respective phase. The continuity equations for immiscible two-phase flow of DNAPLs and water in the porous medium is given by (5,6):

$$\frac{\partial}{\partial x_i}\left[\frac{\rho_\alpha k_{ij} k_{r\alpha}(S_\alpha)}{\mu_\alpha}\left(\frac{\partial P_{ij\alpha}(S_\alpha)}{\partial x_j}+\rho_\alpha g\right)\right] \pm q_{ij\alpha} = \frac{\partial}{\partial t}(\phi \rho_\alpha S_{ij\alpha}), \alpha = \{w, nw\} \tag{1}$$

where x_i and x_j are the Cartesian coordinates in the x and z directions, t is the time, i and j are the direction indices, μ [$\mathrm{ML}^{-1}\mathrm{T}^{-1}$] is the viscosity, ρ [ML^{-3}] is the density, k is intrinsic permeability, k_α [LT^{-1}] is the relative permeability of the phase, and z [L] is the vertical distance taken as positive upward. The α represents both DNAPL and water phases, S is the phase saturation, φ is the medium porosity, q_α [LT^{-1}] is the phase source or sink term, g [LT^{-2}] is the acceleration due to gravity, and P_α is the phase pressure.

When two immiscible fluids are in contact, a discontinuity in phase pressures exists at the interface separating the fluids by the consequence of the interfacial tension, which exists between two phases in contact. The magnitude of the pressure difference depends on the interface curvature at that point, which in turn depends on the saturation of phases. The phase pressures are coupled through the capillary pressure P_C and are a function of saturation:

$$P_C(S_\alpha) = P_{nw} - P_w, \quad \alpha = \{w, nw\} \tag{2}$$

The governing equations have strong nonlinearities such as the dependence of the relative permeabilities $k_{r\alpha}$ and P_C on the respective phase saturations. Parameterization of capillary pressure saturation and the relative permeability saturation relations widely used for the two phases are given by Brooks and Corey (7) and van Genuchten (8).

STATUS OF LITERATURE

The governing equations of multiphase flow are highly nonlinear. Numerical methods of multiphase flow mainly depend on the formulation of the governing equations used for the numerical modeling. The numerical and analytical approaches of the multiphase flow are difficult due to its high nonlinearity and the coupling between the phases. Buckley and Leverett (9) were the first to analyze the multiphase fluid displacement in one dimension by a simplified mathematical model by suppressing the capillary derivative term. Fokas and Yortsos (10) developed a closed form analytical solution for one-dimensional flow with capillary drive by restricting the capillary hydraulic functions. McWhorter and Sunada (11) developed an exact quasianalytical solution using the concept of fractional flow functions known as the flux concentration relations.

A number of numerical models have been developed to simulate the migration of dense nonaqueous phase liquids (DNAPLs) in groundwater. All the models are based on one or another type of primary variables. The multiphase flow equations are highly nonlinear and it requires powerful techniques to handle the coupled equations. The choice of method for solution of multiphase flow is very important. Peaceman (12) used the explicit method and Peaceman and Rachford (13) used the alternating direction implicit (ADI) method. Results showed that the ADI method is unstable for multiphase simulations especially in heterogeneous porous media.

The simultaneous solution (SS) method was first proposed by Douglas and Rachford (14) and later extended and further analyzed by Coats et al. (15), Coats (16), and Sheffield (17) for the petroleum simulation problems. Explicit and alternating direction implicit methods are not stable for two-phase immiscible fluid problems; hence, a simultaneous implicit method was introduced (13) and was the first implicit method to be used successfully for problems in two dimensions. The first convergence analysis of the SS method was presented for two-phase flow by Douglas (18) and later by Coats (16), who analyzed the stability of both the SS and IMPES methods. The implicit pressure explicit saturation (IMPES) method was proposed by Sheldon et al. (19) and Stone and Gardner (20). The basic idea behind this method was to obtain a single pressure equation by a combination of the flow equations. Peaceman and Rachford (21) proposed the leapfrog sequential method, which gives satisfactory results in a limited number of calculations and the truncation error is larger than the simultaneous method. This method leads to an anomalous situation where one of the relative permeabilities becomes zero. Fagin and Stewart (22) developed another type of sequential method and this method is described in detail by Coats et al. (23), in which pressure of one of the phases was taken as one primary variable and was calculated implicitly and the saturation was calculated either explicitly or implicitly using the present value of pressure. This method was also subjected to saturation creep where the relative permeability of one of the phases becomes zero. Aziz and Settari (1) developed a sequential method consisting of two steps. The first step was to obtain an implicit pressure for saturation simulation. In this method, the equations of two phases were combined into one, like in the IMPES method, to obtain a single pressure equation in one phase pressure and the saturation was calculated implicitly using new phase pressures.

Kueper and Frind (5,6) carried out experiments and developed a two-dimensional finite difference model to study the simultaneous movement of DNAPLs and water in heterogeneous porous media. Numerical simulation of DNAPLs infiltration processes in the saturated heterogeneous porous media was studied by means of numerical simulations using the finite element method (24). The two-phase simulator MUFTE developed by Helmig (25) was based on a semidiscrete finite element formulation using a modified Petrov–Galerkin technique, and the nonlinearization was carried out using the Newton–Raphson method. Difference in parameterization of the constitutive relations was studied by Croise et al. (24) for homogeneous media, and the results show that the constitutive relations have significant impact on DNAPLs migration in homogeneous media. Also, the study is carried out for DNAPLs infiltration into heterogeneous media and it shows that the infiltration of DNAPLs is highly dependent on the capillary resistance at the interface between the media.

A comparative study was made between the numerical methods such as fully upwind Galerkin method, which belongs to the classical finite element method, and a mixed hybrid finite element method based on an implicit pressure explicit saturation (IMPES) approach (26). The results show that the control volume finite element approach based on coupled pressure and a saturation scheme is mass conserved locally over each control volume. Also, they observed that the IMPES method was not suited to simulate processes where high changes of capillary pressure with respect to saturation occur.

Coupling of different numerical algorithms for two-phase flow in saturated porous media was carried out using both fully implicit and sequential formulations (27). The influence of field scale heterogeneity on the infiltration and entrapment of dense nonaqueous phase liquids in saturated formulation was studied by Timothy et al. (28). Three node centered finite volume discretizations for multiphase flow in porous media have been developed by Huber and Helmig (26) to study the extent of heterogeneity at the interfaces and their associated interface conditions. Finite volume methods such as the Box method (BOX), control volume finite element method (CVFE), IFDM method, and different combinations of these methods such as BOXIFDM and CVBOXIFDM have been compared. The results show that the CVFE has difficulty generating meshes, which obey the positive transmissibility constraint. The BOX, IFDM, BOXIFDM, and CVBOXIFDM do not have any restriction on the user grid. Also, the results show that the BOX discretization may generate spurious oscillations at the corners of heterogeneities if the Brooks and Corey model is employed. Combinations of all three methods are applicable for any mesh without generating a physical saturation profile at the heterogeneities. The study of effective parameters for two-phase flow in a porous medium with periodic heterogeneities to investigate the feasibility of replacing a porous medium containing heterogeneities with an equivalent homogeneous medium was done by Ashtiani et al. (29). Selecting the proper primary variables for the efficient modeling of the highly nonlinear problems of multiphase flow in a heterogeneous porous fractured medium is carried out by Yu-Shu Wu et al. (30).

ADAPTIVE MODIFIED SEQUENTIAL METHOD

Thomas and Thurnan (31) and Forsyth (32) have described an adaptive implicit method. This involve solving implicit formulations of the governing equations in part of the domain where changes in the primary variables were large, while in the rest of the domain, which is computationally less intensive, the less robust IMPES method was employed. In most practical multiphase simulation problems, large changes in fluid pressure and saturations do not occur throughout the spatial domain at a given time step. Computational effort is therefore inefficiently spent on solving equations in areas where less activity occurs. However, the locations of active zones change with time. A study of an adaptive solution using a fully implicit method is incorporated for the two-phase simulation in the saturated porous medium by Unger et al. (33). They observed that the adaptive solution using a simultaneous method requires extensive checks for the applicability of this procedure at each node and this leads to a negligible computational benefit.

In this work, an adaptive solution using a modified sequential method is used for the modeling. The linearization of the governing equations is carried out using a modified Newton–Raphson method. The modified sequential method developed by Mini Mathew for the simulation of DNAPLs–water in the saturated zone is used in the adaptive solution. The modified sequential method consists of two steps. In the first step, the linearized equation of wetting fluid is used for the simulation of wetting fluid pressure by taking the primary variable of saturation of wetting fluid at the previous iteration on the right-hand side. The Jacobian matrix of wetting fluid pressure is a five-banded matrix and the equation is given by

$$[A_1][P_W]^{n+1/2} = [R_1]^n \tag{3}$$

where $[A_1]$ is an $N \times N$ (N is the number of nodes) Jacobian matrix, $[P_W]$ is a column vector of N unknowns of P_W, and R_1 is the column vector consisting of Eq. 4:

$$\begin{aligned} R_1 = -[[BS_{Wi(j-1)}] + [D''S_{W(i-1)j}] + [E''S_{Wij}] \\ + [F''S_{W(i+1)j}] + [H''S_{Wi(j+1)}]] \end{aligned} \tag{4}$$

where B'', D'', E'', F'', and H'' are the partial derivatives of the governing equation of wetting fluid with respect to the wetting fluid saturation. At the first time step for the wetting fluid pressure simulation, the simulation was carried out for the full domain. The active nodes were identified for the simulation of wetting fluid saturation. The nodes were categorized as either active or inactive in each iteration. For the simulation of wetting fluid pressure, the active nodes were selected in such a way that the difference in saturation of water (wetting fluid) between the present and the previous iteration at that particular node or any one of its surrounding four nodes is less than the specified tolerance level of water saturation. Other nodes, except the active nodes, are taken as inactive nodes for the pressure calculation. On inactive nodes the pressure of wetting fluid is taken from the previous iteration.

In the second step, the wetting fluid saturation is calculated using the nonwetting phase equation. The equation in matrix form is given by

$$[A_2][S_W] = [R_2]^{n+1/2} \tag{5}$$

where $[A_2]$ is an $N \times N$ (N is the number of nodes) Jacobian matrix, $[S_W]$ is a column vector of N unknowns of S_W, and R_2 is the column vector consisting of Equation 6:

$$\begin{aligned} \mathrm{R}_2 = -[[B''''P_{W_i(j-1)}] + [D''''P_{W(i-1)j}] + [E''''P_{Wij}] \\ + [F''''P_{W(i+1)j}] + [H''''P_{Wij+1}]] \end{aligned} \tag{6}$$

where B'''', D'''', E'''', F'''', and H'''' are the partial derivatives of the governing equation of nonwetting fluid with respect to the wetting fluid pressure. For the simulation of wetting fluid saturation, the active nodes were selected in such a way that the difference in water pressure between the present and the previous iteration at that particular node or at any one of its surrounding four nodes is less than the specified tolerance level of water pressure. The computation for the saturation was carried out only for the active nodes and the saturation of inactive nodes was taken from the previous iteration. This procedure was continued in each iteration until the simulation ends.

DNAPLS MIGRATION IN

In this section, an effort is made to study the effect of DNAPLs migration in randomly heterogeneous porous media. The simulation is carried out using ASMSEM model to study the handling power of the numerical method for the DNAPLs simulation on the randomly heterogeneous porous media. The properties of the fluid and medium and the domain properties are: wetting fluid density, 1000 kg·m^{-3}; nonwetting fluid density, 1460 kg·m^{-3};

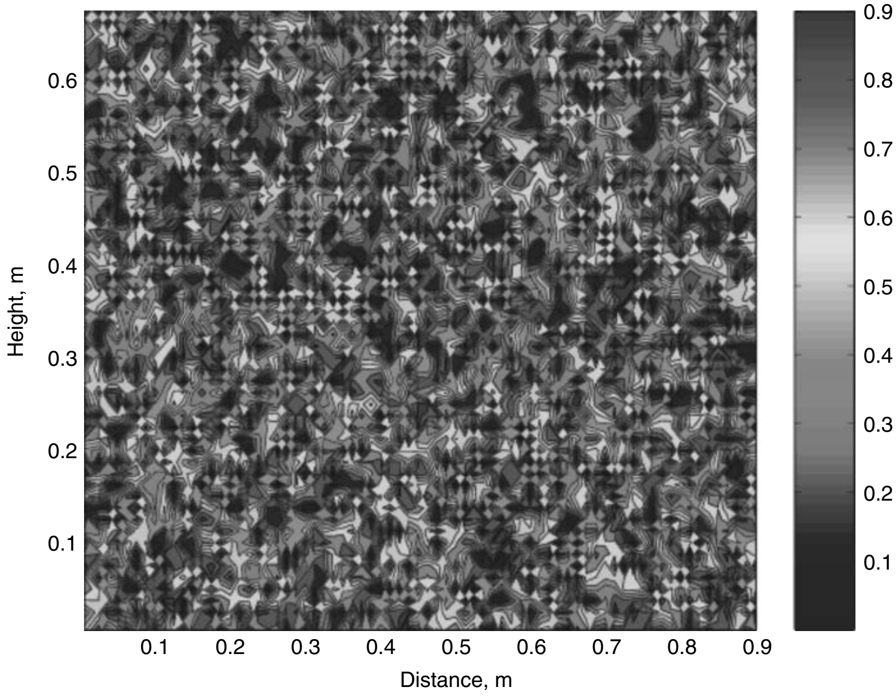

Figure 1. Random permeability field.

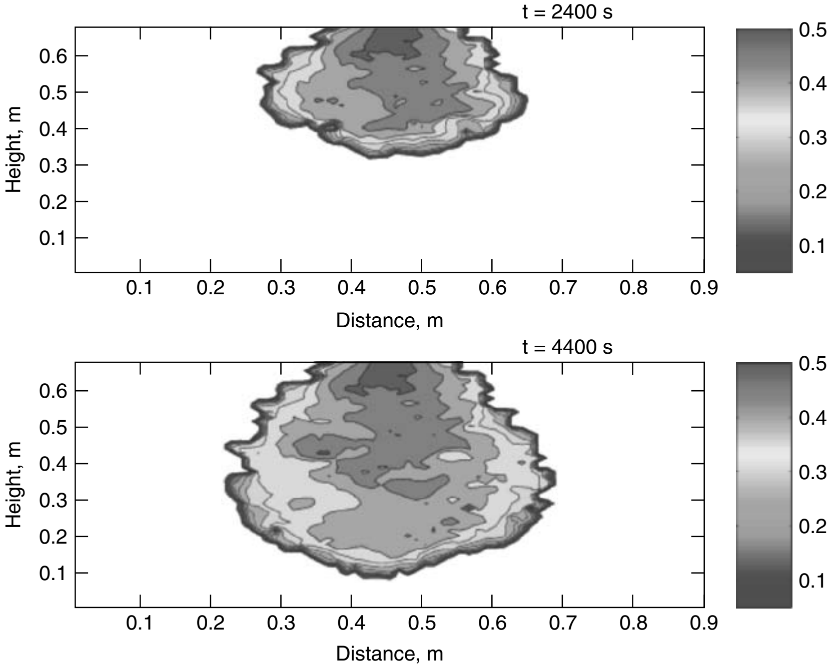

Figure 2. DNAPL migration profiles.

wetting fluid viscosity, 0.001 Pa·s; nonwetting fluid viscosity, of 0.0009 Pa·s; intrinsic permeability, 6.64E-11 m^2; porosity, 0.4; wetting phase residual saturation, 0.09; displacement pressure, 755 Pa; and pore size distribution index, 2.70. In the random porous media, the capillary pressure curve depends on the local value of the absolute permeability and is given by

$$P_C(S_W) = P_d[k^*/k]^{1/2}{S_{ew}}^{-1/\lambda}$$

where k^* is the mean value of the permeability field and the parameters P_d and λ are the Brooks and Corey parameters. The main aim of this study is to verify the handling power of the model using the adaptive modified sequential method for the DNAPLs simulation on randomly heterogeneous porous media. Figure 1 shows the permeability field, which is generated for the present study. The permeability field was generated in such a way that the mean value of the permeability field is equal to the intrinsic permeability of the medium. Figure 2 shows the DNAPLs migration profile after 2400 s and 4400 s.

CONCLUSION

The main mechanisms of DNAPLs migration in porous media have been discussed. Several works in this area, especially about modeling, have been discussed in detail. The main approaches for modeling of DNAPLs migration is presented. The advantage of the adaptive modified sequential method has been pointed out. The developed model is applied on a randomly heterogeneous porous medium to establish DNAPLs migration patterns. Such simulation models will be very useful in planning field experiments for prediction and remediation due to DNAPLs contamination.

THE USE OF SEMIPERMEABLE MEMBRANE DEVICES (SPMDs) FOR MONITORING, EXPOSURE, AND TOXICITY ASSESSMENT

A. Katsoyiannis
C. Samara
Aristotle University of Thessaloniki
Thessaloniki, Greece

INTRODUCTION

Semipermeable Membrane Devices (SPMDs) constitute an innovative approach for sequestering trace/ultra-trace levels of waterborne hydrophobic chemicals and for accurate exposure estimates (1,2). Bioavailable hydrophobic organic contaminants usually occur at trace (<1 ppb) or ultra-trace (<1 ppt) concentration levels in water. The traditional active sampling methods such as liquid-liquid extraction (LLE) or solid phase extraction (SPE) are only partially successful in sequestering these pollutants from water because of the very large water volumes required for processing/analysis. The concentrations of aquatic contaminants can change daily or even hourly, therefore, a great number of samples are required to get a true picture of contaminants present. The limitations in the direct determination of such low concentrations in water have often prompted the use of biomonitoring organisms for exposure estimates. However, the organism-based approach also has inherent problems, including biotransformation and depuration of contaminants, and inapplicability in many exposure situations because of the effects of stress on the biomonitoring organisms that often lead to a lack of proportionality between biomonitoring organism tissue concentrations and ambient exposure concentrations. The SPMDs are lipid-containing polymeric membranes, which function as passive *in situ* samplers of hydrophobic organic pollutants and as physical models of the bioconcentration process (Fig. 1).

Triolein (glyceryl trioleate, $C_{57}H_{104}O_6$) containing SPMDs made of low-density polyethylene (LDPE) were first developed by scientists of the U.S. Geological Survey's Columbia Environmental Research Center (1,3), although similar membranes containing *n*-hexane were previously used by Soedergren (4,5) for simulation of the uptake of pollutants by aquatic organisms. In general, SPMDs can be advantageously used in the following broad areas of application (1):

1. Determination of pollution point sources
2. Estimation of time-weighted average dissolved or vapor phase chemical concentrations

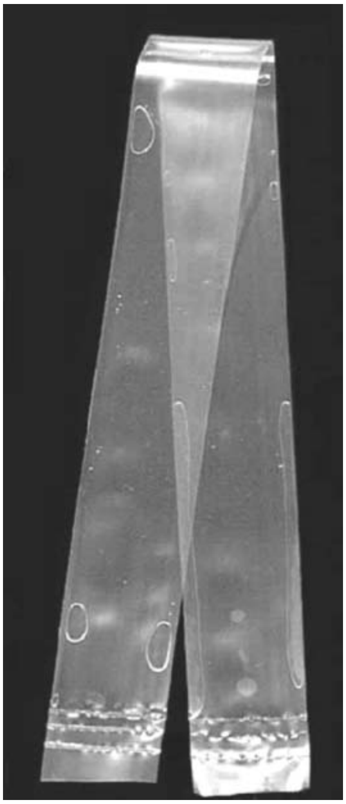

Figure 1. Photo of a semipermeable membrane device (SPMD).

3. *In situ* mimetic concentration of bioavailable chemicals for bioindicator or immunoassay tests
4. Contaminant sequestration in toxicity identification and evaluation (TIE) procedures
5. Estimation of organisms' exposure and bioconcentration potential
6. Determination of the readily bioavailable fraction (dissolved or vapor phase) of a chemical in an environmental compartment for predicting transport, fate, and residue toxicity

SPMD-BIOMEMBRANE SIMILARITIES

The organism-based bioconcentration studies are associated with several problems, such as biotransformation and depuration of contaminants, stress effects caused by noncontaminant stressors or the target contaminants, etc. The SPMD-based approach may offer significant advantages, including: (a) SPMDs do not need to be fed, (b) they do not eat each other or die from disease, lack of oxygen, or from the target contaminants, (c) an SPMD does not move around, will not escape, reproduce, and create an introduced species problem, (d) an SPMD can be used in almost any aquatic environment (cold mountain water, warm desert water, sea water, groundwater), (e) fish can actively depurate some kinds of hydrophobic contaminants, SPMDs don't, and (f) SPMDs can be used to back-calculate the concentration of a waterborne contaminant, but that usually cannot be done with fish.

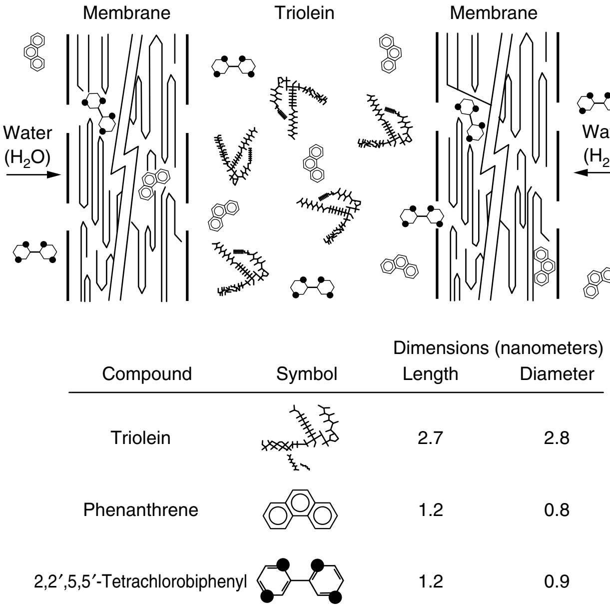

Figure 2. Schematic cross section of an SPMD in an aqueous environment (7).

SPMDs are designed to mimic the parts of animals that cause bioconcentration. The special plastic of SPMDs (LDPE) allows contaminants to pass through to the lipid while excluding water-like membranes of animal cells. The lipid inside (triolein) is similar to a highly purified fish fat. Although the composition of polymeric membranes differ substantially from that of gill membranes (i.e., bilayers of phospholipids and proteins), the diffusion of many lipophilic organic compounds through so-called "nonporous" polymeric membranes appears to simulate diffusion through biomembranes (6). Low-density polyethylene and gill membranes appear to exhibit similar steric exclusion limits with respect to the uptake of hydrophobic organic contaminants (3). Molecules greater than about 600 da (about 10 Åcross-sectional diameter in terms of molecular breadth) are excluded (Fig. 2). Contaminants larger than the exclusion limit or adsorbed on suspended particles (not dissolved) are neither bioconcentrated nor SPMD-available (2,6).

Herve et al. (8) and Prest et al. (9) compared SPMDs and mussels as monitors of bioconcentrating organochlorine compounds. Mussel-SPMD comparisons were species-specific and depended on noncontaminant stressors. However, mussels and SPMDs were found to be complementary in that mussels alone concentrated some compounds, whereas SPMDs alone concentrated others. A comparison between Green-Lipped mussels and SPMDs in Hong Kong coastal waters showed that SPMDs failed to rank the sites in the same order as mussels in terms of organochlorine contaminant concentrations, nevertheless, in localities where mussels cannot survive, SPMDs may be valuable in providing an indication of potentially bioavailable lipophilic pollutants (10). SPMDs and caged channel catfish were also compared for uptake of polychlorinated dibenzo-p-dioxins/furans (PCDD/Fs) and polychlorinated biphenyls (PCBs). Higher concentrations of analytes were found in SPMDs than in catfish (11). On the contrary, concentrations of DDT and its metabolites detected in SPMD extracts were approximately 1000 times smaller than those measured in fish (*Cyprinus caprio*) tissues in the Mississipi Delta (7).

BASICS OF SAMPLING USING SPMDS

SPMDs will, in general, concentrate from water all neutral hydrophobic chemicals having molecular masses <600 da (10 Å in terms of molecular breadth). No other sampling approach offers this broad a range of applicability with respect to chemical class or molecular mass (1,6). Examples of environmental contaminants that have been effectively sampled by SPMDs include polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), polychlorinated dibenzo-*p*-dioxins and furans (PCDD/Fs), moderately polar organophosphate pesticides, alkylated phenols, pyrethroid insecticides, nitroaromatic compounds, neutral organomettalic compounds, and certain heterocyclic compounds (1,2,6,7,12–15). Other neutral chemicals that have been found in dialysates from field-deployed SPMDs include polybrominated diphenyl ethers, trifluralin, pendimethalin, etc. (7,12). The SPMDs are not designed to concentrate ionic species such as ionic metals, salts of organic acids, or very polar chemicals (1).

SPMDs have been applied successfully not only in natural aquatic environments, but also in sewerage systems and waste water treatment plants (2,14,16,17), as well as in the air phase of soils (18) and in the atmosphere (19,20).

The uptake of organic compounds by SPMDs is in accordance with polymer permeability and equilibrium partition theory. As chemical partitioning coefficients between membrane and water (K_{MW}) and between lipid and water (K_{LW}) increase with the lipophilic indicator (K_{OW}), the SPMD sampling rate is expected to rise proportionally. At saturation, the capacity of the SPMD for a hydrophobic chemical is generally related with the compound's K_{OW}, i.e., the higher a compound's K_{OW}, the greater the capacity of the SPMD for that chemical. Neutral organic chemicals that are hydrophobic (i.e., with $\log K_{\mathrm{OW}} \geq 3$) will be concentrated by the SPMD, but for compounds with $\log K_{\mathrm{OW}} \leq 3$, no significant advantage exists in using SPMDs in preference to other sampling procedures (2).

The uptake of HOCs by SPMDs is linear (or integrative) for the first days of deployment, then it becomes curvilinear (partly integrative) and, finally, when it reaches equilibrium, the amount of HOCs taken up is exactly equal to the amount of HOCs lost (Fig. 3). One of the main principals in using SPMDs in sampling is to operate only in the kinetic phase of uptake, where contaminant uptake is linear. Exposure time must therefore be optimized because, during longer exposure periods, equilibrium between the SPMD and sampling media may be approached for certain contaminants (6). The uptake of HOCs with $\log K_{\mathrm{OW}}\mathrm{s} > 4.9$ is usually linear during exposure times <30 days, whereas for compounds with $\log K_{\mathrm{OW}} < 4.9$, equilibrium concentrations of analytes may be reached or approached in ≤30 days (22). A compound with $\log K_{\mathrm{OW}} = 6$ would need 200 days at a constant water concentration and at an effective sampling rate of 10 L/d to reach 90% equilibrium. However, during the initial period, the uptake rate by the SPMD is linear and first-order (23).

In the linear uptake phase, the concentration of a contaminant in the SPMD will be proportional to the concentration in water as a time-weighted average according to the Eq. 1:

$$C_{\mathrm{SPMD}} = C_{\mathrm{W}} R_{\mathrm{S}} \mathrm{t} / M_{\mathrm{SPMD}} \tag{1}$$

where C_{SPMD} is the concentration of the analyte in the SPMD, C_{W} is the concentration of the analyte in water, t is the exposure time in days, M_{SPMD} is the mass of the SPMD, and R_{S} is the SPMD sampling rate (21). Briefly, the analyte sampling rate (R_{S}) for a given analyte is determined from laboratory or field exposures conducted under controlled conditions. As field-deployed SPMDs often become biofouled, the potential impedance to analyte uptake because of aufwuchs layers needs to be accounted for, thus the environmental sampling rate (R_{SC}) is given by Eq. 2:

$$R_{\mathrm{SC}} = R_{\mathrm{S}} F \tag{2}$$

where F is 1 minus the fractional reduction in uptake flux or sampling rate because of fouling (2). Typically, for no or little biofouling, no correction is made. For mild, medium, and heavy biofouling, uptake impedances of 10%, 30%, and 50%, respectively, are assumed.

The SPMD sampling rates have been demonstrated to be independent of water concentrations and salinity. Sampling rates increase with temperature and $\log K_{\mathrm{OW}}$ (i.e., sampling rates increase with increasing hydrophobicity) up to a $\log K_{\mathrm{OW}}$ of about 5.5 (1,21,24). A decrease in uptake rates for compounds with $\log K_{\mathrm{OW}} > 6$ has been observed in similarity to bioconcentration rates in fish (2). Using the above approach and available R_{SC} values (15,21,24), the bioavailable waterborne concentrations

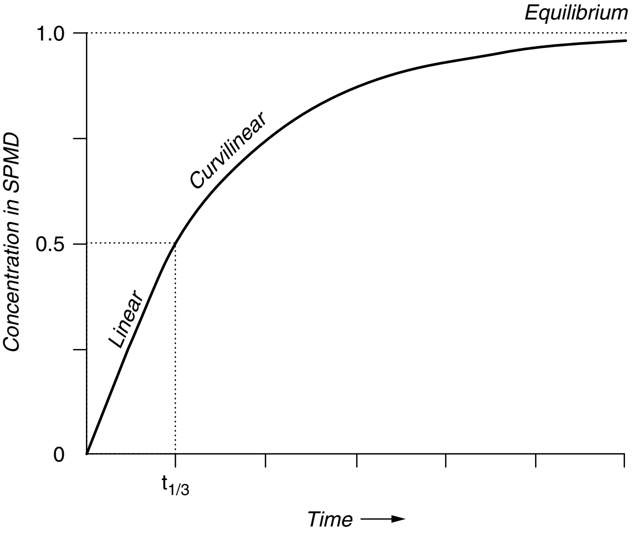

Figure 3. The three phases of SPMD uptake (21).

of typical hydrophobic contaminants have been calculated in many field locations (1,13,25–28).

Any length SPMD with a constant surface area/volume ratio (SA/V) of about 460 cm^2 per ml of triolein, an approximate 0.2 lipid-to-membrane mass ratio, and a 75–90 μm wall thickness is considered to be a "standard SPMD." The uptake rates of specific HOCs by standard SPMDs are presented in Table 1.

SPMDs are great for identifying sources of contamination on small geographical and temporal scales, i.e., when in the study area, the water flow velocities and exposure temperatures are essentially unchanged. A higher observed amount for a particular compound usually indicates a higher exposure concentration. Things become more complicated, however, when between-compound comparisons have to be made (e.g., low K_{OW} compounds may have higher aqueous concentrations, and yet have smaller absorbed amounts because the SPMD sorption capacity is limited) or when substantial between-site differences exist in water flow velocities and temperatures. A third difficulty is that the "SPMD absorbed amount" is not a quantity that is easy to use in environmental fate modeling and in monitoring programs (2). The use of Permeability/Performance Reference Compounds (PRCs) helps to identify and eliminate these problems, establishing a firm link between the absorbed amounts and the aqueous concentrations of contaminants. PRCs are analytically noninterfering compounds, such as perdeuterated PAHs, with moderate to fairly high SPMD fugacity, that are added to SPMD prior to deployment. Their losses during the field exposure compared with losses under controlled laboratory conditions are used to correct for the effects of variations of temperature, diffusion layer thickness, and degree of biofouling on SPMD uptake rates (2,29).

Table 1. R_S Values for Selected HOCs by Standard SPMDs (l/d, 18 °C)

Compound	R_S	Compound	R_S
HCB	2.6^a	PCB-153	4.2^b
α-HCH, β-HCH	0.9^a	PCB-138	4.9^b
Lindane	0.7^a	PCB-180	7.7^b
Heptachlor	3.6^a	Naphthalene	0.9^a
Heptachlor epoxide	2.9^a	Acenapthene	2.3^a
Endosulfan	1.1^a	Fluorene	1.7^a
p-p′-DDE	5.5^a	Phenanthrene	3.4^a
Dieldrin	1.8^a	Pyrene	5.2^a
Endrin	3.1^a	Benzo[a]pyrene	4.3^a
p-p′-DDD	3.1^a	2,3,7,8-TCDD	3.8^a
p-p′-DDT	3.2^a	2,3,7,8-TCDF	3.7^a
PCB-28	2.3^b	1,2,3,7,8-PeCDD	3.4^a
PCB-52	1.8^b	1,2,3,7,8-PeCDF	3.8^a
PCB-101	3.0^b	1,2,3,4,7,8-HxCDD	4.0^a
PCB-118	4.2^b	1,2,3,4,7,8-HxCDF	2.7^a

DEPLOYMENT, PROCESSING, AND ANALYSIS OF SPMDS

SPMDs are available commercially, but they can also be prepared in the laboratory. Once SPMDs are acquired or prepared, they should remain in vapor-tight tins until deployment, and, ideally, they should be stored to −15 °C (1). Several deployment devices have been proposed for the passive sampling with SPMDs (25,27,30), which usually are made of stainless steel or other metals. Use of plastic is not suggested, as it can be a potential interference because of the possible presence of leachable organics. Hardware must be designed so as to minimize abrasion of the membrane, especially

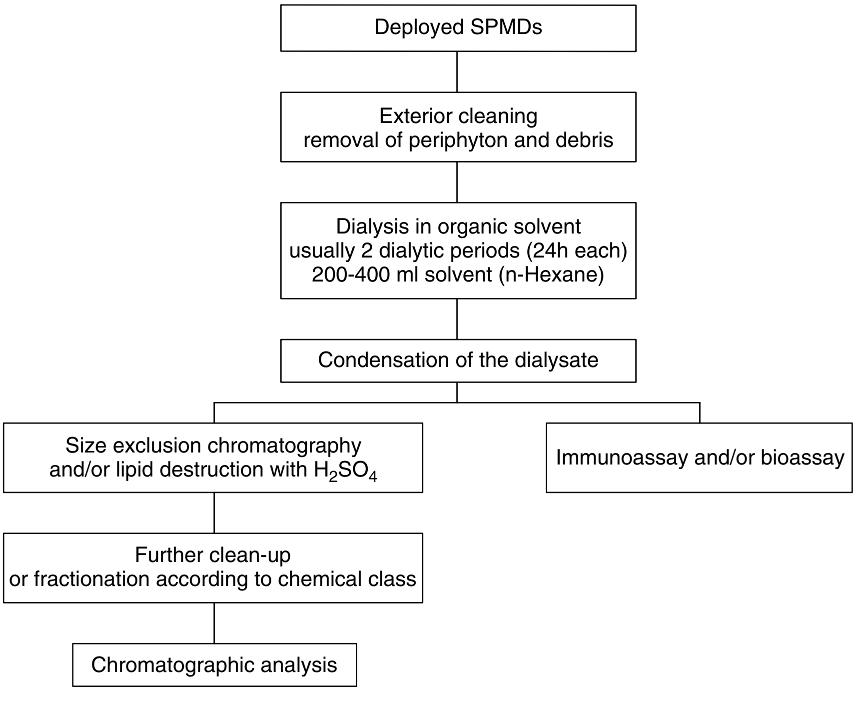

Figure 4. Analytical scheme for the processing of SPMDs.

in turbulent environments (1), and they should also be deployed in such a way that the maximum exposure of membrane surface is ensured. When the deployment period is over, the SPMDs should again be put in vapor-tight tins and kept frozen until analysis.

SPMDs that have been exposed to the aquatic environment can contain a diversity of lipophilic contaminants other than those specifically targeted (3). Also, the outsides of exposed SPMDs are often biofouled by aufwuchs (attached microscopic or macroscopic organisms) and must be cleaned before the targeted residues can be determined (6,13,14,31). Contaminants concentrated in SPMDs are easily recovered by dialysis into organic solvents such as n-hexane, cyclopentane, or cyclohexane (6,14,16,17,19,25–27,30–33). Dialysates from exposed SPMDs can conceivably contain biogenic material from aufwuchs, codialyzed triolein, methyl oleate, and impurities and oligomers from polyethylene (2,3,6). Analytical procedures are therefore required to overcome these impediments. Size exclusion chromatography (SEC) is usually employed to remove interferences, especially codialyzed polyethylene oligomers, oleic acid, and methyl oleate, although oleic acid may be present even after SEC-treatment (1). A solution to this problem may be the application of a destruction technique, like hydrolysis or acidic treatment. The problem with these treatments is that a part of target compounds may also be destroyed. Compounds that resist strongly to acidic treatment are PCBs and some OCPs (34). Fig. 4 is a generalized representation of the analytical scheme.

Quality control of sampling employing SPMDs requires the use of field and trip blanks accounting for contamination of SPMDs by airborne chemicals during the time between opening the can and deployment, and for potential interferences introduced during transport. Laboratory blanks may also be used, together with reagent blanks and duplicate samples, to ensure the quality of results.

The range of concentrations in which HOCs are present in SPMDs can vary from a few pg SPMD^{-1} (14) to μ g SPMD^{-1} (2) or higher depending on the concentration of the specific chemical in water, the size of the SPMD deployed, the uptake rate, and the detection limit of the analytical technique employed. In any case, the concentration of a chemical in the SPMD will be higher than in the ambient water, which is one of the major advantages of the use of SPMDs.

GENERAL

When water wells are constructed in aquifers that occur adjacent to rivers, pumping from the wells commonly causes infiltration of river water toward the wells, thereby increasing the total available water yield. This type of water production has been used extensively in many European countries (1) and, to a lesser extent, in North America.

The flow of river water through permeable riverbed and aquifer sediments, commonly referred to as riverbank filtration, can provide filtration and general purification benefits. Riverbank filtration provides some protection to water supplies from persistent and shock-loaded biological and chemical contaminants that may be present in the river water (2), and commonly provides a first step in the treatment of water supplies (1,3,4); however, in some cases, water quality problems associated with the river water may be transmitted through the aquifer to break through to the wells (5). Riverbank filtration can completely or partially remove suspended solids and pathogens from the infiltrating river water (1,6–11). In addition, the infiltrating river water undergoes chemical modifications, some of which may be beneficial, such as adsorption of metals (6), denitrification (12–15), and biodegradation of organic compounds (15,16). Some chemical changes may be detrimental such as increased hardness (10) and increased concentrations of dissolved iron and manganese (10,12,13,17–19).

In the development and management of river-recharged aquifer systems, the two most important considerations are the sustainability of water quantity and water quality. The quantity of water available is dependent on the river discharge and on the hydrostratigraphy between the riverbed and adjacent pumping wells. The quality of water extracted from the wells is influenced by the quality of the river water, the nature of flow paths from the river to the wells, the travel time in the riverbed sediments and aquifer (9), and the geochemical and mineralogical characteristics of the riverbed and aquifer sediments (19). Development of an understanding of these characteristics is therefore a prerequisite for managing well fields that use induced infiltration of river water.

In 2001, a multidisciplinary investigation of the Fredericton Aquifer was initiated with the objectives of determining:

- stratigraphic controls on the flow path and infiltration flux for river water entering the aquifer,
- the travel time between the river and the pumping wells, and
- the spatial and temporal variation in geochemical reactions that occur as river water infiltrates the aquifer, leading to changes in water quality.

In this contribution, the Fredericton Aquifer, which is considered typical of many alluvial-valley water-supply aquifers, is used as a case study to illustrate possible approaches to the characterization of river-recharged aquifer systems, and describe some of the important stratigraphic, hydrogeologic, and geochemical features of these systems. The combined use of geophysical, hydrogeological, and geochemical methods of investigation has led to a more complete understanding of river water infiltration toward municipal wells and the resulting water quality implications.

FREDERICTON AQUIFER CASE STUDY

The study area is located in Fredericton, New Brunswick, Canada (Fig. 1) (45.87 °N, 66.53 °W). The Saint John River at Fredericton lies in a broad bedrock valley that is partially filled with up to 65 m of unconsolidated sediments. The City of Fredericton obtains its entire water supply (approximately 25,000 m^3/day) from a semiconfined aquifer that lies within the river valley. As shown in Fig. 2, drilling has revealed that the coarse-grained sediments that make up the aquifer have the morphology of a buried esker ridge that runs approximately SE-NW underneath the city and is thought to follow the general drainage direction of the bedrock valley floor. The ridge is up to 30-m thick and contains a large range in particle sizes from sand to boulders (20). The deposit thins as it spreads along the north and south valley walls.

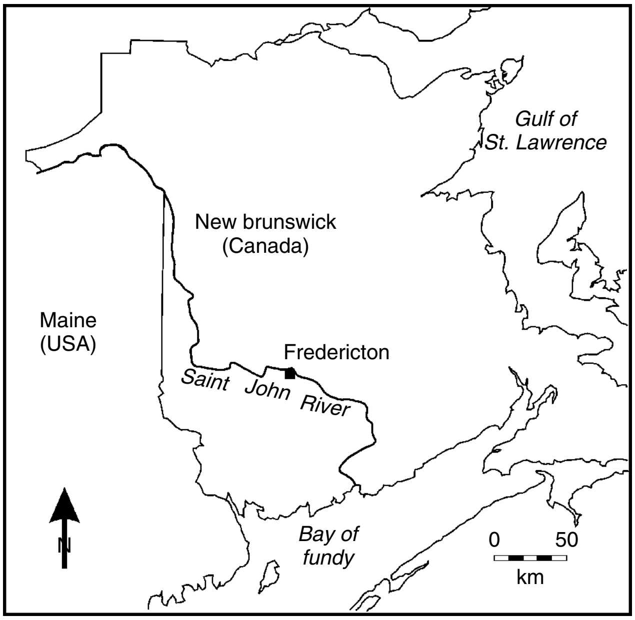

Figure 1. Location of the Fredericton Aquifer case study.

The city currently has eight wells located on the south side of the Saint John River (Fig. 2), and all wells are completed in a sand and gravel aquifer with screen depths between 25 m and 48 m below ground level. Four of the eight wells are located within 150 m of the river. A discontinuous silt/clay unit overlies the aquifer, and in locations where it is discontinuous, referred to as windows, the aquifer is recharged by the river or by precipitation. The aquifer may also be recharged by an upward flux of groundwater from the underlying bedrock.

A history of elevated Mn concentrations has existed in several of the Fredericton supply wells, and Mn concentrations in groundwater from some of the production

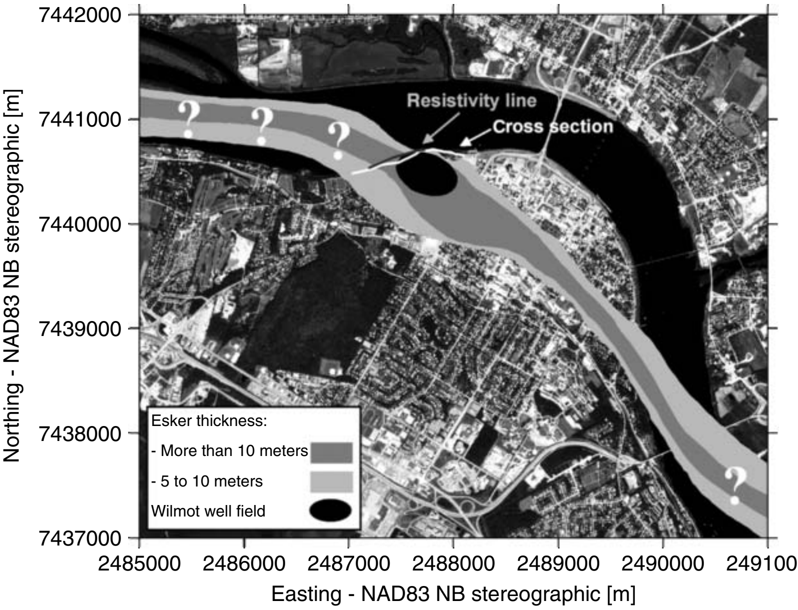

Figure 2. Satellite photo with superimposed map of the buried esker ridge that forms the main part of the aquifer underlying the City of Fredericton and adjacent Saint John River. The well field is highlighted in black [from (21)].

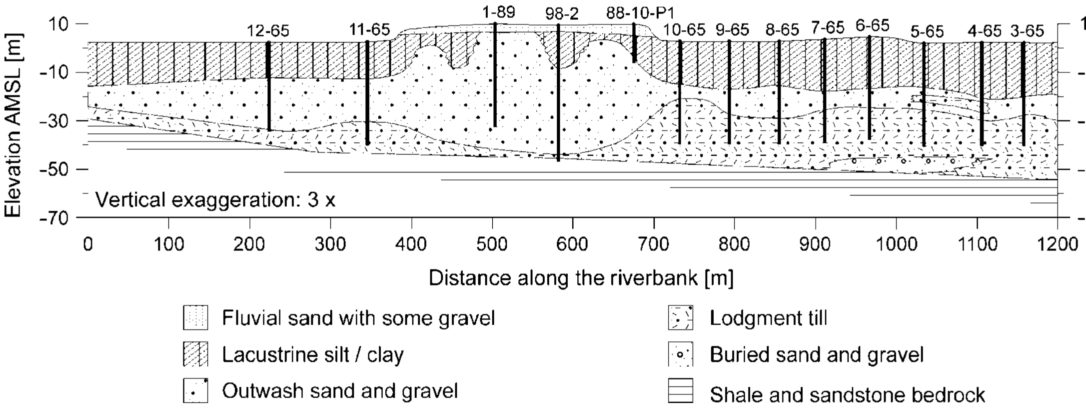

Figure 3. Cross section located along the south shore of the Saint John River and passing obliquely over the buried esker at the edge of the well field as shown in Fig. 2. The rise in surface elevation over the esker ridge reflects the fact that boreholes in that area were drilled atop the river's bank whereas most others were drilled at the river's edge. Borehole logs are from (22) and the City of Fredericton. Undulations in the esker surface are inferred from the resistivity imaging results in Fig. 4.

wells exceed the Canadian Drinking Water Guideline of 0.05 mg/L by up to 3 mg/L. Previous work (19,21) has demonstrated that dissolved organic carbon (DOC) present in the infiltrating river water promotes biogeochemical reactions in the adjacent aquifer, leading to elevated Mn concentrations.

Stratigraphic Controls on River Water Infiltration

In the approximately 50 years since the first water wells were developed in the Fredericton Aquifer, there have been over 700 drill holes completed to sample the unconsolidated glacial and postglacial deposits in the bedrock valley. The information obtained from these drilling activities is extremely useful in developing a general understanding of the glacial stratigraphy, including the aquifer and its enclosing geologic units (Fig. 3). However, despite the large amount of drill-hole data available, the detailed knowledge of stratigraphy below the river that is required to identify discrete flow paths from the river to the wells could not be derived from the drill-hole data. A very large number of additional drill holes would have been required to obtain the necessary geologic information, and such a conventional approach was not feasible because of financial constraints. Consequently, an alternative approach was taken using a variety of near-surface geophysical techniques to determine the subsurface distribution of important stratigraphic units.

Shoreline Resistivity Imaging. The clay content of the silt/clay aquitard unit creates a contrast in electrical conductivity/resistivity with the surrounding sands and gravels. This contrast allows for the effective use of electrical and electromagnetic geophysical techniques for mapping discontinuities (windows) in the aquitard that overlies the aquifer. Resistivity data were first acquired along a 500-m profile located on the shoreline of the river beside the Wilmot Well Field (Fig. 2). The data were acquired in dipole-dipole mode using 10-m dipoles and five apparent resistivity measurements for every current injection location (i.e., $a = 10$ m, $n = 5$) in order to provide a dataset suitable for two-dimensional inversion.

Figure 4 shows the minimum structure resistivity model obtained by inversion (23). The model indicates that the aquitard is laterally continuous near either end of the line and confirms the presence of a window zone in the area where we would expect it based on the cross section in Fig. 3. The interpreted thicknesses of clay/silt on either side of the window (~12–15 m) are in agreement with geologic logs from three boreholes that had previously been drilled on the shore. Below the high resistivity layer that is interpreted to represent the aquifer sand and gravel, a slight decrease occurs in resistivity depths greater than 30 m, which may represent the glacial till layer; however, the depth of penetration and/or resistivity contrast are not sufficient to conclusively define this contact. Most notably, the resistivity image reveals the presence of two silt/clay pods within the window, neither of which had been well defined by drilling. These pods reduce the area available for river water infiltration through the window into the aquifer.

Figure 4 also shows a profile of apparent electrical conductivity as measured along the shoreline with an electromagnetic terrain conductivity meter (Geonics EM31) having an effective depth of exploration of approximately 6 m (24). Comparison of this profile to the resistivity inversion result shows that apparent conductivities are relatively high in areas underlain by the clay/silt aquitard and low where it is absent. The EM method's speed as a reconnaissance tool and sensitivity to the presence of the aquitard window encouraged us to try adapting it for use on the river in the search for the river bottom recharge area.

Riverine Electromagnetic and Seismic Surveys. Although the resistivity survey revealed the width of the potential recharge zone along the shore and its two-dimensional morphology, a need still existed to define this zone underneath the river where the majority of recharge was

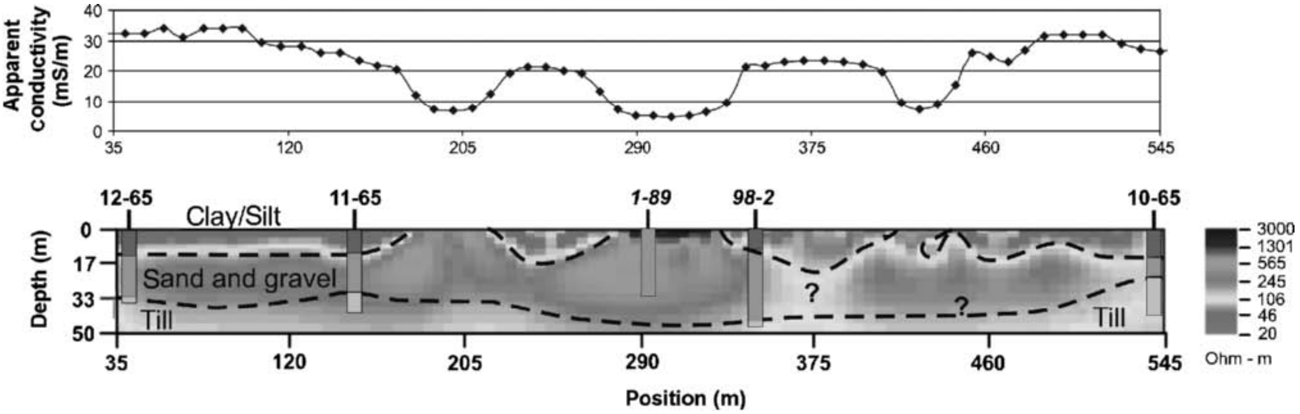

Figure 4. EM31 apparent conductivity profile (top), and resistivity depth section model (bottom) for a 500-m transect located along the shoreline of the Saint John River at the edge of the well field as shown in Fig. 2. Low resistivity zones (30 to 60 ohm-m) indicated by hot colors are interpreted as the conductive silt/clay aquitard, whereas the higher resistivities (>200 ohm-m) are interpreted as sand and gravel. In comparison, the measured resistivity of the river water was approximately 100 ohm-m.

expected to occur. Riverine EM and seismic reflection surveys were carried out for that purpose.

Electromagnetic Surveys. EM31 and deeper penetrating EM34 terrain conductivity meters were adapted for use on the water by deploying them in a nonmetallic canoe and inflatable raft. A DGPS was used to navigate along survey lines and record the locations of measurements made at 2–5 second intervals as the craft moved slowly along the water surface. In order to compensate for variations in apparent conductivity related to variations in water depth (~0.5 to 6 m), we devised an approximate bathymetric correction based on a one-dimensional earth model (23). A measurement of the river water's conductivity (10.3 mS/m) and a bathymetric map extracted from the seismic data described below were used as the basis for these corrections. Finally, the bathymetry-corrected apparent conductivity data were "leveled" to remove small miss-ties at the line intersections that were attributed to temporal drift in the instrument's response.

Figure 5 is a map of the leveled, bathymetry-corrected apparent conductivity measured using the EM34 in such a way as to achieve an effective depth of penetration of approximately 15 m (i.e., vertical dipole mode measurements with a transmitter-receiver coil separation of 10 m). The map created from EM31 data was similar but more strongly influenced by the varying thickness of fluvial sands (~0 to 6 m) overlying the aquitard. The most striking feature in Fig. 5 is the oblong, low conductivity zone trending under the river in a northwesterly to westerly direction. Based on a comparison of the EM31 and EM34 maps, this zone is interpreted as a window in the aquitard where sand and gravel extends upward through the surrounding silt/clay layer. The two elongated high conductivity anomalies within the window were previously detected by the shoreline resistivity survey and are interpreted as silt/clay pods that were deposited within depressions on the paleo-surface of the esker. The strong, erratic anomalies centered 250 m NE of the window are probably caused by metal cables that are known to have been discarded on the riverbed.

Single Channel Seismic Reflection Surveys. Single channel seismic reflection surveys were carried out with the expectation that the interface between aquitard and aquifer would be detectable because of differences in the seismic velocities or densities of the silt/clay and sand lithologies. The instrumentation consisted of an IKB Seistec sub-bottom profiler with an electrodynamic boomer source and integrated hydrophone receiver that was well suited for operation in the shallow riverine environment. Depth penetration was dependent on river bottom type, but many areas yielded excellent records showing reflections with dominant frequencies of 2–2.5 kHz from depths as great as 50 m (23).

Seismic profile C1040, shown in Fig. 6, lies subparallel to the river edge, 100–200 m offshore (Fig. 5). The eastern half of the line, where we expected aquitard material to be present, exhibits excellent reflectivity extending to two-way times as great as 30 ms, which corresponds to a depth of 24 ± 1 m using the average P-wave velocity of 1600 ± 50 m/s deduced for this depth range from borehole seismic surveys carried out on shore (25).

There are two prominent reflectors in this and most other records. The shallower one appears to come from the middle of the silt/clay aquitard where an abrupt increase in P-wave velocity was observed in borehole seismic records (25). The deeper one is thought to be the contact between the aquitard and underlying sand and gravel aquifer. Vestiges of slightly deeper reflectors exist in the record, one of which may represent the contact between the aquifer and glacial till. However, the relatively high frequencies employed in this survey were unable to penetrate far through the coarse-grained sediments underlying the aquitard, and no evidence exists of a reflection from bedrock.

In the central part of the seismic profile below position 460 m, the prominent aquitard reflectors terminate

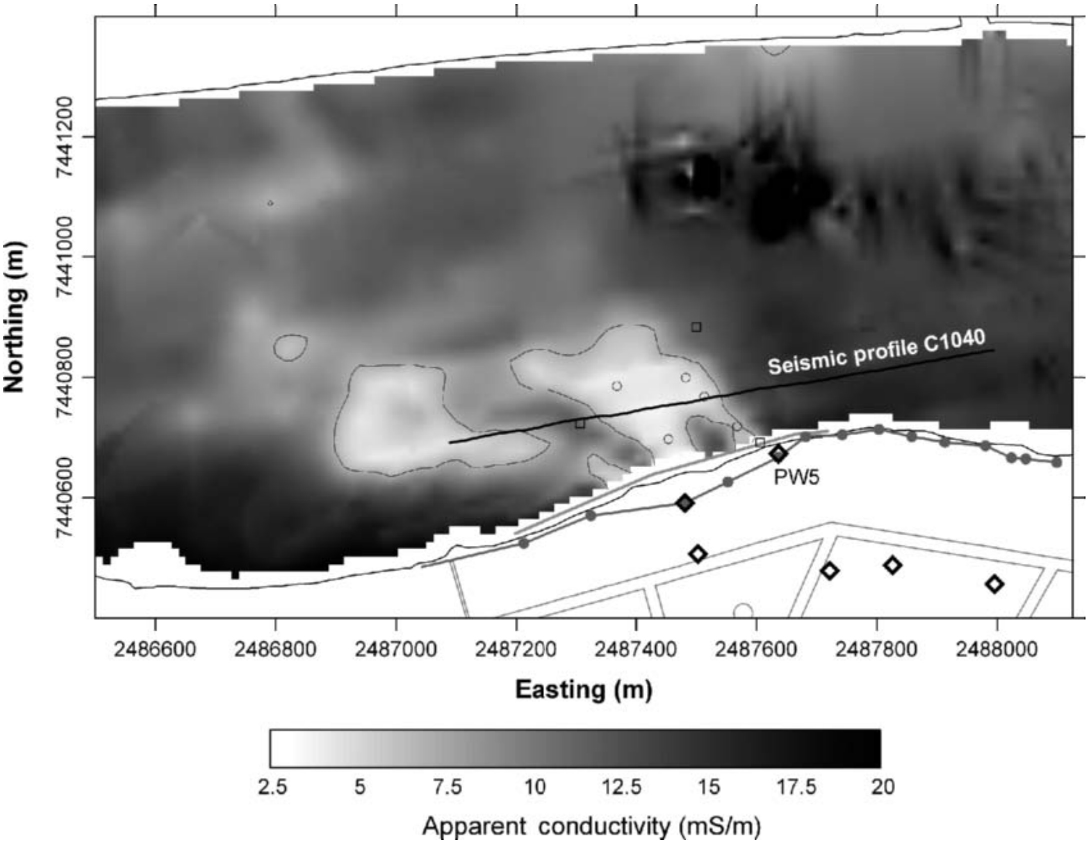

Figure 5. Bathymetry-corrected apparent conductivity map for the bottom of the Saint John River based on data collected with an EM34 terrain conductivity meter having an effective exploration depth of ~15 m. The map reveals a low conductivity zone of irregular shape (approximated by the 7 mS/m contour) interpreted as an aquitard window. The open circles and squares represent eight boreholes, three of which encountered aquitard (squares) and five of which did not. The locations of pumping wells (diamonds) and of the shoreline resistivity transect and cross section are also shown.

abruptly against a zone of low reflectivity. The coincident drops in EM31 and EM34 apparent conductivities shown in Fig. 6 lead us to conclude that an electrically conductive and laminated aquitard is here draped on the edge of the more resistive and massive-textured sand and gravel esker ridge. The region of shallow reflectivity and elevated conductivity observed in the western half of the profile, below positions 140 to 280 m, is similarly attributed to the presence of a silt/clay pod embedded in the top of the esker.

Confirmation of the Geophysical Interpretation. Confirmation of the presence of the aquitard window was provided by a drilling program on the river designed to core the aquifer and install piezometers for hydrogeological and hydrogeochemical investigations. The locations of eight holes drilled from a floating barge are shown in Fig. 5. The five holes identified as open circles were sampled continuously using a split-spoon through uninterrupted sands and gravels to depths ranging from 6 to 25 m below the river bottom. The absence of clay/silt is in agreement with the low bathymetry-corrected apparent conductivities obtained at those locations. In contrast, the three holes shown as open squares in Fig. 5 all encountered clay/silt aquitard material, consistent with their location in areas of elevated apparent conductivities.

Water Travel Times

Travel times between the riverbed and the wells can be assessed using tracer tests; however, because of the logistical difficulties of using artificial tracers in a large river such as the Saint John River, we have used two natural tracers, ^{222}Rn and water temperature. Velocities obtained from these tracers were compared with velocities in engineered slow-sand filtration systems, which are very effective for the removal of micro-organisms and pretreatment of drinking water (26). It must be noted that the velocities obtained to date are based on the assumption of vertical infiltration of river water into the underlying sediments; the actual flow paths will also have a horizontal component that has not been considered. The actual flow paths will therefore be longer, and the corresponding resultant velocities higher, than the vertical velocities we present here.

Water Temperature. The water temperature tracer technique is based on the occurrence of temporal temperature contrasts between the river water and the

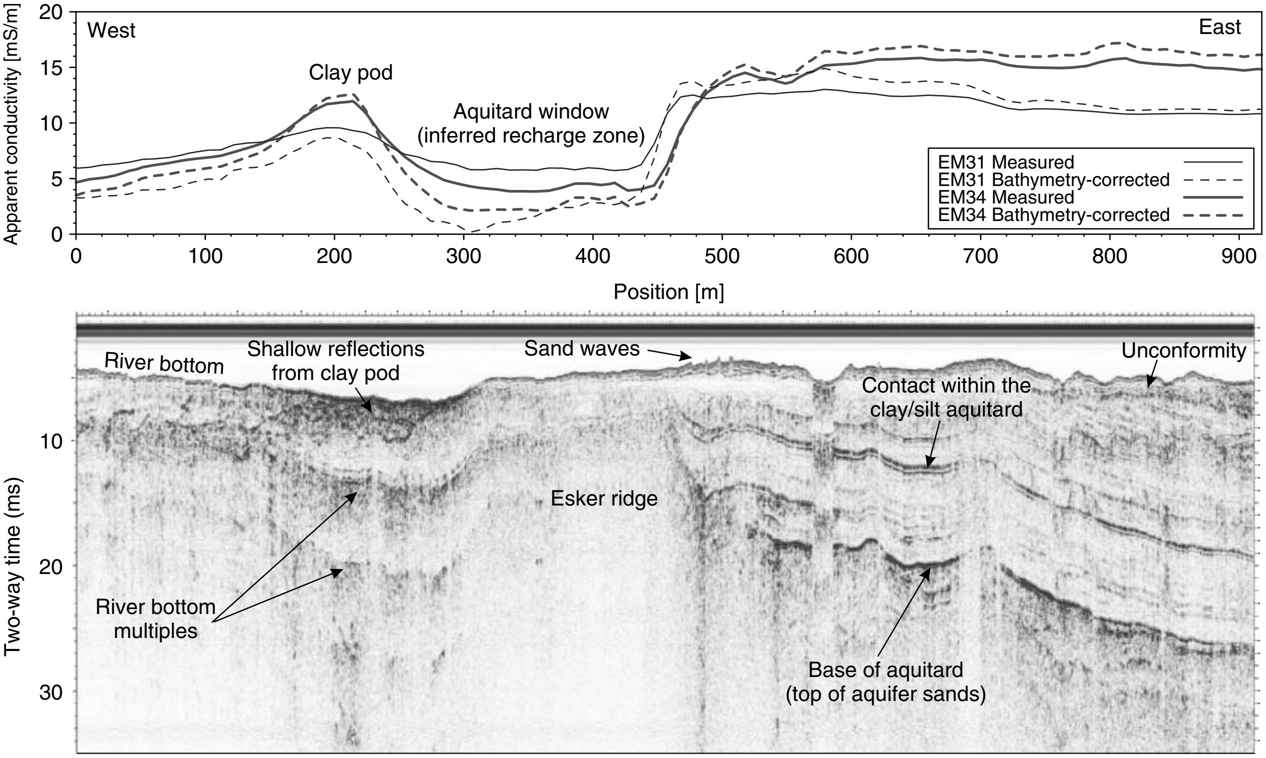

Figure 6. Seismic section and apparent conductivity profiles along the 920-m line C1040 shown in Fig. 5. The seismic record extends to approximately 28-m depth and is displayed with a vertical exaggeration of 12 times. Two strong reflectors, corresponding to interfaces within and at the base of the aquitard, are evident in the seismic data and are draped on the flank of the esker ridge below position 460 m. The apparent conductivity profiles reveal the same contact as well as the presence of a clay pod incised into the esker.

underlying aquifer. The method requires time-series measurements of the groundwater temperature along a flow path from the river toward the wells, and numerical modeling of these time series to determine groundwater flow velocities (27).

Seasonal time-series temperature data were collected at three locations (Fig. 7) within the aquitard window that was identified by EM surveys. At each location, data were collected with temperature loggers located at five or six depths distributed between 1.2 m and 18 m below the riverbed. In addition, one temperature logger was located at the riverbed to record the river water temperature changes.

Figure 8 presents representative data from location T1. The river water temperature decreases in the fall, approaches 0 °C during winter ice cover, and then gradually increases after ice break up reaching a maximum in midsummer. Groundwater temperatures recorded at T1 also exhibit significant seasonal variation with temperatures ranging from slightly greater than 0 °C to 22 °C. With increasing depth below the riverbed, groundwater temperature time series display an increasing lag relative to river water temperature. The lag reflects the time required for infiltration-induced transport of heat from the riverbed to the underlying sediments, and confirms the initial stratigraphic interpretation that, at this location, river water moves downward into the aquifer. Similar trends were also observed in data from locations T2 and T3.

conduction:

$$[\varepsilon\rho^f c^f + (1-\varepsilon)\rho^s c^s]\frac{\partial T}{\partial t} + \rho^f c^f q^f \frac{\partial T}{\partial z} - \frac{\partial}{\partial z}\left(\lambda \frac{\partial T}{\partial z}\right) = 0 \quad (1)$$

where T is the system temperature, ε is the porosity, $\rho^f c^f$ is the volumetric heat capacity of the fluid, $\rho^s c^s$ is the volumetric heat capacity of the solids, q^f is the vertical Darcy flux, and λ is the thermal conductivity, was used to simulate temperatures in the recharge zone. Using the measured river water temperatures as the upper boundary condition, downward Darcy velocities were obtained by trial-and-error adjustment of the hydraulic head boundary conditions to reproduce the temperature time series observed beneath the riverbed. Thermal parameters were derived from correlations between sediment physical properties and thermal properties (27). An example of a comparison between simulated and measured temperature time series for several Darcy velocity values is presented in Fig. 9. For this particular location and depth (T3, 4.7 m depth), a velocity of 0.2 m/day provides a good agreement with the field data. Using this approach, vertical groundwater velocities have been estimated from each of the time-series records at locations T1, T2, and T3, and the results are summarized in Table 1.

Radon. The use of ^{222}Rn as a tracer for determining groundwater travel times is based on the knowledge that soluble ^{222}Rn is formed by the radioactive decay of ^{226}Ra. Given that ^{222}Rn is a gas that partitions readily from water into the air, and that ^{226}Ra is present dominantly in the mineral constituents of rocks and sediments, the activity of ^{222}Rn is generally very low in surface water and increases with travel time after infiltration of surface water into sediments. Steady-state activities are generally reached in saturated groundwater flow systems after residence times of approximately 30 days (29).

Water samples were collected for ^{222}Rn analyses from nested piezometers installed in the riverbed sediments to depths of between 4 and 25 m (Fig. 7). To estimate the steady-state ^{222}Rn activity for the aquifer, samples were also collected from several on-land monitoring wells.

Assuming that ^{222}Rn progenitors (e.g., uranium and radium) are homogeneously distributed throughout the aquifer sediments and that a steady-state ^{222}Rn activity, A_e, is attained, the residence time for infiltrated water can be estimated using (29):

$$t = \ln(1 - A_t/A_e)/\lambda' \qquad (2)$$

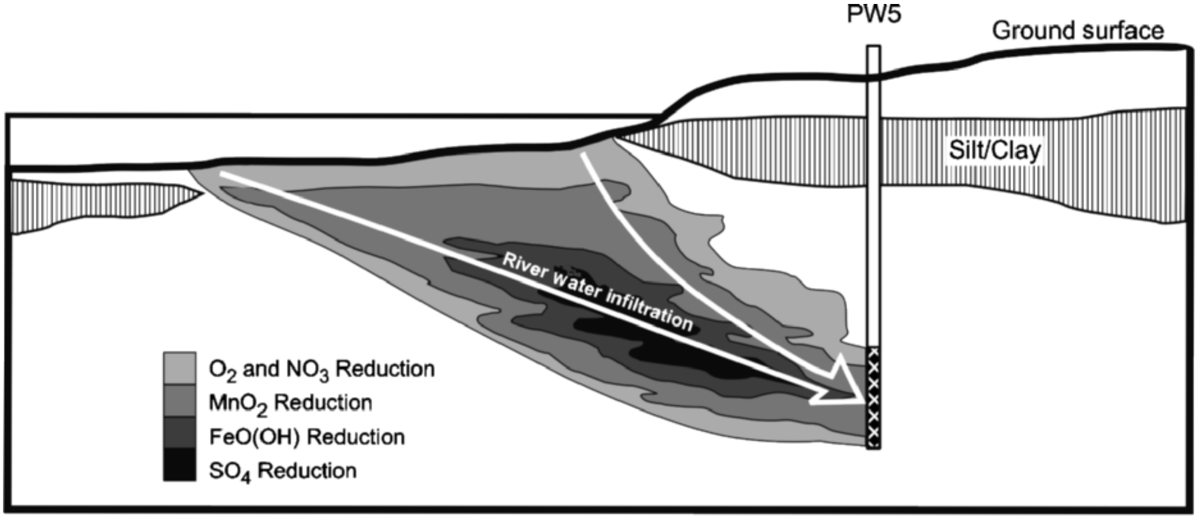
where t is the residence time, A_t is the measured ^{222}Rn activity in each piezometer, A_e is the steady-state ^{222}Rn activity, and λ' is the radioactive decay constant for ^{222}Rn.

A steady-state value of $A_e = 36$ Bq/L was used in Eq. 2 because this was the highest activity found in a series of on-land monitoring wells adjacent to the river. Activities of ^{222}Rn varied with depth and location from 13 to 23 Bq/L at N1, 14 to 22 Bq/L at N2, and 23 to 29 Bq/L at N3. These activities correspond to residence times of 2.4 to 5.5 days at N1, 2.8 to 5.3 days at N2, and 5.5 to 8.8 days at N3. Downward flow velocities were calculated by dividing the piezometer screen (sample) depth by the corresponding residence time, which resulted in a total of eleven estimates of vertical velocity in the infiltration area, which are summarized in Table 1. Heat transport-derived velocities and those based on ^{222}Rn activity are similar in magnitude.

Comparison with Slow-Sand Filtration. Average linear velocities for slow-sand filters are typically in the range of 5 to 20 m/day with sand bed thicknesses of approximately one meter (26). The vertical velocity estimates we have obtained are generally lower that slow-sand filtration

Table 1. Ranges of Vertical Average Linear Velocity (m/day)

Method	T1/N1	T2/N2	T3/N3
Temperature	1.5–2.6	0.2–1.3	0.1–0.2
^{222}Rn	1.1–4.0	1.6–5.0	0.7–2.7



O_2 Reduction
$CH_2O + O_2 => HCO_3^- + H^+$

NO_3 Reduction
$5CH_2O + 4NO_3^- + 4H^+ => 5HCO_3^- + 2N_2 + 2H_2O + 5H^+$

MnO_2 Reduction
$^1/_2CH_2O + MnO_{2(s)} + {}^1/_2H^+ => Mn^{(II)} + {}^1/_2HCO_3^- + OH^-$

FeO(OH) Reduction
$^1/_4CH_2O + FeO(OH)_{(s)} + {}^7/_4H^+ => Fe^{(II)} + {}^1/_4HCO_3^- + {}^3/_2H_2O$

SO_4 Reduction
$2CH_2O + SO_4^{2-} + H^+ => 2HCO_3^- + HS^- + 2H^+$

velocities, and the aquifer sediments under investigation have a much larger "bed" thickness (>20 m) than engineered systems. These characteristics suggest that, in this case, riverbank filtration is conducive to providing pretreatment of the drinking water supply. However, it has also been noted (26) that cold water temperatures (near 1 °C) inhibit biological processes such as the production of natural polymers that are important for micro-organism removal during slow-sand filtration. We have observed such cold temperatures to significant depths in this case study, and therefore it might be expected that micro-organism removal during riverbank filtration will also be seasonally variable.

Groundwater Geochemistry

In order to improve the knowledge of the long-term geochemical evolution of groundwater from wells adjacent to the river, hydrogeochemical investigations were designed to provide an understanding of the influence of the DOC flux from the river on the redox conditions within the aquifer. The approach was to monitor the geochemical conditions along a flow path from the river toward supply well PW5 (Fig. 10). The monitoring was intended to identify spatial and temporal (seasonal) variations in the concentrations of redox-sensitive solutes such as dissolved O_2 (DO), NO_3, Mn, Fe, and SO_4. Aqueous geochemical sampling was conducted during the spring, summer, and fall at piezometers installed in the aquifer below the river bed (Fig. 7).

Thermodynamic principles suggest that the infiltration of DOC to an aquifer system would result in a sequential or stepwise decline in redox conditions, with reactions that provide the greatest energy advantage to microbial catalysts proceeding first, followed by reactions that provide less energy. The general sequence that is expected (30,31) would be the oxidation of DOC coupled sequentially to the reduction of O_2, NO_3, Mn(IV) oxide, Fe(III) oxide, SO_4, and finally CO_2. The O_2, NO_3, and SO_4 would generally be supplied by the infiltrating river water, and the Mn(IV) and Fe(III) are present as oxide or oxyhydroxide minerals in the aquifer sediment, with Fe(III) minerals usually in greater abundance. In accordance with thermodynamic principles, a conceptual model for the redox zonation that may be expected to develop along the flow path during river bank filtration is presented in Fig. 10.

Seasonal Geochemical Variations. The DOC concentration in the Saint John River ranges from 7.9 mg/L in July to 10.9 mg/L in September. Along the infiltration pathway, a general decrease occurs in DOC concentration with depth and distance toward the well, which is greatest (30–50%) in August and September. The concentrations of DO, NO_3,

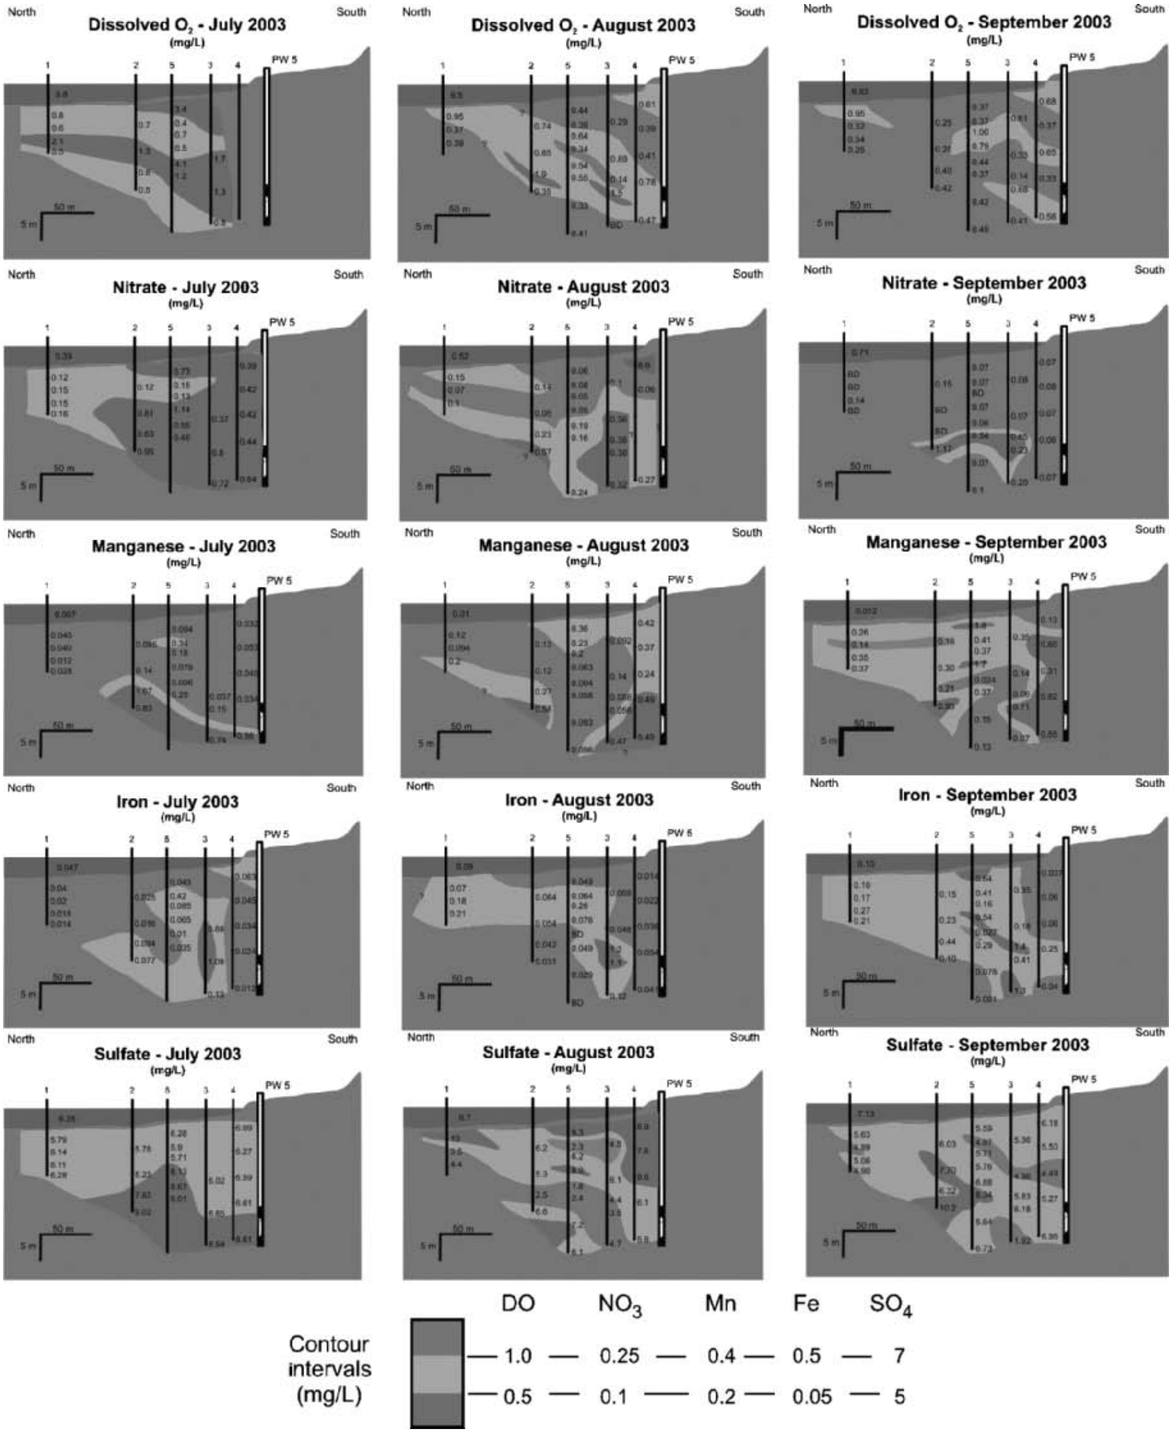

Figure 11. Seasonal (left to right) and spatial variations in redox-sensitive geochemical parameters along the flow path between the Saint John River and City of Fredericton municipal well PW5. Piezometer nests are indicated by vertical lines and individual piezometers (sample locations) are indicated by points on the lines.

Mn, Fe, and, to some extent, SO_4 display significant seasonal variations (Fig. 11). The redox conditions cycle on a seasonal time scale, likely in response to temperature changes in the infiltrating river water. Through the spring and into midsummer, the aquifer temperature is generally less than 5 °C (Fig. 8). The cold temperatures inhibit microbiologically mediated redox reactions between DOC and electron acceptors such as O_2, NO_3, Mn(IV), and Fe(III). As a result, conditions are relatively oxidizing with elevated concentrations of dissolved O_2 and NO_3, and low concentrations of Mn and Fe. Toward late summer and into the fall, the aquifer temperature increases and the system tends toward more reducing conditions, with concentrations of dissolved O_2 and NO_3 declining, and concentrations of Mn and Fe increasing. Localized zones of elevated HS concentrations suggest that SO_4 reduction occurs; however, the seasonal trend toward reducing conditions is not manifest by a widespread decline in SO_4 concentrations as it is for O_2 and NO_3 (Fig. 11).

Spatial Geochemical Variations. Although the decline in dissolved O_2 and NO_3 concentrations and increase in the concentrations of Mn and Fe toward late summer and fall suggests that the reactions noted in Fig. 10 occur, the substantial overlap of the reactions in space that is observed (Fig. 11) indicates that they do not proceed sequentially as suggested by equilibrium thermodynamics, on the contrary, the data suggest that the system is far from equilibrium, which is likely attributable to a combination of variable reaction kinetics for the respective reactions (probably related to mineralogy and microbiological abundance and activity) and a heterogeneous grain-size or permeability distribution that may lead to the development of localized redox gradients at a scale that can not be resolved by the sampling.

With sustained pumping over several decades, the flux of DOC from the river will lead to depletion of the Mn(IV) and Fe(III) oxide minerals in the sediment. The pattern of depletion will be a function of the initial mineral abundance and distribution, the respective rates of oxide-mineral reductive dissolution, and the spatial variations in groundwater flux within the aquifer. However, over time, there should be a general trend toward depletion of Mn-oxides, followed by depletion of Fe oxides. The distribution of dissolved Mn and Fe in August 2003 is consistent with this expectation in that Mn concentrations are highest in the down-gradient region closest to the well, suggesting that Mn-oxide minerals have been depleted along an interface that migrates toward the well with time. The trend in concentrations of dissolved Mn in the water extracted from well PW5 (Fig. 12) is also consistent with the expectation that Mn-oxide mineral depletion will occur in the aquifer sediments.

SUMMARY

The Fredericton Aquifer is a typical semiconfined river-valley aquifer composed of glaciofluvial sand and gravel that is recharged by infiltration of water from a large river. Geophysical surveys have revealed a hydraulic connection to the Saint John River through an irregular-shaped window zone where the aquitard overlying the aquifer has been removed by erosion. Continuous profiling, using electromagnetic terrain conductivity meters deployed in small boats, proved to be the most effective way to delineate the window zone. The river water's moderately low conductivity (10 mS/m) and the relatively shallow depth to the aquitard, contributed to the method's high spatial resolution. Single channel seismic reflection profiles and a shoreline resistivity imaging survey provided important stratigraphic information and evidence to support the electromagnetic interpretation.

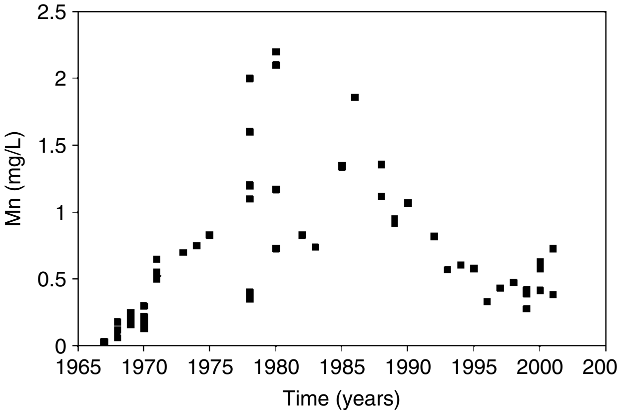

Figure 12. Manganese concentrations in the groundwater extracted from municipal well PW5.

Two natural tracers, water temperature and ^{222}Rn, were used to determine downward flow velocities within the aquitard window located beneath the riverbed. Temperature data was collected continuously to determine seasonal variations and interpreted using heat transport modeling. ^{222}Rn activities for water samples from piezometers nests gave estimates of residence time, which were then used to compute infiltration velocities. The velocities derived from heat transport modeling and ^{222}Rn activities compared well with vertical average linear velocities ranging from 0.1 m/day to 5 m/day. Although these velocities are relatively high for subsurface flow, they are lower than typical velocities in engineered slow-sand filtration systems. As such, it is expected that filtration in the sediments located between the riverbed and production wells will be effective in removing micro-organisms. However, the seasonal occurrence of cold water temperatures in the sediments may cause a lower removal of micro-organisms during certain periods of the year.

The groundwater velocities and seasonal temperature variations measured in the aquifer below the river have a significant influence on the redox reactions that control the concentrations of DO, NO_3, Mn, Fe, and SO_4. The high velocities result in a large flux of reactants (DOC, DO, NO_3, and SO_4), thereby minimizing the potential that reaction rates will be reactant limited. The seasonal temperature fluctuations in the groundwater influence the reaction kinetics for chemical and microbiologically mediated reactions. The seasonal variations in temperature are considered the controlling influence on the aquifer redox conditions, with elevated temperature in late summer and fall contributing to increased reaction rates and a trend toward more reducing conditions. The data suggest that reductive dissolution of Mn oxide minerals as a consequence of sustained pumping over the past 40 years has resulted in the near depletion of Mn oxides along the infiltration flow path to well PW5.

This case study demonstrates the use of near-surface geophysical methods to define stratigraphic complexity in three dimensions, which controls spatial variability of the recharge flux. The geophysical results were especially useful for optimizing the layout of multilevel piezometer nests and mini-piezometers used in the subsequent hydrogeological and hydrogeochemical investigations. The use of the natural tracers, temperature and ^{222}Rn, provides important information about the travel time between the river and the wells. This information allows for an assessment of risk associated with possible contamination events in the river. In addition, the temperature data are important in the interpretation of seasonal variations in groundwater chemistry. In general, riverbank filtration provides a reliable source of recharge to the wellfield in Fredericton. The filtration velocities in the aquifer sediments in the vicinity of PW5 are comparable with those in engineered slow-sand filtration systems. The principle disadvantage of riverbank filtration in this case study is elevated Mn concentrations that are related to the modification of redox conditions in the aquifer as a result of the infiltration of DOC from the river.

Acknowledgments

The authors wish to acknowledge the financial support from the Canadian Natural Sciences and Engineering Research Council (NSERC) through the Canadian Water Network (CWN), the City of Fredericton, and the New Brunswick Department of Environment and Local Government. In addition, the Geological Survey of Canada (Atlantic) provided equipment and personnel support for riverine seismic surveys.
