- attain a total annual water supply (through precipitation) from 2400×10^6 m^3 (Majorca) to $14{,}000 \times 10^6$ m^3 (Sicily; these numbers have partly been derived from the mean annual precipitation and the total area of the islands under consideration and are thus only rough estimates),
- have increasing water demand trends in the foreseeable future, and
- a water consumption structure clearly dominated by agricultural needs.

Though climatically similar, the amount of water supplied to various users differs greatly among the islands. This will have obvious consequences for the measures to be taken to implement the WFD.

The Island Reports and their synthesis led to recommendations aimed at reducing the vulnerability to water scarcity and implementing a sustainable and stakeholder-driven water management regime on the islands. In considering vulnerabilities, three different dimensions of water management have to be taken into account: a physical/environmental dimension, an economic/regulatory dimension, and a social/institutional/political dimension. Details of current and future vulnerabilities to water scarcity are described elsewhere (7), but some of the recommendations are presented in the following. These recommendations are interrelated and overlapping in many ways. They require a holistic, interdisciplinary approach to implement them.

Physical/Environmental Dimensions. The following recommendations have been formulated with regard to the physical and environmental dimensions of water scarcity:

- *Reduce Water Consumption*: The most promising strategies embrace (1) water pricing, an increase in consumer prices or alternatively/additionally quotas on water extraction may be imposed (possibly differentiated between different user groups); and (2) establishment of incentives for reduced water consumption, for example, subsidies for water saving and not—as has often been the case—for water consumption.
- *Change in Water Allocation*: Support of economic sectors accounting for maximum gross-domestic-product generation and employment through government programs. However, care must be taken to avoid possible one-sided economic advantages for specific sectors. Incentives for saving water in water-intensive sectors should be introduced in parallel.
- *Reduce Losses*: (1) Loss of water to the sea either as riverine discharge or through subsea groundwater discharge should be reduced (8), though care must be taken to avoid adverse impacts on biogeochemical cycles and on marine ecosystems in near-coastal waters; (2) reduce losses and contamination of water in distribution networks. On Cyprus, annual losses of drinking water in the distribution network account for 40×10^6 m^3, corresponding to 15% of the total demand and 23% of the total domestic demand (G. Constantinou, Geological Survey of Cyprus, pers. comm., March 2003). Improvement and/or renewal of distribution networks should be pursued where appropriate.
- *Increase Use of Additional Water Resources*: Though largely neglected for a long time, increasing attention is paid to this possible remedy. In particular, potable or irrigation water can be obtained through wastewater recycling, use of brackish water, and rainwater harvesting.

Economic/Regulatory Dimensions. The following actions addressing vulnerability related to economic/regulatory dimensions are recommended:

- Support sectors with high economic potential and small water needs.
- Change agricultural practices: (1) Consult and inform stakeholders about possible alternatives to current cropping patterns with regard to water requirements of plants, watering schedules, and the amount of irrigation water applied per plant (for a summary of possible alternatives, see Reference 9), optimize tillage systems as well as weeding and harvest controls to minimize irrigation; (2) optimize the application of agrochemicals to avoid adverse effects on groundwater quality. The use of agrochemicals and changes in agricultural techniques should be considered holistically to arrive at best practices that maximize yield and also minimize water use and the possible impact of agrochemicals on groundwater quality.
- Eliminate/reduce subsidies for water prices (in the past, subsidies have often contributed either to excessive water use and/or—in the case of agriculture—to cropping patterns that are economically and environmentally unsustainable).
- Promote cultivation of crops that have a high potential on the domestic and the foreign market (eliminate wasting products and water).
- Provide assistance in capacity building of farmers and for investments in modern irrigation technology.
- Provide economic incentives for rational water use in all sectors (e.g., specific water tariffs or relaxation of quotas and limitations in water consumption to those sectors that strive for a more rational use of potable water).

Social/Institutional/Political Dimensions. Reducing vulnerabilities related to social, institutional, and political aspects may be pursued through the following actions:

- Increase public awareness (water use, ownership, conflicts) to enhance the capacity to deal with water scarcity problems.
- Implement comprehensive monitoring of water extraction.
- Improve enforcement of existing rules and regulations.
- Simplify administrative mechanisms to enhance the efficiency of water administration.
- Transfer power from central government institutions to regional and local decision makers that seem better suited to become partners in the EU-WFD than individual users or single municipalities (e.g., TOEBs, Farmers Irrigation Organizations, in Greece).
- Encourage stakeholder-controlled water management structures.
- Ensure/improve an adequate factual basis for political decision making through input from science and stakeholders.

THE NEED FOR INTERDISCIPLINARY WATER STUDIES: THE ADVANCED STUDY COURSE SUSTAINIS

In addressing water management through research and technology projects, one is often faced with a problem different from those outlined. This is the lack of well-trained and motivated young professionals able to face the challenge of interdisciplinary water studies and the implementation of management options. The underlying reason for this problem is in the prevalent focus of traditional universities on specialized and discipline-focused curricula. Though quite adequate and successful in many instances, this kind of training leaves graduates ill-prepared for the type of work required in cross-disciplinary investigations. To resolve this problem at least partly, an Advanced Study Course, SUSTAINIS (Sustainable Use of Water on Mediterranean Islands: Conditions, Obstacles and Perspectives), was devised and implemented. SUSTAINIS was funded by the European Commission and was closely linked to the MEDIS project and its objectives.

Goals and Rationale

The course aimed at introducing 24 graduate students from various disciplinary and national backgrounds to the patterns of water supply and demand, to obstacles preventing rational use of water resources, and to perspectives for sustainable, equitable, and stakeholder-based use of water on Mediterranean islands. To provide them with an opportunity to learn about the specific environmental and socioeconomic features of Mediterranean islands, the course was carried out in Cyprus.

Curriculum and Structure

The emphasis in the teaching lay on demonstrating the complex interrelationships between environmental and societal systems that govern water regimes on Mediterranean islands and the importance of stakeholder-based strategies.

The course comprised lectures by 23 researchers from a variety of professional and national backgrounds, field trips, and discussion forums in the form of role games. The discussion forums were prepared by small, interdisciplinary, international groups of students and exposed the participants to the challenges but also to the advantages of interdisciplinary work.

The curriculum included eight modules:

Module 1: Introduction, Historical and Cultural Background of Water Use in the Mediterranean and Basic Concepts of Environmental Ethics. Cultural practices of management of freshwater resources from antiquity to the present, the recent history of water management and its importance for health, well-being, and prosperity of inhabitants of Mediterranean islands, and concepts of environmental ethics addressing normative issues in water management.

Module 2: Perspectives on Sustainable, Equitable, and Stakeholder-Based Water Management on Mediterranean Islands. Principles and tools for supporting participative water resource planning and management, design and implementation of an integrated water management approach and portrayal of research projects on integrated and sustainable water resources management in the Mediterranean.

Module 3: Essential Geologic and Hydrologic Characteristics of Mediterranean Islands. Characteristics and properties of the geology and hydrology of Mediterranean islands, description of subsurface aquifer conditions and problems related to overabstraction of groundwater resources (saltwater intrusion), and application of models in water management.

Module 4: Current and Possible Future Climatic Conditions and Their Impacts on the Hydrologic Regime. Climatic conditions in the Mediterranean and their effects on the timing and magnitude of precipitation, global and regional climate models and their strengths and weaknesses, review of expected future trends of climate development and their repercussions for water availability in the Mediterranean, and basic concepts and methodologies for integrated climate impact assessments.

Module 5: Current Patterns of Water Consumption, Major Stakeholders, Existing Conflicts, and Resource Policies. Conditions of water resources and common trends of water use with case studies from Cyprus, Malta, and Majorca; irrigation scheduling and water quality for agriculture; threat of deteriorating water quality through the application of agrochemicals and wastewater practices; water and tourism; examples of conflicts between users and possible solutions; and basic resource policies and patterns of political decision making.

Module 6: A Review of Nonconventional Technologies Aimed at Rational Water Management. Optimization of water consumption by employing appropriate and innovative technology like novel irrigation practices in agriculture, water recycling, and reuse for domestic and agricultural purposes, desalinization.

Module 7: Socioeconomic and Administrative Conditions of Water Use on Mediterranean Islands. Estimation of the value of water in its different uses, cost–benefit analysis of water projects, water consumption, public awareness, and alternative models of water management.

Module 8: Political Options, Initiatives, and Conditions for Sustainable Water Management, Specifically in the Context of the EU-WFD. Description of the EU Water Framework Directive, water pricing policies and the implications of the WFD, economic approaches in Integrated River Basin Management, and examples of integrated water management from European countries.

Results of the discussion forums as well as the lectures are published as course proceedings. In addition, a documentary film about the course and the issue of sustainable water use on Mediterranean islands for universities and passing on to stakeholders has been produced.

Student Feedback and Perspective

The student feedback showed that exposure to a wide variety of disciplines and research fields, and interacting with a group of individuals from a wide spectrum of disciplinary and cultural backgrounds were the most important contributing factors for the success of SUSTAINIS. It is expected that the SUSTAINIS course succeeded in teaching students about sustainable water use and management in the Mediterranean and in motivating them to pursue integrated regional studies in their careers.

Acknowledgments

MEDIS and SUSTAINIS were funded by the European Commission (contract numbers EVK1-CT-2001-00092 and EVK1-CT-2002-60001, respectively). We would like to thank Dr. Panagiotis Balabanis, the responsible officer at the Commission, for his support. Thanks are also extended to all partners in MEDIS, all colleagues who served as lecturers in SUSTAINIS, as well as the participants who contributed substantially to the success of the course.

MEETING WATER NEEDS IN DEVELOPING COUNTRIES WITH TRADABLE RIGHTS

Terence R. Lee
Santiago, Chile

The most serious current issue in water management is not water scarcity, but the allocation of water among competing uses and users. The issue of allocation overshadows all other aspects of water management. Unfortunately, almost everywhere, the methods used for water allocation are woefully inadequate to achieve an effective, efficient, and timely distribution of water among uses and users. This failure to allocate water efficiently is the root cause of the widespread perception that water is becoming so scarce as to amount to a crisis. Almost everywhere, water is allocated either according to tradition or by bureaucratic processes subject to political pressures. Economists have long argued that water should be treated as an economic good. If it is treated as an economic good, then its use can be allocated by creating water rights through a market.

In most developing countries, where agriculture accounts for around 80% of water use, the reallocation of the use of water is crucial if water is not to be a limiting resource for future economic growth. It has been convincingly argued that permitting trade in water rights will increase available supplies because consumption will be reduced as water is used more efficiently by all users. This will not only alleviate, but probably even reverse, what many perceive as the coming water crisis.

In any country, however, the decision to introduce a system of tradable water rights requires considering of many issues so that the proposed water market can function smoothly and equitably to meet water needs:

1. In the initial distribution of rights, consideration must be given to both the rights of existing water users and the need to limit any windfall gains that they may receive as the owners of rights.
2. Once rights are allocated, the holder must be assured that the right is clearly and securely defined and appropriately registered.
3. The establishment of individual rights must not give the holders benefits at the expense of society as a whole.
4. Whatever decisions are taken and policies adopted, the system must be as simple as possible.
5. Once a system of water rights is clearly defined and the market is used as the mechanism for water allocation, then the intervention of government should be kept to a minimum.

The approach taken in the initial distribution of water rights is very important if trading in water rights is, in the future, to be the main means for water allocation. The size of any political opposition to the introduction of a water rights market is usually proportionate to the fairness seen in the initial distribution of water rights.

PRINCIPAL ISSUES

Under free market conditions, the trading of rights would result ultimately in the same allocation of water rights regardless of their initial distribution. However, in the expected presence of significant costs in any exchange of rights, the nature of the initial distribution of rights can affect the future efficiency of the market. Information, bargaining, contracting, and enforcement are required for a market to function, and they are not without cost. The initial distribution of water rights can also affect the quantity of transactions, the equilibrium allocation of rights, and the aggregate benefits of water marketing. If the costs of trading in rights are large enough to deter trading, then exchanges will not occur. There will always be a trade-off between promoting efficiency and equity considerations in the initial distribution of water rights.

Alternative initial assignments of water rights among users, whether individuals, ethnic groups, local governments, or environmental protection agencies, will also result in entirely different future sets of bargaining relationships and potentially different patterns of transfers.

Basing the initial distribution of water rights on historic water use is the easiest and the most commonly used system. The rule that has been usually adopted is the historic record of possession of licences or permits for water use under the previous allocation system, or, where such evidence is lacking, according to other benchmarks, such as land holdings. This is usually called "grandfathering." However, it does represent a transfer of wealth, the new water rights, to current water users.

Once a market is established, water rights will be reallocated through voluntary transfers between willing buyers and sellers in the same way as other goods are traded. It must be emphasized that the social impact of market transactions will depend on the initial distribution of water rights and bargaining power. The initial distribution will determine how the benefits from owning water rights are distributed, who has the protection of the state to use water, and who must pay to obtain water rights in the future.

An issue often raised in opposition to establishing markets in water rights is the possibility of windfall gains if existing water users are favored in the initial distribution of rights. Proposed solutions to this issue include taxing transfers, prohibiting transfers, and other restrictions on trading. Such restrictions, however, defeat the purpose of assigning rights and establishing a market. It might be simpler to ignore the problem, which will facilitate the reallocation of water to higher value uses but provide windfall gains to original users. One mechanism that has been used for the initial distribution of rights to avoid windfall gains is auctions, but these can raise the problem of rights going only to those who can pay.

In the initial distribution, care needs to be taken to respect the rights of the disadvantaged, such as poor farmers and indigenous peoples. In Chile, in introducing the market allocation of water, the government put in place and maintains a program to facilitate the legalization of property titles to water rights by poorer farmers; it has been spending more than US$320, 000 annually for this purpose during the last 20 years.

In the initial distribution of water rights, consideration should also be given to establishing minimum flows to protect aquatic and riparian habitats and other uses which, because of strong public goods characteristics from which everyone benefits, cannot compete in the market for water. Where historic uses have preempted the total supply, an argument can be made for a one-time reallocation of water. In Chile, although no provision of this kind is included in the law, the interpretation of the protection of the rights of third parties has been expanded to include environmental protection and ecological flows.

The main advantage of adopting "grandfathering" is that it avoids conflicts and reduces the opposition of existing water users, typically farmers, to the introduction of a market. Irrigation farmers usually argue that they are entitled to receive water rights without charge because they have already paid for the rights implicitly in the purchase price of the land. Under the auction approach, although payments for rights do not represent real economic costs to society as a whole but merely transfers from one group to another, to the users, the payments constitute a financial burden.

THE MARKET ALLOCATION OF WATER

A water market is a water management tool. It is, moreover, a tool that spreads the burden and difficulties of water management among a larger population; it permits greater popular participation in management decisions and can introduce greater flexibility into management systems. The creation of a water market will also demand new skills and attitudes from public administration, judicial systems, and water users, as well as investment in the registration of rights, monitoring and measurement systems and, possibly, in improving water distribution and transportation systems.

A water market will allocate water rights at a price set by the free exchange of the right either for a limited period of time through a lease or in perpetuity by a sale. For a market to work, it is necessary only that there be a tradable margin in water rights, even if the number of rights traded is marginal to the total supply. Water markets can normally be expected to be relatively small or "thin," with few transactions.

Any water allocation system should be both flexible and secure. At the same time, all costs and benefits should be reflected in the decisions that participants make; otherwise, these decisions will be inefficient from an overall social perspective. The system must also be predictable, equable, and fair. This is particularly important in developing societies where economic growth and water use efficiency require achieving a balance in the allocation of water between flexibility and security. Water markets are flexible because markets are by their very nature a decentralized and incentive-oriented institution, rather than centralized and regulatory.

SECURITY OF TENURE

Markets require security of ownership to function. Therefore, it is important that rights be clearly defined and publicly registered. Security of ownership of the right, in turn, helps encourage efficient use, resource conservation, and capital investment. It also helps strengthen and consolidate the autonomy of water user organizations. Security of ownership and the possibility of acquiring water rights in the market, it has been shown, encourage investment and growth in activities that require secure water supplies. Moreover, the reallocation of rights by voluntary exchanges allows market systems to defuse potential political conflicts over water allocation.

The political dimension of a system of secure and transferable water rights arises from the definition and clarification of property rights, which the introduction of such a system requires. The market transfer of water rights reduces political conflicts, as these transfers are always voluntary transactions in which owners of rights will participate only if they believe that it is in their best interest, given the alternative opportunities available. Administrative allocation, in contrast, often generates intense conflicts because granting a water right to one user necessarily precludes another.

Markets can, therefore, reduce conflicts among environmental interests, water suppliers, and polluters by providing natural economic incentives for water conservation and wastewater treatment. Environmental economists often prefer property-right systems to pricing systems because property-right systems can be ecologically more dependable than pricing systems.

WATER MARKETS IN CHILE

Chile is the only country where tradable rights are universal and all water allocation is the result of market transactions. The introduction of water markets in Chile coincided with a major increase in agricultural production and productivity. It is reasonable to conclude that the introduction of tradable, and particularly secure, property rights in water made a noticeable contribution to this overall growth in the value of Chile's agricultural production. This increase occurred within an agricultural sector largely dependent on irrigation, without a significant increase in either the supply of water or the area under irrigation. There has been, however, considerable private investment in improving the existing irrigation infrastructure both on and off the farm. The influence of water markets, however, cannot be fully separated from the effects of other economic factors, especially stable economic policies, trade liberalization, and secure land rights. This notwithstanding, it is recognized that trading in water rights reduced the need for new hydraulic infrastructure, improved overall irrigation efficiency, and has reduced the number of conflicts over water allocation. It also appears to have facilitated the shift from low-value, water-intensive crops to higher value, less-water-intensive crops.

In addition, market transfers of water rights have produced substantial economic gains from trade in some river basins. These gains occur both in trades between farmers and in trades between farmers and other sectors. The economic gains from trade tend to be large between farmers but relatively modest in intersector trade because water has been transferred from profitable farmers to urban drinking water supply; even though the financial gain to the farmer who sells is large, the overall economic gains of the reallocation are relatively small, because both uses have similar social benefits. In Chile, as in other areas of irrigation agriculture, if, prior to the sale, water was not being taken from river or canal by the owner of the right, other farmers would have used it downstream. Transfers among farmers, however, lead to using the water for higher value crops.

WATER USE IN THE UNITED STATES

Frédéric Lasserre
Université Laval
Ste-Foy, Québec, Canada

A STABILIZATION IN TOTAL WITHDRAWALS?

Total water withdrawals in the United States are estimated at 402 billion gallons per day (Bgal/day) in 1995. This is 1.5% less than withdrawals for 1990 and confirms an overall stabilization of withdrawals throughout the country since 1975. That was the first time that withdrawals growth stopped outpacing population increases, implying an intensification of the use of water withdrawn. All major users, thermoelectric, irrigation, and industrial uses, saw their withdrawals stabilize; rural (domestic and livestock) and urban use, on the contrary, witnessed an ongoing trend of withdrawal increase.

The decline in overall water use does not translate into the same pattern for all water sources (Table 1). Saline surface water use grew rapidly after 1965, to reach 71 Bgal/d in 1980, but has declined since then to 59.7 Bgal/d; groundwater use also declined after the 1980 peak. After a similar trend from 1980 to 1990, surface freshwater use, however, started growing again by 1.9% between 1990 and 1995.

On the other hand, after a decrease between 1980 and 1985 and a small increase from 1985 to 1990, consumptive use was back to growing faster than that of population. This trend could be linked to increased urban water use in suburbs. Particularly as urban sprawl takes place in the West, that implies a large share of consumption, such as lawn watering and pools, as will be seen below.

Table 1. Evolution of Water Use in the United States, 1950–1995[a]

	1950	1955	1960	1965	1970	1975	1980	1985	1990	1995

THE DRY WEST STILL THE LARGEST USER AND CONSUMER

Regional Water Use

Wide discrepancies show up immediately when the structure of water use in the United States is examined.

Patterns do appear: they highlight very industrialized and urbanized states such as New Jersey, New York, and Michigan, where water used is concentrated in domestic, industrial, and power generating uses (Table 2). States that have rain-fed agriculture and a small urban population, such as Maine and Vermont, use water mainly for their power and their cities. In highly urbanized and industrialized Texas and California, all uses are strong, except industrial use in California because of an industrial base that does not use a large amount of water; other Western States do show a large dominance of agricultural use, such as in Arizona, Colorado, Idaho, and Montana.

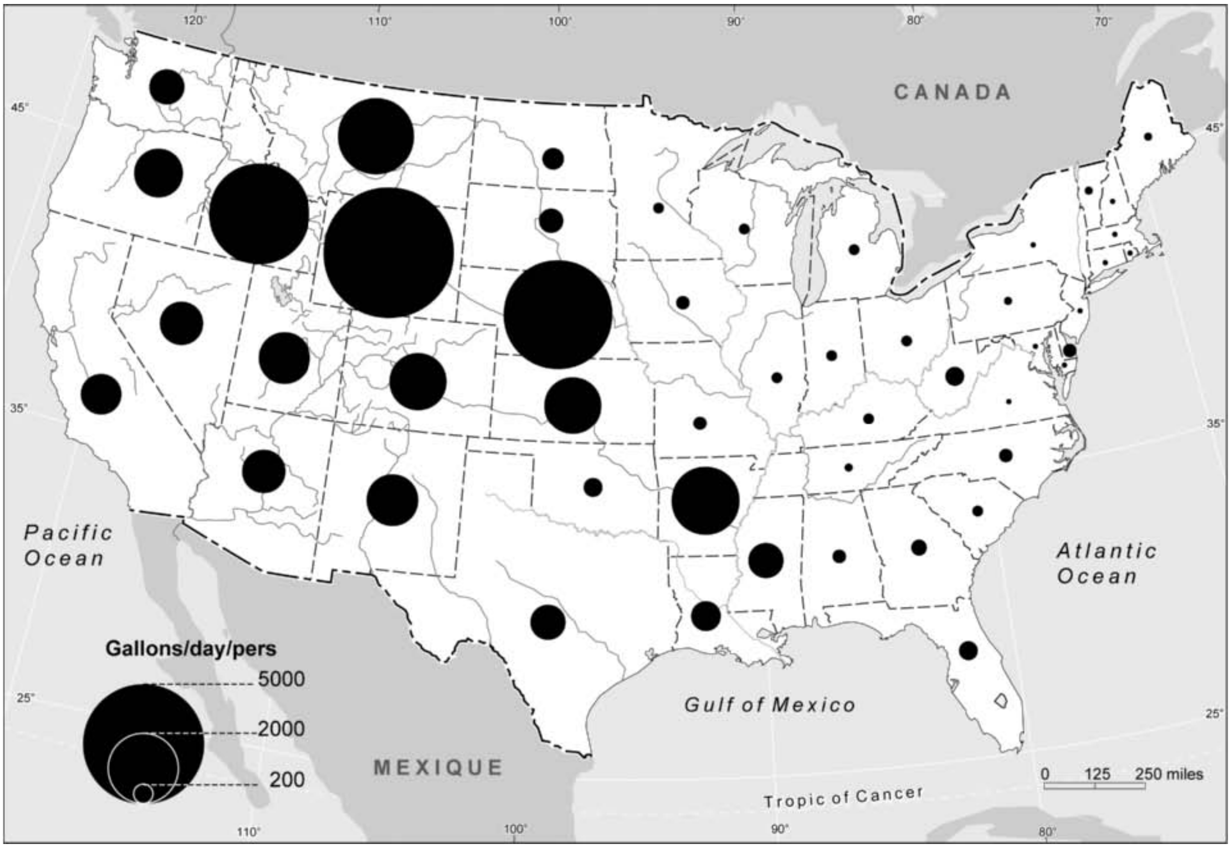

Figure 1. Water consumptive use by state, 1995 (adapted from Reference 2).

Consumptive Use

Regionally, states in the West do show much greater per capita consumptive use, up to 4288 gallons per day per person (gal/d/p) for Nebraska, but it is not the urban use that is responsible for their high consumption (Table 3). Highly urbanized California displays a more moderate figure of 795 gal/d/p (Fig. 1). Large withdrawals for irrigation are required in a dry climate.

AMERICAN WATER USE STRUCTURE COMPARED TO OTHER COUNTRIES

Agriculture remains the main user and consumer of water in the United States, as it is, by a large margin, among developing countries (Table 4). The picture is somewhat subtler among developed countries. Drier countries such as Spain and Greece, unsurprisingly, use a large share of water for agriculture, but water can also be largely used in more humid places that have traditionally rain-fed agriculture, such as Belgium, Germany, and Denmark (Table 5). This trend is explained, as observed in the United States, by farmers turning to irrigation to avoid all risk of yield decrease.

WATER USE MANAGEMENT : RECONCILING DIFFERENT USE STRUCTURES ACROSS THE COUNTRY

The geography of withdrawals and consumption, illustrated by the consumptive use map shown above, is all the harder to manage globally as Western states consume more and more (states west of the 100th meridian accounted for 75.1% of total consumption in 1995), but draw on a smaller share of the resource; water is far more plentiful in the eastern part of the country. From the end of the Civil War, this relative scarcity of water never prevented development schemes and led to large engineering designs that were built to harness the West's major rivers and make up for nature's pattern of groundwater, surface water, and precipitation distribution.

On the other hand, urbanized states in the eastern United States display small consumptive use structures, as low as 19 gal/d/p for Rhode Island and 26 for New York. It is the sheer size of the urban area that is responsible for New York's freshwater supply, not the profligacy of its inhabitants. However, New York and

Los Angeles authorities, for instance, have aggressively promoted water-saving programs with effective results.

Local authorities are acutely conscious of serious water problems in the country. These are twofold. First, although withdrawals are on a stabilizing trend, and consumption was up until a few years ago, withdrawal levels are often locally unsustainable in the long term, especially in the West. Aquifers are being overpumped. The now famous Ogallala aquifer, in the Midwest, is expected to run unusable—not totally dry—in 50 to 70 years at present withdrawal rates. California saw its water consumption increase by 41.5% between 1980 and 2000, still untapped available resources are dwindling rapidly. As other upstream states withdrew small amounts of water for small populations, even Colorado water that California long took for granted is now being reallocated to the “New West” states under the Colorado Compact provisions because Nevada, Arizona, and New Mexico boast extremely fast population growth (Table 6). Between 1980 and 2000, consumptive uses also grew by 42% in Texas, 58.2% in Florida, and 70% in Arizona. Groundwater withdrawals in California exceed its aquifer renewal capacity by 15% (5).

past 20 years have witnessed several phenomena that will question the water use structure: the acceleration of suburban growth, especially in the West; and the persistence of population shifts toward the Sun Belt in the West, Texas, and Florida; and more particularly toward what some geographers call the "New West," interior states such as Nevada, Arizona, Colorado, and New Mexico, where water resources are even more delicate to manage than in California.

This fast increasing population fuels the suburban sprawl that poses a great challenge to water management and distribution authorities; the newcomers are quick to adopt a new lifestyle and behavior that embodies, in their eyes, economic and societal achievement—green lawns, pools, frequent car washes. As a whole, Americans consume about 40 gal/d/p; in the Southwest, per capita daily consumption averages 120 gallons. In cities such as Phoenix and Las Vegas, residents consume more than 300 gal/d/p. In Denver, more than half of the water consumed is attributable to outdoor landscaping (7).

CONSUMING LESS

Water saving measures have thus been enforced by local authorities in various ways. Higher water pricing, for instance, led to a sharp rationalization of industrial water use, water had become a substantial cost for large water users, although trends in industrial restructuring led to a decline in water-intense processes. The same basic economic mechanism is also expected to prevent citizens from using too much water.

Total irrigation withdrawals decreased since 1980 to stabilize around 136 Bgal/d, although risk-averse farmers are more prone to irrigating their fields for fear of a decrease in their yield, even in more humid areas (4, p. 86); irrigated acreage remained stable at 58 million acres since 1980. This stabilization does not mean that there is no room for improvement, especially in the West, where extensive irrigation still often uses flood irrigation. In Idaho, porous soils require constant watering, up to 12 feet of water an acre per season.

This decrease in withdrawals stems from pricing, though it remains very low for farmers compared to urban and industrial users. This discrepancy fuels "water wars" in the West, as urban communities are confronting the first appropriation rights of rural irrigation districts to increase their share of a relatively scarce resource. It also stems from the idea the main resource would become too scarce. These two factors drove farmers to adopt improved irrigation systems and techniques.

DEVELOPING NEW SOURCES

Using and consuming less is an option more and more favored in the United States due to the transition from water-supply management to water-demand management. This shift in focus is attested to by changes in pricing policies as well as in recurring awareness campaigns targeted at citizens, industry managers, and farmers. But increasing supply is not a forgotten option. Grand schemes of damming Canada's untamed rivers and diverting them toward the thirsty Midwest were part of some engineering firms' and government agendas, notably in Québec, up until 1986; large-scale water exports were again contemplated in Canada from 1997 to 2001 but are now banned by a federal law. These projects no longer have the favor of an environmentally aware public, especially in a decade that saw large dams become the focus of environmentalists' anger and campaigning in the United States and throughout the Western world and even against some large projects in developing countries, such as the Narmada Dam project in India.

Reclaimed Wastewater

Reclaimed wastewater, for instance, was long thought of as irrelevant because of cost and safety issues. In 1995, total wastewater use amounted to 1.02 Bgal/d, a 36% increase since 1990 (Table 7). Water recycling is mainly a feature of the dry West. Florida, confronted with acute freshwater supply problems, has invested in extensive reuse programs. Arizona, Wyoming, and Florida appear to be the most effective states in recycling wastewater.

Desalting

Desalting also used to be considered an irrelevant solution because it produced very expensive water. During the last 15 years, improved technological processes have led to a fast decrease in the cost per gallon of water produced, although only urban or industrial users can afford it. Local governments are keenly interested in this technology, as attested to by recent major contracts in Florida, where a plant of 95,000 m^3/ day (25 million gal/d) approved by regional water officials in March 1999, is to be located near Tampa Bay. The water produced should cost between 45 and 55 ¢/m^3, or $1.71 to $2.08/1000 gal.

Desalination is proving very popular in the United States, where built capacity in early 1999 ranked second in the world (Table 8).

HOW WE USE WATER IN THESE UNITED STATES

U.S. Environmental Protection
Agency

Water use is usually defined and measured in terms of withdrawal or consumption—that which is taken and that which is used up. Withdrawal refers to water extracted from surface or ground water sources, with consumption being that part of a withdrawal that is ultimately used and removed from the immediate water environment whether by evaporation, transpiration, incorporation into crops or a product, or other consumption. Conversely, return flow is the portion of a withdrawal that is actually not consumed but is instead returned to a surface or ground water source from a point of use and becomes available for further use.

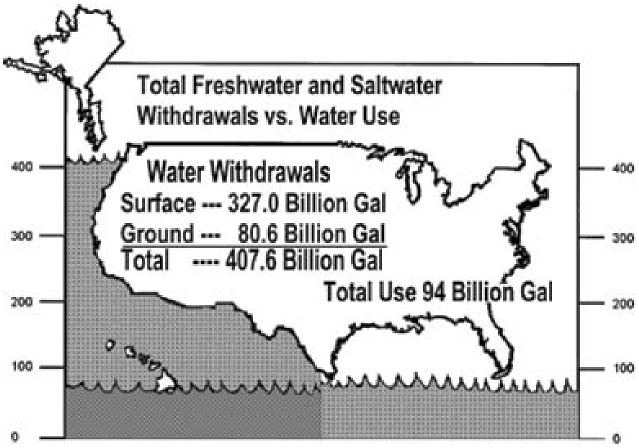

Figure 1. Total daily offstream water use in the United States.

Water use can also be divided into offstream and instream uses. Offstream water use (see Fig. 1) involves the withdrawal or diversion of water from a surface or ground water source for

- Domestic and residential uses
- Industrial uses
- Agricultural uses
- Energy development uses

Instream water uses are those that do not require a diversion or withdrawal from the surface or ground water sources, such as:

- Water quality and habitat improvement
- Recreation
- Navigation
- Fish propagation
- Hydroelectric power production

NATIONAL TRENDS IN WATER USE

National patterns of water use indicate that the largest demand for water withdrawals (fresh and saline) is for thermoelectric generation (47 percent), followed by irrigation (34 percent), public supply (9 percent), industrial (6 percent), mining (1 percent), livestock (1 percent), domestic (1 percent), and commercial uses (1 percent). While thermoelectric generation represents the largest demand for fresh and saline withdrawals, irrigation represents the largest demand for freshwater withdrawal

---

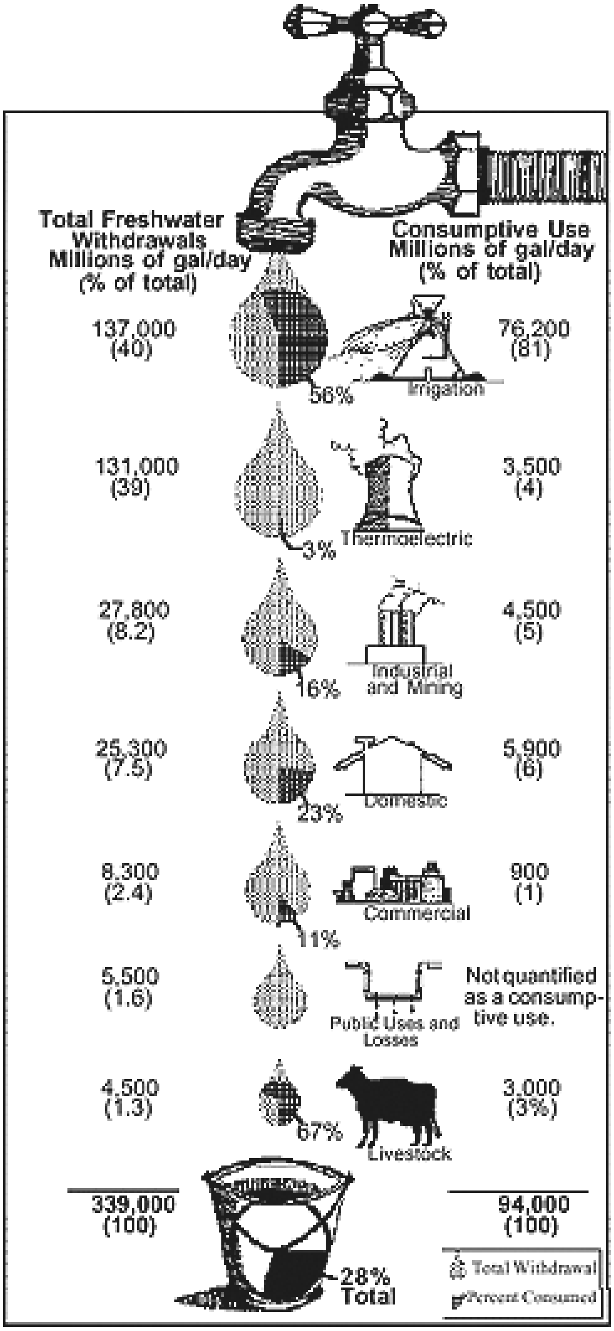

Figure 2. Comparison of freshwater consumptive use in the United States for 1990 by category.

alone (see Fig. 1). Activities that reduce the need to withdraw surface and ground water will lead to many of the beneficial effects of conserving water.

NATIONAL CONSUMPTION PATTERNS

Water consumption varies by water use category, with irrigation consuming the highest percent (81 percent) and commercial the lowest (1 percent) (see Fig. 2). The difference between the volume of water withdrawn and that consumed is the return flow. As more good-quality water is available in return flows, more water is available for other beneficial uses.

Some categories of water use, such as irrigation and livestock watering, consume a high percentage of water that is withdrawn from surface and ground water sources. Thus, less water is available for return flows from these high-consumption activities. Other categories of use like thermoelectric power consume only a small fraction of the water they withdraw.

CATEGORIES OF WATER USE

With several different ways to categorize water use in the United States, this article separates offstream uses into

- Municipal/public supply
- Domestic and commercial
- Industrial and mining
- Agricultural
- Thermoelectric power

MUNICIPAL/PUBLIC WATER SUPPLY

While water withdrawals for public use can be applied to street cleaning, fire fighting, municipal parks, and public swimming pools, keep in mind that municipalities and private suppliers might also provide water for other purposes (domestic/commercial, agricultural, thermoelectric power).

Per capita (per person) use of public water supplies in the United States (1990) averaged 183 gallons per day (gal/d). The average per capita use can vary greatly between communities for any number of reasons, including, but not limited to:

- Climate differences
- The mix of domestic, commercial, and industrial uses
- Household sizes
- Lot sizes
- Public uses
- Income brackets
- Age and condition of distribution system

For instance, per capita use of public water is about 50 percent higher in the West than the East mostly due to the amount of landscape irrigation in the West (see Fig. 3). However, per capita use can also vary greatly within a single state. For example, in 1985 the demand for municipal water in Ancho, New Mexico, totaled 54 gallons per capita per day (gal/cap/day) while in Tyrone, New Mexico, municipal demand topped off at 423 gal/cap/day. Rural areas typically consume less water for domestic purposes than larger towns.

In 1990, water withdrawn nationwide for public supplies totaled 38,530 million gallons per day (Mgal/d) (see Table 1). Although this withdrawal rate represents a 5 percent increase over 1985 amounts, the number of people supplied with water distributed through public systems also increased 5 percent during that same 5-year period. Again in 1990, surface water supplied about

Figure 3. Average use per person (gal/day) of public water in the United States by USGS water region.

Table 1. Fate of Water in Public Water Supplies of the United States, 1990

Receiving Category	Volume, Mgal/day	Percentage of Total
Domestic	21,900	57
Commercial	5,900	15
Public Use Losses	5,460	14
Industrial	5,190	13
ThermoelectricPower	80	<1
Total	**38,530**	**100**

61 percent of the public water supply, with ground water supplying the other 39 percent.

Of the total water withdrawn in 1990 for public supplies representing 11 percent of total U.S. offstream freshwater withdrawals 72 percent went to domestic and commercial uses, 13 percent to industrial uses, and 0.2 percent to thermoelectric power. The remaining 14 percent went to public uses such as fire protection or was lost during distribution (usually due to leaks).

DOMESTIC/COMMERCIAL

Domestic water use includes everyday uses that take place in residential homes, whereas commercial water uses are those which take place in office buildings, hotels, restaurants, civilian and military institutions, public and private golf courses, and other nonindustrial commercial facilities. Combined freshwater withdrawals for domestic and commercial use in 1990 totaled 33,600 Mgal/d, or 10 percent of total freshwater withdrawals for all offstream categories (see Fig. 2).

Typical categories of residential water use include normal household uses such as

- Drinking and cooking
- Bathing
- Toilet flushing
- Washing clothes and dishes
- Watering lawns and gardens
- Maintaining swimming pools
- Washing cars

When divided into indoor uses and outdoor uses, the amount of indoor water use remains fairly constant throughout the year, with the breakdown of typical indoor water uses depicted in Fig. 4. By far the largest percentage of indoor water use occurs in the bathroom, with 41 percent used for toilet flushing and 33 percent for bathing.

Outdoor residential water use, however, varies greatly depending on geographic location and season. On an annual average basis, outdoor water use in the arid West and Southwest is much greater than that in the East or Midwest. Figure 5 compares the national average for residential outdoor water use with that of Pennsylvania and California, with landscape irrigation the primary application. While average outdoor water use in Pennsylvania represents only approximately 7 percent of the total residential demand, in California average outdoor use climbs to about 44 percent of the demand.

INDUSTRIAL AND MINING

Industrial water uses, estimated to be 8 percent of total freshwater use for all offstream categories, include cooling in factories and washing and rinsing in manufacturing processes. Some of the major water-use industries include mining, steel, paper and associated products, and chemicals and associated products.

Water for both industrial and mining uses comes from public supplies, surface sources, and ground water. During the 5-year span from 1985 to 1990, industrial water use in the United States decreased approximately 13 percent. In the same period, mining water use increased about 24 percent.

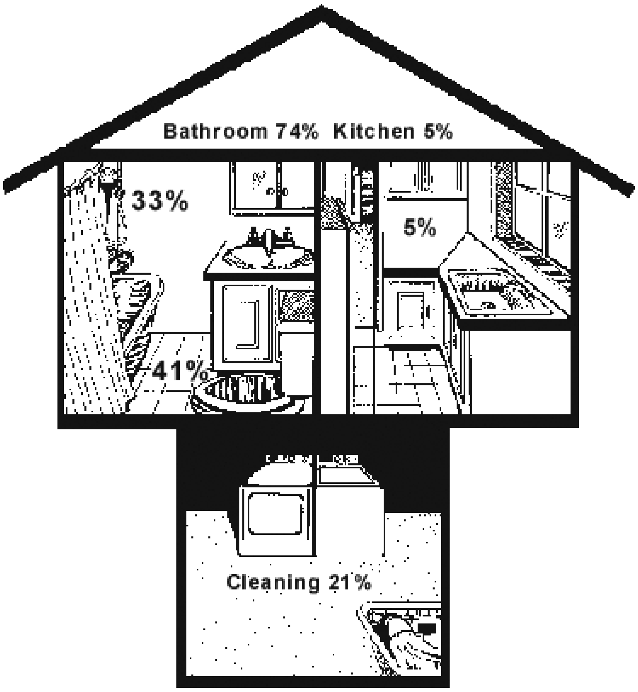

Figure 4. Typical breakdown of interior water use.

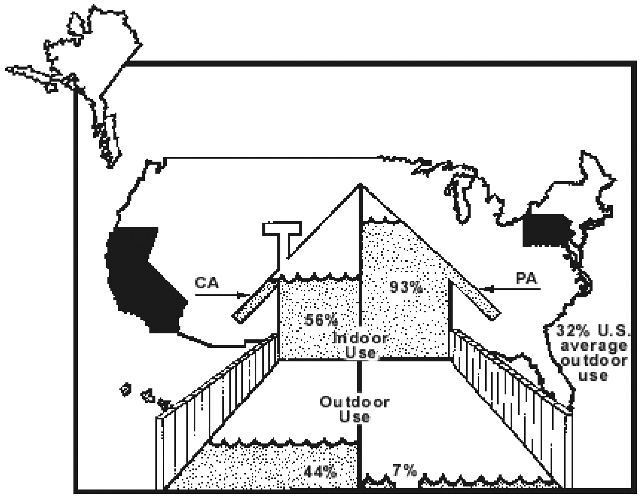

Figure 5. Comparison of average national residential outdoor water use with that of Pennsylvania and California.

AGRICULTURAL

Agricultural water use can be divided between irrigation and livestock. Irrigation includes all water applied to farm or horticultural crops; livestock incorporates water used for livestock, dairies, feedlots, fish farms, and other farm needs.

Estimated annual water use for irrigation remained at about the same level between 1985 and 1990, with approximately 63 percent of the water used for irrigation in 1990 coming from surface water. Approximately 60 percent of the water used for livestock came from ground water sources and the remaining 40 percent from surface water sources. Combined water use for irrigation and livestock represents about 41 percent of total offstream freshwater use for 1990, (see previous Fig. 1) with 40 percent going to irrigation and the lone 1 percent to livestock uses.

Not only can the loss of water from irrigation conveyance systems be significant, but the percentage of consumptive water use for agriculture is high as well an estimated 54 percent consumption in 1985. By 1990 this had climbed to an estimated 56 percent consumption for irrigation uses and 67 percent for livestock uses (see Fig. 2).

THERMOELECTRIC POWER GENERATION

This final category includes water used for the production of energy from fossil fuels, nuclear energy, or geothermal energy. Most water withdrawn for thermoelectric power production is used for condenser and reactor cooling. While 1990 estimates of freshwater withdrawals remained constant from 1985, nearly half again as much saline water was also used.

More than 99 percent of the water used for thermoelectric power production comes from self-supplied surface water, less than 0.2 percent from public supplies. In 1990, water used for thermoelectric power production represented close to 39 percent of total offstream freshwater use in the United States, but only about 3 percent was consumed.

The Mid-Atlantic, South Atlantic Gulf, Ohio, and Great Lakes water resource regions use the largest amounts of water for thermoelectric production. The eastern United States uses about five times more water than the West to produce about twice as much thermoelectric power.

VALUING WATER RESOURCES

Diane Dupont
Steven J. Renzetti

INTRODUCTION

Suppose that consideration is being given to dam a river. The dam will provide benefits in the form of hydroelectric power, water for irrigation, and protection from floods. Conversely, building the dam will also destroy wetlands, fish spawning grounds, and impair recreational opportunities. In deciding whether to build the dam, one important type of information is the value to society of the benefits and damages that will arise. Obtaining estimates of these values requires an understanding of the services that society derives from water, how those services will change with the building of the dam, and the value that society attaches to each service. It is the last of these tasks that this article addresses. Specifically, the purpose of this article is to review briefly how economists estimate the value of water. Because of the importance of water and the increasing costs of maintaining clean water, there has been a large amount of research into this topic (1–5). This article reviews the methods developed by economists to estimate water's value in the next section. Empirical estimates of the various uses of water are discussed later.

THE ECONOMIC PERSPECTIVE ON VALUATION

The starting point for most economic methods for measuring the value of water is an understanding of the structure of household tastes or preferences and firms' productive technologies. This understanding can then be used to develop measures of the benefits of water use and the change in household welfare or firm profits that arise from changes in the price, quantity, or quality of water. These measures, in turn, allow the analyst to determine the maximum willingness to pay (in the case of a change leading to an improvement in welfare) for water. This idea of willingness to pay forms the cornerstone of economic measures of value. (This approach to understanding and measuring value is not without its critics; see the discussion in Reference 1.)

These measures provide estimates of the value of water to the individual user (i.e., the "private" value). This may differ from the social value of water use (the value to all of society) by an individual household, firm, or farm.

There are a number of reasons that social and private values of water use may differ. First, an individual's water use may result in lowered water quality from pollution, and this, in turn, would lower the value of that water for other users and, thus, to society. Second, a farm may use water to increase production of crops that are supported by government subsidies. In this case, the farmer's valuation of the increased output will be higher than society's because of the cost of the subsidies to society.

Another issue complicating the measurement of the value of water is that, like many environmental goods, the value of some of the uses to which water is put are reflected in market transactions and others are not. An example of the former is a farmer purchasing water to irrigate crops—an analyst may be able to infer the value of water to the farmer by using market information on the increase in crop yield brought on by irrigation. An example of the latter is a family enjoying a day of swimming at a municipal beach. In this case, analysts must use "nonmarket" methods to estimate the family's valuation of its recreation.

As Table 1 indicates, economic valuation methods may be categorized into indirect and direct methods. Indirect valuation methods are those that infer a household or firm's valuation of water from its observed market behavior. There are a number of indirect valuation techniques. The derived demand method applies statistical or mathematical programming techniques to observations on market transactions in water to estimate a household's or firm's demand for water. The estimated demand relationship can, in turn, be used to calculate the user's willingness to pay for water. The avoided cost method assesses the value of water by examining the costs that are avoided because water is available. (A related method is the averting behavior method. If households purchase water filters to remove waterborne impurities, then the value to the household of removing the impurities can be estimated by the cost of water filtration.) For example, if a firm is able to release effluents into a lake rather than treating them, then the avoided cost of treatment provides an estimate of the value of the lake's assimilative capacity to the firm. The residual imputation method calculates the value of water to a firm or farm as the difference between the operation's revenues and the cost of all of its nonwater inputs. The hedonic method uses statistical techniques to determine the contribution of water to the total value of marketed commodities. For example, a house of a given size is usually more valuable, the closer it is to a body of water, and hedonic methods can estimate the increase in value that is related to the proximity to water. Finally, the travel cost method is used to estimate households' valuation of water-related recreation experiences by examining the time traveled to a recreational site and out-of-pocket expenses incurred by a family. A greater time traveled implicitly raises the cost of recreation because it usually means more time away from work.

Direct valuation methods are those that survey households to obtain their valuations. The most important direct valuation technique is contingent valuation. In this approach, individuals are presented with information concerning a hypothetical or constructed market and asked to indicate their willingness to pay to achieve a desired good or service. For example, a respondent might be asked to value a potential improvement in water treatment that reduces the risk of illness. This method is valuable for assessing projects before they are undertaken and for assessing households' "nonuse" values of water. For example, some households may be willing to pay a positive amount to ensure access to water some time in the future (6).

EMPIRICAL ESTIMATES OF THE VALUE OF WATER

The preceding section demonstrates that economic researchers have developed the conceptual framework and measurement methods for estimating the value of water. This section briefly points to a number of examples of the results of estimation studies. (The interested reader

Table 1. Economic Valuation Methods

Method	Applications	Comments
	Indirect	
Derived demand	Residential, industrial	Estimated demand curve yields user's valuation of water
Avoided cost	Residential, industrial	Access to clean water allows firms and homes to avoid costs such as water filters
Residual imputation	Agricultural, industrial	Requires information on revenues and costs of nonwater inputs
Hedonics	Residential, recreation	Good for assessing the impacts of changes in water quality
Travel cost	Recreation	One of the earliest methods—in use since the 1960s
	Direct	
Contingent valuation	Recreation, changes in water quality, ecosystems	Only method that can estimate nonuse values (values that arise from an aesthetic appreciation of water or a desire to hold an option to use water in the future)

Table 2. Representative Valuation Studies

Author	Sector/Use	Method	Estimate/Year
		Indirect	
Moore (8)	Agriculture	Derived demand	\$42–70/acre-foot (1989 US\$)
Young and Gray (9)	Industrial waste disposal	Avoided cost	\$0.07–1.28/acre-foot (1972 US\$)
Gibbons (2)	Industrial water intake	Avoided cost	\$6–78/acre-foot (1980 US\$).
Abdalla (10)	Residential	Avoided cost	\$125–330/household (1987 US\$)
Smith, Desvousges and McGivney (11)	Recreation	Travel cost	\$10–20/household (1977 US\$)
		Direct	
Whitehead and Blomquist (12)	Wetland preservation	Contingent valuation	\$6–21/household (1992 CAN\$).
Carson and Mitchell (13)	Recreation	Contingent valuation	\$70–90/household (1990 US\$)

should consult the valuable compilation of empirical estimates of water's value in Reference 7.) The results of a number of representative studies are reported in Table 2 and are discussed briefly below.

Indirect Valuation Studies

Moore (8) compares estimates of the value of irrigation water using the derived demand and residual imputation methods. The author finds that the two methods yield quite different results (the derived demand method provides higher estimated values). This is an important finding as the price paid by some American farmers for irrigation water is based, in part, on their estimated valuation of that water.

Young and Gray (9) and Gibbons (2) employ the avoided cost approach to value industrial water use. In both cases, the authors calculate the costs that firms are able to avoid by being able to dispose of effluents in waterbodies and by using increased water intake rather than in-plant water recirculation. Young and Gray find that the value of water used in industrial waste disposal is relatively low as few costs are actually avoided. Conversely, Gibbons finds a wider range of values for increased intake water substituting for water recirculation because, in some applications, in-plant recirculation must also address reduced water quality.

Abdalla (10) examines household valuation of improvements in the quality of their drinking water supplies by measuring the cost savings of those improvements. These cost savings arise from decreased purchases of water filters and bottled water and from less time needed to boil water. The authors also find that households with children place a higher value on water quality improvements than those without.

Smith et al. (11) address the change in the valuation of sport fishing from changes in water quality at specific sites. The authors do this by investigating the role of water quality in approximately 20 published studies of water-based recreation that use the travel cost method. The principal finding of the Smith et al. study is that increases in water quality increase the demand for, and valuation of, water-based recreation. For example, when applied to data derived from users of the Monongahela River, the average consumer surplus (a measure of willingness to pay net of fishing expenses) for water quality improvements from boatable to game fishing conditions was \$9.96 per household per season (1977 US\$).

Direct Valuation Studies

One of the most important advantages of direct valuation methods is that they can be employed to consider household 'nonuse' values of water. These values arise not from household use of water but rather because households may have an interest in knowing that a particular waterbody has been preserved (possibly for their use in the future). For example, Whitehead and Blomquist (12) employ a contingent valuation survey to examine household willingness to pay for wetlands preservation and the role that information provision plays in determining that value. The authors find that, while many households are willing to contribute toward the preservation of wetlands, as more information is provided about the availability of substitutes for an endangered wetland, respondents' willingness to pay for preservation falls off.

Finally, Carson and Mitchell (13) report on an influential study of American household valuation of enhanced water-based recreational opportunities that could arise from improved water quality. A particularly important feature of this study's methodology is the contingent valuation survey that employs the water quality "ladder" to set out for respondents the various levels of water quality that they are asked to consider. In doing so, the authors frame or present differ levels of water quality ("boatable, fishable, and swimmable", p. 2447) in a way that is comprehensible for most respondents. The results indicate that the sample of households places significant value on improving water quality.

CONCLUSION

The growing scarcity of water creates the need to develop and implement rational methods for allocating water across competing needs. Part of this process of decision-making requires understanding the value that individual households, firms, and farms obtain from their various uses of water. This article has briefly outlined the methods developed by economists to estimate those values.

WATER—HERE, THERE, AND EVERYWHERE IN CANADA

Environment Canada

How much water is there in the world? Scientists estimate over one billion cubic kilometers (one cubic kilometer of water would fill 300 Olympic-sized swimming pools). Water covers nearly three quarters of the earth's surface in oceans as well as rivers, lakes, snow and glaciers. There is water in the atmosphere and water underground. Water evaporates and returns to the land surface in what is known as the *hydrologic cycle*.

In the hydrologic cycle, water evaporates from the ocean into the atmosphere, from there it can precipitate back into the ocean, or onto the land surface. From the land, it can evaporate or transpire back into the atmosphere, or flow overland or percolate underground before flowing back into the ocean. The distribution of the water around the globe varies from season to season and year to year, but the total quantity of water on the earth's surface remains essentially constant. The hydrologic cycle is discussed in detail in Freshwater Series No. A-1, "Water—Nature's Magician."

Although water exists in other forms in the hydrologic cycle, this issue in the Freshwater Series focuses on surface water as it is this water which we see in our everyday lives. Most of the earth's water is salty or permanently frozen. Figure 1 illustrates the proportion of fresh water that is available to us from the world's water supply.

Figure 3.

Figure 2 lists quantities that scientists have estimated for the various types of water that make up the world's supply. These amounts should be regarded as indicators of the relative quantities of water on earth. Owing to the difficulties in estimating volumes of water on a global scale, especially water underground, estimates can vary considerably. What is important is the overall picture that these estimates give.

RIVERS

A river's watershed or drainage basin—the area supplying it with water—is separated from the watersheds of neighboring rivers by higher lands called *drainage divides*. The map shows Canada's continental watersheds, one to each surrounding ocean: the Pacific, the Arctic, and the Atlantic as well as to Hudson Bay and to the Gulf of Mexico. Small watersheds combine to make up regional watersheds, which in turn join others to form continental watersheds.

The world's largest rivers are shown in Fig. 3.

Sculpting the Earth

As a swiftly flowing river, water can erode the underlying terrain. Where the river slope is flatter, the river slows down and deposits materials. This usually occurs in the lower reaches and especially near the mouth of the river, either at a lake or an ocean. A river can carve steep valleys, especially in higher parts of the drainage basin.

In the lower parts of the basin, deposits may create deltas at the river's mouth.

The volume of water flowing in a river, together with the speed and timing of the flows, determines how a river shapes the surrounding landscape and how people can use its waters. Rainfall, snowmelt, and groundwater all contribute to the volume of flow, producing variations from season to season and year to year.

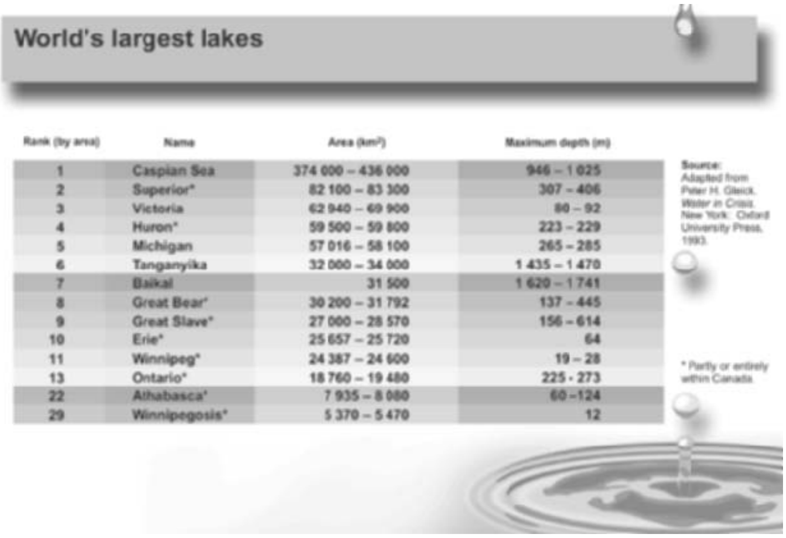
In Canada, most high flows are caused by spring snowmelt. This is the season when floods are most likely to occur. Rainstorms can also cause high flows and floods, especially on small streams. The effects of floods and storms can be much less severe on rivers with large drainage basins. The lowest flows for rivers in Canada generally occur in late summer, when precipitation is low and evaporation along with consumption by plants is high, and in late winter, when rivers are ice covered and the precipitation is stored until spring in the form of ice and snow.

LAKES

Canada has more lake area than any other country in the world (Fig. 4), with 563 lakes larger than 100 square kilometers. The Great Lakes, straddling the Canada–U.S. boundary, contain 18% of the world's fresh lake water.

How is Water Measured?

The Water Survey of Canada, Environment Canada, along with many contributing agencies, measure the rate of flow (discharge) in rivers and record the levels of lakes and rivers at more than 2,600 locations in Canada. Typical river flows are listed in Fig. 5.



World's largest lakes

Rank (by area)	Name	Area (km²)	Maximum depth (m)
1	Caspian Sea	374 000 – 436 000	946 – 1 025
2	Superior*	82 100 – 83 300	307 – 406
3	Victoria	62 940 – 69 900	80 – 92

Note: This table is based on historical data to 1999, extracted from the national HYDAT database.

Figure 5.

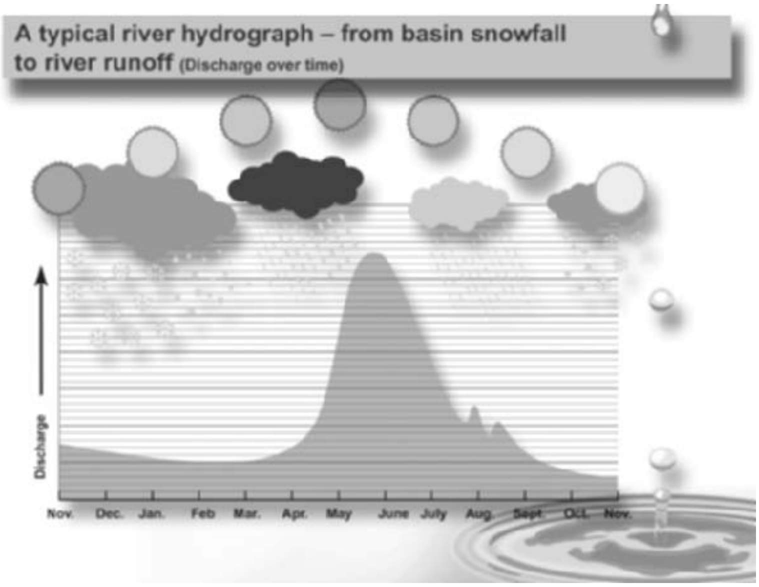

Figure 6.

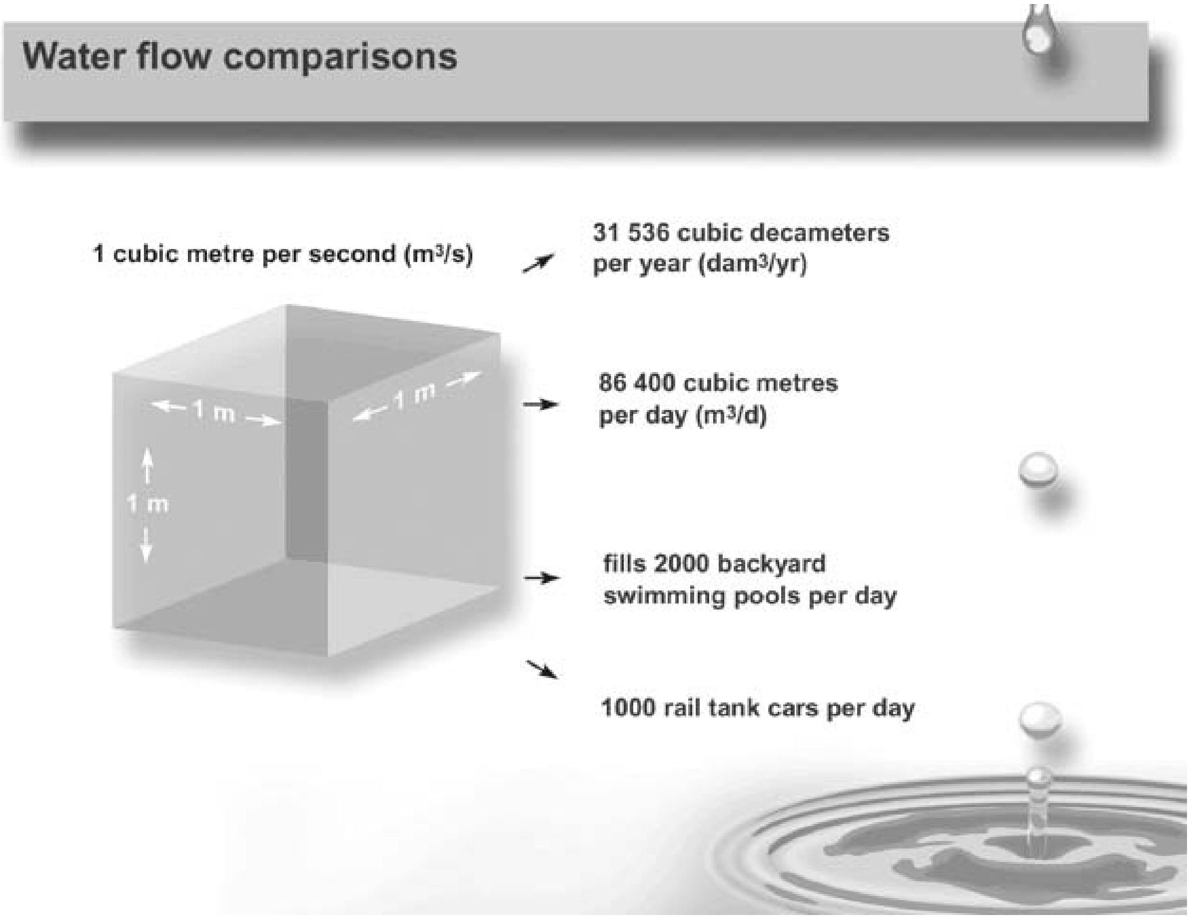

- Water levels are read manually by gauge readers or continuously recorded either digitally or on graph paper.
- Rate of flow (or discharge) requires multiple measurements of channel depth, width, and flow velocity to yield the average discharge in the stream crossing for a given water level. Measurements can be made from a bridge, by wading in a stream, by boat or from a cableway strung across the river. In winter, the measurements are made through the ice.

- With sufficient measurements of flow over a variety of water levels (including extreme lows and highs), a water level-discharge relationship is established at each location. The discharge rate can then be computed from measured water levels.
- Historical records from 5,000 active and discontinued sites permit the estimation of streamflow at ungauged locations.

Creating a Balance—Naturally

The importance of lakes lies in their ability to store water during times of plenty and release it gradually. Thus lakes perform an extremely valuable task in balancing the flow of the rivers on which they are located. For example, the Saskatchewan River, with few lakes, has a maximum recorded flow of 59 times its minimum flow. On the other hand, the St. Lawrence River, which drains the Great Lakes, has a maximum flow of only twice its minimum flow. The difference in flow patterns in these two rivers is partly due to precipitation differences, but results mainly from the vast storage provided by the Great Lakes for the St. Lawrence River compared with the negligible lake storage on the Saskatchewan River.

Creating a Balance—Artificially

Since ancient times, people have built dams to control the outflow from existing lakes or to create new lakes. Dams and their reservoirs have provided:

- A stable source of inexpensive energy
- A more dependable water supply throughout the year
- Flood control downstream
- Recreation

THE UNDERGROUND RESERVOIR

Beneath the surface of the earth is a huge reservoir of fresh water. Groundwater does not rest; it moves continuously, but at a snail's pace, from its point of entry to areas of natural discharge. Groundwater moves so slowly that its speed is measured in meters per day, and even per year. (Surface water velocities are described in meters per second.) Wells intercept some groundwater but most of it continues until it reappears naturally in a spring or a seepage area and joins a watercourse.

Groundwater contributes to Canada's water supply by:

- Feeding streams, producing the entire flow of some streams during dry periods
- Replenishing wells—a valuable source of supply for individuals, communities, industries, and irrigated farms
- Supporting important ecological systems such as wetlands
- Moderating the adverse impacts of acid rain on surface water systems

Additional information on groundwater can be found in: Freshwater Series No. A-5, *Groundwater—Nature's Hidden Treasure*.

NATURE'S FROZEN RIVERS

A huge quantity of fresh water is frozen in polar ice caps and in high mountain glaciers. Snow that is packed down over many years at high elevations becomes glacial ice, which slowly proceeds downslope like a frozen river, under the pull of gravity, and eventually melts to become part of streamflow at lower elevations. If the rate of melting is greater than the rate of accumulation, the glacier recedes; if it is less, the glacier advances.

Glaciers exert a direct influence on the hydrologic cycle by slowing the passage of water through the cycle. Like lakes and groundwater reservoirs, glaciers are excellent natural storehouses, releasing water when it is needed most. Glaciers, however, can release water when you need it least. Glacier-outburst floods, called *jökulhlaups*, can be devastating. Glacier-fed rivers reach their peak during hot summer weather.

SNOWFALL

Much of Canada's annual precipitation comes as snow: in the North, 50%; in the Prairies, 25%; and on both coasts and in southern Ontario, as little as 5%. Snow exerts a marked effect on the distribution of streamflow throughout the year. Instead of immediately infiltrating the soil or running off into stream channels as rainfall does, this water is first stored in the snowpack for several months.

The relatively quick melting of snow in spring causes peak flows, sometimes resulting in floods. Some of the worst and most unpredictable flooding occurs when ice that has not yet melted is carried along in the swollen rivers until it jams, blocking the flow of water and creating a lake behind the jam with attendant flooding. When the ice jam breaks, a tremendous amount of water is suddenly released downstream, and more flooding may result.

FRESHWATER SERIES A-2

Note: A resource guide, entitled *Let's Not Take Water For Granted*, is available to help classroom teachers of grades 5–7 use the information from the Water Fact Sheets.

WATER CONSERVATION—EVERY DROP COUNTS IN CANADA

Environment Canada

The importance of protecting our water resource cannot be overstated. In economic terms, the measurable contribution of water to the Canadian economy is difficult to estimate. In environmental terms, water is the lifeblood of the planet. Without a steady supply of clean, fresh water, all life, including human, would cease to exist.

This article is produced by Environment Canada and is reproduced with permission.

The perception that Canada is blessed with an abundance of fresh water has led to misuse and abuse of the resource: from household toilets that use 18 liters per flush where 6 liters would do, to industrial plants—and some municipalities—that use water bodies as convenient sewers.

In 1999, the average Canadian daily domestic use of fresh water per capita was 343 liters. The quantity, quality and economic problems we face as a result of our use of water are complex but, at least *one* of the causes of these problems is easy to manage—the way we waste water. And, the solution is straight forward—*water conservation*. Simply stated, water conservation means doing the same with less, by using water more efficiently or reducing where appropriate, in order to protect the resource now, and for the future. Using water wisely will reduce pollution and health risks, lower water costs, and extend the useful life of existing supply and waste treatment facilities.

And it's easy. With little change to the way we do things now, or the equipment we use, we can reduce water consumption in the home, and in business, by 40% or more. These pages outline the role of water conservation in addressing problems related to water use and water quality. It also shows us what part we can play as residential consumers in finding solutions.

SUSTAINING OUR WATER SUPPLY

Water is considered a renewable resource: "renewable" referring to that portion which circulates back and forth in the hydrological cycle (described more fully in Freshwater Series A-1, *Water—Nature's Magician*). However, pressures on the resource are growing. For example, between 1972 and 1996, Canada's rate of water withdrawals increased by almost 90%, from 24 billion m^3/yr (cubic meters per year) to 45 billion m^3/yr. But, our population increased by only 33.6% over the same period, illustrating the growth in our thirsty lifestyles. As the readily available supplies of fresh water are being used up, we begin to see that there are real limits to how much water we can count on.

LIMITING FACTORS

- Although Canada has a significant amount of fresh water, we possess only 7% of the world's *renewable* freshwater supply.
- In Canada, 84% of the population lives in a narrow southern band, while 60% of our water supply flows north to the Arctic Circle.
- Our growing population, and our growing thirst for water, are being concentrated in expanding metropolitan areas, and are forcing water regulators and policy makers to find ways to stretch available supplies even further.
- Increasing pollution of surface and groundwater is further reducing the supplies of readily available, clean water.
- Because our water use almost always leads to some degree of deterioration in water quality, the less water we withdraw, the less we upset the natural balance of our aquatic ecosystems. And, the less we upset the ecosystem, the less we have to spend to restore the water quality to an acceptable standard for public use.
- Finally, financing by municipal governments for the treatment of water supplies and wastewater is becoming increasingly constrained.

We can, however, make a significant contribution to solving these problems by reducing unnecessary levels of water use. To do so requires that we identify the areas within our homes, businesses, buildings and processes where we waste water and then make appropriate changes, either in our fixtures, or in our water-using habits.

HOW WATER IS USED

We use water in many ways, and assign different values to those uses. *Instream* uses (e.g., for transportation and recreation) are valued highly, but it has proven difficult to give them a dollar value that has any real meaning. For example, just what would the average consumer be willing to pay to swim in a clean lake or for a chance to catch fish in a clean, unpolluted river?

By far the greater number and variety of water uses occur on land. These are called *withdrawal* uses and, although important to our daily lives, they have tended to be assigned a low value. Water is withdrawn, used and then discharged. Most withdrawal uses "consume" some of the water, which means less is returned to the source than was taken out. And, after it has been used, the quality of the water that is returned is often diminished, which has a negative impact on both the environment and recreational instream uses.

In 1996, five main withdrawal uses accounted for a total annual water intake (extractive uses) of 44.6 billion m^3. These uses are described more fully in Freshwater Series A-4, *Water Works*!.

Thermal power generation includes both conventional and nuclear power generating plants, which withdrew slightly more than 64% of the total water intake in 1996.

Manufacturing accounted for 14% of water withdrawals in 1996. Paper and allied products, primary metals and chemicals were the main industrial users.

Agriculture accounted for nearly 9% of total withdrawals, with the semi-arid Prairie region of Canada accounting for 75% of this total. Agriculture consumes a large portion of what it uses, returning less than 30% to its source where it can be used again. Irrigation is the largest agricultural consumer of water.

Municipal use accounted for 10% of all water withdrawals in 1996, or 12% when similar rural uses were included (excludes industrial uses and large-scale agriculture). In the municipal sector, more than half of the water demand is a result of residential use.

Mining use, including metal mining, non-metal mining, and the extraction of coal, accounted for 1% of all water withdrawals in 1996. Water is used by the mining industry to separate ore from rock, to cool drills, to wash the ore during production, and to carry away unwanted material.

Solutions—the Municipal Challenge

Municipal governments across Canada are beginning to take action to manage the demand for water, instead of seeking new sources of supply. Demand management, incorporating water efficient applications, is rapidly gaining popularity as a low cost, effective way to get more service out of existing systems, thus delaying or deferring the need for constructing new works. The benefits of water efficient techniques apply equally well to rural, private wells and septic disposal systems, as they do to central water and sewer systems in the city.

The wide range of water efficiency initiatives currently being undertaken, can be grouped under four principal categories:

1. Structural,
2. Operational,
3. Economic, and
4. Socio-political.

Most of these water conservation activities fall within the jurisdiction of municipal governments and/or public utilities.

Structural

- metering
- water recycling systems
- wastewater re-use
- flow control devices
- distribution system pressure reduction
- water saving devices (efficient fixtures, appliances and retrofits)
- drought resistant landscaping (xeriscaping)
- efficient sprinkling/irrigation technology
- new process technologies
- plant improvements

Operational

- leak detection and repair
- water use restrictions
- elimination of combined sanitary/storm sewers to reduce loadings on sewage treatment plants
- plant improvements

Economic

- rate structures
- pricing policies
- incentives through rebates and tax credits
- other sanctions (fines)

Socio-political

- public education
- information transfer and training
- regulatory (legislation, codes, standards and by-laws)

SUSTAINING OUR INFRASTRUCTURE

While many communities have access to an abundant water supply, the costs of the infrastructure that provides homes and industry with water and sewer services are straining the available municipal financial resources.

By *infrastructure*, we mean the *water treatment plants* that purify our water, the *water mains* in the ground that transport water, and the *towers* and *reservoirs* that store water. The term includes the *sewer pipes* that carry away wastewater and the *sewage treatment plants* that treat wastewater before returning it to the environment where it often becomes the source of water for communities downstream.

Experts are predicting a growing problem involving municipal water and sewer infrastructure in Canada. In 1991, the value of this investment was estimated to be worth over 90 billion dollars, of which a significant amount is deteriorating with age.

An increasing number of Canadian municipalities are considering water conservation as the key to keeping expansion needs to a minimum. Water conservation also optimizes plant efficiency, while assisting municipalities in financing the replacement of infrastructure that may be over 50 years old in some communities and up to 100 years old in several others.

Communities with older systems in need of extensive repairs or replacement face the most difficult problems.

With all levels of government adopting policies of realistic water pricing and user pay principles, many municipalities have instituted *full cost pricing* to recover the total cost of providing both water and sewer services—including the costs of financing the replacement of older systems and the upgrading of overloaded treatment plants. Higher municipal costs, in turn, mean higher water—and sewer—bills.

The problem of stressed treatment systems is not restricted to communities with piped water and sewer systems. Over the past 25 years, there has been a substantial migration of urban dwellers to the countryside. City-bred water using habits and attitudes are, in many instances, lowering the water table. And, the flood of wastewater produced is stressing the soil's ability to treat septic effluent adequately.

For both urban and rural communities, water conservation can extend the life of this over-stressed infrastructure.

Metering

Tied to price increases, metered households generally show reductions in water use, with the greatest savings occurring during the summer months, when water use is usually much higher due to frequency of lawn watering, car washing and other outdoor uses. In 1999, water use was 70% higher when consumers faced flat rates rather than volume-based rates. And yet, only about 56% of Canada's *urban* population was metered in 1999.

Metering of industry has been common for some time. What's new is the metering of the return flow to the sewer system, particularly as it relates to the industrial sector. Case studies show that including sewage treatment in rate calculations generates greater water savings. An increasing number of municipalities are applying sewer surcharges to residential water bills.

Water Efficient Residential Technology

More than half of municipal water is used by the residential sector. As a consequence, the residential sector represents a logical target for demand management activities. Depending on the nature of the water efficiency program developed, each household can reduce water use by 40% or more.

Leak Detection and Repair

Up to 30% of the total water entering supply-line systems is lost to leaking pipes. In most cases, if unaccounted for water in a municipal system exceeds 10 to 15%, a leak detection and repair program is cost-effective. For example, studies have shown that for every $1.00 spent in communities with leak detection programs, up to $3.00 can be saved.

Rates, Pricing and Public Education

About 55% of Canadians served municipal water pay in ways that do not promote conservation. A 2001 study of rate structures by Environment Canada showed that in 1999, 43% of the population was under a *flat rate* structure (where the charge or assessment is fixed, regardless of the amount of water used). Another 12% were under a *declining block rate* structure (where the consumer's bill rises at a slower rate as higher volumes of water are used); i.e., the more you use, the less you pay per unit.

Only about 45% of the population served was found to be under a rate structure that provided a definite incentive to conserve water: 36% were under a *constant rate* structure (where the bill to the consumer climbs uniformly with the volume used); and 9% were under an *increasing block* rate structure (where a successively higher price is changed as larger volumes of water are used).

Introducing conservation-oriented pricing or raising the price has reduced water use in some jurisdictions, but it must be accompanied by a well articulated public education program that informs the consumer what to expect.

SUSTAINING OUR WATER QUALITY

In addition to water supply and infrastructure issues, water quality is a problem in many Canadian communities. Generally speaking, the decline in water quality is a function of the way we use water. Even something as simple as rinsing dishes in the kitchen creates wastewater that is contaminated to some degree. Once this water enters the sewer system, it must be treated in a sewage treatment plant. These facilities are never 100% effective, which means that some water quality deterioration remains after the treatment process.

Specific causes of impaired water quality are numerous, including: agricultural runoff containing the residues of fertilizers, pesticides and other chemicals, industrial pollution, either directly from the facility, or indirectly from the leaching of chemicals from landfills, or pollution from average households in the form of improperly treated municipal sewage (refer to Freshwater Series A-3, *Clean Water—Life Depends on It*). Nearly 75% of Canadians are serviced by municipal sewer systems. In 1999, 97% of the Canadian population on sewers received some form of wastewater treatment. The remaining 3% of Canadians served by sewage collection systems were not connected to wastewater treatment facilities in 1999 and discharged their untreated sewage directly into receiving water bodies.

For the roughly 25% of the Canadian population served by private wells and septic disposal systems, the news is not much better. These systems were originally designed for houses that were widely separated from their nearest neighbor, such as farmhouses and the occasional rural residence. Yet, today, in many parts of the country, individual private wells are being installed in subdivisions at suburban densities. The primary danger here is that too many wells may pump too much water for the aquifer to sustain itself.

Septic treatment systems associated with these developments can stress the environment in a number of other ways. They are often allowed in less than satisfactory soil conditions and are seldom maintained properly. They are also unable to treat many household cleaners and chemicals which, when flushed down the drain or toilet, often impair or kill the bacterium needed to make the system work (The same applies in urban systems). The end results are improper treatment of wastewater—if not outright failure of the system—and the contamination of adjacent wells with septic effluent containing bacterium, nitrates and other pollutants.

Once these contaminants are in the groundwater, they eventually reach rivers and lakes. In other words, once we have a *pollution* problem, we may be only a step away from a *water supply* problem.

Solutions—in the City and in the Countryside

The irony in all of this is that water quality impacts from overloaded or poorly maintained and operated municipal and private sewage disposal systems are the number one preventable type of pollution in Canada. The answer lies in better, more thorough treatment. And, one of the ways to enhance the treatment process is to limit the amounts of wastewater entering the wastewater stream. Again, water conservation is one of the easiest and cheapest ways to reduce the volume of wastewater flows and improve water quality.

Following a few common sense rules, it should be possible to safeguard your water supply while extending the life of your sewage disposal system, regardless of whether you live in the country or in the city.

Think carefully about the quantities of wastewater your household or business produces, as well as the quality of the wastewater. Do you make it a habit of discarding solvents, cleaners and related chemicals down your drains? If you do, you may be introducing substances that are toxic to the bacterium and other organisms that play a vital role in the treatment of sewage. This statement applies equally well to urban and rural households and businesses.

INDIVIDUAL ACTION—CONSERVING WATER IN THE HOME, COMMUNITY AND AT WORK

As we have seen, water quality and quantity are two sides of the same coin. How does saving water help water quality? Because water saved is water that does not end up in the wastewater stream requiring treatment. This, in turn, reduces municipal pumping and treatment costs and frees up monies that can be used for infrastructure renewal and replacement and protection of supply sources. Less wastewater in the sewage treatment plant also means that the plant has a better chance of doing the job it was intended to do.

So where do we start? The first step is to identify where we use water in the home. Then we need to decide on what to do to reduce the amount of water we use, either by eliminating wasteful practices and habits, or by improving the efficiency of our water using fixtures and devices. Since we waste so much, this should be a relatively easy and painless process. The prime area to target is the bathroom, where nearly 65% of all indoor water use occurs.

What follows are some suggestions for how to get your house or business in order. Based on the three rules of water conservation—*reduce, repair* and *retrofit*—a typical household can reduce water consumption by 40% or more, with or no effect on lifestyle.

REDUCE

Much of the water “consumed” in our daily activities is simply wasted. Taps are left running while we brush our teeth. Dishwashers and laundry machines are operated without full loads. Really, everywhere we use water there is room for improvement. Here are just a few examples for both indoor and outdoor water use.

- Don’t use the toilet as a wastebasket or flush it unnecessarily.
- A quick shower uses less hot water than a full tub (and saves energy too).
- Keep a bottle of drinking water in the refrigerator rather than letting your tap run to get cold water when you want a drink. (Rinse the bottle every few days.)
- More than 50% of the water applied to lawns and gardens is lost due to evaporation, or run-off because of overwatering. Find out how much water your lawn really needs. As a general rule, most lawns and gardens require little more than 2 to 3 cm (1 inch) of water per week.
- To reduce loses due to evaporation, water early in the morning (after the dew has dried).
- When washing a car, fill a bucket with water and use a sponge. This can save about 300 liters of water.

REPAIR

Leaks can be costly. A leak of only one drop per second wastes about 10,000 liters of water per year. Most leaks are easy to find and to fix, at very little cost.

- Leaking faucets are often caused by a worn out washer that costs pennies to replace. Most hardware stores will have faucet repair kits with illustrations showing how to replace a washer.
- A toilet that continues to run after flushing, if the leak is large enough, can waste up to 200,000 liters of water in a single year! To find out if your toilet is leaking, put two or three drops of food coloring in the tank at the back of the toilet. Wait a few minutes. If the colour shows up in the bowl, there’s a leak.
- Toilet leaks are often due to a flush valve or flapper valve that isn’t sitting properly in the valve seat, bent or misaligned flush valve lift wires, or a corroded valve seat. All of these can be fixed easily and inexpensively. To get at the valve seat, which surrounds the outlet hole at the bottom of the tank,

you must first empty the tank. This is accomplished by turning off the inlet tap under the tank and flushing the toilet, making sure to keep depressing the flush lever until no more water drains out of the tank. Then, holding the valve out of the way, sand the corroded or warped valve seat smooth with a piece of emery cloth, if, however, the leak is around the base of the toilet where it sits on the floor, call a professional.

RETROFIT

Retrofit means *adapting* or *replacing* an older water-using fixture or appliance with one of the many water-efficient devices now on the market. While these solutions cost more, they also save the most water and money. Retrofitting offers considerable water saving potential in the home and business, so this issue in the Freshwater Series is devoting considerable space to it.

Toilet Retrofits

When it comes to retrofitting, the prime fixture to target is the toilet. You can: (i) *adapt* your existing toilet in a number of ways, by installing certain water-saving devices inside the tank at the back of the toilet; or, (ii) if the toilet is more than fifteen years old—which means it probably uses about 18 or more liters of water per flush—you can *replace* it with one of the growing number of ultra-low-volume (ULV) toilets, that can be ordered from most plumbing outlets, and use only 6 liters or less per flush.

There are many *toilet adaptations* you can install in the tank of an existing toilet to reduce the amount of water used in a flush cycle. These devices fall into three generic categories:

- water retention devices;
- water displacement devices; and,
- alternate flushing devices.

The most common water retention device available is the toilet dam. A set will save about 5 liters per flush when installed properly. Their main attraction is their low cost (under $10.00 per set) and the fact that they are easy to distribute and install for example, as part of a wider municipally-sponsored retrofit program. Their main disadvantage is that they tend to leak over time by slipping out of adjustment and can slip free and interfere with the moving parts inside the toilet tank, if not routinely checked.

Toilet dam and displacement bag:

The water displacement devices familiar to most people are the *plastic bags* or *bottles* filled with water which are suspended inside the toilet tank. As the name implies, these devices displace several liters of water, saving an equivalent amount during each flush. Like the toilet dam, most displacement devices are inexpensive and easy to install. Their chief disadvantage is that they don't save as much water as other devices and, if they are not installed carefully, they can interfere with the proper operation of the toilet.

One displacement device to stay away from is the *brick*! It can disintegrate inside the toilet tank, leading to excessive leakage at the flapper valve and may even be heavy enough to actually crack the tank.

There are essentially two types of alternative flush devices: *early-closure* and *dual-flush*. They are usually attached to the overflow tube inside the toilet tank. In both cases, they close the flush valve or flapper after the tank is only partially emptied. In theory, this interruption in the flush cycle occurs after the bowl has been cleared. In the case of the dual-flush mechanism, the amount of water saved is dependent upon how long the flush lever is activated—a partial flush for light duty or full flush or heavy duty.

While all of the above toilet adaptations appear to work as intended when first installed, their performance may vary considerably, depending on the toilet design. The best advice is to monitor the performance of the devices periodically. If you discover that it becomes necessary to double flush the toilet, something is in need of adjustment or replacement. Remember that double flushing defeats the purpose of your water conservation efforts and is costing you money.

If you decide that it is time for a *toilet replacement* in your home or business, you are well on your way to significant water savings that you can bank on over the life of the toilet. Replacing a 18 liter per flush toilet with an ultra-low-volume (ULV) 6 liter flush model represents a 70% savings in water flushed and will cut indoor water use by about 30%. Keep in mind that 18 liters per flush, assuming 4.5 flushes per person per day, translates into nearly 30,000 liters of clean, fresh water per year just to get rid of 650 liters of body waste. A 6 liter flush toilet only uses about 10,000 liters to do the same task. Low flush toilets are available for less than $150.00 at most plumbing and supply stores.

Remember, the ULV toilet not only uses less water, *it produces less wastewater*. If your municipality applies a *sewer surcharge* on your water bill, the investment in the better toilet could translate into a 50% reduction in your combined water/sewer bill. If you are on a private well and septic system, you are significantly reducing the loading on your tile field while extending its useful life. To a lesser degree, the same applies to the other water-saving devices described here.

Showerheads and Faucets

After the toilet, the shower and bath consume the most water inside the home. Conventional showerheads have flow rates up to 15 to 20 liters per minute. A properly designed *low-flow showerhead* can reduce that flow by half and still provide proper shower performance. Low-flow showerheads can be purchased in most plumbing supply outlets.

Depending on your preference for finish and appearance, you can select a serviceable low-flow showerhead starting at around ten dollars. Consider one with a shut-off button. The advantage of the shut-off button is that it allows you to be really water efficient if you so choose, by being able to interrupt the flow, while you lather up or shampoo, and then resume at the same flow rate and temperature.

Beware of the type of showerheads that produce such a fine mist that the water is quite cool by the time it reaches your feet. And, stay away from so-called *flow restrictors* that are inserted inside your existing showerhead. They look like a small plastic washer and can produce a fierce, stinging spray pattern which may significantly reduce the enjoyment of taking a shower.

Conventional faucets have an average flow rate of 13.5 liters of water per minute. Install *low flow aerators* to reduce this flow. In the bathroom, a flow rate of 2 liters per minute should do the trick, and in the kitchen a flow rate of 6 to 9 liters per minute is sufficient. Don't bother retrofitting the tap in the utility sink; it is intended to provide large volumes of water quickly, for example, for cleaning or washing, such that low flows will only inconvenience the user.

Outdoors

During the growing season water use can increase by as much as 50%. While lawns require a lot of water, much of this water is wasted—lost due to overwatering and evaporation (see Reduce).

Watering equipment also plays a part in how much water is saved and lost. Ideally, sprinklers should be suited to the size and shape of the lawn. That way, you avoid watering driveways and sidewalks. Installing timers on outdoor taps can be a wise investment.

Sprinklers that lay water down in a flat pattern are better than oscillating sprinklers which lose as much as 50% of what they disperse through evaporation. Drip irrigation systems which apply water only to the roots zone are the most efficient—and the most expensive—alternative.

The water you use to water your lawn doesn't have to come out of a tap. A cistern, which captures and stores rainwater, can be used as a source of irrigation water. A rain barrel can adequately fulfil this function.

Finally, consider a low-maintenance landscape—one which requires little more water than nature provides. Often called xeriscaping, the principles of a low-maintenance landscape are as follows:

- a reduced amount of lawn;
- proper plan selection making use of native grasses, shrubs and trees;
- mulching to reduce evaporative losses around shrubs and trees;
- the use of rain barrels and roof drainage;
- improvements to soils;
- a proper irrigation system; and
- planned maintenance.

The most significant savings of course, come from a reduction in lawn area and switching from exotic plant forms to native species which require less water. In general, lawn areas should not exceed what is useful for play and social activities, and should be limited to the backyard where the family spends the majority of its time.

Solutions—At Work and in the Community

Many of the suggestions made for reducing water use in the home have wider application, both in the workplace, and in the community at large. Low-flow equipment are available for most commercial and toilet applications, instituting them may mean taking a leading role yourself, for example, forming and leading a committee that would address the following questions:

- do your workplace bathrooms, kitchens, etc. have water-efficient toilets, faucets, etc. similar to those discussed for the household?
- if your workplace uses water in its production process or for washing goods or equipment, is this being done efficiently?
- does your community have a water-efficiency assistance program that helps households and business improve their water-use efficiency?
- is the water distribution system properly maintained so that no pollution leaks into it and so that no water is wasted through leaky mains?

THE BOTTOM LINE

Water conservation. The message is clear. If we each save a little, it can add up to major savings in water, energy and money. For the average household, reductions in water use as high as 40% or more are feasible, just by following the steps outlined in this issue in the Freshwater Series.

The benefits don't stop at the household or business. The municipal water and sewer department gets a break on the amount of water it has to pump to our homes and businesses *and* on the amount of wastewater it has to treat in sewage treatment plants. Water conservation can extend the useful life of municipal water supply and treatment plants, and will benefit the operating efficiency—and life expectancy—of private septic disposal systems.

And, finally, water conservation can generate *significant* environmental benefits. It can reduce water diverted and the pollution loadings on our lakes and rivers by reducing the volumes of wastewater which we have to treat. This can help to protect our drinking water and the ecological balance in sensitive aquatic ecosystems.

If we all practice water conservation, everyone—and everything—benefits.

FRESHWATER SERIES A-6

Note: A resource guide, entitled *Let's Not Take Water For Granted*, is available to help classroom teachers of grades 5–7 use the information from the Water Fact Sheets.

ECOREGIONS: A SPATIAL FRAMEWORK FOR ENVIRONMENTAL MANAGEMENT

MD. SALEQUZZAMAN
Khulna University
Khulna, Bangladesh

DEFINITION

An ecoregion may be defined as a scale for planning and analysis in the hierarchy of the earth's ecosystem. It has broad applicability for modeling and sampling, strategic planning and assessment, and international planning of domain, division, and provincial ecological units.

Ecoregionization is a process of delineating and classifying ecologically distinctive areas of ecological land. Each area can be viewed as a discrete system that has resulted from the mesh and interplay of the geologic, landform, soil, vegetative, climatic, wildlife, water, and human factors where ecological functions and processes are continuing. The dominance of any one or more of these factors varies with the given ecological land unit. This holistic approach to land classification can be applied incrementally on a scale-related basis from site-specific ecosystems to very broad ecosystems (1). Ecological processes, evolutionary mechanisms, and geological forces are continually reshaping landscapes across various scales of time and space and result in distinctive but dynamic ecoregions. All of the world's food and most medicines and raw materials are derived from these processes and associated biodiversity. Thus ecoregions gain their identity through spatial differences in a combination of landscape characteristics. Several factors such as topography, hydrology, and nutrients are important to identify these characteristics that may vary from one place to another in an ecoregion.

OBJECTIVE OF ECOREGIONIZATION

The main objective of using the ecoregion as a spatial framework for environmental management is to maximize ecoefficiency by minimizing resource-use conflicts and harmonizing sociocultural needs in the ecoregion. Ecoregions are also used to isolate areas for the interpretation of environmental quality (2). Countries such as Canada and the United States are now using the ecoregion as the coarsest scale for evaluating representative areas (3). This process needs lots of information. The baseline information on ecosystem properties and changing conditions of ecosystems in any specific ecoregion may be collected through a series of monitoring, which affects the management practices in that ecoregion. Knowledge of the ecoregion facilitates; the allocation or linking of sites to a standard ecological hierarchy minimizes the sampling variance and increases the ability to extrapolate results for areas with similar properties.

IMPORTANCE OF THE STUDY OF AN ECOREGION

Ecological integrity, natural capital, and biodiversity are three ecological requirements for environmental management in any ecosystem (4). These three factors should be present as a prerequisite for a healthy ecoregion because an ecoregion itself is a big ecosystem. Among these factors, biodiversity has global importance and combines wildlife value with a rich cultural heritage. Thus each ecoregion has an immense natural value with a colorful and rich cultural heritage bound up with the unique natural heritage of age-old cultural traditions. As each ecoregion is ecologically distinct and strikingly beautiful, an ecoregion attracts the ecotourism that has a great potential to improve the local economy as well as develop a global network for ecobusiness and globalization.

SOME IMPORTANT ISSUES FOR ENVIRONMENTAL MANAGEMENT IN THE ECOREGIONS AROUND THE WORLD

Ensure a Balanced Ecosystem

Every organism, including animals and plants, no matter how small they are, plays a vital role in keeping the systems of the earth as healthy and functioning ecoregions. Removing any species from the complex web of life disturbs the balance of the entire system, resulting in the impoverished life zones left today. Scientific studies have made it clear that a balanced ecosystem is teeming with abundant life in quality and quantity, such as a wetland ecosystem or the ocean. Historical evidence clearly suggests that once the oceans were filled with whales, sea turtles, fish, and other forms of life that seem more identical to a scientific fantasy than reality. Many of them are now extinct. The reality is that the actual populations were exponentially greater than they are today (before human predation began). Once humans began hunting, their appetites were insatiable, and a pattern of imbalance started that may culminate in the complete collapse of some ecosystems of the ecoregion. Thus one of the important aspects of ecoregionization is to keep the ecosystem balance in any ecoregion.

Ensure the Protection of the Natural Heritage and the Environment

The natural heritage and its environment are the identity of any ecoregion, which are also the natural wealth that sustained human communities in comfort and plenty for millennia, such as the rain forest in many countries of the world, for example, Alaska. Recently, the Alaskan rain forest is being destroyed in such a way that the region faces a graver, more permanent threat: the same razed-earth logging that has already devastated the Pacific Northwest. Rain forest logging is perfectly in step with the boom-and-bust rhythm of the Alaskan economy due to poorly planned development spread out over wildlands, slashing of shorelines for beach homes and resorts, limiting public access, and destroying fragile barrier beaches and wetlands. Besides this destruction, it is also destroying a lot of wildlife habitats as well.

Ensure the Protection of the Ethnic Community of the World

Each ecoregion has a special characteristic of the specific group of ethnic community people. They preserve a sustainable livelihood from generation to generation. Now, this sustainability livelihood is challenged for survival. The ethnic community people attempt overexploitation of natural resources such as fish, oil, gas, forest products, and minerals to satisfy their mounting needs induced by globalization and modernization. Recently, some nations have agreed to monitor environmental damage in their ecoregion, establish an emergency response program, protect the sensitive environment, and conserve endemic flora and fauna. However, huge chunks of the ecoregion still lack essential wilderness protections. Oil and gas development threatens the coastal plain and millions of acres at the heart of biological refuges. Recently, a large portion of coral bleaching (hot spot) in coral reefs was discovered throughout the world (5). Coral bleaching is the loss of color from the living coral animal and can cause their death. The color of coral comes from microalgae living in the coral's tissue; when the water surrounding the coral becomes too warm, corals become stressed and expel the microalgae. These microalgae also provide the coral with food, and as the algae fade away, corals starve to death.

Therefore, environmental management and conservation should be adopted first to quickly protect the ecoregion, including its organisms, people, and its total effective surroundings from misuse or damage by human activities; second, to ensure that life support systems and renewable resources are used in an ecologically sustainable manner while supplying the conditions for a satisfactory human existence. Community-based projects will demonstrate the benefits for local people and the environment combining sustainable development and conservation and building up coordination among various activities in the ecoregion. In addition, ecologically sustainable management should be adopted in every ecoregion that will be used to assess the ecological sustainability of the biological resources in the ecoregion.

Environmental justice often plays itself out as a disparity between the rich and the poor, between the "haves" and the "have-nots." Just as environmental justice speaks to issues of poor people and people of color who are disproportionately subject to environmental pollution and public health risks, it also should speak of issues where poor people and people of color do not equally derive opportunities to obtain benefits and values associated with environmental resources.

CONCLUSION

Sustaining ecological processes, the landscape function, and the biological diversity of any ecoregion are important globally, nationally, and locally. Pressure to accommodate a rapidly increasing human population together with increased provision of goods and services has been growing for decades. This has impacted each ecoregion in its sociocultural, economic, and environmental characteristics. Therefore, a multiple scale, transdisciplinary integrated approach, and strategic framework for sustainable environmental planning and management of an ecoregion are needed. In addition, pressure to take action to halt land degradation, breakdown in production systems, decreasing water quality, loss of biodiversity, and global climate change is also needed for any government to improve the way it conserves, protects, and manages ecological processes, habitats, and species in the ecoregion. Furthermore, it must integrate planning and management across multiple scales, nesting the functional requirements of ecological systems and social systems to uphold and restore resilience in the ecological and social systems of the ecoregion for long-term sustainability.

FLOOD OF PORTALS ON WATER

Dick de Jong
IRC International Water and
Sanitation Centre
Delft, The Netherlands

Marta Bryce
CEPIS/PAHO
Delft, The Netherlands

INTRODUCTION

The Internet has been inundated with new gateways and portals on water over the last couple of years, as witnessed by information specialists at the IRC International Water and Sanitation Centre. The New on the Net section in Source Water and Sanitation News (http://www.irc.nl/source/section.php/12) carries 54 news items since July 2002, of which seven refer to "gateway" or portal. Unfortunately, many of them only serve to confuse instead of help people who search the web for water-related information. Part of the problem resides in defining what constitutes a "portal" and what doesn't. Another issue is that most portals do not seem to have a clear notion of their intended visitors—and their motives for visiting. As a result, the portals lack much-needed focus.

Here, we give some recent examples, try to create more clarity by providing definitions and types, discuss key lessons learned, and raise key issues for further discussion and research. This is based on various Internet searches and an annotated selection of various gateways/portals by IRC staff.

Here are five examples of sites, none of which have all the functionality of a portal yet.

1. The closest example of a portal is the BBC Water Portal—The Water Debate (http://news.bbc.co.uk/2/hi/in_depth/world/2003/world_forum/water/default.stm) that was launched early June 2003. This is not only an impressive interactive site for the general public with video, audio, expert views, fact files, and water stories; it also provides fun options such as online opinion polls and a water quiz. However, it does not contain an option for online collaboration.
2. The IRC International Water and Sanitation Centre (established in 1968) family of websites (http://www.irc.nl) provides news and information (including advocacy/communication, publications, and bibliographic database) on low cost water supply and sanitation in developing countries. It has a number of topic sites. It also provides a starting point for the Source Water and Sanitation News service and the InterWATER guide to more than 650 organizations, in collaboration with the Water Supply and Sanitation Collaborative Council. The search engine (Atomz) provides access to all these related sites. The IRC DOC online database contains 15,000 bibliographical entries on developing country water, sanitation and hygiene documents, books, periodicals, videos, and so on. The (www.worldwaterday.org) site maintained by IRC contains information on one topic per year that is selected by the UN. Visitors can add comments and events.
3. Sanitation Connection (http://www.sanicon.net/) is an Internet-based resource that gives access to accurate, reliable, and up-to-date information on technologies, institutions, and financing of sanitation systems around the world. Institutions of international standing contribute to the information base by providing and maintaining a topic of their specialization.
4. Water Portal of the Americas (http://www.Water-Portal-Americas.org) is a combination of a gateway (entryway or portal) and a community of practice. It is basically a search engine, a structure and system for other organizations to copy or fit in. It is still a prototype that may grow into a collaborative portal. "The goal is to provide both an entryway (portal) to water information and to create a water information network, community, and resource that will provide qualified, trusted, and verifiable information and contacts."

   At the March 2003 Third World Water Forum the prototype of a "Water Portal for the America's" was shown by UNESCO/World Water Assessment Programme and the Waterweb Consortium, a year and a half after it was first announced at the Fifth Water Information Summit. The prototype gave an impression of what will be on the site, with only limited content. This is the first regional water portal that is scheduled to become part of the UNESCO WWAP/Waterweb Global Water Portal, as was announced in Japan. Funding for this started in April 2002.
5. The U.S.-based WaterTechOnline (http://www.watertechonline.com/news.asp?mode=4&N_ID=31857) is one of the commercial portals addressing business needs. It contains breaking daily news stories about the water and wastewater treatment industry, as well as industry bulletin boards, searchable supplier directories and article archives, industry opinion polls, new product announcements, and other industry-specific information.

These examples illustrate the proliferation of water portals, gateways, and websites. It also raises questions about the definitions, users, and relevance of these internet-based initiatives.

DEFINITIONS AND TYPOLOGIES

General information on portals can be found on the Portals Community site. This advertises on Google.com as "The Definite Enterprise Portal Resource" and offers Portals information, White papers, networking, and research (http://www.portalscommunity.com/registration/member.cfm?code=TDXTL05).

Defining Water Portals

From About.com and our own sources, a portal is a kind of website and provides a single point of access to aggregated information—a virtual front door. The term originated with large, well-known Internet search engine sites that expanded their features to include e-mail, news, stock quotes, and an array of other functionality. Some corporations took a similar approach in implementing their intranet sites, which then became known as enterprise information or corporate portals.

There are general portals and specialized or niche portals. Some major general portals include Yahoo, CNET, AOL, and MSN. Examples of niche portals that are accessible to the public include Garden.com (for gardeners), Fool.com (for investors), and DPReview.com (for photographers). These are sometimes also called vortals—vertical portals. Private niche portals are those that are used by employees of a company.

Typical services offered by public portal sites include a start page with rich navigation, a directory of websites, a facility to search for other sites, news, a collection of loosely integrated features (some of which may be provided by partners or other third parties) like weather information, stock quotes, phone, and map information, e-mail, and sometimes a community forum. Private portals often include access to payroll information, internal phone directories, company news, and employee documentation.

Here, we define a portal as "a one-stop, client-oriented website that offers visitors a broad array of interactive resources such as news, databases, discussion forums, search options, space to collaborate online, and links on water-related topics."

Searches

IRC staff did various online literature searches:

- On “Water Portals” on all the web search engines in April, May, and June 2003. Of the 45 results shown, 32 were relevant. On Google.com, 22 out of 42 were relevant. The other results were mainly related to game sites.
- On the specialized ICT site Whatis.com there is a lot of information on corporate portals through Best web links, news headlines expert technical advice, and web results.

CONCLUSIONS

Our main conclusions are:

1. There is a wide variety of “portals” on water, definition wise, topic wise, and language wise.
2. Even in the world of corporate portals the concept is subject to confusion in the marketplace (Peter A. Buxbaum, Nov 2001, searchEBusiness). Buxbaum quotes:

   > There are several different types of corporate portals, each sporting different capabilities and each requiring different technologies and technology providers. Experts segment the enterprise portal arena into at least three components. *Information portals* emphasize data and document retrieval and management. *Knowledge portals* enable collaboration and information sharing as well as expertise and knowledge capture. *Application portals* provide end-users with interfaces to enterprise systems. What do all these have in common? As IDC defines it, they all manage end-user access to multiple applications and information sources on the corporate intranet.

   Looking at the software giant SAP’s recent steps in its portal strategy, Buxbaum leaves us with a nagging question: If a software giant like SAP can’t explain portals clearly, how are its potential customers supposed to understand them?
3. Most of the sites that claim to provide a water “portal” can be more correctly described as providing a start page or gateway to web information. There is in fact a flood of gateways, but too many providers are drowning in ambition.
4. An interesting paper that describes pros and cons of a portal from a university point of view in easily understandable language is Kevin Lowey’s University Portals FAQ, *University Web Developers’ Mailing List 2002* (http://www.usask.ca/web_project/uwebd/portals_faq.html).
5. Some interesting findings emerge from a user survey of electronic information services (EIS) among 25 U.K. institutions of higher education. The effect of the Internet on information seeking by staff and students is hugely significant; search engines and known sites are the first resort for most academic queries, as well as for many personal domestic queries. There was a wide range of engines used and indications of haphazard searching.
6. Another major conclusion from the same survey is that subject gateways are notable only for their lack of mention among students and academic staff, although there is some use among library and information staff.

LESSONS LEARNED

The majority of the gateways/portals described here focus on the broadest possible water topic: water resources and management.

The claims for “The Water Portal” cannot be justified. At best we can help clarify what the sites we have selected are focusing on, what they are, what they deliver to visitors (who?), and how interactive they are.

Two good examples of the different approaches are The Netherlands-based start page on water (www.waterpagina.nl) that provides four pages of clickable names divided over 32 categories, compared to the recently established www.h2o-scanner.com. This has a start page from where searches can be done combining countries, segments, issues, and content.

With a portal the emphasis is shifting from a public website showing online pamphlets to a user-oriented website that provides tools, reports, and services specifically designed for that individual.

WHAT NEXT?

By offering its new website architecture to interested partners, IRC started since mid-2003 to develop a family of related websites on water sanitation and hygiene, using the same technical foundation: *A Water Portal Is Born*. The STREAMS coalition of resource centers is going to be the first partner using this opportunity to contribute content through its own segment of this shared platform. More partners will be added.

In 2004 the Portal functionality will be expanded to also contain login functionality to provide Intra- and Extranet opportunities, moderated lists to enable E-conferences, workflow management, and others.

INTERNET ACCESS GAP

A few data on Internet connectivity according to CIA’s World Factbook (http://cyberatlas.internet.com/big_picture/geographics/article/0,,5911_151151,00.html) show the enormous gap between Internet use in the developed and developing world.

The percentage of the population of Internet users in the world in 2002 was around 9%. In The Netherlands and Denmark it was around 61%, in the United States some 59%, in Canada 50%, and in Belgium 36%. In Colombia it was about 2.8%, in Bolivia 0.9%, in India 0.7%, in Nepal 0.23%, in Mozambique and Bangladesh 0.1%, and in Ethiopia 0.03%.

Kamel from Nepal Telcom indicates that there are 8 phone lines per 1000 persons in Nepal. E-mail was introduced in 1993 and Internet in 1994. They have 50 cyber cafes in Kathmandu and 20 in Pokhara. Government official Vandya indicates that IT development is important and Nepal has to continue to develop it. This needs to be done in parallel with other media such as wall newspapers, taking into account that basic literacy is 55% and English literacy 2%.

In Burkina Faso the literacy is only 20% and they have 60 spoken local languages in a population of 2.6 million. A local priest is making a very interesting effort by publishing a quarterly farmers magazine in some of the local languages. He indicates that Internet is useful to find information, but a considerable part of the information in the magazine comes from local farmers.

In terms of difficulties it is clear that the number of users is very low in the South and even more so in rural areas. Another difficulty is that Internet performance gives problems. Downloading in the South, for example, is slow and the cost of access is high. It is often a struggle to access a telephone line let alone high bandwidth facilities. In the preparation for a knowledge management workshop at the Sixth Water Information Summit in September 2003, it was already very clear that files over 1 MB gave a lot of problems. Only after simplifying and zipping them did they become more manageable.

LATIN AMERICA: VIRTUAL LIBRARY ON ENVIRONMENTAL HEALTH

A good example from the achievements and challenges of web use in the developing world is the Virtual Library on Environmental Health (VLEH) of the Pan American Information Network on Environmental Health, REPIDISCA, which has been operating since 1982 in 21 countries of Latin America and the Caribbean with 370 Cooperating Centres. The Pan American Center for Sanitary Engineering and Environmental Sciences, CEPIS/PAHO, of the Pan American Health Organization, PAHO/WHO, is in charge of the regional coordination.

The VLEH disseminates information on water supply, sanitation, and related topics (http://www.cepis.ops-oms.org/indexeng.html). It uses the same methodology as the Latin American and Caribbean Health Sciences Information Centre, BIREME, another information system sponsored by PAHO/WHO. Its architecture is based on six types of information sources and services: electronic publications in full text, secondary sources, teaching material, SDI service, news and discussion lists, and integrating components. The bibliographic database contains more than 134,000 records with abstracts, of which 7553 are full text.

The principles of the VLEH are:

- Equitable access to environmental health information.
- Alliances and consortia for maximizing resource sharing.
- Cooperative work and exchange of experiences.
- Decentralized development and operation at all levels.
- Development based on local conditions.
- Integrated mechanisms for evaluation and quality control.

The VLEH architecture (Fig. 1) is based on the characteristics of its information sources. An information source is any resource that responds to information needs, including information products and services, persons or networks of

persons, and computer programs. The VLEH architecture is organized as follows (Table 1):

1. *Secondary Sources*. Composed of the following databases: bibliographic (more than 134,000 records); institutions (includes the address and names of authorities); events (includes seminars, congresses, and short courses); academic programs (includes diplomas, master, and doctoral programs); journals (includes the titles, electronic availability, and access to full texts); videos (includes material available at CEPIS and Cooperating Centres).
2. *Primary Sources*. Composed of the following databases: full text documents (more than 7500 documents in Acrobat); legislation (more than 1000 laws and regulations in full text related to water quality); HDT (includes 78 issues of the series Technical Dissemination Sheets, published by REPIDISCA); Repindex (includes 88 issues of this series also published by REPIDISCA); indicators (includes data from 45 countries of the Latin American and Caribbean region based on the global assessment of water and sanitation services, 2000).
3. *Teaching Material*. The material training database contains electronic and multimedia sources with added value for teaching purposes; the database on self-instruction courses contains nine courses prepared by PAHO/CEPIS which are also available on CD-ROM.
4. *SDI Service*. Selective dissemination of information (SDI) to update users based on their specific interest profiles. It is also a mechanism for providing information through e-mail to users that lack or have communication constraints via the Internet.
5. *News and Discussion Lists*. Fosters communication among persons, including discussion lists, forums, and virtual communities.
6. *Integrating Components*. Ensure the integration of decentralized information sources, like the REPIDISCA Thesaurus (more than 3000 terms in five languages: Spanish, English, Portuguese, French, and German, with its corresponding hierarchical structure and synonyms) and the Health and Environment Information Locator (gathers other Internet sources on environmental health, based on the Global Information Locator Service, GILS, adopted by the Global Program of the Information Society and the Dublin Core).

Building the virtual library implies the development, adoption, and adaptation of tools to operate information sources according to its architecture.

PAHO's Headquarters, in Washington, DC, hosts the virtual library because its server has higher connection speed. Statistics show that the number of visitors increases every year: 549,469 users have visited our website up to June 18, 2003 (Fig. 2).

Figure 3 shows the number of users per information source from January to June 2003. The source of full-text documents had the highest number of users, indicating that efforts should be concentrated on this information resource.

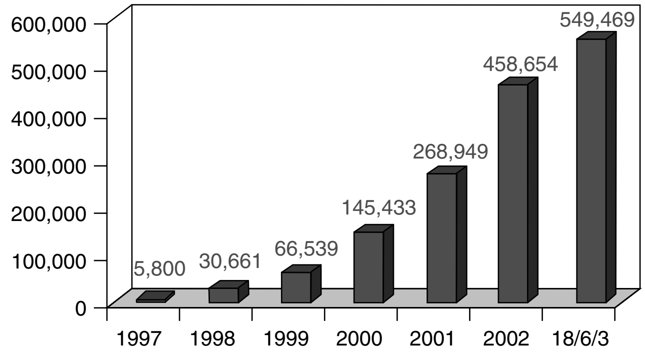

Figure 2. VLEH visitors, 1997–2003 (cumulative).

Every year, comparisons of statistics are done to analyze the trend of the VLEH use, as shown in Fig. 4 regarding the number of visitors per water-related subject.

The VLEH includes 17 additional topics related to CEPIS/PAHO working scope and that of the Sustainable Development and Environmental Health Area of PAHO/WHO. In 2002, the topic with the highest number of visitors was Workers' Health, in 2001 it was the Assessment in Drinking Water and Sanitation, and in 2002 it was the Solid Wastes Assessment.

Throughout its 20 years, REPIDISCA has carried out several user surveys. The last one in 2000 focused on web users and 424 persons replied to the questionnaire. Figure 5 shows the percentage of users per sector.

Regarding the type of user, 35% of them were professionals and technicians, as shown in Fig. 6. It is worthwhile to note that the use of the VLEH increases during weekends.

DIFFICULTIES

The difficulties that CEPIS/PAHO faces now with VLEH are:

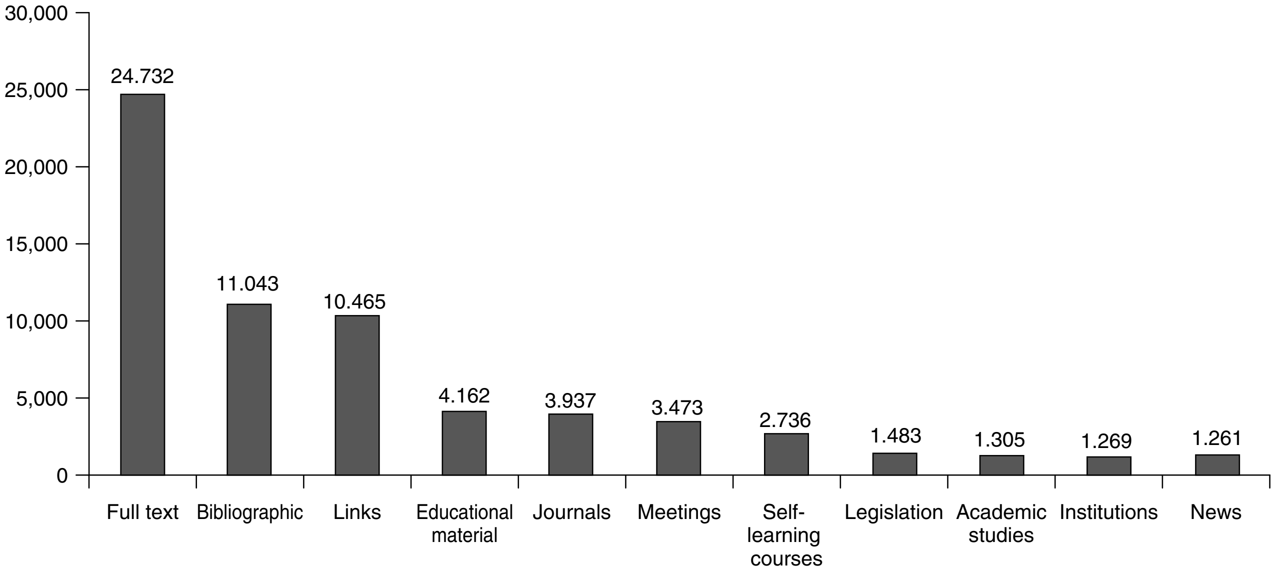

Figure 3. VLEH visitors per information source, January–June 6, 2003.

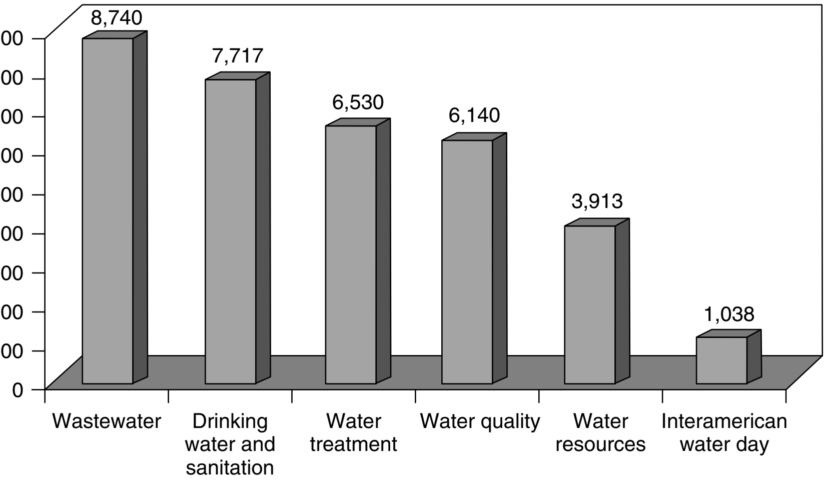

Figure 4. Visitors per water-related subject, January–June 2003.

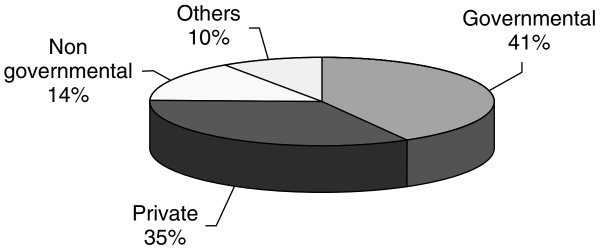

Figure 5. Users by sectors.

- Weakness of national institutions; in many countries water and sanitation utilities have undergone a privatization process.
- Staff reduction in public and private organizations; lack of investment in technical information and lack of resource sharing.
- Poor budgets for acquisition of information.
- Use of commercial software and methodologies in large universities that would not be willing to change their information system to follow the VLEH procedures; thus they need to duplicate the recording of the information they want to record into the VLEH.
- Inadequate updating of the VLEH at the regional and national levels.

Now CEPIS/PAHO has a great deal of information, but the VLEH cannot be just a space to make links with other websites. Users need a place where information is gathered, organized, and contained. Toward this end, CEPIS/PAHO and BIREME are implementing *Shared*, a Dutch technology that allows the production of "fingerprints" of every piece of information that is physically located in another web. These "fingerprints" are kept in a centralized file and weights may also be assigned to the topics of every information item. Institutions using the VLEH methodology will do this work more easily. In the future, it will be necessary to sign agreements to extract information automatically using *Shared*.

If *Shared* is implemented successfully, CEPIS would be able to enter into the Water Web Portal and other relevant sites updating their server of "fingerprints" and repeating the operation every month. The same procedure may be applied by each Cooperating Centre; thus national VLEH would be updated automatically. This will also avoid their regular export and sending of new information to CEPIS and the subsequent follow-up and control of duplicates that is done currently. Finally, regular training should be considered as a must to enable national institutions the use of the VLEH methodology. Workshops have been carried out in eleven countries and as a result they are already operating their own national VLEH.

FUZZY CRITERIA FOR WATER RESOURCES SYSTEMS PERFORMANCE EVALUATION

Slobodan P. Simonovic
The University of Western Ontario
London, Ontario, Canada

INTRODUCTION

One of the main goals of engineering design is to ensure that a system performs satisfactorily under a wide range of possible future conditions. This premise is particularly true of large and complex water resources systems. Water resources systems usually include conveyance facilities such as pipes and pumps, treatment facilities such as sedimentation tanks and filters, and storage facilities such as reservoirs and tanks. These elements are interconnected in complicated networks serving broad geographical regions. Each element is vulnerable to temporary disruption in service due to natural hazards or human error whether unintentional, as in the case of operational errors and mistakes, or due to intentional causes such as a terrorist act. Most of the hazards cannot be controlled or predicted with an acceptable degree of accuracy. Uncontrollable external factors also affect the capacity and the performance of water resource systems. The determination of the load pattern presents unique challenges. Ang and Tang (1) point out that there is uncertainty in all engineering-based systems because these systems rely on the modeling of physical phenomena that are either inherently random or difficult to model with a high degree of accuracy.

The sources of uncertainty are many and diverse and, as a result, impose a great challenge to water resources systems design, planning, and management. The goal to ensure failsafe system performance may be unattainable. Adopting high safety factors is one means to avoid the uncertainty of potential failures. However, making

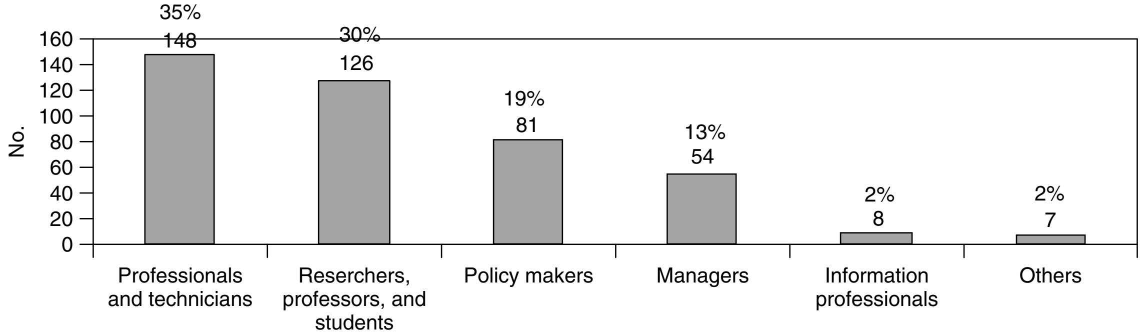

Figure 6. Types of user.

safety the first priority may render the system solution infeasible. Therefore, known uncertainty sources must be quantified. Engineering risk and reliability analysis is a general methodology for the quantification of uncertainty and the evaluation of its consequences for the safety of engineering systems (2). The first step in any risk analysis is to identify the risk, clearly detailing all sources of uncertainty that may contribute to the risk of failure. The quantification of risk is the second step, where the effects of the uncertainties are measured using different system performance indices and figures of merit. The early works of Hashimoto et al. (3,4) are the basis for the use of performance indices to evaluate the risk and reliability of water resources systems. They suggest *reliability, resiliency, vulnerability*, and *robustness* indices as criteria for evaluating the performance of water resources systems. Prior knowledge of the probability density functions of both resistance and load and/or their joint probability distribution function is a prerequisite to the probabilistic approach. In practice, data on previous failure experience is usually insufficient to provide such information. The subjective judgment of the decision-maker to estimate the probability distribution of a random event [subjective probability approach of Vick (5)] is another approach to deal with data insufficiency. The third approach is Bayes's theory, where engineering judgment is integrated with observed information. Until now the probabilistic approach was the only approach for water resources systems reliability analyses. But it fails to address the problem of uncertainty that goes along with human input, subjectivity, and lack of history and records. There is a practical and urgent need to investigate new approaches that can compensate for the ambiguity or uncertainty of human perception.

This contribution investigates the different approaches used to handle the problem of system reliability. Three new fuzzy reliability measures are presented (6): (1) the combined reliability–vulnerability index, (2) the robustness index, and (3) the resiliency index. They are developed to evaluate the operational performance of water resources systems. These measures could be useful decision-making aids in a fuzzy environment where subjectivity, human input, and lack of previous records impede the decision-making process.

FUZZY SETS

Zadeh (7), the founder of the theory of fuzzy sets, defines it as a formal attempt to capture, represent, and work with objects with unclear or ambiguous boundaries. This concept, although relatively new, has its origins in the early application of a multivalued logic notion to overcome the difficulties faced by the dual-logic representation in set theory. Water resources systems are potentially vulnerable to a wide variety of hazards that could limit their satisfactory performance. As a result, risks of future systems failure are often unavoidable (1). The engineering risk index characterizes the safety of water resources systems. The uncertainties associated with various sources of risk undermine the efficiency of this index. Because of these inevitable inefficiencies, all properties of water resources systems are subject to unavoidable and uncertain risk conditions. Different performance measures have been used in water resources systems reliability analyses to describe the system performance under extreme loading conditions (2). The majority of engineering reliability analyses rely on the use of a probabilistic approach. Both resistance and load are considered random variables. However, the characteristics of resistance and/or load cannot always be measured precisely or treated as random variables. Therefore, the fuzzy representation of either must be examined. The case of both fuzzy resistance and fuzzy load is rarely addressed in studies on the subject (6,8).

FUZZY CRITERIA FOR SYSTEM PERFORMANCE EVALUATION

Key Definitions

Failure. The calculation of performance indices depends on the exact definition of unsatisfactory system performance. It is difficult to arrive at a precise definition of failure because of the uncertainty in determining system resistance, load, and the accepted unsatisfactory performance threshold. Figure 1 depicts a typical system performance (resistance time series), with a constant load during the operation horizon. According to the classical definition, the failure state is the state when resistance falls below the load, margin of safety $M < 0.0$ or safety factor $\Theta < 1.0$, which is represented by the ratio between the system's resistance and load, shown in Fig. 1 by the dashed horizontal line.

Sometimes water resources systems fail to perform their intended function. For example, the available resistance from different sources in the case of water resources systems is highly variable. The actual load may also fluctuate significantly. Consequently, in the design of water resources systems, certain periods of water shortage may be a given. The precise identification of failure is neither realistic nor practical. It is more realistic to build in the inevitability of partial failure. A degree of acceptable system failure was introduced using the solid horizontal line, as shown in Fig. 1.

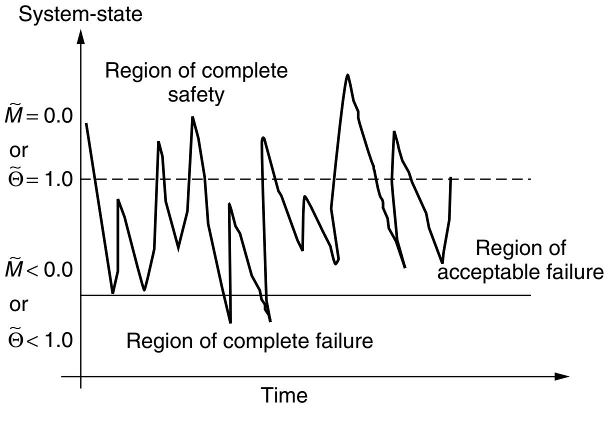

Figure 1. Variable system performance.

The boundary of the acceptable failure region is ambiguous and varies from one decision-maker to the other depending on personal perception of risk. Boundaries cannot be determined precisely. Fuzzy sets, on the other hand, are capable of representing the notion of imprecision better than ordinary sets. The acceptable level of performance can be represented as a fuzzy membership function in the following form:

$$\tilde{M}(m) = \begin{cases} 0, & \text{if } m \leq m_1 \\ \phi(m), & \text{if } m \in [m_1, m_2] \\ 1, & \text{if } m \geq m_2 \end{cases}$$

or

$$\tilde{\Theta}(\theta) = \begin{cases} 0, & \text{if } \theta \leq \theta_1 \\ \phi(\theta), & \text{if } \theta \in [\theta_1, \theta_2] \\ 1, & \text{if } \theta \geq \theta_2 \end{cases} \qquad (1)$$

where $\tilde{M}$ is the fuzzy membership function of the margin of safety; $\phi(m)$ and $\phi(\theta)$ are functional relationships representing the subjective view of the acceptable risk; m_1 and m_2 are the lower and upper bounds of the acceptable failure region, respectively; $\tilde{\Theta}$ is the fuzzy membership function of the factor of safety; and θ_1 and θ_2 are the lower and upper bounds of the acceptable failure region, respectively.

Figure 2 is a graphical representation of the definition presented in Equation 1. The lower and upper bounds of the acceptable failure region are introduced in Equation 1 by m_1 (or θ_1) and m_2 (or θ_2). The value of the margin of safety (or factor of safety) below m_1 (or θ_1) is definitely unacceptable. Therefore, the membership function value is zero. The value of the margin of safety (or factor of safety) above m_2 (or θ_2) is definitely acceptable and therefore belongs in the acceptable failure region. Consequently, the membership value is one. The membership of the in-between values varies with the subjective assessment of a decision-maker. Different functional forms may be used for $\phi(m)$ [or $\phi(\theta)$] to reflect the subjectivity of different decision-makers' assessments.

High system reliability is reflected through the use of high values of the margin of safety (or factor of safety), that is, high values for both m_1 and m_2 (or θ_1 and θ_2). The difference between m_1 and m_2 (or θ_1 and θ_2) inversely affects the system reliability: that is, the higher the difference, the lower the reliability. Therefore, the reliability reflected by the definition of an acceptable level of performance can be quantified in the following way:

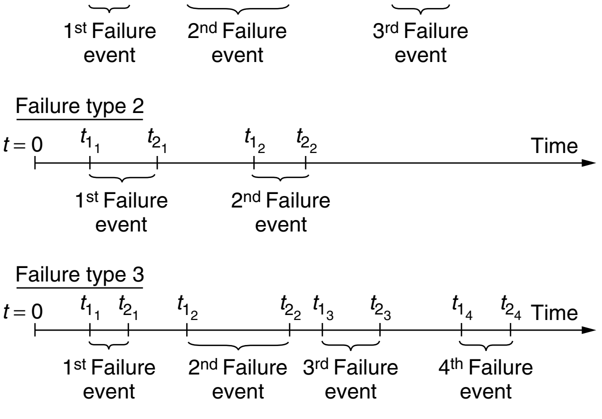

Figure 2. Fuzzy representation of acceptable failure region.

$$LR = \frac{m_1 \times m_2}{m_2 - m_1} \quad \text{or} \quad LR = \frac{\theta_1 \times \theta_2}{\theta_2 - \theta_1} \qquad (2)$$

where LR is the reliability measure of the acceptable level of performance.

The subjectivity of decision-makers will always result in a degree of ambiguity of risk perception. This alternate definition of failure allows for a choice among the lower bound, upper bound, and the function $\phi(m)$ [or $\phi(\theta)$]. This approach also provides an easy and comprehensive tool for risk communication.

Fuzzy System-State. System resistance and load can be represented in a fuzzy form to capture the uncertainty inherent in the system performance. The fuzzy form allows for the determination of the membership function of the resistance and load in a straightforward way even when there is limited available data. Fuzzy arithmetic can be used to calculate the resulting margin of safety (or factor of safety) membership function as a representation of the system-state at any time:

$$\tilde{M} = \tilde{X}(-)\tilde{Y} \quad \text{and} \quad \tilde{\Theta} = \tilde{X}(/)\tilde{Y} \qquad (3)$$

where $\tilde{M}$ is the fuzzy margin of safety; $\tilde{X}$ is the fuzzy resistance capacity; $\tilde{Y}$ is the fuzzy load requirement; (−) is the fuzzy subtraction operator; (/) is the fuzzy division operator; and $\tilde{\Theta}$ is the fuzzy factor of safety.

Compatibility. The purpose of comparing two fuzzy membership functions is to illustrate the extent to which the two fuzzy sets match. Several classes of methods are available, none of which can be described as the best method. The reliability assessment, presented here, involves a comparative analysis of the system-state membership function and the predefined acceptable level of the performance membership function. Therefore, the compliance of two fuzzy membership functions can be quantified using the fuzzy compatibility measure.

Possibility and necessity lead to the quantification of the compatibility of two fuzzy sets. The possibility measure quantifies the overlap between two fuzzy sets, while the necessity measure describes the degree of inclusion of one fuzzy set into another fuzzy set (9). However, in some cases, high possibility and necessity values do not reflect clearly the compliance between the system-state membership function and the acceptable level of performance membership function. For example, let's consider the two system-state functions A and B with the same possibility and necessity values. However, assume that system-state A has a larger overlap with the performance membership function than the system-state B. The overlap area between the two membership functions, as a fraction of the total area of the system-state, illustrates compliance more clearly than the possibility and necessity measures; that is,

$$C_{S,L} = \frac{OA_{S,L}}{A_S} \tag{4}$$

where $C_{S,L}$ is the compliance between the system-state membership function (S) and the acceptable level of performance membership function (L); $OA_{S,L}$ is the overlap area between the system-state membership function (S) and the acceptable level of performance membership function (L); and A_S is the area of the system-state membership function (S). An overlap in a high significance area (area with high membership values) is preferable to an overlap in a low significance area. The compatibility measure can be calculated using

$$CM_{S,L} = \frac{WOA_{S,L}}{WA_S} \tag{5}$$

where $CM_{S,L}$ is the compatibility measure between the system-state membership function (S) and the acceptable level of performance membership function (L); $WOA_{S,L}$ is the weighted overlap area between the system-state membership function (S) and the acceptable level of performance membership function (L); and WA_S is the weighted area of the system-state membership function (S).

Combined Fuzzy Reliability–Vulnerability Criteria

Reliability and vulnerability were used to provide a complete description of system performance in case of failure and to determine the magnitude of the failure event. Once an acceptable level of performance is determined in a fuzzy form, the anticipated performance in the event of failure as well as the expected severity of failure can be determined.

When certain values are specified for the lower and upper bounds [m_1 and m_2 (or θ_1 and θ_2) in Equation 1], thus establishing a predefined acceptable level of performance, the anticipated system failure is limited to a specified range. Systems that are highly compatible with the predefined acceptable level of performance will yield a similar performance; that is, the expected system failure will be within the specified range ([m_1, m_2] or [θ_1, θ_2]). In order to calculate system reliability, several acceptable levels of performance must be defined to reflect the different perceptions of the decision-makers. A comparison between the fuzzy system-state membership function and the predefined fuzzy acceptable level of performance membership function provides information about both system reliability and system vulnerability at the same time (Fig. 3).

The system reliability is based on the proximity of the system-state to the predefined acceptable level of performance. The measure of proximity is expressed by the compatibility measure suggested in Equation 5. The new combined fuzzy reliability–vulnerability index is formulated as follows:

$$RE_f = \frac{\max_{i\in K}\{CM_1, CM_2, \ldots, CM_i\} \times LR_{\max}}{\max_{i\in K}\{LR_1, LR_2, \ldots, LR_i\}} \tag{6}$$

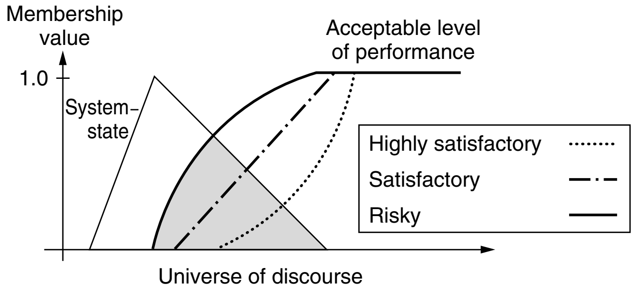

Figure 3. Compatibility with different level of performance membership functions.

where RE_f is the new combined fuzzy reliability–vulnerability index; $LR_{\max}$ is the reliability measure of acceptable level of performance corresponding to the system-state with maximum compatibility value; LR_i is the reliability measure of the ith acceptable level of performance; CM_i is the compatibility measure for the system-state with the ith acceptable level of performance; and K is the total number of the defined acceptable levels of performance. The reliability–vulnerability index is normalized to attain a maximum value of 1.0, by the introduction of the $\max_{i\in K}\{LR_1, LR_2, \ldots, LR_i\}$ value as the maximum achievable reliability.

Fuzzy Robustness

Robustness measures the system's ability to adapt to a wide range of possible future load conditions, at little additional cost (4). The fuzzy form of change in future conditions can be obtained through a redefinition of the acceptable level of performance and a change in the system-state membership function. As a result, the system's robustness is defined as the change in the compatibility measure:

$$RO_f = \frac{1}{CM_1 - CM_2} \tag{7}$$

where RO_f is the new fuzzy robustness index; CM_1 is the compatibility measure before the change in conditions; and CM_2 is the compatibility after the change in conditions.

Equation 7 reveals that the higher the change in compatibility, the lower the value of the fuzzy robustness. Therefore, high robustness values allow the system to better adapt to new conditions.

Fuzzy Resiliency

The time required to recover from the failure state can be represented as a fuzzy set. Because the reasons for a failure may be different, system recovery times will vary depending on the type of failure, as shown in Fig. 4. A series of fuzzy membership functions can be developed to allow for various types of failure. The maximum recovery time is used to represent the system recovery time (10):

$$\begin{aligned}\tilde{T}(\alpha) = (&\max_{j\in J}[t_{1_1}(\alpha), t_{1_2}(\alpha), \ldots, t_{1_J}(\alpha)] \\ &\times \max_{j\in J}[t_{2_1}(\alpha), t_{2_2}(\alpha), \ldots, t_{2_J}(\alpha)])\end{aligned} \tag{8}$$

where $\tilde{T}(\alpha)$ is the system fuzzy maximum recovery time at α level; $t_{1_J}(\alpha)$ is the lower bound of the jth recovery time at α level; $t_{2_J}(\alpha)$ is the upper bound of the jth recovery time at α level; and J is total number of failure events.

The center of gravity of the maximum fuzzy recovery time can be used as a real number representation of the system recovery time. Therefore, system resilience is determined to be the inverse value of the center of gravity:

$$RS_f = \left[\frac{\int_{t_1}^{t_2} t\,\tilde{T}(t)\,dt}{\int_{t_1}^{t_2} \tilde{T}(t)\,dt} \right]^{-1} \quad (9)$$

where RS_f is the new fuzzy resiliency index; $\tilde{T}(t)$ is the system fuzzy maximum recovery time; t_1 is the lower bound of the support of the system recovery time; and t_2 is the upper bound of the support of the system recovery time.

The inverse operation can be used to illustrate the relationship between the value of the recovery time and the resilience. The longer the recovery time, the lower the system's ability to recover from the failure, and the lower the resilience.

CONCLUSIONS

Water resources systems are vulnerable to a wide variety of hazards that could potentially limit their ability to perform satisfactorily. The diversity of uncertainty sources presents a great challenge to water resources systems design, planning, and management. The probabilistic approach usually fails to address the problems of human error, subjectivity, and the lack of system performance history and records. The fuzzy set approach addresses those issues. A fuzzy system reliability analysis is ideally based on the comparison between the fuzzy sets representing both the system's state of safety and the potential for system failure.

A fuzzy reliability–vulnerability measure clearly quantifies the reliability and the vulnerability of multicomponent systems. The quantification is based on the use of appropriate fuzzy compatibility measures to illustrate the relationship between the fuzzy system's state of safety and the fuzzy failure events. The contribution also shows a fuzzy measure, capable of determining the system's ability to adapt to changing conditions. This measure of fuzzy robustness provides a vital tool to assess the system's behavior through the introduction of a wide variety of uncertain conditions. A fuzzy resiliency measure was also presented to capture the system's response to uncertain future failure events. This measure is able to incorporate all types of system responses to potential failure events throughout the life of the design.

The presented fuzzy performance criteria were evaluated using two simple hypothetical cases by El-Baroudi and Simonovic (6).

PARTICIPATORY MULTICRITERIA FLOOD MANAGEMENT

Slobodan P. Simonovic
The University of Western Ontario
London, Ontario, Canada

INTRODUCTION

Flood management in general comprises different water resources activities aimed at reducing the potentially harmful impact of floods on people, the environment, and the economy of a region. Sustainable flood management decision-making requires integrated consideration of economic, ecological, and social consequences of disastrous flood. While economic consideration gets priority in traditional approaches to decision-making, empowerment of stakeholders is an issue that is demanding increasing attention today in many decision-making processes. Flood management activities (i.e., disaster mitigation, preparedness, and emergency management) may be designed and achieved without the direct participation of stakeholders; however, it cannot be implemented without them (1). In order to decide what flood control measures to adopt in a floodplain, the decision-making process should include different stakeholders.

Government policy-makers and professional planners are the first to consider. However, others such as the general public, communities affected by the decision outcomes, nongovernmental organizations, and different interest groups should be included as well. This contribution describes a multicriteria decision-making methodology for participatory flood management (2,3). The methodology should (1) evaluate potential alternatives based on multiple criteria under uncertainty; (2) accommodate the high diversity and uncertainty inherent in human preferences; and (3) handle a large amount of data collected from stakeholders.

METHODOLOGY

Flood management decision-making problems are complex due to their multicriteria nature. For a given goal, many alternative solutions may exist that provide different levels of satisfaction for different issues, such as environmental, social, institutional, and political. These concerns naturally lead to the use of multicriteria decision-making techniques, in which trade-offs among the single objectives can lead to the most desirable solution. Multicriteria decision-making becomes more complicated with the increase in the number of individuals/groups involved in the decision-making process. In reality, the decision-making process often involves multiple stakeholders/decision-makers. Multiple stakeholders' participation introduces a great deal of complexity into the analysis. The decision problem is no longer limited to the selection of the most preferred alternative among the possible solutions according to a single set of preferences. The analysis must also be extended to account for the conflicts among different stakeholders with different objectives. Most of the existing approaches in multicriteria decision-making with a single stakeholder/decision-maker consist of two phases (4): (1) the aggregation of the judgments with respect to all criteria and per decision alternatives; and (2) the ranking of the decision alternatives according to the aggregated judgment. In the case of multiple stakeholders, an additional aggregation is necessary with respect to the judgments of all the stakeholders.

Consider a multicriteria multiparticipant decision-making problem where m alternatives are to be evaluated by n decision-makers, who are using p objectives. The general conceptual decision matrix for the discrete multicriteria multiparticipant problem is shown in Table 1.

Table 1. Conceptual Decision Matrix for a Discrete Multicriteria Multiparticipant Decision Problem

	O$_1$	...	**O**$_p$
A$_1$	a_{11}	...	A_{1p}
...	...	...	...
A$_m$	a_{m1}	...	a_{mp}
DM$_1$	w_{11}	...	w_{1p}
...	...	...	...
DM$_n$	w_{n1}	...	w_{np}

In Table 1, **A** denotes the alternative, **O** is the criterion, and **DM** is the decision-maker/stakeholder. The preference of the decision-maker k $(k = 1, \ldots, n)$ for the objective j $(j = 1, \ldots, p)$ is expressed by w_{jk}, and a_{ij} is the performance evaluation of the alternative i $(i = 1, \ldots, m)$ for each objective j.

The classical outcome of the decision matrix is the ranking of the alternatives. To obtain that, a number of steps are necessary, such as establishing the preference structure, the weights, and also the performance evaluations. All these can be termed as the inputs for the decision matrix. These inputs come from the stakeholder/decision-maker. The decision matrix shows that the inputs can be for the preference of criteria as well as for the performance evaluations. The decision-maker might also have a preference structure for the alternatives. In the case of a multiparticipant decision-making problem, these inputs are to be collected from all the stakeholders.

Equation 1 is a general mathematical formulation of this multicriteria, multiparticipant problem. A payoff matrix can be obtained for the problem where m alternatives are to be evaluated by n stakeholders/decision-makers, who are using p criteria:

$$A^k = (a_{ij})^k = \begin{bmatrix} a_{11} & \ldots & \ldots & a_{1p} \\ a_{21} & \ldots & \ldots & a_{2p} \\ \ldots & \ldots & \ldots & \ldots \\ a_{m1} & \ldots & \ldots & a_{mp} \end{bmatrix}, \quad (k = 1, \ldots, n) \quad (1)$$

Here $A^k_{i.} = (a_{i1}, \ldots, a_{ip})^k$ means that alternatives i are being evaluated by criteria from 1 to p by decision-maker k. The symbol $A^k_{.j} = (a_{1j}, \ldots, a_{mj})^k$ means that the objective j is being used by decision-maker k to evaluate all alternatives from 1 to m.

The solution to this problem is to have each alternative evaluated by all the decision-makers using all criteria. The process can be summarized as the following mapping function:

$$\Psi : \{A^k | k = 1, \ldots, n\} \to \{G\} \quad (2)$$

where G is a collective weighted agreement matrix. It is crucial that this mapping function represents all criteria that the decision-makers use in judging all the alternatives.

Flood management decision-making is always associated with some degree of uncertainty. This uncertainty could be categorized into two basic types: uncertainty caused by inherent hydrologic variability and uncertainty due to a lack of knowledge (5). Uncertainty of the first type is associated with the spatial and temporal changes of hydrologic variables such as flow, precipitation, and water quality. The second type of uncertainty occurs when the particular value of interest cannot be assessed exactly because of the limitation in the available knowledge. The second type of decision uncertainty is more profound in the area of public decision-making such as in the case of flood management. Capturing the views of individuals presents the problem of uncertainty. The major challenge while collecting these views is to find out the technique that will capture those uncertainties and also will be usable in a multicriteria tool.

Participation of Multiple Stakeholders

An aggregation procedure is one of the ways to include information from the participating decision-makers into the decision matrix. The available methods do not seem to be appropriate for flood management for two reasons. The methodology (3) includes representation of inputs from a large number of participants and the analysis of inputs to make them usable for application to various multicriteria decision-making methods. Fuzzy set theory and fuzzy logic are used to represent the uncertainties in stakeholders' opinions. Three possible types of fuzzy input have been considered to capture the subjectivity of the responses from stakeholders. When a stakeholder is asked to evaluate an alternative against a particular criterion, the answer may take one of the following forms: (1) a numeric scale response; (2) a linguistic answer (e.g., poor, fair, good, very good); or (3) an argument (e.g., "if some other condition is satisfied then it is good"). For the first type, the input is quite straightforward. For a type (2) answer, it will be necessary to develop the membership functions for the linguistic terms. Type (3) input can be described by using a fuzzy inference system, which includes membership functions, fuzzy logic operators, and the if–then rule. For this, the membership functions for the input arguments need to be developed first. Then fuzzy operator and fuzzy logic are applied to obtain the output. It should be noted that the interpretation of type (2) and type (3) input values is highly dependent on the shape of the membership functions and the degree of severity chosen by the expert for a particular application.

After receiving the inputs from all stakeholders, the next step is to aggregate those inputs to find a representative value. It is obvious that for all input types considered above, the responses are sure to be influenced by a number of repetitions. This means many respondents can provide the same response. This implies that the general methodologies of fuzzy aggregation cannot be applied for deriving the resultant input from a large number of decision-makers. The fuzzy expected value (FEV) method can be used instead to get the resulting opinion of the stakeholders. Following is the definition of the fuzzy expected value: Let χ_A be a B-measurable function such that $\chi_A \in [0,1]$. The FEV of χ_A over the set A, with respect to the fuzzy measure μ, is defined as

$$\mathrm{FEV}(\chi_A) = \sup_{T\in[0,1]} \{\min[T, \mu(\xi_T)]\} \tag{3}$$

where

$$\xi_T = \{x|\chi_A(x) \geq T\} \tag{4}$$

and

$$\mu\{x|\chi_A(x) \geq T) = f_A(T) \quad \text{is a function of the threshold } T \tag{5}$$

Figure 1 provides a geometric interpretation of the FEV. Performing the minimum operator, the two curves create the boundaries for the remaining triangular curve. The supremum operator returns the highest value of $f_A(T)$, which graphically represents the highest point of the triangular curve. This corresponds to the intersection of the two curves where $T = H$.

The FEV can be computed for all three types of inputs mentioned earlier in this section. For type (1) input, the resultant FEV should be a numeric value between 0 and 1. For both type (2) and type (3) inputs, the resultant FEVs are membership functions. The crisp numeric equivalents of these membership functions can be obtained by applying a defuzzification method and can then be compared with type (1) answers. The centroid of area defuzzification method has been used to return a value obtained by averaging the moment area of a given fuzzy set. Mathematically, the centroid, $\overline{x}$, of a fuzzy set, A, is defined as

$$\overline{x} = \frac{\int_0^1 x \cdot \mu_A(x)dx}{\int_0^1 \mu_A(x)dx} \tag{6}$$

where $\mu_A(x)$ is the membership function of the fuzzy set A.

The resultant FEVs are now the aggregated evaluation of the alternatives from all the stakeholders. They can now be used as the input value in the decision matrix for the multicriteria analysis.

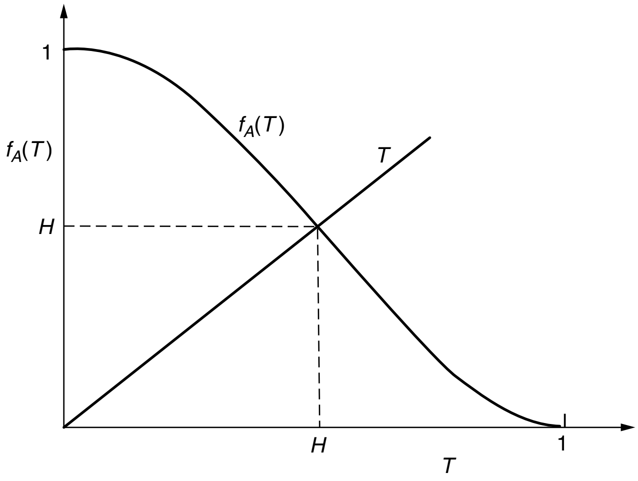

Figure 1. Participatory multicriteria flood management.

Participatory Multicriteria Decision-making Under Uncertainty

Here an innovative modification has been made to the compromise programming multicriteria decision-making technique to accommodate participatory flood decision-making under uncertainty. Bender and Simonovic (6) fuzzified compromise programming entirely and thus formulated fuzzy compromise programming (FCP). The driving force for the transformation from a classical to a fuzzy environment is that there is a need for accurate representation of subjective data in the flood decision-making. It is the theory of fuzzy sets that can represent the subjective data well. Thus, instead of using crisp numbers in the compromise programming distance metric equation, fuzzy numbers are used; instead of using classical arithmetic, fuzzy arithmetic is applied; instead of simply sorting distance metrics, fuzzy set ranking methods must be applied to sort the fuzzy distance metrics. In other words, the fuzzy transformation complicates the interpretation of the results but, on the other hand, models the decision-making process more realistically. Mathematically, the compromise programming distance metric in its discrete form can be presented as

$$L_j = \left[\sum_{z=1}^{t} \left\{ w_z^p \left(\frac{f_z^* - f_z}{f_z^* - f_z^-} \right)^p \right\} \right]^{1/p} \tag{7}$$

where $z = 1, 2, 3, \ldots, t$ and represents t criteria; $j = 1, 2, 3, \ldots, n$ and represents n alternatives; L_j is the distance metric of alternative j; w_z corresponds to a weight of a particular criterion; p is a parameter ($p = 1, 2, \infty$); f_z^* and f_z^- are the best and the worst value for criterion z, respectively (also referred to as positive and negative ideals); and f_z is the actual value of criterion z. The parameter p is used to represent the importance of the maximal deviation from the ideal point. Varying the parameter p from 1 to infinity allows one to move from minimizing the sum of individual regrets (i.e., having a perfect compensation among the criteria) to minimizing the maximum regret (i.e., having no compensation among the criteria) in the decision-making process. The choice of a particular value of this compensation parameter p depends on the type of problem and desired solution. The weight parameter, w_z, characterizes decision-makers' preference concerning the relative importance of criteria. Simply stated, the parameter places emphasis on the criteria that the decision-maker deems important. The parameter is needed because different participants in the decision-making process have different viewpoints concerning the importance of a criterion.

Bender and Simonovic (6) fuzzified compromise programming and thus formulated fuzzy compromise programming (FCP). The driving force for the transformation from a classical to a fuzzy environment is that there is a need for accurate representation of subjective data in the flood decision-making. It is the theory of fuzzy sets that can represent the subjective data well. Thus, instead of using crisp numbers in the distance metric, Equation 7, fuzzy numbers are used; instead of using classical arithmetic, fuzzy arithmetic is applied; instead of simply sorting distance metrics, fuzzy set ranking methods must be applied to sort the fuzzy distance metrics. In other words, the fuzzy transformation complicates the interpretation of the results but, on the other hand, models the flood decision-making process more realistically.

In fuzzy compromise programming, obtaining the smallest distance metric values is not easy, because the distance metrics are also fuzzy. To pick out a smallest fuzzy distance metric, from a group of distance metrics, fuzzy set ranking methods have to be used. A study by Prodanovic and Simonovic (7) compared fuzzy set ranking methods for use in fuzzy compromise programming and recommended using the method of Chang and Lee (8). This recommendation was founded on the fact that Chang and Lee's (8) method gave the most control in the ranking process—with degree of membership weighting and the weighting of the subjective type. The overall existence ranking index (OERI) suggested by Chang and Lee (8) has the following mathematical form:

$$\mathrm{OERI}(j) = \int_0^1 \omega(\alpha)[\chi_1 \mu_{jL}^{-1}(\alpha) + \chi_2 \mu_{jR}^{-1}(\alpha)] d\alpha \tag{8}$$

where the subscript j stands for alternative j, while α represents the degree of membership; χ_1 and χ_2 are the subjective type weighting indicating neutral, optimistic, or pessimistic preferences of the decision-maker, with the restriction that $\chi_1 + \chi_2 = 1$; parameter $\omega(\alpha)$ is used to specify weights, which are to be given to certain degrees of distance metric membership (if any); and μ_{jL}^{-1} (α) represents an inverse of the left part, and μ_{jR}^{-1} (α) the inverse of the right part of the distance metric membership function.

For χ_1 values greater than 0.5, the left side of the membership function is weighted more than the right side, which in turn makes the decision-maker more optimistic. Of course, if the right side is weighted more, the decision-maker is more of a pessimist (this is because he/she prefers larger distance metric values, which means the solution farther from the ideal solution). In summary, the risk preferences are: if $\chi_1 < 0.5$, the user is a pessimist (risk averse); if $\chi_1 = 0.5$, the user is neutral; and if $\chi_1 > 0.5$, the user is an optimist (risk taker). Simply stated, Chang and Lee's (8) overall existence ranking index is a sum of the weighted areas between the distance metric membership axis and the left and right inverses of a fuzzy number.

FLOOD MANAGEMENT IN THE RED RIVER BASIN, MANITOBA, CANADA

The proposed methodology is applied to flood management in the Red River Basin (9–11). One of the flood management problems at the planning stage in the Red River Basin is the complex, large-scale problem of ranking potential flood management alternatives. During the evaluation of alternatives, it is necessary to consider multiple criteria that may be quantitative and qualitative. The flood management process in the basin also involves numerous stakeholders. They include different levels of government, different agencies, private organizations, interest groups, and the general public. They all have different and specific

Table 2. Resultant FEVs

needs and responsibilities during all stages of flood management—planning, emergency management, and flood recovery. There has been increasing concern by the general public about the decisions to be taken on the selection of flood control measures. During the 1997 flood, it was indicated that certain stakeholders in the basin, particularly the floodplain residents, did not have adequate involvement in flood management decision-making. Dissatisfaction has been observed among the stakeholders about evacuation decisions during the emergency management and about compensation decisions during the postflood recovery (10).

The methodology presented in the previous section has been used to collect information from the stakeholders across the Canadian portion of the Red River Basin. In order to evaluate the utility of the methodology, a generic experiment was considered for the study to evaluate three alternative options for improved flood management. Three generic options considered are (1) structural alternatives, (2) nonstructural alternatives, and (3) a combination of both. The selection of criteria against which the alternatives are ranked is one of the most difficult but important tasks of any multicriteria decision analysis. The following two social objectives have been considered in our case study: level of community involvement and amount of personal losses (include financial, health, and psychological losses). A detailed survey has been conducted in the basin to collect the information on the two selected social criteria (12). All three types of inputs obtained from all the stakeholders were processed using the fuzzy expected value method. Table 2 summarizes the results of all three types of inputs (scale, linguistic, and conditional types, which are termed A, B, and C, respectively, in the table) as the evaluation of three alternatives (structural, nonstructural, combination) against two criteria (community development, personal loss). Obtained results show good correlation between the numeric scale type and linguistic type of inputs with an average difference of only 0.029.

The FEVs obtained in Table 2 are used further to rank the three generic alternatives. All questions are considered to carry the same weight. A set of ranking experiments has been conducted to evaluate the impact of different stakeholder groups on the final rank of alternatives: (a) experiment 1—all stakeholders interviewed; (b) experiment 2—stakeholders from the city of Winnipeg; (c) experiment 3—stakeholders from the Morris area (south of Winnipeg); and (d) experiment 4—stakeholders from the Selkirk area (north from Winnipeg).

The final results of four ranking experiments with three generic alternatives and two social criteria are shown in the Table 3 (defuzzified distance metric value and the rank in parentheses). It is obvious that the final rank varies with the experiment, therefore confirming that preferences of different stakeholders are being captured by the developed methodology.

CONCLUSIONS

The analyses of flood management options in the Red River Basin, Manitoba, Canada (3) show the applicability of the methodology for a real flood management decision-making problem. The stakeholders can now express their concerns regarding flood hazard in an informal way, and

Table 3. Final Rank of Flood Management Alternatives

Participants	Alternative 1	Alternative 2	Alternative 3
All stakeholders	13.22 (1)	13.72 (3)	13.29 (2)
Morris	15.43 (2)	16.09 (3)	13.63 (1)
Selkirk	14.63 (3)	14.42 (1)	14.58 (2)
Winnipeg	13.74 (1)	15.25 (3)	13.92 (2)

that can be incorporated into the multicriteria decision-making model. The application of methodology helps in solving the problem of incorporating a large number of stakeholders in the flood decision-making process.

WATER RESOURCES SYSTEMS ANALYSIS

Slobodan P. Simonovic
The University of Western Ontario
London, Ontario, Canada

INTRODUCTION

Water resources planning and management process is a search for the solution of how to meet the needs of a population with the available resources (1). Water resources planning and management is as old as humanity. However, with knowledge and technology development, a change in the living standard of people, and further economic development, the analysis procedure changes.

Principal Objectives for Industrialized Countries

An example of the principal water resources planning and management objectives for industrialized countries is based on the *Principles and Standards for Planning Water and Related Land Resources* used in the United States and introduced by the U.S. Water Resources Council in 1973 and modified in 1979 and 1980 (2). According to them the overall purpose of water resources planning and management is improvement of the quality of life through contributions to national economic development, environmental quality, regional economic development, and other social effects. Under these "principles and standards," the water resources planning process consists of six major steps: (1) specification of the water and related land resources problems and opportunities; (2) inventory, forecast, and analysis of water and related land resource conditions within the planning area relevant to the identified problems and opportunities; (3) formulation of alternative plans; (4) evaluation of the effects of the alternative plans; (5) comparison of alternative plans; and (6) selection of a recommended plan based on the comparison of alternative plans.

Principal Objectives for Developing Countries

Water resources planning and management in developing countries should correspond to a set of criteria distinct from those used in industrialized countries. These criteria should reflect prevailing constraints on physical, financial, and human resources and the need to allocate critically sparse resources to programs that correspond to short- and long-term sociopolitical objectives and promise to be the most cost effective.

The United Nations Industrial Development Organization (UNIDO) (3) recommended that planning analysis consider the following objectives: (1) aggregate consumption, (2) income redistribution, (3) growth rate of national income, (4) employment level, (5) self-reliance, and (6) merit wants. The UN publication treats the problems of evaluating the extent to which projects advance each of the objectives and presents their combination as a measure of "aggregate economic profitability." The UNIDO guidelines, in developing a system of objectives, do not lay any stress on the quality of the environment or other intangible descriptors applied to the quality of human life.

SYSTEMS ANALYSIS

Systems analysis is the use of rigorous methods to help determine preferred plans and designs for complex, often large-scale systems. It combines knowledge of the available analytic tools, understanding of when each is more appropriate, and skill in applying them to practical problems. It is both mathematical and intuitive, as is all planning and design.

Systems analysis is a relatively new field. Its development parallels that of the computer, the computational power of which enables us to analyze complex relationships, involving many variables, at reasonable cost. Most of its techniques depend on the use of the computer for practical applications. Systems analysis may be thought of as the set of computer-based methods essential for the planning of major water resources projects. It is thus central to a modern water resources engineering curriculum.

Systems analysis covers much of the same material as operations research, in particular, linear and dynamic programming and decision analysis. The two fields differ substantially in direction, however. Operations research tends to be interested in specific techniques and their mathematical properties. Systems analysis focuses on the use of the methods.

Systems analysis emphasizes the kinds of real problems to be solved; considers the relevant range of useful techniques, including many besides those of operations research; and concentrates on the guidance they can provide toward improving plans and designs. Use of systems analysis instead of the more traditional set of tools generally leads to substantial improvements in design and reductions in cost. Gains of 30% are not uncommon. These translate into an enormous advantage when one is considering projects worth tens and hundreds of millions of dollars.

DEFINITIONS

There are many variations in the definition of what a system is, but all of the definitions share many common traits. Some kind of system is inherent in all but the most trivial water resources engineering planning and design problems. To understand a problem, the engineer must be able to recognize and understand the system that surrounds and includes it. Some of the reasons for poor system definition in former projects include poor communications, lack of knowledge of interrelationships, politics, limited objectives, and transportation difficulties.

What, then, is a system? The dictionary definition of the term "system" is a mass of verbiage providing no less than 15 ways to define the word. In the most general sense, a system may be defined as a collection of various structural and nonstructural elements that are connected and organized in such a way as to achieve some specific objective by the control and distribution of material resources, energy, and information.

A more formal definition of a system can be stated as

$$\mathrm{S}: \mathbf{X} \to \mathbf{Y} \qquad (1)$$

where **X** is an input vector and **Y** is an output vector. So, a system is a set of operations that transforms input vector **X** into output vector **Y**.

The usual representation of the system definition is presented in Fig. 1. The system's objects are input, output, process, feedback, and a restriction. Input energizes the operation of a given process. The final state of the process is known as the output. Feedback performs a number of operations to compare the actual output with an objective and identifies the discrepancies that exist between them.

To avoid any misunderstanding, let's define some terms often in use: *mathematical model*—a set of equations that describes and represents the real system; *decision variables*—the controllable and partially controllable inputs; *policy*—resulting set of decision variables, when each decision variable is assigned a particular value; *objective function*—quantity used to measure the effectiveness of a particular policy, expressed as a function of the decision variables; *constraints*—physical, economic, or any other restrictions applied to the model; *feasible policy*—a policy that does not violate any constraints; and *policy space*—the subset consisting of all possible feasible policies.

WATER RESOURCES SYSTEM

General formulation of water resources system (4) may be presented as the transformation of available water resources,

$$W_A = \{Q_A, K_A, L_A\} \qquad (2)$$

into required water resources,

$$W_D = \{Q_D, K_D, L_D\} \qquad (3)$$

taking into consideration water quality protection, flood control, and regional and national development plans. Notation used in Equations 2 and 3 includes: Q_A—available quantity of water; Q_D—required quantity of water; K_A—quality of available water; K_D—required water quality; L_A—location of available resources; and L_D—location of demand points.

Mathematical expression of the transformation problem can be given as

$$W_D = T \times W_A \qquad (4)$$

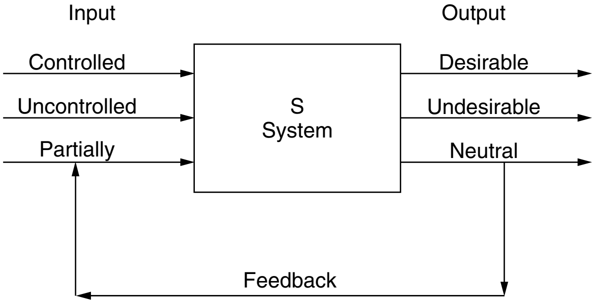

Figure 1. System presentation.

This transformation may be performed through the following three processes:

1. *Water Resources Planning*—formulation of goals and objectives that are consistent with political, social, environmental, economic, technological, and aesthetic constraints; and the general definition of procedures designed to meet those goals and objectives.
2. *Water Resources Design*—selection of a particular combination of resources and a way to use them.
3. *Water Resources Operations*—implementation of procedures in order to achieve preselected goals and objectives.

SYSTEMS APPROACH

The systems approach is a general problem-solving technique that brings more objectivity to the water resources planning/design processes. It is, in essence, good design; a logical and systematic approach to problem solution in which assumptions, goals, objectives, and criteria are clearly defined and specified. Emphasis is placed on relating system performance to these goals. A hierarchy of systems, which allows handling of a complex system by looking at its component parts or subsystems, is identified. Quantifiable and nonquantifiable aspects of the problem are identified, and immediate and long-range implications of suggested alternatives are evaluated.

The systems approach establishes the proper order of inquiry and helps in the selection of the best course of action that will accomplish a prescribed goal by broadening the information base of the decision-maker; by providing a better understanding of the system and the interrelatedness of the system and its component subsystems; and by facilitating the prediction of the consequences of several alternative courses of action.

The systems approach is a framework for analysis and decision-making. It does not solve problems, but it does allow the decision-maker to undertake resolution of a problem in a logical, rational manner. While there is some art involved in the efficient application of the systems approach, other factors play equally important roles. The magnitude and complexity of decision processes require the most effective use possible of the scientific (quantitative) methods of systems analysis. However, one has to be careful not to rely too heavily on the methods of systems analysis. Outputs from simplified analyses have a tendency to take on a false validity because of their complexity and technical elegance.

The steps in the systems approach include (5): definition of the problem; gathering of data; development of criteria for evaluating alternatives; formulation of alternatives; evaluation of alternatives; choosing the best alternative; and final design/plan implementation. Often several steps in the systems approach are considered simultaneously, facilitating feedback and allowing a natural progression in the problem-solving process.

The systems approach has several defining characteristics. It is a repetitive process, with feedback allowed from any step to any previous step. Frequently, because systems analysis takes such a broad approach to problem-solving, interdisciplinary teams must be called in. Coordination and commonality of technique among the disciplines is sometimes hard to achieve. Close communication among the parties involved in applying the systems approach is essential if this understanding is to be achieved.

Definition of the Problem

Problem definition may require iteration and careful investigation, because problem symptoms may mask the true cause of the problem. A key step of problem definition requires the identification of any systems and subsystems that are part of the problem, or related in some way to it. This set of systems and interrelationships is called the environment of the problem. This environment sets the limit on factors that will be considered when analyzing the problem. Any factors that cannot be included in the problem environment must be included as inputs to, or outputs from, the problem environment.

Gathering of Data

Gathering of data to assist in planning and design decision-making through the systems approach will generally be done in conjunction with several steps. Some background data will have to be gathered at the problem definition stage and data gathering and analysis will continue through the final plan/design and implementation stage. Data that are gathered as the approach continues will help to identify when feedback to a previous step is required.

Data will be required at the problem definition stage to evaluate if a problem really exists; to establish what components, subsystems, and elements can reasonably be included in the delineation of the problem environment; and to define interactions between components and subsystems. Data will be needed during later steps to establish constraints on the problem and systems involved in it, to increase the set of quantifiable variables and parameters (constants) through statistical observation or development of measuring techniques, to suggest what mathematical models might contribute effectively to the analysis, to estimate values for coefficients and parameters used in any mathematical models of the system, and to check the validity of any estimated system outputs. When feedback is required, the data previously acquired can assist in redefining the problem, systems, or system models.

Development of Evaluative Criteria

Evaluative criteria must be developed to measure the degree of attainment of system objectives. These evaluative criteria will facilitate a rational choice of a particular set of actions (from among a large number of feasible alternatives), which will best accomplish the established objectives. Some evaluative criteria will provide an absolute value of how good the solution is, such as the cost of producing one unit of some product. Other evaluative criteria will only produce relative values that can be compared among the alternatives to rank them in order of preference, as in economic comparisons such as benefit/cost analysis.

In most complex real-world water problems, more than one objective can be identified. A quantitative or qualitative analysis of the trade-offs between the objectives must be made. For many problems, cost effectiveness would be the primary objective. Cost effectiveness can be defined as the lowest possible cost for a set level of control of a system, or the highest level of system control for a set cost.

Formulation of Alternatives

Formulation of alternatives is essentially the development of system models that, in conjunction with evaluative criteria, will be used in later analysis and decision-making. If at all possible, these models should be mathematical in nature. However, it should not be assumed that mathematical model building and optimization techniques are either required or sufficient for application of the systems approach. Many problems contain unquantifiable variables and parameters that would render results generated by even the most elegant mathematical model meaningless. If it is not practical to develop mathematical models, subjective models that describe the problem environment and systems included can be constructed. Models allow a more explicit description of the problem and its systems and facilitate the rapid examination of alternatives. Effective model building is a combination of art and science. The science includes the technical principles of mathematics, physics, and engineering science. The art is the creative application of these principles to describe physical or social phenomena.

Evaluation of Alternatives

To evaluate the alternatives that have been developed, some form of analysis procedure must be used. Numerous mathematical techniques are available, including the simplex method for linear programming models, the various methods for solving ordinary and partial differential equations or systems of differential equations, matrix algebra, various economic analyses, and deterministic or stochastic computer simulation. Subjective analysis techniques may be used for multiobjective analysis, or subjective analysis of intangibles. The appropriate analysis procedures for a particular problem will generate a set of solutions for the alternatives that can be tested according to the established evaluative criteria. In addition, these solution procedures should allow efficient utilization of personnel and computational resources.

Choosing the Best Alternative

Choice of the best alternative from among those analyzed must be made in the context of the objectives and evaluative criteria previously established, but also must take into account nonquantifiable aspects of the problem such as aesthetic and political considerations. The chosen alternative will greatly influence the development of the final plan/design and will determine in large part the implementability of the suggested solution. Preferably, the best alternative can be chosen from the mathematical optimization within feasibility constraints. Frequently, however, a system cannot be completely optimized. Near optimum solutions can still be useful, especially if sensitivity analysis has shown that the solution (and thus the objective function) is not sensitive to changes in the decision variables near the optimum point.

Final Plan/Design Implementation

Actual final planning/design is primarily a technical matter that is conducted within the constraints and specifications developed in earlier stages of the systems approach. One of the end products of final planning or design is a report that describes the recommendations made.

MATHEMATICAL MODELING

In general, to obtain a way to control or manage a water resources system we use a mathematical model that closely represents the physical system. Then the mathematical model is solved and its solution is applied to the physical system. Models, or idealized representations, are an integral part of everyday life. Mathematical models are also idealized representations, but they are expressed in terms of mathematical symbols and expressions. Such laws of physics as $F = ma$ and $E = mc^2$ are familiar examples. Similarly, the mathematical model of a business problem is the system of equations and related mathematical expressions that describe the essence of the problem. Thus, if there are n related quantifiable decisions to be made, they are represented as decision variables (say, $x_1, x_2, \ldots, x_n$) whose respective values are to be determined. The appropriate measure of performance (e.g., profit) is then expressed as a mathematical function of these decision variables (e.g., $P = 3x_1 + 2x_2 + \cdots + 5x_n$). This function is called the objective function. Any restrictions on the values that can be assigned to these decision variables are also expressed mathematically, typically by means of inequalities or equations (e.g., $x_1 + 3x_1x_2 + 2x_2 \leq 10$). Such mathematical expressions for the restrictions often are called constraints. The constants (coefficients or right-hand sides) in the constraints and the objective function are called the parameters of the model. The mathematical model might then say that the problem is to choose the values of the decision variables so as to maximize the objective function, subject to the specified constraints.

Mathematical models have many advantages over a verbal description of the problem. One obvious advantage is that a mathematical model describes a problem much more concisely. This tends to make the overall structure of the problem more comprehensible, and it helps to reveal important cause-and-effect relationships. In this way, it indicates more clearly what additional data are relevant to the analysis. It also facilitates dealing with the problem in its entirety and considering all its interrelationships simultaneously. Finally, a mathematical model forms a bridge to the use of high-powered mathematical techniques and computers to analyze the problem. Indeed, packaged software for both microcomputers and mainframe computers is becoming widely available for many mathematical models.

The procedure of selecting the set of decision variables that maximizes/minimizes the objective function, subject to the systems constraints, is called the optimization procedure. The following is a general optimization problem. Select the set of decision variables $x_1^*, x_2^*, \ldots, x_n^*$ such that

$$\text{Min or Max}\, f(x_1, x_2, \ldots, x_n)$$

subject to

$$\begin{aligned} g_1\ (x_1, x_2, \ldots, x_n) &\leq b_1 \\ g_2\ (x_1, x_2, \ldots, x_n) &\leq b_2 \\ g_m\ (x_1, x_2, \ldots, x_n) &\leq b_m \end{aligned} \tag{5}$$

where $b_1, b_2, \ldots, b_m$ are known values.

If we use matrix notation, Equation 5 can be rewritten as

$$\text{Min or Max}\, f(x) \tag{6}$$

subject to

$$g_j\ (\mathbf{x}) \leq b_j, \quad j = 1, 2, \ldots, m$$

When optimization fails, due to system complexity or computational difficulty, a reasonable attempt at a solution may often be obtained by simulation. Apart from facilitating trial and error design, simulation is a valuable technique for studying the sensitivity of system performance to changes in design parameters or operating procedure.

According to Equations 5 and 6, our main goal is the search for an optimal or best solution. However, it needs to be recognized that these solutions are optimal only with respect to the model being used. Since the model necessarily is an idealized rather than an exact representation of the real problem, there cannot be any utopian guarantee that the optimal solution for the model will prove to be the best possible solution that could have been implemented for the real problem. There just are too many imponderables and uncertainties associated with real problems. However, if the model is well formulated and tested, the resulting solution should tend to be a good approximation to the ideal course of action for the real problem. Therefore, rather than be deluded into demanding the impossible, the test of the practical success of an operations research study should be whether it provides a better guide for action than can be obtained by other means.

The eminent management scientist and Nobel Laureate in Economics, Herbert Simon, points out that satisficing is much more prevalent than optimizing in actual practice. In coining the term *satisficing* as a combination of the words *satisfactory* and *optimizing*, Simon is describing the tendency of water resources managers to seek a solution that is "good enough" for the problem at hand. Rather than trying to develop various desirable objectives (including well-established criteria for judging the performance of different segments of the organization), a more pragmatic approach may be used. Goals may be set to establish minimum satisfactory levels of performance in various areas, based perhaps on past levels of performance or on what the competition is achieving. If a solution is found that enables all of these goals to be met, it is likely to be adopted without further ado. Such is the nature of satisficing. The distinction between optimizing and satisficing reflects the difference between theory and the realities frequently faced in trying to implement that theory in practice.

SURFACE WATER HYDROLOGY

ACIDIFICATION—CHRONIC

Tim Sullivan
E & S Environmental
Corvallis, Oregon

The objective here is to describe and discuss in general terms, processes that acidify freshwaters (including lakes, rivers, and streams), agents of acidification, watershed features associated with sensitivity to acidification, and associated chemical and biological effects. This is a complicated topic. A variety of acidifying agents and a number of physical and chemical watershed characteristics can make a particular body of water susceptible to acidification. Chronic, long-term acidification of water is addressed, not the short-term (episodic) acidification that sometimes accompanies rainstorms or snowmelt.

First, it is necessary to define a few terms. *Acidification* is generally a decrease in the acid-neutralizing capacity (ANC) of water. It can also be defined as a decrease in pH. ANC refers to the capacity of a solution to neutralize strong acids. It can be measured in a laboratory, usually by the Gran titration procedure. It can also be defined in different ways, based on the measured values of various ion concentrations in the water. Many mathematical models of acid–base chemistry define ANC as the sum of the base cation concentrations ($Ca^{2+} + Mg^{2+} + Na^{+} + K^{+} + NH_4{}^{+}$ [termed SBC]) minus the sum of the mineral or strong acid anion concentrations ($SO_4{}^{2-} + NO_3{}^{-} + Cl^{-}$ [termed SAA]).

$$\mathrm{ANC} = \mathrm{SBC} - \mathrm{SAA} \tag{1}$$

where all ions are in units of microequivalents per litre (μeq/L). ANC defined in this way is approximately equal to laboratory measurements (Gran titrated) of ANC only if the solution contains relatively low concentrations of dissolved organic carbon (DOC) and Al. Both of these latter constituents cause Gran ANC to differ from ANC defined as SBC − SAA (1). ANC reflects the extent to which added strong acids can be neutralized, or buffered, by the nontoxic base cations in solution such as Ca^{2+} rather than by H^{+} and Al^{n+}, which are toxic to some species of aquatic animals and other life forms. The term *acidic* is used to describe a lake, river, or stream (surface water) that has ANC below zero. In other words, if the water is acidic, then the sum of the concentrations of the strong acid anions exceeds the sum of the concentrations of the base cations (SAA > SBC). Thus, a body of water can become *acidified* by increasing the concentration of one or more of the SAA components, by decreasing the concentration of one or more of the SBC components, or a combination of both. There is a rather consistent relationship between pH and ANC, although varying levels of DOC contribute to scatter in this relationship. At ANC = 0, the pH is generally near 5 (Fig. 1).

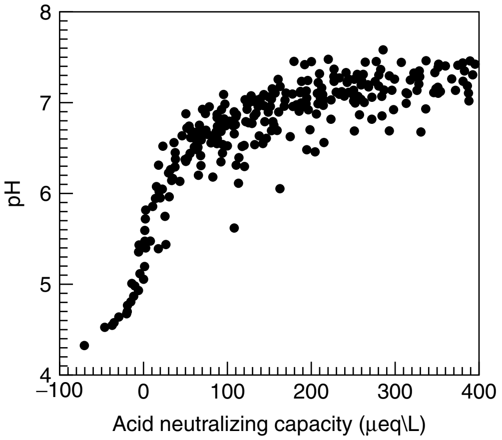

Figure 1. Relationship between pH and ANC in streams sampled by the U.S. EPA's Environmental Monitoring and Assessment Project (EMAP) in the Mid-Atlantic Appalachian Mountains.

Weak acids in solution, such as carbon dioxide, aluminum hydroxides, and organic acids, act as buffer systems that prevent dramatic changes in water pH upon adding small amounts of strong acid. When CO_2 from the atmosphere dissolves in water, it forms carbonic acid (H_2CO_3), which readily dissociates into hydrogen and bicarbonate ($HCO_3{}^{-}$) ions. Bicarbonate constitutes the most important buffer system in most freshwaters because it undergoes the following reaction upon adding strong acid:

$$HCO_3{}^{-} + H^{+} \rightarrow CO_2 + H_2O \tag{2}$$

At low pH (<5.5), the bicarbonate buffering system becomes less important, and the aluminum hydroxide buffering system becomes proportionately more important. In waters that have high DOC, the organic acid buffering system can dominate. In addition to providing pH buffering upon adding strong acid, organic acids also reduce the pH of the solution by up to a full pH unit or more.

Chronic acidification of fresh waters in North America is usually associated with an increased concentration of $SO_4{}^{2-}$. The source of this $SO_4{}^{2-}$ can be air pollution (by acidic deposition, also called acid rain) or geologic sources of sulfur. Acidic deposition is the process whereby S and/or N is transported in the atmosphere and deposited downwind of pollution sources onto water bodies and the terrestrial watersheds that drain into them. The major sources of atmospheric sulfur include coal-fired power plants and industrial facilities. Geologic S can be contributed to surface waters by acid mine drainage (AMD; 2) or other watershed disturbance and subsequent oxidation of sulfur-bearing minerals.

There are also examples of surface waters that have been acidified partially, or even mostly, by increased concentration of $NO_3{}^{-}$. In such cases, the source of the

NO_3^- is generally atmospheric. Nitrogen, in the form of nitrogen oxides and ammonia (which can be converted to NO_3^-), is emitted to the atmosphere largely from motor vehicles, industrial sources, and agriculture. NO_3^- is more likely to be a major contributor to short-term episodic acidification of surface waters, whereas SO_4^{2-} is more commonly associated with long-term chronic acidification. There are numerous exceptions to these general patterns, however.

It is also possible for waters to become chronically acidified due to Cl^- contamination, but this rarely occurs to any degree. Atmospheric deposition of Cl^- in sea spray can cause episodic acidification of surface waters in near-coastal areas, and road salt application can probably contribute in some cases to both chronic and episodic acidification, but there is little evidence that this is of any regional importance.

Thus, SO_4^{2-}, NO_3^-, and Cl^-, alone or in combination, can contribute to chronic acidification of surface waters. Where chronic acidification of North American waters occurs, it is most often from SO_4^{2-}.

Acid mine drainage is an important cause of sulfur-based chronic surface water acidification in mining regions of North America. This problem is especially prevalent in the northern Appalachian Mountains of West Virginia and Pennsylvania, where almost 10% of the streams are chronically acidic as a consequence of AMD (2). AMD results from the exposure to air and water of mine spoils containing sulfide minerals. The minerals are oxidized by a series of chemical reactions and microbial processes to yield high concentrations of sulfate and heavy metals in drainage water and low pH.

In many cases, the added SO_4^{2-} that contributes to chronic acidification is of atmospheric origin. However, it is important to note that, in most regions that receive high levels of S deposition, the primary determinant of whether, and to what extent, a body of water acidifies is not the amount of SO_4^{2-} that is added from the atmosphere and/or from geologic sources. Rather, the most important factor governing surface water acidification is usually the inherent sensitivity of the watershed. In most areas of North America, most watersheds are not sensitive to surface water acidification from atmospheric S deposition because abundant supplies of base cations in watershed soils usually exist. In such nonsensitive watersheds, increased contributions of SO_4^{2-} from the atmosphere are balanced by increased release of base cations from soils, and the drainage water does not acidify. However, some fraction of the surface waters in some regions are acid-sensitive, and increased concentrations of SO_4^{2-} can decrease surface water ANC. To understand this concept, it is helpful to consider the principle of electroneutrality.

The sum of the charges of all positively charged ions (cations) must equal the sum of the charges of all negatively charged ions (anions) in solution, so that

$$\sum \text{Cations} = \sum \text{Anions} \tag{3}$$

In relatively undisturbed freshwaters, these sums can be approximated as

$$\sum \text{Cations} = \text{SBC} + \text{H}^+ + \text{Al}^{n+} \tag{4}$$

and

$$\sum \text{Anions} = \text{SAA} + \text{HCO}_3^- + \text{Org}^- \tag{5}$$

where all ions are in units of μeq/L and Org^- represents a mixture of ill-defined organic acid anions. The valence of Al in Eq. 4 is expressed as n+ because inorganic ionic Al in solution can include a number of species, with varying charges. At a pH less than about 4.5, much of the Al in solution is present as Al^{3+}. At somewhat higher pH (about 4.5 to 5.5), proportionately more of the Al in solution is present as Al hydroxides and Al fluorides whose charges are +1 or +2. At a pH above 5.5, there is little Al in solution. Other ions, such as F^-, Fe^{n+}, Mn^{n+}, for example, are usually present in minor amounts in natural waters and have little impact on the charge balance.

If the concentration of one of the SAA anions, for example, SO_4^{2-}, increases in solution, then one of the other anions (e.g., HCO_3^- or Org^-) has to decrease in concentration and/or one or more of the cations has to increase in concentration to maintain the electroneutrality indicated in Eq. 3.

Combining Eqs. 3–5, we can express the charge balance as

$$\text{SBC} + \text{H}^+ + \text{Al}^{n+} = \text{SAA} + \text{HCO}_3^- + \text{Org}^- \tag{6}$$

Equation 6 can be rearranged to yield the following:

$$\text{SBC} - \text{SAA} = \text{HCO}_3^- + \text{Org}^- - \text{H}^+ - \text{Al}^{n+} \tag{7}$$

and therefore,

$$\text{ANC} = \text{HCO}_3^- + \text{Org}^- - \text{H}^+ - \text{Al}^{n+} \tag{8}$$

Thus, ANC can be defined in more than one way. If Equation 1 holds true, then Equation 8 must also hold true to satisfy the electroneutrality constraint (Eq. 3).

These equations and definitions presume that the mixture of organic acid anions in the water (Org^-) is made up entirely of weak acid anions that contribute ANC to solution. However, Driscoll et al. (3) showed that about one-third of the organic acid anions in Adirondack Mountain, New York, lakes actually exhibit strong acid characteristics and behave more like SO_4^{2-} and other strong mineral acid anions. The remainder of the organic acids act as weak acids. Thus, the contribution of organic acid anions to surface water acid–base chemistry is rather complicated. These substances contain a multitude of functional groups, some of which contribute ANC and some of which lower ANC.

As SAA concentration in surface water increases, the concentration of one or more of the other anions must decrease, and/or one of the cations must increase in concentration to maintain electroneutrality. For surface waters that are relatively high in ANC (greater than about 50 to 100 μeq/L), most of the compensating change is usually an increase in the concentration of Ca^{2+} and other base cations (SBC). In such cases, there is little or no water acidification from the increase in SAA; both the SAA and SBC increase, but the ANC(=SBC − SAA) stays about the same. For surface waters that are relatively low in ANC, in contrast, the compensating change generally involves multiple responses, including decreased HCO_3^- and increased SBC, H^+, and Al^{n+}. Increased H^+ and Al^{n+} can be toxic to aquatic life. In some cases, especially if DOC is relatively high, Org^- also decreases. This latter effect can influence the relative distribution of Al forms between nontoxic organic complexes and inorganic species, some of which are toxic.

The effects of acidification on aquatic life are due mainly to the changes that occur in HCO_3^-, H^+, and/or Al^{n+}. Any change in SBC to compensate for an increase in SAA does not result in acidifying water, although it can contribute to acidification of the soil. Because of the fundamental importance of these processes to water acidification, Henriksen (4) defined a factor, termed the F-factor, as the proportional change in SBC, as opposed to HCO_3^-, H^+, and Al^{n+}, relative to the change in SAA:

$$F = \frac{\Delta \text{SBC}}{\Delta \text{SAA}} \tag{9}$$

In watersheds that are not acid-sensitive, $F \approx 1.0$. In highly to slightly acid-sensitive Adirondack lake watersheds, F varies from about 0.4 to near 1.0.

Thus, for every 1 μeq/L increase in SO_4^{2-} concentration in an acid-sensitive lake or stream, the change in base cation concentrations will often balance much of that increase, and the resulting ANC change will generally be a rather small fraction (often less than half) of 1 μeq/L. There are, however, many highly sensitive watersheds in which ANC change constitutes an appreciable component of the increase in SAA. Within North America, such watersheds are especially prevalent in high mountainous areas of the western United States.

Waters sensitive to chronic acidification from acidic deposition generally had ANC less than about 50 μeq/L prior to the advent of the acidic deposition. In some cases, surface waters having somewhat higher initial ANC (∼50 to 100 μeq/L) have become acidified. Sensitive waters are usually found at moderate to high elevation, in areas of high relief (mountainous), rapid runoff of precipitation (flashy hydrology), and minimal opportunity for contact between drainage water and soils or geologic materials that may contribute weathering products (base cations) to solution. Sensitive streams generally occur in small watersheds (<10 km^2). These are generally the highest, smallest, coldest, and highest gradient streams and their associated lakes. Most acid-sensitive surface waters are underlain by bedrock that is resistant to weathering and/or contains only thin deposits of glacial till. Soils in the watersheds of acid-sensitive surface waters contain relatively small amounts of exchangeable base cations, and the soil base saturation is generally less than 10 to 15%. It is rare to find large lakes or large rivers that are acid-sensitive because large lakes and rivers have large watersheds and therefore, the probability increases that some of the bedrock and soils encountered by drainage water will be rich in base cations.

Chronic acidification of lakes and streams has occurred in areas throughout portions of the eastern United States, eastern Canada, and in parts of the upper Midwest. The areas most heavily impacted include the Adirondack and Catskill Mountains in New York, portions of the Appalachian Plateau in West Virginia, southeastern Canada, the mountains of western Virginia, and the Upper Peninsula of Michigan (5). In some portions of these regions, as many as 10 to 50% of the lake and/or stream resources may have experienced some degree of chronic acidification from sulfur deposition. Some of the most acid-sensitive watersheds in the world occur in high mountain areas of the western United States, including the Front Range of Colorado, northern Rocky Mountains, Sierra Nevada, and Cascade Mountains. However, because the levels of acidic deposition are generally low in most parts of the western United States, the amount of actual chronic acidification has been rather limited in most of these highly sensitive areas. Aquatic ecosystems in the Front Range of Colorado have probably been the most impacted of these western mountain ranges to date, and there the acidification has been more strongly from N than from S.

In general, most of the SO_4^{2-} that is deposited from the atmosphere to a watershed acts as a mobile anion and moves through soils into surface waters. In other words, SO_4^{2-} inputs to the watershed in the form of wet, dry, and cloud deposition are approximately equal to SO_4^{2-} outputs in drainage water. This steady-state condition is approximated in most areas that were previously glaciated, for example, throughout the northeastern United States and southeastern Canada. In the southeastern United States, however, which was not glaciated, soils tend to be much older and more highly weathered. Such soils adsorb some of the deposited sulfur before it reaches surface waters. This process effectively prevents water acidification, at least temporarily. Over time, however, the capacity of the soils to adsorb S becomes depleted as the S adsorption sites on the soil become saturated by continuing S inputs. Therefore, proportionately more of the SO_4^{2-} inputs reach surface waters, potentially contributing to acidification. At the present time, the soils in many areas in the southeastern United States, generally from Virginia to Tennessee and Georgia, are gradually losing their capacity to adsorb S. This will have a profound impact on watershed responses to future changes in S deposition. Model projections suggest that even if S deposition is reduced by more than 70% from 1995 levels, most streams in this region will continue to show an increase in streamwater SO_4^{2-} concentration, which will contribute to further acidification (6). Thus, southeastern U.S. watersheds exhibit a delayed response to S deposition due partly to gradual changes in the extent to which S is adsorbed on watershed soils.

Base cation depletion is another important process that is believed to contribute to a delayed watershed response to acidic deposition. This process is not confined to a particular region, but rather can be important in any watershed that has a low base cation supply and receives moderate to high levels of acidic deposition. Because ANC reflects the difference between the concentrations of SBC and SAA, a decrease in base cation concentrations can contribute to acidification just as an increase in one or more of the SAA constituents such as SO_4^{2-} or NO_3^-. It is believed that continuing levels of acidic deposition are depleting the exchangeable base cation stores in some watershed soils to the point that drainage water acidification is occurring in response to decreased base cation leaching from soils to drainage water. Such a process is not likely unless the soil base saturation (percent of the cation exchange capacity provided by base cations, rather than H or Al) is quite low, perhaps less than about 10%. Several factors can contribute to soils that have low base saturation, including long periods of acidic deposition, land use, (especially logging), and other disturbances that cause substantial erosion. In addition, some soils are naturally low in base cations as a consequence of the geologic makeup of their parent material and soil-forming processes. Recent decreases in the atmospheric deposition of base cations has also contributed to this problem.

In regions characterized by abundant wetlands, natural organic acidity from the breakdown of plant material can have a large impact on the acid–base chemistry of drainage waters. Lakes and streams in such regions are often characterized by relatively high concentrations of DOC (greater than about 5 or 6 mg C/L or 400–500 μM) and associated organic acids. Such lakes are often naturally acidic or low in ANC and show relatively little response of pH to changes in acidic deposition. For example, of the 560 Adirondack Mountain lakes considered most sensitive to acidic deposition (the thin till drainage and mounded seepage lake types), 45% had DOC higher than 6 mg C/L (500 μM) (7). Much of the acidity in these lakes is organic.

Chronic acidification can adversely impact many species of aquatic life, from algae to fish and fish-eating birds. Different species vary in their acid-sensitivity, as do different life forms within a given species. In lakes and streams of the eastern United States, much of the attention has focused on damage to native brook trout (*Salvelinus fontinalis*), which often would be expected in acid-sensitive lakes and streams. However, brook trout are relatively tolerant of acidity in comparison with some of the lesser known forage fish species such as blacknose dace (*Rhinichthys atratulus*). In most cases, brook trout are unable to live in waters that have chronic ANC less than about zero. Adverse episodic effects can occur at higher levels of chronic ANC in the range of 0 to 20 μeq/L or higher. In general, the eggs and larval stages of fish are more acid-sensitive than adults.

Acidification of streamwater also results in adverse impacts on several important orders of aquatic insects, especially mayflies. Acidified streams tend to contain fewer species or genera of these insects than streams that have not acidified. In lakes acidified by acidic deposition, several species of *Daphnia* (Cladocera) are often highly impacted.

Many species of algae, especially diatoms, are acid-sensitive. In fact, the occurrence and relative abundance of the various diatom species can be used to infer past lakewater chemistry. This technique has been used to estimate the acid–base characteristics of lakes during preindustrial times, as a way of quantifying how much acidification has occurred in response to a century of acidic deposition. Such paleoecological studies have involved collecting cores of lake sediment. The cores are then sliced into wafers, which are dated using radioisotopic dating techniques such as ^{210}Pb analysis. The remains of diatom species in each layer provide information about the lake conditions at the time that the sediment layer was deposited at the bottom of the lake (8). Such studies have shown, for example, that of the currently acidic Adirondack lakes, the median lake has acidified by about 37 μeq/L since preindustrial times (9).

Current research on the chronic effects of surface water acidification is focused largely on documenting and predicting the extent of chemical and biological recovery that will occur in response to recent and projected future large decreases in atmospheric sulfur deposition. An additional important research focus concerns identification of the critical load of S or N deposition required to protect against surface water acidification to harmful levels or to allow recovery of acidified waters to chemical conditions that are no longer harmful to aquatic life. Much of this work is focused on lakes and streams in wilderness areas, national parks, and other protected areas.

Additional information on this topic can be found in books by Charles (5) and Sullivan (9).

EPISODIC ACIDIFICATION

Myron J. Mitchell
State University of New York
Syracuse, New York

Episodic acidification is the short-term decrease (≤ 0 μmol$_c$ L^{-1}) in acid neutralizing capacity (ANC) of surface waters due to both natural and anthropogenic factors. ANC is a measure of the ability of water or soil to neutralize added acids and is defined by the reaction of hydrogen ions with inorganic (e.g., HCO_3^-) or organic ions. Decreases in ANC generally result in a decline in pH, sometimes dropping to levels below 4.5 (1). Episodic acidification most commonly occurs during snowmelt or precipitation that results in rapid increases in the discharge rates of surface waters. Typically the decrease in ANC and pH of streams and lakes is accompanied by increases in Al^{n+} concentrations (2). These decreases in ANC and pH and increases in Al^{n+} concentrations have marked effects on water chemistry and freshwater biota.

RELATIONSHIP TO CHRONIC ACIDIFICATION

The importance of surface water acidification has been clearly recognized as an important environmental issue that has often been linked with atmospheric deposition of acidic compounds, such as sulfuric (H_2SO_4) and nitric acid (HNO_3). It has been suggested that acidic deposition has increased the extent and severity of episodic acidification. Both chronic and episodic acidification can be due to both natural (e.g., organic acids) and anthropogenic processes (e.g., strong mineral acids that are associated with SO_4^{2-} and NO_3^-). Often, acidification episodes are most marked in those surface waters near circumneutral pH (3). For surface waters at chronically low pH levels, episodic acidification is relatively less important and in some cases may not be evident (4).

CAUSES OF ACIDIFICATION

Hydrologic Flow Paths

The chemical characteristics and the relative magnitude of an acidic episode are linked to hydrologic flow paths. Hydrologic flow paths vary with landscape features and are also influenced by antecedent moisture conditions. Flow paths affect both the chemical attributes and the reaction time of the water as it drains from terrestrial to aquatic environments. Major hydrologic events such as snowmelt or large rainstorms can cause marked changes in discharge rates and rapid changes in surface water chemistry. Periods of high discharge are accompanied by dynamic changes in the size of water pools (e.g., riparian areas, soil water), flow paths and the relative contributions of different water sources to surface water. A considerable focus has been placed on evaluating the importance of snowmelt episodes in affecting surface water chemistry, especially in those areas of high amounts of acidic deposition and extended periods of snow accumulation. During snowmelt episodes, the most marked changes in discharge rates often occur during “rain on snow.” Such events can result in rapid movement of solutes to surface waters. In addition, flow paths (e.g., water flux via macropores) may develop during high soil moisture conditions that result in little contact of storm water in soil neutralizing processes and thus exacerbate acid pulses. In contrast, during dry conditions, H^+ and mobile anions (SO_4^{2-} and NO_3^-) can accumulate in soils and these ions will be flushed from the soil only during large rainstorms.

Chemical Relationships

Chemical factors affecting episodic acidification vary spatially and temporally among watersheds due to differences in geology, soils, climate, landscape features, and anthropogenic influences.

Dilution of Base Cations. In circumneutral streams that have relatively high concentrations of base cations (especially Ca^{2+}), the dilution of these base cations (as much as 100 to 280 μmol$_c$ L^{-1}) due to rapid increases in water discharge can contribute to rapid declines in ANC.

Sulfate. Pulses of SO_4^{2-} play a major role in episodic acidification in Europe, Canada, and some limited regions in the United States. The importance of SO_4^{2-} in contributing to acidic pulses has been most clearly shown for Europe, especially in those regions that have had much higher atmospheric inputs of sulfur than generally found in North America.

Nitrate. Fluxes of NO_3^- in contributing to acidification are most important in the northeast United States including the Adirondack and Catskill Mountains of New York State. Pulses of NO_3^- are mostly attributed to snowmelt episodes, but marked losses of NO_3^- can also occur during large precipitations that follow extended periods of low water availability. Some of the NO_3^- is derived directly from the snowpack, but most of NO_3^- comes from the soil which has accumulated NO_3^- from the microbially mediated processes of ammonification (N mineralization) and nitrification.

DOC. The contribution of organic acid (DOC) is important in many regions, and its relative role is most evident at those sites where wetlands are notable. Organic acids have been found especially important under saturated conditions in those catchments that have large proportions of peatlands (5).

Sea Salt Effect. The salt effect is an important contributor to chronic acidification in coastal areas of the northeast United States and western Europe. The deposition of neutral sea salts in coastal areas can cause pH and ANC depression (Fig. 1).

MODELING OF EPISODIC ACIDIFICATION

Various types of models have been used in the study of episodic acidification, including simulation and empirical approaches. A large number of physically and chemically

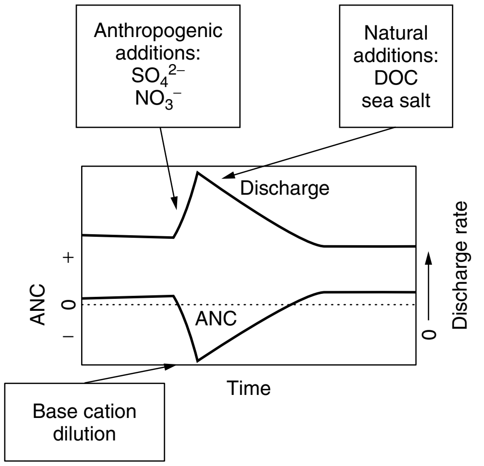

Figure 1. Schematic diagram of factors affecting episodic acidification and changes over time in acid neutralizing capacity (ANC) and discharge rate.

based simulation models have been used to predict acidification (6). Empirical models include four types: solute concentration versus stream discharge, mixing models (such as EMMA, end-member mixing analyses), time series relationships, and multiple linear regression models. The regression model approach has been particularly useful for regional predictions of which surface water sites may be most susceptible to acidic episodes (7).

REGIONAL DIFFERENCES

Episodic acidification has been well documented for the United States, Canada, and Europe. The causes of episodic acidification vary among geographical regions. Within the United States, most of the surface waters showing episodic acidification are in the Northeast and all regions document the importance of base cation dilution. Organic acid (DOC) contributions are most important in the Adirondack Mountains. The importance of NO_3^- is most evident in the Adirondack and Catskill Mountains. In Pennsylvania, changes in SO_4^{2-} concentrations are most important in affecting both episodic and chronic acidification (3). Similarly for Europe, SO_4^{2-} appears to be most often associated with acidic episodes, although in some sites, NO_3^-, DOC, and sea salt may also be important (1). Research in southeastern Canada has suggested the importance of base cation dilution in circumneutral waters compared to low ANC waters where SO_4^{2-} is the primary controller of acidic episodes.

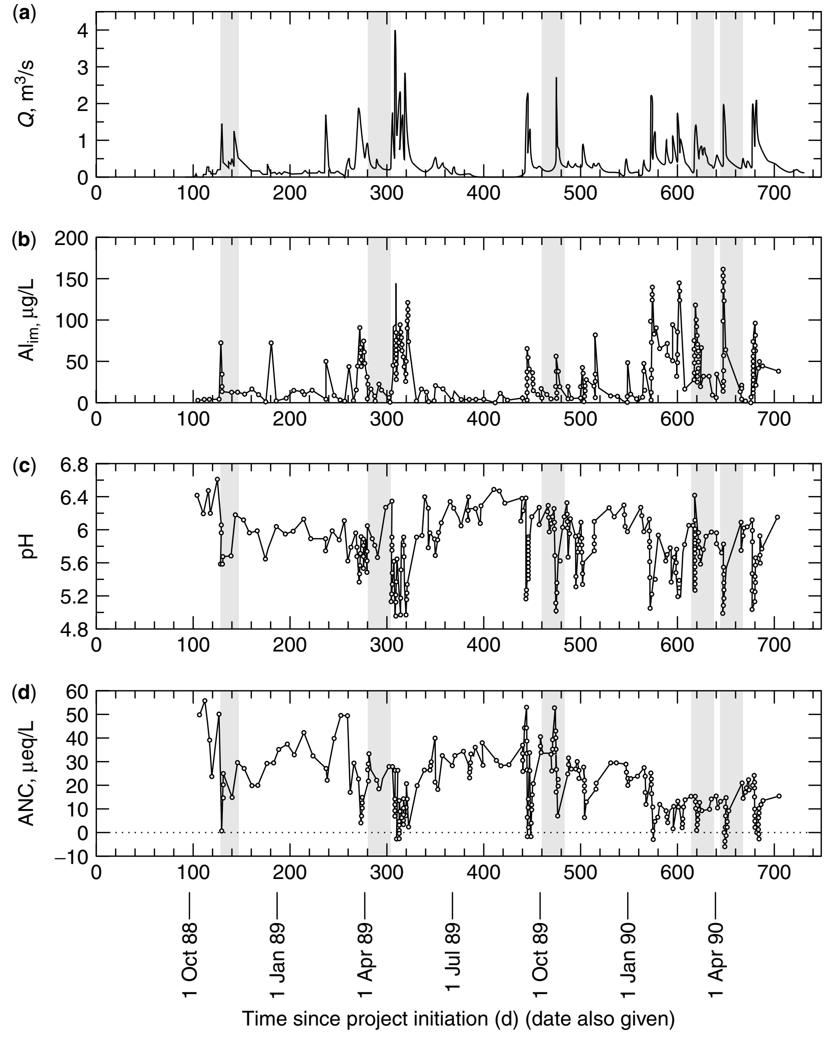

Figure 2. Effects of seasonal changes in discharge in affecting Al_{im}, pH and ANC. High discharge and low ANC coincide with spring snowmelt and fall storms. (**a**) Mean daily discharge (*Q*); (**b**) Al_{im} (inorganic monomeric aluminum); (**c**) pH; and (**d**) acid neutralizing capacity (ANC) for Biscuit Brook in Catskill Mountains, New York, U.S. Shaded areas are times when trout bioassays were conducted (3).

BIOLOGICAL IMPORTANCE

Episodic acidification associated with high concentrations of inorganic monomeric aluminum (Al_{im}), it has been shown, is deleterious to aquatic biota (8). In many regions, there is a general relationship between low pH, low ANC, and high concentrations of Al_{im}, but those surface waters that have lowest pH values do not necessarily have the highest Al_{im} values. The concentration of Al_{im}, it has been shown, is a good predictor of fish mortality. There are, however, major differences in the sensitivity of fish species to acidification, including acid pulses. Some acidic events may coincide with particularly sensitive periods of aquatic biota life cycles (e.g., spawning), so these events may have marked impacts on freshwater ecosystems. Other biotic impacts can include changes in the structure of aquatic communities and losses in biotic diversity (Fig. 2).

ACIDIFICATION OF FRESHWATER RESOURCES

Walter H. Geller
UFZ, Dept. of Inland Water Research
Magdeburg, Germany

GENERAL ASPECTS

All freshwater resources, groundwaters, lakes, and rivers, can be acidified. Inland waters receive acid inputs via the atmospheric path and by direct inflows from surface runoff and from groundwaters. Sources of acids are smoke from burning of fossil combustibles and from volcanoes, acidic wastewater from industrial plants, geogenic acids from weathering of sulfidic deposits at their natural sites, or from oxidation of sulfides with/after mining ores, hard coal, and lignite (1). Accordingly, the acid inputs into ground- and surface waters are either distributed by acid rain over long ranges and large areas, or they are restricted to local impacts by draining of mines, dumps, or sulfidic natural deposits. Both pathways are found in active volcanoes regionally releasing volatile acids into the atmosphere and being direct, local sources of highly mineralized acidic brines. Last but not least, freshwaters can be directly acidified by inflows of industrial wastewater. The effect of acidic inputs is larger in soft water because of the low content of ions and low buffering capacity.

The primary state of acidic waters is changed by secondary processes in soils and rock while seeping through the ground. Thereby, the ionic composition is modified by partial neutralization of the initial acidity and by increased mineralization at low pH. Due to the processes connected with ground passage, the waters usually contain additional dissolved substances, aluminum, iron, and other elements.

The atmospheric pathway distributes anthropogenic acids stemming from gaseous SO_2 and NO_x over large areas of land. During soil passage, this rain acidity can be neutralized in carbonate-rich areas, so that, here, ground- and surface waters are not affected. However, regions that are poor in carbonates (granitic bedrock, gneiss, sand, and sandstone) are sensitive. In a two-step process, the soils first become acidic after complete loss of carbonatic minerals; then, further acidic waters seeping through the soils dissolve further minerals, especially Al silicates.

Acids of geogenic origin can be set free by natural weathering or by weathering processes induced by mining. The first geogenic source of acidity is sulfur (metal sulfides: pyrite or other sulfidic ores) that can be oxidized after contact with air. Seeping water produces sulfuric acid and Fe (II), that later can be oxidized to Fe (III), thereby causing further acidity. The processes of sulfur and iron oxidation are accelerated by sulfur and iron oxidizing bacteria. This type of geogenic acidification is common in many mining areas where we find acidic open pit lakes, acidic streams, or acid mine drainages and tailings.

Another geogenic source of acidity is volcanic activity. Volatile acids are thermally set free as gaseous SO_2, HCl, and HF from the respective minerals. By mixing with steam of meteoric waters, strong acids are formed that dissolve volcanic rock. The resulting outflowing waters are extremely acidic and highly mineralized brines that often emerge in geothermal hot springs at the flanks and top of the volcanoes or collect in crater lakes. Because of the respective dominating buffering systems in the different acidic waters, the pH values are kept within typical ranges (2–5).

Ranges of Proton Concentration, Acidity, and Dissolved Solids

Generally, the content of dissolved minerals that are hydrolyzed during the passage of water through rock and soil increases with the acidity and proton concentration (−pH) of the resulting acidic waters. The total dissolved solids (TDS) increase, over the range from pH 4 to pH 0, from 200 mg/kg to 100 g/kg (Fig. 1).

The relationship between acidity and pH is shown in Fig. 2 for volcanic waters, for pit lakes, and for rain-acidified soft-water lakes. The log-log line is valid for strong acids completely dissociated into protons and anions $[\log_{10}(\text{acidity in eq/L}) = (-\text{pH})]$. The real values of the actual proton concentrations, however, are lower in the acidic volcanic waters where only 30% of the acidity is apparent from the pH. In mining waters of 10 to 30 meq/L acidity, only 12 to 30% of the protons that potentially can be set free are reflected by the pH values. This means that the acidification effect after mixing and dilution with fresh waters is three to eight times stronger than presumed from the actual pH values.

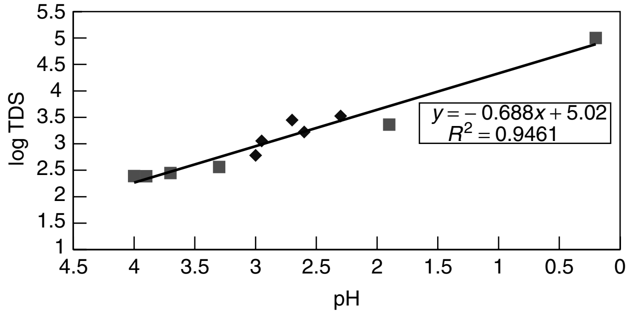

Figure 1. Relationship between the pH of acidic waters of different types and the content of total dissolved solids (TDS in ppm): diamonds: original values for pit lakes; squares: values for volcanic waters from Reference 6.

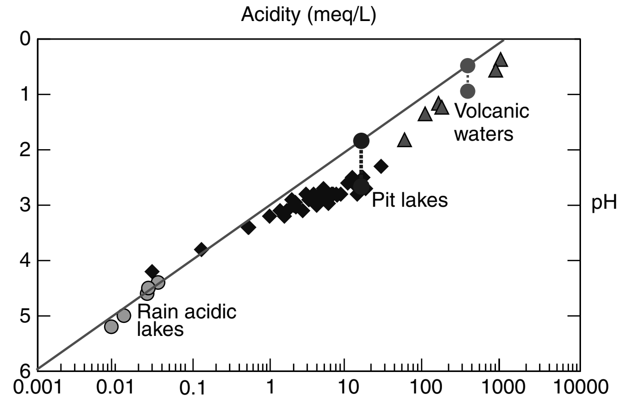

Figure 2. Acidities (measured as base neutralization capacity ($K_{B4.3}$) or calculated from an ion balance) and pH values for acidic volcanic waters (triangles: values from Reference 6), for acidic pit lakes (diamonds: original values and from Reference 7), and for rain-acidified softwater lakes (circles: from Reference 8). Vertical stippled lines show the deviation between the actual proton concentration (pH) and the acidity (or base neutralization capacity) of the waters: in pit lakes, 12 to 30%, and in volcanic lakes, 30% of the acidity is apparent as free H^+ ions.

ATMOSPHERIC ACIDIFICATION: ACID RAIN AND SENSITIVE WATERS

Acidification of Soil and Water and Chemistry of Acidified Soft Waters

Prior to anthropogenic emissions, the only atmospheric acid was carbon dioxide, resulting in weakly acidic rain of pH 5.6. This natural rainwater dissolves only carbonates from soils and weathering bedrock. Therefore, natural freshwaters contain mainly carbonates, HCO_3^-, and CO_3^{2-}, and most fresh inland waters in temperate climatic regions show nearly identical chemical compositions in which the carbonate buffering system dominates at pH 7. Carbonate-poor geological regions have "soft" waters of low mineral content, and carbonate-rich areas show higher mineralized "hard" waters. The relative (!) ionic composition of all natural freshwaters is similar, resulting in a "standard water composition" (2,9).

Only those geological regions that are poor in carbonates are sensitive to acid rain. The critical load is reached when the base saturation (percentage of Ca^{2+}, Mg^{2+}, K^+) decreases below 20% of the total cation exchange capacity (10) or below a limit of acid neutralization capacity (ANC) of 0 to 25 μeq L^{-1} (11). Estimates of the critical loads (11) showed a range between 300 and 800 mg m^{-2} of annual sulfur depositions in geologically sensitive areas (12–15).

Acid rain changes the chemical composition of seeping runoff, ground- and surface waters (8,11). Beyond the critical limits, the interaction between soil and rainwater leads to accumulation of acidity (N and S content). The carbonate and hydrogen carbonate anions in soil and surface waters are replaced by sulfate, and Ca^{2+} and Mg^{2+} cations by H^+ and Al^{3+} (16). Rain-acidified inland waters, after a large-scale process of titration, are carbonate-free, enriched in sulfate and aluminum, and acidic within a range between pH 4.5 and 5.5. In regional surveys of sensitive areas, the frequencies of pH of the respective lakes show bimodal distributions (3,17–20). Two buffering systems are involved. The nonacidified lakes are circumneutral and buffered by the carbon–acid system (CO_2–H_2CO_3–HCO_3^-–CO_3^{2-}). The rain-acidified soft waters are moderately acidic (pH 4.5–5.5) and are buffered by the aluminum system (Al^{3+}–$Al(OH)^{2+}$–$Al(OH)_2^+$–$Al(OH)_3$–$Al(OH)_4^-$) (2,11,21).

Regional Distribution of Rain-Acidified Waters

After the emissions of acid smoke, transport times of 15 to 21 hours were observed from the U.S. Midwest states, where the emissions occurred, to the Northeast states in New England and Canada, where the acid rain was precipitating. Accordingly, models use 15-h and 21-h back trajectories to refer the observed acid rain to the emission sources (22). Similar transport times and distances are known from England to southern Scandinavia. However, longer transports are also known that enable intercontinental atmospheric transport (23). The present global problem areas at risk of surface water acidification (14) are in mid- and northeast North America; in western, central, and northern Europe (24); in the eastern parts of China (25); and in different tropical countries (26–28). The long-term development and large-scale geographic distribution in comparison with the development in North America were described in a 9-year report of 11 EU countries (29). In Norway, 27% of the lakes were acidified, and 9% in both Sweden and Finland, corresponding to 6000 and 3000 lakes, respectively (30). Of a total number of 85,000 lakes (20%) in Sweden, 17,000 were assigned as affected until 1992 (31).

Biological Effects of Acidification on Physiological and Ecosystem Levels

The biological effects of rain acidification on individual groups of organisms and on the ecosystems were extensively studied (3,4,15,17–20,22,29,32–52). As acidity increases and pH decreases, the ecosystems lose major groups of organisms; fish, mollusks, cyanobacteria, and crustaceans. There is a shift to fewer species in all groups and to lower biodiversity. The simplified food web has some new dominating components, such as Dinophyceae, water bugs, sphagnum moss, or mats of filamentous green algae. A combination of stressors was identified: acidity, toxic species of aluminum, more intensive and deeper reaching UV irradiation, and loss of fish-food, such as macroinvertebrate species. In several thousand acidified lakes in southern Norway, the macroinvertebrates disappeared at a pH below 4.8. Many fish species disappeared at a pH below 5.7 in the acidic lakes of the La Cloche Mountains (NY), and no species survived at <pH 4.3 (17,20). About 50% of the populations of brown trout in southern Norway were lost in the respective area till 1975 (43,44). The losses increased with altitude in headwater lakes >1000 m above sea level to more than 80% (4,35). A survey showed till 1990, a total of 9,630 fish populations lost, and 5,405 populations were severely affected. The damaged area covered 25% of Norway (40). In a survey of benthic macroinvertebrates in neutral and acidified streams and in acidic lignite mining lakes in Germany, a maximum of about 50 species was found at pH 8, and the number of species decreased to zero at pH 2 (53,54).

Success of Countermeasures and Long-Term Developments

Countermeasures against acid rain and acidification of soils, lakes, and rivers started (1) by controlling the emissions of acidic smoke and (2) by direct measures applied to acidic waters, mainly liming. The emissions were reduced in North America and in Europe during the last two decades by technical improvements, as documented by monitoring networks (55) and by long-term observations at single sites (56,57). In Europe, the former Eastern countries followed after a one decade delay; the area of former East Germany could be identified by the atmospheric SO_2 content till 1992 (58). In the world's largest liming program in Sweden, 200,000 tons of lime were spread every year for 20 years. Of 6000 lakes treated, about half of the acidified area was restored till the early 1990s (31,59–61). The state of "Acidification of surface waters in Sweden—effects and counteracting measures" in 1993 is described in a series of 12 papers (AMBIO 1993, issue 12/5).

INDUSTRIAL ACIDIFICATION: LAKE ORTA (ITALY)

The input of industrial wastewater into fresh waters caused acidification and contamination. Between 1926 and 1982, prealpine Lake Orta (143 m deep, 1.3 km^3 volume) was heavily polluted by industrial wastewater containing ammonium sulfate and heavy metals Cu, Cr, Ni, and Zn. The development of the pollution and acidification and of the recovery are well documented (62). The annual input of copper reached 70 tons between 1950 and 1954, resulting in mean lake concentrations of more than 0.1 $mg\,Cu\,L^{-1}$. The ammonium input was 3,000 tons $NH_4{}^+$-N per year during the late 1960s. During the 1960s and 1970s, the lake water became acidic (pH 3.9 to 4.5) by oxidation of the ammonium. Fish and populations of animals disappeared nearly completely. After stopping the input of industrial wastewaters, the lake was treated from 1989–1990 by lime suspension. The lake was completely neutralized (pH 6.7–6.9) by using 18,000 tons of powdered limestone (63). To date, this was the world's biggest liming campaign applied to a single lake.

GEOGENIC ACIDIFICATION

Lakes and rivers can be acidified geogenically by volcanic acids and by natural acid tailings originating from ore and coal deposits, from surface-mining dumps, or from drainage of old underground pits. Direct acid input from mine tailings into lakes and rivers results mostly from sulfide minerals such as pyrite and related ores oxidized to sulfuric acid and iron hydroxides.

Natural Geogenic Acidification: Acidic Crater Lakes

In volcanic areas, natural pH values of acid crater lakes range from pH 0 to 5.5 (for volcanoes and their state of activities, see References: 64,65). Crater lakes of many active volcanoes contain highly acidic waters that originate from volatile mineral acids. Sulfuric acid, hydrochloric acid, and hydrofluoric acid, or their volatile forms, emerge from the hot active centers causing subsequent leaching and weathering of rock. These acid waters often collect in crater lakes with given constraints in their physical and chemical properties (66,67). For recent publications on crater lakes, see Reference 67. Several crater lakes and volcanic acid brines were chemically characterized (68–72) and showed a very broad spectrum of dissolved elements, many heavy metals, and high temperatures.

Natural Acidic Tailings from Geological Deposits

Natural acidification can originate from natural mineral sulfides weathering in soils and sediments (73). Examples of lake acidification from ore bodies or from metalliferous black shales in Japan (74) and Canada (75–77) were described. The near-surface weathering could have been initiated by glacial processes; the results are comparable with human mining activities (78). Furthermore, post-glacial isostatic land uplift can bring about long-term weathering of near-surface ores (gossans) (77). Examples of acidic hypersaline lakes in endorheic regions are located in Australia and Chile (79–81). The former existence of ancient lakes of this type was shown in the United States (73).

Acidic Rivers—Rio Tinto

The rivers Rio Tinto and Rio Odiel in southern Spain are natural acid drainages from the Iberian Pyrite Belt, the world's largest deposit of sulfidic ores. There are indications (82) that acid waters existed in the river basin 300,000 years ago (83). In addition to the natural acid drainages, human mining activities increased acidification for about 4,500 years and especially during the last 150 years. The Rio Tinto River is an extreme aquatic environment over its full length of 92 km, it has a mean pH of 2.2 and high concentrations of heavy metals (e.g., Fe 2.3 g/L, Zn 0.22 g/L, Cu 0.11 g/L) (82). The metal pollution is reflected in the estuarine and nearshore marine sediments that contain Fe (11.2%), Cu (0.93 g/kg), Zn (1.15 g/kg), Pb (0.73 g/kg), and Ba (0.66 g/kg) (84).

Acidic Mining Lakes

Lignite surface pits in east Germany (the former GDR) were largely closed after the unification of 1989. The voids that are left or will be filled within a few years will result in 200 pit lakes >1 ha. In Lusatia, the eastern lignite mining district of the former GDR, 63% of the existing pit lakes are acidic, have pH values of 2.3 to 3.5, and show high sulfate concentrations up to 2.5 g/L (85). In the United States, surface coal mining left hundreds of pit voids and lakes in the Appalachians and the Midwest during the first half of the last century (86). In addition, numerous new lakes will originate from 86 major ore mining plants (86). Thirty new pit lakes are expected in Nevada within the next 20 years. Existing acidic pit lakes are Berkeley Pit in Montana, Liberty Pit in Nevada, and Spencerville Pit in California (86). Presently, 19 metal mines are operating in Canada, 74 in Australia, 37 in Chile, 75 in Kazakhstan, and additional ones in other countries (Brazil, Peru, Mexico, Indonesia, Philippines, and in African and Asian countries) (86). Many of the voids left will become future lakes that often will be acidic and contaminated by toxic metals.

The present state of the literature does not permit one to work out satisfactorily the common chemical characteristics and a typology of the mining lakes of the different geological regions and climatic zones. A basic classification was found in regional surveys of lignite pit lakes, where multimodal frequency distributions of pH values similar to those of rain-acidified lakes were observed. The three modal groups of pit lakes are based on three buffering systems: bi-/carbonate (pH 6 to 8), $Al(OH)_x$ (pH 4.5 to 5.5), and $Fe(OH)_x$ [(pH 2 to 4) (87), and citations in (86)].

FRESH WATERS AFFECTED BY ACIDIC INFLOWS

Nonacidified waters, rivers, lakes, and groundwater are affected by mixing with acidic inflows such as acidic rivers from volcanic sources' acid drainages and tailings from natural deposits and from surface and underground mines, or acidic sludges that are accidentally set free by spills (89). In acidic drainages, heavy metals are often found as cocontaminants. Although the compounds are diluted, neutralized, and minerals are precipitated, acids and metals damage the freshwater biota (88). Unexpectedly diverse communities of extremophiles can develop in permanently acidic and metal-rich waters (82,83).

Acidification of Groundwaters by Acid Rain and Mining

The importance of the acidification of groundwater tables is related to the spatial scale of the affected aquifers. The effect of acid rain on springs and brooks in Germany was observed by a monitoring network whose areal distribution was screened by a 3-km grid (90). The results showed acidification of all near-surface groundwaters in regions sensitive because of soils poor in carbonates. The scale of lignite mining in the east German district of Lusatia also generally affects regional groundwater (91).

Acidification of Rivers and Lakes by Volcanic Water

Active volcanoes set free volatile acids (SO_2, HCl, HF) and form acidic brines. Outflows of the resulting acidic crater lakes and volcanic flank springs lead to highly acidic headwaters in catchment areas. Freshwater streams that receive the acidic and toxic volcanic inputs of the headwaters are heavily affected (65). Two examples from Java show the consequences of this sort of pollution. The crater lake of the volcano Kawah Ijen, East Java, contains 32×10^6 m^3 of hot and acidic brine (pH <0.4, TDS > 100 g/kg, SO_4^{2-} 70 g/kg, Cl^- 21 g/kg, F^- 1.5 g/kg). The brine seeps through the crater rim and mixes with the Banyupahit River, where the acidic inflow is only incompletely neutralized by dilution and results in the lack of biota. About 30 km downstream, rice fields are irrigated by the river, discharging 4,000 L/s; the daily load is 150 t SO_4, 2.8 t F, 50 t Cl, 10 t Al, 35 kg Ti, and 4 kg Cu (92). The age of the crater lake and its environmental impacts are estimated at more than 200 years old. Furthermore, the Patuha volcano in West Java has an acidic crater lake, Kawah Putih, and springs of acid brines of pH < 1 containing Al, As, B, Cl, Fe, Mn, and SO_4. The acid streamlets drain into the Citarum River that is contaminated by these potentially toxic elements from the crater lake and, too, is used for irrigation (93). In Argentina at Copahue Volcano, there is a network of acidic waters starting from an acid crater lake, Lago Copahue, and a 13 km-long, extremely acidic river, Upper Rio Agrio (pH 0.6 to 1.6). The river discharges into the glacial Lake Caviahue, where the highly acidic water is diluted to pH 2.5 (68,94). The outflow of the lake, Lower Rio Agrio, is further diluted in its course, but, presumably, damages downstream freshwater stretches by its acidic inputs.

Acidification of Surface Waters by Mine Drainage

In the United States, Kleinmann (1989) reported that 19,300 km of streams are affected by acid mine drainage (AMD). In Europe, a typical case is the Avoca River in southeastern Ireland which is affected by continuous AMD from an abandoned copper and sulfur mine area (88). The AMD of pH 2.7 discharges annually about 300 tons of metals into the river (108 t Zn, 276 t Fe, 6 t Cu, 0.3 t Cd).

In the contaminated river, whose pH is 5.8, macrophytes and fish are eliminated, and macroinvertebrates survive only for short periods outside the mixing zone. The damage to the indigenous biota is due to a combination of metal toxicity, sedimentation, acidity, and salinization (88).

Remediation of AMD and Affected Waters

The acidification of lakes and rivers by acid drainage can be prevented by preclusive measures and direct treatment of the polluting waters as (1) restrictions on running mining activities; (2) "active treatment" of the AMD by addition of alkaline chemicals, often in on-site reactor systems, neutralizing the waters; (3) "passive treatment" using natural geochemical and biological reactions to reduce acidity, pH, and ion concentrations; and (4) insitu treatment of acidic lakes.

Gray (95) developed a scheme to describe (1) the damage of AMD on affected river systems for the site of the Avoca tin mine in Ireland and (2) a management system to avoid damage by a combined application of prevention and remediation by passive treatment methods (88). Gazea et al. (96) published a comprehensive review on treating AMD by using passive systems, such as natural geochemical and biological processes to improve water quality with minimal requirements. The remediation of small-scale acid drainages was reached by sequential flow (1) through anoxic limestone drains for pretreating acidic waters by providing alkalinity, (2) through aerobic wetlands to remove iron through oxidation, and (3) through a series of anoxic cells in compost wetlands to raise the pH and to reduce concentrations of other metals and sulfate (96–100).

In extremely acidic pit lakes, the acidity and content of dissolved substances is one to three orders of magnitude higher than in rain-acidified waters. So, liming is far more expensive, and biological treatment becomes a promising alternative for neutralizing the acidity. The microbial processes (101) used for remediating lakes by insitu methods are summarized by Klapper et al. (97). Sulfate-reducing bacteria can use sulfate as an electron acceptor to reduce both iron and sulfur to form pyrite (102):

$$30\mathrm{CH_2O} + 8\mathrm{Fe(OH)_3} + 16\mathrm{SO_4}^{2-} + 32\mathrm{H}^+$$
$$\Rightarrow 30\mathrm{CO_2} + 58\mathrm{H_2O} + 8\mathrm{FeS_2}$$

Analogous to the process in anoxic cells of passive AMD treatments, the in situ reversion of pyrite oxidation to neutralize the acid water in mining lakes can be promoted by adding organic substances that lead to anoxic zones in and above the bottom sediments or in the hypolimnic waters. A pilot project using in situ remediation techniques on whole lakes was actually run (103,104).

DATA SOURCES

Data and actual reports on inland waters and relevant environmental issues are accessible for different regions and on a global scale from Internet sources (Table 1).

GEOCHEMISTRY OF ACID MINE DRAINAGE

Roger C. Viadero
West Virginia University
Morgantown, West Virginia

Acid mine drainage (AMD) results when metal pyrites come in contact with water and/or air, to form dilute sulfuric acid. For instance, iron pyrite (FeS_2) is the major iron-sulfur impurity found in mined earth, particularly in the eastern United States where coal mining is prevalent. Typically, AMD waters contain elevated concentrations of SO_4, Fe, Mn, Al, and other metal ions. As an example, representative AMD water quality parameters from the Roaring Creek-Grassy Run Watershed, located in Elkins, West Virginia, include pH from 2.4 to 3.3, mineral acidities from 2.4 to 980 mg/L as $CaCO_3$, dissolved iron between 35 and 260 mg/L, and sulfate concentrations from 190 to 740 mg/L.

In contrast, copper and arsenic sulfide compounds associated with "hard rock" mining operations are common in the western United States; such compounds are generally much less prevalent in the east. In such instances, sulfide containing minerals such as pyrrhotite (FeS), arsenopyrite (FeAsS), and chalcopyrite ($CuFeS_2$) can produce acidic drainage when oxidized.

Stochiometrically, the interaction of iron pyrite with water is described by the following reactions:

$$4FeS_2(s) + 14O_2 + 4\,H_2O \longleftrightarrow 4Fe^{2+} + 8\,H^+ + 8SO_4^{2-} \tag{1}$$

$$4Fe^{2+} + 4\,H^+ + O_2 \longleftrightarrow 4Fe^{3+} + 2\,H_2O \tag{2}$$

$$4Fe^{3+} + 12\,H_2O \longleftrightarrow 4Fe(OH)_3(\downarrow) + 12\,H^+ \tag{3}$$

In this process, iron pyrite is oxidized to produce ferrous iron (Fe^{2+}), protons and sulfate ions. Ferrous iron is subsequently oxidized to ferric iron (Fe^{3+}) and precipitates from solution as $Fe(OH)_3(\downarrow)$, the sulfate ions can combine with protons to produce sulfuric acid. The iron solids, which form the characteristic red-yellow/yellow-brown coating on stream beds, can consist of a variety of ferric oxides, hydroxides, or oxyhydroxysulfates, including ferrihydrite [$Fe_3(OH)_4$, $Fe_5HO_8 4H_2O$, or $Fe_5O_3(OH)_9$] and schwertmannite [$Fe_8O_8(OH)_6SO_4$] (1–5). Further, ferrihydrite and schwertmannite are metastable and may eventually dehydrate and recrystallize to form hematite (Fe_2O_3).

Many factors determine the rate of AMD generation, including the presence and activity of bacteria, pH, temperature, and pyrite surface characteristics. The interactions of these factors are complex and readers are referred to the following for additional information on AMD geochemistry: Temple and Koehler (6), Singer and Stumm (7), Kleinmann et al. (8), Nordstrom (9), Hornberger et al. (10), Alpers et al. (11), and Evangelou (12). Further, approaches to managing/remediating various sources of AMD are largely functions of those parameters that govern the rate of AMD generation. Representative sources of information on the prevention and treatment of AMD include Sobek et al. (13), Faulkner and Skousen (14), Skousen and Ziemkiewicz (15), Caruccio et al. (16), and Meek (17).

Bacteria and pH

In many cases, the presence and activity of bacteria control the rate at which AMD forms. For example, in addition to the series of reactions presented previously, iron pyrite can interact with ferric iron according to the following relationship, in which additional acid and dissolved iron ions form:

$$\mathrm{FeS_2(s)} + 14\mathrm{Fe^{3+}} + 8\,\mathrm{H_2O} \xleftrightarrow{k} 15\mathrm{Fe^{2+}} + 2\mathrm{SO_4}^{2-} + 16\,\mathrm{H^+} \tag{4}$$

The rate law expression for the oxygenation of ferrous iron is given as

$$-\frac{d[\mathrm{Fe^{2+}}]}{dt} = k[\mathrm{Fe^{2+}}]p_{\mathrm{Ox}} \tag{5}$$

where p_{Ox} is the partial pressure of oxygen and k is the reaction rate constant. The reaction rate constant, k, is $\simeq 10^{-25}$ L/atm·min at 25 °C at pH < 5.5. Thus, iron oxidation is predicted to be very slow at pH $<$ 5.5. However, it is known through field and laboratory studies that pyrite is rapidly oxidized to $\mathrm{Fe^{3+}}$ at pH values of 2 to 3. In this case, the microorganisms *Thiobacillus thiooxidans, Thiobacillus ferrooxidans,* and *Ferrobacillus ferrooxidans* catalyze the oxygenation of ferrous iron (18). In particular, *Thiobacillus ferrooxidans* catalyzes or mediates the following oxidation–reduction reactions of $\mathrm{Fe^{2+}}$:

$$\mathrm{Fe^{2+}} \longleftrightarrow \mathrm{Fe^{3+}} + \mathrm{e^-} \tag{6}$$

$$4\,\mathrm{H_2O} + \mathrm{S^{2-}} \longleftrightarrow \mathrm{SO_4}^{2-} + 8\,\mathrm{H^+} + 8\mathrm{e^-} \tag{7}$$

Similarly, *Ferrobacillus ferrooxidans* mediates the $\mathrm{Fe^{2+}}$–$\mathrm{Fe^{3+}}$ reaction presented in Eq. 6.

To develop an understanding of the effects of pH on AMD formation, it is necessary to consider the solubility of $\mathrm{Fe^{3+}}$ hydroxide species in water. At equilibrium, the relationship between the $\mathrm{Fe(OH)_3}$ solid, soluble $\mathrm{Fe^{3+}}$ species [presented as—log(soluble iron species)] and pH is given in Fig. 1.

Kleinmann et al. (8) and Nordstrom (9) presented a three-step process of chemical and biologically mediated reactions through which AMD is generated. Note that this sequence is based on processes in the absence of appreciable amounts of alkaline material, in unsaturated systems, where there is an adequate oxygen supply. Thus, applying this rationale to systems that have substantially different characteristics must be done with caution. Stage I occurs at circumneutral pHs, where pyrite is oxidized chemically, as presented in Eqs. 1 and 2. Under such conditions, the $\mathrm{Fe^{3+}}$ concentration is limited by the low solubility of $\mathrm{Fe(OH)_3}$.

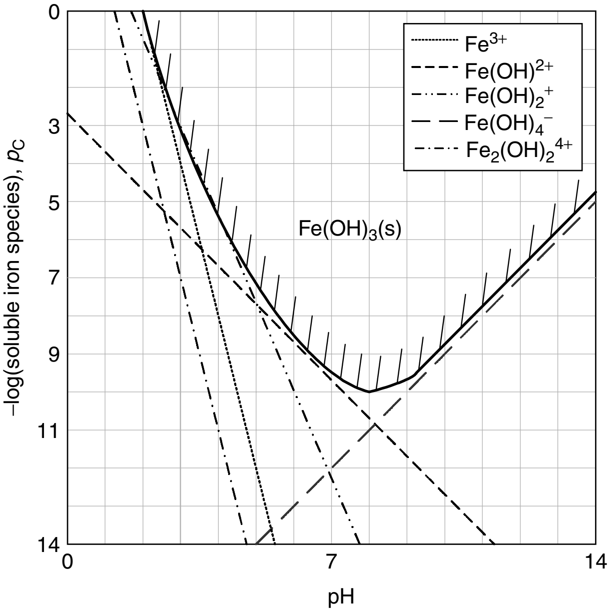

Figure 1. Log concentration versus pH for soluble $\mathrm{Fe^{3+}}$ species in the presence of $\mathrm{Fe(OH)_3(s)}$.

However, some limited oxidation of pyrite by bacteria may occur on the surface of pyrite grains. In Stage II, which occurs at pHs from 3.0 to ~4.5, $\mathrm{Fe^{2+}}$ chemical oxidation is slow; consequently, oxidation is mainly bacterially mediated. In Stage III, the relationship presented previously in Eq. 4 is principally responsible for acid production, which occurs much more rapidly than that in Stages I or II. Typically, Stage III occurs at pH $<$ 3 as $\mathrm{Fe^{3+}}$ becomes increasingly soluble, and the rate of pyrite oxidation can increase rapidly, as presented earlier. However, for pH $<$ 1.5 to 2, the effectiveness of *Thiobacillus ferrooxidans* as a catalyst for the oxidation of $\mathrm{Fe^{2+}}$ decreases (19,20).

One exception to the low pH conditions characteristic of most mine waters includes the case where carbonaceous minerals such as calcite and dolomite impart alkalinity to the water that equals or exceeds the acidity. Dissolution of carbonaceous minerals produces alkalinity, which neutralizes acidity and promotes the removal of Fe, Al, and other metal ions from solution. The result is drainage that is either neutral or net alkaline, though such waters can still have elevated concentrations of $\mathrm{SO_4}$, Fe, Mn, and other AMD-associated metal ions and may require further management.

PROPERTIES OF PYRITE

The rate of acid production depends on the surface area of pyrite exposed to a water solution or air; pyrites with higher surface areas produce more acid than pyrites with low surface areas (21). Similarly, rocks with a high percentage of pyrite produce acidity more rapidly than rocks with a low percentage of pyrite. Further, conclusions regarding the influence of surface defects, such as pitting, on pyrite oxidation rates have been studied by McKibben and Barnes (21). Other investigators have studied the crystal structure of various pyrite samples to explain differences observed in the rates of oxidation among multiple samples. For instance, Kitakaze et al. (22) observed vacant positions in the crystal lattice of pyrite and related variations in such physical properties to differences in oxidation rates. However, further studies are needed to elucidate the specific effect(s) that lattice structure, atomic spacing, and so on, have on pyrite oxidation rates.

THE ARAL SEA DISASTER: ENVIRONMENT ISSUES AND NATIONALIST TENSIONS

Frederic Lasserre
Laval University
Quebec City, Canada

AN UNPRECEDENTED DISASTER UNFOLDING

The village of Muynak was located on an island in the Amu Daria delta in 1956. In 1962, the island had already become a peninsula; in 1970, the sea was 10 km away, then 40 km away in 1980, and 75 km in 1998. The sea bottom became a vast salted desert. In 1987, the retreating sea divided itself in two parts, a small Aral in the north, where the Syr flows, and a large Aral, where the Amu ends its journey when it reaches the sea (Figs. 1 and 2).

Between 1960 and 1998, the level of the small Aral dropped by 13 meters, and the level of the larger by 18 m. The total sea volume was cut by 78% (5,6). The vanishing of the sea constitutes an enormous ecological disaster that radically alters the environmental balance in the region:

- Vast deposits of salts, nitrates and pesticides spread in large quantities on the industrial crops upstream were formed, deposited by water of the Amu and the Syr. The wind now blows on these desiccated deposits, lifting nearly 40 million tons of toxic sediments

Figure 1. The watersheds of the Amu and Syr Rivers (1,2).

each year, and transporting them far inland: this phenomenon poisons the soil, the vegetation, and the inhabitants. The salt fallout can be as high as 500 to 700 kg/ha, which quickly worsens the problem of salt built-up due to poorly drained and excessive irrigation.

- As the Aral Sea, that acted as a climate regulator, gradually disappears, the local climate takes on distinct continental characteristics:
  - The frost-free period was shortened to about 170 days that undermines the profitability of various crops, including cotton, which needs about 200 frost-free days. As a consequence, some farmers have turned to growing rice, a crop that consumes even more water. Summers are shorter but also hotter.
  - Strong winds are more frequent, increasing the amount of toxic sediment that is blown inland. Aral dust has been detected as far away as Belarus, about 2000 km to the West.

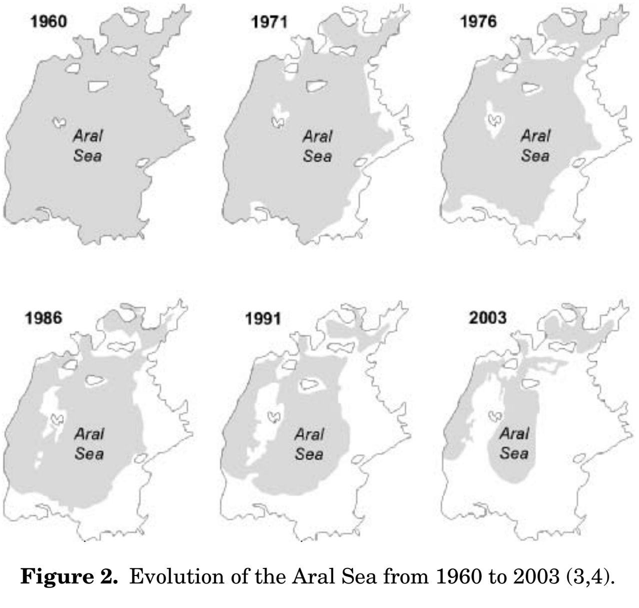

Figure 2. Evolution of the Aral Sea from 1960 to 2003 (3,4).

  - Local rain levels dropped by half in the sea area, and relative humidity dropped by about 30%.
- The salinity of the sea increased from 9.9 g/L in 1960 to 30 g/L in 1994, destroying most of marine life, then to 45 g/l in the larger Aral in 1998 (5). In 1977, the fish catch had already decreased by 75%; in 1982, all commercial fishing had stopped.
- The retreating sea level made the main aquifer level drop, thus drying up several oases around the sea area (7,8).
- Intensive and improperly managed irrigation led to salinization in as much as 95% of cropland (8 million hectares only for cotton), which drives the farmers to increase the amount of fertilizers and water (9,10), thus compounding the water stress.

The Aral Sea, the fourth lake in the world by its surface in 1960, went into a steady decline (Table 1).

On a geologic timescale, changes in the Aral Sea level have been noted: the phenomenon is not, in itself, radically new. The sea is naturally sensitive to variations as it is not very deep (16 m on average) and subject to strong evaporation (about 58 km^3/year, on average). But it is the speed with which the Aral Sea disappeared from 1960 on that hints of human causes, which probably were compounded by natural causes. A sharp decrease in precipitation was observed in the 1970s and 1980s; by itself, it was estimated that it would have led to a decrease in the sea level from 53.5 m in 1960 to 50.8 m in 1986. The rest can be accounted for by large withdrawals for irrigation, a demand all the stronger as rain became scarcer.

DEVELOPING THE VAST CENTRAL ASIAN PLAINS

The Russian Empire introduced cotton in Central Asia in the late nineteenth century. But it became intensively grown under the Soviet regime. In 1937, the Soviet Union, eager to increase its export revenues, became a net cotton exporter. There were social and political goals as well: through the collectivization and the mechanization that were put in place so as to expand large industrial cotton

Table 1. State of the Aral Sea from 1950 to 1998[a]

Year	River Discharge, km^3	Sea Level, m Large Aral After 1987	Surface, km^2	Volume, km^3	Salinity, g/L Large Aral After 1987	Fish Catch, t
1945	62				10	
1960	40	53.41	66,458	1090	10	43,300
1965	31	52.5	63,900	1030	10.5	31,040
1970	33	51.6	60,400	970	11.1	17,460
1975	11	49.4	57,200	840	13.7	2,940
1980	4	46.2	52,500	670	16.5	0
1985	0	42	44,200	470	23.5	0
1987	0	40.5	41,000	404	26.8	0
1989	6	38.6	36,900	330	30.1	0
1990	9	37.8	34,800	304	33.3	0
1993	14 (est.)	37.1	35,424	297	35	0
1998	21 (est.)	31.5	31,541	236	45	0

farms, traditional family farming was destroyed, and with it the remnants of resistance of Central Asian societies toward communism and a centrally planned economy.

Irrigation: The Main Culprit

Water was the key to a vastly expanding cotton production. Canals and dams were planned from 1950 on and built to take the water from the Amu and the Syr to the fields (Table 2). In 1956, the Karakum Canal was inaugurated. It was to irrigate the dry lands of Turkmenistan, when irrigation was considered the solution to humankind's development. In 1980, the highest dam in the world, the Nurek Dam (335 meters high), was commissioned in Tadjikistan.

Thanks to this infrastructural effort, irrigated land grew between 1965 and 1986 at an average rate of 2.1% annually (Table 3). During the same period, water demand doubled. A lot of it was lost through evaporation in open canals or through seepage in uncemented aqueducts. Water drained the fertilizers and the pesticides sprayed over the fields, but smaller amounts reached the sea as more canals were built to develop more acreage. In 1950, 50 km^3 of water flowed into the Aral; in 1990, this volume had dropped to about 7 km^3; the 1990s seem to have been wetter and, combined with the beginning of irrigation rationalization, contributed to an increase of river discharge into the sea. But the amount of water now reaching the Aral is not even enough to stop the sea from retreating, let alone to consider restoring the former Aral, for which at least 35 km^3 would be needed on a regular basis.

After the collapse of the Soviet Union, the Central Asian republics, which were not so eager to become independent, fell into a deep recession. Their main market, Russia, was itself in the throes of economic disarray. Trade was now

Table 2. Development of Irrigated Surfaces, Central Asian Republics, in Thousand Hectares[a]

	1950	1965	1970	1975	1980	1985	1987

[b] Figures from 1993 for cotton production.

to be done at world market prices in convertible currencies, which was not favorable for them, and they realized they were highly dependent on one crop, cotton. Oil and gas reserves were already known at the time, but few pipelines existed to world markets, and all of them went through Russia, which levied a heavy transit fee (11). In 1992, cotton occupied 60% of the cropland in Uzbekistan. In 1998, the crop still represented a third of all Uzbek exports and the main source of hard currencies. Agriculture is 43% of the GDP in Uzbekistan, 46% in Turkmenistan and 33% in Kazakhstan, and employs 22% of the workforce in Uzbekistan. The Kazakh, Turkmen, and Uzbek governments, where most of the crops were grown, thus realized how difficult it would be to reform irrigation practices drastically as the more pressing problems were hardly environmental but the very survival of the economy.

Besides, available water is already insufficient to sustain all crops in the region. About 25% of the irrigated lands in Uzbekistan now receive only about 70% of the water needed for optimal cotton growth (12). But the worst is still to come. The cotton production levels induced the destruction of the Aral, but they are not even sustainable because of salt intrusion that is often fought back by spraying even more water. In 1994, 28% of the irrigated lands in the Aral basin, as against 23% in 1990, were plagued by salt deposits that reduced their productivity by 20 to 50%. Yields were adversely affected. Between 1981 and 1986, cotton production dropped by 21.3% in the Soviet Union, largely caused by salt buildup and poor management. To make up for this lost production, several countries opted to wash out the fields, which was temporarily effective but induced an even faster rise of the water table; irrigated surfaces were also increased, compensating the decreasing yield by larger surfaces, especially in Turkmenistan, where a rise of 31% occurred between 1990 and 1994.

Saving Water?

Irrigation is responsible for about 93% of the water consumption in the two Aral Sea basins. Solutions to the crisis have been known for long: they require a sharp increase in water yield and the reduction, if not the elimination, of the most consuming crops, such as rice, and their replacement with less demanding cereals, such as sorghum or millet (savings expected: 3 km^3). Unprofitable crops could be phased out (a water saving potential of about 15 km^3). The improvement of agricultural techniques in the most profitable cotton fields, notably by introducing more effective irrigation techniques such as sprinklers, could add an additional 8 km^3. The repair, lining, and tightening of canals could help save about 10 km^3.

But these solutions are all costly, whether financially or socially. Besides, they imply cooperation among five governments to implement water sharing and management schemes.

AFTER INDEPENDENCE, THE LONG ROAD TO AN AGREEMENT

When the Central Asian republics were federated states under the authority of the Soviet Union, arbitration and infrastructural development decisions were made in Moscow. The development of the Aral Sea basins through intensive irrigation was not questioned at the time. When independence took place, the resource sharing designed during Soviet times appeared all the more unjust as downstream users, which could benefit from irrigation, pressured the two upstream countries, Kirghizstan and Tadjikistan, not to interfere with water resources stored in reservoirs located in their territories; these very downstream users are also well endowed with hydrocarbon resources. Suddenly becoming independent in 1991 due to the collapse of the Soviet Union, the five republics were forced to face bitter disputes and look for cooperative schemes.

There were tensions, even before 1991. In 1989, clashes took place between Kirghiz and Tadjik farmers over water allotments. In the Osh area in Kirghizstan, another clash between Uzbeks and Kirghizs caused 300 deaths in 1990. Along more and more closed borders, patrols are organized to prevent border crossings and irrigation canal sabotage.

Bitter disputes have emerged between Turkmenistan and Uzbekistan, as the former keeps expanding its irrigated acreage, thanks to the Karakum Canal, consuming larger amounts of the Amu Daria. Tension is altering relations between Uzbekistan and Tadjikistan, as the latter is complaining about the heavy prices Uzbekistan is demanding for the gas it delivers, whereas water in the Amu flows freely from Tadjikistan to Uzbekistan; Tadjikistan threatened to bill Uzbekistan for the resource, on the basis that the water comes from its territory. Tension also disrupted relations between Uzbekistan and Kirghizstan over the use of the Toktogul Dam water. Built during the Soviet era in mountainous and water-rich Kirghizstan, it was mainly meant to store water during the winter to provide water for the irrigated lands of the Ferghana Valley downstream, mainly in Uzbek territory. In January 2001, the Kirghiz government defaulted on its gas payments to Uzbekistan; the Uzbek government suspended gas deliveries that are mainly used for urban heating. Kirghizstan opened the Toktogul Dam sluices to produce electricity. The induced flood destroyed several dikes in the Uzbek Ferghana region. The Kirghiz pressure peaked when, after 15 days of letting the reservoir gradually empty to generate electricity, Kirghizstan notified the Uzbek government that they would not be able to guarantee water deliveries for the next growing season. This diplomatic skirmishing over energy deliveries bore fruit inasmuch as an agreement was signed by both countries for more cordial relations, recognizing the interests of Kirghizstan in using the waters of the Syr River—but it also underlined the acute tensions over the use of this very water.

It is not that the five Central Asian republics have not undertaken negotiations. As early as 1993, they signed the *General Agreement on the Crisis of the Aral Sea*, also signed by Russia, which provided water sharing cooperative mechanisms and technical cooperation to improve agricultural yields. Because of poor funding and lack of political will, the agreement was never enforced. As of 1995, the European Union and USAID stepped up their cooperation by creating large funds to help the functioning of institutions such as the *Interstate Council* *for Addressing the Aral Sea,* or the *Optimization of the Use of Water and Energy Resources in the Syr-Darya Basin* project. So far, progress has been very slow.

THE TEMPTATION OF UNILATERALISM OR SOVIET STYLE MANAGEMENT

Soviet-style planning led to the idea that water was not particularly scarce; when it did become so, gigantic diversion of Siberian rivers, the Ob and the Ienissei, were designed by engineers to cope with the issue, only to be stopped in 1986 by Mikhail Gorbachev. It is all the more difficult for the Central Asian republics to reach an agreement as they lack financial resources to implement any conversion scheme in agriculture because cotton is a major export resource for the three downstream users. Besides, the economic recession that was triggered by the disintegration of cooperation within the former Soviet Union creates social unrest on which political opposition, particularly Islamic movements, capitalize to question the governmental authority, especially in Uzbekistan. In the latter, difficulties in reforming agriculture are compounded by the strong lobby of industrial cotton farmers.

Nationalist rhetoric, often associating water issues with ethnic tensions, developed in the region. This trend must be analyzed in the framework of tensions erupting between states as they close their respective borders and as governments have been charged with encouraging nationalist stances that help them stay in power in these troubled post-Soviet times. Besides, Uzbekistan is increasingly considered by its neighbors as pursuing a regional power policy (13).

Economic pressures and the slow progress in negotiations have encouraged several governments to act unilaterally to protect their interests. For instance, in 1994, Turkmenistan unilaterally resumed the extension of the Karakum Canal, thereby triggering strong protests from Uzbekistan. The annual volume diverted into the canal reportedly amounts to between 15 and 20 km^3 (14). Similarly, in 1998, Kazakhstan succeeded in building a dike between the Little (or Northern) and the Large Aral, trying to keep the flow of the Syr Daria in the Little Aral to restore it gradually. The World Bank showed interest in the project. The Little Aral level grew by several meters and a few fish species have been reintroduced. The Kazakh government hopes that this project can help save the Little Aral, but it also means that the Large Aral is doomed, as any conservation project must rely only on the Amu Daria. Uzbekistan strongly protested against the Kazakh scheme. Kazakh officials replied that Uzbekistan has not shown any real desire to reduce its water consumption.

CONCLUSION

The Aral Sea is disappearing because of the development of unsustainable levels of agricultural demand for irrigation. Cotton is a major crop in Central Asia. The Soviet government vastly expanded this culture for social, political, and industrial reasons. To do so, water development was planned regionally without considering the various federated republics.

When they became independent in 1991, the harsh economic recession and social unrest made any move to reform agriculture and implement water-saving measures difficult. Nationalist tensions, played upon by bureaucracies and governments, also played a role in stalling the negotiations that had begun as early as 1992. The Aral Sea keeps receding, and the temptation of unilateral decision-making remains strong in the five republics. Water withdrawals for irrigation have decreased since 1985, but they remain far too high to prevent the Aral Sea from disappearing.

Failure to reach an agreement could doom the disappearing sea, all the more if peace prevails in Afghanistan. A quarter of the drainage basin of the Amu Daria lies in that country. If peace is to return there, agriculture will resume, and with it, irrigation, thereby further reducing the available volume for Turkmenistan and Uzbekistan.

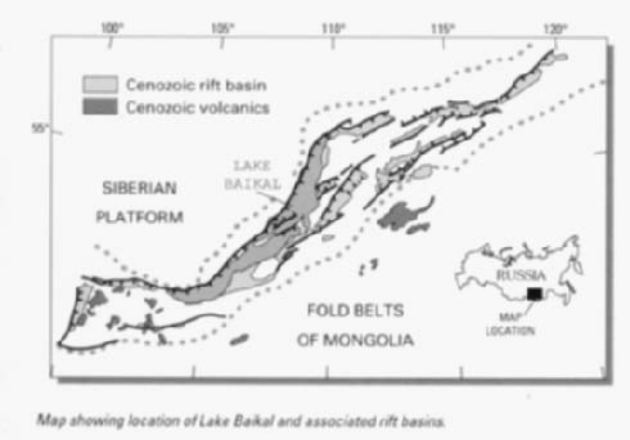
LAKE BAIKAL—A TOUCHSTONE FOR GLOBAL CHANGE AND RIFT STUDIES

Deborah Hutchinson
Steve Colman
U.S. Geological Survey

> "The Lake Baikal rift system is a modern analogue for formation of ancient Atlantic-type continental margins. It tells us the first chapter in the story of how continents separate and ultimately develop into ocean basins like the Atlantic Ocean."
> —Deborah Hutchinson
>
> "Lake Baikal is a unique, nearly pristine environment for the study of global change. Nowhere else in the world can we go to study so long a record of such an important, but little known, part of the global climate system."
> —Steve Colman

THE SPECIAL ENVIRONMENTAL AND GEOLOGICAL SETTINGS OF LAKE BAIKAL PROVIDE UNPARALLELED OPPORTUNITIES FOR RESEARCH AND FOR INTER-NATIONAL COOPERATION

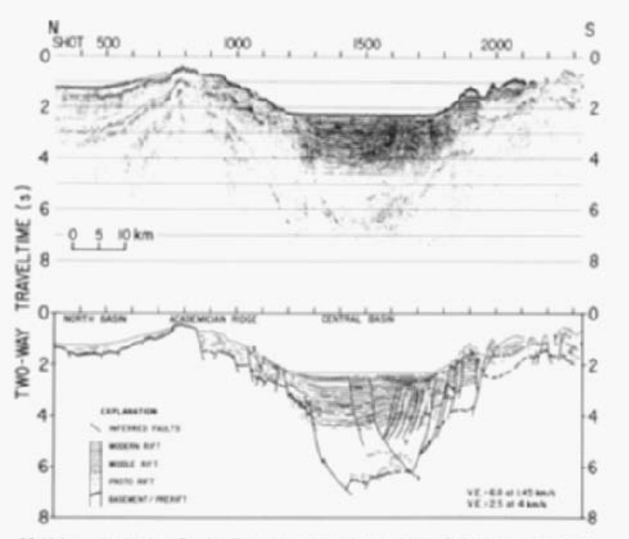
Lake Baikal is to Russia what the Grand Canyon is to the United States: a magnificent natural resource that instills national pride and awe. The Presidents of the United States and the Russian Federation recognized the uniqueness of Lake Baikal. In a recent Joint Statement, they affirm the need to conserve the environment of Lake Baikal and to use its potential for research in limnology, geology, and global climate change. The **U.S. Geological Survey's** (USGS) Office of Energy and Marine Geology and Office of International Geology, supported by the Coastal Geology Program and the Global Change and Climate History Program, are involved in broad collaborative programs to study Lake Baikal with the **Russian Academy of Sciences** and with a number of American universities through the (U.S.) **National Science Foundation**.



Map showing location of Lake Baikal and associated rift basins.

UNDERSTANDING THE ORIGIN OF THE LAKE BAIKAL RIFT CONTRIBUTES TO UNDERSTANDING ONE OF THE FUNDAMENTAL PHENOMENA BY WHICH THE HISTORY OF THE EARTH IS RECONSTRUCTED

Continental rifts, like the Lake Baikal rift, and their end products, such as passive continental margins like the east coast of the United States, are ubiquitous in the Earth's geologic record. They contain information from which a significant amount of the Earth's history has been interpreted. Due to their high sedimentation rates, large rift lakes like Lake Baikal have great potential for providing high-resolution information about both tectonic and climatic change. Significantly, sedimentary deposits of continental rifts are also associated with many of the Earth's hydrocarbon and mineral deposits.



Multichannel seismic reflection line across central part of Lake Baikal showing seismic data (top) and interpretation (bottom). The thickest deposits are confined to a narrow trough that is 15 to 20 kilometers (9 to 12 miles) wide.

USGS AND RUSSIAN COOPERATIVE STUDIES HAVE BEGUN TO RESOLVE THE THREE-DIMENSIONAL GEOMETRY OF THE LAKE BAIKAL RIFT

Sediments of Lake Baikal reach thicknesses in excess of 7 kilometers (4 miles), and the rift floor is perhaps 8 to 9 kilometers (more than 5 miles) deep, making it one of the deepest active rifts on Earth. The shallowest sediments may contain the only known freshwater occurrence of natural gas hydrates. Maps of complex fault patterns and changing depositional environments provide the first opportunities to describe the development of the lake and to help explain its unique flora and fauna.

The RV Vereshchagin, a coring and high-resolution seismic vessel, docked on central Lake Baikal.

UNIQUE CHARACTERISTICS OF THE LAKE BAIKAL ENVIRONMENT COMBINE TO PRODUCE AN ESPECIALLY PROMISING SITE FOR STUDIES OF CLIMATE HISTORY

Lake Baikal is the largest freshwater lake on Earth containing 23,000 cubic kilometers of water, or roughly 20 percent of the world's total surface fresh water. It contains as much fresh water as the Great Lakes of North America combined. At over 1,600 meters (5250 feet), it is the deepest lake in the world, and at perhaps more than 25 million years old, the oldest as well. The water of Lake Baikal is so fresh that calcium carbonate does not survive in the fossil record. Despite the lake's great depth, its water is well-oxygenated throughout creating unique biological habitats.

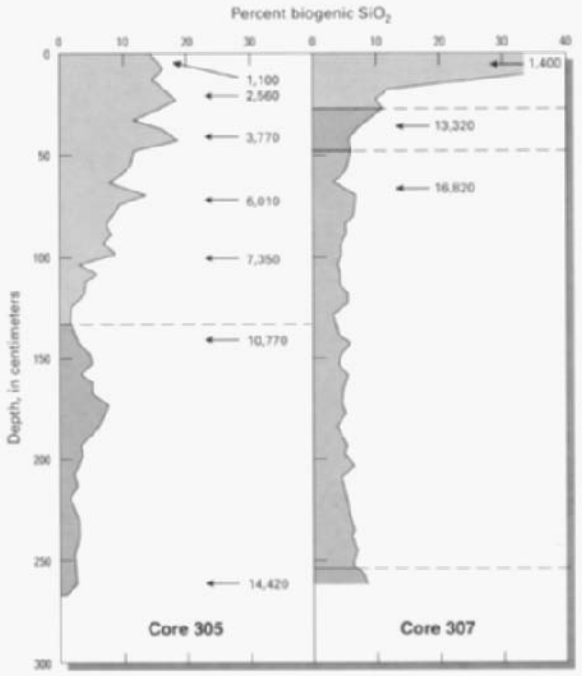
THE HIGH LATITUDE OF LAKE BAIKAL MAKES IT PARTICULARLY SENSITIVE TO CLIMATIC VARIATIONS

Climate variations, including those resulting from atmospheric accumulation of carbon dioxide, are more pronounced at higher latitudes. Although the lake contains a record of glaciation of surrounding mountains in its sediments, it is unique among large, high-latitude lakes in that its sediments have not been scoured by overriding continental ice sheets.

Ice-based drilling rig being tested on a small marginal lake in North Baikal. Photo by D. Williams.

UNITED STATES AND RUSSIAN STUDIES OF SEDIMENT CORES TAKEN FROM LAKE BAIKAL PROVIDE A DETAILED RECORD OF CLIMATIC VARIATION OVER THE PAST 250,000 YEARS

Much attention is focused on numerical models of climate change but there have been few means for reliably testing or modifying boundary conditions of general circulation models. Studies of sedimentary environments in Lake Baikal provide important opportunities to establish ground truth for general circulation models. Very little data exist for long-term climate change from continental interiors; most of the data record derives from the marine or maritime environments. Finally, studies of past environments contribute to understanding the extent to which human activity affects natural conditions in the lake.



Graph showing percentage of biogenic silica in two Lake Baikal cores. Since diatoms and algae are the most important microorganisms in the lake, biogenic silica is a measure of primary productivity. Radiocarbon ages in years are shown by arrows. First-order changes are caused by glacial (blue)-interglacial (red) cycles, with transitions shown in purple. Second-order fluctuations, such as the peak at 3,770 years, are due to shorter climatic events.

SEISMIC AND SEDIMENT CORE ANALYSES ARE USED TO FIX FUTURE DRILLING SITES IN LAKE BAIKAL

Ice-based drilling operations begun in early 1993 are providing longer (over 100 meters in length) cores of Baikal sediments. Analyses of these cores are expected to reveal the climatic, environmental, and geological history of the region as far back as 5 million years. Seismic data will be tied to cores and drill samples to estimate rates of climate change and to map the history of the lake and rift. Very deep drilling in Lake Baikal remains technologically challenging; therefore, the deepest deposits of the rift are not likely to be sampled soon. However, the potentially very long record of sedimentation in Lake Baikal provides unique opportunities to understand the Cenozoic climate history of the Earth and to describe how continents begin to break apart, giving rise to new ocean basins.

BASE FLOW

Sharad K. Jain

Vijay P. Singh
Louisiana State University
Baton Rouge, Louisiana

Water may reach a river by flowing over the catchment surface, moving through the soil, or through groundwater. Based on the path taken by water, streamflow may be divided into surface flow, interflow, and base flow. The ASCE (1) defined base flow as the runoff that has reached the stream or river by passing first through the underlying aquifer, rather than by flowing directly on the ground surface. Thus, base flow is that portion of streamflow that is naturally and gradually withdrawn from groundwater storage or other delayed sources. The other names of base flow are groundwater flow, seepage flow, low flow, and fair weather flow.

Perennial streams depend on base flow for discharge between runoff producing events. The presence of base flow around the year indicates humid climate and a shallow water table that is hydraulically connected to the stream. Base flow is absent in (semi)arid climates and areas of deep groundwater. Of course, it is assumed that the streamflow is not influenced by storage or diversion.

FACTORS AFFECTING BASE FLOW

Base flow depends on precipitation, geologic conditions, and hydrogeologic controls that govern groundwater movement. Sources, such as lakes, marshes, snowpack, and channel bank, may also supply water for base flow. At a given time, more than one source may be supporting base flow. Climate influences recession through recharge and evapotranspiration.

Base flow contribution to streamflow varies widely according to the geologic nature of the water-table aquifer. A measure of the amount of water available from a water-table aquifer is the coefficient of storage, or specific yield. The lateral movement of groundwater is slower than vertical movement because the hydraulic gradient is smaller for lateral movement. For this reason, groundwater "mounds" and water tables beneath ridges may be at higher elevations than stream channels. This provides a gradient that directs base flow to the stream. The supply from groundwater to the channel will continue as long as the necessary gradient is present. If no additional infiltration recharges an aquifer, the hydraulic gradient decreases as water moves to the stream from higher elevations. Consequently, less water will be discharged to the stream with time. This process is called base flow recession.

Bank storage may also contribute to base flow depending upon the position of the water table, riverbank material, soil characteristics near the riverbank, and the rise and fall of the stream. Usually, bank storage is largely depleted by the time the base flow peak occurs. Other water-table aquifers such as fractured rocks and solution cavity rock openings also contribute base flow to streams. The important parameters related to groundwater outflow are the total length of perennial streams, average basin slope, and drainage density. Singh provides a detailed discussion on base flow (2).

BASE FLOW RECESSION

Streamflow recession represents withdrawal of water from storage without inflow. It constitutes the falling limb of a hydrograph to the right of the point of contraflexure. When all surface runoff has passed, the flow in the stream consists of base flow. Figure 1 shows components of a typical hydrograph.

Base flow is at maximum immediately after a storm because precipitation has just recharged the water table. As water is withdrawn from an aquifer, groundwater supplies are diminished and base flow decreases. This process continues until all groundwater available for base flow is exhausted or additional recharge occurs.

Many different forms of base flow recession curves have been proposed. These are discussed in what follows.

Simple Exponential

The basic differential equation that governs the flow in an aquifer was presented by Boussinesq in 1877 (3). Boussinesq solved this equation by assuming that the Depuit assumption of negligible vertical flow holds and the effect of capillarity above the water table can be neglected. This assumption leads to the solution,

$$Q_t = Q_0 \exp(-t/a) \tag{1}$$

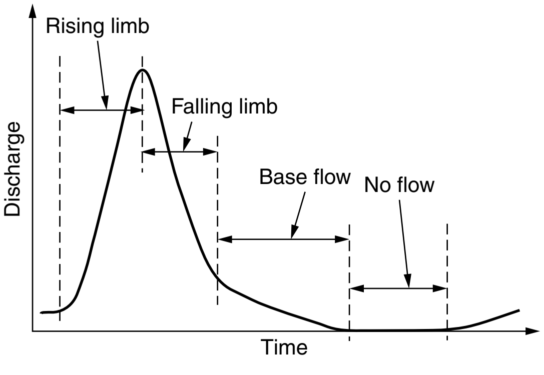

Figure 1. Sections of a streamflow hydrograph.

or its alternate forms

$$Q_t = Q_0 k_r^t \tag{2}$$

$$Q_t = Q_0(10)^{-t/b} \tag{3}$$

where Q_0 is flow at time $t = 0$; Q_t is flow at time t; and a, k, and b are constants. Parameter k_r is known as the recession constant or the depletion factor. It is a dimensionless quantity that depends on the unit of time selected (commonly, it is 1 day). It lies in the interval [0,1] and is normally greater than 0.7. Constants a and b, known as storage delay factors, have the dimension of time. Constant b denotes the time required for the flow to decrease by a factor of 10 or one log cycle (see Fig. 2). Similarly, constant a denotes the time required for the flow to decrease by a factor equal to e, or one natural log cycle, as shown in Fig. 3. In other words, a is the time elapsed between any discharge Q and Q/e of the recession and is related to the 'half flow period' by (4)

$$a = -t_{0.5}/\ln(1/2) \tag{4}$$

where $t_{0.5}$ is the time required to halve the streamflow. Parameters a and k_r are related by

$$a = -t/\ln k_r$$

$$k_r = (10)^{-l/b} \tag{5}$$

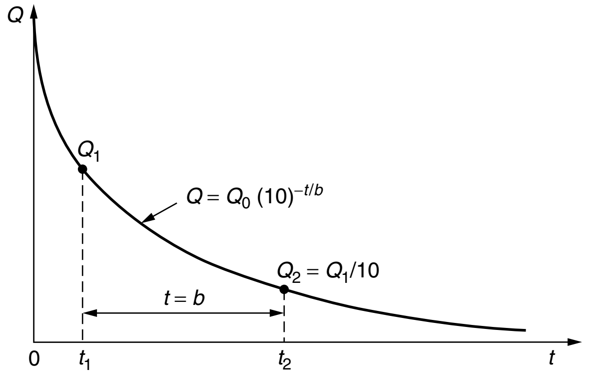

Figure 2. Base flow recession: determination of storage delay time b.

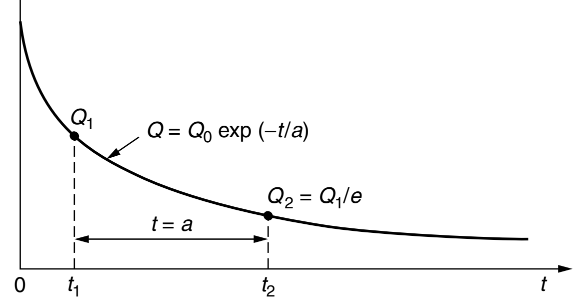

Figure 3. Base flow recession: determination of storage delay time a.

Horton (5) suggested a nonlinear recession equation, known as Horton's double exponential:

$$Q_t = Q_0 \exp(-a_2 t^m) \tag{6}$$

where a_2 and m are constants.

Singh (6) derived ideal base flow curves by solving the Boussinesq equation using a finite-difference equation for two cases: a shallow aquifer and fully penetrating stream and a deep aquifer and shallow-entrenched stream.

More on Exponential Recession

Equation 1 represents a first-order process or an exhaustion phenomenon expressed by

$$ds/dt = -Q, \quad Q(0) = Q_0 \tag{7}$$

and

$$s = aQ \tag{8}$$

where s is storage. The solution of Eqs. 7 and 8 is Eq. 1. The form of Eq. 1 does not change if discharges are replaced by volumes. The volume of flow during the time from $t - T$ to t is given by

$$\begin{aligned} V &= \int_{t-T}^{t} Q\,dt = \int_{t-T}^{t} Q_0 \exp(-t/a)\,dt \\ &= aQ_0[\exp(T/a) - 1]\exp(-t/a) \end{aligned} \tag{9}$$

For a fixed time interval T, such as 1 day,

$$V = V_0 \exp(-t/a) \tag{10}$$

in which

$$V_0 = aQ_0[\exp(t/a) - 1] \tag{11}$$

Thus, the recession constant can be estimated from Eq. 10. It may be preferable to use volumes instead of discharge because volume is less sensitive to errors than discharge.

Double Exponential

When base flow is plotted on semilog paper, the resulting curve is nonlinear which can be represented (5) by a double exponential of the form,

$$Q = Q_0 \exp(-mt^n) \tag{12}$$

where $\exp(-m) = k_r$ is the recession constant and n is a constant. Parameters m and n can be obtained either graphically or by using the method of least squares. By taking the log of both sides of Eq. 12 twice,

$$\ln(Q_0/Q) = mt^n \tag{13}$$

$$\ln[\ln(Q_0/Q)] = \ln(m) + n\ln(t) \tag{14}$$

Equation 14 represents a straight line.

Hyperbola

Another equation for a stream located on a horizontal impermeable lower boundary with an initial curvilinear water table and zero water-level elevation in the stream is of the form

$$Q = Q_0/(1 + ct)^2 \tag{15}$$

where c is a constant. This equation will hold where the groundwater storage is at its maximum after surface runoff stops or if no further precipitation or snowmelt occurred until the streamflow ceased. Parameter c can be estimated as

$$c = [(Q_0/Q)^{0.5} - 1]/t \tag{16}$$

The outflow from storage can be represented by a general non linear relation,

$$Q = kS^p \tag{17}$$

where S is storage and k and p are constants. The recession will be concave downward for $p > 1$ and upward for $p < 1$. Values of p greater than unity are typical of many catchments (4). The superposed exponential equation represents recession flow as a superposition of n exponential terms; each shows the response of a linear reservoir whose recession constant is c_i:

$$Q_t = \sum_{i=1}^{n} Q_{oi} \exp(-t/c_i) \tag{18}$$

Ice-Melt Recession

For snow and ice-melt conditions, base flow recession can be represented by (7)

$$Q = at^{-n} + b \tag{19}$$

where a, b, and n are constants. As time increases, Q asymptotically approaches a constant value b. This may typify base flow recession for permanent snow and ice. Constants a, b, and n can be determined either graphically or by using the method of least squares.

An exponential equation for base flow recession in watersheds that have permanent ice and snow is of the form (7),

$$Q = a + (Q_0 - a)k_r^t \tag{20}$$

where a and k_r are constants. This is similar to Eq. 19, where Q asymptotically approaches a constant value as t increases.

Base Flow Recession as Auto Regressive Processes

The base flow recession Eq. 2 can also be written as

$$Q_{t+1} = k_r Q_t \tag{21}$$

However, this equation is an approximation and contains errors due to a linearity assumption. The input data also contain some errors and, therefore, Eq. 22 can be written as

$$Q_{t+1} = k_r Q_t + \varepsilon_{t+1} \tag{22}$$

where ε_t are independent, normally distributed errors that have zero mean and a constant variance. This equation represents a first-order autoregressive process, denoted by AR(1), where k_r is the autoregressive parameter. If the errors are additive in log-space, Eq. 23 becomes

$$Q_t = k_r Q_{t-1} e^{\varepsilon t} \tag{23}$$

Vogel and Kroll (8) noted that the error structure of Eq. 23 is more representative of actual streamflow records. Base flow recession can also be interpreted as an AR(2) process:

$$Q_t = (\varphi_1 Q_{t-1} + \varphi_2 Q_{t-2})\varepsilon_t \tag{24}$$

Another way to look at recession is as an analogy with a linear reservoir where the storage–outflow relationship is assumed linear:

$$S = kQ \tag{25}$$

where S is storage, Q is outflow, and k is a constant whose dimension is time. The continuity equation for a reservoir is

$$I - Q = dS/dt \tag{26}$$

Assuming that the inflow is zero and letting $Q(t_0) = Q_0$ (the outflow at $t = t_0$) yields

$$Q_t = Q_0 \exp[-(t - t_0)/k] \tag{27}$$

Equation 2 can be written in discrete form as

$$Q_{j\Delta t} = Q_0 k_r^j = Q_{(j-1)\Delta t} k_r \tag{28}$$

where $t = j\Delta t$. Comparing Eq. 27 with Eq. 28,

$$k = -\Delta t/\ln k_r \tag{29}$$

Substituting from Eq. 27 in Eq. 26, letting $I = 0$, and integrating,

$$S_t = -Q_0/\ln k_r \tag{30}$$

DETERMINATION OF BASE FLOW RECESSION CONSTANTS

The recession constant k_r or parameters a and b can be determined in a number of ways.

Graphical Method

Constants a and b can be determined by constructing Figs. 2 and 3 and choosing any two values of discharge that satisfy the condition specified there. Note that these constants vary with the choice of discharges. Therefore, it is appropriate to obtain a number of values of a and b

and then take an average. Alternatively, one can take the logarithm of Eqs. 1–3,

$$\ln(Q) = \ln(Q_0) - t/a \tag{31}$$

$$\ln(Q) = \ln(Q_0) + t\ln k_r \tag{32}$$

$$\log(Q) = \log(Q_0) - t/b \tag{33}$$

Base flow discharge Q can be plotted against time on a semilog paper using any of Eqs. 31–33. The recession parameters can be determined by fitting a straight line to the plotted data. Alternately, one can also plot Q_{t-1} versus Q_t on a simple graph. For example, if Eq. 2 is valid, this plot will result in a straight line passing through the origin. Its slope will be k_r. Similar interpretations can be advanced for Eqs. 2 and 3. For example, Eq. 1 can be recast as

$$Q_t = Q_{t-1}\exp(-T/a) \tag{34}$$

where Q_t is the discharge at time t and T is the time interval between Q_{t-1} and Q_t. The plot of Q_{t-1} versus Q_t should give a straight line that has the slope $\exp(-T/a)$. Obviously, the slope depends on the time interval, which is commonly 1 day.

Least Squares Method

James and Thompson (9) determined the recession constants by using the least squares method. Any of Eqs. 1–3 can be used with this method. For illustration, Eq. 2 is recast as

$$Q_t = k_r Q_{t-1} \tag{35}$$

The recession constant can be estimated by minimizing the sum of the squares of the differences between the observed and computed values of discharge:

$$R = \sum_{t=1}^{N}(Q_t - k_r Q_{t-1})^2 \tag{36}$$

where N is the number of discharge values and Q_t corresponds to the observed values. To estimate k_r, the derivative of R with respect to k_r is set equal to zero to yield

$$k_r = \sum_{t=1}^{N} Q_t Q_{t-1} \Big/ \sum_{t=1}^{N} Q_{t-1}^2 \tag{37}$$

Statistical Methods

The recession constants can be estimated by the method of moments. Only one parameter is to be estimated, so the first moment about the origin will suffice. Again, any of Eqs. 1–3 can be used. To illustrate, consider Eq. 1. Let $M_1(Q)$ be the first moment of Q about the origin. Then,

$$M_1(Q) = \int_0^\infty tQ_0\exp(-t/a)dt \Big/ \int_0^\infty Q_0\exp(-t/a)dt = a \tag{38}$$

Thus, recession constant a for a given base flow sequence is equal to the first moment of that sequence about its origin.

If Eqs. 22 or 24 are treated as regression equations, the least-squares method can be used to estimate the recession constant. For the AR(1) model given by Eq. 22, the ordinary least squares estimate of k_r is

$$k_r = \frac{\sum_{t=1}^{n-1} Q_{t+1}Q_t}{\sum_{t=1}^{n-1} Q_t^2} \tag{39}$$

where n is the total number of consecutive observations for a site.

While comparing the various techniques to estimate recession constants, Vogel and Kroll (8) found that the recession constant obtained by treating the base flow as an AR(2) process that has an additive residual in log-space (e.g., Eq. 24) led to a regional regression model of low-flow statistics that has the highest R^2, lowest standard error, and highest t-ratios of model parameter estimates.

MASTER BASE FLOW RECESSION CURVE

The master base flow recession curve is a composite recession curve that represents mean recession behavior. Of course, the information about recession variability is lost in the process. This curve can be constructed in several ways (7); the most popular are experimentation and the correlation method.

Experimentation involves observing the discharge at a number of time intervals encompassing the entire dry-weather period. These are then plotted against time on semilog paper, and a best fit straight line is drawn through the plotted points. The resulting curve is a recession curve.

The correlation method involves plotting the discharge for the initial day of each segment on log-log paper, starting with the largest discharge, against discharge T time units later (where $T = 1/2$, 1, 2, 5, etc.). Plotting is continued for as many segments as possible until a good correlation is established for drawing a line. The points above the line represent surface flow and those below it represent recession.

Algorithms for Selecting Recession

The beginning of a recession segment can be a fixed discharge or a variable. A fixed value restricts the domain of recession analysis to flows less than that value. The beginning may also be specified as a certain time after the rainfall or after the peak of the hydrograph. Sometimes, some initial values are ignored to minimize the influence of surface flow, and some values near the end may be ignored to obviate the influence of the next storm.

Vogel and Kroll (8) describe an automatic hydrograph recession selection algorithm to separate the recession part from the discharge data. In this, a recession begins when a 3-day moving average begins to decrease and ends when the same begins to increase. Recessions longer than 10 days or more were identified by them.

Applications of Base Flow Recession

A major practical application of base flow recession is forecasting low flows in a river for drought management, planning drinking water supply, maintaining water quality in the river, or ecological planning. Other applications of base flow analysis are determining the relation between hydrologic and geologic parameters of a drainage basin, evaluating the effect of agricultural practices, locating suitable areas for induced infiltration, controlling withdrawal of groundwater for irrigation during low flow periods, and determining storage requirements to maintain minimum flow in rivers.

BASE FLOW SEPARATION

Base flow separation, also called hydrographic analysis, is the process of separating surface runoff from base flow. Even though such separation is somewhat arbitrary and subjective, it is useful in many analyses. Several techniques have been developed for base flow separation. Some popular techniques are described below.

Area Method

The area method of base flow separation is based on a nonlinear relation between time and area (10):

$$N = bA^{0.2} \tag{40}$$

where A is the drainage-basin area in km^2, b is a coefficient equal to 0.8, and N is the time in days from the hydrograph peak (see Fig. 4). This equation is not suitable for smaller watersheds. It generally gives a longer time base. For example, if $A = 1000$ km^2, then $N = 3.18$ days, if rainfall occurs for 6 hours, its effect will be felt for more than 3 days.

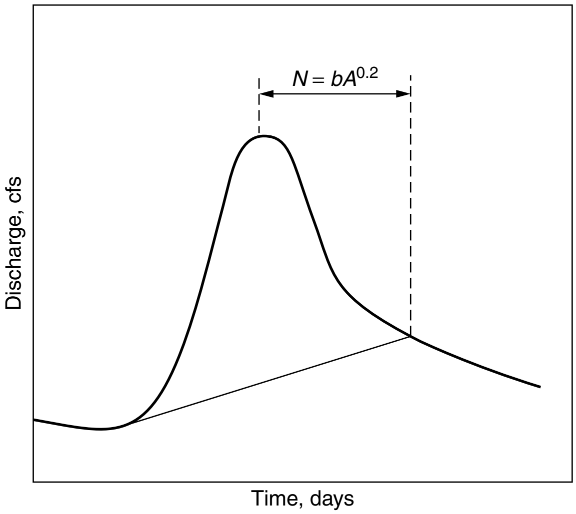

Figure 4. Base flow separation based on area.

It is convenient to draw a separation line directly from the chosen groundwater discharge on the receding limb to the point under the hydrograph peak. Although this linear separation does not represent the true boundary between direct runoff and groundwater runoff, the error may be acceptable in most cases.

Three-Component Separation

Three-component separation involves separating surface runoff, interflow, and base flow. The method, developed by Barnes (11), is based on Equation 2 and is illustrated in Fig. 5. First, streamflow recession is plotted on semilogarithmic paper. In Fig. 5, the groundwater recession plots approximately as a straight line, where $K_r = 0.992$. By extending this straight line under the hydrograph to the point directly under the point of inflection E and to B on line AB, points B and J are connected arbitrarily by a straight line. The area under the hydrograph above BJH is considered direct flow and that area below BJH is considered groundwater flow. The direct runoff is replotted, and a straight line IL where $K_r = 0.966$ is fitted and extended to point I directly under inflection point E and to the beginning point M. The line MIL divides the replotted hydrograph into surface runoff on top and interflow below.

Singh and Stall Method

Although Barnes' method has been used for quite some time, it is subjective and has many shortcomings, as pointed out by Kulandaiswamy and Seetharaman (12). Several methods have been developed to overcome these drawbacks and remove subjectivity. The method developed by Singh and Stall (13) is described here.

1. Select single peak hydrographs that are not closely followed by another stream rise.
2. Estimate the storage delay factor K_b and the range of base flow Q_b.

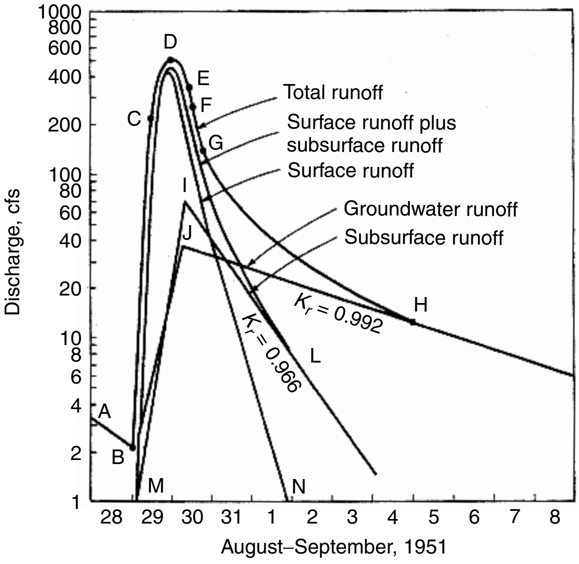

Figure 5. Three-component hydrograph separation.

3. Using an average value of K_b for the desired range of Q_b, begin at a suitable value of Q_b where the hydrograph shape suggests the end of flow from the surface runoff stored in the channel system, and compute daily values of Q_b by progressing backward in time to within 1 or 2 days of the inflection point on the hydrograph recession. Draw the straight-line base flow hydrograph.
4. Subtract Q_b from Q_T, the total discharge and plot the $(Q_T - Q_b)$ hydrograph on a semilog paper. Draw a best fit straight line.
5. Draw a few $(Q_T - Q_b)$ hydrographs by using slightly higher and lower values of K_b. The value of K_b that makes the $(Q_T - Q_b)$ plot nearest to a straight line is adopted. The straight line is denoted as the Q_s line, and the number of days for Q_s to drop in amount by one log cycle is the value of K_s in days.
6. Compute $(Q_T - Q_s)$ by starting a few days after the inflection point on the Q_T hydrograph, and obtain the base flow hydrograph. Note the time in days T_b by which the base flow peak lags behind the hydrograph peak.
7. Analyze a number of hydrographs to obtain sets of values of K_b, K_s, T_b, and the range of Q_b for which a particular K_b is suitable.
8. Draw base flow recession curves for both growing and dormant seasons.
9. Compute values of Q_s using different values of K_s. Add Q_b and Q_s to get Q_T. Draw traces of total hydrograph recessions by starting from various points on the base flow recession curve. The Q_T recessions will define the average limits within which actual Q_T recessions will lie.

Base Flow Separation using Digital Filters

Graphical methods of base flow separation are inconvenient for processing a long streamflow record. Digital filters are helpful in such situations. Basically, streamflow is partitioned into two components:

$$Q(i) = Q_l(i) + Q_h(i) \tag{41}$$

where $Q_l(i)$ is the low-frequency component and $Q_h(i)$ is the high-frequency component. The first can be interpreted as base flow and the second as overland and quick interflow.

A filter employing the two-parameter algorithm of Boughton (14) assumes that base flow at the current time is a weighted average of the direct runoff and the base flow at the previous time interval. Let $Q_b(i)$ and $Q(i)$ be the base flow and total streamflow for the time interval i. Then,

$$Q_b(i) = [p/(1 + C)]Q_b(i - 1) + [C/(1 + C)]Q(i) \tag{42}$$

subject to

$$Q_b(i) \le Q(i)$$

where p and C are the parameters of the model; p can be interpreted as a recession constant. The two-parameter algorithm was found the most satisfactory by Chapman (15). In this case, the parameters have less effect on the BFI (base flow index which is the ratio of the long-term ratio of base flow to total stream flow) than other models. Furey and Gupta (16) developed a filter from a physical point of view.

Chemical and Isotopic Techniques

Chemical and isotopic tracers provide another means to separate a hydrograph into components. An additional advantage of this method is that one can also identify the spatial source of water. The technique has been applied in many studies (17,18). However, its use in base flow separation requires elaborate field work and laboratory analysis that is time-consuming and expensive.

RIVER BASINS

Stefano Pagliara
Francesca Dellacasa
Università di Pisa
Pisa, Italy

RIVER BASIN DEFINITION AND DELINEATION

A river basin (also called drainage basin, watershed, or catchment) is the area that provides runoff to a given section of a stream and is separated from adjacent basins by a divide. All surface runoff produced by precipitation that falls within the area is discharged through the lowest point in the divide.

Basins are delineated on topographical maps, integrated if necessary with aerial photographs or field survey; a line is drawn that encloses all drainage lines and depressions in the basin and passes through the highest points. It is assumed that the movement of groundwater follows the surface divides, but in areas characterized by a particular geologic structure, it is possible that the phreatic divide does coincide with the topographic divide; large amounts of water could be transported below the surface from one basin to another. In this case, the groundwater divide needs to be determined by hydrogeologic prospection.

A river basin is generally considered the fundamental unit for geomorphologic and hydrological studies; it can be treated as an open system that receives energy from the climate (input) and loses energy by evapotranspiration to the atmosphere and by stream flow and sediment yield through the basin mouth (output) that determine storage changes in groundwater and soil moisture (Fig. 1).

A river basin may be described by a Geographic Information System (GIS) combined with a digital elevation model (DEM). A GIS is an electronic system of maps connected to tables of data that describe the features on the maps; a DEM represents a spatial distribution of elevations. The DEM can be structured by a square-grid network, a contour-based network, or a triangulated irregular network (TIN) (1). In a raster-based GIS, the basin is subdivided into uniform grid cells; to each of these cells, numerous attributes relative to basin characteristics can be attached. The GIS system is a useful tool for automating much of the geometric data acquisition necessary for hydrologic analyses (2). A raster-based GIS is well suited to the application of hydrologic rainfall–runoff models based on distributed parameters. Alternatively, the GIS procedure allows computing average basin parameters for the entire watershed that are necessary as input in lumped parameter hydrologic models.

BASIN CHARACTERISTICS

A river basin is composed of several subsystems: the drainage basin itself in its areal extent, and the channel system, in which by a further subdivision, we can distinguish the channel cross section, the channel reach, and the channel network. It is important to describe the river basin in quantitative terms to understand the processes and to analyze the interrelationships existing among these characteristics.

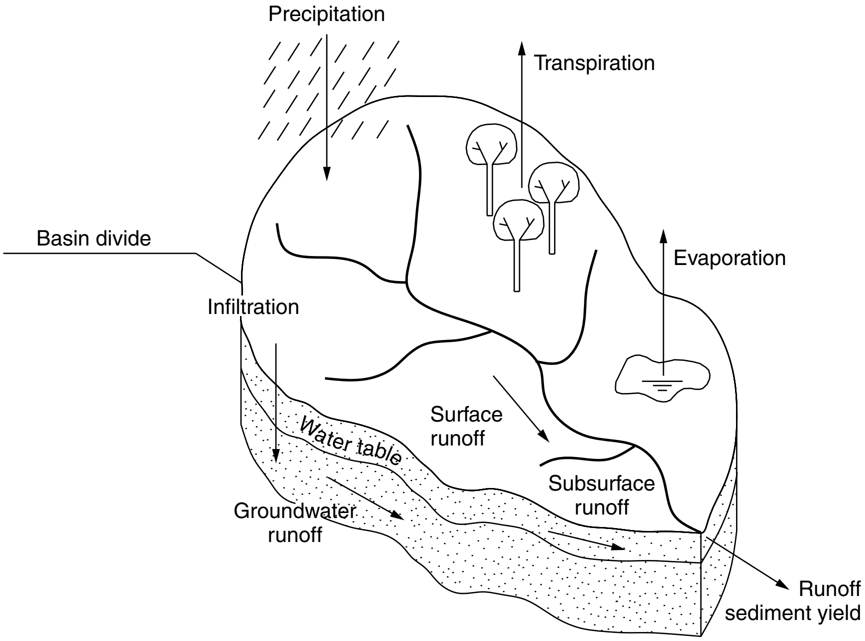

Figure 1. River basin.

Drainage Basin

A river basin's characteristics can be subdivided into topographic, rock and soil, vegetative and land use, and climatic characteristics.

Topographic Characteristics. Topographic characteristics directly influence the transport of water and sediment within a basin. Topographic attributes may be described by index of area, length, shape, and relief.

Basin Area. The area of a drainage basin is the area enclosed by the curve obtained by projecting the basin divide on a horizontal plane. This represents its most important physical parameter because it is correlated with almost every other characteristic, but for this reason it is not always easy to interpret its significance.

Empirical relations between stream discharge Q and basin area A assume the form,

$$Q = aA^b \tag{1}$$

where Q represents some index of stream flow such as the mean annual flood (3). The value of exponent b generally varies from 0.5 to 1.0. Stream flow per unit area is inversely proportional to area because intense precipitation tends to occur on a restricted area. Sediment yield per unit area in many regions, it has been found, is inversely proportional to basin area. Erosion is predominant in small basins, whereas in large basins, there are, in proportion, more locations for temporary sediment storage.

Basin Length. Basin length is usually defined as the length of the mainstream measured along the main channel from the outlet to the basin divide. Length is closely related to area, and a large number of rivers seem to satisfy the relation expressed by Hack:

$$L = 1.4A^{0.6} \tag{2}$$

where L is the stream length in miles and A is the area in square miles (4). The exponent 0.6 suggests that geometric similarity is not preserved as a river basin increases in area because A/L^2 decreases and the basin tends to elongate, becoming longer and narrower.

Basin Shape. The basin shape normally tends to a pear-shaped ovoid, but many substantial deviations from this shape due to geologic constraints have been observed. Several parameters have been proposed to describe basin shape. The form factor F is defined as what is F?

$$R_f = \frac{A}{L^2} \tag{3}$$

where A is the drainage basin area and L the basin length.

The basin circularity compares the basin area with the area of a circle that has the same perimeter p:

$$R_c = \frac{4\pi A}{p^2} \tag{4}$$

The basin elongation is defined as the ratio of the diameter of a circle that has the same area as the basin to the basin length:

$$R_e = \frac{2\sqrt{A}}{L\sqrt{\pi}} \tag{5}$$

R_e assumes values from 0.6 to 0.8 in regions of high relief, and in areas of low relief, values near one have been observed. The usefulness of these shape factors has been analyzed, and the elongation ratio has proved to be the parameter best correlated with hydrology (5). The basin shape affects the stream-flow hydrograph, in particular, the lag time and the time of rise.

Relief. The hypsometric area–altitude analysis expresses the relation between basin area and elevation. It is obtained by plotting the area above a certain elevation versus the elevation itself. The shape of the *hypsometric curve* gives an indication of the basin's geologic evolution any stage in the erosion cycle. The hypsometric curve is useful if hydrologic variables such as precipitation or evaporation, which vary with altitude, are studied.

The *mean basin elevation* can be obtained by integrating of the area–elevation curve and dividing the result by the drainage area; the median elevation is defined as the elevation that corresponds to 50% of the drainage area.

The *maximum basin relief* is the elevation difference between the highest point on the basin perimeter and the basin outlet.

The *basin slope* is a major factor in the overland flow process, and several methods have been developed for determining its average value because of the variation in land–surface slope throughout the basin. In the grid-square method, a grid of uniformly spaced lines is established over a map of the basin, and the slope of a short segment of line normal to the contours is determined at each grid intersection. The basin slope is then calculated as the mean of the resulting local slopes. In the random-coordinate method, the procedure is the same except that the points where the local slope is evaluated are randomly located over the basin (4). Basin slope can also be determined by measuring the total length L_{tot} along contours at contour intervals Δz and calculating the average value:

$$i = \frac{\Delta z L_{\mathrm{tot}}}{A} \tag{6}$$

Computations by this formula are time-consuming, but by introducing a DEM, they become more feasible. However, using a DEM, it is also possible to calculate the slope of each individual square or triangle in a raster or TIN model, respectively, and to use these values to compute the average basin slope.

The peak discharge per unit of basin area is strongly correlated with the mean basin slope. In basins that have a high relief ratio, the lag time and time of hydrograph rise are shorter, and the peak discharge rate is higher (Fig. 2A). Sediment erosion that takes place mainly during peak stream flow is also correlated with basin relief.

Rock and Soil Characteristics. Rock and soil characteristics determine the rate of rainfall infiltration into the soil

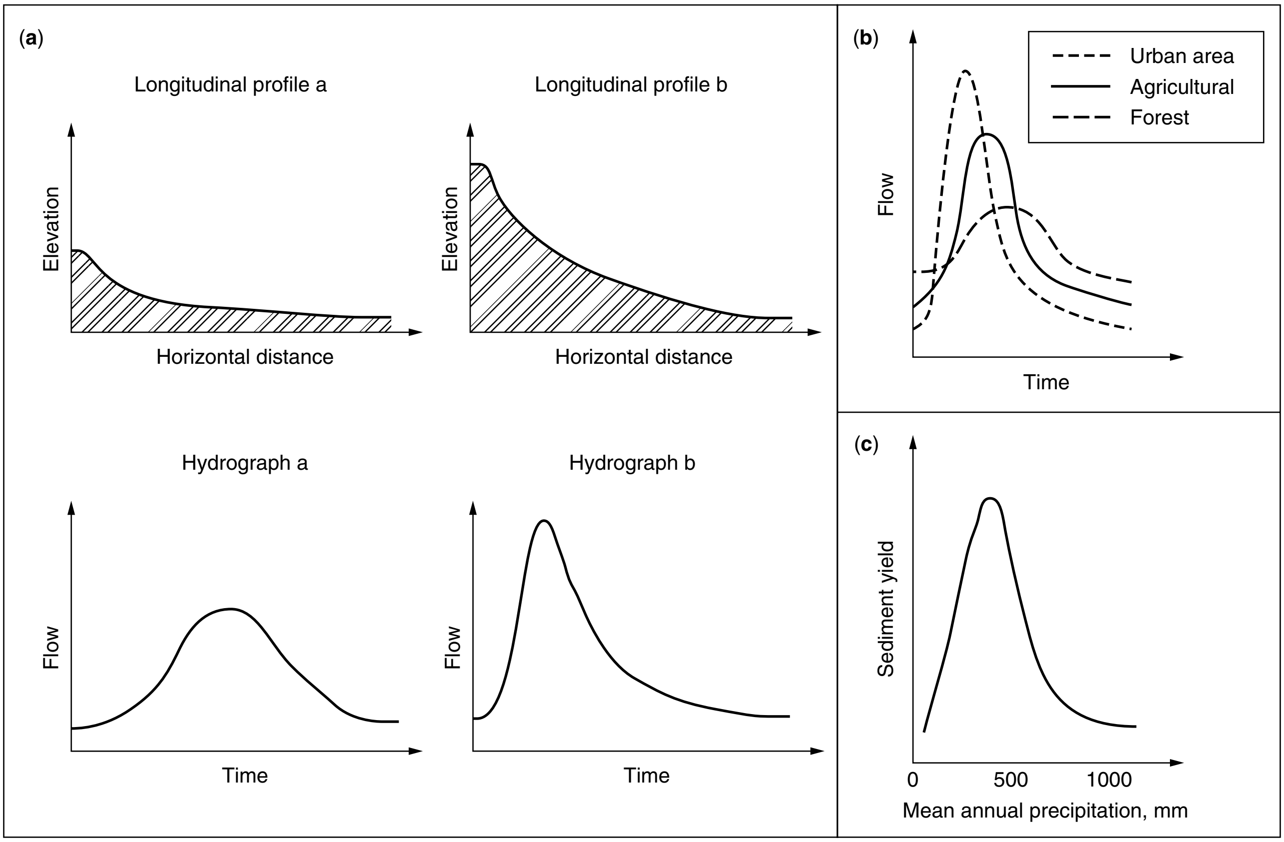

Figure 2. Influence of relief (**a**) and vegetative cover (**b**) on runoff and influence of climatic characteristics (**c**) on sediment yield.

and thus affect runoff. The character of the rock beneath the basin with regard to these processes can be expressed by porosity and permeability. *Porosity* is the percentage volume of voids in a material and is a measure of the amount of water that can be retained by a deposit; *permeability* provides an index of the ability of a material to transmit water and is a function of soil texture, grain size, density of grains, and particle shape. The Soil Conservation Service has classified most soils into four hydrologic soil groups A, B, C, and D, dependent on their infiltration rate (6):

— group A: deep, well-drained sand;
— group B: sandy loam;
— group C: clay loam;
— group D: clay soils of a high swelling potential.

The geology of a basin affects the type and the amount of material available for erosion and transport. The extent of removal and transport of sediment is influenced by the physical and chemical properties of the rock. The vulnerability of soils to weathering can be evaluated by several indexes of soil erodibility which depend upon particle size, moisture content, permeability, dispersion properties of the soil and shear resistance.

Vegetation and Land Use Characteristics. Vegetative cover is a significant factor influencing drainage basin dynamics because it affects the amount of net precipitation that reaches the ground surface through interception, evapotranspiration, and infiltration, and also the water and sediment rate produced by the basin.

Interception losses are given by the sum of precipitation retained on vegetative surfaces such as leaves, stems, and tree trunks. The amount of water captured by vegetation depends on the amount of leaf cover; the type, age and density of vegetative cover; seasonal variations; the amount, duration, and intensity of precipitation; and antecedent moisture conditions.

Vegetative cover also determines losses by evapotranspiration, which is the combination of evaporation from plant surfaces and transpiration of water from plants. Evapotranspiration is related to plant characteristics and environmental conditions, such as atmospheric pressure and moisture, air temperature, wind speed, soil moisture, and light intensity.

The effect of vegetative cover is also displayed by an increase in soil infiltration capacity due to the resistance afforded by vegetation, which slows down overland flow and thus allows the water to have more time to enter the soil surface and flow to the plant roots which make the soil more previous to infiltrating water. The type and density of vegetation, the presence of plant litter on the soil surface, and the depth and density of roots may influence infiltration dynamics.

The vegetative cover influences stream-flow runoff in a basin (3). As the vegetation extent decreases, passing from forested areas to agricultural land and further to urban areas, the range of flows between peak and low flows becomes wider, and the peak discharge is amplified and occurs earlier (Fig. 2B).

Sediment production by erosion depends on land use character, especially cover density. Vegetal cover has a protective influence against erosion processes. A dense cover such as grass reduces the flow velocity and operates simultaneously as a protection covering the underlying soil. Sediment production is maximum from cultivated land, decreases in pasture land, and is minimum in forest and wild land.

Climatic Characteristics. Climatic characteristics govern the amount of water received at the surface. Sediment yield is broadly correlated with mean annual precipitation (7). Maximum values occur in semiarid areas, where the proportion of precipitation available for surface runoff and therefore for erosion is greater. In more arid and more humid areas, sediment production decreases because of the reduced runoff potential and the increase in vegetative cover, respectively (Fig. 2C).

Channel System

Channel Cross Section. The shape and size of alluvial channel cross sections are strongly correlated with stream discharge. Numerous relationships that express the variation in channel characteristics, such as top width, mean depth, mean velocity, slope, with discharge at a particular section and between cross sections have been developed (9). As discharge increases downstream, surface width and mean depth tend to increase, whereas slope decreases. Downstream variations in channel form are influenced by local factors such as type and quantity of sediment load, rock type, superficial deposits, and vegetative cover. Thus, quantitative relationships between hydraulic geometry and discharge may be applied only locally in the same region where the data from which the equations are derived have been obtained, for example, to estimate stream flow from channel measurements in a site where no stream-flow records are available.

Channel Reach

Channel Slope. The slope of the principal drainage channel can be estimated by several methods (Fig. 3A). The simplest method consists of dividing the difference in elevation between the source and the mouth by the length of the channel (Definition 1). The slope can also be determined by calculating the slope of a line drawn on the channel profile through the lowest point such that the area under it equals the area under the profile curve (Definition 2). Channel slope affects flow velocity, travel time, and sediment transport capacity, so it influences water and sediment routing through the basin.

Channel Patterns. River channel patterns have been classified into meandering, braided, and straight (Fig. 3B).

A channel is meandering where it assumes the form of a number of loops or bends. The *sinuosity* is the ratio of channel length to valley length and has an average value of 1.5. Meander wavelength and amplitude range

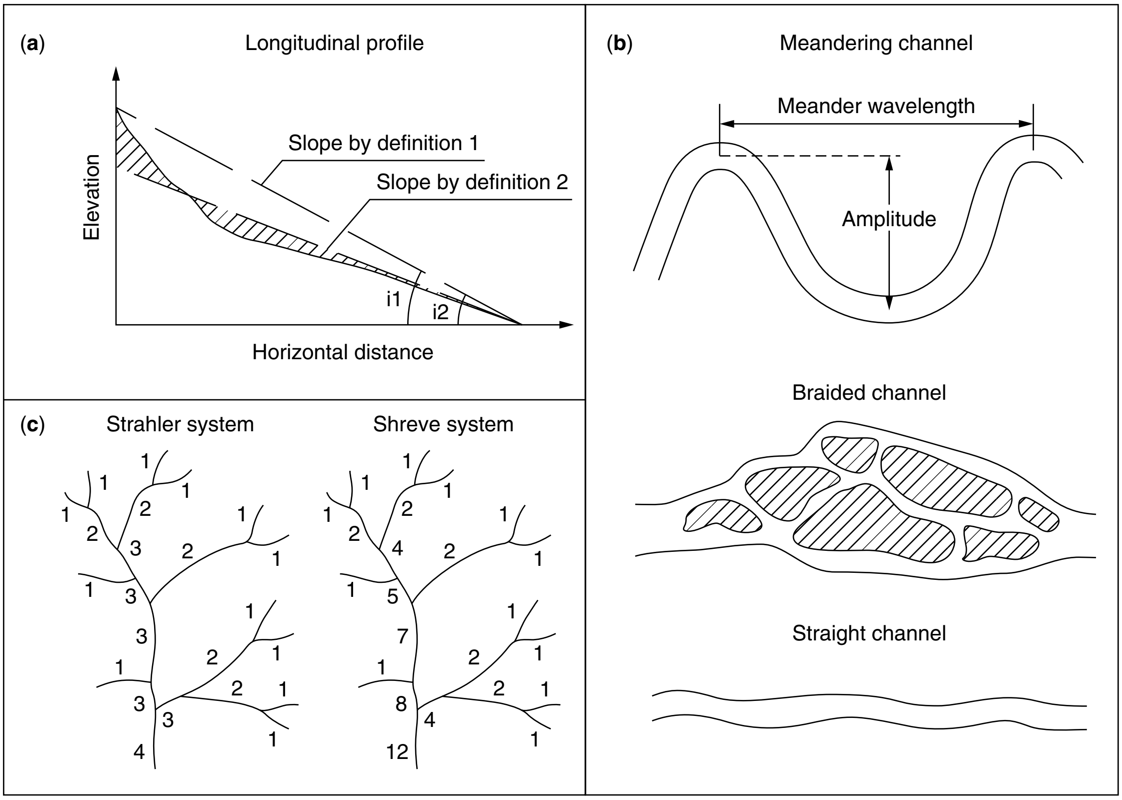

Figure 3. Channel system: (**a**) Channel slope definition; (**b**) channel pattern description; (**c**) stream order designation.

from 7 to 10 and from 3 to 20 times the channel width, respectively (7). Meander wavelength has proved to be strongly correlated with discharge. A channel is braided where the stream bifurcates into two or more intertwined channels separated by islands or bars. Braided channels are characterized by wide, shallow beds of coarse material. The factors that contribute to the development of braided channels are essentially bed-load availability, irregularity of stream flow, intense precipitation which causes high peak discharges, and high slopes (3). Perfectly straight channels are seldom found in nature, so the definition of straight channel has been extended to a channel whose sinuosity is less than 1.25.

Channel Network

Drainage Density. The density of a channel network is the total length of channels per unit area. Values of drainage density observed range from 1 to 248 km/km^2. High density is observed in basins that have weak and impermeable rocks, sparse vegetation, and a steep relief. Network density depends on climatic characteristics, and it varies with mean annual precipitation in the same way as sediment yield because high sediment delivery corresponds to a well-developed channel network. Drainage density is inversely related to precipitation-effectiveness Thornthwaites index P-E which adjusts monthly precipitation by a function of monthly average daily temperature to account for evapotranspiration losses (4). This relation shows the effectiveness of vegetative cover in erosion control. Other basin characteristics such as lithology and land use, and in particular, rock permeability, influence drainage density because they affect the infiltration–runoff rate. Network density is an important factor in the formation of flow. As it increases, peak discharge per unit area increases, and time-to-peak decreases, so that a basin that has a high drainage density is characterized by an efficient drainage system and rapid hydrologic responses.

Stream Order. A channel network may be described by designation of a stream order using with one of the systems developed by Strahler and Shreve to determine the position of a stream in the hierarchy of tributaries (Fig. 3C). In the Strahler system, all fingertip tributaries have order one; two first-order channels joining produce a second-order segment, and so on; if two channels of different order join, the resultant link has the order of the tributary of higher order. In the Shreve system, all fingertip tributaries have magnitude one, and each downstream channel segment has a magnitude equal to the sum of all the first-magnitude segments that are tributary to it. The basin order is a measure of the branching within the basin and is related to the size of channel network and to the amount of stream flow. Stream order is very sensitive to map scale which should always be specified together with the method of ordering used. The Strahler method is the most widely used method today, especially combined with the laws of drainage composition, whereas the Shreve method gives a description of a drainage network closer to physical reality with regard to stream discharge.

Horton's laws of drainage composition relate stream numbers, stream lengths, and drainage areas to stream order by simple geometric relationships (4). The bifurcation ratio R_B is defined by

$$R_B = \frac{N_u}{N_{u+1}} \tag{7}$$

where N_u is the number of streams of a given order and N_{u+1} is the number of the next higher order. Bifurcation ratios tend to be constant in a given basin and assume characteristic values between three and five. The law of stream numbers is expressed by

$$N_u = R_B^{k-u} \tag{8}$$

where k is the highest order within the basin. Similarly, the laws of stream lengths and drainage areas indicate a geometric progression of order:

$$\overline{L}_u = \overline{L}_1 R_L^{u-1}, \overline{A}_u = \overline{A}_1 R_A^{u-1}, R_L = \frac{\overline{L}_u}{\overline{L}_{u-1}}, R_A = \frac{\overline{A}_u}{\overline{A}_{u-1}} \tag{9}$$

where L_u is the mean length of streams of order u, A_u is the mean area of basins of order u, R_L is the length ratio, and R_A is the area ratio, whose ranges of values are 1.5–3.5 and 3–6, respectively.

An alternative model has been proposed by Shreve using the probabilistic–topological approach. It assumes that in the absence of climatic and geologic constraints, channel networks evolve at random; all topologically distinct channel networks (TDCN) of a given magnitude are equally probable (5). Shreve used the term "link" for stream segments between nodes (sources, junctions, or outlet) and distinguished exterior links, which extend from a source to the first junction, from interior links, which connect two successive junctions or the last junction with the outlet. Furthermore, he assumed that exterior and interior link lengths are random variables whose separate probability distributions are independent of position within the basin. Shreve showed that the most probable network in a random population closely conforms to Horton's law of stream numbers.

More recently a new approach has been developed for analyzing drainage network composition, which shows that river basins have a self-similar organization, that is, the same shape is found at another place in another size. This property can be interpreted by Mandelbrot's fractal theory which introduces fractals as irregular geometric shapes that have identical structure on all scales (8).

RIVER BASIN PLANNING AND COORDINATION

Peder Hjorth
Lund University
Lund, Sweden

A river basin is a functional entity where water is the integrating factor. What happens in one location will impact any downstream location. Sometimes there are upstream impacts as well, for instance, backwater effects upstream of a dam. Thus, water management must be coordinated and concerted to result in desired outcomes in different parts of a drainage basin. To this end, there is a need for effective communication across institutional and disciplinary boundaries.

As stated in Agenda 21 [a wide-ranging blueprint for action to achieve sustainable development worldwide). Adopted by United Nations Conference on Environment and Development (UNCED), Rio de Janireo, June 3–14, 1992.], freshwater is a unitary resource. Long-term development of global freshwater requires holistic management of resources and recognition of the interconnectedness of the elements related to freshwater and freshwater quality. Failures in these respects have resulted so that there are few regions of the world that are still exempt from problems of loss of potential sources of freshwater supply, degraded water quality, and pollution of surface and groundwater sources.

In chapter 18 of the Agenda, current wisdom concerning water management is summarized, and it is stated that freshwater resources are an essential component of the earth's hydrosphere and an indispensable part of all terrestrial ecosystems. Water is needed in all aspects of life, and the general objective of water management is to make certain that adequate supplies of water of good quality are maintained for the entire population of this planet, while preserving the hydrologic, biological, and chemical functions of ecosystems.

It is pointed out that the extent to which water resources development contributes to economic productivity and social well-being is not usually appreciated. Thus, a spreading scarcity, gradual destruction, and aggravated pollution of freshwater is allowed to go on without much attention from responsible agents/institutions. A major problem is the fragmentation of responsibilities for water resources development among sectoral agencies such as those concerned with water supply and sanitation, agriculture, industry, urban development, hydropower generation, inland fisheries, transportation, recreation, and low- and flatland management.

In addition, different, but inherently linked aspects of catchment management, such as water quality, water quantity, and the processes of erosion and deposition, are frequently managed by different institutions. Often, there is also a division of responsibility for surface water issues and groundwater issues, respectively. These aspects need to be coordinated if we are to create the synergy needed to achieve the desired water status. Coordination is needed at both the political and technical levels.

An important starting point is that water should be managed at the river basin level and be seen as an integral part of the ecosystem, a natural resource, and a social and economic good, whose quantity and quality determine the nature of its use.

Efficient coordination is essential for the dynamic, interactive, iterative, and multisectoral approach called for. The holistic management of freshwater as a finite and vulnerable resource urgently calls for integrating sectoral water plans and programs within the framework of national economic and social policy. Various levels of complexity should be recognized when coordinating activities by different agents or organizations. Simplistic solutions should be avoided.

Four basic requirements can be identified:

1. management of the whole resource;
2. clear links between catchment functions;
3. emphasis on prevention and mitigation rather than responses;
4. adoption of multifunctional win–win solutions.

Water management should take into account long-term planning needs as well as those with narrower horizons. The long-term need should be related to the principle of sustainability; the more short-term objectives would be focused on the prevention and mitigation of water-related hazards.

The International Conference on Freshwater in Bonn, 2001, stated that water management arrangements should take account of climate variability and expand the capacity to identify trends, manage risks, and adapt to hazards such as floods and droughts. Anticipation and prevention are more effective and less expensive than having to react to emergencies. Early warning systems should become an integral part of water resources development and planning. It was also stated that systematic efforts are needed to revive and learn from traditional and indigenous technologies (for example, rainwater harvesting) around the world.

Closer links should be established between development and disaster management systems. Exposure to flood risks should be minimized through wetland and watershed restoration, better land use planning, and improved drainage. The greater fluctuation in resource availability associated with presumed climatic changes is causing concern, as many regions experience increasingly severe flooding and/or drought problems. The solutions to some of these problems can be sought locally, whereas others have to be dealt with in international forums.

Thus, the scale of issues must be understood to allow for a prioritized approach. Often, issues are perceived differently by different groups of people, and myths about their severity are legion. For instance, within basins embracing several nation states, the attitudes of those states in the headwaters is typically different from the attitudes of the states in the lower reaches of the river. Headwater states do not wish to be held to guarantees of water quantity or of water quality demanded by their downstream neighbors. Downstream countries are, very naturally, concerned about the prospects of any upstream dam construction which may affect the regime or total quantity of flow, especially by major diversions of water into or out of the basin (1).

With regard to existing uncertainty and lack of precise knowledge, it is essential to monitor continuously and evaluate what happens to water quality and quantity at key points and to make sure that the information gained is made available to those who need it, when they need it.

Strategies and programs need to be tied to indicators that enable actors to assess progress. As we are swamped by a wealth of information, a major problem is that we have difficulties in discriminating between information, useful knowledge, and science. Therefore, it is essential to have few but relevant indicators of high explanatory value. Jiménez-Beltrán (2) claims that efficient indicators should

1. show development over time and be policy relevant (there should be an explanation why a specific indicator has been developed);
2. be few in number and people should get used to their presentation and understand the message;
3. be closely linked to objectives to become efficient tools in decision-making.

In the United Kingdom, local Agenda 21 efforts show that indicators work best when they are developed in participatory ways. In communities of all kinds, "everyday experts" are getting involved in the monitoring and evaluation process, and results are starting to change policy (3).

On a more conceptual level, Brown (4) suggests that to be efficient, indicators should be

1. holistic—measuring if the catchment is worked with as a whole;
2. cooperative—measuring the degree of working together with shared responsibilities;
3. composite—measuring the degree of inclusion of the full range of diverse elements and the degree to which elements have been arranged to fit together;
4. coordinated—assessing the mechanisms for continuing cooperation; and
5. long term—assessing the durability of relationships and processes and assessing the progress toward a shared vision.

Basic to all activities is a baseline assessment. We have to know where we start from before we can decide how to go to the desired conditions. Such assessment, including the identification of potential sources of freshwater supply, comprises the determination of sources, extent, dependability, and quality of water resources and of the human activities that affect those resources. It is a prerequisite for evaluating the possibilities of water resources development. There is, however, growing concern that, in a time when more precise and reliable information is needed, hydrologic services and related bodies are less able to provide this information, especially concerning groundwater quantity and quality.

In most places, there is a need to strengthen the institutional arrangements for water assessment. This is not just about efficient collection of data, but also about processing, storage, retrieval, and dissemination to users of information about the quality and quantity of available water resources at the level of catchments and groundwater aquifers.

Prior to such strengthening, it is necessary to prepare catalogues of the water resources information collected and/or held by government services, the private sector, educational institutes, consultants, local water-use associations, and others. It is essential to build on what exists by strengthening and coordinating the different bodies involved in the collection, storage, and analysis of the relevant data.

There is a need to strengthen the technical support by installing additional observation networks, developing systems for data storage, and systems for data retrieval. However, strengthening of the human resource base in numbers and skills seems to be equally important.

BIOACCUMULATION

Zhi-Qing Lin
Southern Illinois University at Edwardsville
Edwardsville, Illinois

Bioaccumulation is a process by which a chemical from the environment accumulates in an organism's body over time. Bioaccumulation occurs when there is a concentration increase of the chemical in the tissues of an organism.

Bioaccumulation results from mass equilibrium where the uptake of a chemical into the body of an organism exceeds the elimination of the chemical from the body. As such, a chemical that is eliminated immediately after uptake will not be bioaccumulated in an organism.

Uptake of a chemical means entrance of the chemical into an organism primarily from water or soil, directly or through consumption of foods that contain the chemical. A chemical can be taken up through roots or leaf surfaces in plants and by breathing, ingesting, or absorbing through the body surface in animals. Uptake of a chemical in plant cells can occur against its electrochemical potential gradient through the process of active transport. For example, selenate ($SeO_4{}^{2-}$) and arsenate ($AsO_4{}^{2-}$) are taken up via sulfate and phosphate transporters in the root plasma membrane, respectively.

The elimination of a chemical from an organism includes excretion and/or metabolism of the chemical. Elimination is the primary process by which an organism can reduce its chemical burden. Excretion is the removal of toxicants or excess chemicals from the body of plants or animals. A chemical taken up into the body of an animal can be eliminated by urination and defecation, whereas salt-tolerant halophytes can excrete sodium and other ions from their leaf surfaces.

A chemical can also be eliminated from an organism by transforming the original chemical into a new chemical, a process termed metabolism. Inorganic selenate can be taken up and biologically reduced or methylated into organic selenium compounds that can be volatilized into the atmosphere (1). Metabolism can also break down a large organic compound into small molecules or eventually mineralize the compounds into water, CO_2, and nutrients. Metabolism of an organic compound by an organism is termed biodegradation.

An organism's ability to take up or eliminate a chemical varies among species and depends on physiochemical properties of the chemical. Chemicals that are water-soluble will be taken up and readily eliminated by an organism. Persistent organic compounds are generally not water-soluble and are difficult for organisms to metabolize or degrade. These compounds tend to have a greater potential to accumulate in fat or lipid tissues.

Bioaccumulation can sometimes substantially increase the concentration of a chemical in the tissues of an organism. When the concentration of a chemical becomes higher in an organism than in the environment (e.g., water, soil, or air), the bioaccumulation process is specifically termed bioconcentration. The extent of bioconcentration can be expressed by the bioconcentration factor ($BF = C_{org}/C_{env}$), which is a ratio of the concentration of a chemical in an organism (C_{org}) to the concentration of the same chemical in the living environment (C_{env}). If a plant species can accumulate an exceptionally high level of a metal (e.g., about 1% dry weight for zinc and manganese or 0.1% for copper and nickel in shoots) without having harmful effects, the species is termed a metal hyperaccumulator. *Astragalus bisulcatus* is a selenium hyperaccumulator that can accumulate about 0.5% (dry weight) of selenium in shoots.

A chemical that is bioconcentrated/bioaccumulated is not homogeneously distributed in the body of an organism. Distribution of an accumulated chemical varies significantly among tissues/organs, species, and chemicals. For instance, fat-soluble chemicals (e.g., polychlorinated biphenyls—PCBs) accumulate primarily in fat, cadmium in kidneys, and mercury in livers. Such organ-specific accumulation of a chemical may impose a potential hazard to an organism because the chemical can reach a critical body burden in those target organs. This can even occur in organisms that are exposed only to low levels of a toxicant in the environment.

Plant roots generally accumulate higher concentrations of metals (e.g., lead and manganese) than shoots. The distribution of a chemical in a plant can be described by its translocation factor ($TF = C_{shoot}/C_{root}$), the ratio of the concentration of the chemical in shoots (C_{shoot}) to the concentration in roots (C_{root}). A larger translocation factor means that a greater proportion of the chemical is accumulated in shoots compared to that in the roots. Similarly, the ratio of the shoot concentration (C_{shoot}) to the soil concentration (C_{soil}) of a chemical is termed the phytoextraction coefficient ($FC = C_{shoot}/C_{soil}$). Phytoextraction is one of the phytoremediation approaches using plants to remove toxicants from contaminated waters and soils. Plants with high phytoextraction coefficients can remove a large amount of pollutant by harvesting the chemical-laden shoots at contaminated sites.

One of the important environmental concerns associated with bioaccumulation is biomagnification, whereby the concentration of a chemical increases at each higher trophic level through a food chain. Biomagnification can result in a concentration increase of two to three orders of magnitude between two trophic levels. Therefore, due to biomagnification through the entire food chain, the concentration of a chemical in top predators may reach tens of thousands times the concentration in the water column. For example, through a water–plankton/algae–fish food chain at the Kesterson reservoir in Central California, selenium in fish was biomagnified 35,000 times from selenium-contaminated drainage water. Very high concentrations of selenium result in reproductive deformities and death of fish and waterfowl (2).

The term bioaccumulation is sometimes used to refer to the total amount of a chemical accumulated in the body of an organism. The amount of a chemical accumulated in an organ or tissue depends on both the chemical concentration and the actual biomass in which the concentration is determined. For example, a higher bioconcentration of selenium in *Astragalus bisulcatus* does not necessarily mean that a greater total amount of selenium from the environment can be accumulated in the plant because the species grows slowly and the total biomass production is small. To overcome such biological limitations, scientists are currently applying new biotechnology to combine the genome of a tolerant, slow-growing, selenium hyperaccumulator, such as *Astragalus*, with that of a less tolerant, but fast growing nonhyperaccumulator, for example, *Brassica juncea*, to develop a somatic hybrid plant that could increase the phytoremediation potential (3).

BIOTIC INTEGRITY INDEX TO EVALUATE WATER RESOURCE INTEGRITY IN FRESHWATER SYSTEMS

Lizhu Wang
Brian B.Weigel
Wisconsin Department of
Natural Resources
Monona, Wisconsin

Many varied and complex environmental problems, particularly row crop and grazing agriculture, urbanization, highway building, timber harvesting, and water projects such as dams, water withdrawals, and stream channel modifications have seriously affected the health of freshwater resources in many parts of the world. The health of aquatic resources can be measured in many ways. Among them, biotic (or biological) integrity is a concept most commonly used by the public, biologists, resource managers, and policy makers to measure the status of aquatic systems.

Biotic integrity is "the capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitat of the region." This concept was first proposed by Frey (1) and later applied by Karr and Dudley (2) in discussing an ecological perspective on water quality goals.

Aquatic systems of high biotic integrity have a biological community in which composition, structure, and function have not been seriously altered by human activities. Such systems can withstand or rapidly recover from some perturbations imposed by natural environmental processes and survive many major disruptions induced by humans. Aquatic systems that lack integrity are often degraded and when further perturbed by natural or human-induced events are likely to change rapidly to an even more undesirable status.

Biotic integrity should not be confused with biotic diversity. Biotic diversity (or biodiversity) refers to "the variety and variability among living organisms and the ecological complexes in which they occur" (3). More thorough definitions include multiple organization levels (e.g., genes, species, and ecosystems) as fundamental components of biodiversity to distinguish it from the much simpler concept of species diversity (4).

Fundamental differences exist between biotic integrity and diversity. Biotic integrity refers to a system's wholeness, including the presence of all appropriate elements and occurrence of all processes at appropriate rates, whereas diversity is a collective property of system elements (5). Biotic integrity is also associated with conditions under which the biotic communities evolved, but diversity may not necessarily measure such an aspect. For example, introducing exotic species or genes from distant populations may increase local diversity, but it reduces biotic integrity. Some aquatic management activities for increasing harvestable products or services of economic value may not necessarily correlate with biotic integrity. A large amount of harvestable products in some systems may indicate low biotic integrity (6).

FACTORS AFFECTING BIOTIC INTEGRITY

Biotic communities in aquatic systems have evolved over millions of years. The environmental conditions under which biotic communities evolved can be classified into five major groups (6). The energy source group includes the type, amount, and particle size of organic materials entering an aquatic system from the surrounding terrestrial zones and internal primary production. The water quality group includes temperature, turbidity, dissolved oxygen, pH, nutrients, heavy metals, and natural and synthetic inorganic or organic chemicals. The habitat group includes substrate type, water depth, water current velocity, habitat complexity, and reproduction and hiding places. The flow regime group includes water volume and temporal distribution of floods and low flows. The biotic interactions group includes competition, predation, disease, and parasitism. Regional climate, landscape topography, geology, soil type, and watershed land-cover type largely determine the factors within these five groups. Without human disturbance, the factors in aquatic systems and their watershed conditions are in dynamic equilibrium, which operates under natural weather cycles. As such, many of these factors have natural patterns of temporal and spatial variation.

When watershed lands are converted from forest, prairie, or wetland to agriculture and urbanization, the dynamic equilibrium between the elements in an aquatic system and its watershed is broken, causing degradation in aquatic resources. Degradation is intensified by aggressive farming practices such as overapplying fertilizers, pesticides, and herbicides to improve crop yields, concentrating livestock in high densities to increase production efficiency, and channelizing streams and draining wetlands to expand agricultural acreage. Urban development further degrades aquatic resources by increasing toxicants, nutrients, and storm-water runoff, in turn, causing more frequent and severe flooding, accelerated channel erosion, and an altered stream channel and substrate composition. Agricultural and urban land-use impacts cause major changes in aquatic communities and thus, biotic integrity within the system.

WHY USE BIOTIC INTEGRITY TO MEASURE WATER RESOURCE HEALTH

The combined influences of human-induced stressors are often difficult to detect, particularly across diffuse urban areas or agricultural landscapes. For example, water quality impacts are often associated with increased surface runoff from rainstorms or snowmelt. These episodic events can be assessed only by continuous monitoring, which is expensive and time-consuming. Even from continuous monitoring, runoff volumes and characteristics tend to be highly variable, and long time-series of data are required to evaluate trends. If changes in concentrations of a pollutant are detected, its effects on the health of the aquatic ecosystem often remain unclear.

Chemical and physical criteria are insufficient to protect water resources. The earliest anthropogenic threats to water resources were often associated with human health, especially disease-causing organisms and oxygen-demand wastes. Early emphasis was on controlling these contaminants in urban areas, where effluents exceeded the natural waste assimilating capacities of water, by using chemical and physical indicators as primary regulatory tools to protect water resources; this has eliminated or greatly reduced the known-source problems. However, water resource quality and quantity continued to decline despite massive governmental regulatory efforts. Nonpoint-source pollution inputs, those originating from diffuse areas such as farm fields and parking lots, were not extensively reduced by chemical and physical criteria alone. For example, in 1986, nonpoint-source pollution affected 65% of the impaired stream length, 76% of the impaired lake area, and 45% of the impaired estuary area in the United States (7).

Biotic assemblages represent the end point of the combined influences of human-induced perturbations (8). As such, biotic indicators can provide measures of water resource health, although diffuse disturbances within a watershed, from agriculture or urbanization, have many physical and chemical effects on a waterbody. Direct measures of biotic assemblages, such as fish, aquatic insects, and algae, are cost-effective and ecologically relevant ways to assess human impacts on aquatic resources. Because the biotic assemblages consist of a variety of species that have different life histories, sensitivities to degradation, and functions in the ecosystem, they respond to a range of human disturbances. A few appropriate samples of the assemblage can provide unique insight into the condition of the aquatic system and the causes of degradation. Biotic assemblages are accurate and easily measured indicators of the overall quality or health of water resources (9).

BIOTIC INDICATORS

Numerous assemblage-level indicators are available for assessing human impacts on aquatic systems. The most commonly used and effective indicators for water resource health can be grouped into three categories: tolerance, taxa richness and diversity, and reproducing and feeding ecology. Most indicators were developed empirically, based on observed responses to a gradient of degradation, rather than experimental tests of sensitivity to a specific stressor. This approach is appropriate because human activities invariably have multiple interactive impacts on aquatic ecosystems that are often diffuse and cumulative. Although different types of indicators tend to be most sensitive to different environmental impacts, the best indicators are sensitive to most or all stressors that are typical of watershed disturbance.

Tolerance measures are based on the documented relative sensitivity of particular taxa to disturbance. The presence or abundance of taxa that have a known degree of sensitivity to a particular stress is a measure of the degree of that stress within the system. For example, Hilsenhoff (10) developed an aquatic macroinvertebrate index to assess organic pollution or the addition of excessive nutrients to a waterbody, which is a common consequence of agriculture and urbanization. Each taxon was assigned a tolerance value based on its sensitivity to organic pollution. The index was the weighted average, based on relative abundance, of the tolerance values of all of the taxa collected in a semiquantitative sample. If most of the taxa and individuals present were sensitive to organic pollution, then the index score was good, but if the assemblages were dominated by taxa tolerant of organic pollution, then the index score was poor. By their nature, tolerance measures tend to be relatively narrow in their sensitivity, but they have been strong indicators of water resource health.

Taxa richness is based upon the premise that the number of taxa is related to the amount and type of human disturbance. Diversity measures are based on the premise that both the number of taxa and evenness of the distribution of individuals among taxa are related to the amount and type of stress. Usually, richness and diversity are inversely proportional to stress, although this may not hold for “cold-water” streams where fish assemblages are dominated by salmonids. In warm-water streams, strong negative relations have been reported between watershed disturbance and both fish taxa richness and diversity, where the number of native, sensitive taxa decreased as stress increased. High natural variability in diversity scores has caused diversity measures to lose popularity, but taxa richness continues to be one of the most reliable and accepted indicators worldwide.

Reproducing and feeding ecology measures categorize organisms into groups that use similar reproduction and food resources. Multiple classification systems exist for classifying organisms by reproducing and feeding ecology, but most are based on combinations of what the animals eat, where they forage, how they acquire food, and what substrate they spawn on. Documenting the relative abundance of organisms that rely on each reproducing or feeding class reflects the habitat and food web conditions in which they live. Such measures also reflect the availability of essential life-cycle elements, energy flow, and nutrient dynamics, as well as the balance of these components between a water body and its surrounding terrestrial environment. Energy production and flow are difficult to measure directly, but biota provide surrogate measures.

MULTIMETRIC INDEXES OF BIOTIC INTEGRITY

A multimetric index of biotic integrity (IBI) combines a variety of different indicators, termed metrics, including tolerance, taxa richness, and reproducing and feeding ecology, into a single index that reflects structural, compositional, and functional attributes of an assemblage (9,11). By incorporating several different metrics, IBIs are sensitive to a wide range of human disturbances. Potential metrics are selected based on knowledge of aquatic systems, life history of the organisms, literature reviews, and historical data. The candidate metrics are evaluated and eliminated if they are not robust or show little relationship to human disturbances for the particular region and waterbody type of interest. The ability to interpret individual metrics is retained, even though the metrics are combined into a multimetric index.

An IBI must be regionally calibrated to take into account and correct for natural variation in assemblages owing to the biogeography or ecological conditions of the waterbodies. For example, it is well established that in the absence of human perturbations, larger streams tend to have more fish species than smaller streams and certain river basins have richer fish faunas than other basins because of geomorphic history. It is initially difficult to discern which factors are influencing the biotic metrics, natural environmental variability or human disturbance. Waterbodies that suffer relatively little human disturbance yet are influenced by the same regional set of natural environmental conditions (e.g., geology, climate, and waterbody type or size) are used as references to provide a baseline for comparison with waterbodies of unknown condition. Well-designed IBIs take natural differences into account and have metrics based on standards that are specific to the region and type of waterbodies for which they are intended.

Individual metric scores and final IBI values are relative to the set of reference waterbodies for a particular waterbody type and region. Test waterbody conditions are compared with a set of reference conditions to indicate their deviation from optimal conditions. Ranked scores, for example 5, 3, and 1, are assigned to each metric according to whether its value approximates, deviates somewhat from, or deviates strongly from the values expected at the reference condition. The overall index value is the sum of the ranked scores from all of the individual metrics. The highest possible score indicates a waterbody that is comparable to those that have the lowest stress within that region, and those of reduced quality have lower values. Based on the final value, one can qualitatively classify a water body as having good, fair, or poor health.

Fish Index of Biotic Integrity

Fish IBI is used worldwide and is especially popular in the United States. The IBI was first developed by Karr (12) for stream fish in the central United States. This version of IBI consists of 12 metrics that reflect basic structural and functional characteristics of fish assemblages: (1) number of native species; (2) number of darter species; (3) number of sucker species; (4) number of sunfish (excluding green sunfish) species; (5) number of individuals in sample; (6) number of intolerant species; (7) percent green sunfish; (8) percent hybrid individuals; (9) percent omnivores; (10) percent insectivorous cyprinids; (11) percent top carnivores; and (12) percent disease, tumors, fin damage, and other anomalies.

Because IBI is regionally specific, many versions of fish IBIs have been developed to meet the needs in several parts of the United States, Canada, France, Mexico, Australia, Belgium, Guinea, India, Namibia, and Venezuela. Many versions have also been adapted to specific types of waterbodies, including headwater streams, wadeable streams, nonwadeable rivers, cold-water streams, cool-water streams, lakes, wetlands, and estuaries.

During the past 20 years, fish IBIs have been broadly used to document impacts of watershed land uses on the health of streams, rivers, and lakes. One example of the studies that comprehensively evaluated the impacts of urbanization on streams using IBI was conducted in Wisconsin, United States (13). In this study, fish communities in 54 warm-water and 38 cold-water streams were sampled by electrofishing stream segments that were 35 times the mean wetted stream width or at least 100 m. Fish were sampled between late May and early August, when low stream flows facilitated sampling effectiveness and large-scale seasonal fish movements were unlikely. During sampling, efforts were made to collect all fish observed, and all captured fish were identified, counted, and then returned to the stream alive. The collected data were then entered into a computerized database, and an IBI value was calculated for each stream. The cold-water and warm-water IBI versions used here were specifically developed for the study region. The scores for both versions ranged from 0–100; higher scores indicated better stream health. One simple way to evaluate impacts of urban land use on stream health is to plot percentages of watershed urban land use against the IBI scores (Fig. 1). Some streams had very healthy conditions, and others did not. These plots indicated that at low percentages of urban land use, the stream conditions were varied. At low levels of urbanization (less than 12%), urban influences were weaker than other stressors, such as agriculture. As the proportion of urban land use increased in the watersheds, the fish IBI values decreased sharply. When land use exceeded certain levels, the stream health was consistently poor. Such a relation indicated that as urban land use increased, urbanization dominated over all other land uses and played the strongest role in influencing stream health.

Karr (12) noted several advantages of using fish IBIs to measure stream health: (1) life history information is extensive for most fish species; (2) fish communities generally include a range of species that represent a variety of trophic levels and include foods of both aquatic and terrestrial origins; (3) fish are relatively easy to identify; (4) both acute and cumulative effects can be evaluated; and (5) the general public can relate conditions of fish community to water resource health. The disadvantages of using fish as indicators include (1) seasonal and diel fish movements, (2) intensive field sampling effort, and (3) modifying the IBI for specific geographic regions and waterbody types.

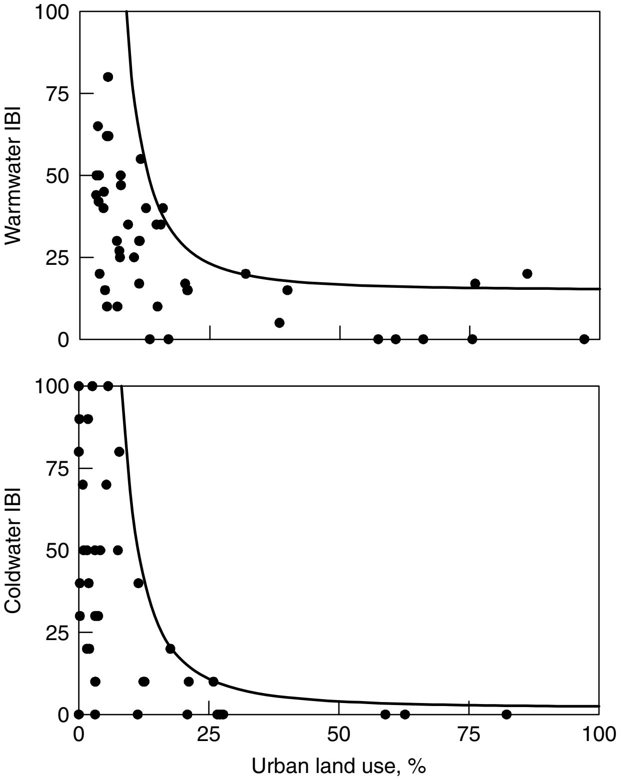

Figure 1. Relationships between watershed urban land use and fish index of biotic integrity for 54 warm-water and 38 cold-water streams in Minnesota and Wisconsin, United States. The land uses in the study watersheds are predominated by either agriculture or urban. At low level urbanization, urban influences of fish are weaker than other stressors, such as agriculture. As percentages of urban land in a watershed increase, fish IBI values decrease sharply and when urban land exceeds a certain level, the stream health is consistently poor.

Macroinvertebrate Index of Biotic Integrity

The macroinvertebrate IBI concept was extended from fish IBI and has been widely used in streams, rivers, and wetlands in North America. One of the early macroinvertebrate IBIs was developed for streams in Ohio, United States (14). This IBI, called the Invertebrate Community Index (ICI), consisted of 10 compositional and structural community metrics: (1) total number of taxa; (2) number of mayfly taxa; (3) number of caddisfly taxa; (4) number of dipteran taxa; (5) % mayfly composition; (6) percent caddisfly composition; (7) tribe tanytarsini midge composition; (8) percent other dipteran and noninsect composition; (9) percent tolerant organisms; and (10) number of Ephemeroptera–Plecoptera–Trichoptera taxa. Metric scoring criteria were developed through a quantitative calibration process in which reference values were plotted against a log-transformed watershed area.

Macroinvertebrate IBIs have also been broadly used to document human impacts on the health of streams, rivers, and wetlands in North America and other parts of the world. One example of such a study was also conducted in Wisconsin, United States, in which stream macroinvertebrate IBI values were empirically linked with watershed and local stressors (15). In this study, streams were stratified by region to account for natural environmental variation. Standardized methods were used to kick-sample macroinvertebrates from 397 independent streams and identify the samples in the laboratory. Kick-sampling is a method for dislodging macroinvertebrates by kicking the substrate and letting the current wash the organisms into a net; it is typically done in riffle or run habitats that have coarse substrates.

Quantifying human disturbance entailed using standardized methods to characterize the watershed land cover and assess the local in-stream and adjacent terrestrial (riparian) habitat upstream of the sampling point. Land cover categories included urban, row crop agriculture, forage crop agriculture, wetland, forest, and open water. Local habitat characterizations included assessment of the riparian vegetation, bank erodability, livestock grazing, macroinvertebrate food sources, channel morphology, and streambed. These local and watershed measures of human disturbance were summed to give an overall environmental condition value to each site. Likewise, several macroinvertebrate metrics were combined into a multimetric IBI to give an overall biotic integrity value to each site. A plot from 209 streams in the central–southeast region of Wisconsin shows how values of environmental condition were related to macroinvertebrate IBI values (Fig. 2). Streams of excellent environmental condition typically had relatively high proportions of forests, wetlands, and open water and a low percentage of urban land cover on the watershed scale. On the local scale, these excellent streams had a variety of food sources, relatively undisturbed riparian conditions, and a heterogeneous habitat structure, including riffles, meanders, and woody debris. The macroinvertebrate assemblages

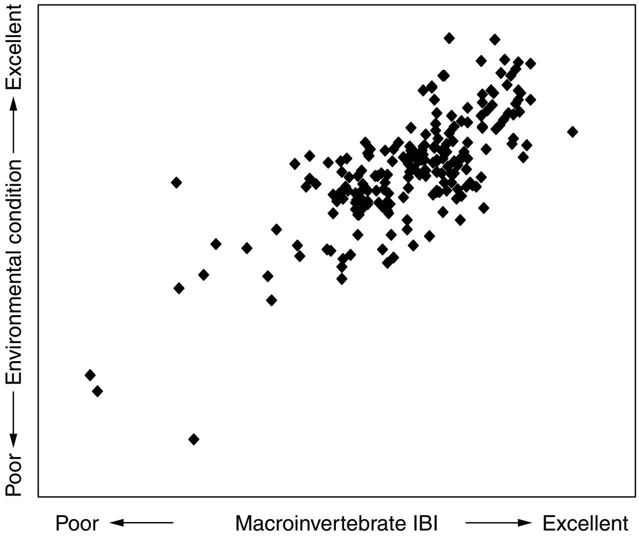

Figure 2. Macroinvertebrate index of biotic integrity tailored to small streams in central and southeast Wisconsin, United States ($n = 209$). The poorest streams had high proportions of urbanization or agriculture in their watersheds and local habitat stress. Macroinvertebrates in the poorest streams were tolerant to organic pollution, had no individuals from the relatively sensitive insect orders Ephemeroptera, Plecoptera, and Trichoptera, and had low taxa richness.

at these excellent streams had high species richness, were intolerant of organic pollution, and were comprised predominantly of intolerant taxa from the insect orders Ephemeroptera, Plecoptera, and Trichoptera, as opposed to Diptera. The empirical model indicated that extensive agriculture and urbanization impacted the biological community strongly and significantly.

There are several advantages of using macroinvertebrates to evaluate the health of aquatic systems. Macroinvertebrate assemblages consist of a variety of species whose different life histories are sensitive to a multitude of degradation types and play an important functional role in stream ecosystems. The assemblages can respond to a range of human-induced effects on streams. Macroinvertebrate assemblages represent the end point of the combined influences of hydrology, physical habitat, and water quality and it has been shown, respond predictably to these factors within specific geographical regions (9). Similar to the fish IBI, the disadvantages of using the macroinvertebrate IBI to measure the health of aquatic systems include (1) seasonal variation in their relative abundance, (2) intensive efforts for field sampling and taxa identification, and (3) modifying the IBI for particular geographic regions and waterbody types.

Periphyton Index of Biotic Integrity

The multimetric periphyton IBI was developed to measure the health of aquatic systems. Periphyton are algae attached to hard substrates like the rocks that comprise a streambed. The states of Montana and Kentucky were among the first to develop a multimetric periphyton IBI in the United States. Bahls' (16) periphyton IBI for Montana streams included three metrics based on soft-bodied taxa and four metrics based on diatom taxa. Metrics for soft-bodied taxa included dominant phylum, indicator taxa, and number of genera. Diatom metrics included the Shannon–Wiener diversity index, a pollution index, a siltation index, and a similarity index for comparison with a reference condition. Kentucky's stream periphyton IBI consisted of diatom species richness, species diversity, percent community similarity to reference sites, a pollution tolerance index, and percent sensitive species (17).

Periphyton respond to a variety of pollutants and can be used to diagnose the probable causes of health impairment in aquatic systems. Some periphyton can be sensitive to pollutants that other organisms tolerate relatively well, partly because periphyton cannot avoid pollutants due to their sedentary nature. Periphyton occur in most aquatic habitats, and typically have greater taxonomic richness than fish and macroinvertebrate. Although sampling periphyton is relatively easy, identification must be in a laboratory and it is labor-intensive. Typically, periphyton have rapid reproduction rates and short life cycles, and thus, they respond quickly to perturbation. However, this quick response to stress appears to increase their natural variation, which can make the detection of changes resulting from human perturbation more difficult.

PREDICTIVE MODELING

The River Invertebrate Prediction and Classification System (RIVPACS) and Australian River Assessment System (AusRivAs) are predictive models that quantify river health as the degree to which a waterbody supports the biota that would be expected there in the absence of human disturbance. These models were initially developed in the United Kingdom (18) and later modified for Australia (19), other parts of Europe, and North America.

In the process of assessing aquatic health, an empirical model of reference waterbodies is created that incorporates the natural environmental factors that are unlikely to be affected by human activities, yet influence the taxa there. This model predicts the taxa that occur under least-impacted, reference conditions. The observed biotic taxa (O) at a test waterbody are compared with the taxa that the predictive model expects (E) to find in the absence of human stress, and the deviation is expressed as a ratio (O/E). Impairment is inferred if the O/E values measured at a test site fall outside the error inherent in the predicted E and estimated O/E.

In the multimetric approach, the predictive model method can provide site-specific prediction of the composition of biota in test waterbodies, the assessment requires no assumptions regarding the specific types of stress that affect biota, and it uses independent data for matching test conditions with reference conditions. The predictive modeling approach is difficult to apply in regions where not many undisturbed reference waterbodies can be found. This approach has not been tested for organisms other than benthic macroinvertebrates.

SUMMARY

Biotic indexes for evaluating the health of freshwater systems are used increasingly as they are becoming more standardized and cost-effective, and presenting their results is easier. Many human-induced changes in the physical and chemical properties of water resources are difficult to detect because of their temporal and spatial variation. Even when water resources are monitored using broad temporal and spatial coverage, physical and chemical measurements are insufficient to protect water resources because many human influences cannot be measured by using a physicochemical approach. Furthermore, biotic assemblages represent the end point of the combined influences of human disturbance on aquatic environments, and thus, biotic indexes provide a measure of overall water resource health.

Many aquatic organisms, including fish, benthic macroinvertebrates, and periphyton, can be used as indicators of aquatic ecosystem health. During the past 20 years, many IBI versions for fish, benthic macroinvertebrates, and periphyton have been developed worldwide to meet the needs of localized climate, zoogeological zone, and thermal and hydrologic regimes. All multimetric IBIs share several features. The overall index score is the sum of the scores of several individual metrics. Each metric represents a different attribute of the structure, composition, or function of the biotic assemblage. Natural environmental or biogeographic factors that influence these attributes are taken into account in applying the index. Metrics are chosen and calibrated largely based on empirical data. Metric scores from references, those representing the least impacted waterbodies within a region, provide a standard for comparison. Each metric is sensitive to one or more types of environmental degradation. Each of the fish, benthic macroinvertebrate, and periphyton IBIs has its strengths and weaknesses. We need to use IBIs in combination with physical habitat and water chemistry assessments to establish criteria that direct human activities toward improvement and protection of water resource health.

The predictive modeling approach, such as RIVPACS, is different from the multimetric method. Instead of using multiple metrics, it uses the ratio between observed and expected for the occurring probability of aquatic organisms. However, both predictive model and multimetric approaches use regional reference sites and achieve similar goals in assessing the health of water resources.

REVERSAL OF THE CHICAGO RIVER

Richard Lanyon
Metropolitan Water
Reclamation District of Greater
Chicago
Chicago, Illinois

INTRODUCTION

Through the end of the nineteenth century, the rapidly growing city of Chicago was plagued with frequent epidemics of waterborne diseases. The city's death rate was one of the highest in the world. Despite the widespread installation and use of sewers beginning in 1855, the problem persisted. In fact, the sewers, while providing some adequate local drainage, only moved the public health hazard to the Chicago River and, inevitably, to Lake Michigan. As the lake also supplied the city with its drinking water, a vicious cycle existed. Successive efforts were undertaken to move the water intakes farther from shore. But, in time, the plume of pollution would reach farther out into the lake, enveloping the intakes. At this time, acceptable technology for the treatment of large quantities of potable water or sewage was nonexistent.

By the 1880s, it became clear that the only viable solution was to discharge the sewage across a subtle subcontinental divide 10 miles distant from the Lake Michigan shoreline. There, the Des Plaines River, a tributary of the Illinois and Mississippi Rivers, could be reached. A deep channel from Chicago to Joliet would be necessary. A new governmental entity, a sanitary district, was created and charged with the job of building the channel. When its work was finished, a mere decade later, this remarkable project resulted in the excavation of 42,230,000 cubic yards of rock and soil, construction of 460,000 cubic yards of masonry for channel walls and bridge abutments, and the erection of 31 bridges. The total cost was $33.5 million. Today, the 28-mile constructed channel is called the Chicago Sanitary and Ship Canal, although to its builders, it was referred to as the Main Channel.

COMMISSION FORMED

The City of Chicago Common Council responded to citizen demands in January 1886 by taking its first official action to solve the problem of the Chicago River: It formed the Commission on Drainage and Water Supply. The commission's charge was to outline a solution to the problem within 1 year, in time for legislative action by the Illinois General Assembly. The commission issued its 36-page preliminary report in January 1887, which presented three alternatives for sewage disposal: (1) discharge sewage into Lake Michigan away from the city, (2) dispose of sewage on land, and (3) discharge sewage into the Des Plaines River.

Cost estimates were based on a projected population of 2.5 million, roughly three times the then current population. Discharge to the lake was estimated at $37 million, disposal on land at $58 million, and discharge to the Des Plaines River at $28 million. Discharge to the Des Plaines River was the recommended solution based on cost and a belief that it was a more reliable technology.

The commission set the parameters for design of a large channel from Chicago to Joliet, using as input the plans of others as well as their own creative ideas and the results of their exhaustive investigations. Determining adequate capacity was based on meeting three fundamental needs of the city and region: storm flow, sanitation, and navigation. The commission recommended a channel cross-section area of 3600 square feet and a velocity of 3 feet per second. The resulting discharge capacity of 10,000 cubic feet per second was intended to serve a population of 2.5 million people. It was the commission's opinion that the channel capacity would prevent backflows into the lake and protect the water intake cribs located two miles offshore. The commission estimated the cost to build the channel at $20.3 to $24.5 million. It also recognized the potential for water power development because of the steep descent of the Des Plaines River near Lockport (see Fig. 1).

The scope of the recommendations and the size of the undertaking required the state legislature to authorize the formation of a new unit of local government. The city of Chicago was in debt to the legal limit, and the task at hand would require considerable financial resources. A new entity encompassing a larger area could borrow anew, could have a larger tax base than the city, and would have powers beyond the city limits. A legislative commission began work in May 1887, writing what would become an authorizing statute: "An act to create sanitary districts and to remove obstructions in the Des Plaines and Illinois rivers," effective July 1, 1889. The Governor of Illinois rapidly approved, opening the way for the sanitary district to be formed by referendum.

Typical of Chicago's political muscle, within 6 months, the proponents had established the boundaries of the new Sanitary District of Chicago (SDC), conducted the referendum, which passed by a whopping 70,958 to 242,

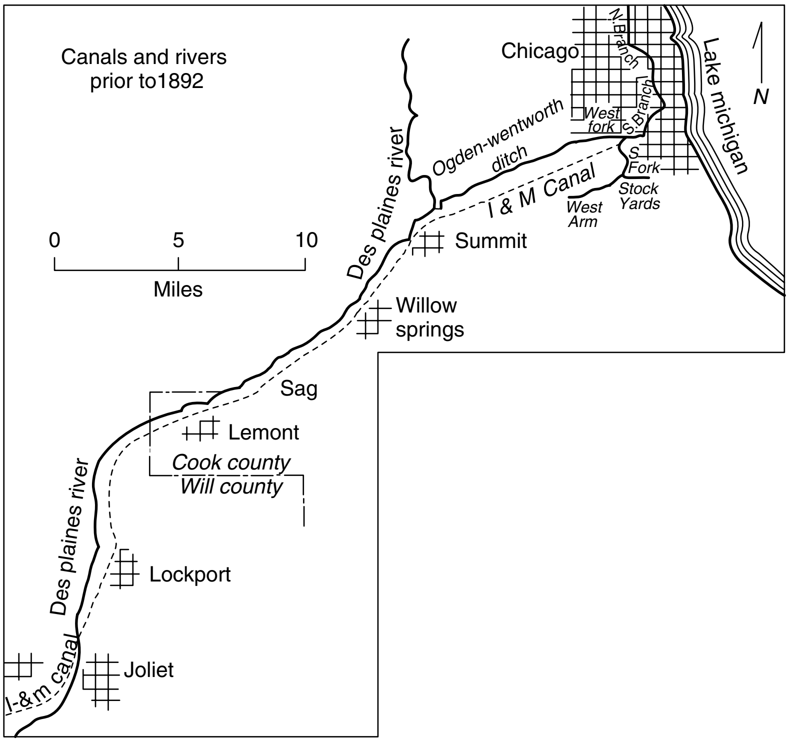

Figure 1. Canals and rivers prior to 1892.

elected nine trustees, and had them sworn in. The SDC was officially organized by January 1890. However, the new entity had to wait out two legal challenges, which went up to the Illinois Supreme Court. By June 1890, the court affirmed the authority of the SDC. Now the SDC could borrow money, approve a tax levy, and begin work.

MAIN CHANNEL WORK BEGINS

The SDC's first step was to select a Chief Engineer and direct him to present to the Board of Trustees (Board) not less than four routes of a channel to cross the 8 miles between the South Branch and Summit and to make investigations of the Des Plaines River valley. The intent was to build a channel and two pumping stations: one to lift the waters of the South Branch into the channel and the other to lift the water out of the channel into the Des Plaines River. It was also anticipated that the Des Plaines River would have to be enlarged to accept the additional flow. However, over a year went by with little progress as the board was divided and a succession of chief engineers did not survive the dissention. The third chief engineer was able to put together a plan that the board, with several new members, could agree on in January 1892.

In the spring of 1892, the board focused on getting the 14.8-mile rock section of the Main Channel designed and under construction. It was assumed that excavation in rock would be more difficult and time consuming than excavation in the earth. June 1893 saw the appointment of Isham Randolph as Chief Engineer (the fifth one), and this finally brought stability to the SDC Engineering Department as he remained in this position to 1907.

The rock section began at Willow Springs and ended at Lockport (see Fig. 2). New surveys and subsurface investigations were constantly revising knowledge of the route. The channel route was west of the I&M Canal and east of the Des Plaines River. The surface of Niagaran dolomite was very close to or formed the bed of the Des Plaines River throughout much of the reach from Sag to Lockport. From Willow Springs to Sag, the rock surface was high enough that a channel with a discharge capacity of 10,000 cubic feet per second (cfs) was required by the act. Throughout the rock section, the channel is rectangular with a width of 160 feet and a channel depth of 24 feet. In June, 14 contracts were awarded and work began on September 3, 1892, with a ceremony at the Cook-Will County Line. Some of the rock excavation contractors proceeded apace and their work was completed by 1895, 1 year earlier than anticipated. Other contractors were plagued with various problems, and the work was not completed until 1899.

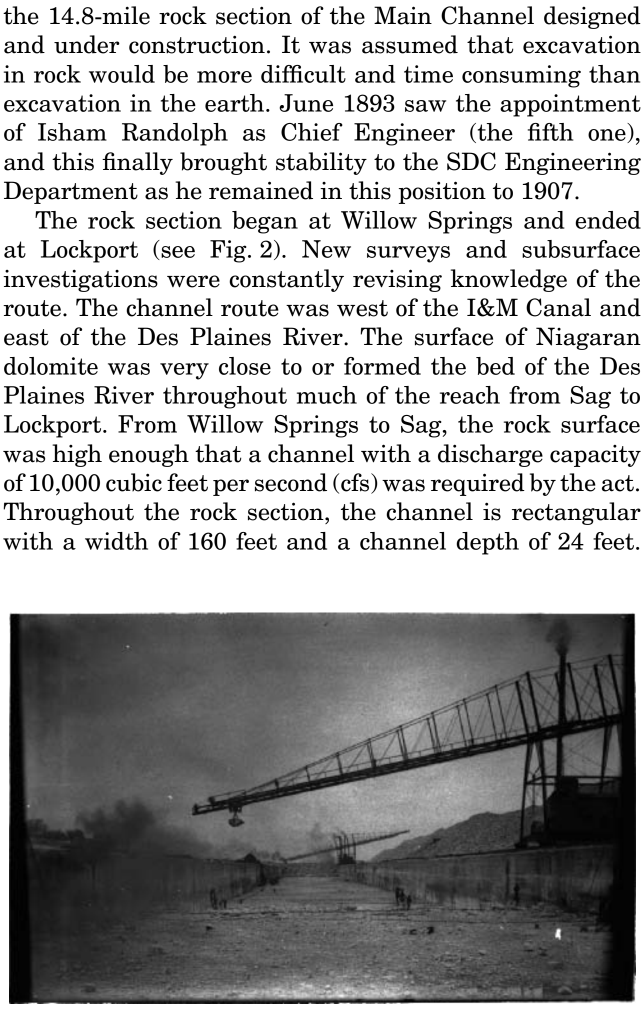

Figure 2. Excavation of the rock section.

To make room for the Main Channel between Summit and Lockport, the eastward meanders of the Des Plaines River had to be relocated; thus an aggregate of 13 miles of river diversion channels was constructed as well as a continuous levee separating the Main Channel and river. Keeping the river out of the construction area where the Main Channel was being constructed was a continuing problem for the contractors during flood periods.

Next to go under contract was the 6.2-mile earth and rock section from Summit to Willow Springs. Again, the route follows the I&M Canal and Des Plaines River. At Summit, the route of the Des Plaines River turns north, separating from the routes of the Main Channel and I&M Canal, which turn toward Chicago. Six contracts were awarded in January 1893 for channel excavation, and all work was completed by 1899. The channel was trapezoidal in cross section with a bottom width of 210 feet, side slopes of 2 horizontal to 1 vertical, and a depth of 24 feet. Because rock was encountered in this section, the act required the channel to have a discharge capacity of 10,000 cfs.

The earth section of the Main Channel extended from Summit to the West Fork, beginning just west of Robey Street (now Damen Avenue) in Chicago. As no rock was encountered in the channel cross section, the act allowed construction of a channel with a capacity of only 5,000 cfs. The act contemplated that as the population grew, the channel capacity would be increased to 10,000 cfs. This eventually happened in 1912. This lesser capacity channel had a bottom width of 110 feet, side slopes of 2 horizontal on 1 vertical, and a depth of 24 feet. This reach was notable because of the many railroad crossings. As a result of negotiations with railroads for one of the crossings, the SDC was obligated to also construct the one-third mile-long Collateral Channel connecting the Main Channel to the West Fork along the alignment of what is now Albany Avenue. The short bypass channel relieved the railroads of having two movable bridges within one-half mile of track right-of-way.

The 7.2-mile earth section reach was divided into eight contracts, the first six of which were awarded in December 1893. The last two contracts, awarded in May 1894, provided for dredging and transporting the spoil by scow to the lakefront to be used as fill for the creation of what is now Grant Park. Other spoil was deposited in what is now Douglas Park and used as fill for local streets and boulevards. Because of the delayed construction of a major railroad crossing, dredged channels extended from the West Fork to Western Avenue along the route of the Main Channel and to the Main Channel north embankment along the Collateral Channel. Work on these eight contracts was completed in either 1898 or 1899.

To control the discharge of water from the Main Channel, two more contracts were awarded in 1895 and 1896 for construction of the Lockport Controlling Works.

These works consisted of seven vertical gates, each 30 feet wide and 20 feet high, and a 160-foot long sector-type dam, called the Bear Trap Dam. The dam could be lowered to allow flow over its top, providing for sensitive discharge control. The gates were raised to provide for rapid increases in discharge over a short time period. These two types of control were necessary because the end of the Main Channel was 35 miles from Lake Michigan and the lake level could change rapidly on short notice. These control structures were among the largest in the world at the time, comparable with controls on the outlet of Lake Superior and on the Ohio River.

THE JOLIET PROJECT

Near Lockport, the Des Plaines River began a relatively steep descent to Joliet, at some places flowing over exposed dolomite. Once in Joliet, the river was joined by the I&M Canal where several successive dams created navigation or power pools. Planning for a channel through Joliet would require more study and dealing with the I&M Canal Commissioners and the City of Joliet. Complicating the matter was the physical setting north of Joliet. The river channel meandered from east to west across the valley floor; the I&M Canal and two railroads were on the east side of the valley, and several industries with water power developments were along the river.

The confluence of the new channel and the I&M Canal required modifications to the tow path, locks, and dams, but the canal commissioners were slow to come to terms with the SDC. The SDC proceeded with work and was sued by the canal commissioners. Three contracts were awarded in early 1898 for the 5.1 miles of work. Because of the lawsuit and other contract problems, the work was not completed until 1901. However, enlargement of the Des Plaines River channel capacity was completed by late 1899.

SOUTH BRANCH IMPROVEMENTS

By August 1895, 28 miles of the Main Channel were under contract, and rock excavation was nearly complete near Lemont. The SDC needed to improve the capacity of the Chicago River and the South Branch so that it could deliver the flow of water from Lake Michigan as required by the act. The river had many bends and constrictive bridge openings, was shallow in spots, and was always busy with boat traffic. Fortunately, no time would be consumed in debate over the route.

The U.S. Army Corps of Engineers (Corps) had plans to improve the Chicago River, so the SDC concerned itself with improvement of the 5-mile reach of the South Branch between Lake and Robey streets. All work in the South Branch was subject to permits issued by the Corps, but the SDC would often begin work before a permit was issued. One contract was awarded in May 1897 for removal and replacement of dock walls and dredging to pass 5000 cfs in a channel 200 feet wide and 20 feet deep. Other contracts were awarded in 1898 for replacement of two center pier bridges with restrictive openings and a large bypass conduit around a restrictive bridge opening that could not be enlarged. All work was sufficiently completed by 1899 to provide for the design capacity.

The act made reference in many locations to a navigable waterway, maximum velocities, and minimum depths and widths, all of which defined the conditions for safe commercial navigation. However, the act made no reference to bridges. Lacking statutory definition, the matter of bridges was discretionary to the SDC, which caused much debate and division among the members of the board. As there was no navigation lock at Lockport, navigation on the Main Channel was not an immediate priority. The bridges were put under contract late in the 1890s, and all substructure work was completed by late 1899 before the Main Channel was placed in service in January 1900. The SDC built or funded the construction of 31 bridges to effect the reversal of the Chicago River. The 13 bridges over the Main Channel were designed and constructed to eventually be made movable to allow for passage of boats.

REVERSING THE FLOW

To place the empty 28-mile-long Main Channel into operation, water would need to be added slowly so as not to cause damage by rapidly rising water levels or swift currents. Despite not having specific approval from the Governor, water was let in at the Chicago end beginning on January 2, 1900, through a wooden flume in the earth dike across the south end of the Collateral Channel. The filling continued to January 14 when the water level in the Main Channel reached the water level in the West Fork. The next day, the earth dam across the Main Channel west of Western Avenue was cleared away by dredges and the waters on each side came together. After 13 days of filling, the water level came to rest, to wait for the Governor's approval to discharge at Lockport.

A special commission had been appointed by the Governor to inspect the work and advise on satisfactory completion of the work. The SDC vowed to wait for the Governor's approval before releasing water from the Main Channel at Lockport. The Board and commission members traveled to Lockport on January 17, 1900, to be at the Lockport Controlling Works when the approval came. The Governor's approval was received by telegram, and the Bear Trap Dam was lowered slightly below the water level to allow a thin sheet of water to flow over its top (see Fig. 3). After a brief ceremony, the valves controlling the dam were opened and the massive 160-foot-long dam disappeared beneath the water. A torrent of water rushed out of the Main Channel over the dam toward the Des Plaines River. On this chilly day in the first month of the new century, slightly more than 10 years after passage of the authorizing act and after more than 7 years of construction, the Main Channel was now in operation to save Chicago from its own waste.

The reversal of the Chicago River has been supplemented with other works, and the diversion of water from out of the Great Lakes basin has been the subject of extensive litigation, but the reversal of the river has never been interrupted.

Figure 3. A total of 4250 cubit feet per second passes over the Bear Trap Dam.

FLOOD CONTROL IN THE YELLOW RIVER BASIN IN CHINA

Rongchao Li
Delft University of Technology
Delft, The Netherlands

GENERAL INFORMATION ON THE YELLOW RIVER

The Yellow River (see Fig. 1), the second longest river in China originates in the Yuguzonglie Basin in the Tibet Plateau in west China and enters the Bohai Sea in the east. It is 5464 km long, has a water level difference of 4480 m, and the basin area is 795,000 km^2, 8.28% of China. In the entire Yellow River Basin, 98 million people are settled.

The most important water resource in the Yellow River Basin is precipitation. The annual precipitation is concentrated in the period from July until October. The average annual runoff of the Yellow River is 58 billion m^3 (1987). About 10 to 20% of the runoff is discharged from March until June, and 60% is discharged in the flood season from July until October. The interannual runoff distribution is also not uniform. The ratio between the maximum and the minimum value can be up to 3.4. Since 1919, a dry period that was longer than 5 years occurred twice. The annual average runoff during these dry periods was 39 billion m^3. The total amount of groundwater in the basin is 40 billion m^3 (excluding the interior basin). The exploitable amount of groundwater is 12 billion m^3. The distribution of groundwater is not uniform in the basin (1).

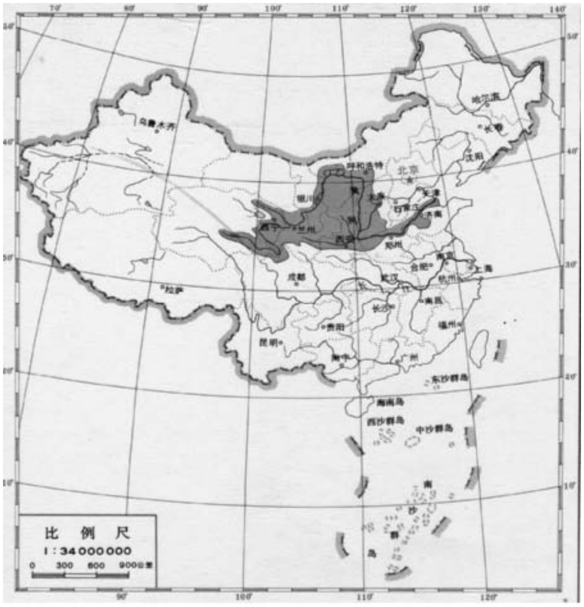

Figure 1. Location of the Yellow River Basin in China.

GENERAL CONDITIONS FOR FLOODING AND SEDIMENTATION

The frequent occurrence of extensive flood disasters is related to its geography (high in the west and low in the east) and to its uneven temporal and spatial distribution of precipitation. As recorded since the third millennium B.C., the Yellow River has overflowed its dikes 1590 times and changed its course 26 times. Nine of those were major course changes. The range of the course divagation covers an area of 250,000 km^2. Thousands of people were killed in many floods. The cycle of flooding and death earned the Yellow River the name "China's Sorrow."

Flooding in the Yellow River Basin

There are two kind of floods in the Yellow River: storm-caused floods that occur between July and October and ice-jam floods that normally occur in February (1). The main floods of the Yellow River occur in July and August. These are peak floods of short duration that rise and fall quickly. Historical investigations show that the largest flood occurred in 1843; the peak discharge was 36,000 m^3/s. The maximum flood measured occurred in 1958; the peak discharge was 22,300 m^3/s at Huayuankou; see Fig. 2 (1). This flood is used to determine the design level of the lower reach. The design level at Huayuankou hydrologic station is 22,000 m^3/s, and the probability is once in 1250 years. The construction of the Xiaolangdi dam is not included in

Figure 2. Main hydrology station in the Yellow River Basin (*Source*: Yellow River Water Conservancy Commission).

this design level. Table 1 shows the total flood frequency analysis for the lower reach of the Yellow River.

In spring, ice-jam floods often occur between Huayuankou and the estuary. The riverbed slope is shallow in this part, so the velocity of the water is low. The flow direction from west to east changes from a low latitude to a higher latitude at the Bohai Sea. This results in a higher temperature at Huayuankou than in the estuary. The average winter temperature near the estuary is 3.4 °C lower than at Huayuankou. For this reason, in 80% of the years, the river freezes, and because of this, in most of these years, ice-jam floods happen. According to the statistics, between 1950 and 1983, there were 29 years in which the river froze. In 1951 and 1955, serious ice floods occurred. The length of the frozen river was 550 km. and 623 km. respectively. In history, the ice-jam floods frequently broke dikes. According to rough statistics between 1883 and 1936, ice-jam floods broke dikes in 21 years.

The extreme floods measured at Huayuankou are from different geographical sources, and these floods also have different characteristics. A classification has been made for the different floods based on historical floods and for a few floods shown in Table 2. The classification is as follows:

- The inflow upstream of the Sanmenxia reservoir and comparatively small inflow downstream of the Sanmenxia reservoir mainly compose the flood. This type of flood has a high flood peak, a large flood discharge, and high sediment concentration.
- The flood is composed mainly of the inflow downstream of the Sanmenxia reservoir. This type of flood has a rapid flood rise, a high flood peak, low sediment concentration, and a short forecast period.
- Half the flood is composed of the inflow upstream of the Sanmenxia reservoir and half of the inflow downstream of the Sanmenxia reservoir. This type of flood has a small flood peak, a long duration, and low sediment concentration.

Sediment in the Yellow River Basin

The majority of the sediment sources in the basin are situated in the upper and the middle reaches. In the upper reach, the average sediment concentration is only 6 kg/m^3, and the average sediment transport is 142 million tons. In the middle reach, the river flows through a loess plateau. Due to the fine grain sizes and the restricted vegetation in the loess plateau, soil erosion can cause a huge sediment load, especially during storms. During a storm, the sediment concentration in the river can rise to more than 500 kg/m^3 (1), as illustrated in Fig. 3.

One of the important characteristics of the Yellow River is that water and sediment originate in different regions. In the upper reach, the annual sediment input is 8.7%, whereas the annual runoff is 54% of the annual input. In the middle reach, the annual runoff is 36%, whereas the sediment input is 89%. From Xiaolangdi to the Bohai Sea, the lower reach, the surface area is limited, and the annual runoff depends mostly on the tributaries, the

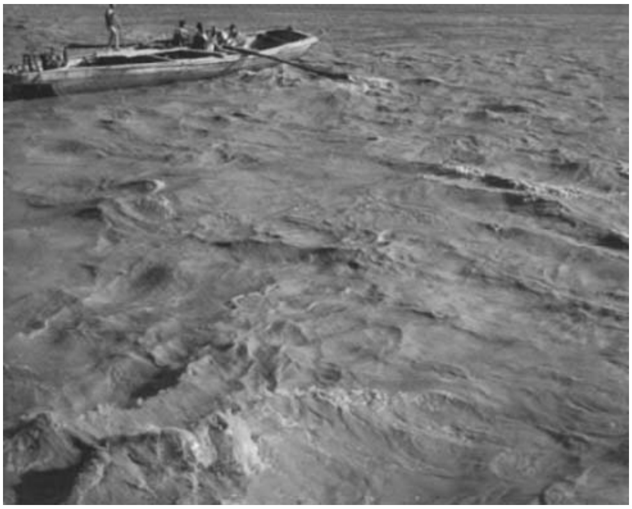

Figure 3. Yellow River: High sediment concentration flow (2).

Yilouhe and the Qinhe. The annual runoff of the lower reach is 10%, and the sediment input is 2% of the annual input. Due to severe soil loss in the middle reach, on average, 1.6 billion ton of sediment enters the river channel at Huayuankou annually, of which about 1.2 billion ton is carried to the estuary region, leaving behind a substantial amount to contribute to the silting of the river channel (1). This results in high deposition in the riverbed of the lower reach. Due to this, the riverbed fills up, on average, 0.1 meter every year. By the time, the Yellow River reaches Kaifeng, it runs 10 m above the surrounding plain. Some Ming and Song dynasties' artifacts 500 to 800 years old lie under 5 to 8 m of silt at Kaifeng City. The present riverbed above its floodplain is about the same as the old course that was breached and abandoned in 1855 (http://www-geology.ucdavis.edu/GEL115/115CHXXYellow.html). Therefore, nowadays, the Yellow River is called a "suspended" river. In Fig. 4, the *Q*/*h* relation for different years at Huayuankou is shown. This figure shows the impact of the decreasing flood conveyance due to the rise of the riverbed. Even for a normal peak flood of 5000 m^3/s the water level rose about 2 meters in the period 1958–1996. It is expected that the process of bed level raising will continue in the near future.

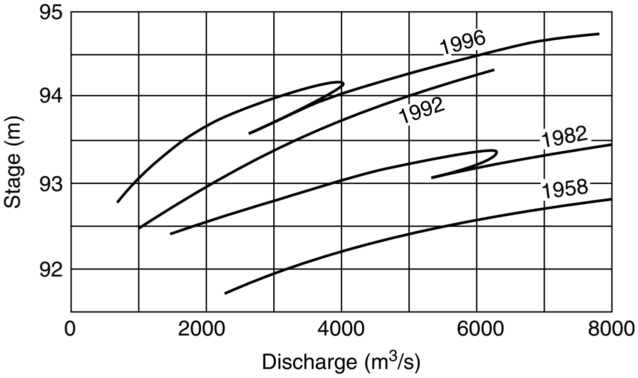

Figure 4. Water level-discharge relation for three floods (3).

FLOOD CONTROL IN THE YR BASIN

Historical Flood Management in the Yellow River

As the most sediment-laden river of the world, the extreme sediment load of the river causes problems in water resources management and flood protection (1). The first inhabitants of the Yellow River floodplains and the surrounding areas lived with floods. They escaped from flood inundation by living in highlands or moving far away from flood-prone areas. Legends say that before the first manager of Chinese waters, Yu The Great (twenty-first century B.C.), built dikes on the lower reaches, barriers to block or store the water in large holding areas were tried for a long time. Yu The Great was great because of his innovation to direct flow to the sea by dikes. The first recorded river training by construction of levees started probably in the Warring State periods (770–221 B.C.) when the Yellow River was not yet a suspended river.

During the Han Dynasty (206 B.C. –220 A.D), disasters of flood breaches and course shifting were more overwhelming than ever before along with sediment deposition in the lower reach as well as more intensive human activities in the loess plateau and in the floodplain. And the Yellow River lower reach has gradually become a suspended river. Because the heavy silt load cut the effectiveness of flood control, it is of key importance that enormous constant efforts are made to maintain equilibrium with the river. To tackle the flooding in the Yellow River, one prominent water manager Ja Rang stated his "three measures on

River treatment (flood management)" around 7 B.C. The first measure, the best option according to Jia Rang, was to return the river to the abandoned course. However, this idea proved to be impossible at that time because of the limited technological capability when the abandoned channel was seriously silted. The second measure was to dissipate the power of the river by draining off water for irrigation in the lower reach and diverting relatively silt-free streams into the Yellow River to increase the silt-carrying capacity. The last measure was to strengthen dikes to contain the river. This measure was his last choice. He believed that the endless need for dike raising was a waste of time, labor, and resources.

After Ja Rang, Wang Jing proposed and carried out river channel stabilizations in 69 A.D so effectively that there were no major dike breaches for the next nearly 1000 years. His methods included dredging, strengthening the levees at dangerous points, digging new channels for tributaries in rough terrain, and building numerous sluice gates. A thousand years later, Pan Jixun (1521–1595) was remarkable in the Ming Dynasty (1368–1644) because he advocated building strong close dikes to contain the river so that it would scour its own narrow channel. This was the first forceful statement against the ancient principle of dividing the flow to dissipate the river's power. This strategy was also followed by Jin Fu in the early Qing Dynasty (1644–1922 A.D) to stabilize the river for a certain period.

Present Flood Control in the YR

During the early decades of the twentieth century, flood control in the Yellow River basin has evolved as a combination of traditional management practices, influences from European-based industrial society, and new technical and organizational features from modern Chinese society. The views on flood management were determined by the famous Chinese flood managers, Li Yizhi, Shen Yi, Zhang Hanying, and Wang Huayun. In the mid-1950s, a multipurpose plan for permanent control of the river was initiated. This plan included the construction of more than 40 dams and projects to moderate the river's flow (and produce energy).

Today, on the upper and middle stream of the Yellow River, there are 173 large and medium-sized reservoirs whose total storage capacity is 55.2 billion m^3. Downstream of the Sanmenxia reservoir (see Figs. 2 and 5), two large flood retardation basins—the Beijinti and the Dongpinghu—were constructed. Their storage capacity is 2 billion m^3 each and detention area 2316 km^2 and 627 km^2, respectively. Altogether 5000 bank protection works with a total length of 585 km were built. In this way, the flood control works can resist peak discharges of 22,000 m^3/s (1958 flood) at the Huayuankou hydrologic station (1958 flood), corresponding to a 60-year return period. The Xiaolangdi Reservoir whose a storage capacity is 12.65 billion m^3 on the lower reach increased the protection standard there to a return period of 1000 years (4).

The flood control engineering system that has been gradually formed since 1950 is to retain water in the upper and middle reaches, drain water at the lower reach, and divert and detain water on both sides of the river, guided by the notion of "stabilizing the flow by widening the channel." The lower reach flood control system is shown in Fig. 5. The engineering works for retaining water include

- the Sanmenxia reservoir at the main course of the Yellow River, which controls 91.4% of the total basin area;
- the Luhun reservoir and the Guxian reservoir on the Yi River and Luo River, designed to reduce the flood risk for the lower reach of the Yellow River and the city of Luoyang, combined with the Sanmenxia and Xiaolangdi reservoirs; and
- the Xiaolangdi reservoir which controls 92% of the total basin area and has a total capacity of 12.65 billion m^3 and a long-term effective capacity of 5.1 billion m^3.

Currently, both structural and nonstructural measures are adopted in Yellow River flood control. Structural measures include reservoirs, diversion structures, retardation

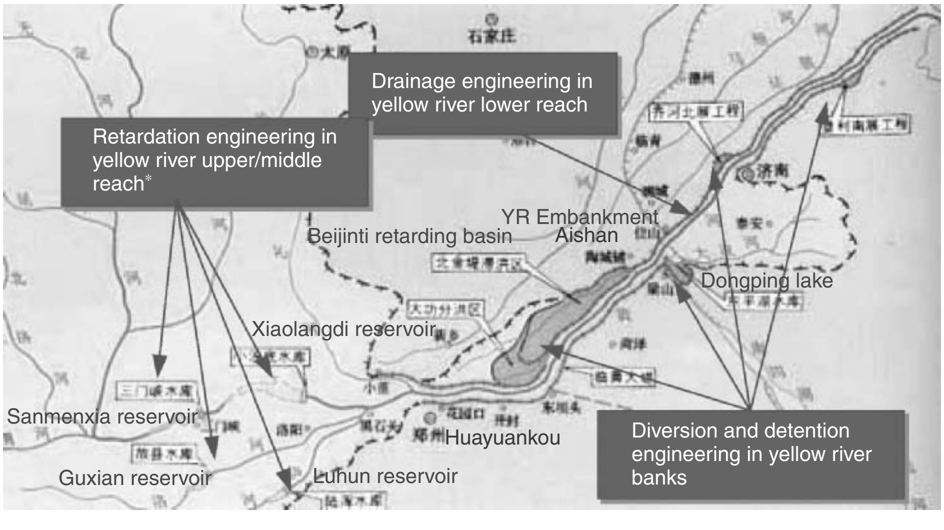

Figure 5. The flood control system of the Yellow River lower reach. Note: The upper reach's retardation engineering is not shown in this figure.

basins, embankment, dredging, and channel modifications. Nonstructural measures includes the flood control organization system, the flood control communication system, the hydrology monitoring and forecasting system, the flood regulation, command and decision making support system, the management of flood plain, and the diverting and detaining area.

Measures for Reducing Flood Risk

As stated above, the Yellow River delivers about 1.6 billion tons of sediment per year to the lower reach, resulting in an average content of 35 kg/m^3. In the reaches with the highest concentration rates, the river contains more then 10 million kg of sediment per kilometer of which 90% is from the loess plateau in the middle reach of the river between Longmen and Tongguan. Due to the heavy sedimentation, the bed level rises in the lower reach. Where in the past the river changed its course when the riverbed was too high for the surrounding area, at present embankments, buttresses, and control works harness the river and fix the river in its place. The sediment has no place to go but deposit in the lower reach. Due to human activities such as deforestation in the middle reach, soil erosion enhances the sedimentation process in the lower reach even more. At present, the riverbed is as high as 5 to 10 meters above ground level, creating a situation where in case of a dike breach during a flood, the damage can be enormous. Reducing this flood risk can be done in two ways, by reducing the peak flow and by increasing the channel capacity.

Reducing peak flow can be and presently is achieved by retention of water upstream, by detention in basins in the lower reach and by controlled flooding on floodplains. The problem of retention is difficult coordination with other water users, among whom are the Ministry of Power and farmers; when water is to be released to create a buffer and when water is to be retained to relieve downstream flooding, to increase the power generating capacity, and to conserve water for demand in the dry season.

Capacity can be increased by reducing sedimentation and by raising the embankments. Increasing capacity is currently attempted by four types of measures:

- dredging to enlarge flow cross section.
- decreasing erosion by soil conservation projects. Large afforestation projects in the middle reach have started to conserve the soil from eroding. The main focus is on simultaneous development of agriculture, forest, and animal husbandry.
- prevention of transport of sediment to the lower reach by trapping sediment in large basins or reservoirs. The recently built Xiaolangdi reservoir is constructed to trap sediment for 10 to 15 years, until the reservoir is as small as 30% of its original size. This will prevent about eight million cubic meters of sediment from flowing into the lower reach.
- increase capacity by raising the embankments, but there are financial as well as physical limits to keep doing so.

Despite all these measures, the problems remain. Even though the flood risk is momentarily decreased by Xiaolangdi, in 15 years, the risk will reach the same level again and will increase every year. Besides this, flooding in an area of 120,000 km^2 between Xiaolangdi and Huayuankou is still uncontrolled. A maximum of 13,000 m^3/s can be transported in this section, which corresponds to a 1 in 100 year event.

Analysis of Flooding in the Lower Reach of the Yellow River

Looking at the water resources system of the lower reach of the Yellow River, as described in the last sections, it can be concluded that 50 years have passed now without any dike-outbreak flooding in the lower reach. Two of the reasons are the three dike elevations on the lower reach and relatively low discharges. It cannot be concluded, however, that the danger of dike-outbreak flooding has been sufficiently prevented. In fact, the risk is still there, and a number of factors have even increased the risks. The following are reasons that the risk is still there (5):

1. Low design flood discharge. The present design flood discharge of the Yellow River on its lower reach is 22,000 m^3/s at Zhengzhou with a probability of 2.2% (without taking into account the Xiaolangdi reservoir), taking all the dikes and detention basins into account.
2. The construction of the Xiaolangdi reservoir. If flood control and silt reduction become the most important functions, the Xiaolangdi project can improve the situation for about 15 years. Around 2015, new measures have to be adopted to keep flood control in the lower reach at least at the same level.
3. Poor quality of flood control works. There are 832 km of dike sections whose height is lower than the design water level on account of the steady filling up of the riverbed. There are 340 km of weak dike sections.
4. The strongly varying width of the river between Xiaolangdi and Gaocun. The width varies between 5 and 20 km.
5. Increasing danger of earthquakes. The lower reach of the Yellow River is located in a strong faulting area. It is predicted that in a large part of the area an earthquake of strength 7–8 on the Richter scale may occur within the next 50 years, and there is even a possibility of earthquakes of strength 9 in some areas (6).

These are the reasons that the risk has increased and is still increasing:

1. Densely populated detention areas, whose population is still growing. Beijindi detention area and Dongping Lake house millions of people and are therefore not suitable any longer to store water in case of a flood with a short forecast period (less than 24 hours).
2. Inside the flood-prone areas, approximately 78 million people live. The industrial development is high in these areas, and the economic importance

of these areas is high. The potential for flood damage has increased enormously in recent years, so a dike breach would cause a disaster.

3. The increasing number of people who live in the floodplain. The total number of people who live outside the dikes in the lower reach is 1.8 million. In Henan province only, it is already 1.10 million. These people are very seriously threatened by floods.
4. Decreasing flood conveyance capacity of the river channel. Owing to the construction of reservoirs on the upper reach and irrigation development in the whole basin, discharge in the main channel of the Yellow River has decreased and sedimentation on its lower reach has increased considerably in recent years. As a result, the water level for the same discharge is much higher than before.
5. The role of the YRCC in the distribution decisions for the reservoirs. The Sanmenxia reservoir, for instance, is under the jurisdiction of the YRCC. The management of Xiaolangdi project is not yet known. If it is run under one set of operating priorities, it can improve the flood control in the lower reach. On the other hand, a different set of priorities may enable Xiaolangdi to deliver economically interesting hydropower.

Overall, it can be said that due to the decreasing flood conveyance and the low design flood discharge, the probability of a serious flood increases rapidly. If a flood occurs, the structural flood prevention measures such as dikes and detention areas do not meet the required standard or cannot be used. The increasing population and the economic development would cause much more economic damage in case of flooding than 10 years ago. Moreover, it can also be expected that the number of casualties will be much higher than 10 years ago. The laws and the executive authorities are not able to control the number of people living outside the dikes and related unspecified dike building inside the flood-plain. So still a lot has to be done to improve flood control in the lower reach.

Looking at the measures taken to control the river in the last 50 years, the approach focuses on flood prevention by raising and strengthening the embankments and the construction of dams like Sanmenxia and more recently Xiaolangdi. However, it seems that the traditional methods cannot find sustainable solutions and create a sustainable and safe WRS for the LYR and the flood-endangered areas around this part of the river. The danger of floods is still there and, for the reasons mentioned before, the danger is even increasing.

For the future, different research projects have started, and measures are proposed. Bypasses are also suggested. Theoretically, one could dig out an alternative route for the river, complete with levees. Some scholar even suggested where the bypass can be located and which region would benefit from the Yellow River discharge from a regional economic and ecological view point. However, such an artificial bypass would be incredibly expensive, and the consequences for social activities and ecosystems are uncertain.

CHIRONOMIDS IN SEDIMENT TOXICITY TESTING

Paul K. Sibley
University of Guelph
Guelph, Ontario, Canada

INTRODUCTION

Historically, assessments of water quality have largely been based on the evaluation of water-borne contaminants and water quality criteria established by comparing aqueous concentrations of compounds to their toxicity determined in water-only exposures. It was not until the mid-1970s that it was realized that contaminants, particularly hydrophobic compounds, also occurred in sediments, often at high concentrations. With this new understanding came the realization that water quality criteria based solely on aqueous concentrations were insufficient to regulate contaminants that existed predominantly in sediments and would, therefore, not adequately protect benthic organisms. To develop appropriate and effective criteria for regulating sediment-associated contaminants, the need to develop new methods capable of assessing sediment toxicity became apparent. This need led to the birth of the field of sediment toxicology.

Since it was first recognized that sediments served as both a source and a sink for many contaminants, research in the field of sediment toxicology has largely focused on the development and validation of methods to assess toxicity. Detailed reviews that document the collection and manipulation of sediments, selection of test species, development of test methods, optimization of test conditions and experimental design, and validation of freshwater sediment toxicity test methods are provided in Nebeker et al. (1), Giesy and Hoke (2), Burton (3,4), Ankley et al. (5,6), Ingersoll et al. (7,8), and Diamond et al. (9). A critical consideration in the development of sediment toxicity tests is the selection of appropriate test species. Although several invertebrate species now play an integral role in the assessment of sediment toxicity in freshwater systems (10), arguably none have been used more extensively than the two midge species *Chironomus tentans* and *C. riparius*.

The genus *Chironomus* (Diptera: Chironomidae) includes a large number of species globally, many of which occur ubiquitously in aquatic habitats. To date, seven species of *Chironomus* have been used in sediment toxicity testing: *C. tentans* (nearctic populations of *C. tentans* are now known as *C. dilutus* [Shabanov et al. (11)], *C. riparius, C. plumosus, C. attenuatus, C. prasinus, C. crasssiforceps*, and *C. tepperi*. Of these, *C. tentans* and *C. riparius* have dominated the sediment toxicology literature, with the former being used predominantly in North America and the latter predominantly in Canada and Europe. Both species have been incorporated into standard test methods (12–14), and their application in sediment toxicity testing has been reviewed in detail (10,12,15). The adoption of these two midges in sediment toxicity assessments reflects their importance to the food webs of aquatic systems (e.g., ecological relevance), relative sensitivity to contaminants, tolerance of a wide range of sediment characteristics, and benthic mode of existence (8). From a practical standpoint, both midges have short generation times and are therefore easy to culture and available for year-round testing, are relatively insensitive to manipulation during culturing and toxicity testing, and have wide acceptance among regulatory agencies.

In light of the dominant application of both *C. tentans* and *C. riparius* in sediment toxicity testing, including the availability of standard protocols, this review will focus on these two species, with the goal of providing a pragmatic overview of their application in sediment toxicity assessment. For information on the application of the other species of *Chironomus* listed above in toxicity testing, the reader is referred to Sanchez and Tarazona (16) (*C. prasinus*), Wilson et al. (17) (*C. tepperi*), Peck et al. (18) (*C. crassiforceps*), Fargasova (19) (*C. plumosus*), and Darville and Wilhm (20) (*C. attenuatus*).

BIOLOGY OF *C. TENTANS* AND *C. RIPARIUS*

The biology of *C. tentans* and *C. riparius* has been described in detail elsewhere and is thus only briefly described here. For information of the biology of *C. tentans*, the reader is referred to Sadler (21), Hall et al. (22), Ineichen et al. (23,24), Sibley et al. (25,26), and Watts and Pascoe (27). For information on the biology of *C. riparius*, the reader is referred to Edgar and Meadows (28), Caspary and Downe (29), Downe (30), Rasmussen (31,32), Watts and Pascoe (27), and Hooper et al. (33).

C. tentans and *C. riparius* are holometabolous insects and thus have a life cycle that consists of an egg, larval, pupal, and adult stage. The larval stage in *C. tentans* lasts approximately 23 days at the recommended test temperature of 23 °C (34). In contrast, the larval stage of *C. riparius* lasts between 15 and 18 days at a temperature of 20 °C, depending on the life stage (e.g., egg versus newly hatched larvae) that initiates the test (35). However, in a study comparing the relative sensitivity of the two midges to selected contaminants, Watts and Pascoe (27) found that the duration of the larval stage for *C. riparius* and *C. tentans* was comparable at 22 °C. Larvae of both species pass through four instars and are generally comparable in size (based on head capsule width) up to the fourth instar. Thereafter, larvae of *C. tentans* grow considerably larger than those of *C. riparius* (27). Toward the end of the fourth instar, larvae of both species become inactive and cease to grow; this period is followed by pupation, which lasts 1–2 days. In both species, emergence follows a bimodal pattern (protandry) in which males emerge 2–5 days before females (26,35). Males can be distinguished from females by the presence of plumose antennae. Males of both *C. tentans* and *C. riparius* are capable of multiple matings, whereas females are not receptive to additional matings once they have been inseminated (26,30). Impregnated females of both species oviposit a single egg mass the day after insemination. Female *C. tentans* will occasionally produce a small secondary egg mass, but these eggs are usually not viable. Although *C. tentans* has been reported to produce egg masses containing up to 2300 eggs (22), 800–1000 is more typical (25,26). In contrast, egg masses of *C. riparius* typically contain between 400 and 600 eggs (36). Unmated females generally do not oviposit and resorb the egg mass. However, unmated females of *C. tentans* may occasionally produce an egg mass containing nonviable eggs (25). In *C. tentans*, adult females live up to 5 days, whereas males live up to 7 days.

ACUTE SEDIMENT TOXICITY TESTS

The most commonly applied standard test using both *C. tentans* and *C. riparius* is the 10-d survival and growth assay (1,7,10). The 10-d version using *C. tentans*, along with its 10-d counterpart using the amphipod *Hyallela azteca*, has been evaluated in an interlaboratory study of precision (3). The procedures and schedule for conducting a 10-d test are provided in Table 1. Although the test procedures described below and in Table 1 are those for *C. tentans*, the test conditions and requirements are similar for both species. The reader is referred to ASTM (13) and Environment Canada (14) for specific test methods for *C. riparius*.

The 10-d test method for *C. tentans* consists of exposing 10-d old larvae to a contaminated sediment at 23 °C with a light:dark photoperiod of 16:8 and an illumination of 500–1000 lux (7,12). Test chambers consist of 300 ml beakers containing 100 ml of sediment and 175 ml of overlying water. The number of replicates recommended for an assay is eight per treatment, although fewer (not less than 3) may be used. Each beaker is fed 1.5 ml of a 4 g/L Tetrafin fish food slurry each day. After the 10-d exposure period, larvae are sieved from the sediment and enumerated to determine survival. A test is considered to be acceptable if survival in the control or reference sediment is ≥70% (Table 2). If growth is to be measured,

Table 1. Test Setup and Activity Schedule of the *C. tentans* Acute Sediment Toxicity Test

Test Day	Activity
−1	Add 100 ml of homogenized sediment (or fine sand if water only exposure) to each replicate beaker and place in appropriate holding tank. Allow sediment to settle (about 1 hr), and then add 1.5 ml of Tetrafin fish food slurry (4 g/L) to each beaker.
0	Randomly allocate 10 larvae (50% must be in third instar) to each replicate beaker using a Pasteur pipette. Let beakers sit for 1 hr after addition of the larvae. After this period, gently immerse/place all beakers into the exposure system.
1-end	On a daily basis, check assay system and add 1.5 ml of food to each beaker. Dissolved oxygen should not fall below 2.5 mg/L. Reduce feeding rate or frequency if persistent low-dissolved oxygen occurs.
10	Sieve the sediment from each beaker to recover larvae for growth and survival determinations. Place recovered larvae from each replicate in preashed aluminum pans and oven dry for 24 hours at 90 °C.
11	Weigh dried larvae to the nearest hundredth milligram. If ash-free dry weight is to be determined, ash the pan and larvae at 550 °C for 2 hours. Allow pans to cool to room temperature in a desiccator and reweigh. Individual larval dry weight is determined as the difference between the total mean dry weight and total mean ashed weight divided by the number of surviving larvae per replicate.

Adapted from Ingersoll et al. (7).

larvae are placed in pre-ashed aluminum weigh pans, dried at 90 °C for 24 hours, and weighed once they have returned to room temperature. In instances where dry weight may be influenced by different sediment particle size characteristics, larval weight should be determined as ash-free dry weight (37). In this approach, the dried larvae in the aluminum pan are ashed at 550 °C for 2 hours and reweighed as above. The ash-free dry weight is determined as the difference between the dried weight and ashed weight. Larval weight is typically expressed on an individual basis (e.g., milligram dry weight per individual). However, Call et al. (38) showed that dry weight varied depending on the number of surviving larvae, with higher weights recorded in sediments with lower survival. They found that this bias was removed by expressing larval dry weights as total weight per replicate.

Once collected the data must be analyzed statistically. A detailed account of statistical procedures for analyzing data generated from both acute and chronic (see below) toxicity tests is beyond the scope of this document. For general guidance, the reader is referred to U.S. EPA (12) and Environment Canada (39).

Based on a comparison of LC50s, Watts and Pascoe (27) compared the relative performance and sensitivity of *C. tentans* and *C. riparius* in sediment toxicity tests with cadmium and lindane. They found no difference in sensitivity in exposures to cadmium but showed that *C. tentans* was significantly more sensitive than *C. riparius* to lindane. The latter result is consistent with the findings of Pauwels and Sibley (10) who compared the relative sensitivity of several sediment test species based on LC50 values obtained from a survey of the sediment toxicology literature. In most cases, *C. riparius* was found to be less sensitive than *C. tentans*.

CHRONIC SEDIMENT TOXICITY AND LIFE CYCLE TESTS

In response to the need for chronic evaluation of sediment toxicity, Benoit et al. (34) introduced a life cycle test using *C. tentans*. A parallel test was developed using the amphipod *Hyallela azteca* (40), and collectively, these two assays represent the only standardized tests currently available for evaluating the effects of sediment-associated contaminants over the full life cycle of a benthic organism (12,13). Although a long-term toxicity test using *C. riparius* has apparently been developed (41), this test has not been standardized and appears to have received little attention in recent years. Nonetheless, *C. riparius* has been applied in several long-term studies that have incorporated emergence and reproduction (42,43). Given its close similarity to *C. tentans* in most aspects of its life history, *C. riparius* could probably be readily adapted for use in life cycle testing following the standard procedure for *C. tentans*.

The recommended exposure system, required testing apparatus, and experimental design for conducting a life cycle test with *C. tentans* is described in detail in Benoit et al. (34) and U.S. EPA (12). Table 3 summarizes the activity schedule for a typical life cycle test. The test is initiated with first instar larvae that are <24 hours old. The egg cases are transferred to a glass petri dish (do not use plastic petri dishes as the larvae will quickly

Table 2. Test Acceptability Criteria (Survival and Growth) and Recommended Criteria (Emergence, Reproduction, and Percent Hatch) for Control Organisms in 10-d Tests with *C. riparius* and *C. tentans* and the *C. tentans* Life Cycle Test

Endpoint/Condition	10-d Test		Life Cycle Test
	C. tentans	*C. riparius*	
Survival	70%	70%	70%[a]
Growth	0.48 mg afdw[b]/individual	Not determined	0.60 mg dry weight/individual or 0.48 mg afdw/individual
Emergence	N/A	N/A	≥50%
No. of eggs/egg mass	N/A	N/A	≥800
Percent hatch	N/A	N/A	≥80%

Adapted from USEPA (12) and ASTM (13). N/A = Not applicable

[a] Measured at 20 days.

[b] afdw = ash free dry weight.

Table 3. Test Setup and Activity Schedule for Conducting a Life Cycle Chronic Sediment Toxicity Test with *C. tentans*

Test Day	Activity
−4	Start reproduction flask with cultured adults (10:30 male:female ratio).
−3	Collect egg cases (6−8) and incubate at 3 °C.
−2	Check egg cases for viability and development.
−1	Check egg cases for hatch and development. Add 100 ml of homogenized sediment (or fine sand if water only exposure) to each replicate beaker, and place in appropriate holding tank. Allow sediment to settle (about 1 hr), and then add 1 ml of Tetrafin fish food slurry (4 g/L) to each beaker.
0	Transfer egg cases to a glass crystallizing dish containing control water. Discard larvae that have already left the egg cases. Add 1 ml food to each beaker before the larvae are added. Randomly allocate 12 larvae to each replicate beaker using a Pasteur pipette. Let beakers sit for 1 hr after addition of the larvae. After this period, gently immerse/place all beakers into the exposure system.
1-end	On a daily basis, check assay system and add 1.5 ml of food to each beaker
6−10	Set up schedule for auxiliary male beakers as described for day −4 to day 0 above.
20	Randomly select four replicates from each treatment, and sieve the sediment to recover larvae for growth and survival determinations. Place recovered larvae from each replicate in preashed aluminum pans and oven dry for 24 hr at 90 °C. Install emergence traps on each of the remaining reproductive replicates.
21	Weigh dried larvae to the nearest hundredth milligram. Ash the pan and larvae at 550 °C for 2 hr. Allow pans to cool to room temperature in a desiccator and reweigh. Individual larval dry weight is determined as the difference between the total mean dry weight and total mean ashed weight divided by the number of surviving larvae per replicate.
23-end	On a daily basis, record emergence of males and females, pupal and adult mortality, and time to death for previously collected adults. Each day, transfer adults from each replicate to a corresponding reproduction/oviposition (R/O) chamber. Transfer each primary egg mass from the R/O chamber to a corresponding petri dish and monitor for incubation and hatch. Record each egg case oviposited, number of eggs produced (using a direct count or the ring method [Benoit et al. (34)]), and number of hatched eggs.
30	Place emergence traps on auxiliary male replicate beakers.
33-end	Transfer males emerging from the auxiliary beakers to individual inverted petri dishes. The auxiliary males are used for mating with females from corresponding treatments for which most males have already emerged (because of protandrous emergence).
40-end	After 7 d of no emergence in a given treatment, terminate that treatment by sieving the sediment to recover remaining larvae, pupae, and pupal exuviae.

Adapted from Benoit et al. (34).

attach to the bottom and become difficult to move), and only larvae that emerge from the egg cases after this transfer should be used to initiate the test. The larvae are transferred to the exposure beakers using a Pasteur pipette and the aid of a microscope. This stage of the assay can be difficult for those who lack practice in manipulating larvae of this size (typically <1 mm), and it is recommended that the user become familiar with this procedure before initiating an assay. However, starting a test with larvae at this life stage, which is typically the most sensitive to contaminants, may yield the most accurate estimate of toxicity. To aid in the successful transfer of these small larvae, the user can periodically verify the number of larvae in the pipette by holding it up to a light and against a black background. Typically each beaker receives 12 larvae, although tests using 10 larvae have been conducted successfully (44).

A unique aspect of the life cycle test is the addition of auxiliary beakers on day 10. These beakers are necessary to supply males to compensate for the protandrous emergence pattern of *C. tentans*; without the auxiliary beakers, many of the later emerging females would not have males with which to mate, diminishing the ability to adequately assess reproduction. The auxiliary male beakers are set up following the same procedures as those described for the beginning of the test.

The primary endpoints measured in the life cycle test are survival (at 20 days and at the end of the test), growth, emergence, and reproduction. If desired, additional measurements on pupal and adult survival may be recorded. Growth and survival are determined after 20 d in the same manner as described for the 10-d test. Emergence is assessed daily over a 20−30-day period using emergence traps placed on top of each beaker (34). The emergence traps double as reproductive chambers in which mating takes place and females can oviposit. Reproductive output is determined by counting the number of eggs in each egg case; this is achieved by counting the number of eggs in five equidistant rings along the egg rope and multiplying by the total number of rings in the egg case (34). The eggs are incubated until hatch is complete (approximately 6 days); at which time, remaining eggs are counted; the difference between the number of unhatched eggs and the total number of eggs from the original count provides an estimate of percent hatch. In situations where eggs are difficult to count because of poorly formed egg cases, they may be counted directly by dissolving the egg case in dilute acid (34). The life cycle test is terminated when no hatch has been observed in the control or reference sediment for a period of 7 days. Test acceptability criteria for survival and growth and recommended criteria for emergence and reproduction are provided in Table 2.

The *C. tentans* life cycle test has been evaluated in a round-robin precision evaluation, the results of which are summarized in U.S. EPA (12), and it has been used successfully in several evaluations of contaminated sediments and water-borne exposures (25,26,34,44−46). With the length of the *C. tentans* life cycle test ranging from 45 to 60 days, this test is resource-and labor-intensive relative to the 10-d test. However, because the life cycle test includes effects on survival, growth, emergence, and reproduction, it yields a substantial amount of information that can comprehensively evaluate potential risks of contaminated sediments to benthic invertebrates. Furthermore, a significant benefit of having detailed, synoptic information on survival, growth, emergence, and reproduction is that this can be applied in population modeling as has been done recently for both *C. tentans* and *C. riparius* (26,33,47,48).

FUTURE APPLICATIONS OF CHIRONOMUS SPP. IN SEDIMENT TOXICITY TESTING

With the availability of standard sediment testing procedures and clear guidelines for their use in sediment ecological risk assessment (ERA), recent efforts have been directed toward the development of sediment quality criteria/guidelines (SQGs) for the protection of benthic communities. A detailed description of the different types of SQGs and their basis is beyond the scope of this document; for information on SQGs, the reader is referred to Long et al. (49,50), Ingersoll et al. (8), MacDonald et al. (51), and U.S. EPA (52). Future refinements in sediment ERA, along with the development of appropriate SQGs, will continue to require sediment toxicity information, and it is likely that species of the genus *Chironomus* will continue to play a key role in this regard. Some areas for future methodological development in support of sediment ERA are briefly described below.

An area of recent activity in the field of sediment toxicology has been the development and validation of *in situ* test methods. Both *C. tentans* and *C. riparius* have played a central role in the development of *in situ* sediment testing methods (53–60). *In situ* tests involve the transplantation of organisms cultured under laboratory conditions to the field where exposure takes place in specialized exposure apparatus (53,54,59,60). In most cases, *in situ* tests have been developed and evaluated in relatively shallow habitats because of the difficulty in deploying organisms remotely in deeper waters. Although *in situ* assays involving *Chironomus* spp. have been evaluated, none have been developed into standardized protocols.

Another potentially important area for future development in sediment toxicity testing with both *C. tentans* and *C. riparius* will be in the area of endocrine disruption (ED). Few invertebrate assays are currently available to investigate sediment-based ED, but recent studies have shown that species of *Chironomus* may be useful in this application. From a physiological standpoint, *Chironomus* spp. undergoes complex biochemical changes, characterized by dramatic shifts in the titers of ecdysteroids, associated with both molting and pupation. Recent evidence indicates that the activity of certain ecdysteroids can be altered by endocrine disrupting compounds (61,62), which enhances the sensitivity of organisms during these sensitive life history stages. In this context, these developmental stages may serve as ideal focal points for the development of ED-based assays using these midges (63). Some research has already been conducted in this area. Watts et al. (43) used *C. riparius* growth and reproduction to evaluate ethynylestradiol (E2) and Bisphenol A but found little evidence of ED. Hahn et al. (61) found that mortality of males was twice as high as females in exposures of *C. riparius* to tebufenozide and hypothesized that this could reflect ED. Several studies have used mentum deformities in *C. riparius* as an indicator of ED. For example, Meregalli et al. (64) noted increased rates of mentum deformities after exposure to nonylphenol, whereas Meregalli and Ollevier (65) found that the rate of mentum deformities after exposure to E2 was not affected. Vermuelen et al. (66) found significant mentum deformities in *C. riparius* after exposure to lead and mercury but not ß-sitosterol, a known endocrine disrupting compound.

A common attribute of these studies was that ED was inferred secondarily through measurements on growth, reproduction, and deformations. No attempt was made to directly link changes in hormone levels to the biological effects observed. Recently, however, Hahn and Schultz (62) attempted to quantitatively link growth changes, determined by examining the development of imaginal discs in fourth instar *C. riparius* larvae exposed to tributyltin, to changes in the concentration of ecdysteroids in incubated prothoracic glands measured using radioimmunoassay. They showed that ecdysteroid synthesis decreased in females at 50 ng/L, with a corresponding decrease in the rate of imaginal disc development. In contrast, ecdysteroid synthesis increased in males at 500 ng/L, with a corresponding increase in the rate of imaginal disk development. These results may pave the way for the development of a standardized sediment bioassay using *Chironomus* spp. that can be applied in the assessment of sediment-associated ED.

Another potentially promising area in the development of sediment test methods with *Chironomus* spp. is the application of cell lines. In fact, epithelial cell lines have been used for over a two decades in relation to molecular-and genetic-based research with *C. tentans* (67–69). Recent studies have begun to elucidate hormone regulation and signaling pathways using these cell lines (70,71), whereas others have examined receptor binding affinity relationships using excised imaginal disks of *C. riparius* maintained in epithelial cell line media (72). The information derived from these studies may provide the necessary foundation for the development of an invertebrate-based cell line using *C. tentans* that could be applied individually to assess contaminants in aquatic environments or in conjunction with endocrine-based assays (see above) for assessing endocrine disruption.

A final area that may prove useful in the assessment of sediment toxicity is the development of behavioral endpoints. Behavioral changes often precede acute and chronic effects; yet behavioral endpoints have been sorely underused in the field of aquatic and sediment toxicology. Behavioral changes are likely to be strongly linked to acute and chronic responses (73), which enhance the ecological relevance of sediment bioassays using *Chironomus* spp. In *Chironomus* spp., activities such as ventilation, tube construction, and feeding could be developed into readily measured behavioral endpoints that may be more sensitive indicators of sediment contamination than many of the traditional measurement endpoints (e.g., survival, growth, etc.) (74).

CIENEGA

Leo S. Leonhart
Hargis + Associates, Inc.
Tucson, Arizona

Cienega is both a hydrologic and ecological term used primarily in the southwestern United States and northwestern Mexico to designate a riparian marshland. The term cienega derives from the Spanish phrase *cien aguas* (literally "hundred waters" or more figuratively, "place of one hundred springs"). The modern Spanish equivalent is *ciénaga* ("marsh, swamp").

Most often, the term cienega refers to broad riparian areas of slowly flowing or ponded water, populated by dense vegetation. Such hydrologic conditions are unique in the Southwest because of the limited and declining number of perennially flowing stream reaches in the arid Southwest. Cienegas may also result from the discharge of springs or other conditions involving shallow or discharging groundwater. The term has also been applied to more diverse aquatic habitats throughout areas of Hispanic influence.

In South America, cienega generally refers to floodplain lakes that have open water (1). Thus, any marshy area within the Chihuahuan-Sonoran-Mohave desert region may be called a cienega. In upland environments in Arizona, the term cienega has been used to refer to marshy to bog-like meadowlands fed by seepage, precipitation, or moving waters bordering headwater streams (1). A database maintained by the Arizona Chapter of The Nature Conservancy (TNCA) lists 160 named cienegas in the Arizona region, including two in New Mexico; 34 in Sonora, Mexico; and one in Chihuahua, Mexico. Efforts are underway to verify and characterize each site (2).

Like many other wetland habitats, cienegas have been characterized as vanishing landforms, owing primarily to certain anthropogenic factors. However, increasing awareness of the significance and uniqueness of wetlands in general has resulted in various programs to maintain and restore such areas.

HYDROLOGIC CONDITIONS

As in all wetland environments, perennial moisture at shallow soil depths, if not standing water, is requisite for a cienega. These conditions, however, are rare in arid or semiarid landscapes, where surface drainage is typically ephemeral and flows only in response to direct surface runoff. In such dry climates, the water table is generally found at considerable depth below the base of the streambed, and groundwater discharge is thereby unable to contribute baseflow. Ephemeral streams are often incised due to high loading during high intensity, short duration precipitation. Historical information indicates that arroyo cutting and incisement of many stream reaches in the Southwest began near the end of the nineteenth century from both climatic and anthropogenic changes. In contrast to typical ephemeral drainages, groundwater beneath cienegas is generally at, or very near the surface, thereby supporting baseflow and a variety of wetland species. Additionally, the cross-channel profile in cienegas is comparatively shallow and broad, sometimes extending thousands of feet across.

Cienegas can form as a result of various hydrologic, geologic, and/or ecological conditions. To sustain indigenous wetland species, cienegas require replenishment of water at rates in excess of evaporation and transpiration rates. This replenishment is supplied from shallow or discharging groundwater that occurs due to structural and/or topographic factors underlying the streambed. Hendrickson and Minckley (1) have noted various in-stream conditions that may form cienegas along stream courses. These include alternating aggradation and degradation by floods, causing alternating concave/convex stream profiling; beaver damming; slope breaks, such as at the toes of bajadas or alluvial fans; upfaulted bedrock causing localized thinning of alluvial material; channel base level adjustments with time; and impoundments caused by debris such as from slumps and landslides. Efforts to restore former cienega areas have involved constructing various types of dams and impoundments.

ENVIRONMENTAL CONDITIONS

Cienegas are wetland ecosystems and thereby represent transitional environments from terrestrial to aquatic systems. Classified wetland ecosystems require three conditions: (1) the land environment supports predominantly aquatic flora at least periodically, (2) the substrate comprises mostly saturated soils, and (3) submergence and/or saturation of the substrate persists at least for some time during the annual growing season (3). Hendrickson and Minckley (1) defined three types of cienegas in the Southwestern United States initially based on elevation. Their elevation tiers included

- High-elevation (>2,000 m) cienegas described as marshy to bog-like alpine and cold temperate meadowlands.
- Midelevation (1,000 to 2,000 m) cienegas resulting from perennial springs and headwater streams, typically found in semidesert grasslands and evergreen woodlands.
- Low-elevation (<1,000 m) cienegas occurring as subtropical marshes in oxbows, behind natural levees, and along margins of major streams.

TNCA has noted features and characteristics common to all tiers, including groundwater at or very near the soil surface; perennial surface water; occurrence within basins, usually within unincised channels; and dominant herbaceous, perennial flora, including terrestrial, aquatic, or semiaquatic species, where scattered, less dominant woody species occur (4). These characteristics further demonstrate that cienegas meet the wetland classification criteria of Cowardin et al. (4).

Because cienegas represent comparatively lush, moist areas, they offer sharp contrast to adjacent dryland ecology. The combination of slow to stagnant water, the baffle effect of dense emergent flora, and the senescence and decay of this vegetation results in accumulation of rich organic detritus in the cienega basin. This detritus comprises a nutrient-rich substrate that enhances the overall productivity of these wetland areas.

A typical botanical progression from wettest to driest zones in a desert cienega might include emergent flora such as reeds (cattails, sedges, rushes) within the wettest areas. Salt-tolerant species such as salt grass might be found along the margins of the wetted areas, where remnant salts accumulate after evaporation. Broadleaf trees, such as various species of willow, cottonwood, and the invasive tamarisk, if present, might be found farther upland. These species adapt to less saline, less saturated soil conditions. Still farther upland, as depth increases to the water table, one might find a progression toward mesquite bosques. The availability of water and resultant luxuriance of forage in such semiarid regions often result in increases in herbivore populations (Fig. 1). In turn, this has been cited as a potential factor in the demise of these habitats (1).

Figure 1. San Pedro River National Conservation Area cienega near St. David, Arizona. Note vegetation transition from sacaton grasses to senescent bullrush to woody species (photo by B. Scully).

Examples

Cienega Creek, Pima County, Arizona. Cienega Creek, located in southern Arizona, represents a discontinuous stream that has perennial flow along certain reaches. Perennial flow along this reach supports a rich riparian habitat that has prompted the county to designate a portion of the reach as Cienega Creek Natural Preserve. The cienega exists primarily as a result of bedrock structural control over groundwater flow. Gravimetric investigations within the Cienega Creek basin have indicated that flow occurs as a result of upwardly dipping, low permeability bedrock that results in thinning of the overlying alluvium so as to force groundwater to daylight through the streambed. These sudden changes in depth to bedrock have been associated with high-angle faulting (5,6). A longitudinal profile of this regime is illustrated in Fig. 2.

Southern Arizona. Cienegas similar to Cienega Creek have been noted historically throughout southern Arizona including the San Simon, Sulphur Springs, Aravaipa, and San Pedro Valleys. Extensive archaeological research within these areas has shown that human settlements in the vicinity of such areas date back to 8000 B.C. and use continued through recent native American cultures (1,7,8). Accounts of the Mormon Battalion tell of grassy bottomlands with "... salmon trout, up to three feet long," "... profuse and luxuriant [cane grass up to six feet high]," along the San Pedro River (9). Accounts of stream conditions in the San Pedro River near St. David, Arizona, in the late nineteenth century suggest that the channel profile was flat and marshy, in contrast to its present-day incisement (10). The incisement has been attributed to a variety of anthropogenic factors including groundwater pumping, grazing, agriculture, and removal of beaver dams. There have been also been accounts of significant changes in the overall hydrologic conditions attributed to a 1887 earthquake centered to the south in Sonora, Mexico. Reports of liquefaction, new springs, disappearance of former surface water and springs, and changes in water levels in wells have all been noted (11).

Cienega de Santa Clara, Colorado River Delta. The Cienega de Santa Clara is a remnant of the former desert estuary of the Colorado River. This nearly 15,000-acre wetland habitat occupies an oxbow area of the Colorado River. Diversions from the river now limit its replenishment; the remaining flow represents irrigation drainage pumped

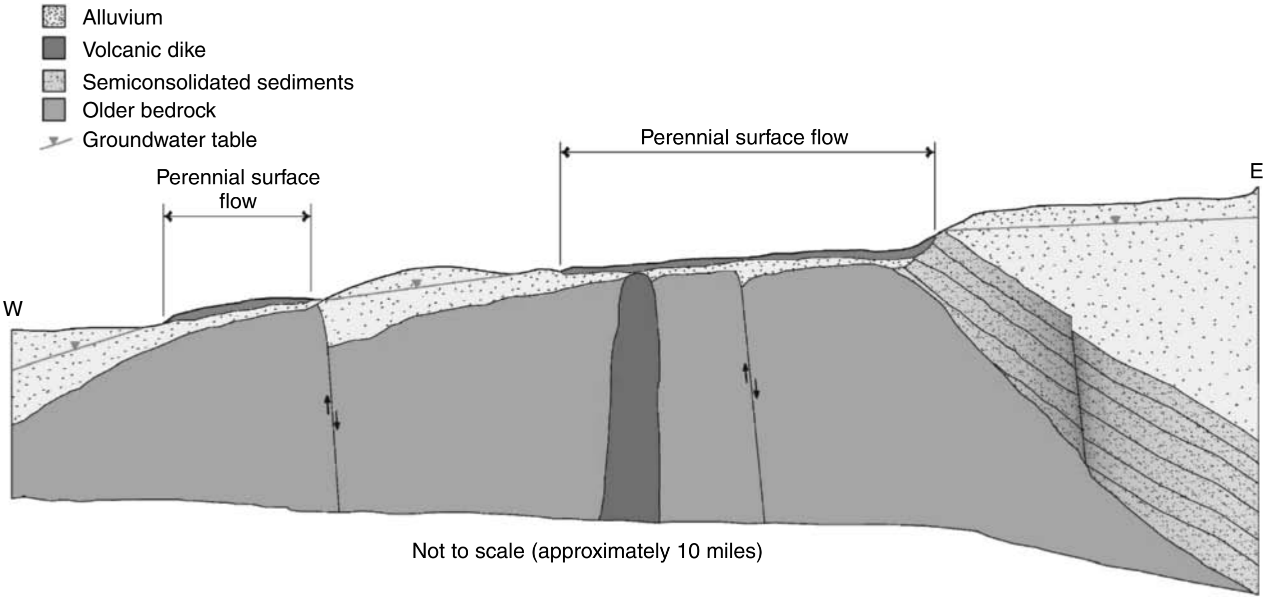

Figure 2. Conceptualization of structural components producing intermittent flow in Cienega Creek, Pima County, Arizona (5).

from agricultural land in the United States. Thus, the existence of the cienega is primary the result of anthropogenic water management. Owing to the high rate of evaporation as well as the salinity of the influent agricultural drainage, the Cienega is mildly brackish. Recent concerns over the survivability of the habitat have arisen from consideration of diverting the irrigation outflow through a desalination plant in the United States (12). This would have the combined impact of reducing the quantity of flow and increasing salinity as a result of splicing in saline blowdown from the desalination plant (13).

RELATED TERMS

Other equivalent or related terms are billabong, bog, bottomland, carr, fen, heath, marsh, pantano, riparian, mangrove, mire, moor, muskegs, oxbow, peatland, playa, pocosin, pothole, salt marsh, slough, swamp, vernal pool, and wetland. These terms relate to various types of wetland environments, but the hydrologic conditions that form them and the ecological communities that inhabit them may differ greatly. Many terms are local and regional.

Within the Southwestern United States and Northwestern Mexico, there have been numerous such water-related terms referred to in the journals of Spanish explorers, including those of Father Eusibio Kino, a late seventeenth century missionary, who made more than 150 *entradas* (“journeys” or “reconnaissance”) across the Sonoran desert during his 24-year residence. During such journeys along *El Camino del Diablo*, Kino made various references to *cienegas, tinajas*, or *tanques* (“water tanks” or “jars”), and *aguajes* (“watering holes”) along the way.

TIME-AREA AND THE CLARK RAINFALL-RUNOFF TRANSFORMATION

Bahram Saghafian
Soil Conservation and
Watershed Management
Research Institute
Tehran, Iran

INTRODUCTION

In 1945, Clark introduced a synthetic unit hydrograph whose variants have been widely applied in rainfall-runoff transformation. The Clark model, designed to consider the shape of the watershed, has two components. First, the excess rainfall is translated to the outlet based on a time-area (TA) histogram. Second, attenuation due to channel storage effects is achieved by routing the time-area hydrograph into a concentrated linear reservoir. The TA method is linear and may be considered an extension of the well-known rational method. Although Clark's original concept was semidistributed over space and invariant in time, some of its recent extensions are fully distributed (e.g., (1–4)) and time variable (4).

PRINCIPLES OF THE CLARK MODEL

Let us assume that the watershed of interest, subject to a given excess rainfall, can be divided into several zones ordered by the timing of their contributions to the outlet runoff (Fig. 1). Following the convolution rule of the unit hydrograph theory, the (excess) rainfall-runoff may be transformed by

$$Q_j = \sum_{k=1}^{j_0} E_k A_{j-k+1} \tag{1}$$

where j is the time step number, Q is the runoff outlet discharge, E is the excess rainfall intensity, and A is the area of the zone. In Eq. 1, $j_0 = j$ when j is less than or equal to the time step corresponding to rainfall duration (j_r), and $j_0 = j_\mathrm{r}$ otherwise. The application of Eq. 1 requires knowledge of the time-area histogram (TAH) which represents the time order of zone areas contributing to outlet runoff. Derivation of the TAH is a critical step in the Clark procedure and will be discussed later. Equation 1 is also known as the time-area method and constitutes the translational component of the rainfall-runoff transformation.

A fictitious linear reservoir comprises the second component of the Clark unit hydrograph which represents the attenuation effects. The storage–outflow relation of the linear reservoir is usually expressed by

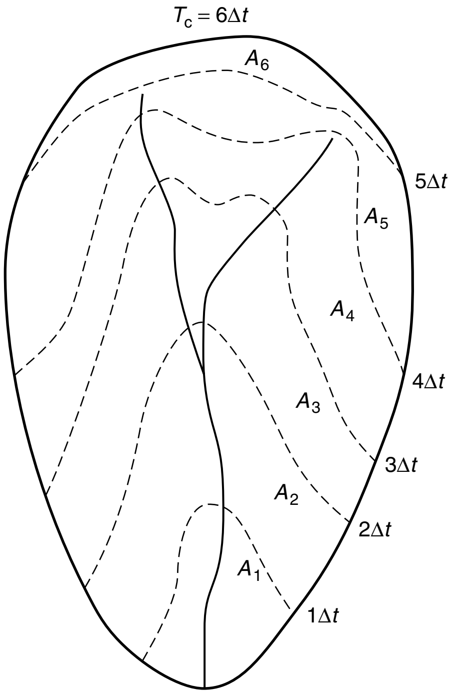

Figure 1. A watershed divided into zones (A_i) by isochrones (dashed lines).

$$S = KO \tag{2}$$

where S is the storage, K is the storage coefficient, and O is the outflow discharge. K is a characteristic of the reservoir and has the dimension of time. The Clark hydrograph is thus obtained by routing the time-area hydrograph of Eq. 1 into the reservoir of Eq. 2. One can write the continuity equation for the reservoir as follows:

$$Q - O = \frac{dS}{dt} \tag{3}$$

where Q is the inflow discharge of Eq. 1 and t is time. For a given time step Δt, Eq. 2 expands to:

$$\frac{Q_1 + Q_2}{2} - \frac{O_1 + O_2}{2} = \frac{S_2 - S_1}{\Delta t} \tag{4}$$

in which indexes 1 and 2 refer to the beginning and end of the time step. Combining Eqs. 2 and 4 results in the following form:

$$O_2 = C_0 Q_2 + C_1 Q_1 + C_2 O_1 \tag{5}$$

where

$$C_0 = \frac{\Delta t}{2K + \Delta t}$$

$$C_1 = \frac{\Delta t}{2K + \Delta t}$$

$$C_2 = \frac{2K - \Delta t}{2K + \Delta t} \tag{6}$$

Note that $C_0 = C_1$ and the summation of C coefficients in Eq. 6 is equal to one.

Example

The following example illustrates the calculation of a unit hydrograph and a total hydrograph based on the Clark model. Assume that the time-area histogram of a small 1000-ha watershed is given in Table 1. Also, $K = 30$ min and $\Delta t = 15$ min.

1. Determine the 15-min Clark unit hydrograph for 1 cm unit depth.
2. Determine the discharge hydrograph corresponding to an excess rainfall intensity of 10 mm/h over the (0–30) min period and 5 mm/h over the (30–45) min period.

Solution

1. Table 2 summarizes the unit hydrograph calculation based on Eqs. 1 and 5
2. There are two possible approaches for solving this part. One is to use the unit hydrograph, as shown in Table 3. The second is to bypass the unit hydrograph and calculate the total hydrograph directly from the time-area histogram, storage coefficient, and excess rainfall hyetograph. This is shown in Table 4.

CLARK MODEL PARAMETERS

Application of Clark's model requires knowledge of some key parameters that are physically or conceptually derivable from watershed characteristics, or, alternatively, from historic rainfall-runoff data. These parameters include the time of concentration (T_c), the time-area histogram (TAH), and the linear reservoir storage coefficient (K).

Several definitions have been proposed for the time of concentration. One of the oldest definition introduces T_c as the time for (a drop of) water to travel from the most distant part of the watershed to the outlet. Some literature emphasizes that the distance has a hydraulic base, not necessarily a geometric base. Another definition deals with the wave travel time from the most hydraulically remote point to the outlet of the watershed, which is essentially the time elapsed for all parts of the watershed to contribute to the direct runoff at the outlet. In graphical analysis of a combined hyetograph-hydrograph, T_c is also defined as the time between the end of excess rainfall and the inflection point on the falling limb of the hydrograph (Fig. 2). It is assumed that the inflection point indicates the end of direct runoff. Time of concentration is essentially a function of rainfall intensity and watershed characteristics. Refer to Saghafian (5) in the *Encyclopedia of Water* for further information about time of concentration and how it differs from time to equilibrium.

A fundamental step in applying the Clark model is constructing the TAH. But first, we have to turn our attention to the concept of an isochrone. An isochrone is a contour of equal travel time to the outlet or a line connecting all watershed points that have the same travel time to a common outlet. The isochrones start and end only at the watershed boundary. The time-area histogram, also known as the time–area graph,

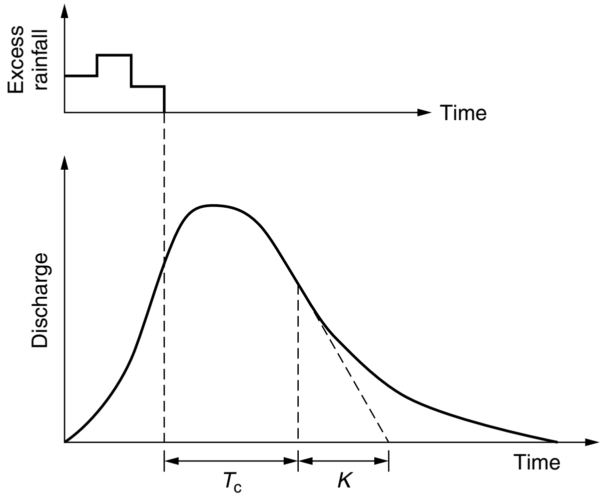

Figure 2. Graphical representation of time of concentration (T_c) and storage coefficient (K).

is a discrete time histogram of the incremental areas enclosed by adjacent isochrones, which are apart by a finite time interval Δt (Fig. 3a). TAH represents the time distribution of sequential areas participating in surface runoff generation at the outlet. To construct the TAH, the watershed time of concentration must be divided into a number of equal time intervals, which are the travel time differences between adjacent isochrones. The isochrone spacing and construction of a TAH will be discussed later.

Some literature also introduces a concept known as a time-area diagram. A time-area diagram is the plot of area, on the y axis, whose travel time is less than or equal to a given time, shown on the x axis (Fig. 3b). From the TA diagram, one can determine the area that contributes to the outlet runoff for any given time. A TA diagram is a continuous time function. A time-area curve (Fig. 3c), or TAC, is the derivative of a TA diagram and is equivalent to the TAH when Δt tends to zero.

The TAH can be looked upon as the basis for a unit hydrograph. When an excess rainfall of 1.0 unit depth over Δt time duration is applied to a TAH through Eq. 1, then a unit hydrograph of Δt duration is produced. For example, TAH's y axis, say, in m^2, multiplied by 0.01 m (1.0 cm) of rainfall depth and divided by the value of Δt, say, in seconds, yields a unit hydrograph whose ordinates represent discharge in m^3/s and its volume is equal to 1.0 cm or 0.01 m across the total watershed area. When both the rainfall duration and the TAH Δt tend to zero (i.e., the isochrone time difference becomes smaller and smaller so that the TAH turns into a continuous time-area curve), an instantaneous unit hydrograph is formed.

Clark's linear reservoir storage coefficient is a physical character of the watershed that cannot be directly measured. It is, however, graphically defined as the negative of the discharge divided by the slope of the hydrograph at the point of inflection on the recession limb.

$$K = \frac{-Q}{dQ/dt} \tag{7}$$

According to Fig. 2, K is equal to the time interval between the point of inflection and the point at which the tangent to the point of inflection intersects the time axis.

An alternate way of determining Clark parameters for gauged watersheds is to use recorded rainfall-runoff to calibrate a Clark-based model for unknown parameters. For ungauged watersheds, regional empirical relations may be developed using the rainfall-runoff data of gauged watersheds in the region. In different parts of Australia, for example, relations of the following type are commonly adopted (6,7):

$$T_c = m_0 L^{m_1} S^{m_2} \tag{8}$$

$$K = n_0 L^{n_1} S^{n_2} \tag{9}$$

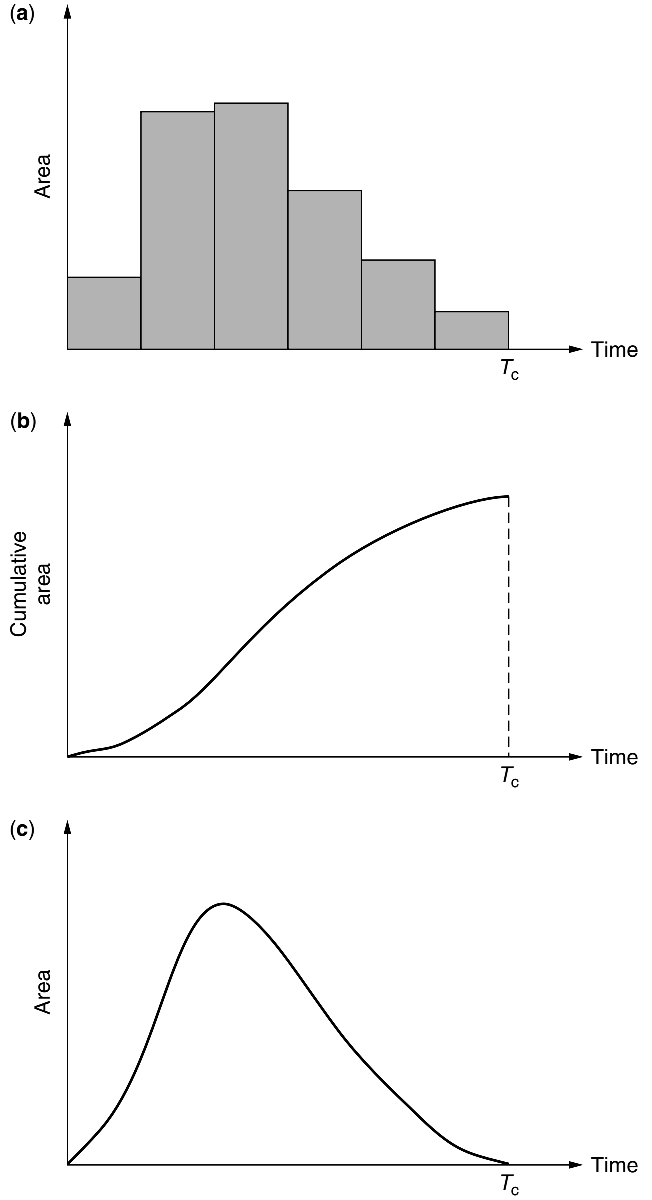

Figure 3. (**a**) Time-area histogram, (**b**) time-area diagram, and (**c**) time-area curve.

where L is the main stream length, S is the main stream slope, and m's and n's are constants for homogeneous regions.

A COMPREHENSIVE ISOCHRONE SPACING METHOD

Saghafian and Julien (8) derived a general formula for the travel time from the most hydraulically remote point to the watershed outlet:

$$T_{\mathrm{w}} = \int_0^L (1-\gamma)\left(\frac{a_1}{Q_e}\right)^{\gamma}\left(\frac{n}{a_2^{2/3}S_0^{1/2}}\right)^{1-\gamma} dx \qquad (10)$$

where T_{w} is the total travel time equal to the time to equilibrium, L is the total length along the hydraulically longest flow path; x is the distance measured along the flow path; Q_e is the equilibrium discharge; a_1, a_2, and γ are flow cross-sectional parameters; S_0 is the bed slope corresponding to the *kinematic time to equilibrium*; and n is the Manning roughness coefficient. T_{w} in Eq. 10 is also a theoretical form of time of concentration. Note that travel time in Eq. 10 can also be computed for points other than the watershed outlet by changing the upper integral limit. Therefore, the travel time may be computed for all locations in the watershed using Eq. 10, and isochrones can be derived.

The equilibrium discharge Q_{e} passing through a given cross section at location x, is equal to the spatially integrated excess rainfall rate over the drainage area of that cross section. In mathematical terms, Q_{e} may be expressed by

$$Q_{\mathrm{e}}(x) = \int_0^{A(x)} E\,dA \qquad (11)$$

where $A(x)$ is the upslope drainage area or flow accumulation at distance x and E is excess rainfall intensity at any point draining to x. To solve Eq. 10, the spatial variability of excess rainfall and that of the drainage area along the hydraulically longest flow path must be known.

The total travel time, T_{w}, can be separated into the travel time for overland flow, T_{wo}, and for channel flow, T_{wc}. If the cross-sectional area and the hydraulic radius can be expressed by relations of the form $A_x = a_1 h^{b_1}$ and $R = a_2 h^{b_2}$, where a_1, a_2, b_1, and b_2 are constants for a given cross section and h is the flow depth, then,

$$\gamma = \frac{2b_2}{2b_2 + 3b_1} \qquad (12)$$

when Manning's equation is used. For overland flow and flow in wide channels, a_2, b_1, and b_2 equal unity and $\gamma = 2/5$ (8). If the excess rainfall intensity E is uniform in space, then $Q_{\mathrm{e}} = EA$, and the term $1/E$ can be taken out of the integral. Thus, the travel time is proportional to $E^{-\gamma}$. For watersheds that have wide channels,

$$T_{\mathrm{w}} = CE^{(-2/5)} \qquad (13)$$

where C is a watershed hydrogeomorphologic index conglomerating spatially distributed characteristics such as surface roughness, slope, flow length and flow accumulation, drainage pattern, and channel geometry. Comparing Eq. 13 with the available empirical formulas of time of concentration, one observes that most empirical formulas ignore the effect of rainfall intensity.

SIMPLIFIED ISOCHRONE SPACING METHODS

Laurenson (9) proposed an early method of isochrone spacing. He assumed that the travel time from any point in the watershed to the outlet is proportional to $\sum(l_i/{S_i}^{1/2})$, where l_i is the length of the ith reach along the flow path of that point toward the outlet and S_i is the slope of the reach. The summation is over the entire flow path. The procedure starts by selecting a number of points on all elevation contours distributed uniformly. The flow paths to the outlet originating from all points are plotted. The flow reaches are bounded by adjacent contours that have uniform elevation differences of, say, H. Therefore, the value of ${l_i}^{3/2}/H^{1/2}$ may be computed for any reach, where the slope has been substituted by H/l_i. That is to say that the travel time is proportional to $l^{3/2}$, provided that the reaches are measured between adjacent elevation contours. Once the summation values are computed for all points, they are divided by the largest summation value which represents the maximum travel time. This yields the relative travel times for the points selected. Now the isochrones can be plotted by interpolating the point values. It is easy now to develop the TAH. Geographic information systems (GIS) can be deployed to facilitate and improve the procedure. A difficulty of this method is that an independent estimate of the absolute value of maximum travel time, or the time to equilibrium, is still required for further application of the time-area method.

Pilgrim (10) argues that, based on some tracer observations in a 96-acre watershed with a dense stream network in Australia, the ratios of velocity of different reaches to that of the longest reach vary markedly with discharge. This amounts to variable distribution of isochrones corresponding to different floods. This variability is weaker for medium to high discharges observed, however. The tracing data collected by Pilgrim (10) confirmed that flood velocities tend to increase slightly in a downstream direction through the watershed, despite decreasing slope.

Some methods rely on physiographic and geomorphological parameters to determine isochrone spacing. Pilgrim (10) examined several isochrone spacing parameters versus tracer data corresponding to two discharges collected in a small watershed. Four of the parameters were as follows:

$$\sum l_i \tag{14a}$$

$$\sum \frac{l_i}{{S_i}^{1/2}} \tag{14b}$$

$$\sum \frac{l_i}{{S_i}^{1/2}{R_i}^{2/3}} \tag{14c}$$

$$\sum \frac{n_i l_i}{{S_i}^{1/2}{R_i}^{2/3}} \tag{14d}$$

where l_i is the length of the ith reach, S_i is the slope, R_i is the hydraulic radius, and n_i is the Manning roughness. Hydraulic radius was estimated through field observations and geometric relations corresponding to bankful discharge. The first parameter assumes uniform velocity throughout the stream reaches. It was proposed by Clark (11) but was later neglected. Other parameters consider those reach characteristics believed to represent velocity. Parameter 14b is similar to that proposed by Laurenson (9). The last two more complex parameters gave the best overall estimates, and the commonly used second parameter was poorest. The first parameter, simply derived from topographic maps, was of accuracy comparable to that of more complex parameters. These parameters give the relative location where isochrones intersect with streams. The method must be extended somehow to overland parts of the watershed so that the isochrones can be extended to watershed boundaries. Even then, the value of time of concentration or the maximum travel time must be known so that the time-area transformation can be applied.

If no specific TAH is available, HEC (12) proposed a simple dimensionless cumulative time-area diagram as follows:

$$\begin{aligned} A^* &= 1.414(T^*)^{1.5} && \text{if } 0 < T^* < 0.5 \\ 1 - A^* &= 1.414(1 - T^*)^{1.5} && \text{if } 0.5 \le T^* < 1 \end{aligned} \tag{15}$$

where A^* is the cumulative area as a fraction of total watershed area and T^* is the fraction of T_c. This equation has been implemented in the HEC-1 model.

Kull and Feldman (3) assumed that travel time for each cell in a watershed is simply proportional to the time of concentration scaled by the ratio of travel length of the cell over the maximum travel length, that is, the average velocity of runoff traveling from any point to the outlet is assumed uniform and constant. Each cell's excess rainfall is then lagged to the outlet by the cell's travel length. Travel time in overland and in channels follows similar proportionality, and travel length and the watershed time of concentration must be determined a priori. The method is equivalent to the distributed form of the first parameter considered by Pilgrim (10). This approach has been implemented in the HMS model (13), a new version that replaces the HEC-1 model.

TIME VARIABLE ISOCHRONE METHOD

Rainfall intensity generally varies over time, so travel times will inevitably change. That is to say that the assumption of storm-independent unit hydrograph ordinates, represented by A's in Eq. 1, is not valid and time variability actually occurs in isochrone maps and TAHs. The use of the variable isochrone technique in rainfall-runoff transformation was first proposed by Saghafian et al. (4). In this technique, isochrone spacing and time-area histograms are updated at those time steps where rainfall intensity changes. Any TAH derived then corresponds to a given rainfall intensity and generates a partial hydrograph. The total hydrograph is derived by convoluting partial hydrographs. The numerical procedure is briefly described as follows.

The watershed is first discretized by a raster grid. The time-variable isochrone algorithm consists of four components. The first component derives terrain-based features by taking digital topographic data, usually in vector format, as input and generates raster terrain maps such as a depressionless digital elevation model (DEM), flow direction, and flow accumulation (i.e., an upslope drainage area). The temporal and spatial distributions of excess rainfall are determined by the second component, which requires soil infiltration parameters as well as the spatiotemporal variation of rainfall intensity. The third component uses maps derived in conjunction with the map of the roughness coefficient to develop differential (pixel scale) and total cumulative travel-time-to-outlet maps, based on Eq. 10, and a time series of isochrone maps corresponding to various excess rainfall intensities. The fourth component performs TA convolution to calculate the total runoff hydrograph. This hydrograph can then be routed into the linear reservoir.

The third component is a critical part of the computations. To generate a cumulative travel-time map, isochrones of equal travel times are derived, and the areas bounded by adjacent isochrones are determined. Aggregate time-area histograms may be sufficient for uniform excess rainfall, but the spatial extent of the areas in a given travel-time range is quite important in runoff computation when dealing with spatially variable excess rainfall. In the latter case, the equilibrium discharge map of Eq. 11 is directly substituted in Eq. 10 for travel-time calculations. Then, instead of TAH, a "time-discharge" histogram (TDH) is constructed based on the equilibrium discharge map divided by isochrones. TDH itself represents the runoff hydrograph for any period of constant excess rainfall intensity.

Note that the third component must be repeated N times, where N is the number of excess rainfall intensity maps. This is equal to the number of excess rainfall intervals of constant intensity. The final output is N isochrone maps. However, in watersheds where with wide channels subject to uniform excess rainfall, we need to execute the third module once. After derivation of the TAH for any value of excess intensity (say, E_1), the TAH of, say, E_2 intensity may be easily produced by scaling the time axis by the ratio $(E_2/E_1)^{-0.4}$. Resampling of the time axis of all TAHs may be necessary to achieve a common time interval.

In the fourth component, N incremental hydrographs corresponding to N isochrone maps are determined by convolution. These incremental hydrographs, delayed by their corresponding excess intensity times, are then superimposed to yield the total hydrograph.

GENERAL REMARKS

1. One of the major advantages of the Clark model is that the temporal rainfall pattern can be accounted for. Using the newly proposed Clark-based models discussed before, the spatial distribution of rainfall may also be considered in runoff computations.
2. It is possible to derive a discharge hydrograph directly from a TAH and an excess rainfall hyetograph. This bypasses the Clark unit hydrograph and is advantageous when only a single hydrograph is to be computed.
3. Clark's original idea has been upgraded to a fully distributed time-variant approach by Saghafian et al. (4). The proposed approach can handle the spatial distribution of excess rainfall, and it can also consider the variation of travel time due to the dynamics of excess rainfall.

STREAM CLASSIFICATION

WAYNE D. ERSKINE
State Forests of New South Wales
Beecroft, New South Wales, Australia

Stream classification is important for characterizing the features of individual rivers or sections of river and also for determining the similarity of different streams. The latter is essential to assess which rivers are suitable for extrapolating of research results from elsewhere. Various schemes have been proposed for specific disciplines and purposes. There is no universally accepted stream classification scheme because they all require modification to apply to rivers different from those used to construct the scheme Therefore, classificatory schemes should be continuously revised and updated.

STREAM CLASSIFICATION HIERARCHY

A nested hierarchical scheme based on the channel network which places the stream within a drainage basin or watershed context is the best approach to stream classification. Table 1 defines the characteristics of, and range of scales for, each hierarchical level. Figure 1 clearly

Table 1. Hierarchical Framework of Stream Classification Proposed by References 1 and 2 and Illustrated in Fig. 1

Classification Level	Scale (River Length)[a] Small	Large	Essential Features
Watershed or drainage basin	$>10^3$ m	$>1,000$ km	Watershed/subwatershed scale boundary conditions
Valley segment	$>10^2$ m	100–1,000 km	Length of valley of essentially constant form and external conditions
Reach type	>10 m	10–100 km	Length of river exhibiting relatively homogeneous channel characteristics or a consistent pattern of repetitive/alternating characteristics
Channel unit or mesohabitat	$>10^0$m	0.1–10 km	Area of relatively homogeneous bed material, flow velocity, and flow depth
Microhabitat	10^{-1}m	<0.1 km	Patch of similar flow velocity, substrate, and cover

[a] Scale is only indicative and must be appropriate to basin or watershed size which is highly variable.

illustrates the relationships between each classification level, where each forms the environment of its subsystem at lower levels. The smallest linear spatial scale has been taken from Frissell et al. (1) who concentrated on small mountainous forested streams. However, the size of each level increases with watershed area and runoff. Each level of the classification scheme is now discussed.

Watershed

This is the highest level of the classification scheme (Table 1) and was proposed by Frissell et al. (1) for use in bioclimatic regions. Such regions have not been defined for many parts of the world. Nevertheless, the watershed can be characterized by other general watershed characteristics, such as the Koeppen–Gieger climatic region which provides an indicator of the natural hydrology of a river. In addition, geomorphic regions have been defined for most countries and provide a good indicator of the potential energy and bedrock confinement of a river. The nature of sediment supplied to rivers can be gauged from the generalized geology. Vegetative cover and land use partly determine sediment yields which exert a strong control on stream characteristics.

Valley Segment

Following Bisson and Montgomery (2), a valley segment refers to the valley form based on the dominant types of sediment input and transport processes (Table 1). The Frissell et al. (1) classes for valley segments have been expanded to allow for the full range of conditions likely to be experienced when attempting to classify streams. *Bedrock* valleys have high sediment transport capacities because of steep slopes and close lateral and vertical confinement. *Colluvial* valleys are partly filled with poorly sorted sediment supplied from the surrounding hillslopes. *Alluvial* valleys are partly filled with sediments deposited by the present or former river and by floodplain flows. *Lacustrine* valleys refer to those superimposed on lake sediments because many rivers discharge into terminal lakes or flow for some distance over exposed lake beds. *Aeolian* valleys are those where rivers cut through, or are dissipated in, sand dunes. *Artificial* valleys are those created by human construction such as urbanization, drainage, flood mitigation, and irrigation.

RIVER REACHES

River reaches are homogeneous lengths of channel within which hydrologic, geologic, and adjacent watershed

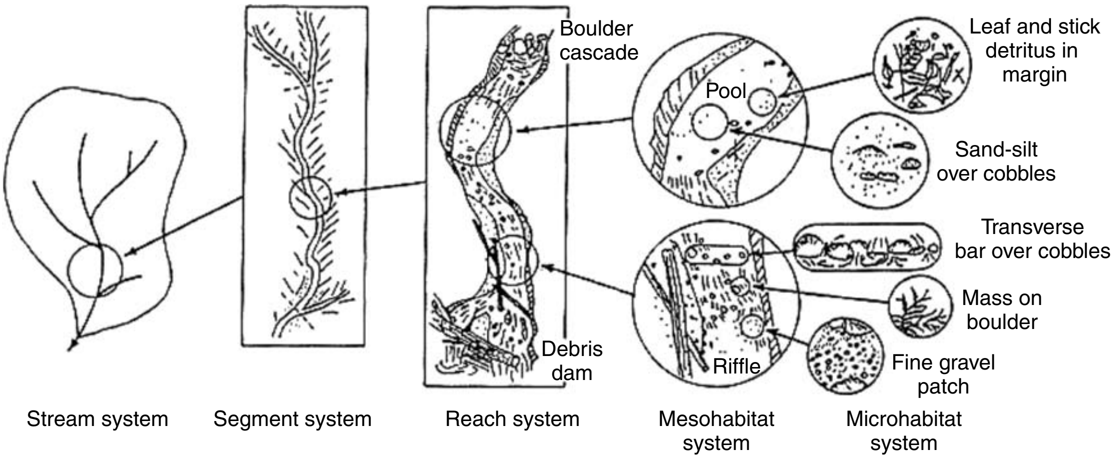

Figure 1. Hierarchy of a stream system proposed by Reference 1. The stream system is also called the watershed or drainage basin, the segment system is also called the valley segment, and mesohabitats are also called channel units (2).

surface conditions are sufficiently constant so that a uniform river morphology (3) or a consistent pattern of alternating river morphologies is produced (4). Bisson and Montgomery (2) proposed that channel reaches consist of relatively homogeneous associations of channel units, which distinguish them from adjoining reaches.

Reaches are typically 10–100 km long (Table 1). The core length of a reach is relatively easy to identify, but it is often more difficult to define precisely the boundaries of the reach due to its transitional nature (5). Bisson and Montgomery (2) proposed that provisional reach boundaries could be identified from topographic maps, vertical air photographs, and geology and soil maps, and then the channel units could be determined from selective field surveys. However, any method based on field surveys will be costly and time-consuming. There is also a problem of determining how to interpolate spatially from the sample site to the reach when the whole river is not sampled. Furthermore, a lot of detailed channel unit measurements often do not meaningfully define reach boundaries (4).

There is no agreement as to which criteria should be used to identify river reaches. Geomorphic criteria dominate most of the published schemes because reach identification is usually based on interpretation of vertical air photographs or other remotely sensed data. The schemes of References 3 and 6–10 used up to 25 different geomorphic criteria, and a similar trend is exhibited by ecologically based schemes.

Reach identification is an iterative process based on cross-checking between map and air photograph patterns and the channel units observed in the field. Therefore, periodic revisions of stream reaches should be expected as more data are collected, spatial variations in channel characteristics are better documented, and the controls on stream morphology are better understood (4).

Where appropriate, reaches can be given a formal name usually comprising three terms. The first term is based on a geographic name for a location within or near the reach; the second is a geomorphological or ecological descriptor for one of the dominant characteristics of the reach; and the third, when needed, is the term reach or zone. For example, the *Willis sand zone* on the Snowy River, Australia, is 93.5 km long and was named after Willis (the area at the New South Wales/Victorian border on the Snowy River, which is located within the reach) and the extensive sand storage that occurs in the long, relatively flat parts of this reach that are sandwiched between shorter, steeper bedrock sections (4,11).

Channel reaches can be placed into specific reach types such as those defined by Rosgen (8,9). However, Rosgen's classes must be expanded if they are to be applied universally so as to include reach types that are not currently recognized. For example, two such reach types are floodouts (12,13) and low-energy, straight channels (14,15) that are common in many parts of Australia. There are other reach types that also need to be added to the Rosgen scheme.

After identifying and naming channel reaches, each should then be allocated to one reach type for each valley segment. Each reach type can be given a simple descriptive name based on its geomorphic characteristics, such as sandstone gorge, anabranching river, or straight, low-energy river. This is more meaningful than the alphanumeric naming system of Rosgen (8,9). For example, "sandstone gorge" is a more informative name than "A1." Correlations between rivers should be based on reach type.

Channel Units

Hawkins et al. (16) defined channel units as "..quasi-discrete areas of relatively homogeneous depth and flow that are bounded by sharp physical gradients..". Recent research has demonstrated that each channel unit exhibits different physical characteristics and can also be associated with habitat-specific assemblages of fish species (17,18). Figure 2 outlines the channel units that are commonly recognized by geomorphologists and fish ecologists as useful for stream classification. A three-tiered system was proposed by Hawkins et al. (16) so that the user can select the level of channel unit resolution appropriate for the question being addressed. At the highest level, a bipartite division of channel units has been adopted, namely, slow water and fast water (Fig. 2). Each higher level channel unit has then been subdivided into two types, which are then further subdivided on the basis of hydraulic characteristics and the principal kind of habitat-forming structure or process (Refs. 2, 16, and 19).

Channel units are defined on the basis of low flow or baseflow conditions, and slow water habitats consist of various types of pools, which are formed by either erosion (*scour pools*) or damming (*dammed pools*). For the scour pool category (Fig. 2), additional classes have been added to those of Bisson and Montgomery (2) and Hawkins et al. (16) based on Webb and Erskine (19) and are outlined in Table 2. Each scour pool is now briefly defined. A *plunge pool* is a deep pool eroded at the base of a waterfall (2). Turner and Erskine (20) coined the term *"scour hole"* for large, deep holes eroded at the boundary of a bedrock gorge with alluvium. There is no waterfall at the transition from bedrock gorge to alluvium, and hence, the holes are not plunge pools because there is no vertical drop. Furthermore, scour holes are often sand-floored rather than lined by boulders or bedrock (20). Unlike Bisson and Montgomery (2), Hawkins et al. (16), and Grant et al. (21), *step pools* are differentiated from plunge pools because of the substantial difference in the surface area and depth of the pools and in the height of the fall at the upstream end of the pool. Step pools are usually orders of magnitude smaller and have smaller falls into them. They are small pools eroded by a fall over bedrock, boulders, and log steps in steep channels and are more closely spaced than free-formed pools associated with riffles (21). *Free-formed pools* are intended to cover standard pools eroded by high flows in many alluvial channels (22). They are rhythmically spaced five to seven channel widths apart and are closely associated with riffles, which are formed by the deposition of the sediment eroded from the pools by high bankfull flows (22). *Eddy pools* are eroded by turbulent eddies downstream of obstructions and are proportional to the size of the obstruction which is usually bedrock, boulders, or large woody debris. *Trench*

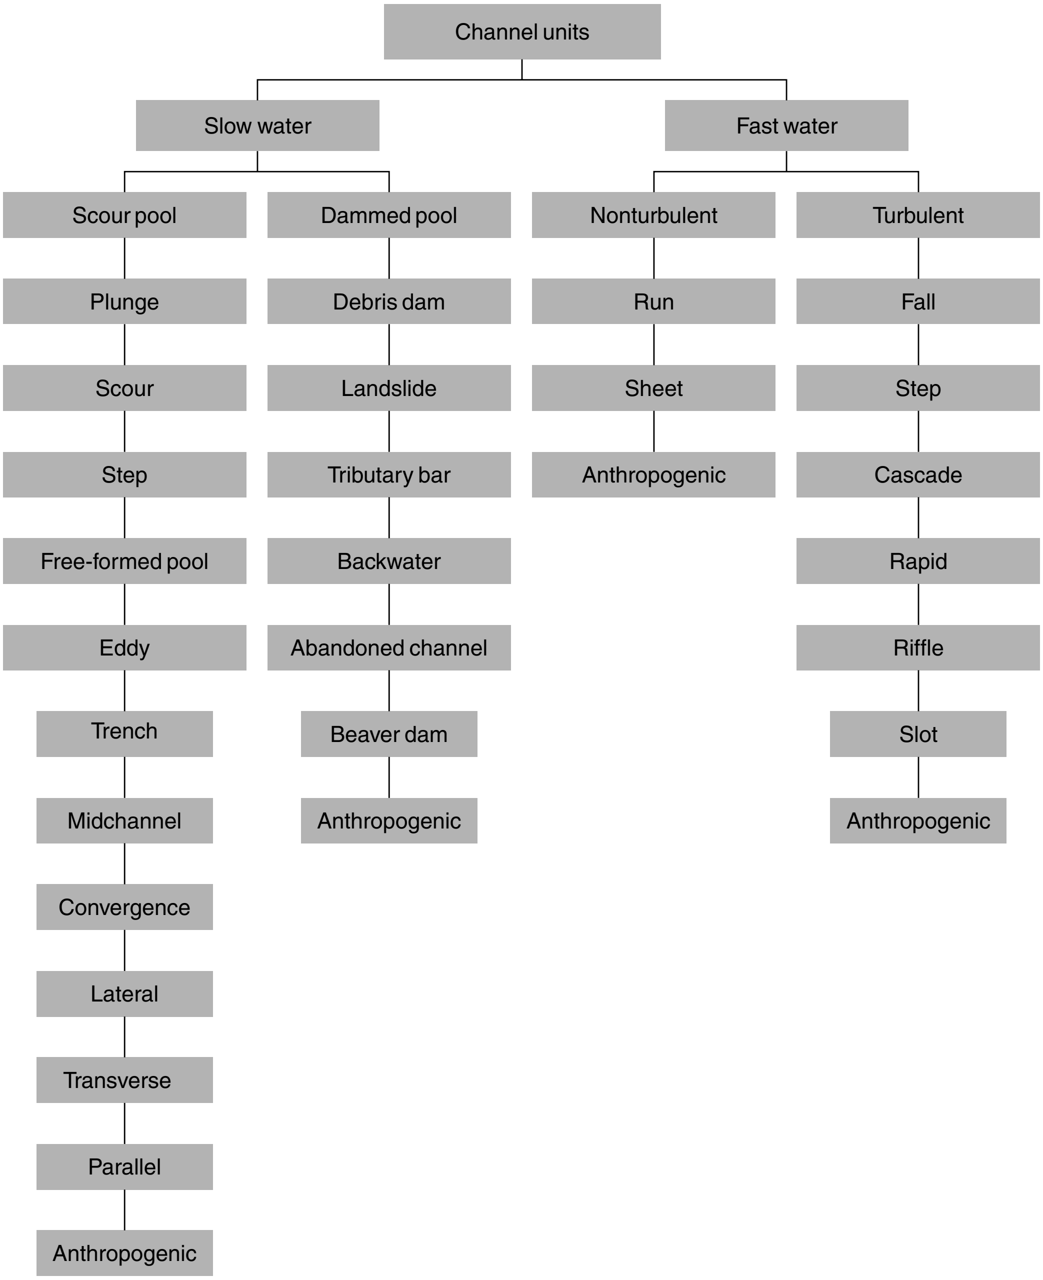

Figure 2. Channel units adapted from References 2, 16, and 19.

pools are uniformly eroded deep pools sandwiched between resistant, usually bedrock banks. They are a feature of the inner bedrock channels of Schumm et al. (23). *Midchannel pools* are formed by flow constrictions that concentrate scour in the center of a river. They differ from trench pools in that the constriction is oriented perpendicularly to the channel rather than parallel. *Convergence pools* form by the erosion of converging currents from two channels. These may be two independent channels (that is, a tributary joining the main stream) or two channels that form part of a braided or anabranching network. *Lateral* or *longitudinal scour pools* develop by erosion along or beside an obstruction or resistant material on one side of a river. They are common on bends where the river impinges against bedrock or large bank-attached pieces of large woody debris (19). *Transverse scour pools* are formed by scour under suspended, immobile pieces of bank-attached, channel spanning large woody debris or trees aligned transverse to the flow direction (19). *Parallel scour pools* are eroded by continuous scour at the head and around both sides of bed-attached large woody debris or large boulders aligned parallel to the flow direction and not attached to the banks (19). *Anthropogenic scour pools* are included for completeness to account for scour induced by human structures.

For the dammed pool category (Fig. 2), the classes of Bisson and Montgomery (2) and Hawkins et al. (16) have been slightly expanded (Table 2). *Debris dam pools*

Table 2. Types of Pools or Still-Water Channel Units

Pool Type	Formative Process	Common Locations
Plunge pool	Large-scale turbulent scour at base of waterfall	Immediately below high outcrops of resistant bedrock or the edge of escarpments
Scour hole	Large-scale turbulent scour at transition from resistant bedrock to alluvium	Where faults or monoclines cut across a river
Step pool	Small-scale turbulent scour below bedrock, boulder, or log steps	Steep upper reaches of channels or in reaches with high loadings of large woody debris
Free-formed pool	Large-scale, rhythmically spaced turbulent scour by flood flows in gravel and/or sand-bed streams	Alluvial reaches and often associated with bends
Eddy pool	Turbulent scour by eddies associated with obstructions, such as large boulders or large woody debris	Bedrock-confined reaches, where rivers flow across resistant bedrock or floodplain reaches with large riparian trees
Trench pool	Turbulent scour at channel constrictions between bedrock walls	Gorges, bedrock-confined reaches or localized outcrops of resistant bedrock
Midchannel pool	Turbulent scour at channel constrictions oriented at right angles to the river	Localized outcrops of thin resistant bedrock that strikes at right angles to the river
Convergence pool	Turbulent scour by converging currents from two channels	Tributary junctions, multichannel reaches (braided and anabranching rivers) or where flood chutes rejoin the main channel
Lateral longitudinal scour pool	Turbulent scour along an obstruction or resistant material	Wherever a river locally impinges against large woody debris or resistant bedrock; generally in higher energy reaches than transverse scour pools
Transverse scour pool	Turbulent scour under suspended, bank-attached, channel-spanning large woody debris or trees aligned transverse to flow	Wherever a river is flanked by a riparian forest and stream power is insufficient to remove suspended timber totally
Parallel scour pool	Continuous large-scale turbulent scour at the head and along both sides of bed-attached large woody debris or boulders aligned parallel to the flow	Wherever a river is flanked by a riparian forest, and stream power is insufficient to redistribute an obstruction from the center of the channel to either bank
Anthropogenic scour pool	Small- and large-scale turbulent scour induced by an engineering structure, such as on the downstream side of a weir or dam.	Essentially random depending on location of road crossings, sites with good foundations for a structure, etc.
Debris dam pool	Impoundment by large woody debris	Wherever a river is flanked by a riparian forest and stream power is insufficient to remove obstruction totally
Landslide dam pool	Impoundment by the debris transported by a landslide	Steep upland reaches where there are high rainfall intensities and cohesive soils
Backwater pool	Pools where one channel is dammed by another or where a local channel expansion prevents active flow	Can occur throughout river systems
Disconnected pool	Impoundment of a water-table window away from the main channel by a bar of sediment	Wherever bars are well developed
Abandoned channel pool	Ponding of a deep section of a former river course	Where floodplains are well developed
Beaver dam pool	Impoundment of water by a woody barrier constructed by beavers (*Castor canadensis; Castor fiber*)	Where beaver colonies are present
Anthropogenic dammed pool	Impoundment of water by an engineering structure, such as a weir or a causeway	Essentially random depending on location of road crossings, sites with good foundations for a structure

are impounded by one or more pieces of large woody debris that is anchored in the channel. *Landslide dam pools* are impounded by the debris deposited by a mass movement into the channel. Tributary-mouth bars are downstream elongated sediment bodies originating at the confluence of one, usually smaller channel with another (24). Such bars can accumulate in the channel, impounding a pool upstream (25). *Backwater pools* occur along the edges of channels at local expansions or at junctions with secondary channels. Flow separation envelopes with reverse or upstream-directed currents are often present in the expansions. *Disconnected pools* are completely separated from the main channel at low flows by a bar or mound but are deep enough to be a window in the water table. They may be associated with secondary channels. *Abandoned channel pools* are ponded sections of a cutoff or avulsion that have no surface water connection to the main stream. *Beaver dam pools* are formed by impoundment by a woody barrier constructed by beavers (*Castor canadensis; Castor fiber*). *Anthropogenic dammed pools* are included for completeness to account for structure-induced impoundment.

Fast water habitats are divided into *nonturbulent* and *turbulent* channel units (Fig. 2). A *run* is a deeper, slower, less steep fast water bedform than a riffle (see below) that exhibits no supercritical flow. A *sheet* is a section of uniform water flow over smooth bedrock of variable gradient. An *anthropogenic nonturbulent unit* is one constructed by humans such as a causeway.

Turbulent fast water channel units (Fig. 2) are similar to the classes of Bisson and Montgomery (2) and Hawkins et al. (16) and are characterized by supercritical flow and hydraulic jumps sufficient to entrain air and create localized patches of white water. However, different definitions are proposed below for some of their channel units. *Falls* are high, essentially vertical drops, spanning the whole channel. The distinction between a fall and a bedrock, boulder, or log step (see below) is height. Falls are higher than the bankfull channel depth and excavate plunge pools at their bases. *Steps* are low (less than bankfull channel depth), essentially vertical drops over bedrock boulders or logs that may not span the channel. *Cascades* are steep sections composed of a series of bedrock, boulder, and/or log steps that span the channel in a staircase fashion separated by closely spaced step pools (21). More than 50% of the stream exhibits supercritical flow. *Rapids* are less steep than cascades and consequently exhibit irregular bedrock, boulder, and/or log steps that partially or fully span the channel (21). Between 15 and 50% of the stream displays supercritical flow. *Riffles* are less steep than rapids and do not display bedrock, boulder, or log steps (21). They are characterized by shallow subcritical flow, and only 5–10% of the water surface area exhibits supercritical flow (21). The chutes of Bisson and Montgomery (2) and Hawkins et al. (16) have been renamed *"slots"* because chute already has an established, alternative meaning in geomorphology, namely, a secondary flood channel across the inside of a bend or parallel to the main channel. An *anthropogenic turbulent unit* is one constructed by humans such as a dam spillway.

Microhabitats

Microhabitats are patches within a particular channel unit that have relatively homogeneous substrates, water depth, flow velocity, and cover (Table 1 and Fig. 1). No attempt is made to define classes here because of the large number of classes involved.

COASTAL WETLANDS

Susan-Marie Stedman
NMFS F/HC
Silver Spring, Maryland

GENERAL

Coastal wetlands include a variety of wetland types such as salt marshes, bottomland hardwood swamps, fresh marshes, seagrass beds, and mangrove swamps. Although many people think of tidal salt marshes when they hear "coastal wetlands," there are many wetlands in coastal areas that are neither tidal nor salty. Coastal wetlands can be defined as all wetlands in coastal watersheds, that is, watersheds that drain to the ocean or to an estuary and extend landward to the limit of tidal influence (Fig. 1). Great Lakes wetlands are often considered coastal wetlands as well, but the remainder of this discussion focuses on coastal wetlands associated with the Atlantic and Pacific Oceans and the Gulf of Mexico. Coastal wetlands can be next to streams, behind barrier beaches, on deltas, in isolated depressions, or in numerous other places in coastal landscapes. Coastal wetlands such as seagrass beds also occur in bays, estuaries, or other shallow coastal waters. Whether a coastal wetland is tidal or nontidal, fresh or saline, it influences and is influenced by the entire coastal watershed.

Like all wetlands, coastal wetlands are sometimes easy to recognize, but they also can be very difficult to distinguish from uplands when obvious signs of water are absent. Coastal wetlands can occur in areas with standing water, tidal flooding, or only periodic or seasonal flooding. Coastal wetlands, like other coastal environments, are very dynamic, responding to the effects of waves, winds, currents, sea level changes, subsidence, and human alterations of the landscape and hydrology. For example, barrier beaches along the Atlantic coast of the United

Figure 1. Coastal watersheds based on U.S. Geological Survey hydrologic units.

States tend to "roll" toward the land in response to relative sea level rise (1), causing the salt marshes directly behind these beaches to be buried by the beach as new areas of salt marsh become established behind the beach on areas where wind or water carries sand. Coastal marshes around brackish ponds can change from salt marshes to fresh marshes if the pond's connection to salt water is blocked by drifting sand or a road. Coastal fresh marshes along streams may expand or shrink depending on the changing location of the river channel.

Coastal wetlands make up about 30% of the wetlands in the continental United States, or approximately 27 million acres. The Gulf of Mexico region includes 51% of the coastal wetlands in the lower 48 states. The south Atlantic region contains another 30%, which means that approximately 81% of coastal wetlands in the continental United States are in the southeast. The entire Pacific coast (excluding Alaska and Hawaii) contains less than 2%. Most coastal wetlands (77%) occur in or adjacent to estuaries. The Ten Thousand Islands estuary in southern Florida, known for its mangroves and extensive areas of forested, shrub, and fresh marsh in the Everglades, contains the largest acreage of coastal wetlands in the United States, followed by the Mississippi Delta estuary, and the Albemarle/Pamlico Sound estuary (2).

Only approximately 18% of coastal wetlands are truly estuarine (having water with a salinity of at least 0.5 ppt) and only about 25% are tidal. The most common coastal wetland type is forested and scrub-shrub, which comprises 63% of the coastal wetlands in the continental United States. The next most common coastal wetland type is fresh marsh (16%), followed by salt marsh (15%) and tidal flat (4%) (2).

ECOLOGICAL IMPORTANCE

Coastal wetlands are among the most productive ecosystems in the world, comparable to tropical rain forests and coral reefs. An immense variety of microorganisms, plants, insects, amphibians, reptiles, birds, fish, and mammals can be part of a wetland ecosystem. Coastal wetlands can be thought of as "biological supermarkets." They provide large volumes of food that attract and support many animals. The combination of shallow water, high levels of nutrients, and high primary productivity is ideal for the development of organisms that form the foundations of the foodweb, supplying food for many species of fish, shellfish, insects, amphibians, birds, and mammals. A small percentage of wetland vegetation is eaten directly by fish and invertebrates, but most is decomposed by bacteria, producing an organic soup that feeds organisms such as amphipods, shrimp, crabs, snails, shellfish, and finfish. These organisms in turn support a broad food chain that includes a variety of fish, birds, and mammal populations such as deer, muskrat, and manatee.

Coastal wetlands are extremely important to birds, which use them for feeding, resting, and/or nesting. Major migratory flyways follow coastal wetlands along the Pacific and Atlantic Oceans. Many shore birds are wetland-dependent, including gulls, terns, plovers, and sandpipers. Waterfowl such as bay ducks (canvasback, redhead, etc.) and sea ducks (bufflehead, harlequin duck) are dependent on coastal wetlands, and some declines in coastal waterfowl populations are thought to be linked to the decline in coastal wetlands (3).

Coastal wetlands are also important nurseries for juvenile marine organisms. The shallow water and often-abundant plant growth are ideal for sheltering animals from predators until the animals are big enough or fast enough to avoid predators outside the wetland. Some fish, including species of herring and bass, use coastal wetlands as both a spawning area and nursery, whereas others, such as some species of shrimp and the ladyfish (a popular sportfish) spawn in the open ocean, leaving the juveniles to migrate via coastal currents to coastal wetland nurseries. Even adult fish often use coastal wetlands as refuge from larger predators or environmental stresses such as storms or floods.

Coastal marshes and estuaries provide essential habitat for over 75% of the fish caught commercially and recreationally in the United States (4). Popular species such as spotted seatrout, scup, butterfish, mullet, spot, salmon, gag grouper, Pacific herring, white grunt, summer flounder, menhaden, pink shrimp, spiny lobster, Atlantic croaker, and blue crab all use coastal wetlands as juveniles or adults for feeding and refuge. Bluefish and striped bass, important recreational species, depend on salt marshes for the small fish that are an important part of their diet. Menhaden, one of the most important commercial species landed in the United States, has a particularly strong tie to salt marshes and their detrital food chain. All of these species, and many others too numerous to list here, depend on healthy abundant coastal wetlands to support their populations.

Coastal wetlands are also important for keeping coastal waters clean. Coastal ecosystems receive virtually all the water flowing off the upland landscape—water that may contain fertilizers, pesticides, sewage, sediment, or toxic chemicals. Coastal wetlands filter out sediment and some chemicals, reducing the amount of pollution that washes into bays and the ocean.

TRENDS

Coastal wetlands are among the most imperiled ecosystems in the world. By the mid-1970s, over half of all salt marshes and mangrove forests present in the precolonial United States had been destroyed (5). California, a large coastal state, has lost over 90% of its wetlands. Florida and Louisiana, two coastal states with the greatest acreage of wetlands, have lost about half of their original wetland area. Louisiana alone is losing between 16,000 and 25,000 acres of wetlands a year, which is the highest sustained wetland loss rate in the country (6). Most of that loss is occurring in coastal areas.

No long-term national data set is available for coastal wetlands, although some programs, such as the U.S. Fish and Wildlife's National Wetlands Inventory (NWI), track estuarine wetlands and the U.S. Department of Agriculture's Natural Resources Inventory (NRI) has been used to estimate loss of tidal wetlands (7) and wetlands in coastal counties (8). Coastal wetland losses were estimated by Gosselink and Bauman (9) as approximately 20,000 acres per year from 1922 to 1954 and approximately 46,000 acres per year from 1954 to 1974. NRI data for the period between 1982 and 1987 indicate that tidal wetland loss on nonfederal lands was approximately 20,000 acres per year. However, tidal wetlands make up only about 25% of all coastal wetlands, so the total coastal wetland loss for that time period would have been greater. Most recently, Brady and Goebel (8) estimate wetlands losses on nonfederal land in coastal counties from 1992 to 1997 to have been about 24,000 acres per year. The net loss of wetlands in coastal counties was nearly three times the net loss of wetlands from inland counties. Nearly all of these losses were to freshwater nontidal coastal wetlands.

According to the NWI, the rate of wetland loss of all wetlands nationally has decreased from 458,000 acres per year from the mid-1950s to mid-1970s (10) to approximately 58,000 acres per year from 1986 to 1997 (11). While the national wetland loss rate has decreased to less than one-eighth of what it once was, the rate of coastal wetland loss appears to be decreasing much less (about one-half of what it was) and much more slowly.

Many factors are responsible for coastal wetland loss. In the early part of this century, coastal wetlands were drained and used for farming or grazing. More recently, coastal wetlands have been filled or dredged for roads, houses, golf courses, marinas, and other development. In some parts of the world wetlands are being destroyed for aquaculture. In other places, such as Louisiana, wetlands are being lost to open water due to a combination of factors including canals dredged through the marshes, dams on the Mississippi River reducing sediment to the marshes, land subsidence, and sea level rise. Even wetlands that are not actually filled or dredged are becoming degraded due to pollution, changes in water flows, and invasion by weeds or other non-native plants and animals.

Coastal wetland losses can be directly traced to population pressures and other human changes occurring along the coast. Coastal populations have increased steadily since 1970. Currently, over half the population of the United States lives in coastal counties, at densities about five times greater than those of noncoastal counties (12). This trend of people moving to coastal areas is expected to continue in the coming decades. Expanding populations place enormous pressures on existing natural resources, particularly wetlands, which are very vulnerable to changes in water flow, pollution, and habitat fragmentation. During the period from 1992 to 1997, nonfederal land in coastal counties contained 20% of the wetlands in the continental United States but experienced 31% of the wetland losses. Sixty-six percent of wetlands lost in coastal counties was the result of development while only 41% of wetlands lost in inland counties was due to development (7).

Coastal wetland loss from anthropogenic factors is magnified by global considerations such as sea level rise. Along much of the U.S. coast, relative sea level is rising at a rate of between a few inches to a foot or more per century (1). In fairly flat coastal plains, a few inches of rise in sea level can mean that the coastline moves hundreds of feet inland. Coastal wetlands can and do move inland with rising sea level, but in developed areas roads, houses, parking lots, and other human structures interfere with this natural migration of coastal habitats.

Fortunately, the importance of coastal wetlands and their vulnerability have come to the attention of scientists, governments, and nongovernment organizations. Research into the restoration of coastal wetlands and on-the-ground application of this research have yielded promising results, allowing for the restoration of some types of coastal wetlands. Through programs like those funded under the Coastal Wetlands Planning, Protection, and Restoration Act, federal and state agencies in the United States are working together to reduce the loss of wetlands in particularly fragile areas such as coastal Louisiana. And in many places, local governments are developing land use plans to protect coastal wetlands while nongovernmental organizations develop support for these programs and advocate for additional funding for restoration. With these efforts as a starting point and additional protection and restoration efforts in the future, coastal wetlands will continue to provide enormous benefits to the ecology and economy of the world.

FRESHWATER COLLOIDS

JAMIE R. LEAD
University of Birmingham
Birmingham, United Kingdom

INTRODUCTION

Colloids are defined on the basis of size; at least one dimension is in the range 1 nm–1 μm ($10^{-9} - 10^{-6}$ m). Below 1 nm is the dissolved or solution phase, and above 1 μm is the particle phase. In practice, this distinction is usually made by operational methods such as ultrafiltration and filtration (1). Other techniques such as centrifugation have also been used as separation techniques. Although useful and widely used, this operational definition is inadequate for a number of reasons. First, there are practical considerations such as experimental artifacts due to filtration and mass-based, rather than size-based, separation by centrifugation. Second, the terminology is not compatible with thermodynamic conceptions according to Stumm and Morgan (2), who defined colloids as species for which a chemical potential could not be defined. Gustaffson and Gschwend (3) delimited colloids from both the dissolved phase and the particle phase, based on the chemical and hydrologic properties of the system.

Dissolved and colloid species were distinguished on the basis that the colloid forms a distinct chemical phase whose interactions with other components is different from solution phase interactions. The distinction between colloid and particle phases was based on the idea that colloids have a tendency to remain in the water column whereas particles tend to settle to the sediments.

As noted, this distinction is in part based only on size and also includes colloid chemistry and mass and hydrologic conditions. In this conception, a colloid may be so defined in one waterbody but may not be classed as a colloid in another water-body. This is similar to the distinction made elsewhere in the literature (4,5), where the behavior of colloids in surface waters is dominated by aggregation and the behavior of particles is dominated by aggregation. In porous media, colloids and particles may also be governed by retention and migration in the pores, respectively (4,6). This idea of settling particles and nonsettling colloids has important implications for their transport and fate in the environment.

PHYSICAL, CHEMICAL, AND MICROBIOLOGICAL PROPERTIES OF COLLOIDS

To understand the role and properties of colloids (aggregation, sedimentation, pollutant binding), it is essential to understand that their nature is essentially cross-disciplinary, requiring knowledge of their chemical, physical, and microbiological properties. A number of the physicochemical properties of colloids are important in this respect: they include size, shape, density, chemical composition, and surface charge. Activities of microorganisms are also important in producing and removing colloids from freshwaters and in binding trace pollutants. Colloids are also not 'pure' compounds but are intrinsically polydisperse (containing a range of sizes) and chemically heterogeneous. This inhomogeneity in size and chemistry reflects the wide variety of different sources and sinks for forming and eliminating of colloids. For example, colloids are produced by the weathering of rocks and soils and by the death, lysis, and degradation of biological cells. Additionally, colloids are destroyed by their aggregation into larger particles and sedimentation and by their use as a food source by other organisms.

Typically, freshwater colloids consist of biological, organic, and inorganic materials. These include microorganisms such as bacteria and their debris; humic substances, which are the degradation products of plants and other biota; microbial exudates, primarily polysaccharides and proteins; and weathering products such as clays and oxides. Colloids are not pure phases of these different materials, but the phases are intimately linked.

Sampling, Fractionation and Analysis

Although colloids are intimately linked mixtures of phases, they are very unstable and easily modified. Indeed, even the act of sampling may alter their composition (1,6). This instability is linked to aggregation, microbial growth and death, modification of organic matter, sorption to container walls, changes in solution conditions, and temperature. Sampling and analytical procedures must therefore be carefully chosen, the prime requirement is that they are as minimally perturbing as possible. Ideally, analysis would be performed *in situ*, although this can rarely be achieved in practice. The sampling step itself should be quick with a minimum of handling, storage, and transport. Full details of sampling procedures are given in the two previous references.

Fractionation, usually performed by size, is often required to reduce the complexity of colloids. A number of methods have been used. The main method is filtration, although centrifugation, field-flow fractionation (FFF), and others are now employed. Again, the main criterion for successful use is nonperturbation of colloids during fractionation, one that is rarely, if ever fully met.

A number of standard techniques exist to characterize the microbiological (e.g., flow cytometry) and bulk chemical composition of colloids (e.g., inductively coupled plasma mass spectrometry, ICP-MS), although these are outside the scope of this paper. Other techniques of great importance for the direct analysis of freshwater colloids include electron and force microscopy and various light scattering techniques. Each technique has its own advantages and limitations for example, transmission electron microscopy allows direct visualization of nanometer-scale material and the analysis of major elements on a single particle basis. However, sample preparation may be problematic, despite the advances made in the past 10 years. In addition, quantification of results is difficult. Due to the different strengths of each technique and the complexity of the colloids, coupling of two or more methods on-line is advantageous (e.g., FFF-ICP-MS) as is the use of a number of complementary techniques to analyze the same sample.

ENVIRONMENTAL IMPORTANCE

Freshwater colloids have been studied primarily because of their role in chemically binding trace pollutants (metals and organics) and thus altering the transport and bioavailability of pollutants. Additionally, they have been studied in relation to water treatment processes and as a food source for aquatic microorganisms. The physical and chemical nature of colloids means that they can bind a large, often dominant, fraction of trace pollutants (7). In particular, they have high surface area. Consequently, a large number of functional groups, which can bind trace metals, are presented to the solution. Additionally, the functional groups themselves strongly bind the metals. Although less well-developed experimentally and theoretically, the binding of organic pollutants by colloids has also been investigated. It is generally thought that the organic component of colloids controls binding.

The chemical binding of metals by colloids has two implications for metal biogeochemistry. First, uptake and effects of the metals by biota are modified, and second, environmental transport of the metals is affected.

Colloids, it is thought, act to reduce biotic uptake to aquatic organisms such as microorganisms and fish. The widely used Free Ion Activity Model (8) assumes that bioavailability is directly related to the free ('dissolved') metal ion: related models (9) have explained reduced uptake by the decreased diffusive mobility and chemical lability of the colloid-bound metal. Despite the successes of these and other models (such as the Biotic Ligand Model), much remains to be understood about the interrelationships between colloids and biota and subsequent effects on metal bioavailability and toxicity.

Colloids affect transport and cycling of trace metals through a number of mechanisms. As mentioned in the definition, one definition of colloids is based on their transport behavior in water. Colloids are small enough that mixing processes maintain them in the water column, whereas particles are large enough so that they sediment out of the water column. This simple mechanism provides an important method for the geochemical fractionation of associated pollutants in surface waters. In lakes, settling of particles is one of the main 'self-purification' mechanisms for removing metals from the water column (10). Additionally, in groundwater, the flow of colloids through porous media may govern the transport of associated pollutants.

CULVERT DESIGN

Xing Fang
Lamar University
Beaumont, Texas

A culvert (Fig. 1) is a conduit placed under a road to convey surface water from one side to another. In addition to its hydraulic function, it must also carry construction and highway traffic and Earth loads; therefore, culvert design involves both hydraulic and structural design. Culvert design involves selection of the type of culvert and size to pass the design discharge without overtopping of the road and without erosion on either end of the culvert. For economy and hydraulic efficiency, engineers should design culverts to operate with the inlet submerged during flood flows, if conditions permit. Culverts are constructed from a variety of materials and are available in many different shapes and configurations. When selecting a culvert, engineers should consider roadway profiles, channel characteristics, flood damage evaluations, construction and maintenance costs, and estimates of service life. The most common shapes for culverts are circular, pipe-arch and elliptical, box (rectangular), modified box, and arch. Common culvert materials include concrete (reinforced and nonreinforced), steel (smooth and corrugated), aluminum

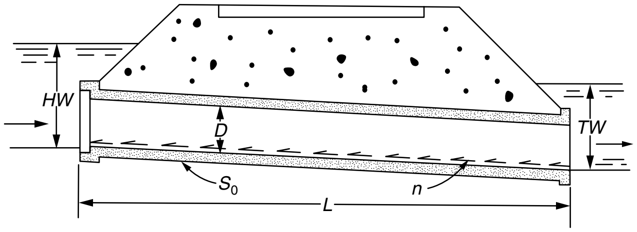

Figure 1. A typical culvert with submerged inlet and outlet.

(smooth and corrugated), and plastic (smooth and corrugated). The selection of material for a culvert depends on several factors that can vary considerably according to location. One should consider the following groups of variables: (1) structure strength, considering fill height, loading condition, and foundation condition; (2) hydraulic efficiency, considering Manning's roughness, cross-section area, and shape; (3) installation, local construction practices, availability of pipe embedment material, and joint tightness requirements; (4) durability, considering water and soil environment (pH and resistivity), corrosion (metallic coating selection), and abrasion; and (5) cost, considering availability of materials. Do not base culvert material selection solely on the initial cost. Replacement costs and traffic delay are usually the primary factors in selecting a material that has a long service life for a culvert design.

Energy is required to force flow through a culvert. This energy takes the form of an increased water surface elevation on the upstream side of the culvert. The depth of the upstream water surface measured from the invert at the culvert entrance is generally referred to as headwater depth (*HW* in Fig. 1). The flow through a culvert can take different forms and is a function of several variables, such as cross-sectional size (e.g., inside diameter *D* in Fig. 1) and shape, bottom slope (S_o), length (*L*), conduit roughness (usually in terms of Manning's *n*), entrance and exit design, and water depths at the upstream (headwater) and the downstream of the culvert (tailwater, *TW* from outlet invert in Fig. 1).

Both entrance flow and exit flow can be broadly classified as submerged (e.g., in Fig. 1) or free. Two types of flow controls are in culverts: inlet control and outlet control. For inlet control (Fig. 2), the control section is located at or near the culvert entrance, and the discharge through the culvert is dependent only on inlet geometry (size, shape, entrance type) and headwater depth (HW) because the conduit can convey more discharge than the inlet will allow. For the inlet control, if the outlet is not submerged, most flow in the conduit is open channel flow; if the outlet is submerged, part of the flow near the entrance can still be open channel flow, but flow near the outlet is pressurized pipe flow. For outlet control (Fig. 3), the control section is at or near the culvert outlet, and the discharge through the culvert is dependent on all hydraulic factors upstream from the outlet. For example, flow condition in Fig. 1 is an outlet control, and all hydraulic factors *HW, TW, L, D, n,* and S_o affect discharge through the culvert.

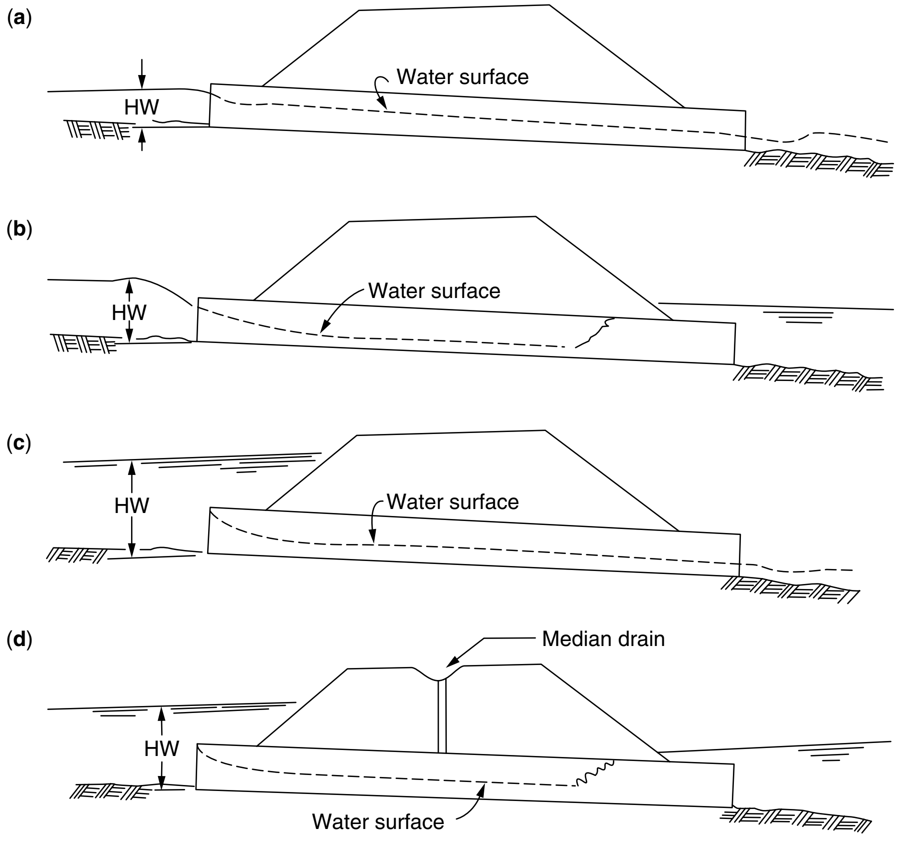

Figure 2. Types of inlet control for a culvert: (**a**) inlet and outlet unsubmerged; (**b**) inlet submerged, outlet unsubmerged; (**c**) inlet submerged only; and (**d**) inlet and outlet submerged [from Normann et al. (1)].

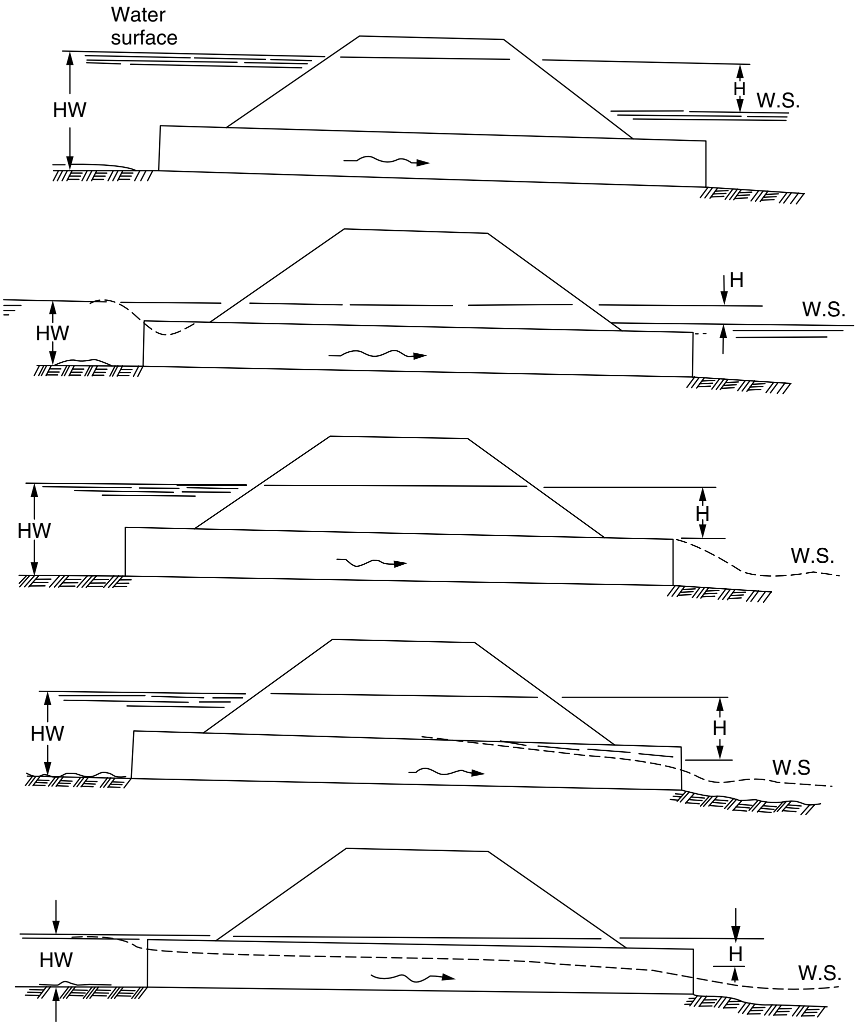

Figure 3. Types of outlet control for a culvert [from Normann et al. (1)].

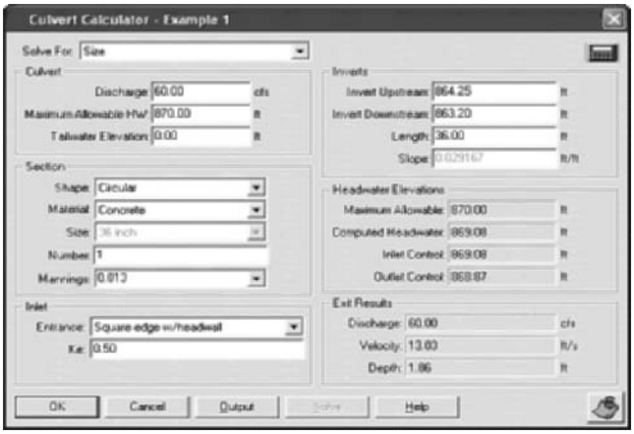
The flow velocities from a culvert are likely to be higher than in the channel because a culvert usually constricts the available channel area. These increased velocities can cause streambed scour and bank erosion in the vicinity of the culvert outlet. Therefore, two basic culvert design criteria exist: allowable headwater (*HW*) and allowable velocity. Allowable headwater usually governs the overall configuration of the culvert. However, the allowable outlet velocity is the governing criterion in the selection and application of various downstream fixtures and appurtenances to slow the flow from the culvert. An engineer may improve culvert hydraulic capacity by selecting appropriate inlets (e.g., projecting, mitered, straight, flared, and parallel wingwalls). Many different inlet configurations including both prefabricated and constructed-in-place installations can be used by the engineer. When selecting various inlet configurations, one should also consider structural stability, aesthetics, erosion control, and fill retention.

The culvert design process typically includes the following basic steps:

1. Define the location, orientation, shape, and material for the culvert to be designed. One may consider more than a single shape and material.
2. With consideration of the site data, establish allowable outlet velocity and maximum allowable headwater depth.
3. Based on design discharges from hydrologic study of upstream watershed and associated tailwater levels, select an overall culvert configuration including culvert hydraulic length, entrance conditions, conduit shape, and material.
4. Perform hydraulic analysis to determine headwater depth and outlet velocity by using computer software or monographs.
5. If computed results do not satisfy the specified values at step 2, optimize the culvert configurations, and go back to step 3. Sometimes it may be necessary to treat any excessive outlet velocity separately (additional energy dissipation structures) from the headwater requirement.

Culvert design typically requires complex hydraulic calculations, especially to appropriately incorporate energy losses caused by entrance, friction, and exit. Equations, tables, and charts for culvert design can be found in many textbooks (2,3) or design manuals (1,4–6).



Solve For: Size

Culvert
Discharge: 60.00 cfs
Maximum Allowable HW: 870.00 ft
Tailwater Elevation: 0.00 ft

Section
Shape: Circular
Material: Concrete
Size: 36 inch
Number: 1
Mannings: 0.013

Inlet
Entrance: Square edge w/headwall
Ke: 0.50

Inverts
Invert Upstream: 864.25 ft
Invert Downstream: 863.20 ft
Length: 36.00 ft
Slope: 0.029167 ft/ft

Headwater Elevations
Maximum Allowable: 870.00 ft
Computed Headwater: 869.08 ft
Inlet Control: 869.08 ft
Outlet Control: 868.87 ft

Exit Results
Discharge: 60.00 cfs
Velocity: 13.03 ft/s
Depth: 1.86 ft

Figure 4. Culvert calculator in CulvertMaster (7).

Many computer models, e.g., HY8 by the Federal Highway Administration (FHWA) of the U.S. Department of Transportation, "CulvertMaster" developed by Haestad Methods, Inc. (7), and CULVERT2 (English units) and CULVERT3 (metric units) by the California Department of Transportation, are also available. Application of computer software is recommended because of complexity in culvert hydraulic computations. One must choose the shape and profile and establish the culvert dimensions by iterative application of the computation procedures until headwater and outlet velocity are reasonable. Sometimes it is possible to select culverts consisting of more than one box in wide channels to convey design discharge. The Culvert Calculator in CulvertMaster can solve for size, discharge, and headwater elevation for a culvert. The Calculator organizes information for a culvert into seven areas (Fig. 4): solve for, culvert, section, inlet, inverts, headwater elevation, and exit results. Figure 4 shows an example for sizing of a single, circular, concrete culvert (roughness n = 0.13) with square edge entrance and design discharge of 60 ft^3/sec and 36 ft long. The result for the culvert size is 36 inches; flow has inlet control because the headwater elevation for inlet control is greater than the one for outlet control.

DILUTION-MIXING ZONES AND DESIGN FLOWS

RAMAKAR JHA

National Institute of Technology
Roorkee, Uttranchal, India

INTRODUCTION

The possibility that a pollutant will be discharged accidentally or intentionally into a stream/river is a matter of constant concern to those diverting and using water from streams and rivers. It is essential for water resources planners and managers to understand the physical processes involved in a stream/river prior to the implementation of any water resources projects. When a pollutant is discharged into a stream/river, it is subjected to initial dilution immediately due to the density difference between the receiving water and the pollutant.

The longitudinal, vertical and two-dimensional profiles of pollutant concentration indicate the density gradient between the pollutant and the receiving water. After initial dilution, the processes are governed by advection, reaction, and dispersion phenomena that tend to modify the initial pollutant concentration.

Advection phenomena represent the downstream transport of a discrete element of the waste load by the stream flow.

The reaction phenomena represent the decay of biodegradable materials in the waste under the action of naturally occurring bacteria in the stream. The dispersion phenomena represent that under the influence of turbulence, eddy currents, and similar mixing forces, a discrete element of the waste load tends not to remain intact, but mixes with adjacent upstream and downstream elements. In rivers and streams, the influence of dispersion phenomena is usually relatively small compared with advection and reaction phenomena; however, it can be important in some circumstances.

When a slug load results from a spill or accidental dump, dispersion effects can have an important influence on resulting peak concentrations, particularly at longer distances from the point of discharge (Fig. 1). Intermittent discharges, such as storm runoff, are also influenced by dispersion. However, for continuous discharges (e.g., from wastewater treatment plants) and steady-state flow conditions, dispersion effects are usually insignificant (Fig. 2).

As a result of these processes, the pollution level downstream from a wastewater disposal site varies in time and space. In the following sections, the importance of diluting pollutants downstream of their discharge based on various physical processes, the mixing length of pollutants (mixing zone), and design flows have been described.

IMPORTANCE OF DILUTION

The purpose of dilution is to reduce the concentration of pollutants in discharges below applicable standards. All

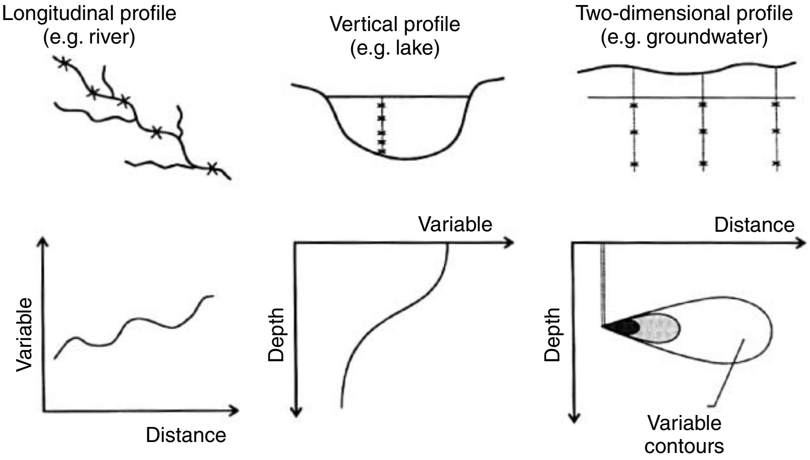

Figure 1. Spatial movement of water quality variables.

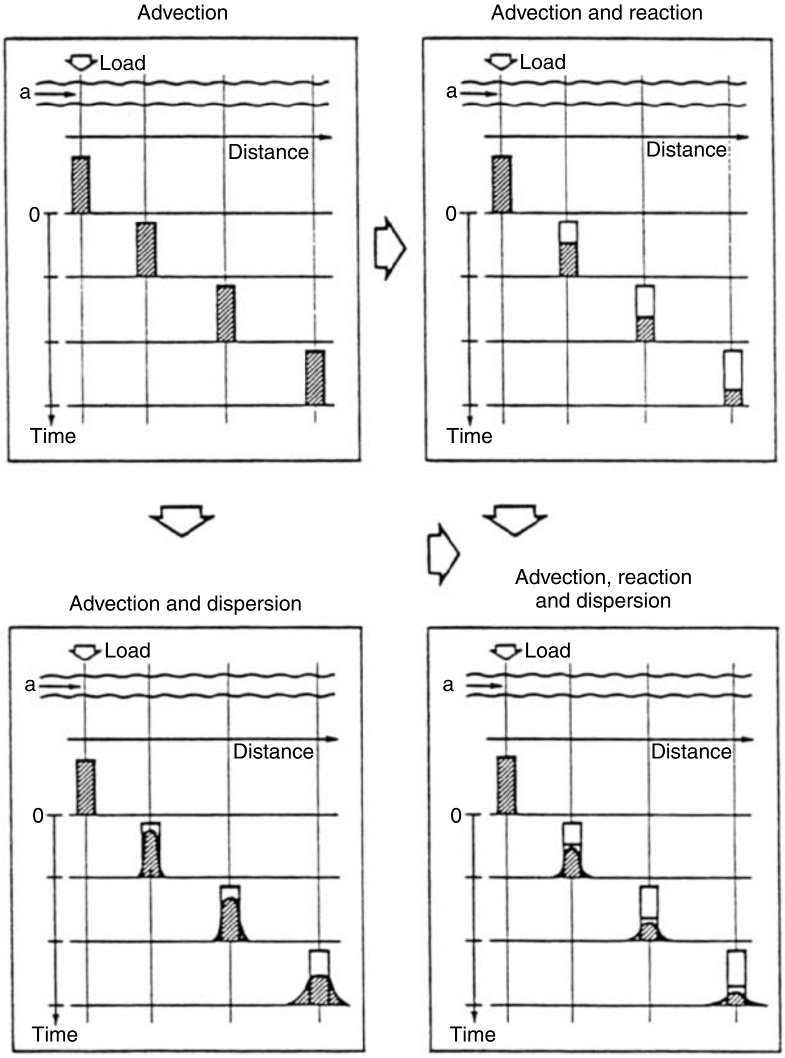

Figure 2. Transport mechanism for waste loads.

applicable water quality standards and nondegradation limits must be met at the end of a mixing zone. Through the first decades of the twentieth century, wastewater disposal practices were based on the premise that "the solution to pollution is dilution" (1). Dilution was considered the most economical means of wastewater disposal and as such was considered good engineering practice. It is one of the main processes for reducing the concentration of substances away from the discharge point. Dilution is more important for reducing the concentration of conservative substances (those that do not undergo rapid degradation, e.g., metals) than for nonconservative substances (those that do undergo rapid degradation, e.g., some organic substances).

Although dilution is a powerful adjunct to self-cleaning mechanisms of surface waters, its success depends upon discharging relatively small quantities of pollutants into large bodies of water. Growth in population and industrial activity and attendant increases in water demand and wastewater quantities preclude the use of many streams for diluting raw or poorly treated wastewaters or pollutants. In the United States, legal constraints further limit using waterbodies for wastewater dilution (1). Under present regulations, maximum allowable loads are set independently of dilution capacity. Only when the standard maximum loads result in violating in-stream water-quality standards, is dilution capacity considered, and then the increment of treatment necessary is determined.

To understand dilution phenomena due to increasing pollutant load in streams/rivers, different scenarios were obtained by plotting the changes in discharge versus simultaneous changes in the concentrations of various substances (2). As shown in Fig. 3, different curves may represent timescales that vary from a single storm to that of several years' duration. In the figure, curve (1) shows a general decrease in concentration with discharge, which implies increasing dilution of a substance introduced at a constant rate (e.g., major cations, particularly when concentrations are high). This is also characteristic of point source discharges such as municipal sewage and many industrial point sources. Curve (2) shows a limited increase in concentration generally linked to the flushing of soil constituents (e.g., organic matter, nitrogen species) during runoff. Curve (3) is basically the same as curve (2), but a fall in concentration occurs at very high discharges indicating dilution of soil-runoff waters. Curve (4) shows an exponential increase in concentration; this occurs for total suspended solids and all substances bound to particulate matter. The curve represents the increase in particulate matter due to sheet erosion and bed remobilization. Substances bound to such particulate include phosphorus, metals, and organic compounds, predominantly pesticides and herbicides. Curve (5) in the hysteresis loop is observed as time is introduced as an additional parameter to the sediment discharge relationship shown in curve (4). Such patterns can be seen for total suspended solids, dissolved organic carbon, and sometimes nitrate. The peak in sediment concentration occurs at X (advanced) before the occurrence of the peak discharge at Z. Curve (6) indicates a water source to the river of constant, or near constant concentration (e.g., chloride in rainfall, groundwater, and outlet from a lake).

From Fig. 3, it is found essential to determine the stream/rivers dilution capacity prior to the development of mathematical modeling and water quality simulations.

The dilution capacity of the receiving water can be defined as the effective volume of receiving water available for diluting the effluent. The effective volume can vary according to in-stream discharge and any other input source of discharge. In streams/rivers, in particular, the effective volume is much greater during the monsoon than during a lean period. It is important to consider concentrations of substances in the worst case scenarios (usually lean flow in summer, for example, when pollutants might be carried further into a sensitive location) when calculating appropriate discharge content conditions. The dilution capacity of a stream can be calculated by using the principles of mass balance. If the volumetric flow rate and the concentration of a given material are known in both the stream and waste discharge, the concentration after mixing can be calculated as follows:

$$C_sQ_s + C_wQ_w = C_mQ_m \tag{1}$$

where C represents the concentration (mass/volume) of the selected material, Q is the volumetric flow rate (volume/time), and the subscripts s, w, and m designate stream, waste, and mixture conditions.

MIXING ZONES

Wastewater effluents are discharged into streams and rivers to minimize any potential adverse effects on river water quality by suitable siting of outfalls. The stream zone between the outfall and the nearest cross section of uniform concentration distribution is known as a "mixing zone." The mixing of effluent with the river water takes place by the "jet effect" in the near-field region as shown in Fig. 4 (MixZon Inc., 2003).

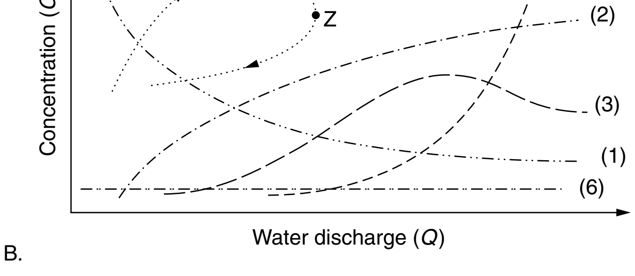

Figure 3. Patterns of concentration from discharges into streams/rivers.

Figure 4. A single port buoyant jet in cross flow deflected by the ambient current (near-field flow).

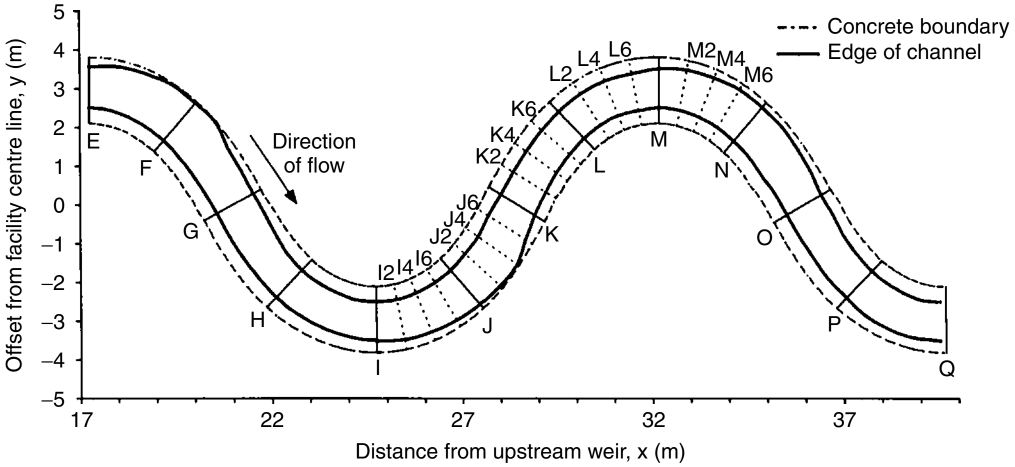

Figure 5. Typical channel geometry and section numbering.

The distance below the outfall where the effluent spreads across the channel width is termed "crossing distance." Within the mixing zone, apportion of the cross section termed "limited use zone" (LUZ) or "zone of noncompliance" occurs wherein the concentration of a pollutant may not comply with a specified water quality objective. The remaining portion of the cross section known as the "zone of passage" serves as a suitable habitat for fish and other desirable aquatic life. Note that in the far-field region, the mixing of effluent with the river water takes place due to lateral and longitudinal dispersion. A typical example of meandering given by Boxall et al. (3) is shown in Fig. 5. The cross-sectional profile and velocity pattern of flow at different sections of the channel are shown in Fig. 6. It can be seen from that figure that the maximum velocity profiles are always on the convex (right) portion of the channel looking downstream. When a pollutant is discharged at the bottom or on the surface of the different sections, the length of the mixing zone varies due to variation in velocity profiles. Also, the location of injection of pollutants (on the surface or at the bottom) changes the mixing phenomena, which can be well observed in Fig. 7.

It can be seen from the Fig. 7 that vertical mixing is usually complete in a short distance below the outfall or injection point, whereas lateral spreading is more gradual resulting in lateral concentration gradients. Ultimately, the cross-sectional concentration distribution attains uniformity at some distance below the outfall.

Mixing zones are prohibited in ephemeral waters or where there is no water for dilution (4). In a mixing zone, it is proposed to have high in-stream discharge for proper dilution and to meet standards at a boundary for the balance of the waterbody. It is the means for expediting mixing and dispersion of sewage, industrial waste, or other waste effluents in receiving waters.

Early workers (5–15) in the field devised mixing-zone concepts based on the lateral, vertical, and longitudinal dispersion characteristics of the receiving waters. Formulas predicting space and time requirements for diluting certain pollutants to preselected concentrations were also developed. The mixing behavior of a discharge depends largely on the depth of the ambient water, the momentum and buoyancy of the discharge, the spatial orientation of the discharge system, and the effects of many other factors. As a result, the mixing zone and mixing length are essential variables required for assessing the pollutant concentration/load downstream of the mixing zone.

Consideration of how to compute the distance from an outfall to compute mixing is a separate more complicated topic. However, the order of magnitude of the distance from a single point source to the zone of complete mixing is obtained from (16)

$$L_m = 2.6U\frac{B^2}{H} \tag{2}$$

for a side bank discharge, and from

$$L_m = 1.3U\frac{B^2}{H} \tag{3}$$

for a midstream discharge. In these equations,

L_m = distance from the source to the zone where the discharge has been well mixed laterally, in ft,

U = average stream velocity in fps,

B = average stream width in ft,

H = average stream depth in ft

DESIGN FLOW

The central problem in water quality management is assigning allowable discharges to a waterbody so that a designated water use and quality standard is met using basic cost–benefit principles. The following steps are required for proper design flow and waste load allocation in streams/rivers:

- evaluation of waste load input and in-stream discharge
- dilution phenomena and water quality response
- mixing length of pollutants in streams/rivers

Figure 7. Three-dimensional representation of dye tracer measurements below different injection points.

- desirable water use and evaluation of water quality criteria that will permit such uses
- relationship between load and water quality and selection of projected conditions
- It is generally not sufficient to make a scientific engineering analysis of the effect of waste load inputs on water quality. The analytical framework should also include economic impacts which, in turn, must also recognize the sociopolitical constraints that are operative in the overall problem context.

To illustrate overall waste load allocation and a design flow problem for dissolved oxygen, a schematic diagram given by Thomman and Muller (17) is presented (Fig. 8).

It can be seen from Fig. 8 that for properly allocated waste loads in streams/rivers, DO values do not fall below the standard limits (as shown in the lower part of the figure). In the figure, there are several points at which

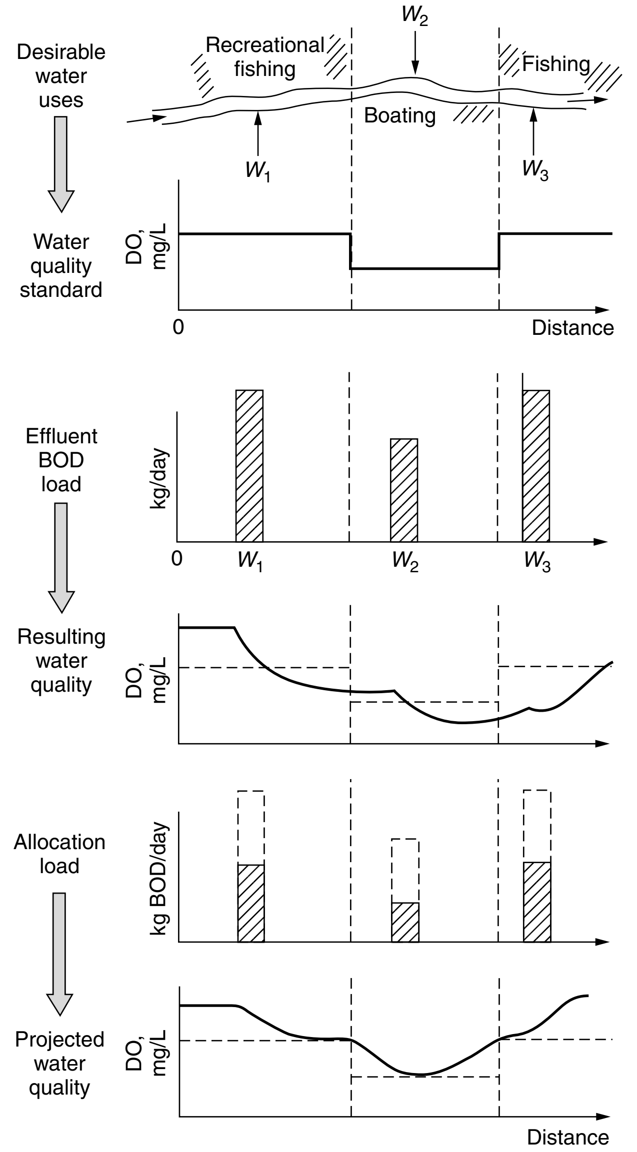

Figure 8. Representation of waste load allocation problem for dissolved oxygen.

careful judgments are required to provide a permissible waste load allocation. Determination of design conditions, including flow and parameters, must be evaluated for a waste load allocation. The specification or projection of flow and parameter conditions under a given design is a most critical step and is a combination of engineering judgment and sensitivity. The concentration at the outfall can be controlled by

(1) reducing the effluent concentration of the waste input by (a) wastewater treatment, (b) industrial in-plant process control, and (c) eliminating effluent constituents by pretreatment prior to discharge to the municipal sewer or by different product manufacturing for an industry;

(2) reducing the upstream concentration by upstream point and nonpoint source controls;

(3) reducing the effluent volume by (a) reduction in infiltration into the municipal sewer system, (b) reduction of direct industrial discharge volumes into the sewer system, and (c) reduction, for industry, of waste volume through process modifications;

(4) increasing the upstream flow by low flow augmentation, that is, release from upstream reservoir storage or from diversions from nearby bodies of water;

(5) increasing the environmental, in-stream degradation rate of the substance.

TYPICAL EXAMPLES OF DILUTION IN STREAMS/RIVERS OF INDIA

In India, all 14 major rivers including Ganga, Yamuna, Gomti, Cauvery, and Damodar are polluted. The Rivers Damodar and Yamuna are the most heavily polluted. Many parts of these rivers do not have any dissolved oxygen, and no wonder that they fail to support the growth of desirable aquatic fauna and flora. The River Ganges is heavily polluted at Allahabad, Kanpur, Varanasi, Patna, and Bhagalpur. The cross section and BOD/DO contours at Kanpur and Varanasi are shown in Figs. 9 and 10, respectively (18).

As can be seen from Figs. 9 and 10, the BOD concentrations found are very high at the pollutant outfall site. There is a significant amount of variation in BOD across the river. A similar situation has been observed in the longitudinal direction also due to dilution and mixing. The variation in dissolved oxygen (DO) downstream of the sewage outfall on the River Ganges, at Varanasi is shown in Fig. 11. As can be seen, the DO pattern at Assi Ghat in Varanasi, India, was monitored at different locations in longitudinal and transverse directions (19,20), and the river shows a nearly perfect dilution ratio. Similar studies were also, carried out for River Kali, a highly polluted river in India (18,21).

SUMMARY

Dilution, mixing zone, and design flows are interlinked issues that have been addressed here. Now, a better understanding of the mixing zone is available in the literature, and there are softwares like CORMIX (MixZon Inc., 2003) that can very elegantly perform mixing zone analysis. In the literature, near-field and far-field analysis of mixing of pollutants has also received attention. However, there are still challenges ahead, and these are related to the presence of a dead zone, adverse flow gradients, and curvilinear flows.

OVERVIEW

Drainage ditches are common landscape features found in urban, industrial, and agricultural settings. Just as diverse as the environment in which they can be found, ditches have a wide array of physical and structural parameters. They may be lined by concrete, rock (rip rap), bare soil, or vegetation. Some ditches are small enough to step across, while others may require different methods of moving from one side to the opposite. Ditches, by their very nature, are water conveyance features. Natural ditches, formed as gullies, have been prominent landscape features in areas of topographical relief since the Earth was formed. Investigations of historical gully formation find ditches associated with primitive slash-and-burn agriculture. Drainage ditches have historically been efficient methods for transporting water away from moist or wet areas. The most obvious illustration is found in agricultural fields, where production acreage is surrounded by a myriad of drainage ditches (Figs. 1–3). Moving stormwater or excess irrigation water away from crops is the primary focus of agricultural drainage ditches.

In industrial areas, ditches are often the first postmanufacturing "treatment" area for discharges before the effluent reaches a receiving stream. The discharge pipe often empties into a vegetated drainage ditch, which will transport water to a river, lake, or stream. Urban settings are laced with interspersed ditches of varying sizes, again with the primary objective of removing stormwater from residential areas. Many urban ditches are lined with concrete, which further encourages water movement. Unfortunately, this also negates many positive water quality enhancement opportunities that drainage ditches possess.

Figure 1. Constructed ditch draining farm field.

Figure 2. Overgrown constructed ditch draining farm field.

Figure 3. Natural drainage canal in farm field.

Ditches may also serve to deliver water to areas for irrigation purposes. In western states where water supplies are closely managed, ditches provide an important conduit for water transportation. The California Gold Rush resulted in construction of over 5000 miles of canals to transport water to gold fields. Today, California supplies over half of the fruits, vegetables, and nuts for the United States (plus exports) on 3% of the nation's cropland because of its 9.5 million irrigated acres, due in part to the extensive network of canals and ditches. Thus, the topic of drainage ditches covers a broad spectrum of conveyance systems in time and space located from agricultural to urban settings. For our purposes, discussion is focused on ditches located in agricultural settings.

Engineering techniques associated with ditches have evolved so that an excellent level of confidence can be achieved in ditch design. Studies of open channel flow began in natural channels, but major knowledge breakthroughs have come through investigations of constructed channels. The use of laboratory flumes in the twentieth century greatly accelerated the knowledge base necessary for the current area of challenge—modeling. Energy, friction, channel roughness, Froude numbers, and critical depth of flow are some of the parameters where historical research provides the basis for aquatic habitat design.

Although drainage works have been in existence for over 2500 years, they are not without controversy (1). During the Middle Ages, ditches exsiccated English fens to increase agricultural production landscape. While beneficial for farmers, fen draining was seen as a direct threat to both fishermen and fowlers (1). In the early to mid-twentieth century, the U.S. government strongly favored drainage of wetlands and swamps to boost agricultural acreage, facilitate transportation, and combat mosquito and other vector-borne illnesses (2). As a result, fewer than half of the original U.S. wetlands remain (1). Without drainage, however, the fertile Midwest states of Ohio, Indiana, Illinois, and Iowa would still be largely swamps or land too wet for viable agriculture production (1). The last congressionally mandated decennial census of U.S. drainage (1985) indicated 110 million acres of agricultural land profited from drainage, and the net capital value of farm drainage work was estimated at $25 billion (1).

The U.S. Department of Agriculture's Natural Resource Conservation Service (USDA NRCS) promotes the use of conservation practices to improve soil and water quality. Under the broad topic of conservation are two standards for excess water removal, Practice 607 (Surface Drainage, Field Ditch) and Practice 608 (Surface Drainage, Main or Lateral) (3). Neither specifically addresses water quality enhancement.

Data in Tables 1–5 summarize available global drainage ditch research from the 1960s to 2004. As is common in progression of research, initial studies searched for basic information (e.g., surveys or nutrient loading). Later research focused more on current themes.

CURRENT AND FUTURE DIRECTIONS

Currently, experimental agricultural drainage ditch research is being primarily conducted with three institutions in the United States: Arkansas State University

Table 1. Ecological Research Conducted on Agricultural Drainage Ditches

Research	Location	Results	Reference
Floristic survey	Eastern Saudi Arabia	More than 100 plant species in canals	4
Flora	The Netherlands	78% of *Spirogyra* (algae) in Netherlands found in ditches and pools; some ditches had >20 species	5
Flora	United States	Maintenance of weeds on ditch banks	6–8
Flora	Mississippi Delta, United States	Ditches without surrounding riparian cover have increased nutrient concentrations	9
Macroinvertebrate	Rhône Delta, France	Description of copepod, *Cletocamptus retrogressus*	10
Macroinvertebrate	Germany	Discovery of aquatic beetle, *Dytiscus semisulcatus*	11
Macroinvertebrate	United Kingdom	Ephemoptera and Plecoptera present in nutrient-enriched ditches	12
Macroinvertebrate	Wicken Fen, United Kingdom	Rotation of ditch maintenance allowed Ephemeroptera establishment and survival	13
Macroinvertebrate	United Kingdom	Importance of vegetated refuges to survival of uncommon gastropods	14,15
Macroinvertebrate	Yakima Valley, Washington, United States	Successful overwintering of beneficial and harmful insects in ditches	16
Fish	Germany	Suggested management practices to offset fish population damages	17
Macrofauna	The Netherlands	Random distribution of macrofauna taxa in ditch sampling analyses	18
Fauna	Canada	90% of fish species utilizing drainage ditch habitat spawned in ditch	19
Fauna	United Kingdom	Ditch age and bank profile contributed to differences in individual ditch fauna	20
Flora/fauna	Elbe Estuary, Germany	Floral/faunal shifts as a result of pesticide applications and eutrophication in ditches	21
Plant and invertebrate interaction	Germany	*Anopheles* (mosquito) occurrence related to ditch plant succession	22
Floodplain diversity	Lower Frome floodplain, United Kingdom	Slow moving Rushton Ditch contributed largely to floodplain biodiversity	23

Table 2. General Research Conducted on Agricultural Drainage Ditches

Research	Location	Results	Reference
Design criteria	Malaysia	Integrate engineering and agricultural practices to maximize land productivity	24
Drain cleaning	Australia	Necessity of cleared drains in sugarcane production to maintain ditch carrying capacity	25
Maintenance	United Kingdom	Recommend dredging cycle of 3 years to maintain diverse floating and aquatic plants	26
Mechanical harvesting	The Netherlands	Determination of plant cutting times for maximum species richness on sand and peat soils	27
Upland ditches	United Kingdom	Little ecological advantage gained with ditches (grips) in uplands	28
Model	The Netherlands	Modeling determined critical nutrient loading dependence on ditch depth	29,30
Watershed hydrology	France	Differences seen between watersheds with and without ditches	31
Hydrology	United Kingdom	Physical-based hill slope model to understand changing catchment runoff regimes	32
Hydrology	United Kingdom	Drain interaction with channel hydrology (DITCH) model indicated higher ditch water levels did not improve ecology	33
Hydrology	United States	Correspondence between peak flows of ditches and rivers	34
Best management practice (BMP)	United States	Suggested use of ditches as BMP for nutrient and pesticide mitigation	35

Table 3. Nutrient Research Conducted on Agricultural Drainage Ditches

Research	Location	Results	Reference
Phosphorus	Australia	Decrease in phosphorus after traveling through bare drains; increase in phosphorus after passing through grass pasture	36
Phosphorus	New Zealand	Drainage sediments act as phosphorus sinks	37
Phosphorus	Delaware, United States	Ditch sediment biologically reactive phosphorus similar to that of topsoils of adjacent fields	38,39
Nitrate	River Eider Valley, Germany	Increase in retention time resulted in decrease in nitrate due to vegetation and organic debris accumulation	40
Nutrients	The Netherlands	No increase in phytoplankton in nutrient-enriched ditches	41
Nutrients	The Netherlands	90–95% phosphorus removal; low nitrogen removal	42
Nutrients	St. Lucie County, Florida, United States	Nutrient concentrations in citrus grove ditch water higher than concentrations in vegetable farm ditch water	43
Nutrients	United States	Ditches around baitfish farms are of benefit	44
Nutrients	Arkansas and Mississippi Deltas, United States	Ditches help remediate aquaculture effluent	45
Nutrient loading	United States	Seasonal variation of nutrients by distinctive ditch size	46,47
Nutrient standards	The Netherlands	Failure of general standards to support minimum water; need to be specific	48
Nutrients + pesticides	The Netherlands	Increase in macrophyte biomass and stored nitrogen and phosphorus	49
Herbicide + nutrient loading	South Saskatchewan River, Canada	Loadings diluted by storm; no significant increase in concentration	50

(ASU), Ohio State University (OSU), and the University of Minnesota (UM). ASU's research site includes a series of newly constructed vegetated drainage ditches, catchment ponds, small meanders, and riparian areas. Innovative research, in conjunction with the USDA Agricultural Research Service's National Sedimentation Laboratory, will highlight contaminant fate and transport, partitioning, mitigation, and ecological benefits of ditches alongside agronomic research. OSU continues to conduct research on the benefits of one-stage and two-stage ditches for longevity, water quality, and ecological enhancements (73). The University of Minnesota Southwest Research and Outreach Center recently constructed two 200-m open drainage ditches to study sediment and nutrient removal from drainage water (74).

Our literature review indicated ditch research is centered in the United States, The Netherlands, the United Kingdom, and Germany. Research thrusts range across topics of this decade, including greater understanding of basic hydrological and trapping processes, ditch contributions to pollution, contaminant processing by ditches, and maintenance. Future investigations must view drainage ditches holistically as water conveyance segments of a watershed. While basic studies on habitat, maintenance, and function are needed, research must define the ditch's role as a key facet of edge-of-field conservation

Table 4. Pesticide Research Conducted on Agricultural Drainage Ditches

Research	Location	Results	Reference
Herbicide retention	France	70% decrease in diflufenican with ditch surface contact	51
Herbicide transport	United Kingdom	99% of sulfosulfuron load found in first 4% of flow	52
Herbicide transport	United Kingdom	Mecoprop transport following storm event exceeded U.K. concentration guidelines	53
Herbicide (Linuron)	The Netherlands	Amendment decreased pH and dissolved oxygen; no effect on plant composition; diatoms and cryptophytes decreased; cladocera and copepods increased	54–56
Insecticide effects	The Netherlands	Vegetated systems (*Elodea*) sorbed the majority of applied chlorpyrifos; sediment was sink where no vegetation present; effects on macroinvertebrates occurred four times faster in open versus vegetated water	57–59
Lambda-cyhalothrin (insecticide)	The Netherlands	Sediment–pesticide sorption lower in areas with vegetation; alkaline hydrolysis main pesticide transformation process	60
Esfenvalerate	Mississippi Delta, United States	Toxicity measured in ditch; concentrations from 50-acre runoff mitigated to no observed effects levels in 510 m of vegetated ditch	61,62
Atrazine + lambda-cyhalothrin	Mississippi Delta, United States	Reduce pesticides from 5-acre runoff to no observed effects level in 50 m of vegetated ditch	63
Bifenthrin + lambda-cyhalothrin	Mississippi Delta, United States	Reduce pesticides from 50-acre runoff to no observed effects level in 650 m of vegetated ditch	64,65
Pesticides	California, United States	78% of ditch samples toxic—affected estuary	66
Spray drift buffer	The Netherlands	Buffer zone (3-m width) around ditch banks lowered spray drift by 95% in ditches	67
Insecticide + nutrients	The Netherlands	Increase in phytoplankton abundance; grazers effected by pesticide amendment	41
Insecticide + nutrients	The Netherlands	Increase in macrophyte biomass and stored nitrogen and phosphorus	49
Herbicide + nutrient loading	South Saskatchewan River, Canada	Loadings diluted by storm; no significant increase in concentration	50
Monitoring	Lower Fraser Valley, Canada	Consistent presence of diazinon and dimethoate in ditch water	68
Monitoring	Canada	4% of sampled ditches were toxic to *Ceriodaphnia dubia*; 14% impaired *C. dubia* reproduction; trace amounts of organophosphate insecticides	69

Table 5. Sediment Research Conducted on Agricultural Drainage Ditches

Research	Location	Results	Reference
Sediment	United States	Danger of Mississippi and Illinois River agricultural field ditches eroding	70
Sediment	United States	Cost is $0.45 per cropland acre to remove Ohio sediment from ditches; losses could be reduced by 25% with best management practices	71
Sediment	United States	Decreased sediment removal cost by implementing best management practices in Illinois, Indiana, Ohio, and Idaho	72

and pollution reduction systems. Given negative aspects of direct drainage, modifications that ameliorate ditches should blend habitat improvement with utilitarian design.

DRAINAGE NETWORKS

Xiangjiang Huang
Jeffrey D. Niemann
Colorado State University
Fort Collins, Colorado

A drainage network is the configuration of the stream courses in a river basin. Drainage networks are the products of fluvial erosion processes. As erosion incises at a point on the land surface, that point becomes lower, which allows it to collect more flow. As the flow increases, the erosion rate also increases. This positive feedback ultimately produces a dendritic network of channels within a river basin. The drainage network is responsible for the surface transport of water, sediment, and contaminants out of the basin.

EXTRACTION OF DRAINAGE NETWORKS FROM DIGITAL DATA

Channel networks are commonly extracted from digital elevation models (DEMs), which are considered alternatives to traditional topographic maps. Before the drainage net is extracted, the DEM is usually processed to remove pits and flat areas that are artificially generated in the production of the DEM. To define the channel network, the direction that water flows on the surface must be determined for every grid point in the DEM. Then, the amount of flow passing through each point can be calculated and the channel heads can be identified.

The first task is the identification of the flow directions. The three prevailing methods are (1) single flow directions, (2) multiple flow directions, and (3) continuous flow directions. When single flow directions are used, water is assumed to travel from a grid point to the neighbor that produces the steepest downward slope (1). When multiple flow directions are used, the flow from a grid point is distributed to all neighbors that are lower than the grid point. The proportion of flow that each neighbor receives depends on the slope produced between the grid point and that neighbor (2). The method of single flow directions is usually adequate for convergent parts of the topography (e.g., valley bottoms), but multiple flow directions is more accurate for areas of divergent flow (e.g., hilltops). The method of continuous flow directions assigns a flow direction in any direction, not just the directions of the eight neighbors (3). Eight triangular facets are formed by connecting a grid point with its neighboring points, and the downslope vector is determined for each of these facets. The flow direction associated with the grid point is the direction of the steepest downslope vector from all eight adjoining facets. Once the flow directions are determined from any of these methods, the number of grid cells (or topographic area) whose flow would pass through a selected grid point can be determined. This accumulated area is known as the contributing area or drainage area.

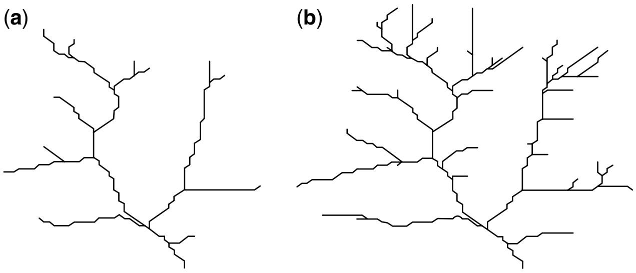

Figure 1. The effect of different critical contributing areas on drainage network extraction from a DEM: (**a**) with a threshold of 125 pixels and (**b**) with a threshold of 25 pixels.

One key issue in deriving channel networks from DEMs is the identification of channel heads. Flow directions and contributing areas are defined for all grid cells in a DEM, but not all grid cells contain a channel. Channel heads are widely defined as the points where fluvial processes become important agents of erosion. The simplest approach for channel head identification is to select a contributing area threshold (4). One way to select this threshold is to identify the contributing area at which “feathering” of the channel network occurs. When the threshold is too small, the smallest channels will often run parallel to each other making the network appear feathered. Figure 1 shows the effect of choosing different contributing area thresholds on the drainage net extracted from a DEM. A series of field studies (5) found that the location of channel heads is better described as a threshold that depends on both the contributing area and the local slope. Observations also suggest that real channel networks are usually much more extensive than the blue lines on USGS quadrangle maps.

STATISTICAL PROPERTIES OF DRAINAGE NETWORKS

The Strahler ordering system (6) is the most common method to identify distinct channels within a channel network. The rules of this ordering system are (1) streams beginning at a channel head are order 1; (2) when two streams of equal order ω meet, a stream of order $\omega + 1$ is created; and (3) when streams of unequal order meet (e.g., ω and $\omega - 1$), the channel segment immediately downstream has the higher order of the two joining streams (e.g., ω). Figure 2 shows an example of the Strahler ordering system. The largest stream order in a basin is common as a qualitative measure of basin size.

The relationship between streams of different order can be described by Horton’s laws (7), which include the laws of stream numbers, stream lengths, and basin areas. The law of stream numbers is expressed as

$$\frac{N(\omega)}{N(\omega + 1)} = R_B$$

where $N(\omega)$ is the number of streams of order ω and R_B is called the bifurcation ratio. The bifurcation ratio characterizes the propensity of the drainage network to branch. The law of stream lengths is expressed as

$$\frac{\overline{L}(\omega + 1)}{\overline{L}(\omega)} = R_L$$

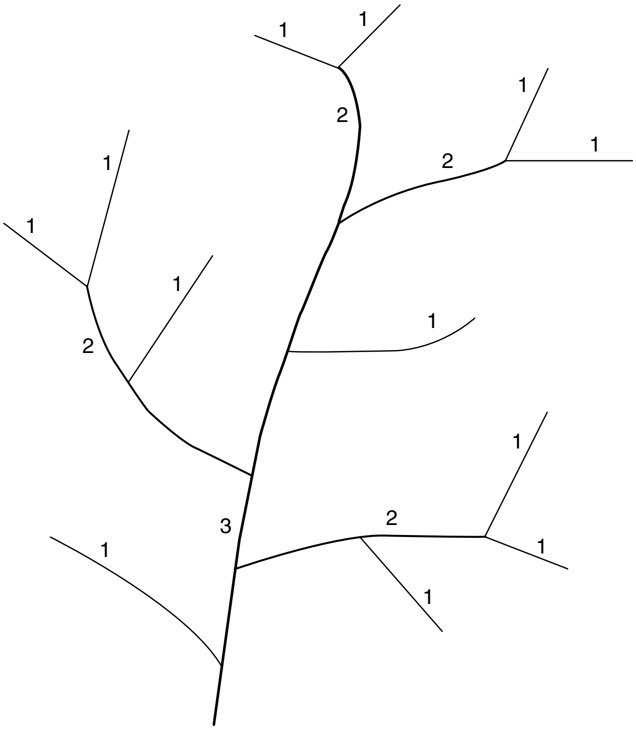

Figure 2. Strahler ordering of a third-order river basin.

where $\overline{L}(\omega)$ is the mean length of streams of order ω and R_L is called the length ratio. The length ratio describes the typical increase in stream length that occurs with increasing stream order. The law of basin areas is expressed as

$$\frac{\overline{A}(\omega+1)}{\overline{A}(\omega)} = R_A$$

where $\overline{A}(\omega)$ is the mean area contributing to streams of order ω and R_A is called the area ratio. Typical values for R_B, R_L, and R_A are 4, 2, and 5, respectively. The fact that Horton's laws hold for most real and simulated drainage networks has led some researchers to suggest that the laws are largely a product of the ordering system and thus not particularly useful for differentiating between different networks.

Natural drainage networks are also considered to be scaling-invariant or fractal objects. Loosely speaking, a fractal is an object that appears statistically similar when viewed up-close at a fine resolution or from a distance at a coarse resolution. Several empirical characteristics of river basins are products of this property. For example, Hack's law (8) describes the power-law relation between the length of a basin's main channel L and the basin's area A:

$$L \propto A^{0.57}$$

The main channel can be defined by identifying the longest channel in a basin when measured from the basin outlet to the channel head along the stream. The fact that the exponent in Hack's law is above 1/2 (the value one would expect from simple geometry) has been shown to be a result of the fractal sinuosity of the stream course. Another product of the scaling-invariance is the slope-area law, which can be written:

$$\overline{S} \propto A^{-\theta}$$

where A is contributing area (or equivalently basin area) and θ is a scaling exponent, which typically ranges from 0.3 to 0.7. $\overline{S}$ is the mean local slope for channel locations that drain basins with area A.

Some impacts of channel networks on the hydrologic response of a basin can be characterized by the drainage density and width function. The drainage density D_d is a measure of topographic texture and stream spacing and can be defined as

$$D_d = \frac{L_T}{A}$$

where L_T is the total length of stream channels in a basin. The drainage density is closely related to the average hillslope length and has been widely employed to predict characteristics of runoff production and the hydrologic response to precipitation events.

The width function is a graph that describes the probability distribution of flow path lengths in a basin. The x-axis of a width function spans the range of distances between the grid points in a basin and the basin outlet, where distance is measured along the flow paths. The width function's y-coordinate indicates the number of grid points that have the specified distance from the basin outlet (topographic area is often used instead of the number of grid points). Notice that the width function is closely related to the basin's unit hydrograph. In fact, if flow speed was constant throughout a basin, the width function would be nearly equivalent to the unit hydrograph.

The basin circularity ratio R_C (9) is a measure of the basin shape and can be defined as

$$R_C = \frac{4\pi A}{P^2}$$

where P is the length of the basin perimeter. It indicates how closely the basin resembles a circle. The closer the circularity is to 1, the greater the similarity to a circle. Another measure of basin shape is the form factor R_F, which can be written as

$$R_F = \frac{A}{L_x^2}$$

where L_x is the maximum length between the basin outlet and the opposite boundary (10). Numerous other measures of basin shape are available. More elongated basins tend to have hydrologic responses that are more distributed in time, whereas compact basins tend to exhibit more peaked hydrographs.

DYES AS HYDROLOGICAL TRACERS

Jarai Mon
Markus Flury
Washington State University
Pullman, Washington

INTRODUCTION

Dye tracers have been used in hydrological investigations for more than a century. In 1877, uranine (fluorescein) was used as a tracer to test the hydraulic connection between the Danube River and the Ach Spring in southern Germany (1). In 1883, the French physician des Carriéres successfully proved the source of a typhus epidemic in the city of Auxerre by conducting a tracer experiment with the dye aniline (2). First systematic investigations on the suitability of dyes as tracers were conducted even before the turn of the century (3). Subsequently, the use of dyes as tracers became a common practice in hydrological investigations (4–6).

A classic example of the use of dyes in hydrology is the study of residence times and pathway connectivities in Karst (7). Further applications range from studying dispersion in streams and lakes, to determine sources of water pollution, and to evaluate sewage systems. In the vadose zone, dyes have been mainly used to visualize flow patterns (6).

Thousands of different dyes are commercially available (8), but only a few are suitable for hydrological investigations. Many dyes have been studied specifically for their suitability as hydrological tracers, and recommendations were made on "best" dye tracers (9–12). Depending on the specific applications, different chemical characteristics of a dye may be desirable. For instance, for visualization of water flow in soils, a dye should be clearly visible and trace the water movement accurately. In this particular case, the dye will preferably be blue, red, green, or fluorescent to contrast distinctly from the soil background. The accurate tracing of the water movement demands that the dye does not sorb too strongly to subsurface materials, which poses limitations on the chemical characteristics of a dye.

Here, we summarize tracer characteristics and the applications of dye tracers in surface and subsurface hydrology. We then discuss the limitations and potential problems in using dyes for tracing water flow and solute movement. Selection of an appropriate dye is critical for the success of a tracing study. We present a case study on the application of quantitative structure-activity relationships (QSARs) for screening, selecting, and designing optimal dye tracers for a specific use.

TRACER CHARACTERISTICS OF DYES

Dye tracers, particularly fluorescent dyes, are often preferred over several other types of tracing materials because of their unique characteristics. Many dyes (1) can be readily detected at a concentration as low as a few micrograms per liter, (2) can be quantified with simple and readily available analytical equipment, (3) are nontoxic at low concentrations, and (4) are inexpensive and commercially available in large quantity (7,12,13). In addition, because of their coloring properties, dyes allow us to visualize flow pathways in the subsurface. Many dye tracing studies conducted in the past 10 years have clearly demonstrated that flow patterns in the subsurface are often highly irregular; an example of a nonuniform infiltration front in a sandy soil is shown in Fig. 1.

Despite these desirable characteristics, important drawbacks exist in using dye tracers. Dye tracers are not conservative tracers; i.e., they sorb to subsurface media and do not necessarily move at the same speed as the water to be traced. The sorption behavior of dyes is influenced by the properties of the subsurface materials and the chemistry of the aqueous phase (9,12,14–16). Some dyes degrade when they are exposed to sunlight, e.g., uranine (10,17,18), and some can be degraded by microorganisms. Consequently, dye tracers may behave differently under different natural environments. Thus, the suitability of dye tracers should be tested before they are used in hydrological studies.

An "ideal" water tracer is a substance that (1) has conservative behavior (i.e., does not sorb to solid media, is resistant to degradation, and stable in different chemical environments); (2) does not occur naturally in high concentrations in the system to be investigated; (3) is inexpensive, (4) is easy to apply, sample, and analyze; and (e) is nontoxic to humans, animals, and plants (6). These requirements are difficult to meet for a single chemical. Different types of dyes have been proposed as best suitable water tracers, and these dyes are discussed below.

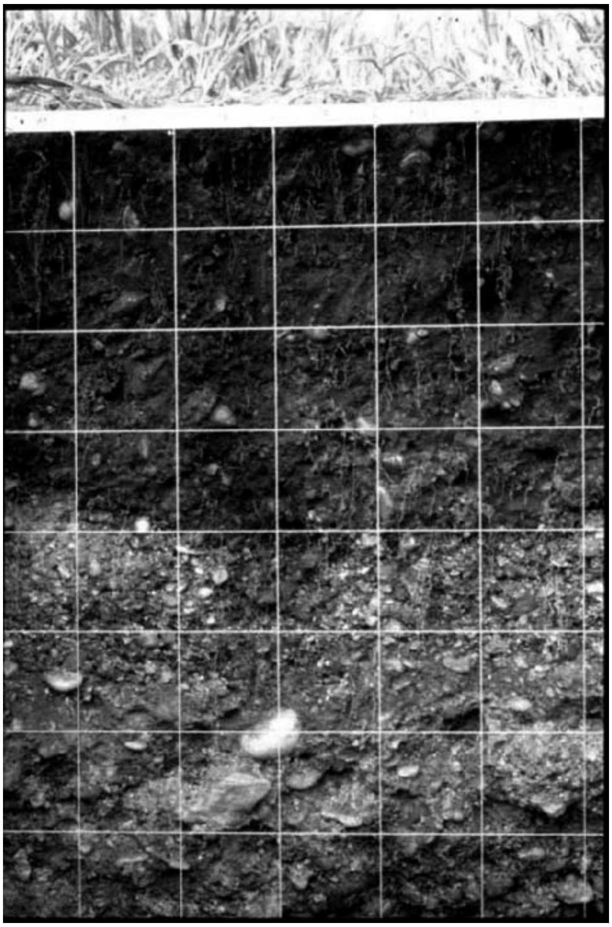

Figure 1. Visualization of flow patterns in soils using a dye tracer (Brilliant Blue FCF). Grid size is 10 cm.

SURFACE WATER, GROUNDWATER, AND VADOSE ZONE TRACERS

Fluorescent dyes are frequently used in surface and groundwater applications and, to some degree, in vadose zone hydrology. Certain dyes, such as rhodamine WT and uranine, are used for surface water, groundwater, and vadose zone applications, whereas others, such as Brilliant Blue FCF, are exclusively used as vadose zone tracers. Many of the common dye tracers (Table 1) belong to the chemical class of the xanthene dyes. The structures of commonly used dyes are shown in Fig. 2.

Dye tracers have been used in measuring flow velocity, travel time, and dispersion in rivers and streams (19,20). Among the dyes commonly used as surface water tracers (Table 1), the most frequently used one is rhodamine WT (20–23). Uranine has been recognized as a good hydrological tracer, but its susceptibility to photochemical decay (17) is of concern in tracing surface water.

Dye tracers have also been used to study groundwater flow velocity, flow direction, hydraulic connections, and aquifer characteristics (4,5). Uranine and rhodamine WT are the two most commonly used tracers in groundwater studies (Table 1). However, these two dyes should not be used as cotracers because rhodamine WT degrades to carboxylic fluorescein, which may confound tracer quantification (13). Rhodamine WT is highly water soluble, easily visible and detectable, photochemically more stable than uranine, and has a moderate tendency for sorption (13). Commercially available tracer-grade rhodamine WT contains two isomers (Fig. 3), which have different sorption properties (24). The para-isomer of rhodamine WT sorbs less to different aquifer materials than did the meta-isomer (24,25). Consequently, the two isomers travel with different velocities in subsurface media, which lead to chromatographic separation (24). In groundwater tracer studies, like in surface water tracing, dye tracers can be easily detected or quantified in water samples using fluorometers or spectrophotometers. Methods and software for designing and analyzing tracer tests are available (13,26–28).

In the vadose zone, dyes are mainly used to delineate water flow patterns. Flow pathways in soils, sediments, and fractured rock have been visualized using dye tracers (29–33). Many dyes have been tested in search for an

optimal vadose zone dye tracer, and different dyes have been recommended (6). Most commonly used vadose zone tracers are listed in Table 1. Brilliant Blue FCF has gained acceptance as a good dye tracer for visualization of flow patterns (12,33) and solute transport in the vadose zone (34–36). In the vadose zone, dye tracer analysis is not as simple as in surface water or groundwater tracer studies, particularly if tracer concentrations are to be determined. Image analysis or fiber-optic spectroscopy can be used to measure tracer distributions in soil profiles (37,38).

LIMITATIONS IN USING DYES AS TRACERS

Most dyes are organic molecules, and their interactions with other materials in the subsurface are influenced by environmental conditions. Generally, dye tracers sorb to solid surfaces and the degree of sorption depends on surface properties and solution chemistry. Solubility, photochemical decay, absorption spectra, and fluorescence of dyes are often affected by environmental conditions, such as temperature, sunlight, acidity, and alkalinity. Thus, not only properties of the dyes but also of the environment in which dyes are to be applied often limit the use of dyes as tracers.

Sorption of dyes to subsurface media is one major limitation for using dyes to trace water flow pathways. Sorption causes dyes to move with a slower velocity than water. Some dyes can mimic the movement of certain chemicals rather than the flow of water. For instance, rhodamine WT mimiced the movement of atrazine (39).

Dyes selected as hydrological tracers often contain functional groups, such as carboxylic and sulfonic acids, which contribute to high water solubility and decrease sorption (9,40). However, the functional groups cause dyes to have pH dependent properties. The properties of mineral surfaces may also change with pH, i.e., negatively charged surfaces may become neutral or positively charged as pH decreases, and sorption of anionic dyes may increase. Therefore, the sorption of dyes should be tested before dyes are applied as tracers.

Fluorescence of dyes may change under different environmental conditions. For instance, fluorescence intensity of rhodamine B increases with decreasing temperature (17). The presence of electron donating ions, such as chlorine, bromine, and iodine, in water samples as well as changes in solution pH can cause fluorescence quenching (10,19).

SELECTION OF DYE TRACERS FOR SPECIFIC USES

QSAR Approach as an Alternative to Experimental Screening

Screening is a basic step for selection of the most suitable dye tracers for specific uses, but experimental screening of thousands of commercially available dyes is not practical. An efficient technique (accurate, simple, fast, and inexpensive) is necessary to find the most suitable dye tracer for a specific investigation. A promising screening technique is the use of QSAR.

QSARs relate the molecular structure of a chemical to its activity. Although this technique has been used extensively in pharmacology, it has also been applied to estimate environmental fate and risk of organic chemicals (41–44). QSAR models are based on calculated molecular descriptors and selected measured data that describe the property to be predicted. A statistical model then allows us to predict the properties of structurally similar chemicals that have not yet been experimentally tested.

QSAR Case Study Using Triarylmethane Dyes

We illustrate the use of QSAR for dye tracer screening using the example of the triarylmethane dyes. These dyes are often used as food dyes, and because they are highly water soluble, they have preferable characteristics as dye tracers (6). Brilliant Blue FCF, one member of this dye class, is commonly used as a vadose zone tracer. Other members, however, may be even better suited as dye tracers. We developed a QSAR model with triarylmethane dyes to predict their soil sorption characteristics. Four triarylmethane dyes were selected as a training set: Brilliant Blue FCF (C.I. Food Blue 2), FD&C Green No. 3 (C.I. Food Green 3), ORCOacid Blue A 150% (C.I. Acid Blue 7), and ORCOacid Fast Green B (C.I. Acid Green 9). These four dyes share the same molecular kernel but differ in numbers, types, and positions of functional groups [Fig. 3(a)–(d)].

We experimentally measured soil sorption parameters of the four dyes and used QSAR to relate these parameters to the structural properties of the dyes. Soil sorption was determined by batch sorption experiments similar to the ones described in German-Heins and Flury (16). A sandy soil (Vantage, WA), pH 8, and 0.01 M $CaCl_2$ solution were used for the sorption experiments. A Langmuir sorption isotherm was fitted to the experimental data to obtain the two adsorption parameters, the Langmuir coefficient K_L and the maximum adsorption A_m (Table 2), using a normal nonlinear least-squares method (45). The Langmuir isotherm describes the relation between sorbed (C_a) and aqueous concentrations (C_s) at equilibrium as (45):

$$C_a = \frac{A_m K_L C_s}{1 + K_L C_s} \tag{1}$$

Structural properties (molecular descriptors) of the dyes were calculated using the MDL QSAR (version 2.1, 2002, MDL Information System, Inc., San Leandro, CA). The MDL QSAR program converts molecular structures to structural properties, such as molecular connectivity indices (MCIs), molecular volume, and surface area. Stepwise linear regression analyses were applied to select the descriptors that are well correlated to the experimental parameters (46,47). The statistical significance was assumed at $p \leq 0.05$.

The cross validation technique tested the predictability of the models. Randomization tests were performed to check the probability that correlation occurred by chance. The models that achieved the best quality of statistics were selected for estimation of each sorption parameter. The two QSAR models, one for estimation of K_L and another for estimation of A_m, were established as follows:

1. Langmuir coefficient (K_L) model:

$$K_L = -54.47({}^9\chi_p) + 183.75 \tag{2}$$

where K_L has units of L/mmol and ${}^9\chi_p$ is the ninth-order simple path molecular connectivity index.

2. Maximum adsorption (A_m) model:

$$A_m = -45.72({}^9\chi_p^v) + 35.88 \tag{3}$$

where A_m has units of mmol/kg and ${}^9\chi_p^v$ is the ninth-order valence path molecular connectivity index.

Prediction of Soil Sorption Using QSAR Models

Approximately 70 hypothetical molecules were created based on the structure of Brilliant Blue FCF, and their sorption parameters were estimated using the QSAR models (Equations 2 and 3). These molecules all shared the same molecular kernel as Brilliant Blue FCF but were different in number and position of SO_3 groups. The effects of different numbers and positions of SO_3 groups on soil sorption parameters, i.e., K_L and A_m values, of the new compounds were examined.

Table 2. Comparison of Langmuir Coefficient (K_L) and Maximum Adsorption (A_m) for Test and Hypothetical Triarylmethane Dyes

Triarylmethane Dyes	C.I. Nr.	Number of SO_3 Groups	Langmuir Coefficient K_L (L/mmol)	Maximum Adsorption A_m (mmol/kg)

Dye set 2	none	2	8.1 to 31.5	2.0 to 8.7
Dye set 3	none	3	−8.5 to 14.7	−2.9 to 4.1

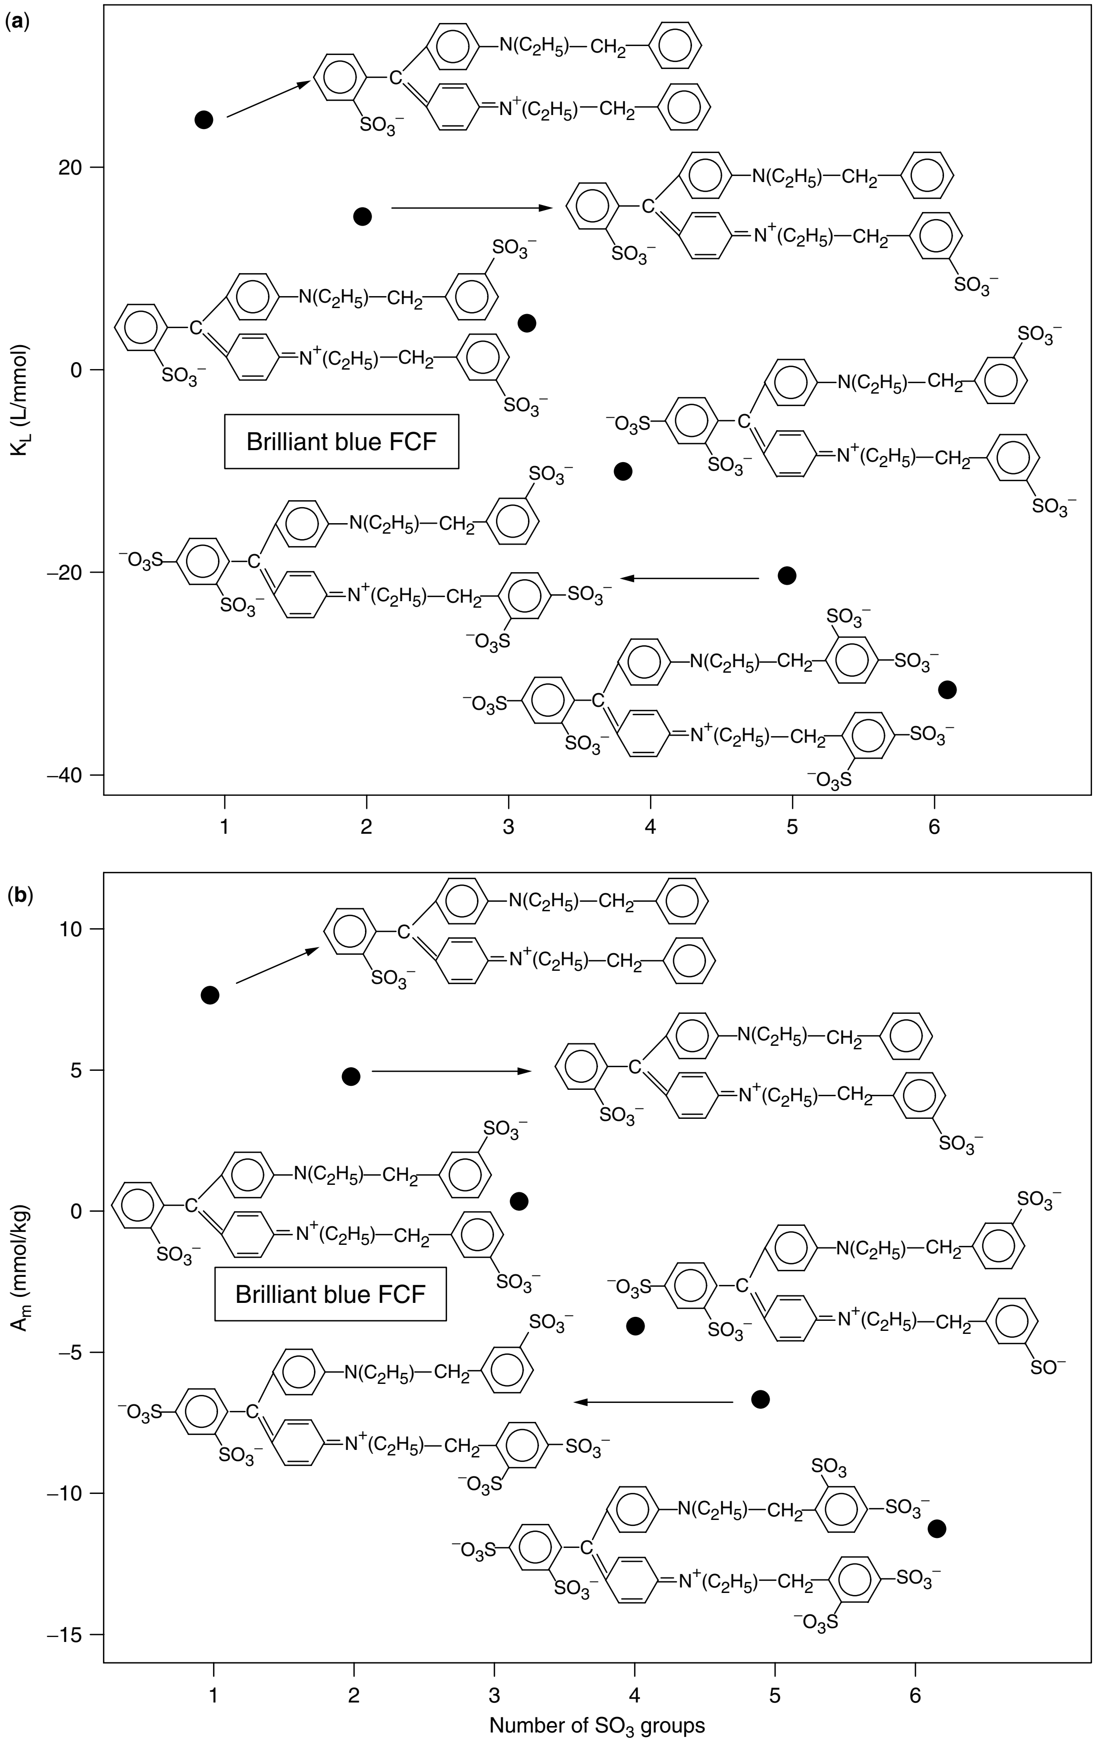

Figure 4. Changes in (**a**) Langmuir coefficient, K_L, and (**b**) adsorption maximum, A_m, as a function of the number of SO_3 groups on the molecular kernel of triarylmethane dyes.

The QSAR modeling indicates that the more SO_3 groups are attached to the molecular kernel, the smaller will be the soil sorption: Both K_L and A_m values decreased with the increasing number of SO_3 groups (Fig. 4). Negative K_L and A_m values were calculated by the models. Negative values are physically not possible, except in the case of ion exclusion. The predicted values should be considered as relative, rather than as absolute, measures for comparing the sorption of the chemicals.

QSAR modeling also to examined the effects of the positions of the SO_3 groups at the molecular kernel. Three sets of hypothetical molecules were created, which contained one, two, or three SO_3 groups attached at different positions at the benzene rings of the triarylmethane kernel. Set 1, which contained one SO_3 group, consisted of six molecules, set 2 (two SO_3 groups) consisted of 22 molecules, and set 3 (three SO_3 groups) consisted of 31 molecules. The range of the predicted K_L and A_m values is listed in Table 2. The large variation in K_L and A_m values within each group of chemicals showed that the sorption parameters were strongly influenced by the positions of the functional groups.

Many dyes in sets 2 and 3 had lower K_L and A_m values than did the four test dyes. The hypothetical dyes with four to six SO_3 groups attached to triarylmethane kernel [Fig. 3(e) and (f)] had considerably smaller K_L and A_m values than did the test dyes. These hypothetical dyes are likely better conservative tracers than are any of the test dyes.

The K_L and A_m values of C.I. Food Green 3 were lower than were those of C.I. Food Blue 2 (Brilliant Blue FCF). Between these two readily available dyes, C.I. Food Green 3 may be a better tracer than Brilliant Blue FCF for hydrological investigations in the vadose zone.

SUMMARY

Dye tracers are frequently used in hydrological investigations. Although dyes have unique tracer characteristics, some limitations and problems are associated with using dyes as hydrological tracers. Most dyes sorb to subsurface media, so that tracer characteristics of dyes should be tested under the specific conditions under which dye tracing is to be conducted.

An accurate and cost-effective screening technique is necessary for selection of optimal dye tracers. QSARs offer a powerful tool for screening of a large number of dyes in a short time. We conducted a QSAR case study using triarylmethane dyes. The results of the QSAR modeling indicate that many hypothetical triarylmethane dyes have considerably lower sorption characteristics than do the triarylmethane dyes currently used as tracers, and they likely are good tracer candidates.

FLOW-DURATION CURVES

Robert M. Hordon
Rutgers University
Piscataway, New Jersey

The flow-duration curve is a cumulative frequency curve that shows the percentage of time that specified stream's discharges were equaled or exceeded during a period of record (1). It combines in one curve all of the flow characteristics of a stream, ranging from flood flows to drought situations.

In sharp contrast to a hydrograph where time is on the *x* axis, chronology is not shown in flow-duration curves. If the period of record on which the curve is based is sufficiently long, it may be considered a probability curve and therefore, is used to estimate the percentage of time that a specified stream's discharge will be equaled or exceeded in the future.

INTRODUCTION

The temporal sequence of flows is not included in the preparation of flow-duration curves, so one cannot tell from the curve itself whether periods of low or high flow occurred during one dry or wet period or were scattered over several years (2). However, the curve is very useful

FLOW-DURATION CURVES

Robert M. Hordon
Rutgers University
Piscataway, New Jersey

The flow-duration curve is a cumulative frequency curve that shows the percentage of time that specified stream's discharges were equaled or exceeded during a period of record (1). It combines in one curve all of the flow characteristics of a stream, ranging from flood flows to drought situations.

In sharp contrast to a hydrograph where time is on the *x* axis, chronology is not shown in flow-duration curves. If the period of record on which the curve is based is sufficiently long, it may be considered a probability curve and therefore, is used to estimate the percentage of time that a specified stream's discharge will be equaled or exceeded in the future.

INTRODUCTION

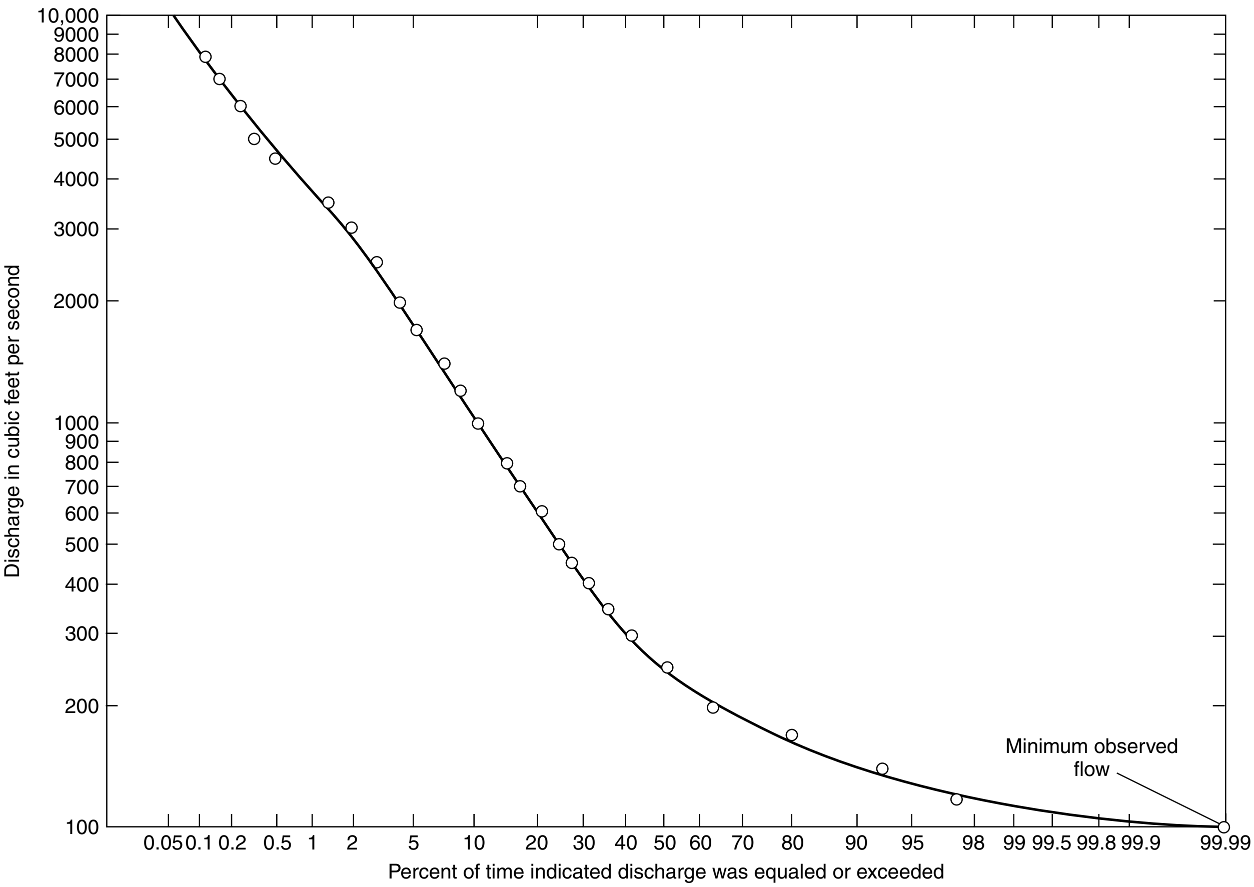
The temporal sequence of flows is not included in the preparation of flow-duration curves, so one cannot tell from the curve itself whether periods of low or high flow occurred during one dry or wet period or were scattered over several years (2). However, the curve is very useful for studying the flow characteristics of a stream for the entire range of discharge that can vary across several orders of magnitude.

Although flow-duration curves can be based on weekly or monthly averages, the greatest accuracy is reached in using the day as the unit of time. Therefore, it is recommended that flow-duration curves used in hydrologic analysis be based on mean daily discharges for the period of record.

As streamflow generally has a log-normal distribution, flow-duration curves are usually plotted on logarithmic probability graphs where the *x* axis represents the percentage probability that a given discharge was equaled or exceeded during a given period and the *y* axis indicates discharge in either cubic feet/second or cubic meters/second. A sample flow-duration curve for Bowie Creek near Hattiesburg, Mississippi is shown in Fig. 1. Note that the *x* axis ranges from 0.05 to 99.99% and the *y* axis is scaled logarithmically from 100 to 10,000 cubic feet/second (two orders of magnitude).

THE RELATIONSHIP BETWEEN CURVE SHAPE AND GEOHYDROLOGY

It is widely recognized that the shape of the flow-duration curve provides very useful information about the geohydrologic characteristics of watersheds. Steeply sloping curves indicate “flashy” streams where the flow is largely from direct runoff and where there is limited groundwater storage. For example, the flow-duration curves for the South Branch Raritan and Great Egg Harbor Rivers in New Jersey for the 1931–1960 time period are shown in Fig. 2. The South Branch Raritan River in North Jersey drains consolidated rock formations such as Precambrian granites and Paleozoic limestones. In contrast, Great Egg Harbor River in the unconsolidated formations of the Coastal Plain of South Jersey is underlain by thick seaward-dipping deposits of sand (3). The geohydrologic differences between the consolidated rocks of North Jersey and the unconsolidated sedimentary formations of the Coastal Plain are illustrated by the different slopes in Fig. 2. First, discharge on the *y* axis for both rivers has been equilibrated by using cubic feet per second/square mile values to make the flow independent of watershed size (4). Second, note in Fig. 2, that the discharge values are higher for the South Branch Raritan River at high flow conditions (0.01–20% exceedance values) and lower at low flow conditions (80–99.5% exceedance values). This difference is to be expected as the groundwater storage is much greater in the Coastal Plain than in the consolidated rock formations of northern New Jersey.



Manual of hydrology: part 2, low-flow techniques

Figure 1. Duration curve of daily flow, Bowle Creek near Hattiesburg, Mississippi, 1939–1948.

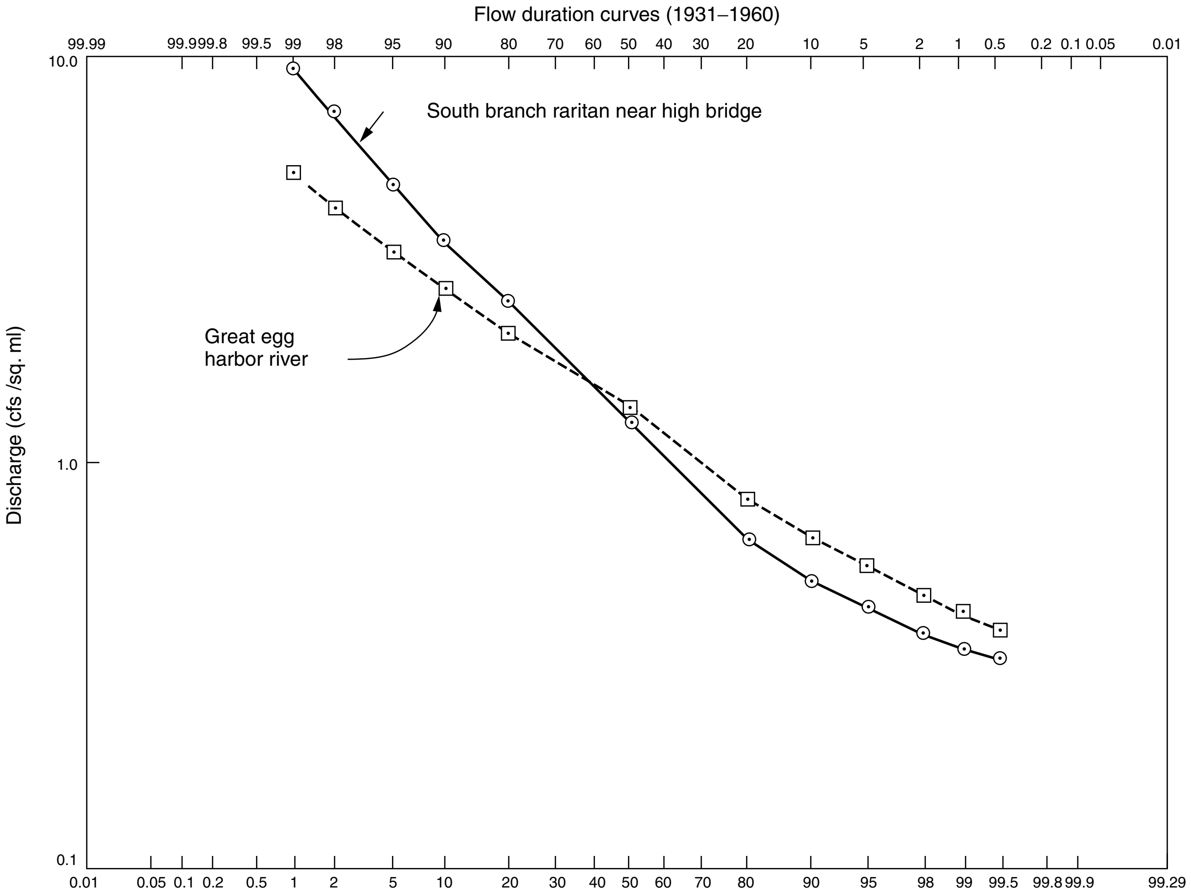


Figure 2. Percentage of time indicated discharge was equaled or exceeded.

An even better example of differential geohydrology and its effect on flow-duration curves is shown in Fig. 3. Both the South Branch Raritan River and Stony Brook at Princeton in New Jersey are underlain by consolidated rock formations. However, the geologic formations within the Stony Brook watershed include a large proportion of Lockatong argillite, a very tight, poorly fractured rock that is notorious for its poor groundwater yields and limited water storage. As in Fig. 2, discharge on the y axis has been equilibrated, in this case by using (mgd) million gallon per day/square mile values.

Note the precipitous decline of the slope of the curve for Stony Brook in Fig. 3, indicating the strong effects of the minimal amounts of groundwater in storage in the argillite formation. The flow-duration curve data were plotted on log-probability graphs, so the decline in expected flow is even more pronounced.

VARIABILITY INDEXES

One of the major characteristics of streamflow is its variability. This variability reflects the variability in precipitation as modified by the physical characteristics of the watershed. These physical characteristics include the differential geohydrology of consolidated and unconsolidated rock formations and the water storage available in lakes, swamps, and wetlands. Another factor that will become of increasing importance in streamflow variability is the anthropogenic factor as exemplified by the effects of urbanization on the hydrologic cycle. Streams are subject to more regulation in the form of water supply diversions, interbasin transfers of both raw water and treated effluent, and low flow release requirements, so the natural flow of a stream may become very difficult to measure, particularly in heavily urbanized smaller basins.

One quantitative measure of streamflow variability is the slope of the flow-duration curve itself. The steeper the slope, the greater the variability. A numerical index of variability was introduced by Lane and Lei (5) that is defined as the standard deviation of the logarithms of stream discharge at 10 points on the curve between the 5% and 95% exceedance values (5, 15, 25, ... 95%).

Miller (6) noted that many flow-duration curves tend to be nearly straight lines on log-probability paper between the 20 and 80% exceedance points. The curves above and below these points depart strongly from a straight line and would not be suitable for a numerical index. Thus, Miller (6) suggested using a simple index by dividing the discharge at the 20% point on the curve by the discharge at the 80% point. Flashy streams have high indexes, whereas streams of relatively uniform flows (such as those in the Coastal Plain) have low indexes. One additional benefit of this easily calculated index is that the resulting ratio is dimensionless, thereby facilitating the comparison of streamflow variability in varied locations.

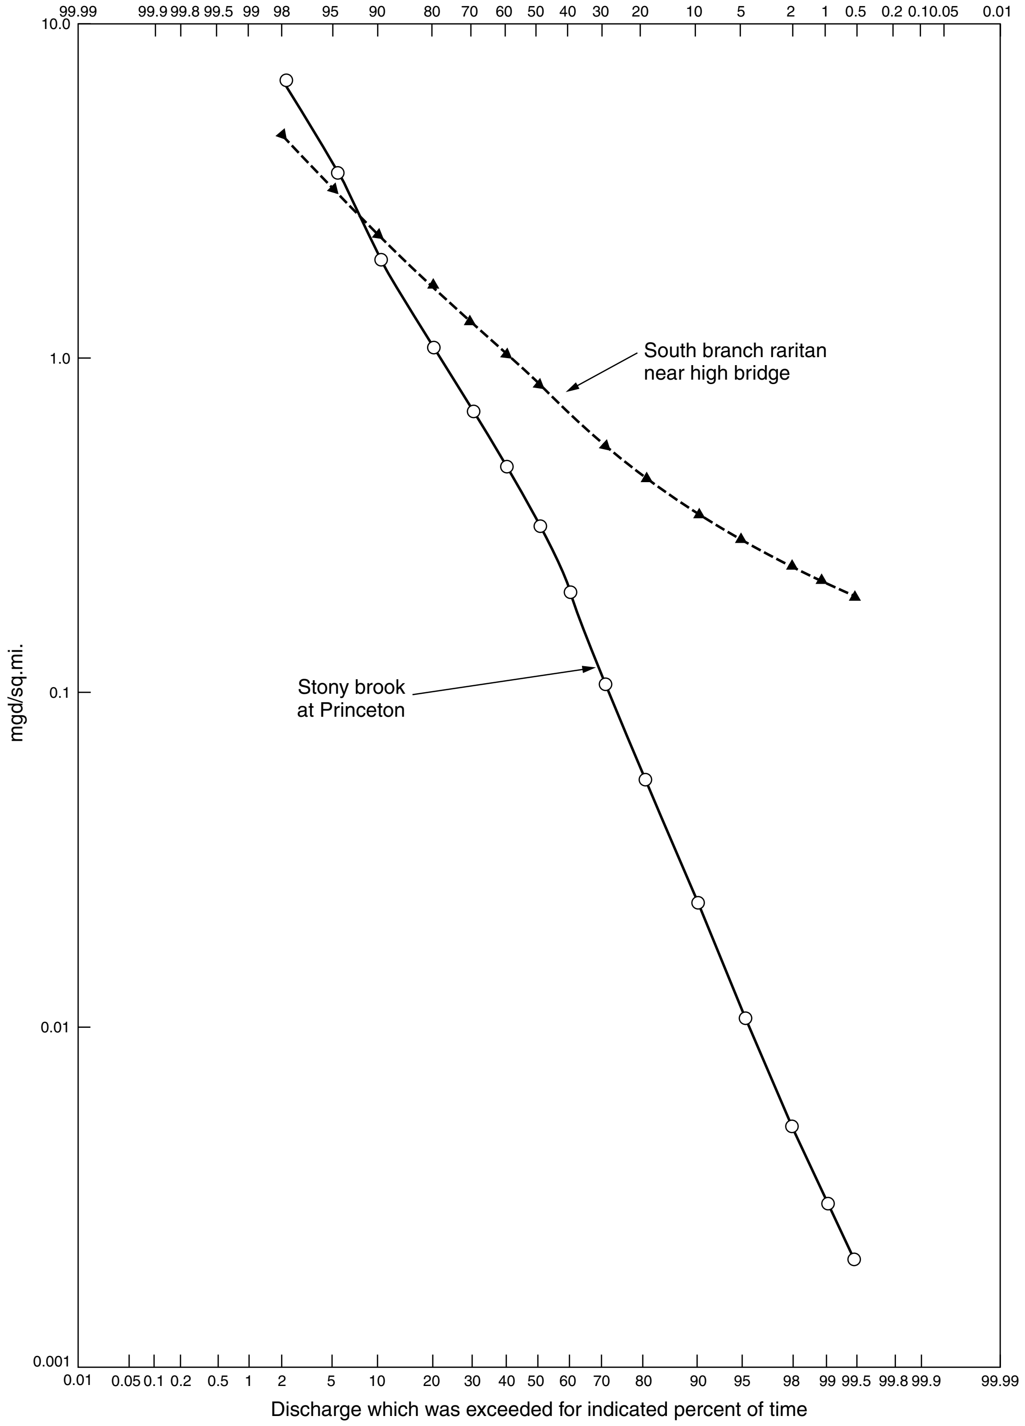

Figure 3. Flow-duration curves; Stony Brook at Princeton, 1954–1975; South Branch Raritan near High Bridge, 1919–1975.

SUMMARY

A flow-duration curve is a graph, usually plotted on log-probability paper, that shows the percentage of time that streamflow at a gaging station is either equaled or exceeded. Important information about the hydrologic and geologic characteristics of a watershed is revealed in the shape of the curve. Curves that slope steeply represent streams of very variable flows that reflect large inputs of overland runoff. Conversely, curves of gentler slopes are indicative of basins that have large amounts of groundwater in storage that result in flows of higher constancy.

ENVIRONMENTAL FLOWS

GEOFFREY PETTS
University of Birmingham
Birmingham, United Kingdom

The ecological integrity of riverine ecosystems depends on their natural dynamic character (1). Sustaining the natural functioning of aquatic and water-dependent ecosystems in the face of growing human demands is a major challenge (2). Its solution requires the allocation of water to protect aquatic ecosystems from the impacts of abstraction and river flow regulation (see Regulated Rivers), and this is one of five facets to freshwater management for the twenty-first century (see Water in History). It also requires acceptance of a multiuse ethic to provide flexible water budgets to support ecological functions in both dry and wet years (3).

Rivers are the arteries of fluvial hydrosystems comprising the river itself, riparian zone, floodplain, and alluvial aquifer. These four-dimensional systems are influenced by longitudinal processes, vertical and lateral fluxes, and strong temporal changes. Flow is the driver. Flow defines the environmental domains within which biological communities develop, including the vertical exchanges between surface and groundwater. High flows interact with the sediment load, and also with downed trees and driftwood (4), to shape the channel and floodplain morphology and to structure the complex mosaic of physical habitats that comprise a river corridor.

A major constraint to the advancement of tools for allocating flow to meet in-river needs was the lack of scientifically based models (5). In the 1960s and 1970s, early attempts to set *instream flows* for rivers focused on the annual minimum flow expressed as a hydrological statistic, commonly as either a flow duration statistic (such as the 95th percentile flow) or as a fixed percentage of the average daily flow (ADF), with several studies proposing 20% ADF to protect aquatic habitat in streams.

From the early 1980s, more complex approaches to determine instream flows were introduced that make the assumption that physical habitat attributes provide an index of suitability for biota. The most well known of these flow–habitat methodologies, Physical Habitat Simulation (PHABSIM), integrates the changing hydraulic conditions with discharge and the habitat preferences of one or more selected species. The method relies on three principles: The chosen species exhibits preferences within a range of habitat conditions that it can tolerate; these ranges can be defined for each species; and the area of stream providing these conditions can be quantified as a function of discharge and channel structure. In the majority of cases, these methodologies developed instream-flow guidelines that focused on the needs of a single species, usually a salmon or trout, although more advanced approaches considered the needs of different life stages. More recent advances of these approaches include, for example, assessment of flows (1) to encourage the upstream migration of salmon from the estuary to the spawning grounds, (2) to provide good quality habitat for spawning, and (3) to maintain the intragravel environment for egg development over winter for fry at emergence in late winter and for juvenile fish in spring and summer.

By the early 1990s, the science and management of *regulated rivers* had expanded from the determination of *instream flows* to *environmental flows*. Many schemes now applied more complex flow–habitat models to address wider issues than the instream needs, for example, the *hydraulic habitats* of a single species. These new approaches address the sustainability of communities and ecosystems. They address the access of aquatic biota to seasonal floodplain and riparian habitats as well as the need for high flows to sustain the geomorphological dynamics of the river corridor and floodplain habitats (6). They provide more sophisticated approaches to setting minimum flows and enable advancement of an ecologically acceptable flow regime concept (7,8), which recognizes that a set of minimum flow constraints does not provide sufficient protection for river ecosystems. Different life stages and different species benefit from different flows at different times of the year, and in different years. Rivers must be protected in wet years as well as drought years because high flows provide optimum conditions for some species and are also responsible for sustaining the quality and diversity of in-channel and riparian habitats.

The basic environmental principles needed to formulate policy decisions and management approaches on environmental flows have been summarized by Naiman et al. (9). These focus on the need to sustain *flow variability* that mimics the natural, climatically driven variability of flows at least from season to season and from year to year, if not from day to day. The two fundamental general principles are:

1. The natural flow regime shapes the evolution of aquatic biota and ecological processes.
2. Every river has a characteristic flow regime and an associated biotic community.

From these were developed four specific principles for advancing the provision of environmental flows (10):

1. Flow is a major determinant of physical habitat in rivers, which in turn is a major determinant of biotic composition.
2. Maintenance of the natural patterns of connectivity between habitats along a river and between a river and its riparian zone and floodplain is essential to the viability of populations of many riverine species.

3. Aquatic species have evolved life history strategies primarily in response to the natural flow regime and the habitats that are available at different times of the year and in both wet and dry years.
4. The invasion and success of exotic and introduced species along river corridors are facilitated by regulation of the flow regime, especially with the loss of natural wet–dry cycles.

In addressing the issues of environmental flows, water managers must become water-and-habitat managers, and holistic management strategies are being developed to support their activities (6). However, a continuing failure by policymakers to give due recognition to the array of goods, services, and other benefits provided by aquatic ecosystems (9), to the complexity of ownership and rights of access to these, and of how to integrate livelihood issues into water and ecosystem resource-management decisions remains a major issue.

EUTROPHICATION (EXCESSIVE FERTILIZATION)

G. Fred Lee
Anne Jones-Lee
G. Fred Lee & Associates
El Macero, California

INTRODUCTION

"Eutrophication" is the process of a waterbodys becoming increasingly rich in aquatic plant life such as algae and aquatic macrophytes (water weeds). It is driven by the increasing input of aquatic plant nutrients, principally nitrogen and phosphorus, from natural and anthropogenic sources. Although natural eutrophication takes place over geologic time, activities of people that increase the aquatic plant nutrient inputs to waterbodies can rapidly accelerate this process and cause cultural eutrophication. Thus, the term "eutrophication" has become synonymous with "excessive fertilization" or the input of sufficient amounts of aquatic plant nutrients to cause the growth of excessive amounts of algae and/or aquatic macrophytes in a waterbody such that beneficial uses of the waterbody (i.e., water quality) are impaired. Beneficial uses of waterbodies that stand to be impaired by the presence of excessive amounts of aquatic plant life include domestic and industrial water supply, recreation, and fisheries.

Because of the public health and environmental quality significance of these water quality impairments, myriad strategies have been advanced to evaluate and regulate excessive fertilization and nutrient input to waterbodies, with varying degrees of technical validity and demonstrated effectiveness. This chapter reviews what should be considered in assessing the impacts of nutrients that are added to a waterbody on the waterbody's eutrophication-related water quality. References are provided to more detailed discussions of the issues covered.

IMPACTS OF EXCESSIVE FERTILIZATION ON WATER QUALITY

The excessive fertilization of waterbodies is a long-standing, well-recognized water quality problem throughout the United States and other countries. It is manifested as excessive growths of planktonic (suspended) algae, attached algae, and aquatic macrophytes (water weeds). Aquatic macrophytes can be floating forms such as water hyacinth or duckweed or attached-emergent forms. Water quality problems caused by these growths, discussed in detail by Lee (1), are summarized below.

Domestic Water Supplies

When raw water supplies contain large amounts of algae and some other aquatic plants, the cost of treatment increases and the quality of the product may be diminished. Planktonic algae can shorten filter runs. They can also release organic compounds that cause tastes and odors and, in some instances, serve as trihalomethane (THM) and haloacetic acid (HAA) precursors. THMs are chloroform and chloroform-like compounds; HAAs are low-molecular-weight chlorinated organic acids. These compounds are produced when the precursors react with chlorine during the disinfection process and are regulated as human carcinogens.

Violations of Water Quality Standards

Excessively fertile waterbodies can exhibit marked diel (over a 24-hr day) changes in pH and dissolved oxygen concentrations that can result in repeated short-term violations of water quality standards. During daylight, algal photosynthesis removes CO_2 from the water, which increases the pH; algal respiration in the night releases CO_2 and lowers the pH. In late afternoons, the pH of excessively fertile water can be found to exceed the water quality standard for pH. Similarly, algae produce oxygen during photosynthesis, but they consume it during respiration. Just before sunrise, after sufficient nighttime algal, bacterial, and other organism respiration, dissolved oxygen concentrations can be below water quality standards for protection of fish and other aquatic life. Excessively fertile waterbodies that thermally stratify (develop a thermocline) often exhibit dissolved oxygen depletion below the thermocline because of bacterial respiration of dead algae. Richards (2) showed that one phosphorus atom, when converted to an algal cell that subsequently dies, can consume 276 oxygen atoms as part of the decay process.

Toxic Algae

One major stimuli for the U.S. EPA's recently increased attention to excessive fertilization is the *Pfiesteria* problem in Chesapeake Bay (3); fish kills occurred there because of the presence of toxic algae. Fish kills associated with toxic algae have occurred in various waterbodies around the world, including off the west coast of Florida, for many years. In addition, blue-green algae at times excrete toxins that are known to kill livestock and other animals that consume the water.

Impaired Recreation and Aesthetics

Excessive growths of attached algae and aquatic macrophytes can impair swimming, boating, and fishing by interfering with water contact. Severe odor problems can also be caused by decaying algae, water weeds, and algal scums.

Water clarity—defined by the depth of the waterbody at which the bottom sediments can be seen from the surface—is an aesthetic quality that is compromised by eutrophication. Waterbodies with high degrees of clarity (i.e., the bottom can be seen at depths of 20 or more feet) have low planktonic algal content; in more eutrophic waterbodies, the sediments can only be seen at a depth of a few feet. The greenness of water, which contributes to diminished water clarity and is caused by the presence of algae, can be quantified by measurement of planktonic algal chlorophyll. Inorganic turbidity also diminishes water clarity and can influence the perception of greenness of a waterbody. Often, high levels of planktonic algal chlorophyll can be present in a shallow waterbody or river without the public's perceiving it to be excessively fertile, if the water is brown because of inorganic turbidity.

Impact on Fisheries

As illustrated in Fig. 1, fertilization increases total fish production (biomass). However, as Lee and Jones (4) discussed, it can adversely affect the production of desirable types of fish, especially at high fertilization levels. In stratified waterbodies, algae grow in surface waters, die, and settle to the hypolimnion (bottom layer) where they are decomposed. As noted above, the oxygen demand created by algal decomposition can be sufficient in eutrophic waterbodies to deplete the hypolimnetic oxygen, which means that the desirable coldwater fish (e.g., salmonids, trout) that normally inhabit the cooler hypolimnion cannot survive there because of insufficient oxygen. Thus, the higher fish production characteristic of highly eutrophic waterbodies is typically dominated by rough fish, such as carp, which can tolerate lower dissolved oxygen levels.

Shallow Water Habitat

Emergent aquatic vegetation in shallow waters provides important habitat for various forms of aquatic life. As

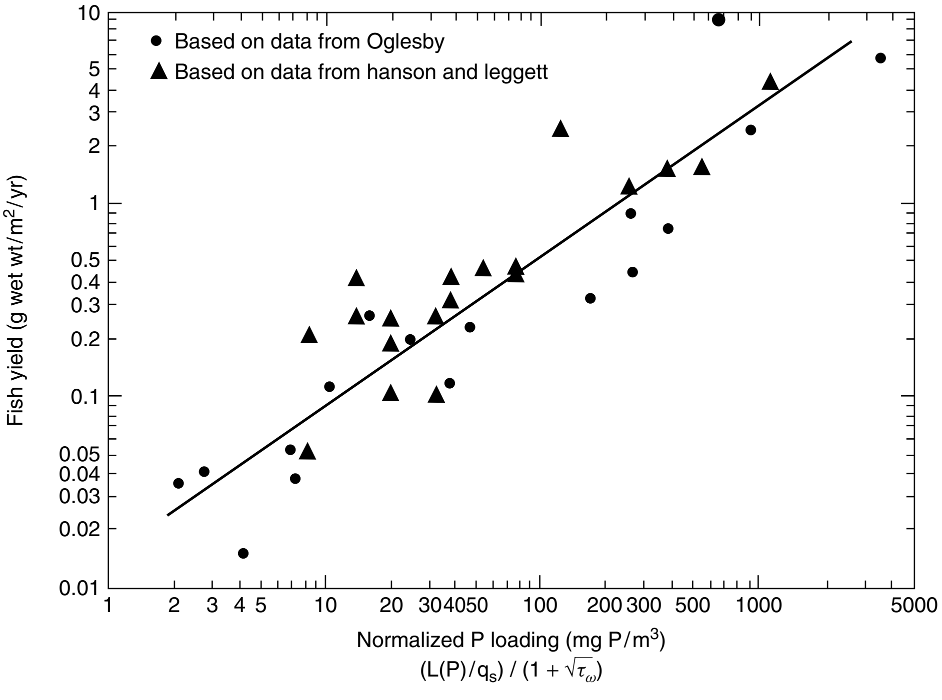

Figure 1. Relationship between normalized P load and fish yield [from Lee and Jones (4)].

discussed by Lee (1), increased planktonic algal growth reduces light penetration (water clarity), which in turn inhibits the growth of emergent vegetation. This process can result in loss of significant aquatic life habitat.

Overall Impacts

Excessive fertilization is one of the most important causes of water quality impairment of waterbodies. In its last National Water Quality Inventory, the U.S. EPA (3) listed nutrients as the leading cause of impairment of lakes and reservoirs.

CONTROLLING EXCESSIVE FERTILIZATION

Algae and other aquatic plants require a wide variety of chemical constituents, light, and appropriate temperatures to grow. Of those factors, however, only nutrient input is amenable to sufficient control to effect a meaningful decrease in algal and aquatic plant biomass to reduce the adverse impacts of excessive fertilization. The issues of which nutrient(s) should be controlled, sources of the nutrient, what type of and how much control is needed, and the positive impacts of the control must be addressed in a eutrophication management program.

Limiting Nutrient

For managing algal populations, the primary focus should be on control of the nutrient that is present in the least amount compared with algal needs, i.e., the limiting nutrient. Increasing or reducing the amount of that nutrient available to algae will affect an increase or a decrease in the algal biomass that can be sustained. This process is illustrated in Fig. 2, which shows that additional growth occurs in response to additional input of the limiting nutrient up to the point at which it is present in greater amounts than can be used. Nitrogen and phosphorus are the nutrients that typically limit algal growth. Phosphorus is more often the limiting nutrient in freshwater waterbodies, whereas nitrogen is often the limiting nutrient in marine waters. Although the potassium content of some soils can limit the growth of terrestrial plants, potassium is not an element that limits aquatic plant growth.

To determine which nutrient is limiting algal growth in a particular waterbody, some have relied on the comparison of the concentrations of nitrogen and phosphorus to the "Redfield" stoichiometric ratio of these elements in algae (16:1 atomic basis or 7.5:1 mass basis) shown in Eq. 1.

$$106\ CO_2 + 16\ N + 1\ P + \text{trace elements} \Rightarrow \text{algae} + O_2 \qquad (1)$$

It is presumed that if the ratio is smaller than this, N would be limiting, and vice-versa, which can give misleading results and lead to unreliable nutrient control measures because whatever the "ratio," either or both could be present in ample amounts for algal growth (5). Rather, it is the concentration of algal-available forms of nutrients at peak biomass—when the algal growth is being limited—that should be assessed. If the concentration of either has been decreased by its utilization to below growth-rate-limiting concentration, reasonable certainty exists that that nutrient is limiting algal growth.

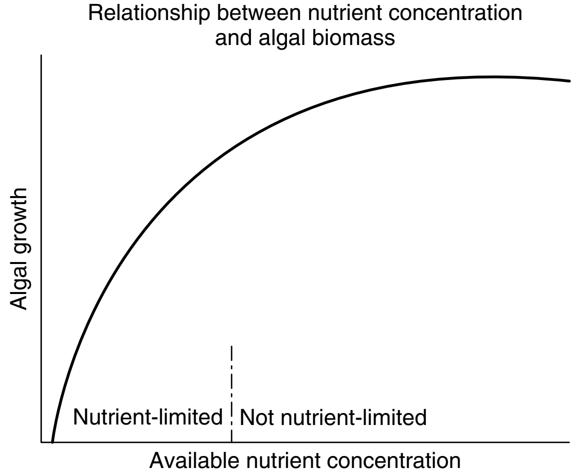

Figure 2. Relationship between nutrient concentration and algal biomass [from Lee and Jones-Lee (4)].

Typically, growth-rate-limiting concentrations for phosphorus are on the order of 2 to 8 μg/L available P, and for nitrogen, 15 to 20 μg/L available N. It is important to recognize, however, that even growth rate-limiting concentrations can support appreciable algal biomass if sufficient time is available for algal growth to occur. Furthermore, in many highly fertile waterbodies, neither nitrogen nor phosphorus is limiting algal growth. Both can be present above growth-rate-limiting concentrations—i.e., on the plateau of the algal growth-nutrient concentration relationship in Fig. 2.

AVAILABILITY OF NUTRIENTS

Nitrogen and phosphorus exist in aquatic systems in many different forms, only some of which can be used by algae and aquatic plants. Therefore, in assessing the limiting nutrient in a waterbody or evaluating the control of nutrient input to a waterbody, it is essential to consider the forms in which the N and P exist in the loading sources and waterbody. Algal available forms of nitrogen are nitrate, nitrite, ammonia, and after conversion to ammonia, some of the organic nitrogen. The fraction of the organic nitrogen that is available is site-specific and depends on its source and age. Under limited circumstances, some blue-green algae can fix (utilize) atmospheric nitrogen gas (N_2) that is dissolved in water and use it as a source of nitrogen for growth. Soluble orthophosphate is the form of phosphorus that is available to support algal growth. Most particulate phosphorus and organophosphorus compounds, and oxygen-phosphorus polymer chain and ring compounds (condensed phosphates), do not support algal growth.

In developing nutrient criteria, the U.S. EPA (6,7) has been focusing on total phosphorus rather than on algal-available forms. This approach can misdirect control programs to sources whose control will not result in cost-effective improvements in eutrophication-related water quality. For example, it was well established many years ago that most of the particulate phosphorus in agricultural and urban stormwater runoff is not available to support algal growth. Lee et al. (8) reported on their extensive research as well as on the findings of others on this topic in a review of these issues for the International Joint Commission for the Great Lakes. From both short-term and long-term (one-year) tests, they found that the algal available P in agricultural and urban runoff can be estimated as the sum of soluble ortho-P and about 20% of the particulate P. Thus, most particulate P in agriculture and urban stormwater runoff from a variety of sources is not available for algal growth.

The lack of availability of much phosphorus in soils is well known to the agricultural community, which finds that total P in soils is not a reliable measure of plant-available P. As discussed by Lee and Jones-Lee (9), nutrient criteria for regulating agricultural and urban stormwater runoff should be based on soluble orthophosphate and nitrate plus ammonia plus about 20% of the particulate P and N. However, if the source of the P and N is algae, then most of the total N and total P will be mineralized and in time will become available to support algal growth.

SOURCES AND CONTROL OF ALGAL NUTRIENTS

Domestic Wastewater Discharges

Lee and Jones (10) reviewed the North American experience in controlling the excessive fertilization of waterbodies. They reported that domestic wastewater discharges are one of the most significant and controllable sources of available nutrients contributing to eutrophication. To control phosphorus from this source, tertiary treatment of the wastewaters is commonly practiced. Chemical treatment using alum (aluminum sulfate) typically costs a few cents per person per day for the population served by the treatment plant. Enhanced biological treatment of domestic wastewaters may also significantly reduce the phosphorus content of domestic wastewaters. Typically, either chemical or enhanced biological treatment can reduce the phosphorus concentration in domestic wastewater effluent by 90% to 95%. The authors estimate that the domestic wastewaters of more than 100 million people in the world are treated for phosphorus removal to reduce the excessive fertilization of the waterbodies receiving the wastewater discharges.

Nitrogen can also be removed from domestic wastewaters although not as readily as phosphorus. Nitrogen removal generally involves nitrification of the ammonia and organic nitrogen to nitrate, followed by denitrification. The cost is typically five to ten times greater than for phosphorus removal. Although phosphorus control in domestic wastewaters is widely practiced, nitrogen control has only been implemented to a limited extent because of the higher cost and because for most freshwater waterbodies, phosphorus control is the more effective way to control excessive fertilization.

Land Runoff

Another source of nutrients for waterbodies is runoff from land. Based on the U.S. Organization for Economic Cooperation and Development (OECD) Eutrophication Study data for about 100 waterbodies' watersheds located across the United States, Rast and Lee (11) determined nutrient export coefficients for the main categories of land use. Shown in Table 1, these coefficients define the mass of N and P that runs off a unit area of watershed land annually.

Although the export coefficients for a given watershed depend on the particular setting, the values in Table 1 have shown reliability in several areas for estimating the potential significance of various types of land use in contributing nitrogen and phosphorus from a watershed. More specific nutrient export coefficients for agricultural lands should be evaluated based on soil characteristics, types of crops grown, and other factors that tend to influence the amount of nitrogen and phosphorus exported from the land. Although these coefficients are for total N and total P, when used in the Vollenweider–OECD eutrophication modeling approach discussed subsequently, the availability of the loading is taken into account.

Nutrient Runoff Control BMPs

Controlling nitrogen and phosphorus in runoff from rural land has not been highly successful. Sharpley (12) reviewed the experience in trying to achieve a 40% reduction in nitrogen and phosphorus loads from agricultural lands in the Chesapeake Bay watershed. He indicated that limited progress has been made toward achieving that goal after about 15 years of effort. Similarly, Logan (13) reported that little progress has been made in effectively controlling phosphorus from agricultural runoff in the Lake Erie watershed.

Sprague et al. (14) reviewed factors that affect nutrient trends in major rivers of the Chesapeake Bay watershed. They noted the difficulty discerning major changes in the contribution of nutrients from agricultural lands in the watershed caused by year-to-year variability in nutrient export. This variability is related to several factors, including climate. They indicated that one of the principal methods for nutrient reduction from agricultural lands has been land retirement, i.e., termination of agricultural activities on the land.

Various "best management practices" (BMPs) have been implemented to control nutrient export from

Table 1. Watershed Nutrient Export Coefficients [from Rast and Lee (11)]

	Export Coefficients ($g/m^2/y$)		
Land Use	Total Phosphorus	Total Nitrogen	
Urban	0.10	0.5	0.25*
Rural/Agriculture	0.05	0.5	0.20*
Forest	0.01	0.3	0.10*
Other:			
Rainfall	0.02	0.8	
Dry Fallout	0.08	1.6	

*Describe nitrogen loadings for waterbodies in Western United States.

agricultural activities, including grassy strips, buffer lands, altering fertilizer applications, and so on. The U.S. EPA (15) discussed the current information on BMPs to control potential pollutants derived from agricultural lands. Although claims are made as to their effectiveness, it is evident from the U.S. EPA review and the authors' experience that there is a lack of quantitative understanding of the cost-effectiveness of BMPs for control of nutrients from agricultural activities (16). Quantitative studies are urgently needed to determine how various BMPs influence phosphorus and nitrogen export from the land, efficacy for controlling eutrophication, as well as costs associated with controlling phosphorus export to various degrees (e.g., 25%, 50%, and 75%). This information then needs to be viewed in the context of what agricultural interests of various types can afford relative to market prices, including issues of foreign competition. Maintaining agriculture through subsidies is a long-standing tradition in the United States. The control of nutrients from agricultural lands for the benefit of downstream waterbody users may also become one of the subsidy issues that will need to be considered to keep agriculture viable (although subsidized) in many parts of the United States.

Importance of Light Penetration

Algal growth in almost all waterbodies is light-limited to some extent. Turbidity and natural color diminish the penetrability of light into a waterbody, which affects the extent to which algae can use available nutrients. In fertile waterbodies, where the presence of abundant planktonic algae reduces the penetration of light further by self-shading, algae can photosynthesize only in the upper few feet of water. It is important to understand the influence of inorganic turbidity and natural color on the coupling between nutrient loads and eutrophication-related water quality. Although erosion from a waterbody's watershed may increase the nutrient load, it also increases the turbidity in the waterbody, which in turn decreases light penetration and thereby slows algal growth. Thus, control of erosion in a waterbody's watershed can result in greater algal growth for the same nutrient concentration than would occur if the waters were still turbid from erosion in the watershed.

Issues That Need to be Considered in Developing Appropriate Nutrient Control Programs

Several key issues need to be considered and evaluated in formulating nutrient control programs, the most important of which is the relationship between nutrient load and eutrophication-related water quality in the waterbody of concern. Each waterbody has its water quality-related load—a response relationship that needs to be defined.

First, the nature of the water quality impairment needs to be defined, which includes defining what the problem is (e.g., recreation impairment, aesthetics, tastes, and odors), when the water quality problems occur (e.g., summer, fall, winter, and spring), how eutrophication is manifested (planktonic algae, attached algae, and macrophytes), and the desired eutrophication-related water quality characteristics. Next, the limiting nutrient during the period of concern and the primary sources of that nutrient should be determined. Each source should be evaluated for the availability of nutrients, the controllability of the available nutrients, and the cost of implementing and maintaining the control strategy. Finally, a reliable modeling approach needs to be applied to estimate the improvement in eutrophication-related water quality that would be effected by the estimated expenditures for the potentially viable control options.

Desired Nutrient-Related Water Quality

The first step in developing appropriate nutrient load criteria is to identify the eutrophication-related water quality problem as well as the desired outcome of management for the waterbody. Types of problem/solution goals that may be identified include, as discussed above, preventing violations of average or worst-case-diel DO or pH standards, controlling algae-caused domestic water supply raw water quality problems (e.g., controlling tastes and odors, lengthening filter runs, reducing THMs, etc.), or increasing water clarity (Secchi depth). This evaluation should be done through a public process conducted by the regulatory agency because the public's perception of eutrophication-related water quality can be site-specific. In those areas where there are numerous waterbodies with marked differences in lake water clarity, for example, the public has the opportunity to compare waterbodies that are green with those that are clearer. There, the public's perception of high water quality is different from that in areas where all waters have the same general greenness because of planktonic algae.

Nutrient control must be undertaken with appropriate consideration of factors that govern how the nutrient loading is used within the specific waterbody. Eutrophication modeling can integrate these factors to relate nutrient load to eutrophication-related water quality response. Basically two types of eutrophication models exist:

- An empirical, statistical model, such as the Vollenweider–OECD eutrophication model discussed subsequently herein, developed from a large database quantifying how nutrient concentrations or loads relate to the nutrient-related water quality characteristics of the waterbody.
- Deterministic models, in which differential equations can describe the primary rate processes that relate nutrient concentrations/loads to algal biomass.

Deterministic models have several drawbacks for use in eutrophication management. Because of the number of equations incorporated into a deterministic model, no unique solution exists to the model. "Tuning" the model to match the nutrient loads and eutrophication condition in the waterbody of interest at the outset may not properly represent the conditions and response after nutrient load alteration. Thus, its ability to reliably meet the goal of management evaluation, i.e., predicting the benefit to be gained by management options, is limited.

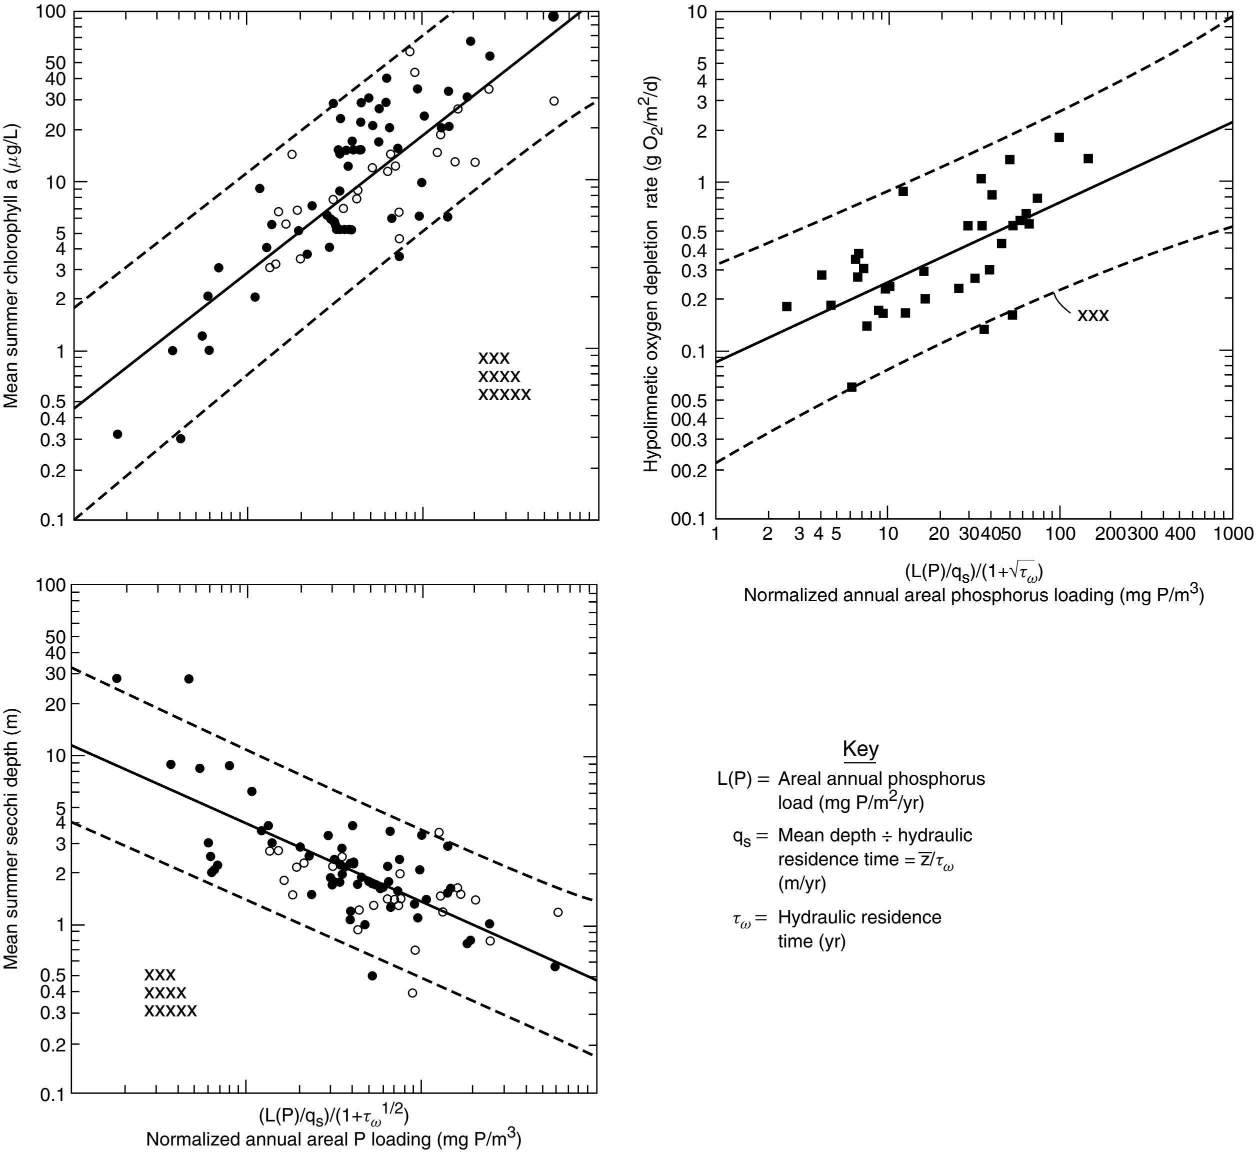

Figure 3. Relationships between normalized P load and eutrophication-related water quality response—U.S. OECD Eutrophication Study Results [after Rast and Lee (17)].

If the water quality problem is related to planktonic algae, the Vollenweider–OECD eutrophication modeling approach is the recommended approach for determining the reduction in nutrient loads/concentrations necessary to achieve the desired nutrient-related water quality in many lakes and reservoirs. Described by Rast and Lee (17) and amplified by Jones and Lee (18,19), this model empirically relates normalized phosphorus loading to eutrophication-related water quality parameters of chlorophyll, water clarity, and hypolimnetic oxygen depletion rate through relationships formulated by Vollenweider (20). These relationships take into account the influence of the key factors of the waterbody's mean depth, hydraulic residence time, and surface area on the utilization of phosphorus by algae within a waterbody. These models, based on the OECD (21) and post-OECD Eutrophication Study data, are shown in Fig. 3. Each point in each figure represents a lake, reservoir, or estuary for which the nutrient load and eutrophication response had been measured for at least a year to generate the model point. Jones and Lee (19) updated this model with data for more than 750 waterbodies in various parts of the world (Fig. 4). The use of this modeling approach and its reliability for predicting the changes in response parameters after a change in nutrient loading has been described by Rast et al. (22).

Rate of Recovery

One of the issues of particular concern in eutrophication management is the rate of recovery of a waterbody after reduction in the nutrient/phosphorus loads. Because large amounts of phosphorus are stored in lake sediments, some have incorrectly concluded that reducing the phosphorus load from the watershed would result in little improvement in water quality, especially in a waterbody with a long hydraulic residence time. However, Sonzogni et al. (23)

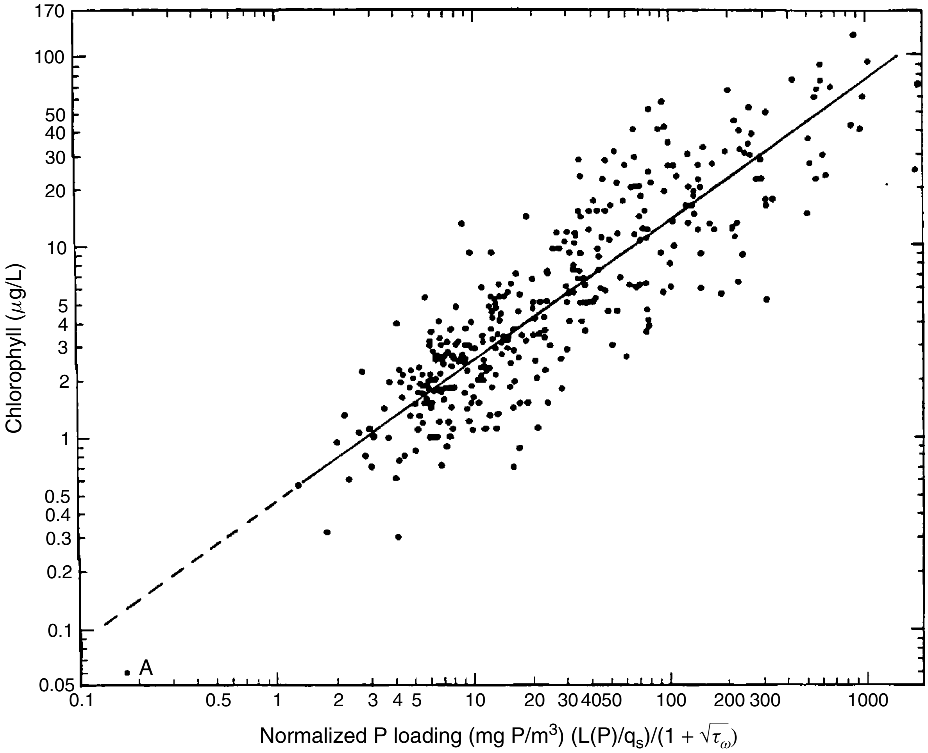

Figure 4. Updated relationship between normalized P load and planktonic algal chlorophyll response [after Jones and Lee (18)].

demonstrated that the rate of response in eutrophication-related water quality to reduction in phosphorus loading is governed by the phosphorus residence time in the waterbody. The P residence time in years is the total mass of phosphorus in the waterbody water column divided by the annual load, which is typically much shorter than the hydraulic residence time.

CONCLUSIONS AND RECOMMENDATIONS

Excessive fertilization, eutrophication, is a major cause of water quality impairment. Domestic wastewaters, urban stormwater runoff, and agricultural runoff/discharges are significant sources of nutrients that contribute to excessive fertilization of some waterbodies. Site-specific investigations are needed to determine the contribution of algal-available nutrients from these sources and the extent to which they can be controlled. Using the Vollenweider–OECD eutrophication modeling approach, the expected improvement in beneficial uses that could be achieved in many lakes or reservoirs by affecting a given load reduction and the expected recovery time can be estimated.

CULTURAL EUTROPHICATION

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

The phrase "cultural eutrophication" (= cultural enrichment) is becoming widely used to denote organic pollution resulting from human activities. Humans, through their various cultural activities, have greatly accelerated this process in thousands of lakes around the globe. Cultural or anthropogenic "eutrophication" is water pollution caused by excessive plant nutrients. Increased productivity in an aquatic system sometimes can be beneficial. Fish and other desirable species may grow faster, providing a welcome food source (1). Eutrophication produces "blooms" of algae or thick growths of aquatic plants stimulated by elevated phosphorus or nitrogen levels. There has been some uncertainty as to whether algal blooms result from increased concentrations of nitrate or phosphate or from some other cause. It is now commonly accepted that algal growth in fresh waters is generally restricted by phosphate concentrations, whereas in marine waters, it is restricted by nitrate concentration (2). In freshwaters, the nitrate concentration might, however, influence the kinds of algae that grow, some of which taint in drinking water or are toxic to animals.

Bacterial populations increase due to larger amounts of organic matter. The water becomes cloudy or turbid and has unpleasant tastes and odors. Cultural eutrophication can accelerate the "aging" of a waterbody enormously over natural rates. Lakes and reservoirs that normally might exist for hundreds or thousands of years can be filled in a matter of decades.

Cultural eutrophication also occurs in marine ecosystems, especially in near-shore waters and partially enclosed bays or estuaries. Partially enclosed seas, such as the Black, Baltic, and Mediterranean Seas, tend to be in especially critical condition (1). During the tourist season, the coastal population of the Mediterranean, for example, swells to 200 million people. Of the effluents from large cities, 85% go untreated into the sea.

SOURCES OF NUTRIENTS

Humans add excessive amounts of plant nutrients (primarily phosphorus, nitrogen, and carbon) to streams and lakes in various ways. Runoff from agricultural fields, field lots, urban lawns, and golf courses is one source of these nutrients. Untreated or partially treated domestic sewage is another major source. Sewage is a particular source of phosphorus to lakes when detergents contain large amounts of phosphates. The phosphates act as water softeners to improve cleaning action, but they also are powerful stimulants to algal growth when they are washed or flushed into lakes.

Agricultural Runoff

The enrichment material in agricultural runoff is derived from fertilizers applied to crops and from farm animal houses. Nitrogen used as fertilizer may be converted to nitric acid in soil and solubilize calcium, potassium and other ions, which become highly liable to leaching.

Domestic Sewage

Sewage is the most common source of nutrients and organic matter and undoubtedly, the greatest contributor to the eutrophication of lakes and ponds. Large quantities of nitrogen and phosphorus excreted by humans and animals enter into sewage. Phosphatic detergents in sewage (without tertiary treatment) may contain 15 to 35 mg/L of total nitrogen and from 6–12 mg/L of phosphorus (3). Untreated sewage, besides nutrients, also adds large quantities of nitrogenous organic matter.

Industrial Wastes

The nutrients in industrial effluents are variable in quality and quantity, depending on the process and type of industry. The wastes from certain industries, particularly fertilizers, chemicals, and food, are rich in nitrogen and phosphorus. Organically held phosphorus is more soluble, and there is concern that it will leach into surface waters, giving concentrations of 1 mg pL or more, when large amounts of cattle and pig slurries are applied to sandy soil, as in the Netherlands (2).

Urban Runoff

Urban runoff contains storm water drainage with organic and inorganic debris from various paved and grassed surfaces and fertilizers from gardens and lawns.

EFFECTS OF CULTURAL EUTROPHICATION

1. The excessive growth, or "blooms," of algae promoted by phosphates changed the water quality in Lake Erie and many other lakes. These algal blooms led to oxygen depletion and resultant fish kills. Many native fish species disappeared and were replaced by species more resistant to the new conditions. Beaches and shorelines were fouled by masses of rotting, stinking algae.
2. Decomposition of algal bloom leads to oxygen depletion in water. This with a high CO_2 level and poor oxygen supply, aquatic organisms begin to die, and the clean water turns into a stinking drain.
3. Algae and diatoms attain a high degree of dominance due to overfertilization. Algae and rooted weeds interfere with hydroelectric power, clog filters, retard water flow, and affect water quality and water works.
4. Macrophytes, particularly *Hydrilla*, *Potamogeton*, *Ceratophyllum*, and *Myriophyllum*, assume high population densities and make near-shore and shallow regions unsuitable for any purpose.
5. Filamentous green algae, such as *Spirogyra*, *Cladophora*, and *Zygnema*, form a dense floating mat or "blanket" on the surface when the density of the bloom becomes sufficient to reduce the intensity of solar light below the surface. These blankets often give shelter to several undesirable insects, including mosquitoes.
6. Eutrophication of a moderate level may be beneficial to fish production as it increases the food supply for fish in the form of algae. Fish ponds are often fertilized with nutrients to accelerate algal growth and increase fish productivity. But because the level of eutrophication increases due to human activities, the dominance of algal groups is taken over by blue-greens and the edible or game fish are replaced by hardy species of very little economic value.

FISH CELLS IN THE TOXICOLOGICAL EVALUATION OF ENVIRONMENTAL CONTAMINANTS

LEONARD I. SWEET
Environmental Energy Group,
Engineering Labs Inc.
Canton, Michigan

INTRODUCTION

Aquatic life at risk to modulation by environmental contaminants include fish and their organs, tissues, cells, and subcellular processes. Through branchial, dermal, and oral absorption, as well as biomagnification, it is highly probable that fish are exposed to many chemical species, their metabolites, and their mixtures (e.g., aromatic hydrocarbons, carbamates, heterocyclic compounds, heavy metals, organophosphates, and halogenated compounds). Sources of toxicant exposure include primary anthropogenic emissions, municipal and hazardous waste landfills, incinerators, episodic and diffuse loadings, as well as global secondary sources that involve complex cycling across air–water (e.g., deposition, rain, snow), sediment–water, and biotic interfaces (e.g., vegetation, fish, birds).

Environmental contaminants of concern require research into their accumulation potential, toxicological potency, and heath effects, because they can adversely affect aspects of fish life histories through direct effects (e.g., on developing eggs and larvae) or by more indirect means (e.g., immunosuppression, and enhanced skin and liver disease). Chemical contaminant exposure can interfere with critical phases of the cellular response by destroying, sensitizing, or otherwise altering the functions of cells.

Fish models are increasingly recognized as useful for basic research, biomedical (e.g., carcinogenicity, pathology) and biotechnological applications (e.g., functional and comparative genomics, DNA isolation), and toxicity/environmental safety testing (e.g., lethality, endocrine and androgen modulation, developmental and immunotoxicity). Within these disciplines, fish cells are recognized as an important model because fish are among the oldest and most diverse vertebrates known, are an ecologically critical and pervasive species, are abundant and widely distributed, play a major role in the energetics of trophic levels, have feasible and practical considerations as test organisms (e.g., small size, economical maintenance and use, fecundity, smaller volume of test chemical use and disposal), and often as top predators are at additional risk of bioaccumulating chemical contaminants.

Fish species that are increasingly being used in toxicity testing include the following: rainbow trout, lake trout, fathead minnow, bluegill, zebrafish, guppy, carp, barbels, mummichog, yellow perch, and medaka. Trends in microbiotesting and high volume/throughput testing will lead to further developments in cost-effective microscale aquatic toxicity testing that use fish cells. Fish cells are also becoming recognized as more relevant toxicologically; recent evidence suggests that bloodborne environmental contaminants may be more bioavailable for transport inside the cell, versus transport to circulating binding proteins, than previously suspected. Surrogate tissues such as blood may also serve as an indication of target tissue exposure and cellular stress. The use of fish cells also enables investigations that seek to characterize the mechanisms of toxic effects.

Trends in Toxicity Testing

Prominent trends in toxicity testing include more *in vitro* tests and especially *in vitro* mechanistic assays, aimed at appreciating the importance of the molecular and cellular bases for the effects of chemical toxicants. For example, the assessment and role of cellular apoptosis in immunotoxicological methods is gaining recognition. Characterizing xenobiotic-induced or inhibited apoptosis provides the opportunity to detect subtle and reversible changes in the normal activity of cells and aids in explaining fish stress and time from exposure to toxicity. Other popular end points include heat shock proteins, signal transduction, endocrine modulation, oxidative stress, enzyme induction, influence of inflammatory mediators and endotoxin exposure, and cholinesterase activity. Further, cells harvested from hepatocytes and gills remain prominent choices for toxicity testing. These toxicological end points at biological and biochemical cellular levels attempt to evaluate the functional competence of specific organ systems and individuals.

In vitro response tests are often selected for the following reasons: primary cell exposures provide the necessary dose–response and mechanistic toxicity data; *in vitro* tests require minimal sacrifice of whole fish and minimal use of chemicals; tests are subject to less ethical scrutiny when using cells versus whole animals; and *in vivo* exposure response tests are often impractical because the fish are collected some distance from the laboratory and are only available infrequently and seasonally. The measured end points for assays with fish cells lines often include detection by flow cytometry and fluorescence microscopy. With regard to fish systems, *in vitro* immune cell toxicity studies have focused on the reduction of viability (e.g., assays such as trypan blue, neutral red differential uptake) or reactivity (e.g., phagocytic indexes).

Biomarkers are increasingly employed to evaluate chemically induced alterations in fish at the molecular, biochemical, cellular, or organismal level. These techniques that detect cellular departures from homeostasis may be applied in experimental effect studies or field monitoring and may be destructive or nondestructive to the fish test organisms. However, many of the classical biomarkers of exposure such as enzyme induction and tissue residue fail to identify toxicological hazards and clinical implications adequately that can impact exposed individuals and populations.

In all cases, good laboratory practice and appropriate methods for analgesia, anesthesia, and euthanasia must be employed. Standard operating procedures for tissue harvesting and cell isolation must be designed to minimize handling time prior to preservation or assay testing.

Importance and Policy Relevance

Fish, such as the lake trout in the Great Lakes, can be designated sentinel species of ecosystem health and are useful indicators for assessing chemical contaminant stress. Fish cells in toxicology research can delineate the magnitude of adverse effects of environmental contaminants and one can also extend the relevance of the data to understanding *in situ*, *in vivo*, and ecosystem end points.

With regard to assessing aquatic ecosystem health, toxicological end points at the cellular level can attempt to evaluate the structural integrity and functional competency of specific organ systems and individuals and attempt to address both quantitatively (e.g., internal and biologically effective dose) and qualitatively (e.g., early biological effect, altered structure/function) the more subtle toxic effects of low level contaminant exposure. The fish cell toxicity end point is important because it is rarely possible to predict the effects of urban, industrial, and agricultural pollutants on aquatic biota based solely on the composition and concentrations of contaminants. Thus, employing fish cells in the toxicological evaluation of environmental contaminants is important because it provides a potentially valuable risk assessment component, as well as tools for policy-makers and environmental, epidemiological, and fishery scientists.

Although the fish cells are important models of investigation independently, there is comparative evidence that fish cells and those of higher vertebrates are functionally similar. Further, ambient exposure routes for fish may approximate chronic inhalation tests in mammalian and vertebrate models. However, there are important differences between fish and human cells (e.g., the greater membrane rigidity, volume, surface area, and presence of a large nucleus in fish red blood cells).

In addition, there are potential challenges and obstacles in the interpretation and extrapolation of *in vitro* studies of fish, including (1) relevance of *in vitro* dose levels employed in the laboratory compared to *in vivo* environmental exposures; (2) ability to rule out concurrent exposure to other chemical, biological, or physical stressors; and (3) ascertaining clinical/environmental significance based on statistical significance.

Nonetheless, *in vitro* investigations of this type have advantages over *in vivo* and field studies for the following reasons: control over environmental exposure conditions, potentially reduced variability between experiments, the ability to evaluate thousands of individual cells readily, and the requirement of a small quantity of test chemicals to complete the exposure–response studies.

From an institutional viewpoint, some environmental policies state that contaminant-induced cellular changes are to be considered in decision making because they may directly influence ecologically important parameters, as well as human welfare. The science as applied to fish cells may not be sufficiently developed to allow rigorous hazard assessments, but there remains growing scientific and policy understanding of the subtle yet adverse effects of persistent contaminants on fish physiology.

Bioavailability and Mode/Mechanism of Action

In the aquatic environment, it is important to distinguish between the forms of toxicant exposure especially with regard to bioactivity, biodistribution, and potential toxicity. Speciation and bioavailability are strongly dependent on environmental factors (e.g., pH, redox state, dissolved oxygen, humic content, selenide and sulfide levels, mineral content, mercury content), physicochemical factors (e.g., solubility, partitioning, metal–ligand complexing, ionization), and biological factors (e.g., presence of methylating or demethylating microbes). In teleost species, some of the bioavailability is determined by the pH and chloride concentration of the stomach; at low pH and high chloride concentration, stomach conditions favor the formation of species more readily transported into the blood stream. There are also a number of intrinsic and extrinsic factors that may interact with toxic end-point parameters under investigation (e.g., reproductive status, age, stress, nutrition, toxicant mixtures, previous exposure, predation, food chain effects, habitat, density, environmental stochasticity, concurrent infections, stress, species, and genotype).

Knowledge of chemiometabolic enzyme and receptor systems in fish may prove useful in improving the interpretation of toxicological studies. Fish can clear select chemical toxicants via metabolic routes to a minor degree (e.g., feces, extraction from gill membranes, urine, bile, eggs, and mucus). It should be noted that in fish, as in mammals, the most important enzymes of chemical biotransformation include cyt-P450, UDP-, glucuron-, glutathione-, and sulfotransferases; and they are found most appreciably in the liver, although activity is found in the gills, intestines, and kidney. Interestingly, research evidence supports the presence of the aryl-hydrocarbon (Ah) receptor in teleost fish.

Characterizing the mechanisms of action of chemical toxicants is important for physiological, toxicological, and therapeutic reasons. For instance, once incorporated into biological tissues, the physiological and toxicological effects of metals are regulated by binding to specific ligands and excretion, involving competition for transport and cellular sites and inhibition of enzyme systems. Chemically induced toxicity may involve cell volume changes, alterations in cell permeability, and phospholipid structure. These chemically induced changes may lead to suppressed cell competence, induced or inhibited normal cell proliferation, altered hematology, altered ion balance and metabolism, and enhanced susceptibility to disease states. Certainly mechanistic investigations in ecotoxicology and etiopathogenesis have gained increasing importance especially with regard to prophylactic measures.

Uncertainty Analysis

By definition, uncertainties are inherent in ecological risk assessments and must be addressed in toxicological evaluations using fish cells. The sources of uncertainty include measurement or estimation of variables, natural variability/environmental stochastic over time and space (e.g., rainfall, wind velocity, temperature), and use of models that do not accurately reflect the environment or exposed populations of concern.

During toxicity testing, there is potential for notable individual variations in sensitivity and response. Certainly, it should be noted that overall *in vitro* toxic effects on fish do not necessarily also lead to *in vivo* toxicity. Many *in vitro* systems lack cell-to-cell contacts that may make them behave differently, as well as the influence of regulation by other physiological systems (e.g., nervous or immune). *In vitro* toxicology and mechanistic models are only as good as the level of *in vivo* understanding, and both must be considered in characterizing a chemical hazard. Further, subtle perturbations in cell function following *in vitro* exposure may not in every instance result in a relevant clinical effect, especially given the functional reserve, complexity, and adaptive responses. Other considerations for explaining differences in sensitivity can be attributed to genetics (e.g., expression of metallothionein), metabolism (although Phase I and II metabolism is similar to that of mammals), DNA repair, as well as the varying complexity of teleost fish tissue (e.g., for the immune system, the absence of lymph nodes, tonsils, bone marrow, and the presence of the pronephros).

Other sources of uncertainty are inherent and include experimental design and conduct, variability in chemical composition and purity, variability between sexes, variability across experiments, experimental uncertainty, animal to human extrapolation, higher dose to lower dose extrapolation, difference between commercial and environmental chemical species, persistence and exposure duration, and human variability in exposure and sensitivity. Finally, there is a fundamental assumption in toxicity testing that may lead to uncertainty—that lab tests of single individuals and relatively constant exposures are predictive of field-based intermittent exposures.

SUMMARY

In the end, the significance of studying fish cells in environmental toxicology and hazard assessment research is twofold: *first*, it provides comparative results of a battery of potential *in vitro* assays as an alternative system to *in vivo* toxicity tests and for screening and evaluating chemicals of concern; and *second*, it provides methods for diagnosing and predicting modulation and toxicity from low level exposure to environmental chemical agents that will aid in defining the mechanisms responsible for the observed effects. More investigations into the cellular responses of fish when given equally relevant and equitoxic doses are an important avenue for further study. A battery of available toxicity test methods on fish and fish cells will remain a backbone of environmental safety testing and chemical/biological risk analyses, especially given economic, logistical, and ethical concerns.

FISH CONSUMPTION ADVISORIES

Gary A. Buchanan
Alan Stern
Gloria Post
Division of Science, Research, and Technology
Trenton, New Jersey

INTRODUCTION

Fish consumption advisories can be defined as government health advice issued to the public concerning deleterious substances in fish and/or shellfish (e.g., crabs). These advisories typically provide advice on avoiding or limiting the consumption of certain types or sizes of fish, or on the number of fish meals to consume over a period of time in order to limit health risks. Fish consumption advisories were first issued in the United States in the mid-1970s (1).

HISTORY

Occasional contamination of shellfish and, to a lesser extent, finfish with pathogens and parasites has long been recognized as a potential public health hazard. Prior to fish consumption advisories addressing risks from environmental chemical contaminants, biological (e.g., bacterial) contamination resulted in the closure of shellfish beds and the removal of contaminated harvests from commerce. Such actions tend to be legally enforceable and function through the exercise of public health law. As such, they are not technically advisories, which, by their nature, are provided as guidance and rely on voluntary adherence. Nonetheless, experience with such actions paved the way for governments to consider fish consumption advisories as part of their larger public health responsibility. The recognition of environmental mercury poisoning through fish consumption in the Minimata Bay area of Japan in the 1950s raised the public consciousness about the potential for anthropogenic chemical contamination of dietary fish. However, at that time, and for several decades afterwards, concerns about mercury in fish focused on frank poisoning resulting from highly elevated levels. In addition, the impact of the Minimata contamination on an entire community consuming a common source of fish tended to focus attention on commercial fish. The indirect sources of mercury contamination of otherwise pristine waterbodies and its impact on recreational and subsistence anglers was not fully recognized until the early 1990s. Thus, mercury contamination in fish was treated similarly to biological contamination, and was addressed through regulatory control of permissible mercury levels in commercial fish. By the mid-1990s, recognition that mercury in fish posed health risks more subtle than frank poisoning led to the adoption of consumption advice to recreational and subsistence anglers based on maintaining exposure below a “virtual” safe level and, at the same time, advising fish consumption up to the maximum safe exposure level. The intent of this approach is to maximize the nutritional benefits to be derived from safe levels of fish consumption while avoiding the health risks associated with contaminant exposure. More recently, this approach has been applied to commercial fish, with the federal government (i.e., U.S. Food and Drug Administration, FDA) and various state governments issuing consumption advise for fish whose contaminant levels are nonetheless within regulatory limits for sale.

In general, the first major fish consumption advisories were issued for PCBs (polychlorinated biphenyls). In 1973, the FDA established a tolerance (i.e., a regulatory limit) of 5 parts-per-million (ppm) PCBs for fish in interstate commerce. The FDA subsequently lowered this tolerance to 2 ppm in 1984. Initially, many states used FDA action levels or tolerances in setting fish consumption advisories. However, unlike mercury, PCBs were recognized as carcinogens. Historically, noncarcinogens are considered to have a threshold level of exposure, below which no adverse effects are anticipated, whereas carcinogens have been considered to pose some risk at any level of exposure. Thus, rather than the all-or-nothing regulatory approach initially adopted for mercury, the presumption of some risk at all levels of consumption raised the need for advice that attempted to balance low risk against continued consumption. The FDA’s tolerance limit was not established with such a goal in mind, and thus, starting in the late 1980s and early 1990s, some states began issuing consumption advise to recreational and subsistence anglers that was designed to keep lifetime cancer risk from consuming PCBs in fish within an “acceptable” range. Based on historical concepts of “acceptable” cancer risk, this range generally extended from a risk of one-in-a-million (1×10^{-6}) to one-in-ten-thousand (1×10^{-4}) of developing a PCB-attributable cancer over the course of a 70-year lifetime. This approach was subsequently applied to known or suspected carcinogenic pesticides (e.g., chlordane).

SCOPE

Advisories are issued by local, tribal, state, and national (e.g., U.S. EPA) agencies. Typically, most advisories are issued by the state health department or environmental/natural resource agency. Based on data compiled by the U.S. EPA (2), 48 states had issued a total of 3,089 advisories in 2003, including species-specific, water body-specific, and statewide advisories. These advisories covered 35% of the nation’s total lake acres and 24% of the nation’s total river miles, and included coastal waters. Together, mercury and PCBs account for the great majority of advisories, with chlordane, dioxin, and DDT accounting for nearly all of the remaining advisories (2). A listing of all state advisories can be found on the U.S. EPA website (http://www.epa.gov/ost/fish/). In 2004, the U.S. FDA together with the U.S.EPA (3) issued a national mercury advisory for commercial and recreationally caught fish. This advisory included a "do not eat" advisory for shark, swordfish, king mackerel, or tilefish for the sensitive population (women of childbearing age, pregnant and breastfeeding women, and children). It also advised this sensitive population to check local fish advisories, or if no advice is available, to limit intake to one (6 ounce) meal per week of locally caught fish. Australia and New Zealand have offered similar advice for higher trophic level commercial species (e.g., marlin, shark, swordfish). The European Food Safety Authority (4) has also issued a mercury advisory to this sensitive subpopulation in the European Union concerning consumption of fish. Member countries in the European Union, other countries, and regional governments also issue fish advisories (e.g., British Food Standards, Health Canada, Ontario Ministry of the Environment) (5).

THEORY

Fish consumption advisories seek voluntary reduction of risk through modification of fish consumption behavior. Regulatory restrictions are generally applied when fish enter into commerce or when the risk posed by consumption is clear and immediate. In contrast, advisories tend to be predicated on the notion that government has, at most, limited authority to regulate individual behaviors like fish consumption. At the same time, government operates under a mandate to protect the public health, which is generally seen as a responsibility to advise, inform, and educate. Nonetheless, occasions exist where health risks are imminent or sufficiently elevated as to justify regulations closing specific waterbodies to fishing for some or all species. Often no clear *a priori* dividing line exists between conditions requiring advisory and regulatory actions, and decisions are often made on a case-by-case basis. Advisories are most appropriate when the risk is low to moderate, and are potentially balanced by associated benefits such as nutrition and the continuation of cultural practices. The most basic type of advisory is dichotomous—eat/don't eat. This approach is simple to communicate, but offers little opportunity to consider benefits as well as risks. More sophisticated advisories provide consumption frequency advice (e.g., no restriction, eat once per week, eat once per month... don't eat). Which frequency of consumption is recommended depends on the concentration of the contaminant in the particular species of fish such that eating a typical size serving with the specified frequency will not result in exceeding the maximum acceptable risk level. Thus, a fish for which an eat-once-per week advisory is issued would generally have about 25% of the concentration of the same contaminant as a fish for which an eat-once-per month advisory is issued. Consumption frequency approaches allow consumers to eat the maximum amount of fish that is consistent with remaining within a safe level of exposure or an "acceptable" level of risk. As the contaminant level in any given fish is not known, advisories are derived by extrapolating contaminant data from a limited sample of a given species of fish from a specific water body. Sometimes regional or statewide advisories are constructed by generalizing sample data from a group of representative waterbodies. Various statistical approaches are used for this extrapolation, including averaging concentration and selecting a concentration representing a given percentile of the distribution of sampled fish.

Advisories are generally constructed using common, default assumptions for factors such as body weight and portion size. For contaminants to which one subgroup in the population is more sensitive than the general population (such as methylmercury, which effects fetal neurological development at levels below those causing neurotoxicity in adults), advisories may provide separate advice to the sensitive group and the general population, which includes using different default body weights appropriate to each group

METHODS

Sampling

Fish tissue contaminant data are needed in order to develop fish advisories. Sampling methods vary by region and target species. Collection methods include traps, gill nets, trawls, electrofishing, hook and line fishing, as well as purchase from recreational or commercial fishermen. Fillet samples are typically analyzed, as these are often the target tissue for consumption, but some cultures do cook whole fish. Specialized tissues can also be targeted for certain species (e.g., hepatopancreas or "green gland" for crabs and lobster) in addition to the muscle. Individual fish samples or composite samples (i.e., multiple fish per sample) can be collected depending on needs and budget. Information on monitoring strategy, field procedures, target species, and target analytes are detailed by the U.S. EPA (6).

Analysis

A variety of methods are used to measure contaminants in fish species. Analytical methods and instrumentation have improved dramatically over the past few decades, allowing lower detection limits and compound discrimination (e.g., PCB congeners). For mercury, the cold vapor atomic absorption spectrophotometry is typically used (7). For organic contaminants (e.g., PCBs, pesticides, dioxins/furans, and polycyclic aromatic hydrocarbons), the methods vary, but gas chromatography/electron capture detection (GC/ECD) or GC/mass spectrometry (GC/MS) techniques are normally used (7). Additional information on sample handling, analytical methods, quality assurance, quality control, and data analysis are available (e.g., 6).

Risk Assessment

Risk-based advisories may be based on carcinogenic effects or noncarcinogenic effects. A toxicity factor (slope factor or reference dose, as described below) is based on toxicity data, usually from experimental animals and, less often, from humans. Advisories based on carcinogenic effects generally assume that no threshold exists below which there is no risk, so that any exposure to the contaminant poses some risk of cancer. Therefore, a target lifetime risk level (typically 10^{-4} to 10^{-6}, or 1 in 10,000 to 1 in 1,000,000) is chosen based on policy rather than scientific considerations. A carcinogenic potency factor (also called a slope factor) that relates daily dose to risk is developed from the toxicity data and is used to determine the daily dose of the contaminant (7).

$$\text{Daily Dose (mg/kg body weight/day)} = \frac{\begin{array}{c}\text{Lifetime Risk}\\ \text{(unitless)}\end{array}}{\begin{array}{c}\text{Potency factor}\\ \text{(mg/kg/day)}^{-1}\end{array}} \quad (1)$$

Advisories based on noncarcinogenic effects use the assumption that a threshold exists below which adverse effects other than cancer, such as organ toxicity, developmental effects, or reproductive effects are unlikely. A reference dose (in units of mg/kg body weight/day), below which no adverse effects are expected in the overall population, is developed by applying appropriate uncertainty factors to the dose at which effects occur in animals or humans, which is the daily dose that generally forms the basis for risk-based consumption advisories for noncarcinogenic effects.

Consumption advisories for fish with a given contaminant concentration can be derived as follows:

$$\begin{array}{c}\text{Consumption}\\ \text{Rate (meals/day)}\end{array} = \frac{\begin{array}{c}\text{Daily Dose}\\ \text{(mg/kg/day, see above)} \times\\ \text{Body Weight (kg)}\end{array}}{\begin{array}{c}\text{Contaminant}\\ \text{Concentration (mg/kg)} \times\\ \text{Meal Size (kg/meal)}\end{array}} \quad (2)$$

Assumptions must be made for meal size (typically 8 ounces or 227 grams) and body weight (typically 70 kg for an adult male and 62 kg for a pregnant female). Equation 2 provides the consumption rate in meals/day. If the consumption rate is calculated to be sufficiently large (e.g., 1 meal/day or greater), the advisory can be given as “unlimited consumption.” If the resulting consumption rate is less than the frequency corresponding to “unlimited consumption,” the advisory can be expressed in a convenient unit, such as meals/week, meals/month, meals/3 months, or meals/year. If the consumption rate is less frequent than a reasonable minimum (e.g., less frequent than once per year), the advisory may be given as “Do not eat.” The equations given above are a generalized form of the approach given by the EPA (6), which provides separate equations for carcinogens and noncarcinogens.

Separate fish consumption advisories may be developed for a contaminant to protect the general population and sensitive subpopulations. For example, for methyl mercury and polychlorinated biphenyls (PCBs), neurologic development is the endpoint of concern in the developing fetus, nursing infant, and young child. For the general population, paraesthesia (tingling of the extremities) is the endpoint of concern for methyl mercury and cancer is the endpoint of concern for PCBs.

Fish consumption advisories that do not rely directly on the risk-based approach described above have also been issued. For example, a general advisory has been issued by some states (e.g., Pennsylvania), advising consumption no more than one meal per week of freshwater sport fish. This approach is based on the precautionary principal that can be stated as: in the absence of specific data and given the tendency for bioaccumulative contaminants to be present in freshwater fish, it is prudent to limit consumption.

Another possible approach, for chemicals for which background dietary exposure from sources other than fish results in considerable risk, is to base the advisory on permitting a fractional increase above the background level. For example, background exposure to dioxin, primarily from dietary sources including meat and dairy product, have been estimated to result in a lifetime cancer risk of 1 in 1000 or 10^{-3} (8). This risk level is far above the risks typically used as the basis for risk-based consumption advisories. In such a case, the risk-based advisory approach would limit the consumption of fish, which is a beneficial part of a healthy diet, without actually providing any substantial reduction in risk from dioxin and related compounds.

ADVISORY EXAMPLE

Local or state advisories are typically more specific in terms of fish size, water body, and/or population as compared with national advisories. For example, in New Jersey, mercury advisories for largemouth bass list an advisory of “one meal per month” in Newton Lake for the general population and “do not eat” in Cooper River Lake for children and women of childbearing age (Table 1). Whereas, dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) advisories in the Passaic River, NJ are “do not eat” for all fish species for all consumers (9).

COMMUNICATION

A very important aspect of fish consumption advisories is outreach to the public. Advisories result in public health protection only if their message is received, understood, and acted on. Outreach activities involve identifying populations at risk, developing an effective communication strategy, and implementation of that strategy using a variety of methods. For example, government agencies have used a variety of techniques, both traditional and unique, to get the advisory message to the public. Examples include publications (e.g., brochures), listing of advisories with fish regulations, posting on web pages, issuing press releases, public service announcements, videos, posting of warning signs at boat ramps and other public access points, direct outreach efforts using local community groups, and toll-free numbers. Risk communication guidance is available from government sources (e.g., 1).

Table 1. Example of Fish Consumption Advisory (8)

		Advisory/Prohibition		
		General Population[a,b] Range of Recommended Meal Frequency		High-Risk Individual[b,c]
		Lifetime Cancer Risk of 1 in 10,000	Lifetime Cancer Risk of 1 in 100,000	Recommended Meal Frequency
Location	Species	Do Not Eat More Than	Do Not Eat More Than	Do Not Eat More Than
Cooper River Lake (Camden Co.)	Largemouth Bass	Four meals per year	Do not eat	Do not eat
	Common Carp			
	Brown Bullhead	One meal per week	One meal per month	One meal per month
	Bluegill Sunfish			
Newton Lake (Camden Co.)	Bluegill Sunfish	One meal per week	One meal per month	One meal per month
	Brown Bullhead			
	Largemouth Bass	One meal per month	Four meals per year	Four meals per year
	Common Carp		One meal per year	Do not eat
Passaic River downstream of Dundee Dam and streams that feed into this section of the river.	All fish and shellfish*	Do not eat		Do not eat

[a] Range of Recommended Meal Frequency corresponds to a cancer risk of 1 in 10,000 to 1 in 100,000 over a lifetime.

[b] Eat only the fillet portions of the fish. Use proper trimming techniques to remove fat, and cooking methods that allow juices to drain from the fish (e.g., baking, broiling, frying, grilling, and steaming). One meal is defined as an eight-ounce serving.

[c] High-risk individuals include infants, children, pregnant women, nursing mothers, and women of childbearing age.

*Selling any of these species from designated waterbodies is prohibited in New Jersey (N.J.A.C. 7:25-18A.4).

FISHERIES: HISTORY, SCIENCE, AND MANAGEMENT

Robert T. Lackey
United States Environmental
Protection Agency
Corvallis, Oregon

The overall goal of fisheries management is to produce sustainable biological, social, and economic benefits from renewable aquatic resources. Fisheries are classified as *renewable* because the organisms of interest (fish, shellfish, reptiles, amphibians, and marine mammals) usually produce an annual biological surplus that, with judicious management, can be harvested without reducing future productivity. In contrast, *nonrenewable* resources (oil, coal, iron, and copper) are available in fixed quantities and are not replaced except over geologic time.

The benefits that humans gain from a fishery are diverse and may be enumerated in several ways. Most commonly, benefits are computed as *commodity* output—the weight or number of fish produced. Commodity output may be further split between the animals harvested by capture (fishing for wild animals) or culture (produced as captive animals)—commonly called the *capture* fisheries and the *culture* fisheries, respectively.

FISHERIES MANAGEMENT

The benefits are commonly measured as wholesale or retail economic *value* of the commodity output. Such benefits are easily calculated for *commercial* fisheries because the products are usually sold, but for sport or *recreational* fisheries, the quality of the fishing experience is very important, so measures of catch in weight, number, or value only partially measure the benefits provided to fishermen or to society. Measurements of the indirect economic value of recreational fishing that include the quality of the fishing *experience*, however, remain controversial. Even in commercial or subsistence fisheries, substantial benefits may be associated with *cultural* or *religious* aspects. Although such benefits are difficult to measure, they may be very important to the participants.

Beyond the direct benefits derived from harvested fish or the fishing experience, benefits are also derived by individuals and society from simply *knowing* that a particular natural resource exists (often called *existence* value). Society and individuals receive intangible benefits from preserving species and habitats, especially those in danger of extinction. Such benefits are often significant, but, like the benefits from recreational fishing, they are also exceedingly difficult to quantify in economic terms. The whale fishery is an example for which the value of leaving the animals unharvested currently is of greater benefit (primarily intangible) in most societies than the value (economic) of the harvested animals.

Whether or not measurable, fisheries management is increasingly being guided by ecological benefits mandated in treaties, laws, and government policies. For example, the *Convention on Biological Diversity* obligates signatory nations to preserve their biological diversity to the maximum possible extent. Many nations also have laws to protect species at risk of extinction, and these laws may be important constraints on the scope, type, and intensity of fishing that will be permitted.

In practice, the overarching management policy goal for managing a nation's fisheries is often stated in general terms such as:

> To ensure the attainment and continued satisfaction of human needs for present and future generations in an environmentally non-degrading, technically appropriate, economically viable, and socially acceptable manner, and such that land, water, plant, animal, and genetic resources are maintained.

The challenge for the fisheries manager is to translate such a general policy goal into a practical, effective program to maximize the benefits of specific fisheries to society.

FISH VERSUS FISHERIES

The words "fish" and "fisheries" have several meanings, and these terms often cause confusion. As traditionally used in fisheries management, *fish* typically includes the entire suite of *aquatic* organisms that are harvested (mackerel, tilapia, tuna, guppies, sea turtles, seals, whales, sea urchins, clams, squid, and frogs), or *could* be harvested if their numbers permitted. Thus, the term *fish* is not solely the *fin fish* (fish that have fins), so a fisheries manager may work with turtles, squid, or sponges, rather than fin fish. *Shellfish* (clams, crabs, lobsters) are also included under the broad definition of *fish*. In contrast to *fisheries* managers, *wildlife* managers generally deal with terrestrial mammals and birds (deer, wolves, bears, ducks, hawks, and whooping cranes).

A *fishery* is defined generically as a system composed of three interacting components: the aquatic biota, the aquatic habitat, and the human users of these renewable natural resources. Each of these components influences the fishery's performance. Understanding the entire system and its parts is often essential to successful management of a fishery.

There are many different types of fisheries and they may be classified in several ways:

- **Type of environment** (freshwater habitats—lakes, reservoirs, rivers, streams, and ponds; saltwater habitats—estuarine, coastal, and open ocean).
- **Method of harvest** (seining, trolling, trawling, fly casting, spearing, and dip netting).
- **Type of access permitted** (open access to fishing, open access with regulation, limited or purchased access, private property).
- **Organism of concern** (salmon, shrimp, bass, turtles, squid, cod, sharks, sea horses, whales, and swordfish).
- **Purpose of fishing** (commercial fishing for a product to sell, subsistence fishing for direct food consumption, or recreational fishing for sport and leisure).
- **Degree of wildness** of the target animals (totally wild and free-roaming animals, totally captive animals grown in ponds, or animals spawned in captivity, but released in the wild to be captured when they mature).

HISTORY OF THE HUMAN/FISH RELATIONSHIP

Fish have occupied an important place in human society for thousands of years. Early humans obtained fin fish, shellfish, and other aquatic life along the shores of lakes, rivers, and oceans. Archeological records document the use of fish spears 90,000 B.P. (90,000 years before present), nets 40,000 B.P. and fish hooks 35,000 B.P. The earliest documented human communities dependent on fishing were in the vicinity of Lake Mungo (Australia) 30,000 B.P. and Crete 8,000 B.P. The Egyptian aristocracy fished as a leisure activity at least 4,000 B.P. Fish have been raised in captivity for several thousand years.

As better preservation techniques developed (drying, smoking, and salting) and transportation improved, *commercial* fishing in the Middle Ages began shifting from local, small-scale activities to commercial, large-scale enterprises. Boat design and construction advanced, along with corresponding improvements in fishing gear and preservation techniques, especially the advent of canning. Canning represented a particularly important advancement because it permitted long-term storage and large-scale distribution of fishery products.

Cod fishing off eastern North America began in earnest in the early 1500s. By the 1600s, whaling was a prominent activity in many high seas locations. In the late 1800s, steam-powered ships, along with mechanized fishing techniques and refrigeration, enabled development of the large-scale industrial fisheries that still exist today. During the past 100 years, the global level of fishing has expanded continuously, a trend disrupted only briefly during the two world wars. After World War II, the intensity of commercial fishing especially increased.

Today, commercial fishing continues as a major economic sector in many countries. In addition to the large worldwide value of the catch, approximately 36 million people (15 million full-time, 13 million part-time, and 8 million occasional) are employed in the capture and culture fisheries.

Although documented for thousands of years, *recreational* fishing only relatively recently has become an activity enjoyed by large numbers of people. The sport surfaced during the Renaissance as a socially acceptable leisure activity and received broad visibility from the 1653 publication of *The Compleat Angler* by Izaak Walton. By the mid-1800s, recreational fishing was an important and common activity, particularly in North America and Europe. The scale of recreational fishing expanded greatly after World War II, especially in North America.

Millions of people fish recreationally, and they support a multibillion-dollar sport fishing industry worldwide (fishing gear and equipment, bait, boats, motors, outdoor clothing, lodging, and food). Recreational angling ranges in extremes from the serenity of fly-fishing in a remote alpine stream, to the noise and excitement of a bass fishing tournament held in a large reservoir, to the excitement of a child catching its first fish from the bank of a pond.

Beyond the widespread pursuit of wild fish for commercial or recreational purposes, many aquatic species are now successfully raised in aquaculture facilities. Raising fish in captivity (especially various carp species) for food has been practiced in China for at least 4,000 years. The Chinese also developed effective means to breed and raise fish for ornamental purposes, an early precursor to today's vast aquarium market. By the mid-1900s, carp, tilapia, catfish, trout, salmon, and shrimp were widely raised for the *food* market; several of these and other species such as pike, sunfish, bass, and walleye were raised for *stocking* to enhance recreational fishing opportunities.

CURRENT USES OF FISHERIES RESOURCES

More than 4,000 species of aquatic animals are harvested worldwide, totaling approximately 120 million metric tons annually. The total harvest includes *capture* fisheries (fish caught by nets, trawls, hooks) and *culture* fisheries (fish grown in ponds, cages, hatcheries), generally called *aquaculture*. The harvest tonnage from *capture* fisheries quadrupled between 1950 and 1990, but has leveled off or even declined since 1990. Harvest from *aquaculture* continues to increase. Fisheries harvest data are often of questionable accuracy, but the most recently available data on the combined capture and culture harvest suggest that China is the world's leading fish producer (32.5%), followed by Japan (5.1%), India (4.5%), United States (4.4%), and Russia (3.9%).

Aquacultural production continues to increase in importance worldwide and now accounts for approximately one-fifth of the total fish produced. Atlantic salmon, cultured in cages and pens, are raised in Norway, Scotland, Chile, Canada, United States, and elsewhere and provide fresh fish to the retail market year-round. Catfish, grown in ponds in the southern United States, and trout, grown in hatcheries in the northern United States, provide high quality, reliable, year-round products to the national retail market. Carp and tilapia are produced in large numbers, especially in Asia and Africa, and provide the primary source of animal protein for humans in those areas.

Worldwide annual per capita consumption of fish and shellfish is approximately 34 pounds (15 kg), but this varies considerably among regions and individual countries. Per capita consumption of fish has nearly doubled since the 1960s. Europeans and Asians tend to have the highest per capita consumption. Annual per capita consumption in the United States is approximately 15 pounds (7 kg); tuna, shrimp, pollock, salmon, and catfish are the top five.

In North America, the economic vitality of some rural communities depends on catering to the needs of recreational fishermen (fishing equipment, outdoor clothing, boats, motors, trailers, food, and lodging). In 1996, the estimated 35 million American adults (age 16 and older) who fished recreationally spent more than US$37 billion for goods and services related to the sport. The indirect economic impact of this direct expenditure totaled more than US$108 billion.

The market for aquarium and ornamental fish is important worldwide and continues to increase. Fish to supply this market are obtained from both wild and captive stocks. The live fish department is one of the most popular and profitable in many pet stores. Accompanying the sale of live fish is a market for aquaria, aquarium supplies, and, of course, fish food and medicine. Approximately 10 million ornamental *saltwater* fish are imported annually throughout the world. The number of *freshwater* fish imported is much higher and includes more than 5,000 species worldwide. The value of the U.S. retail ornamental fish market (live animals for aquaria and ornamental ponds only) is approximately US$3 billion.

CHARACTERISTICS OF AQUATIC ENVIRONMENTS

Lakes, streams, ponds, oceans, and estuaries are biologically productive, but their productivity has ecological constraints, and these constraints can be reduced by human actions. Many aquatic habitats have been altered by human actions (dredging, filling, damming, road building, pollution, and introduction of nonindigenous species), and their potential for producing sustained fish harvests has been reduced.

Variability is a pervasive characteristic of all ecosystems. Even in the total absence of human activity, aquatic ecosystems exhibit considerable fluctuations in the abundance of individual species. Fish species may vary in abundance several fold between years. In some years, there may be tremendous spawning success. In other years, the same species may have little or no reproduction. Variability in the aquatic environment makes it challenging to assess the likely biological consequences of fisheries management options such as adjusting harvest levels, changing gear regulations, or even placing a moratorium on fishing.

Climatic changes also alter the productive capacity of aquatic environments over the long term. Subtle shifts in ocean currents may cause some fish populations to collapse and others to thrive. Some changes in fish abundance caused by climatic or ocean shifts may happen over centuries and are not apparent without data sets of a century or more. Droughts, so apparent in their ecological effect on the terrestrial landscape, are also important to the aquatic environment, but their effects are usually much less visible. Major regional droughts, for example, are often correlated with increased upwelling of deeper, nutrient-rich ocean waters that stimulate increases in fish production. Even in the absence of all human activity, climate shifts cause the size of salmon runs to vary year-to-year and decade-to-decade.

EVOLUTION OF FISHERIES MANAGEMENT CONCEPTS

The history of fisheries management reflects the conventional wisdom of the day. During the past two centuries, the level of ecological understanding has greatly increased. Prior to the 1800s, most people presumed that biological resources from inland and marine waters were inexhaustible, given the level of harvest possible by the modest number of people who fished and the limited effectiveness of their fishing gear.

By the mid-1800s, the idea of unlimited natural riches from inland waters and the ocean was no longer credible. One popular approach to overcoming nature's constraints on sustainable harvest was to apply *animal husbandry* concepts, including the idea that "seeding nature" with fish produced in captivity would permit much greater levels of fishing. Conventional wisdom held that *aquaculture* could produce a nearly unlimited supply of fish of superior quality and according to a predictable schedule, just as farmers had long achieved for domestic livestock. In captivity, fish could be fed a high quality diet, protected from predation, and the quality of the product improved by selective breeding. If aquaculture performed as hoped, fisheries managers would no longer have to depend on the vagaries and limitations of nature for fisheries products.

For many species in many situations, aquaculture has worked well. Culture techniques greatly improved in the late 1800s. Selective breeding created animals better adapted to life in captivity. However, the expectation that aquaculture would be a solution to nature's limitations was not fully realized.

By the early 1900s, the limitations of aquaculture as a tool to supplement or replace wild fish were being recognized and *harvest regulation* was considered the more effective way to ensure sustained harvests. However, because the scientific underpinnings for many harvest regulations were poor and public pressure to continue heavy fishing was great, regulations were often modest, poorly enforced, and produced disappointing results in limiting harvests to sustainable levels.

As the recognition increased the need for regulations to control overfishing, an appreciation emerged that *habitat* was a limiting factor in fish yields, especially in inland and coastal waters. Thus, efforts to improve stream, lake, and estuarine habitats became more common throughout North America and continue today.

By the mid-1900s, *scientific* fisheries management was the dominant paradigm. The idea underlying this approach was that every fish population had the potential to produce a harvestable surplus and the largest surplus that could be harvested annually from that population (*maximum sustainable yield*) could be estimated by rigorous scientific analysis (stock assessment). The job of the fisheries manager was to control fishing pressure, using various regulations, at a level such that sustainable catch levels could be achieved in perpetuity. However, fishing pressure, as always, was very difficult to control; many fisheries ended up being overharvested, and yields eventually declined.

In the 1970s, the concept of *optimum sustainable yield* became popular, primarily in response to concerns that efforts to maximize the catch in recreational fisheries management overlooked, or at least undervalued, many important benefits that fishermen and society received. Less commonly, it was also used in managing commercial fisheries. Management goals using this approach tended to weigh more heavily the *quality* of the fishing *experience* or the *socioeconomic* aspects of fishing and to place less emphasis on the actual catch. Maximum benefits to society were usually achieved at catch levels *below* the maximum sustainable yield.

By the late 1900s, the trend in recreational fisheries management was toward *species* and *habitat* protection, especially in inland and coastal waters. The widespread recognition that some aquatic species were at risk of extinction led to public pressure to reverse such trends. The main causes of the decline of fish species was habitat alteration and introduction of nonnative fish species. Only rarely was overfishing the primary cause of precipitous declines in fish abundance. In fact, most endangered fish species have never been fished. "Endangered species" and "species at risk" legislation directed government agencies and fisheries managers to emphasize protecting species above catch. Under such legislation, fishing may be permitted only if it does not jeopardize legally protected species.

A recent trend in recreational and commercial fisheries management has been the emergence of the *stakeholder approach*. A stakeholder is any citizen or group potentially affected by, or having a vested interest in, an issue, program, action, or decision. The idea behind involving stakeholders in fisheries management is that society has a wide range of conflicting views on what fisheries management goals should be; therefore, it is desirable to include input from the full range of stakeholders in the process of defining goals and selecting management measures. Fisheries management plans developed with stakeholder involvement, it is assumed, therefore, have a higher likelihood of garnering widespread support.

Comanagement represents a further development of the stakeholder approach where some of the authority to manage the fishery is vested in the fishermen themselves or in organizations such as Indian or tribal governments. There are many current and proposed variants of comanagement, but they all transfer a degree of regulatory authority from government fisheries agencies to fishermen, associations, or other organizations. In some fisheries, a market is created for individual, transferable, fishing rights. In such situations, the right to fish may be purchased in an open market.

A widely accepted development in fisheries management has been the *precautionary principle*. The basic concept is that decision-makers (e.g., fisheries managers) ought to err on the side of caution in managing natural resources. Often the scientific basis for fisheries management decisions contains considerable uncertainty. Given the highly unpredictable future environmental and social conditions, it is wise for managers to use caution in managing fisheries.

LAKE FISHERIES MANAGEMENT

Lakes (including reservoirs formed by man-made dams) vary from large (Great Lakes, Caspian Sea) to small (farm ponds, minuscule alpine pools).

Maintaining at least reasonable good water and habitat quality is absolutely essential to nourishing healthy fish populations. Pollution control and abatement, although typically outside the direct purview of fisheries managers, are essential if management goals are to be achieved.

For large lakes, fisheries management involves primarily assessing, then selecting, fishing or harvest levels that are sustainable. Other management techniques include *intentional* introduction of nonnative species (e.g., Pacific salmon to the Great Lakes), or control of *unintentional* and undesirable introductions (e.g., sea lampreys in the Great Lakes).

There are more management options for small lakes and reservoirs. Small lakes may be manipulated by altering water levels or habitats (e.g., improving spawning areas, adding brush piles to provide hiding places for fish) or altering water quality (e.g., fertilizing low nutrient lakes, reducing the flow of nutrients into lakes that have excessive nutrients) to increase the productivity of desirable species. In some circumstances, improving access to the lake may promote greater use by fishermen. In extreme cases, small lakes may be *chemically rehabilitated* (e.g., all fish are removed by complete poisoning and a desirable mix of fish species reintroduced). Regulation of lake fishing usually involves limits on the *catch* (species, number, and size that may be kept), *time* (season and hours when fishing is permissible), and *gear* (type of fishing equipment and bait that may be used).

Reservoirs often present additional challenges to fisheries managers because they are built for other primary purposes (e.g., flood control, electricity generation, irrigation, water storage, transportation), and these uses often conflict with secondary purposes, such as achieving fisheries benefits for society. Water level fluctuations in many reservoirs, both daily and seasonally, which often result from electricity generation, flood control, and irrigation practices, have profound consequences for reservoir fish populations. In practice, fisheries managers must work collaboratively with many other groups to achieve a mix of societal benefits. Only a few of the benefits from most reservoirs are associated with fish, fishing, and environmental quality.

Management of many small lakes tends to be the responsibility of a single governmental or nongovernmental entity, greatly simplifying fisheries management. Large lakes, on the other hand, tend to have more complex managements, involving multiple agencies. Such inter-jurisdictional decision-making greatly compounds fisheries management problems. For example, because five nations surround the Caspian Sea, managing the sturgeon fishery (which produces highly valued caviar) sustainably has been difficult due to the lack of a single, enforceable management plan. As a result, Caspian Sea sturgeon populations have dropped 90% during the past several decades.

RIVERINE FISHERIES MANAGEMENT

Riverine systems describe a continuum of aquatic systems ranging from small creeks a few miles long to rivers the size of the Amazon, Mississippi, McKenzie, Yukon, and Columbia. One important characteristic is that many riverine systems pass through, or form the boundaries between, different political jurisdictions. Multiple political and management jurisdictions often result in unsatisfactory management of riverine fisheries when agencies fail to cooperate toward achieving common societal goals.

Rivers, especially larger ones, commonly undergo extensive habitat alteration resulting from human activities such as building dams, dikes, bridges, shipping channels, and waste treatment plants. Also, because of dikes and other structures, it is common to lose the connections between rivers and their productive flood plain channels and backwaters, habitats that often provide essential spawning and nursery areas for fish. In many cases, fisheries managers must work with highly altered ecosystems that are no longer suited for the fish species most valued by the public.

Harvest regulations are important in river fisheries, but habitat protection and improvement are especially important. Many rivers, both large and small, are severely polluted or altered by domestic, farm, and industrial waste, agricultural and urban runoff; water withdrawal for domestic, agricultural, and industrial use; siltation; and riparian (streamside) alterations. Poor water quality caused by pollution and lack of habitat diversity are often the limiting factors in developing successful fisheries management programs in rivers. The effects of pollution may be very subtle and indirect. Certain pollutants, for example, may make fish more vulnerable to predation by slightly reducing their ability to sense the presence of a predator.

Unlike lakes, streams and rivers are flowing systems that have a notable self-cleansing ability. Rapid turnover of water can lead to faster recovery of water quality than that in lakes or wetlands, where nutrients and pollutants may remain trapped in sediments for many years. However, the lower, coastal sections of rivers are often slow-moving and are often long-term repositories for contaminants.

Habitat alterations that adversely affect fish are common in riverine systems. The Colorado River of the southwestern United States, for example, is subject to numerous flow diversions and is reduced to a mere trickle by the time it reaches the Gulf of California. The Columbia River and its tributaries, arguably the most regulated river system in the world, contain 250 “large” dams and several thousand “small” ones. Such highly altered habitats no longer favor native fish species, many of which are migratory. Under these altered habitat conditions, certain nonnative fish species may prosper, and many native species are reduced in number or even extirpated.

Small riverine systems (streams, brooks, and creeks) are especially vulnerable to overfishing, habitat destruction, and the effects of land-use practices such as farming and urbanization. In extreme cases, management may include prohibition of fishing or, at least, highly restrictive fishing regulations. At the other extreme, some large riverine systems, especially in their lower reaches, may be managed similarly to large lakes and coastal fisheries. Commercial fishing may be the dominant type of fishing in many large rivers, especially in tropical areas.

COASTAL FISHERIES MANAGEMENT

The marine environment immediately adjacent to land supports *coastal fisheries* and includes nearshore marine, estuarine, and intertidal ecosystems. An *estuary* is a coastal waterbody that has a free connection to the ocean, and alternately with the tides, exhibits characteristics of both fresh- and saltwater environments. Because marine biota move into coastal rivers, the lower, intertidal reaches of rivers are often included as coastal fisheries. Intertidal environments are particularly important as nursery areas for the juveniles of many valuable saltwater fish species.

Coastal fisheries present an array of challenges to the fisheries manager. Human population density tends to be higher along the coasts, and this means that aquatic coastal habitat is likely to be substantially altered (e.g., sea walls, dredging, draining, and buildings) or polluted (e.g., from municipal and industrial waste, ship discharge, and runoff). One of the greatest challenges in managing coastal fisheries is the loss of coastal wetlands. These wetlands provide habitat for many adult fish and shellfish and are also essential breeding and rearing areas.

Coastal fisheries are also often heavily harvested, and there tend to be serious conflicts among user groups. Surf fishermen, crabbers, shrimp trawlers, oil extractors, shippers, boaters, swimmers, and sightseers all use the coastal environment in ways that often conflict with each other. Use can be intensive. There are more than 9 million salt water recreational anglers in the United States.

A major change in coastal fisheries management began in the 1970s as some nations extended their offshore management jurisdiction in an attempt to control fishing by foreign nations. In 1982, most nations adopted the United Nations *Law of the Sea Convention*, which recognized the 200-mile line separating the high seas from waters in the *exclusive economic zone* of the adjacent nation. If desired, individual nations could extend their exclusive economic zone to 200 miles under international law. The United States did so in 1983. In spite of the Law of the Sea Convention, overall fishing pressure has generally remained heavy, especially in exclusive economic zones, because domestic fleets soon replaced foreign fleets.

OPEN OCEAN OR HIGH SEAS FISHERIES MANAGEMENT

Open ocean fisheries are those that operate away from the coasts and often outside of any nation’s territorial waters. The two general categories of fish that are targeted in such fisheries are the *pelagic*, or open-water-dwelling, fish and the *demersa*l, or bottom-dwelling, fish. Pelagic fish species tend to feed and travel near the ocean surface. Demersal fish species tend to live on the continental shelves closer to shore. Tuna and swordfish are examples of commercially important pelagic species; cod, hake, flounder, and toothfish are important demersal species.

The inadvertent capture of nontarget species (called *bycatch*) is a serious management challenge in many fisheries but especially for open ocean and coastal fisheries. Perhaps a third (sometimes much more) of the catch is discarded by fishermen as not marketable. Bycatch may be the young of valued sport or commercial fish species or important food sources for sport or commercial fish species. Shrimp trawlers, for example, catch and discard large quantities of small fish while pursuing the much more valuable shrimp. Various types of fishing gear used by commercial fishermen can injure, and often kill, protected animals such as seabirds, marine mammals, and sea turtles. For example, the indirect catch of dolphins in tuna fishing has led to consumer boycotts and a demand for “dolphin-safe” tuna products. Likewise, devices that effectively exclude turtles from capture have been incorporated into the trawls used by commercial shrimp fishermen.

Habitat alteration caused by certain fishing gear is also a concern in some locations. Trawling (trawls are large, heavy nets dragged by fishing boats) may alter the physical and biological characteristics of the seabed, in particular sea grass beds and coral reefs, in ways detrimental to the well-being of target fish populations. Thus, fisheries managers may have to balance how to minimize the habitat alteration of sea floors caused by trawls while still permitting capture of the target species.

Serial depletion of fish populations is another challenge to managers of open ocean fisheries. Typically, this means that fishermen move to new fishing grounds as those closer to home are depleted. A related type of serial depletion is that caused by the development and use of improved fishing gear that allows fishermen to exploit new fishing grounds as the old ones are depleted. A recent trend has been for open ocean fishermen to move into fishing more deep water environments as more accessible nearshore stocks decline.

Open ocean fisheries management is currently in a state of flux; intense international efforts are being exerted to make them economically and ecologically viable within a framework of producing sustainable, but profitable catches. For example, one challenge for fisheries managers is the heavy subsidies many nations provide to commercial fishermen which creates *excess fishing capacity*. In many cases, fishing would not otherwise be profitable, but subsidies in the form of tax incentives or cash payments make it cost-effective for fishermen to continue fishing. Thus, in many cases, the laws of supply and demand that would tend to prevent overfishing do not come into play.

DIADROMOUS FISHERIES MANAGEMENT

Diadromous fish are those characterized by a life cycle of either spawning in freshwater environments and spending their adulthood in marine environments (*anadromous* species) or spawning in marine environments and spending adulthood in freshwater environments (*catadromous* species). Diadromous fisheries represent unique challenges to fisheries managers because target species often cross multiple jurisdictions. Unless management efforts are well coordinated, the combined effect of decisions by different jurisdictions can result in serious depletion of these resources.

Anadromous fish (e.g., salmon, American shad, striped bass, smelt, and sturgeon) are important species commercially and recreationally. Many rivers no longer support major spawning runs of anadromous fish.

Until the 1800s, large runs of Atlantic salmon were found in many coastal rivers of both western Europe and eastern North America. By the middle to late 1800s, salmon runs in the eastern United States and western Europe had been drastically reduced by the effects of overfishing, dams, and pollution. Overall, runs continue to be much reduced on both sides of the Atlantic. The largest remaining runs, although small by historic standards, occur in eastern Canada, Iceland, Ireland, Scotland, and the northern rivers of Norway. Aquaculture has largely replaced harvested wild fish as the source of Atlantic salmon for the retail market.

The seven species of Pacific salmon found on both sides of the North Pacific also have, overall, declined significantly from historic levels, but not as dramatically as Atlantic salmon. Hatchery production has been used to maintain some runs in the southern region of the range (e.g., Japan, Korea, California, Oregon, and Washington). In California, Oregon, Washington, Idaho, and southern British Columbia, runs have been depleted by past overfishing, dam construction, water withdrawal for irrigation, competition with hatchery-produced salmon, competition with various nonindigenous fish species, predation by marine mammals and birds, and climatic and oceanic shifts. Runs in the northern half of the range (e.g., Russian Far East, Alaska, Yukon, and northern British Columbia) are in much better condition. The northern runs have been abundant for the past several decades, but are likely to decline somewhat for several decades because ocean conditions in the North Pacific tend to shift on such a several-decade time cycle.

Striped bass, native to the East and Gulf coasts of North America, have been introduced to the Pacific Coast and are now found from Baja California to British Columbia. Overall, the species in its original range is less abundant than it was historically, but, nevertheless, catches are still substantial. Some runs on the west coast of North America do very well. The causes of the decline in its original range are similar to those that precipitated the drastic declines in salmon runs (i.e., dams, water diversions, pollution problems, and overfishing).

American shad are found from the Gulf of Mexico up the Atlantic coast and as far north as New Brunswick. Generally, in their native range, shad runs are much reduced from historic times due to dams, pollution, and overfishing. American shad have been introduced to the west coast of North America and have done well in some rivers, especially the Columbia and Sacramento—San Joaquin.

Several species of anadromous sturgeon are also of particular concern. Some are highly prized for their roe (eggs often sold as caviar) and must be carefully managed to avoid overfishing. Other sturgeon species are at risk of extinction, and drastic national and international measures may be required to protect these species.

Many other species have anadromous forms (e.g., smelt, alewife, blueback herring, and cutthroat, rainbow, brown, and brook trout) that support substantial fisheries in certain locations. In other locations, they are important in fisheries management because they are at risk of local extinction. Like salmon, all of these anadromous fishes are extremely vulnerable to dams and other impediments to migration; they are also sensitive to water diversions and pollutants.

A few species, such as American eels, are *catadromous*—they spawn in the ocean, but live their adult lives in freshwater. Eels are important commercial species in certain regions. They occur in rivers, lakes, estuaries, coastal areas, and open ocean. Their distribution ranges from the southern tip of Greenland, along the coast of North America, the Great Lakes, the Gulf of Mexico, the Caribbean, and as far south as northern South America. Most of the catch is exported to Europe and Asia.

AQUACULTURE

Aquaculture continues to expand its importance in both commercial and recreational fisheries management. The growth of aquaculture has been especially rapid during the past decade.

Food production is the most common objective in aquaculture. Commonly raised species are carp, Atlantic salmon, rainbow trout, catfish, tilapia, shrimp, oysters, mussels, and seaweed. Currently, one-third of the total world food fish supply is obtained from aquaculture, and this portion is increasing. The amount of farmed fish produced worldwide has more than doubled since 1989.

Producing fish in captivity for subsequent stocking to enhance, maintain, or initiate fishing is also important, especially in North America. Trout are commonly raised in the United States and Canada to support fisheries subject to intensive recreational fishing, the so-called "put-and-take" fisheries. On the Pacific coasts of North America and Asia, commercial enterprises operate hatcheries to maintain runs of salmon artificially to meet market demand, a practice called *ocean ranching*. After being hatched and reared from eggs, juvenile salmon are released to migrate to the ocean, spend several years growing to adult size, then return to the hatchery of origin to spawn. At the hatchery, they are captured, and some are then spawned artificially to obtain eggs for the next generation. The rest are processed for market.

A fairly recent development in fisheries management, *conservation aquaculture*, uses aquacultural techniques to produce fish threatened by extinction. These "captive breeding" efforts may be the only hope of preserving or recovering certain fish species or populations when natural reproduction is compromised.

SPECIES AND HABITAT PRESERVATION

By the 1990s, management objectives for many freshwater fisheries in North America had shifted from optimizing commodity output to protecting habitat or preserving imperiled species. Concerns about loss of *biological diversity* and *biological heritage* often eclipsed concerns for sustaining commercial or recreational catches. This was especially true for the Pacific coast salmon fisheries and fisheries in more remote, pristine areas such as national parks and wilderness areas.

Overall, alteration of aquatic habitat (e.g., dam construction, flood control structures, dredging to facilitate water transportation, filling to create useable land, sediment and pollution runoff, and acid rain) is one important cause of the tenuous status of many fish species. Thus, protecting fish *habitat* has become a prime focus of many fisheries management agencies.

Nonindigenous fish species (those not native to the area) include both *exotic* species (those from a foreign land), and *nonnative* species (those that have expanded beyond their native range), and they often adversely affect valued native fish populations. Nonindigenous species often compete with or prey upon commercially or recreationally important fish species. They may also hybridize with closely related native species and cause a distortion in the gene pool. Nonindigenous species have contributed to the decline of approximately two-thirds of the threatened or endangered fish in the United States. Many nonindigenous fish introductions have been the result of intentionally releasing bait fish after a day's fishing, unintended releases from international shipping activities, and releases and escapes from the aquaculture and aquarium trades.

Not all nonindigenous fish species are perceived as management problems. Many highly valued and heavily harvested fish species were intentionally introduced by fisheries managers and continue to enjoy widespread public support. Among the most widely introduced fish species in North America are Pacific salmon; rainbow, brown, and brook trout; striped bass; walleye; small- and largemouth bass; and bluegill. Recent trends in fisheries management have been away from introducing fish outside their native range.

Legislation to protect species from extinction also has affected the management priorities of fisheries agencies. For example, the U.S. Marine Mammal Protection Act (1972) and the U.S. Endangered Species Act (1973) are now the legal drivers for management of some fisheries (e.g., over much of the range of Pacific salmon in the United States, the primary management goal is to prevent extinction, not to increase catch).

Internationally, the *Convention on Biological Diversity* (1992) imposes legal obligations on all signatory countries to conserve their biodiversity, manage their fisheries resources in a sustainable manner, and promote fair and equitable distribution of the benefits of each nation's genetic and biological resources.

ECOSYSTEM MANAGEMENT

Beginning in the 1980s, a widespread view emerged that managing fisheries should be broadened in scope to include the entire ecosystem; hence, the rise of *ecosystem management*. A precise, universally accepted definition of ecosystem management has yet to emerge, but it is generally seen as the application of ecological, economic, and social information, options, and constraints to achieve desired social benefits within a defined geographic area and for a specified period.

Part of the appeal of ecosystem management is that it may better balance the suite of benefits (e.g., food fish, recreational fish, preserving endangered species, and preserving ecosystems) that society values. To date, ecosystem management has been most commonly implemented in public forests in North America. Efforts are now under way to apply the same concept to large lakes and open ocean ecosystems.

Adaptive management, the process of improving management effectiveness by learning from the results of carefully designed decisions or experiments, is often included in ecosystem management frameworks. The philosophy underlying adaptive management is the recognition that the ecological consequences of many fisheries management decisions are too uncertain to predict with confidence. Therefore, management decisions ought to be tentative and used to learn how the ecosystem responds. The information derived from such decisions allows the manager to adapt future decisions to reflect what has been learned from past decisions.

Another trend in fisheries management, now commonly practiced in Europe, is using the river basin as the management unit. River basins, or watersheds, have long been used in water management and pollution abatement but have only recently been adopted in fisheries management. River basins tend to be the preferred geographic level of fisheries management that international organizations use.

FUTURE OF FISHERIES MANAGEMENT

In the future, fisheries management will continue to reflect the overall values and preferences of the society within which it operates. Fisheries managers will strive to produce sustainable benefits from renewable biological resources, but society's needs will continue to evolve, resulting in different, and often conflicting, management goals. Efforts to maintain or increase the catch are likely to be tempered by society's growing interest in protecting the environment and preserving imperiled species.

Fish and fishing will remain important factors in the daily lives of many people but especially so in those areas where animal protein from agriculture is in relatively short supply. Overall, harvest pressure on most aquatic environments will continue to increase in concert with rising demand for animal protein for use as human and animal food and for recreation opportunities.

Harvest restrictions in many fisheries are likely to become more constraining as fisheries managers attempt to maintain sustainable yields and avoid fishery collapses. International trade in fisheries products is likely to be scrutinized to a greater degree in response to perceived environmental damage caused by excessive or inappropriate fishing. To counter past overfishing in the ocean, for example, there is likely to be increasing public pressure to create legally protected areas where fishing is forbidden (e.g., fish parks, marine reserves, and marine sanctuaries).

Protecting fish habitat will continue as a primary management goal in the future. There will be a continuing emphasis on protecting the environment in general and water quality in particular. The emphasis in enhancing water quality is likely to shift from controlling specific sources of pollution to reducing pollution from large-scale runoff. Fisheries managers will increasingly be focusing on water quality enhancement and pollution abatement. Introduction of nonindigenous species and genetically altered fish will be of increasing concern to fisheries managers.

In the future, aquaculture will likely provide a larger percentage of the total worldwide production of fisheries products. Domestication, genetic selection, genetic engineering, and other technological developments are likely to be employed to enhance aquacultural production.

FACTORS AFFECTING FISH GROWTH AND PRODUCTION

Roger C. Viadero
West Virginia University
Morgantown, West Virginia

The health and subsequent growth of fish are directly related to the quality of water in which the fish are raised. In general, factors affecting fish growth and production in freshwater aquatic systems can be classified as physical, chemical/biochemical, or a combination thereof. The physical properties of water that are important to fish production and growth include temperature and the concentrations of suspended and settleable solids; important chemical parameters include pH, alkalinity, hardness, and metals (e.g., iron, aluminum, calcium, etc.) The solubility of oxygen and ammonia gases, which vary as a function of other parameters such as temperature, are also key parameters in maintaining fish health. Recommended water quality criteria for salmonids are

Table 1. Summary of General Recommended Water Quality Criteria for Salmonids[a]

Analytic Parameter	Water Quality Criteria
pH	6.5–8.0 standard units
Total hardness and alkalinity	10–400 mg/L as $CaCO_3$
Calcium	<160 mg/L
Magnesium	<15 mg/L
Iron	<0.1 mg/L
Aluminum	<0.01 mg/L
Manganese	<1.0 mg/L

[a] Reference 1.

presented as typical chemical requirements of freshwater fish in Table 1 (1). However, note that specific water quality requirements are highly species dependent and further references should be consulted.

TEMPERATURE AND DISSOLVED OXYGEN (DO)

Water temperature is one of the most important physical factors affecting fish growth and production. Fish are cold-blooded animals which assume approximately the same temperature as their surroundings. Typically, fish are classified broadly as cold, cool, or warm water, depending on their tolerance for particular temperature ranges. Within each temperature classification, fish survival is bounded by an upper and lower temperature, between which an optimum temperature for growth exists. When temperatures vary outside the optimum range, decreased tolerance to changes in water quality constituents (particularly metabolites such as ammonia) and a decrease in immunological response can occur. Consequently, decreased growth/productivity and in some cases, mortalities, may result, depending on the magnitude of the deviation from the optimum temperature. For example, the survivable temperature range for rainbow trout (*Oncorhynchus mykiss*) is ~1 to 26 °C. However, depending on the reference source, the "optimum" temperature range for growth is 13 °C to 21 °C (1).

Representative optimum temperature ranges for common freshwater fish species are presented in Table 2. The survivable and optimum temperature ranges vary among species, so readers are referred to the comprehensive enumerations of temperature limitations for many freshwater fish species presented by Colt and Tomasso (2), Boyd and Tucker (3), Tomasso (4), Barton (5), Meade (1), and Andrews and Stickney (6).

Water temperature can also affect the solubility of gases which are important to fish health (e.g., dissolved oxygen and ammonia). In general, the solubility of gases decreases when water temperature increases because the chemical species have a greater affinity for the gas phase than the aqueous phase (7). For example, the dissolved oxygen concentration over a range of temperatures is presented in Table 3 (8).

Dissolved oxygen concentrations near saturation (≥95% saturation) are recommended for fish health and productivity (1). Further, the addition of oxygen to fish culture waters via aeration systems can aid in reducing the toxicity of un-ionized ammonia by driving the volatile gas off through mixing/aeration (9). Due to the toxicity of ammonia to fish, nitrogen species are presented and discussed later in a separate section.

Table 2. Representative Optimum Temperature Ranges for Common Freshwater Fish Species[a]

Name	Optimum Temperature Range, °C
Coho salmon (*Oncorhynchus kisutch*)	11–17
Rainbow trout (*Oncorhynchus mykiss*)	13–21
Smallmouth bass (*Micropteur dolomieui*)	18–24
Walleye (*Stizostedion vitreum vitreum*)	20–23
Channel catfish (*Ictalurus punctatus*)	25–30
Talapia (*T. mossambicia*)	28–30
Bluegill (*Leptomic machrochirus*)	29–32

SOLIDS

Solids in water can be in either suspended or settleable form; each can have both direct and secondary effects on the ability of water to support fish. High suspended solids concentrations, measured in the field as turbidity, can irritate fish gills and thus, lead to respiratory deficiencies in fish. Further, suspended solids can decrease water clarity and thus photosynthesis, which can lead to adverse affects on aquatic vegetation and consequently, on herbivorous fish species. High sedimentation in natural waterways can smother fish eggs. Similarly, sedimentation can degrade benthic macroinvertebrate habitats and thus have substantial adverse impacts on insectivorous fish species (10).

Organic matter is also often associated with the solid phase; thus, high suspended and/or settleable solids concentrations can indicate sources of increased oxygen demand in the water which may then lead to oxygen deficiencies for fish. Further, a direct linkage between organic solids loading and bacterial gill disease, as well as amoebae gill infestation, has been reported (11); solid-phase organic matter serves as a host site for opportunistic pathogens.

To control the effects of solids adequately on fish growth and productivity, it is recommended that total solids concentration be maintained at $\leq$80 mg/L. A comprehensive overview of solids removal technologies is presented in Metcalf and Eddy (12) and Wedemeyer (13). Additional representative works related to specific solids management technologies in fish culture systems include Viadero and Noblet (14), Kristiansen and Cripps (15), Summerfelt (16), and Chen et al. (17).

pH

In general, a pH of 6–9 is needed to support aquatic flora and fauna (7), though specific requirements are species-dependent. For instance, rainbow trout (*Oncorhynchus mykiss*) are relatively intolerant to acidic conditions, whereas green sunfish (*Lepomis cyanellus*) and *Rhinichthys atratulus* (black nose dace) are often found in waters recovering from impairment related to acid drainage (10). Other concerns related to fish growth as a function of pH include increases in toxicity of aluminum and ammonia at elevated pH (18,19).

ALKALINITY AND HARDNESS

Carbonate alkalinity is a measure of water's ability to neutralize strong acids due to the presence of carbonate species and is thus an important factor in buffering waters against abrupt changes in pH (7). In natural waters, carbonate alkalinity is derived mainly from the dissociation of $CaCO_3(s)$ and is consequently, directly related to water hardness. Further, elevated water hardness decreases the toxicity of metals such as copper and zinc through the formation of soluble metal–inorganic ligand complexes which are typically not as readily bioavailable to fish as free metal ions (7,18,20–23). A definitive recommended limit for total hardness in fish culture waters is not clear (22), though Heath (24) and Meade (1) noted positive effects on fish health in waters with hardness in excess of $\sim$400 mg/L as $CaCO_3$. In contrast, low alkalinities generally only contributed to fish stress when concentrations of CO_2, a weak acid often found in groundwater, were elevated.

DISSOLVED METALS

The metals of greatest concern for fish growth and production include copper, zinc, tin, cadmium, mercury, chromium, lead, nickel, arsenic, and aluminum (24). The USEPA (25) has listed several of these elements as priority water quality pollutants for human consumption of fish, including mercury, cadmium, and selenium. Heinen(18) synthesized the USEPA "priority elements" along with other metals of concern for effects on fish growth and production, as presented in Table 4.

Table 4. Prioritized List of USEPA "Priority Elements" and other Metals of Concern for Effects on Fish Growth and Production[a]

Analytic Parameter	Water Quality Criteria, Listed in Order of Importance
High	Mercury, cadmium, selenium
Medium	Arsenic, lead
Low	Chromium, copper, zinc, antimony, nickel, silver, beryllium, thallium

[a] Reference 18.

In addition to the priority pollutants listed in Table 4, other metals, including iron and aluminum, can have adverse effects on fish productivity and growth. For instance, both ferrous and ferric iron (Fe^{2+} and Fe^{3+}, respectively) can be toxic to fish. Ferrous iron was reportedly more toxic to fish than ferric iron, though in well-aerated waters, Fe^{3+} is the dominant form of dissolved iron. Ferrous iron, however, may be detrimental to fish health if precipitated in large quantities as $Fe(OH)_2(s)$, as it may "clog" fish gills (18).

Aluminum is toxic to rainbow trout (*Oncorhynchus mykiss*) at lower concentrations than those of other metals because it can accumulate on the gills as aluminum hydroxide and cause respiratory impairment (18). In addition, aluminum is highly toxic to trout in both dissolved and suspended forms; however, the symptoms of poisoning are different, depending on the form/phase of aluminum. Dissolved aluminum tends to cause acute mortalities, and suspended aluminum results in more chronic effects such as respiratory difficulties indicated by gill hyperplasia (26). It has been recommended that concentrations of total aluminum (both dissolved and suspended) be maintained at less than 0.01 mg/L for normal growth and survival of trout. However, the effects of complexation between aluminum and inorganic ligands may abate the effect of high dissolved aluminum concentrations by rendering a fraction of aluminum less bioavailable than free Al^{3+} ions (27).

Criteria for calcium and magnesium concentrations in trout waters are based on limited data (18); common recommendations include calcium concentrations $\leq$160 mg/L (22) and magnesium concentrations $\leq$15 mg/L, though an alternative limit of 28 mg/L Mg has also been suggested by (28).

NITROGEN SPECIES

Total ammonia nitrogen (TAN) is comprised of two species: (1) un-ionized ammonia (NH_3), which is highly toxic to fish and (2) ionized ammonia ($NH_4{}^+$), which is not believed to be toxic to fish (29). The widely accepted TAN limit for "no effect" is 0.0125 mg/L NH_3-N (29–31).

Long-term exposure to subacute un-ionized ammonia concentrations can decrease productivity (29,32) and change gill structure which may result in death from oxygen deficiency (11,33,34). Reduced growth of rainbow trout was observed at a concentration of 0.0166 mg NH_3-N/L. However, fish may be able to maintain sufficient oxygen uptake by changing cardiovascular and respiratory behaviors, though activity would decrease (35,36).

Water chemistry can also impact ammonia toxicity. For example, it has been widely reported that increased salinity and divalent cation concentrations may reduce the toxicity of NH_3-N by altering the osmoregulatory systems of fish and decreasing membrane permeability (29,37,38). Soderberg and Meade (29) studied acute and chronic toxicity to determine the effect of calcium and sodium on the toxicity of un-ionized ammonia to Atlantic salmon (*Salmo salar*) and lake trout (*Salvelinus namaycush*) and found that ionic strength was important in determining the effect of NH_3-N exposure on different species and sizes of fish. Temperature and pH were also significant water quality parameters because they affect the solubility and speciation of ammonia in solution. Methodologies to account for the effects of pH, temperature, and ionic strength are presented in Soderberg (9) and Soderberg and Meade (39).

Nitrite (NO_3^-) is produced by *Nitrosomonas* sp. through the biochemically mediated oxidation of ammonia. Nitrate concentrations in excess of 0.55 mg/L can result in methemoglobinemia, a condition in which the iron in blood cannot transport oxygen. As a consequence, oxygen uptake by fish becomes limited.

WATER NEEDS FOR FRESHWATER FISHERIES MANAGEMENT

Harold L. Schramm, Jr
U.S. Geological Survey
Mississippi State, Mississippi

THE SCOPE OF FISHERIES MANAGEMENT

"Fishery management" is variously defined, but common to all definitions is manipulating fishery resources to produce sustainable benefits for people. Fishery management relies on principles of aquatic ecology but focuses on the use of fishery resources.

A "fishery" has three components: the fish, the habitat, and the users (people). Effective fishery management embraces all three components. It is important to recognize that "the users" often are people who catch fish for sale or recreation, but the users are not necessarily consumptive. The thrust of this article, the dependency of fishery management on water, necessitates a focus on the habitat component of fisheries. However, no component is completely independent of the others, and the linkage between people and habitat is especially influential on fishery management.

WATER QUALITY

Good water quality is essential to fish survival, growth, and reproduction. Most fish require dissolved oxygen concentrations above 5 mg/L (parts per million), and 3 mg/L is considered stressful for many warm-water fish. Brief periods of hypoxia can be lethal. Fish survive over a pH range of 4.5–10, and acidic inputs from mine drainage or precipitation can be lethal. Freshwater fish vary in their tolerance of salinity; some species can survive in seawater, but others can tolerate less than 10% seawater. Many heavy metals and pesticides and their derivatives are toxic to fish, but some chemicals, such as mercury and PCBs, are accumulated by fish to levels toxic to other animals, particularly mammals and birds. Ammonia and nitrite can be toxic at less than 2 mg/L. Some evidence is now available that hormones in discharge water can disrupt endocrine function and interfere with fish reproduction. Tolerances of fish to water quality variables may vary among life stages; for example, eggs or larvae may tolerate much lower salinity or concentrations of a toxic chemical than adults.

Point-source pollution, although not abated, is relatively well controlled in most developed countries compared with nonpoint pollution—in essence, runoff from the watershed. Inputs of otherwise nontoxic and biologically essential chemicals, such as nitrates and phosphates, can have beneficial or benign effects on aquatic systems. However, excessive levels of these chemicals that result from agriculture, confined animal rearing facilities, and domestic and municipal development have dramatic effects on receiving waters and cause undesirable shifts in aquatic ecosystem structure and function. In this regard, it is important to recognize that many chemical inputs to aquatic systems are not directly injurious to fish but, by altering the composition and abundance of other biota, indirectly influence the health and survival of fish populations. A common example is oxygen depletion that results from planktonic algae blooms or excessive growth of aquatic plants (macrophytes). Although the plants usually produce the oxygen needed to sustain fish and other aquatic life, dense macrophytes or algae blooms fueled by high phosphorus concentrations can consume oxygen at night and during reduced-light conditions and cause fish kills. Oxygen depletion can also occur at the end of the growing season when excessively abundant plant material dies and decomposes.

WATER QUANTITY

It is obvious that fish need water, but there are aspects about water quantity that are far from obvious and are often overlooked by managers. In standing water systems, the amount of water impacts fish by affecting the types and amounts of habitats available and may alter thermal conditions. Declines in water level generally result in reduced areas of desirable aquatic habitat, and reduced water volume, in turn, impacts physicochemical conditions. Most freshwater fish spawn in relatively shallow water, and drawdowns at that time can cause spawning failures. The young of many fish find both shelter and food in shallow water, littoral zones (the nearshore area where rooted aquatic plants grow); dewatering these habitats reduces fish growth and survival and may result in year class failures. However, seasonal declines in water level can be desirable in shallow lakes where periodic drying of littoral zones is necessary to oxidize accumulated organic matter and consolidate soft, detritus-rich bottom sediments.

Rivers and streams are dynamic systems in terms of amount (discharge) and level (stage) of water, but the fish endemic to these systems are adapted to the annual cycle of fluctuations. Although peak and low flows and stages may vary from year to year, the annual cycle of rise and fall (the hydrograph) is rather predictable. Alteration of the annual hydrograph, such as may occur when a river is dammed for flood control or water supply, can interfere with spawning and recruitment by decoupling river elevation and thermal cycles, preventing access to essential habitats for floodplain-spawning fishes, or failing to provide necessary current velocity for fish that require flowing water for successful reproduction. River fluctuations are also important to adult stages of many fishes. Seasonal inundation of the floodplain provides access to rich food supplies for many fish, and receding waters flush nutrients, organic material, and biota, including small fish, into the river. As such, this “flood pulse” strongly influences fish production in river–floodplain ecosystems. High river stages also connect the river to floodplain lakes that were former river channels. Connection with the river can supply nutrients to the lake and allow in and out movements of fish. This connectivity, even if brief, unites the numerous different habitats in rivers necessary to sustain the diverse fish assemblage.

ALTERATION OF AQUATIC HABITATS

Water is essential to fish, but it is also essential to society and economic development. Natural river flows are altered for flood control, navigation, hydropower generation, water supply, and other anthropocentric purposes. Most of these purposes are accomplished by constructing dams to impound water and regulate flows. Dams are barriers to fish migrating to upstream spawning habitats and often curtail or even eliminate spawning. Further, the lake conditions created by dams eliminate habitats and flowing water essential to part or all of the life cycle of many native riverine fish. Reservoirs, by serving as sediment and nutrient traps and biological filters, can reduce the nutrients and sediments available to downstream systems. The resulting oligotrophication results in reduced fish production in downstream waters, a rather ironic reversal of escalating nutrient accumulation (eutrophication) common to many lakes and reservoirs.

Sedimentation is probably the greatest threat to river and stream fisheries resources. Although sedimentation is a natural process, excessive sediment input into waterways results from poor land management on the watershed. Sediment covers hard and rough bottoms essential for spawning and juvenile or adult stages of many fishes. The sediment smothers bottom-dwelling invertebrates; many are important food sources of fish; others are important to energy cycling in the stream. Sediment also provides an unstable substrate; thus, aquatic vegetation and bottom-dwelling animals that live in and on these soft substrates are often washed away during floods.

Natural thermal cycles are important to fish production, and “thermal enrichment” can be a form of pollution. Thermal enrichment, usually resulting from discharge of cooling water from electric generating plants or industry, can benefit fish production by lengthening the growing season and may benefit users by lengthening the fishing season. Unfortunately, adverse impacts usually outweigh benefits. Elevated temperatures can stress kill fish, alter their metabolic requirements, alter predator–prey dynamics, cause out-of-season spawning, and result in replacement of cool- and cold-water fish with species tolerant of warmer water. Water temperatures lower than natural thermal conditions can also be problematic. Coldwater, hypolimnetic discharges from reservoirs can reduce aquatic production downstream, impact fish growth and recruitment, and alter the fish assemblage in favor of cold-tolerant species.

BIOTIC POLLUTION

Introduced aquatic species are an expanding and insidious form of pollution. Introduced species arrive in waterways by various means, including intentional but ill-advised introductions. The greatest source of aquatic nuisance species is intercontinental shipping. More than 160 nonnative species have been documented in the Great Lakes. Most, if not all, arrived in the ballast water of large ships. These alien species can alter water quality, change the pathways of energy and nutrient flow, alter habitats, prey on or compete with native species, hybridize with native species, and introduce diseases and parasites. Rarely are the effects beneficial; and most introduced species, once established, cannot be eliminated.

COORDINATED MANAGEMENT

Most public-access waters are multiple-use resources. As such, fishing is just one use of a waterbody, which is especially true for the more than 10 million acres of large impoundments in the United States. These systems were built to accomplish one or more purposes—hydropower, flood control, water supply, and navigation—invariably directed at achieving social or economic benefits. Fishing, although typically included in benefit analysis, was not a primary purpose for constructing large reservoirs. Fulfilling the primary purposes for which the reservoir was built dominates reservoir operation, often diminishing fishery values. In the last two decades, resource managers have become more sensitive to fishery needs.

SHIFTING TO MORE HOLISTIC MANAGEMENT

The study of inland waters (limnology) is only a little more than a century old, and modern fishery management has been developing for only half that long. As knowledge grows, perspectives and paradigms shift. Fishery managers now recognize the value of managing fish assemblages rather than single species. Furthermore, managers are realizing that lakes and rivers are not isolated microcosms but rather part of larger watersheds or ecosystems, and what happens on the watershed or in a land-water ecosystem affects what happens in the water. Future management of fishery resources requires coordination and cooperation among diverse interests.

AN OUTLINE OF THE HISTORY OF FISHPOND CULTURE IN SILESIA, THE WESTERN PART OF POLAND

Maria A. Szumiec
Polish Academy of Sciences
Chybie, Poland

The need for pond construction in Silesia arose from the lack of large natural waterbodies and the long distance to the sea. The abundance of water, benign climate, fertile soils, the growing demand for fish in the developing towns; and the possibility of transporting fish along the rivers favored the development of fish farming.

The Silesian territory (Fig. 1) situated on the junction of Slavonic and German nations was affected by numerous wars, but at the same time, it was a center where various cultures existed (2). The political position of Silesia changed several times. From 990 to 1327–1329, it belonged to Poland. The foundation of the Wratislawia bishoprics by Bolesław the Brave, the Polish king of the Piast dynasty, in 1000 was an important moment in the history of fishpond culture because monasteries were the first to play an important role in fish culture in the Middle Ages. In the twelfth century, division among the sons of a Polish prince from the royal dynasty of Piast gave rise to many Silesian principalities.

In 1327–1329, the different political orientation of the Silesian princes caused it to affiliate with the Czech Kingdom (Fig. 2). From the fifteenth century the southern part (Teschenensis and Oppoliensis-Ratiboriensis) was called Upper Silesia and the northern (Wratislawiensis), Lower Silesia. In 1526, Silesia became a part of the Habsburg Empire; in 1763 the entire Silesian territory was incorporated into Prussia; in 1918, it was partly affiliated with Poland, and in 1945, Silesia became part of Poland. Political, social, economic, and climatic variations distinctly affected the history of Silesian fishponds, which for ages played a manifold role in alleviating freshets and floods of rivers during wet periods and served as water resources during dry years.

This outline is based on secondary sources, chiefly the Polish literature including Czech, German, and Moravian citations. The historical data are derived from Encyclopedia PWN (1983–1987) (3).

THE FIRST PERIOD

The first development and breakdown of fishpond culture occurred between the twelfth and middle of the fifteenth century. Probably, Cistercians began to breed fish in ponds in the eleventh or twelfth century. Fishpond farming developed after the rivers and natural waterbodies had been wastefully exploited owing to the increasing population and strict observance of fasting. The highest progress in fish farming occurred in the fourteenth century and resulted from a rapid economic progress accompanying the growing mining industry and developing trade. Numerous fishponds as well as the introduction of the carp, probably from Czech and Moravia, allowed people to meet the religious demands. Devastating and depopulating wars, chiefly the incursion of the Tatars, obstructed fishpond development. The Hussite and Polish-Czech-Hungarian wars for the Czech throne ended the first period of development of fishpond culture in Silesia. Unfavorable climatic events were also responsible for this situation (4–6), although the outstanding development of fishpond culture might point to the fourteenth century as the warm climate phase.

THE SECOND PERIOD

In the middle of the fifteenth century, pond culture revived and developed till the end of the sixteenth century although some authors point to the sixteenth century as the beginning of the Little Ice Age (7). It resulted from a fairly peaceful time, warmed climate, popularization of carp culture and also due to privileges bestowed, mostly upon the oligarchy, by Ladislau of the Polish royal dynasty of Jagiellon, the king of Czech and Hungary.

Numerous ponds belonged to principalities and nobility, also to burghers, monasteries, and peasants. At the time of the highest development of pond fish culture, some places in the Silesian territory had the character of a lake district. Imagining the landscape at that time gives a map of a part of Upper Silesia elaborated in 1725 after a significant reduction in pond area in this territory (Fig. 3).

The fish from Upper Silesian ponds were transported by the River Vistula to Cracovia the capital of Poland

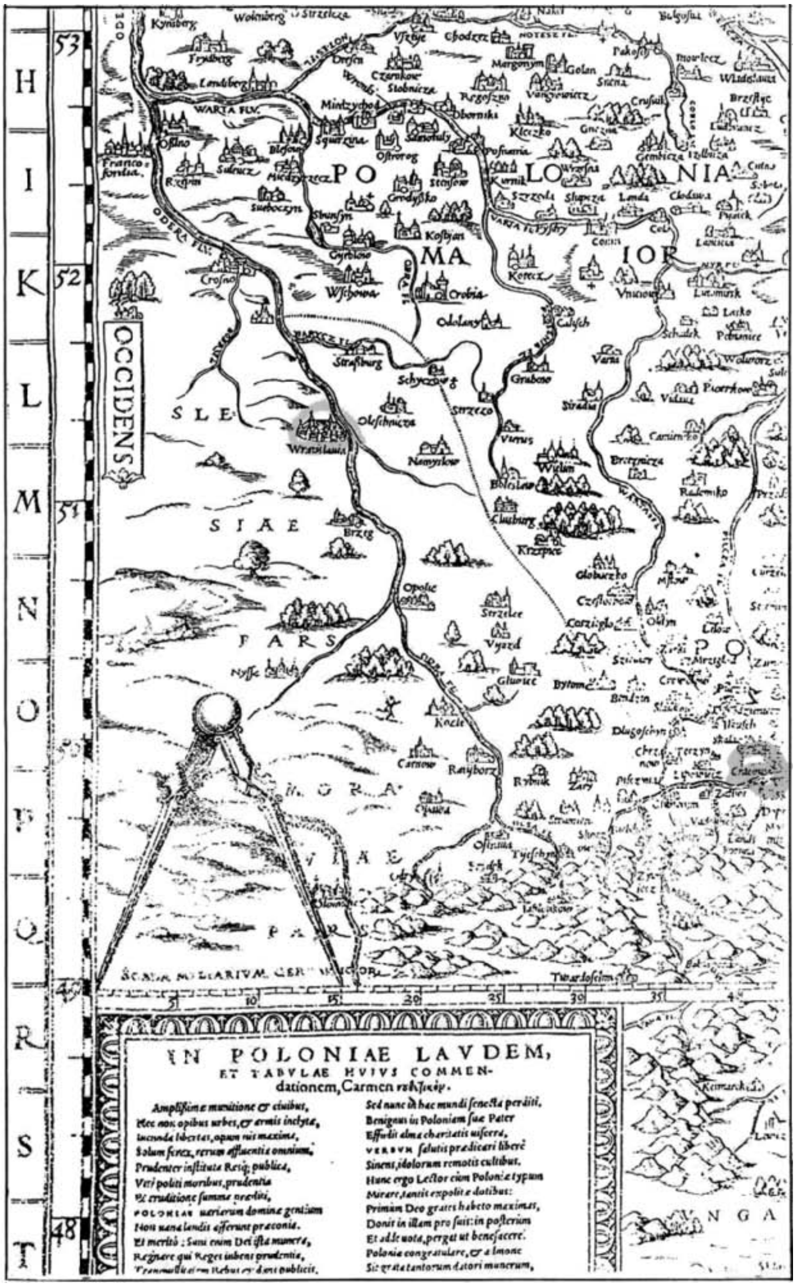

Figure 1. Silesia from a part of Venceslaus Grodeccius' map 1558–1562 (1).

where the king's court and an increasing number of citizens created high demand for fish. In some estates, the income from pond farming was estimated at 50–60% of total income.

The fish caught were distinguished as white and black fish; pike and carp were mentioned separately (Fig. 4). The separate rearing of fish fry in small ponds, chiefly by peasants, points to the high level of fish culture at that time. The need for the development of technologies for pond construction and water leveling found response in one of the first technical books in Polish written by Olbrycht Strumieński and printed in Cracow in 1573 (Fig. 5).

In towns, fishers' guilds were organized to preserve the acquired rules of fishing in rivers and of fish trading. A Czech annalist, J. Dubravius, in 1600 highly appreciated pond farming in Silesia, highlighting the abundance of inexpensive fish in comparison with Czech, Moravian, or Austrian (8,10).

Pond complexes also alleviated and prevented frequent freshets and floods in mountainous regions where forests disappeared owing to developing ferrous metallurgy. In periods of drought, pond waters were used to irrigate fields. Ponds were also built to reclaim marshy sites and to increase the area of cropland and meadows.

THE THIRD PERIOD

At the beginning of the seventeenth century, the fish farming economy collapsed, and this lasted to the middle of the nineteenth century. This was above all due to

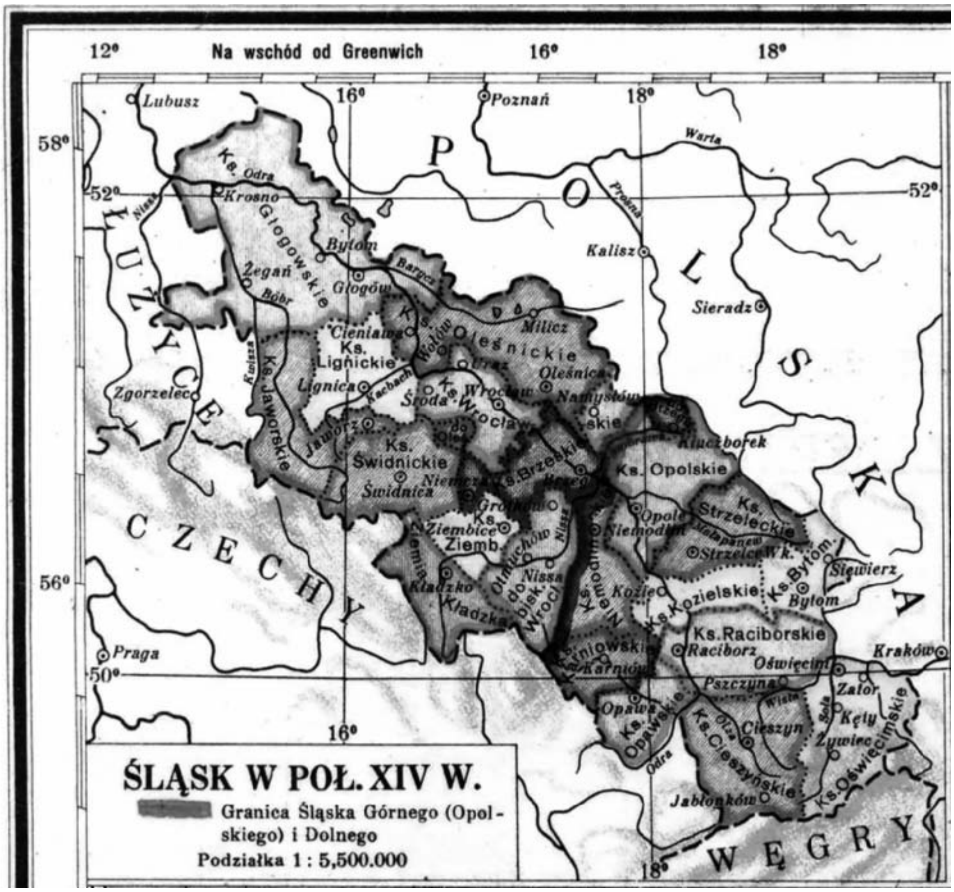

Figure 2. Partition of Silesia in the middle of fourteenth century. Semkowicz, W., Szkolny Atlas Historyczny. 1932, 2nd ed., 8, Książnica—Atlas, Lwów—Warszawa.

the Thirty Years' War (1618–1648) waged on a religious background. The war severely affected Upper Silesia. The behavior of foreign armies passing through the territory, for whose protection they had been called, had the most devastating effects. The majority of soldiers treated this province as enemy terrain causing enormous violence and the devastation made all inhabitants of numerous villages flee. The breakdown of agriculture due to depopulation created hunger and pestilence. Together with a very high contribution paid by the regent on behalf of the Austrian Empire, these events accounted for the poverty of the region (11). The religious repression was a further unfavorable stress on this country. The reconstruction of devastated ponds was impeded by the depopulation; however, the centers of large pond farms were renovated with the help of the villein service. A decrease in the level of groundwater due to the development of coal mining in Upper Silesia dried up shallow peasant ponds (Fig. 6).

The strengthening of the feudal social system and the excessive burden of villein service also affected peasant fish farming unfavorably. The primitive ineffective method of rearing all generations of fish in one pond returned (12,13). In Upper Silesia, the area of ponds decreased by 60% after the Thirty Years' War. A further reduction of about 20% occurred in the eighteenth century owing to the devastating Austrian–Prussian wars (1740–1742 and 1744–1745) (8). The high profit from cereal cultivation contributed to the decline of the fishpond economy and further reduced the area of ponds in the eighteenth century (12). However the area of ponds still reached 30,000 ha in Silesia, about 30% of the whole water surface area in the region at the turn of the nineteenth century (Fig. 7).

In the nineteenth century, the abolition of villein service made the renewal of pond farming very difficult in Upper Silesia because the work was based chiefly on the serf system. In Lower Silesia, the area and number of ponds was reduced to a smaller degree; they were reconstructed by hired specialists, although the regulation and canalization of the River Odra by Prussian authorities decreased the groundwater level and contributed to the disappearance of numerous irrigated territories, also fishponds.

A probable reason for the breakdown of the fishpond culture might also have been the cold weather that prevailed from the midseventeenth to the midnineteenth centuries whose maximum was in the midseventeenth (4,14–16). The cooling, called the Little Ice Age, was also confirmed by decreasing carp sales and an increasing price of this fish species in the Plesnensis Principality from 1690–1810 (Fig. 8).

THE FOURTH PERIOD

A period of continuous development in pond carp culture began from the middle of the nineteenth century and was maintained till the present. It resulted from a fairly

peaceful time at the end of the nineteenth and the beginning of the twentieth centuries. The expansion of numerous studies on carp physiology and diet played an important role, but the main impulse for the culture development was observations by Tomas Dubisz of an accidental transfer of larvae during a freshet from spawning ponds to nursery ponds, previously plowed and sown with clover (Fig. 9) (18).

The observation caused him to introduce a new method of carp rearing, which ensured the abundance of food for

carp fry and shortened the rearing period of the market carp from 6–7 to 3 years. The effects of the fishpond culture also increased due to the warm period from the middle of nineteenth century (4,13). In Upper Silesia, most large fishponds were reconstructed by making them smaller and shallower; this created beneficial conditions for an increase in food resources for the carp and facilitated fish culture technology. However, during this time, large areas of ponds that vanished were turned into land ecosystems.

In the twentieth century, further steps in the intensification of fish culture consisted of the introduction of nitrogen–phosphorus fertilization in ponds. The application of this method in the 1950s increased yields from several kilograms to several hundred kilograms from 1 hectare of pond. A new intensified method of carp rearing introduced in fishery practice in the 1970s was based on greater stock densities and feeding fish pellets which covered the requirements of fish. By this method, yields rose to several thousand kilograms from 1 hectare. The polyculture of carp and herbivorous fish and the aeration of pond waters maintain proper environmental conditions (19).

In recent years, great attention was paid to the fishponds as ecosystems integrated with a catchment. Methods of the semi-intensive carp production, introduction of the polyculture with herbivorous fish species, and limited pond fertilization should ensure the sustainable functioning of carp ponds in river drainage. Moreover, these ecosystems enrich the river drainage in many ways (20).

An den Erzherzoglichen Fiſchmeiſter, uſw. Herrn
Thomas Dubiſch,
Sketſchau. Oeſterr. Schleſien.

Wer da beiträgt, ſeinen Mitbürgern geſunde und wohlſchmeckende Nahrung zu beſchaffen, den darf man preiſen. Seit einer Reihe von Jahren haben in vielen Landen der Erde viel edle Männer hierfür auch dadurch geſorgt, daß ſie die Teiche, die Seen, die Bäche, die Ströme reicher an edlen Fiſcharten zu machen ſtrebten, nachdem allzulange von den Fiſchern ſorglos nur geerntet war, ohne zu ſäen, ohne rückſichtsvoll zu ſchonen – ohne, ſagen wir es: das Waſſer zu beſtellen, wie man die Aecker beſtellt, wenn ſie reiche Frucht geben ſollen. Schöne Erfolge ſolcher Arbeiten beginnen ſich zu zeigen, und das Herz des Menſchenfreundes erbaut ſich hieran um ſo mehr, da weithin über die Erde ein brüderlicher Austauſch nicht bloß der Erfahrungen, ſondern auch edlen Fiſcharten von Land zu Land, ja von Welttheil zu Welttheil ſtattfindet. Wir ſtehen zur Zeit noch mitten in dieſer Bewegung, aber wenn einſt ein ruhiger Forſcher zurückblickt, die Reſultate feſtſtellt und die Männer zählt, welche beſondere Verdienſte in dieſer Sache hatten – dann, geehrter Herr Dubiſch, wird ſehr warm auch Ihrer gedacht werden! Von frühester Jugend an ſind Sie mit vollem Eifer Fiſcher geweſen, haben aber nicht allein Fiſche fangen gelernt, ſondern ſich auch deren Pflege im Zoologiſchen Garten zu Wien gewidmet. Schon vor einem Vierteljahrhundert ward Ihnen eine große Auszeichnung für Salmonidenzucht verliehen. Aber Ihr größtes Verdienſt iſt ſicherlich die verbeſſerte Karpfenzucht – was Sie hierin leiſteten, kann Ihnen niemals vergeſſen werden. Das Dubiſchverfahren iſt ein weltberühmtes Wort geworden. In dieſer Beziehung hat auch der Deutſche Fiſcherei-Verein Ihnen ſehr viel Dank zu ſagen. Nicht in Heimlichkeit hüllten Sie Ihre ſchönen Erfolge bei dem erlauchten Erzherzog, dem Sie faſt zwanzig Jahre lang zu dienen die Ehre hatten. Sie zogen Schüler heran, welche Ihre Methode verbreiteten, und wenn der Deutſche Fiſcherei-Verein ſeine Mitglieder zum Beſten des Vereins zu Ihnen entſendete, ſo belehrten Sie dieſelben ohne Rückhalt, ſo daß wir großen Vortheil davon genoſſen haben und ſicherlich noch viel mehr genießen werden, wenn Ihre der Natur abgelauſchten Maßnahmen immer mehr in ihrer Zweckmäßigkeit, weil auf Naturgeſetzen begründet, erkannt werden. Im Stillen haben Sie alſo gewirkt, von hochgeſinnten Patrioten auf das Wärmſte anerkannt – wir nennen den Profeſſor Nowicki und den Baron Waltmann – es drängt uns aber, Ihnen auch Namens unſeres Vereins und aller Fiſchereifreunde Deutſchlands unſern innigſten Dank auszuſprechen, Ihnen jede Lebensfreude zu wünſchen. Möge es Gottes Wille ſein, daß Sie noch lange Jahre in ungetrübter Geſundheit verbringen.

FLOODS

Steven Jennings
Eve Gruntfest

(from *The Handbook of Weather, Climate, and Water: Atmospheric Chemistry, Hydrology, and Societal Impacts*, Wiley 2003)

INTRODUCTION

The interface between humans and hydrologic features across Earth's surface has helped shape human culture. From the earliest agricultural, complex societies established along some of the great rivers of the world to the bustling seaports of today, humans have gained from the myriad advantages of living in proximity to water. Fertile soil, ease of transportation, and availability of resources (both materials and energy) have allowed for the development of complex material and intellectual cultures. The relationship between water and humans also brings a great deal of risk. Flooding is one of these risks. The impact of floods on humans has been evident from *Genesis* to tonight's evening news. Early Mesopotamian maps may have been drawn to facilitate the reestablishment of property lines after flooding. While the impacts of flooding on humans have been positive in the case of fertile floodplains that support much of the world's agricultural productivity, there is the potential for a great deal of negative impact (Brown, 1984; Clark et al., 1985). Losses of life and property have focused the efforts of scientists, engineers, and government agencies on the prediction, control, and mitigation of floods and flood damage.

In spite of efforts to deal with flooding problems, monetary losses continue to rise at an alarming rate. In Venezuela in December 1999, two weeks of heavy rain resulted on December 15th in flash floods laden with soil, vegetation, and debris. Damages of US$3.2 billion, or 3.3% of the country's gross domestic product were reported. At least 20,000 people were killed. Generally, the number of lives lost due to flooding remains high. However, improvements in flood warnings particularly for major large-scale storms such as cyclones and typhoons have had dramatic effects. The severe 1991 cyclone in Bangladesh resulted in 140,000 dead and property losses of US$2.0 billion. A cyclone of similar intensity in 1993 resulted only in the loss of 126 lives. The early warnings and cyclone shelters accounted for the major improvement (www.ndndr.org). China has also witnessed a reduction in the number of lives lost to floods. While 3000 people died in 1998 floods, the 1998 floods were as great as those of 1931 and 1954 where the loss of lives was 145,000 and 33,000, respectively (www.ndndr.org). In October 1998 hurricane Mitch was the worst in the eastern Caribbean since 1780 when a hurricane killed 22,000 people. The death toll from Mitch is reported as 11,000. More than 3 million people were left homeless or were severely affected (www.ncdc.noaa.gov/ol/reports/mitch/mitch.html).

Floods take a variety of forms with the interplay of several factors leading to the inundation of normally dry land. Wohl (2000) identifies four primary challenges in reducing escalating flood damages. These are (1) estimating flood magnitude for a given recurrence interval, (2) accurately forecasting floods based on rapidly evolving weather conditions, (3) effectively operating flood-warning and evacuation procedures, and (4) establishing and enforcing land-zoning regulations. This chapter first discusses the contexts and causes of flooding, the first two points addressed by Wohl (2000). The second topic is the complex human responses to floods, points 3 and 4 of Wohl (2000). Many of these topics are illustrated with examples of floods.

DEFINITION OF FLOODS

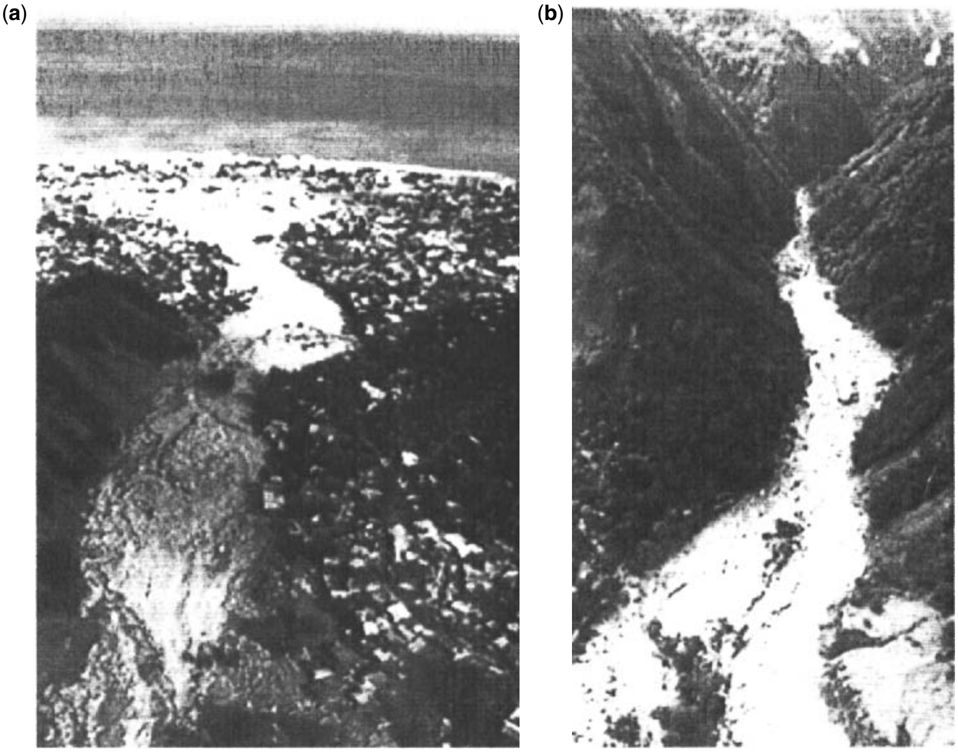
Streams are linear water features that flow under the impetus of gravity. The amount of water contained in a stream is usually regulated by contributions of groundwater and surface runoff to the stream channel (Zaslavsky and Sinai, 1981; Knighton, 1998). Much of the time water in a stream flows within the confines of its channel. When inputs of water increase sufficiently, stream discharge leaves the stream channel and covers all or parts of the adjacent floodplain. Since the floodplain surface is usually a virtually flat surface and near the elevation of the stream channel, water can easily spread over the floodplain once water exceeds the elevation of the stream's banks. Most floods develop over a period of days or months as discharge increases gradually (Hirschboeck, 1987, 1988). Flash floods by contrast occur suddenly with little warning and are of short duration. Semiarid and arid areas are likely to experience flash floods (Reid and Frostick, 1987; Hassan, 1990). Flooding is not always associated directly with stream channels. Flooding occurs any time when water covers a surface that is normally not under water. Flooding can occur in coastal areas, low lying areas with poor drainage, or locations with inadequate urban drainage systems.

FACTORS THAT LEAD TO FLOODING

Floods have a multitude of causes. Some causes are related to what would be considered natural processes that would occur whether humans are present or not. Many causes have been affected by human activities. In some cases the severity of floods and the types of damage are a direct result of agriculture, urbanization, and the areas selected for development. In all cases flooding is related to increased discharge in stream channels.

Saturated Soil

Much of Earth's surface is covered by a weathered cover of regolith. Whether forming a true soil with well-developed horizons or a weakly developed detrital cover, the regolith is composed of a mix of mineral particles, organic fragments, and pore space. Commonly, much of the pore space is filled with air and to a lesser extent water. When large amounts of precipitation are received in a region, the pore space fills with water as the input of water from precipitation exceeds the output of water from the soil column to the water table. Decreases in



(a) (b)

Figure 1. Quebrada San Julián upstream of Caraballeda showing evidence of recent debris flows and flash floods. Note the high slope angles, large numbers of debris flow scars, and abundance of new alluvium and colluvium in the channel bed and fan surface.

infiltration lead to increases in runoff. The lag time between the precipitation event and the arrival of water to stream channels decreases significantly when soil saturation occurs. As a result, peak discharge increases significantly and the likelihood of overbank flow is high (Smith and Ward, 1998). Spatially, soil saturation may occur over large-scale basins, which leads to flooding in large areas. The peak discharge flows downstream and becomes concentrated in higher order streams causing flooding. In many cases saturation follows a period of high amounts of precipitation over a prolonged time period, possibly weeks or months (Wolman and Gerson, 1978; Ward and Robinson, 1990).

Basin Characteristics

Surface characteristics influence infiltration and runoff rates (Roberts, 1989; Kuhnle et al., 1996). Impervious surfaces such as exposed bedrock or a paved road accelerate surface runoff, thus decreasing lag time between the precipitation event and entrance of water into a nearby channel. Urbanized areas, therefore, with large percentages of impervious surface such as roofs, streets, and parking lots coupled with an engineered drainage system designed to move water quickly to stream channels greatly increase the chances that some flooding will occur after a significant precipitation event (Wolman, 1967; Hammer, 1972; Roberts, 1989; Newson, 1992). Conversely, rural areas with large areas of soil, natural vegetation, and the potential for a faster infiltration rate are less likely to have significant flooding resulting from a single precipitation event. Removal of as much as half the forest cover and a decrease of marsh land along the Yangtze River in China has led to increased flooding. Half a billion people, or 45% of China's total population, reside on the banks or floodplains of the Yangtze and the area produces about 42% of China's gross domestic product. In 1998, 79.6 million people in three Chinese provinces were affected by repeat flooding on the Yangtze. The floods killed more than 3000 people. Fourteen million people were evacuated and 21 million were made homeless (Weather.ou.edu/spark/AMON/v2_n3/News/DR_980819-China12.html).

Topography

Topography will influence the rate at which precipitation will be incorporated as stream discharge (Patton, 1988). Steep, rocky canyon walls have low infiltration rates as well as a great deal of potential gravitational energy that leads to the concentration of discharge during a short period of time (Strahler, 1964). Alluvial plains usually have a much longer lag time between a precipitation event and the introduction of runoff water into a stream channel. When land cover on steeper slopes is affected by perturbations such as wild fire or building-related oversteepening of slopes, the likelihood of mass movement events is greatly increased. These events are usually related to unstable regolith on steep slopes, which is susceptible to failure when sufficient precipitation is received. For example, see Fig. 1.

High Amounts of Precipitation

Flooding is created by the delivery of larger than normal amounts of runoff into stream channels (Smith and Ward, 1998, p. 67). Periods of above-average precipitation lead to floods. In some cases seasonal variability leads to great fluctuations in stream discharge. Wet–dry subtropical or monsoonal climates with distinctive seasons of precipitation lead to fluctuations from dry stream channels to potential flooding events. These cyclical events are related to large-scale atmospheric circulation patterns that operate through an annual or longer period. In the midlatitudes, the annual migration of subtropical high pressures and the polar front lead to distinct precipitation patterns. In the tropics, monsoonal flow can lead to large precipitation events (Milne, 1986). On longer time scales El Niño and La Niña events are persistent over several years and can lead to wet or dry conditions over large areas of Earth's surface from the Equator to the midlatitudes (Waylen and Caviedes, 1987; Pearce, 1988; Ely et al., 1994).

Extended Wet Periods

In many cases flooding is caused by the reception of precipitation over an extended time period, on the order of weeks to months, that leads to the saturation of soils in a large-scale region (Rodda, 1970b; Smith and Ward, 1998). This saturation leads to increased runoff at a time when streams are at capacity (Ward and Robinson, 1990). Additional water introduced to stream channels cannot be conveyed in the channel but is spread across the floodplain. Wet periods are related to synoptic conditions such as the position of the polar front that delivers cyclonic storms in quick succession. Poleward migration of subtropical air masses over continental areas such as the Mississippi River Basin help to supply large amounts of water to be precipitated by frontal activity. For example, see Fig. 2. In some locations rainfall may fall on snow-covered or frozen ground (Thomas and Lamke, 1962). These waters are unavailable to the hydrologic cycle as long as they remain in a solid form. In the case of the former, rainfall may accelerate the introduction of water into the stream network as snowmelt augments the precipitation already being received (Kattelman, 1990; Naef and Bezzola, 1990; Caine, 1995). The latter will greatly decrease the infiltration capacity of the soil causing most of the precipitation to quickly enter the stream network (Horton, 1933).

Decaying Tropical Cyclones

Some of the largest precipitation amounts received as the result of a single meteorological event have been associated with the movement of tropical cyclones (e.g., hurricanes, cyclones, and typhoons) poleward and over continents. These powerful cyclonic storms carry large

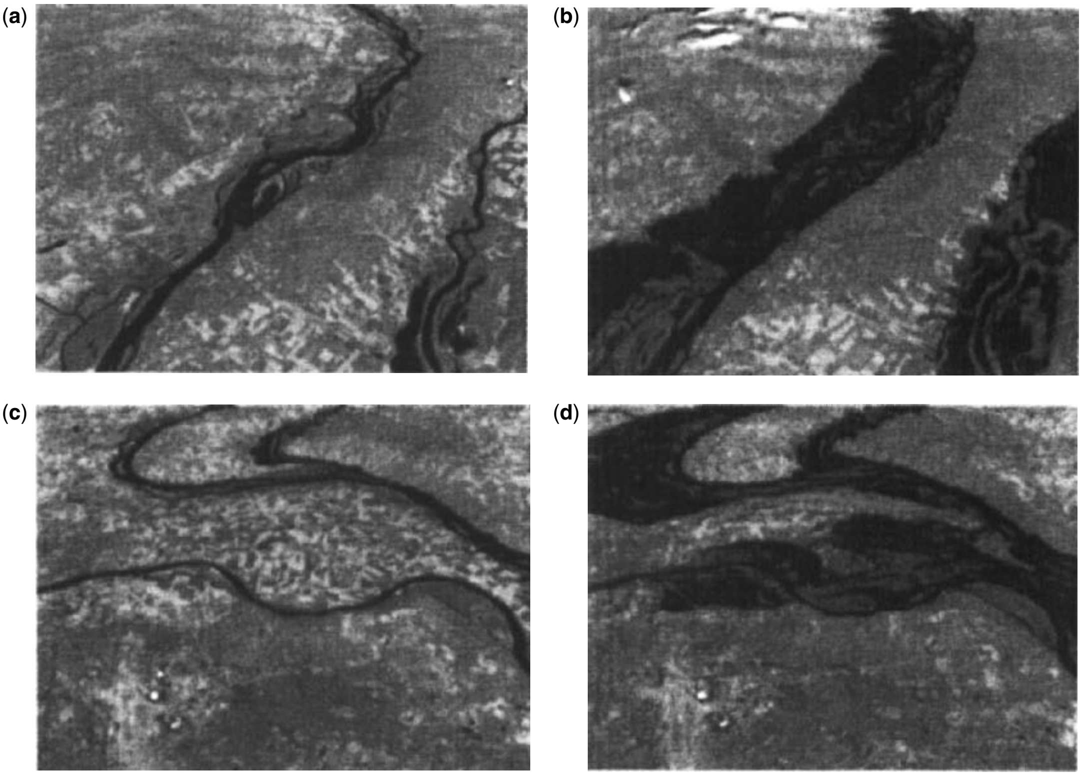


Figure 2. These scenes show various sections of the Mississippi River near St. Louis before and just after the 1993 floods, which peaked in late July/early August. The images show the area as seen by the LandSat Thematic Mapper (TM) instrument. The short-wave infrared (TM band 5), infrared (TM band 4), and visible green (TM band 2) channels are displayed in the images as red, green, and blue, respectively. In this combination, barren and/or recently cultivated land appears red to pink, vegetation appears green, water is dark blue, and artificial structures of concrete and asphalt appear dark gray or black. Reddish areas in the scenes during the flood show where water had started to recede, leaving barren land. See online version for color.

Figure 3. Water and sand washed inland to make travel difficult in North Topsail Island, North Carolina, after hurricane Fran.

amounts of warm moist air over land surfaces. While wind speeds associated with these storms decrease quickly after landfall, these decaying storms are capable of delivering precipitation over wide areas during a relatively short period of time, on the order of days to weeks. In some cases cyclonic storms associated with the polar front may exacerbate conditions by introducing a lifting mechanism that leads to increased condensation and precipitation. The relatively low-lying coastal plain of eastern North America is especially susceptible to damage from these types of storms (Bailey and Patterson, 1975; Hirschboeck, 1988). For example, see Fig. 3. In 1998 hurricane Mitch produced as much as 50 to 75 inches of precipitation in some areas of Central America. At least 11,000 deaths were associated with hurricane Mitch and more than 3 million people were left homeless or were severely affected (www.ncdc.noaa.gov/ol/reports/mitch/mitch.html).

Intense Thunderstorms

Thunderstorms are usually intense, short-lived storms that produce high winds, hail, and heavy rainfall. These storms can be caused by convection in moist tropical air masses over continental surfaces or fast-moving cold fronts that displace those moist air masses (Hirschboeck, 1987). When these storms develop over mountainous areas where the precipitation is concentrated by the topography the potential for large, catastrophic floods is great (Hall, 1981). For example, see Fig. 4. The eastern slope of the Rocky Mountains and the southwestern deserts of North America are common locations for the development of thunderstorms. As moist air encounters higher elevations in these locations, it is forced to rise. Unstable atmospheric conditions are created as mountain slopes heat and in turn heat the atmosphere. Adiabatic cooling causes condensation and the development of large cumulonimbus clouds that can reach the upper altitudes of the troposphere. Sometimes there is little movement associated with a thunderstorm or thunderstorm complex, with respect to the ground; heavy precipitation concentrated in a small geographical area can have catastrophic results.

Figure 4. Arizona flash flood, Wenden, Arizona. This community was flooded twice in late October 2000 when waters from Centennial Wash swept into the town. (Photo courtesy of U.S. Small Business Administration).

Quick Snowmelt

The storage of water in the form of snow temporarily removes that water from the hydrologic cycle. In many cases this sequestration of water is short term. Snow accumulates during winter especially at higher elevations and latitudes. With the onset of warmer spring and summer conditions, snowmelt supplies water to streams. A typical early warming may mean that snowmelt may be accelerated with large amounts of runoff entering stream channels. Mountain ranges in mid-latitude coastal regions such as the Coast Ranges and Sierra Nevada of California receive a significant portion of their annual precipitation in the form of snow. It is possible for warm early spring rains to fall on the snowpack, causing much faster runoff than normal (Bolt et al., 1975; Church, 1988). Another source of snowmelt is the subsurface introduction of heat from volcanic activity. Large volcanoes can be high enough to support permanent snow and ice cover. High temperatures associated with volcanic activity lead to the instantaneous melting of snow and ice. The melt water is commonly mixed with pyroclastic debris to form lahars (Smith, 1996).

Failure of Flood Control Structures

A variety of humanly constructed structures are used in an effort to limit the extent and severity of flooding (Gregory, 1995). Dams and levees are common flood control structures designed to contain water within designated areas (Brookes, 1985, 1988). These structures can fail because of construction errors, poor design, and overtopping by water (Biswas and Chatterjee, 1971; Costa, 1988). Flood control structures can fail because of the failure of a key component. For example, a spillway that erodes away has the potential to lead to the catastrophic failure of the entire dam as the water cuts downward. Sound structures may fail when the water retained by the structure exceeds the height of the structure. Large precipitation events or the displacement of water in a reservoir have the potential to send water flowing over the flood control structure (Kiersch, 1964). This may lead to the failure of the structure through erosion. Flooding may be exacerbated by these structures since a feature such as a levee tends to raise the stream level well above the floodplain. When a levee fails, a large amount of fluvial energy is concentrated through that break and a great deal of damage can occur near the break.

Cyclonic Storm Created Surges

In low-lying coastal locations a temporary increase in sea level associated with the approach and landfall of storms with significantly high winds and low central pressure can cause significant damage. Sea level rises in response to low pressure as it passes over ocean surfaces. Additionally, the upper portion of the water column is pushed into waves by the high winds. Storm surges can be more than 5 m above the normal high tide (Rappaport, 1994). In some areas such as bays coupled with low-lying deltas, like the Bay of Bengal and the mouth of the Ganges, where storm energy is concentrated, storm surges can reach high levels causing significant flooding (Frank and Husain, 1971; Murty and Neralla, 1992). Barrier islands are also susceptible to flooding by storm surges. Development on barrier islands along the southeastern coast of North America has led to rising property damage related to storms.

Mass Movement Events

A variety of mass movement events, while strictly not fluvial events, behave in a similar way to floods (Carson, 1976). The gravitationally fueled downhill movement of poorly consolidated regolith results from the introduction of meteoric water that adds weight and decreases hillslope cohesion. These events can do significant damage. Several types of mass movement events are composed of a larger percentage of sediments than a typical stream. Events such as mudflows, or lahars, commonly may approach the viscosity and velocity of streams. Valleys can be filled with fine-grained sediments as the deposits dewater following the initial surge of water and sediment. A variety of factors lead to mass movement events. The removal of plant cover by fire may expose soil surfaces so that infiltration rates may increase and lead to the accumulation of water along failure planes in the regolith. In areas with a subtropical wet–dry climate, such as the Mediterranean climate type, the burning of plant cover during the dry season and a subsequent wet season before the reestablishment of plant cover leads to mass wasting events (Rice et al., 1969; Campbell, 1975).

Human Responses to Flooding

There are no accurate estimates of the population in the world's floodplains. Even in the United States, only broad estimates are available, but the trends to increased vulnerability are clear. In 1955 U.S. floodplains had 10 million occupants. Thirty years later the number doubled to 20 million and by the mid-1990s about 12% of the national population lived in areas of periodic inundation. One sixth of the nation's floodplains are urbanized, and they contain more than 20,000 communities susceptible to flooding. Half of these communities have been developed since the early 1970s (Burby, 1985; Montz and Gruntfest, 1986; Alexander, 1993).

Many of the people at risk do not understand the potential consequences of the hazards they face. In the United States, flood damages exceed $2 billion annually. Only 20 to 30% of eligible structures are insured against flooding. Federal and state disaster assistance accounts for most of the difference. In the United States, almost two-thirds of the residential flood losses result from events that occur once every 1 to 10 years, even though the 100-year floodplain regulation is standard (Alexander, 1993).

In the United States, floods tend to be repetitive phenomena. From 1972 to 1979, 1900 communities were declared disaster areas by the federal government more than once, 351 were inundated at least three times, 46 at least four times and 4 at least five times. As of 1993, the United States was said to spend $9 billion a year on flood control and $300 million on flood forecasting (Alexander, 1993; Conrad, 1998).

Definitions of Structural and Nonstructural Measures

Adjustments to floods can be broadly classified into structural and nonstructural measures. Nonstructural approaches involve adjustment to human activity to accommodate the flood hazard (White, 1964; James, 1975; White, 1974) whereas structural methods are based on flood abatement or the protection of human settlement and activities against the ravages of inundation.

Structural change involves modification to the built environment to minimize or eliminate flood damage directly or flood channel construction changes. For example, see Fig. 5. Structural measures are expensive. They may give the illusion of security but the record shows otherwise (Alexander, 1993). The security can be temporary. A flood can occur that is bigger than the design of the channel or levee, and changing priorities in flood control projects that require higher reservoir levels for recreation or water supply can diminish the efficacy of structural measures (Williams, 1998).

The failure of structural flood control works poses a significant threat to the lives of the people who live

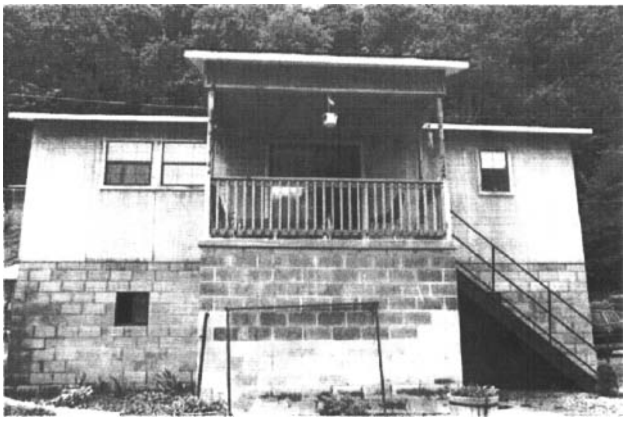

Figure 5. Elevated home in West Virginia is a mitigation success story. Risk is greatly reduced to homes elevated before a flood.

downstream from a massive structural project such as a dam. More than 2000 people died in 1969 in Italy when the Vaiont Dam collapsed (Blaikie et al., 1994). Because of stringent engineering standards and a system of inspections, the United States has seen few major failures. However, many structures are at the end of their design lives of 50, 75, or 100 years.

Structural flood control is still the dominant idea in many parts of the world. Following the 1927 Mississippi River floods, when river levees collapsed and 200 people died, 700,000 were displaced, and more than 135,000 buildings were damaged (Moore and Moore, 1989), the Army Corps of Engineers did not abandon its dream of controlling all floods. Rather, it proposed building large dams upstream to reduce flood peaks to the capacity of the floodway between the levees (Williams, 1998).

Until the 1970s, most flood loss reduction efforts involved structural solutions. Although nonstructural measures were discussed as alternatives, they were rarely implemented. The shift from mostly structural to mixed structural/nonstructural measures began in the 1970s and continues today. The mix of adjustments varies for each situation. In Europe almost all measures that are taken have elements of combined structural and nonstructural measures. There has also been a move to be antistructural. Some dikes are being removed in favor of nonstructural or more environmentally sensitive techniques (Smith and Ward, 1998).

Nonstructural measures include floodproofing, land-use planning, soil bioengineering, warning systems, preflood mitigation efforts, and insurance. The simplest nonstructural measure is to accept the loss. Another nonstructural measure is to provide postflood relief. Protection of floodplain residents and users, and the supply of relief when they suffer damage, are forms of hidden subsidy (Alexander, 1993). This category includes aid provided by the Red Cross, voluntary organizations, and governmental agencies.

Nonstructural measures include flood insurance and land-use management, acquisition and relocation, floodproofing, preflood mitigation preparedness, outdoor warning systems, and soil bioengineering.

DISCUSSION OF NONSTRUCTURAL MEASURES

Flood Insurance, Floodplain Mapping, and Land-Use Ordinances

In 1968 the U.S. National Flood Insurance Program (NFIP) was launched. It made affordable insurance available to residents in flood-prone areas. In 1999 more than 18,000 communities belonged to the program. Participating local governments require developers to meet minimum standards designed to avoid damages that might be inflicted by a catastrophic 100-year flood. The program also requires property owners to purchase flood insurance to receive a federally insured mortgage (Myers, 1996). Flood insurance is a means for placing some of the burden of losses onto the people who take (or make) the risk, namely the floodplain users and residents (Alexander, 1993). Communities can participate in a Community Rating System, established by the Federal Emergency Management Agency (FEMA), that allows them to show innovative strategies to reduce flood losses in return for lower insurance premiums for floodplain residents.

Before a community can participate in the flood insurance program, the flood hazard must be recognized, assessed, and mapped. These assessments include flood history, cost and types of past flood damages, maps of the limits of the 100-year flood (or other designated flood) on a topographic map, compilations of profiles and cross sections of the river to show the levels of past floods, and compilations of flood frequency curves and locally representative hydrographs.

FEMA works with the state and community governments to identify their flood hazard areas and publishes a Flood Hazard Boundary Map of those areas. When a community joins the NFIP, it must require permits for all construction or other development in these areas and ensure that the construction materials and methods used will minimize flood damage. However, there is not careful monitoring to be sure that reducing flood hazard in a particular area does not increase flood potential elsewhere. Often, the problems are just shifted to different locales. In return the federal government makes subsidized flood insurance available to those whose structures were in the flood hazard area prior to issuance of the flood maps. All others are eligible for flood insurance at actuarial rates. FEMA issues a Flood Insurance Rate Map after the Flood Insurance Study of risk zones and elevations has been prepared (http://floodplain.org/Jan32.htm).

Acquisition and Relocation

The most effective measure to reduce losses is to keep the floodplains free of development. However, in many river valleys in the world, it is too late for that option. One of the most promising strategies for reducing flood losses is the public acquisition of developed land susceptible to flooding (Conrad, 1998; www.fema.gov/mit/homsups.htm). The authorization for U.S. federal cost sharing for relocation is more than 30 years old. However, only recently have communities, tired by chronic flooding, taken advantage of funding packages and relocated. In one case, the entire town of Valmeyer, Illinois, was relocated. The town had a long history of floods. In 1943, 1944, and 1947 unusually high levels of the Mississippi caused flooding in the nearby bottomlands affecting Valmeyer. After the 1947 floods, the U.S. Army Corps of Engineers raised the levees protecting the reach of the flood-plain to 47 ft. On August 1, 1993, the flood overtopped the levees inundating Valmeyer, prompting its ultimate relocation. Since 1993 nearly 20,000 properties in 36 states and one territory have been bought out and over 25,000 families have moved from floodplains (http://www.nwf.org/nwf/pubs/higherground/intro.html).

Floodproofing

Floodproofing is a range of adjustments aimed at reducing flood damages to a structure or to the contents of buildings. There are three categories: (1) raising or moving the structure; (2) constructing barriers to stop floodwater from entering a building; and (3) wet flood proofing (U.S. Army Corps of Engineers, 1997).

Detection and Response Warning Systems

New technological advances in stream and rain gage networks and the increased regional floodplain management efforts have led to the adoption of thousands of local flood-warning systems. Many are simple detection systems and do not provide any mechanism for alerting the population at risk. In the United States until the 1990s warning or detection systems were planned and administered primarily at the local level.

Since then, the federal government including the Bureau of Reclamation, the U.S. Army Corps of Engineers, the National Oceanic and Atmospheric Administration, and the Federal Emergency Management Agency have actively participated in the installation and maintenance of detection and warning systems. Many systems are still managed by regional or local entities, but the percentage of federal dollars has increased substantially. Standards have also been established to help make the systems more compatible across regions (U.S. Department of Commerce, 1997).

An automated integrated network of stream and rain gages is being used in more than 1000 communities in the United States to help provide lead time for floods. Most of the systems are developed through collaborative efforts of many agencies. These ALERT systems (automated local evaluation in real time) have performed many functions other than flood warning, including helping in water supply decision making, fire weather forecasting, pollution monitoring, and providing data for river recreationists (Gruntfest and Huber, 1991). The availability of real-time data on the Internet also has increased interest in these monitoring systems (Gruntfest and Weber, 1998). The State of Arizona is developing a network for flood warning throughout the state. More than 30 agencies and communities are working together on the comprehensive ALERT system (http://www.alertsystems.org/saas/).

Warning systems may be nothing more than “cheap payoffs of the raingods.” Too often communities install rain gage/stream gage monitoring systems without a plan for getting the warning message disseminated. A warning system is only necessary once poor land-use decisions have been made, allowing people to settle in harm’s way. Many of the systems being built are not being adequately maintained to be reliable (Gruntfest and Huber, 1991; Parker and Fordham, 1996). Public education encouraging people to heed environmental cues is also being used. It is particularly difficult to provide adequate lead times for flash floods. Some communities do have drills to test the reliability and completeness of their systems to be sure the systems will operate when the conditions warrant.

As of 2001 a combination of factors increase the likelihood that automated detection systems may become more popular and more valuable. More powerful, less expensive computers, and World Wide Web access provide opportunities for inexpensive real-time weather data. While real-time stream and rain gage networks may be originally installed for flash flood forecasting, many agencies and users find the data useful for alternative purposes.

Soil Bioengineering

Anchored plantings along stream banks serve as the basis for this technique. Soil bioengineering and biotechnical engineering are cost-effective and environmentally compatible ways to protect slopes against surficial erosion and shallow mass movement. These approaches provide alternatives to structural channel “improvements.” They raise questions about the notion of why engineers ever considered that concrete-lined channels should be considered “improved” (Gray and Sotir, 1996). Generally, bioengineering solutions must also include a strategy to carry floodwaters away.

The bioengineering technique is gaining support throughout the United States and Europe. It is less expensive to install and less expensive to maintain as well. The broader adoption of soil bioengineering may radically alter floodplain management.

Combined Structural and Nonstructural Measures to Reduce Flood Losses

From the first attempts to reduce flood losses in the United States, structural measures were preferred for three main reasons: (1) their benefits appeared to be relatively easy to measure, (2) they did not require extensive and politically controversial land-use planning, and, (3) the federal cost-sharing agreements encouraged communities to select the most expensive engineering projects. These reasons were supported by a faith in the technology of structural measures to protect people and property from floods.

The record now shows that in spite of massive expenditures, flood losses have continued to rise. Since the 1960s, especially in the United States, there has been a call for a shift from primarily structural measures to control floods to nonstructural measures (Galloway, 1994; Larson, 1996; Williams, 1998). Land-use control is one of the most effective ways of reducing flood hazards. Statutes, ordinances, regulations, and compulsory purchases can be employed and relocation can be subsidized. A floodway left undeveloped through the city can become beautiful public open space.

CONCLUSION

Floods are generally caused by the combination of large amounts of precipitation and basin topography. For example, saturation of soils caused by large amounts of precipitation can lead to flooding. Urbanization of a drainage basin increases the amount of runoff reaching a channel and decreases the lag time between a precipitation event and peak flow. A variety of weather events lead to flooding, including extended wet periods, decaying tropical cyclones, intense thunderstorms, and quick snowmelt. In some cases humanly constructed structures designed to prevent flooding collapse, causing flooding or accentuating flooding. In low-lying coastal areas storm surges may cause significant flooding. Mass movement events are similar to flooding, although the proportion of sediments to water is larger than an alluvial flood with the outcome just as disastrous.

Humans respond to flooding in a variety of ways. Broadly defined these fall into two categories, structural and nonstructural measures. Structural measures include dams and dikes. Through time the efficacy of structural features has been questioned, and there has been a shift from purely structural approaches to controlling floods to a mix of structural and nonstructural flood mitigation strategies. Nonstructural measures include flood insurance, floodplain mapping, and land-use ordinances, acquisition and relocation, floodproofing, detection and response warning systems, soil bioengineering, and combined structural and nonstructural measures to reduce flood losses. Some progress is being made in addressing the hazards associated with flooding. The reduction of flood impacts continues at great expense, but vulnerability will continue to rise as long as more people build in floodplains, increasing the risk of catastrophic floods. Even the best warnings will not eliminate the risks increasingly being taken around the globe.

FLOOD CONTROL STRUCTURES

Stefano Pagliara
Pietro Chiavaccini
Universitá di Pisa
Pisa, Italy

INTRODUCTION

Flood control structures are necessary to diminish the effects of excess water in streams. They can be distinguished in structures that provoke a reduction of peak flows and in structures that divert floodwaters through flood bypasses. Sometimes levees can also be used to control flood events.

STRUCTURES ABLE TO REDUCE PEAK FLOWS

They can be divided into retarding basins and reservoir flood storage.

Retarding Basins

The purpose of a retarding basin is to prevent flooding by controlling peak flows from storms to a level that could be safely carried by the downstream system (1).

It consists of a dam placed immediately upstream from the reach to be protected, preferably in an area where a great water volume is obtained with a small dam (2). The outlet discharge is generally regulated by valves or gates. The effect of a storage reservoir can be described with the equation of continuity:

$$Q_{in}(t) - Q_{ou}(t) = \frac{dV}{dt} \tag{1}$$

where Q_{in} is the inlet discharge, Q_{ou} the outlet discharge, and V the stored volume of water. Generally, the outlet discharge is a function of the water depth in the reservoir. A schematic draw of a storage reservoir is shown in Fig. 1, whereas the effect of water discharge is illustrated in Fig. 2. It is evident by a reduction of the peak flow and a modification of the duration of the flood event.

The type of the outlet should be chosen with respect for the storage characteristics of the reservoir and the nature of the flood problems. An ungated sluiceway is more preferable than a spillway operating as a weir, even if the latter is necessary for emergency discharge of a flood exceeding the design magnitude of the outlets.

Reservoir Flood Storage

Where flood damage at a number of locations on a river can be significantly reduced by construction of one or more reservoirs, or where a reservoir site immediately upstream from one damage center provides more economical protection than local protection works, reservoir flood storages should be considered. These structures permit storage of a portion of the flood flow in a selected area, generally placed laterally to the river. The reservoir is fed with a lateral weir (Fig. 3). The release of the volume of the stored water is ensured by gates or valves and regulated in a way that the emptying happens after the flood has passed.

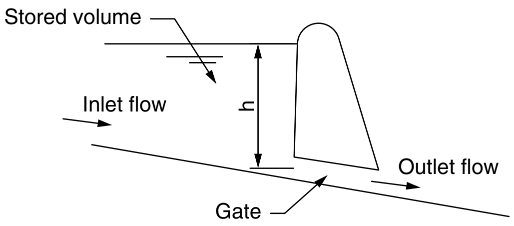

Figure 1. Schematic representation of a retarding basin.

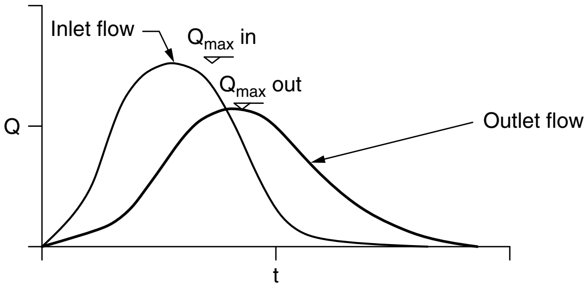

Figure 2. Effect of a retarding basin on flood discharge.

The effect of a storage reservoir is a diminution of peak flow without a modification of the duration of the flood (Fig. 4). The weir is dimensioned for the difference between the peak inflow (Q_{max} upstream) and the maximum discharge allowable downstream (Q_{max} downstream). Its height should be determined by evaluating the cost of the structure, because the taller it is, the longer it is. Besides, the height influences the point in which storage begins (point A of Fig. 4).

DIVERSION STRUCTURES

Flood bypasses ensure the diversion of floodwaters, which permits reduction of the flow passing in the original stream

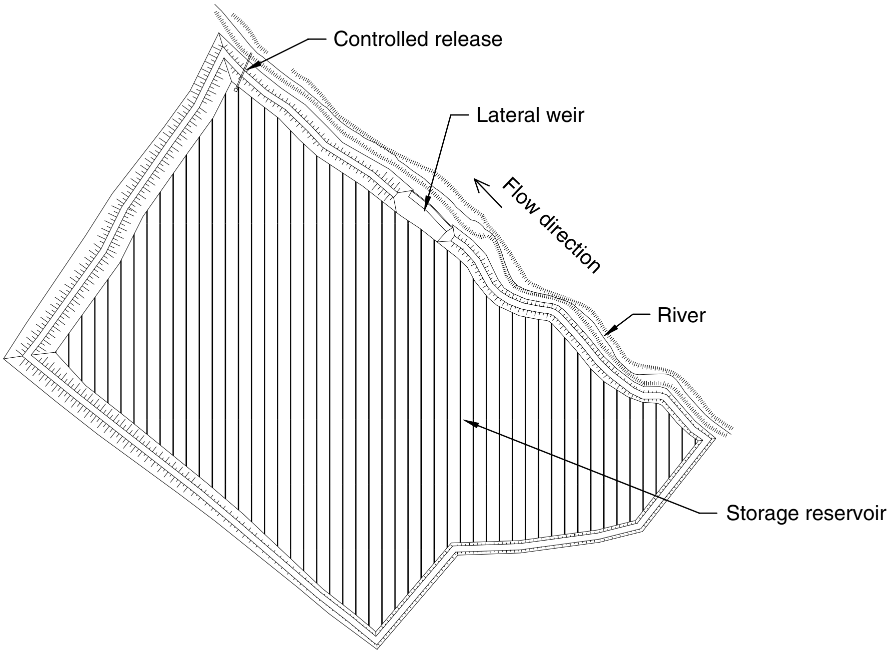

Figure 3. Storage reservoirs.

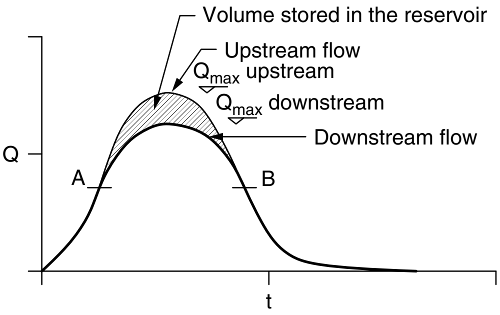

Figure 4. Effect of storage reservoir on flood.

to the allowable value (3). The diversion may return the water to the same channel at a point downstream or deliver it to another channel or different watershed. Besides, it not only conveys water in another reach, but also stores a substantial volume temporarily, thus serving as a large shallow reservoirs.

The diversion can be a second river working permanently (Fig. 5a) or if floodwater leaves the river at a controlled point, it works only during flood events (Fig. 5b). In the first case, modification to river morphology happens because there is a variation of the water tractive force in the original stream because of the diminution of the discharges. In the second case, the diversion remains dry for a long time and maintenance is necessary.

Admission of water to the bypass is achieved in different ways. In many cases, a low spot in the natural bank or a gap in the levee line is used. In some cases, a low section of the levee is created in a way that, when once overtopped, is washed out, and full discharge capacity is developed into the bypass. In other cases, a sill or a weir is used so that overflow occurs at a definite river stage. This last solution is suggested when overflow occurs frequently and the need for replacement of the levee section exists.

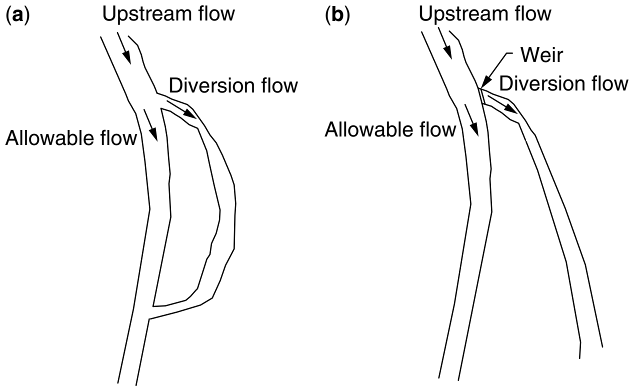

Figure 5. Diversion of flow.

LEVEES

Levees represent a barrier preventing overtopping (4). Levees are longitudinal dams erected parallel to a river and can be earth dikes or masonry construction. In the last case, they are called flood walls.

Levees are more used because their cost is low and material is easily available. They are generally built of material excavated near the river and placed in layers and compacted (Fig. 6). To increase the impermeability of the levee, a core of clay or sheetpile septa can be used. A drain ditch or tile line along the back toe of the line is advisable and the back slope should be flat enough to contain the seepage line.

The width of the top should be enough to permit the movement of maintenance equipment with a minimum of about 3 m. Bank slopes are usually very flat because the low cost of the material, and they should be protected against erosion by sodding, planting of shrubs and trees, or use of riprap. Global stability should be verified during the design of the levee.

When dimension of leaves are not compatible with available area flood walls can be used to reduce the space. They are designed to withstand the hydrostatic pressure (including uplift) exerted by the water when at flood level. Sometimes flood wall is backed by an earth fill, and in case of low discharges, it works as a retaining wall.

CONCLUSION

Flood control structures ensure a reduction of risk and damage in case of a flood event. The commonly used structures for mitigation of flood damage have been investigated, pointing out the difference and the significant characteristics to proceed in a correct design.

FLOODS AS A NATURAL HAZARD

Luis Berga
ETSIn Caminos
Barcelona, Spain

The natural hazards suppose an important impact for human life and produce serious social effects and grave economic losses. Natural disasters constitute a constraint on the sustainable development, affecting its three basic mainstays: economics, social, and environmental.

In spite of the efforts made by the International Decade for Natural Hazard Reduction of the United Nations (1–3), the natural disasters in the world have experienced an increasing evolution during the last decades of the twentieth century, producing, at present, a mean of some 40,000 victims per year and mean economic losses of more than $60 billion per year. The number of major natural disasters during the period between 1950 and 1999 has been multiplied by 4.4, and by more than 15 times with relation to the economic damages (Fig. 1 and Table 1) (4,5).

The economic losses because of natural disasters are increasing with an exponential trend, having tripled during the last decade of the 1990s, with a current evaluation of more than $60 billion per year, as is shown in Fig. 2 (5).

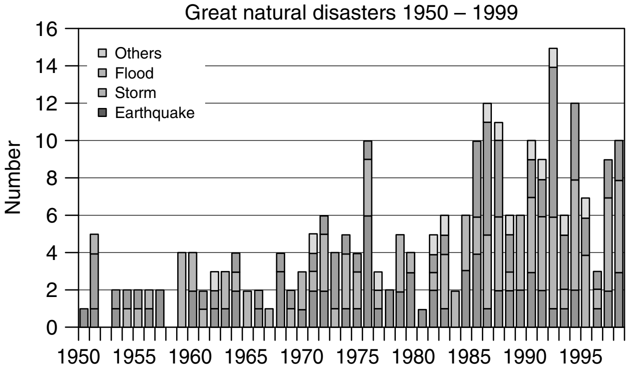

Figure 1. Number of natural disasters 1950–1999 (5).

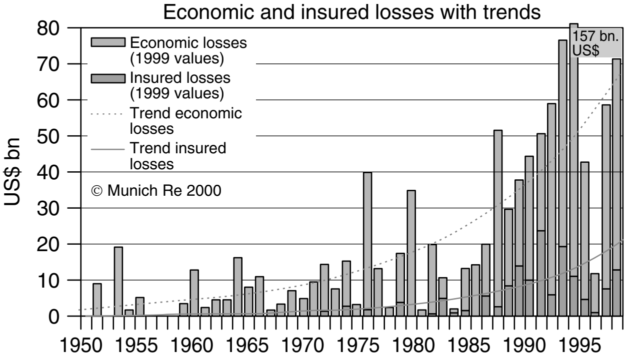

Figure 2. Natural disasters. Economic and insured losses with trends.

The greatest natural disasters of the last decades that have produced economic damages greater than $10 billion are shown in Table 2. It can be observed that of the 19 disasters, 8 are big floods, such as those of 1993 in the United States; 2002 in Central Europe; 1991, 1996, and 1998 in China (Fig. 3); those of North Korea in 1995; and those of the year 1999 in Venezuela, with more than 30,000 victims.

The floods constitute the most important disaster among the natural hazards. Floods represent about 30% of the total number of natural disasters and economic damages, and almost 25% of the fatalities produced by the natural disasters (Fig. 4). The extensive and enhanced statistical data show that, in the period 1975–2001, some 95 significant floods per year have been produced, which have caused a mean of some 11,000 fatalities per year, and have affected some 150 M people per year, which signifies that in the last decade of the twentieth century, 25% of the world population has been affected by the floods (6).

In recent decades, the impact caused by floods has been very important, and Table 3 refers to the most catastrophic floods that have occurred in the last fifteen years.

So then, experience shows that the impact caused by natural disasters and floods continues to increase progressively and, in many countries, constitutes a veritable restraint to sustainable economic development. For this, the UN decided in 1987 to create the International Decade for Natural Disaster Reduction (IDNDR) for the period 1990–2000 with the objective of reducing, by way of concerted international action, especially in the developing countries, the loss of lives, material damages, and the social and economic disorders caused by the natural

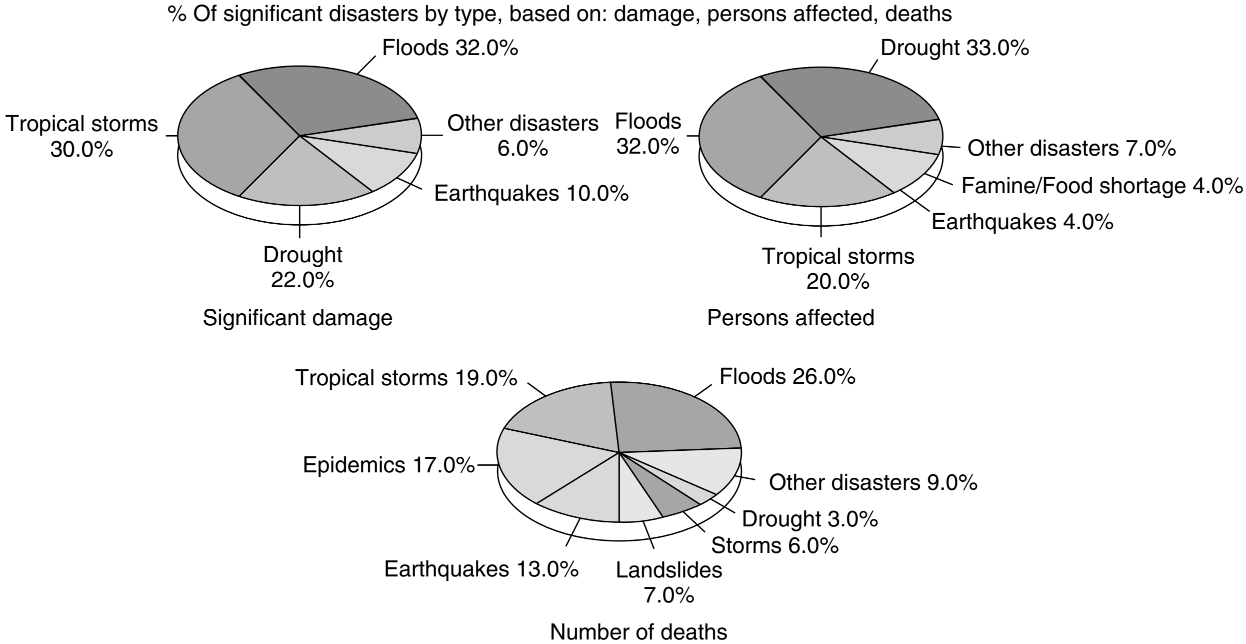

Figure 3. Major disasters around the world 1963–1992. Percentage of significant disasters by type, based on damage, persons affected, deaths.

hazards. Among the essential elements of the activities of the IDNDR, the following points stand out (3,7):

1. Greater emphasis in planification and preventive measures.
2. Adoption of integrated actions (structural and nonstructural) for the reduction of the disasters.
3. Establishment of forecasting and alarm systems compatible with the technology and culture of the countries.
4. Development of a social conscience of the necessity of the reduction of the impacts.

In order to continue the activities developed by the IDNDR and promote international cooperation, the UN has implanted the International Strategy for Disaster Reduction (ISDR), resolution of the General Assembly 54/219 of the year 2000 (8). Among the principal objectives of the ISDR, the urgent need to develop further and make use of the existing scientific and technical knowledge to reduce the vulnerability to natural disasters,

stands out bearing in mind the particular needs of developing countries.

The ISDR has recently published a global review of disaster reduction initiatives "Living with Risk," which is "the first comprehensive effort by the United Nations system to take stock of disaster reduction initiatives throughout the world. This report discusses current disaster trends, assesses policies at mitigating the impact of disasters, and offers examples of successful initiatives. It also recommends that flood risk reduction be integrated into sustainable development at all levels—global, national and local" (6).

FLOOD SOURCE MAPPING IN WATERSHEDS

BAHRAM SAGHAFIAN
Soil Conservation and
Watershed Management
Research Institute
Tehran, Iran

INTRODUCTION

Flood control projects are designed to protect people and properties against floods' adverse effects. No unique methodology exists, however, to identify flood source areas and to evaluate their contribution to the flood characteristics at any downstream point of interest. The number of nested hydrometric stations and the amount of available flood data measured simultaneously at the stations are usually insufficient for ranking flood source areas. This constraint leads us to take advantage of hydrologic simulation models.

Lumped modeling approach in flood studies precludes spatial prioritization with respect to downstream flood response. Thus, semi- or fully distributed modeling approaches are appropriate for flood control studies in large watersheds. However, the main issue is how to identify and prioritize watershed flood source areas based on their contribution to the flood response at the main outlet. The proposed methodology is also useful to determine source erosion and pollution areas.

UNIT FLOOD RESPONSE APPROACH

In this section, the approach proposed by Saghafian and Khosroshahi (1) for flood source mapping is briefly described. This approach enables identification and ranking of flood source areas within a watershed. Although the approach can be extended to a fully distributed discretization scheme, we consider delineated subwatersheds to represent homogeneous unit areas. Unit areas that produce the largest contribution to the flood peak at a given point subject to flooding (usually the outlet of the watershed draining the area of interest) are given highest rank among all source area units. One must note that ranking of subwatershed units based on their contribution to the discharge at the main outlet is not necessarily equivalent to the ranking based solely on the magnitude of peak discharge produced at the outlet of each unit. Another issue is that the nearest or largest subwatershed unit may not cause the largest impact on the outlet flood peak. These issues are studied later when a case study is presented. Particular emphasis will be put on the routing in the stream network that connects subwatershed areas because storage is a key factor in how flood source areas influence the outlet flood response. It is expected that the effect of stream routing is more pronounced for more frequent floods.

The flood source mapping procedure starts with collection of watershed data and historic rainfall-runoff data recorded at rain and stream gauges located inside or outside the watershed. A semidistributed rainfall-runoff model with stream routing capability is selected, and the model is properly calibrated and validated against the flood data of at least one hydrometric station located near the outlet of the watershed. Then the model is setup for the watershed of interest, if different from the watersheds bounded at hydrometric stations for which the model was calibrated.

Subwatersheds' flood hydrographs are simulated for a selected design storm, and flood routing is performed in the channel network connecting the outlets of subwatersheds to the watershed's main outlet. The routing results in a base outlet hydrograph. Then, in successive runs, each subwatershed unit is singly removed, and the resultant hydrographs at the main outlet are simulated (Fig. 1). The changes in flood peak of the generated hydrographs relative to the peak of the base hydrograph are computed. The procedure may be repeated for other design storms, and the sensitivity of the results could be examined.

We may now define a flood index to measure unit area contribution to the flood peak at the main watershed outlet:

$$FI_k = \frac{Q_{p,all} - Q_{p,all-k}}{Q_{p,all}} \times 100 \qquad (1)$$

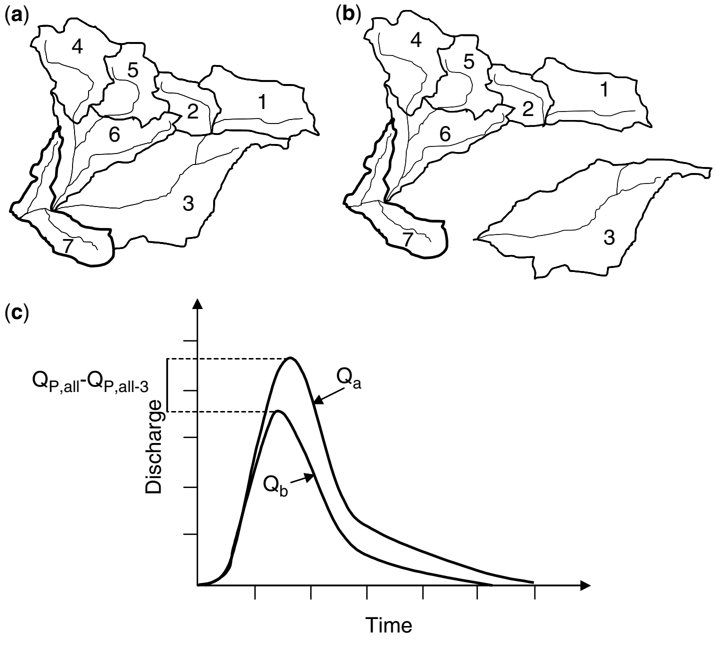

Figure 1. Unit flood response application on a watershed: (**a**) subwatershed units, (**b**) unit 3 removed, and (**c**) simulated flood hydrographs corresponding to cases (**a**) and (**b**).

where *FI* is the gross flood index of the *k*th subwatershed (in percent), $Q_{p,all}$ is the peak discharge of the base hydrograph (in m^3/s), $Q_{p,all-k}$ is the peak outlet discharge when the *k*th subwatershed is removed (in m^3/s), and A_k is area of the *k*th subwatershed (in km^2).

A different flood index can also be expressed in terms of contribution per unit area of subwatersheds as follows:

$$fi_k = \frac{Q_{p,all} - Q_{p,all-k}}{A_k} \tag{2}$$

where *fi* is the flood index of the *k*th subwatershed based on unit subwatershed area (in $m^3/s/km^2$).

The approach outlined above is entitled "unit flood response," abbreviated by UFR, based on its similarity to the unit response (UR) approach in groundwater management. In the UR approach, a groundwater model simulates the influence of a unit change in sink/source rates at selected well locations on design variables, such as hydraulic head or velocity, at specified locations (2). Suitable groundwater quantity/quality management scenarios may be studied based on the UR application. Although nonlinearity can be preserved by the model used in the unit flood response approach, the UR in groundwater studies assumes linearity by superimposing the individual unit responses at given locations.

A CASE STUDY

Damavand watershed with an area of 758 km^2 lies at 51°,46′,40″ to 52°,12′,05″ E longitude and 35°,32′,48″ to 35°,51′,39″ N latitude. High and low elevations in this relatively steep watershed are 4003 m and 1250 m above sea level, respectively. Rangeland, mostly in poor condition because of overgrazing, is the dominant vegetation cover. Agricultural areas are concentrated in the middle and outlet parts of the watershed. Average annual precipitation is reported as 443 mm. Although most precipitation occurs in the winter and early spring, severe floods in the region are often caused by high-intensity summer storms. The region is generally categorized as a flood prone area. As a result of limitations imposed by gradual availability of funds, one of the primary aims of flood control studies in this watershed is to identify and rank areas with higher impact on the outlet flood peak.

Boundary of Damavand watershed and its seven subwatersheds along with the contour map were digitized in a geographic information system (GIS). Maps of digital elevation model (DEM) and land slope were generated by the GIS. Figure 2 shows subwatershed boundaries on the DEM background. Table 1 summarizes some of the physiographic characteristics of the subwatersheds. A land-use map was produced through processing a Landsat satellite image of the area and field inspection. SCS curve number layer was generated by overlaying maps of land use and hydrologic soil groups (Fig. 3). Then, average subwatersheds' CN values were determined (see Table 1).

HEC-HMS hydrologic model (3) is applied in this case study. Specifically, SCS unit hydrograph method and Muskingum technique were applied to simulate rainfall-runoff transformation at subwatershed scale and stream routing, respectively. Rainfall intensity corresponding to the design storm of 50-year return period with duration equal to the watershed concentration time was drawn from the intensity-duration-frequency (IDF) curve of a local station. Average rainfall temporal pattern was developed at the same station, but no particular spatial pattern was considered in this case study.

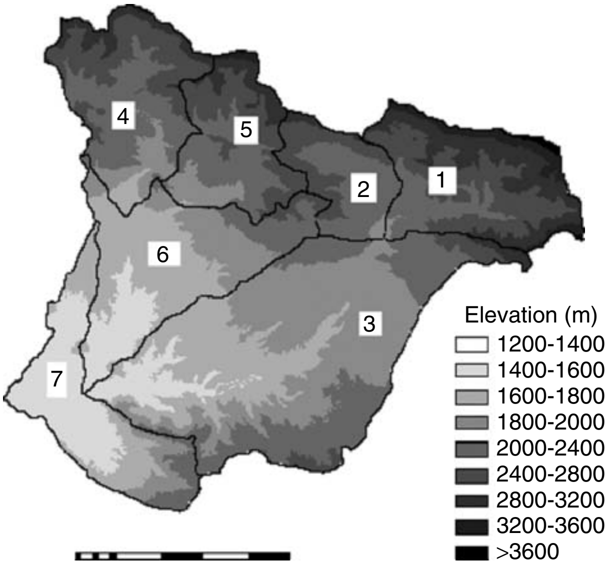

Figure 2. Subwatersheds of Damavand watershed on digital elevation model background.

Table 1. Damavand Subwatersheds Characteristics

Subwatershed Unit [1]	Area (km^2) [2]	Land Slope (%) [3]	Max Stream Length (km) [4]	Distance to Outlet (km) [5]	Stream Slope (%) [6]	Curve Number II [7]
1	97	47	16.8	32.1	10.5	81
2	46	27	12.3	32.1	5.3	71
3	253	19	36.2	4.8	5.1	78
4	96	37	19.3	18.6	8.2	80
5	70	35	14.8	20.7	6.7	80
6	112	12	24.9	4.8	6.7	78
7	84	13	16.4	0	6.0	86

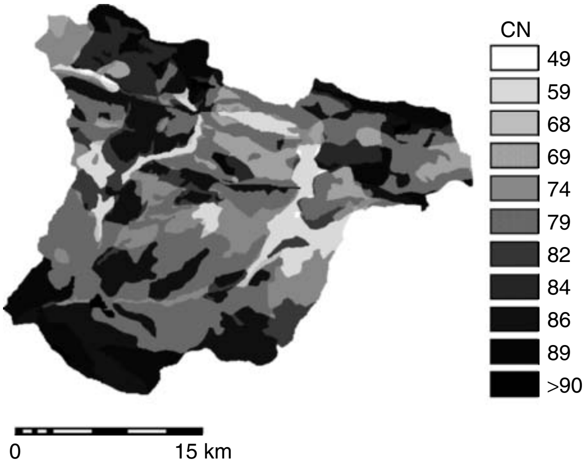

Figure 3. Map of curve number.

FLOOD INDEX ANALYSIS

HEC-HMS model was calibrated and validated for a number of rainfall-runoff events recorded at the outlet of the watershed. Calibration parameters were SCS initial loss and lag time. The 50-yr, 12-hr storm was simulated with peak discharge at the outlet of each subwatershed shown in Column 2 of Table 2. A peak discharge of 371.9 m^3/s was produced at the watershed outlet. The simulated outlet peak discharges after removing each subwatershed are reported in Column 4 of Table 2. For example, the peaks corresponding to cases with and without subwatershed 3 are 371.9 m^3/s and 270.0 m^3/s, respectively. Therefore, the peak is reduced by 101.9 m^3/s when subwatershed 3 is completely removed. Subwatershed 3's *FI* and *fi* flood indices are equal to $101.9/371.9 = 27.4\%$ (Column 5, Table 2) and $101.9/253 = 0.40$ $m^3/s/km^2$ (Column 7, Table 2), respectively. The priorities based on the absolute peak discharge contributions (*FI*) and per unit subwatershed area peak discharge contributions (*fi*) are respectively listed in Columns 6 and 8 of Table 2.

The overall mixed ranking of subwatersheds in Columns 3, 6, and 8 in Table 2 highlights the complex interdependent effect of subwatershed area, subwatershed characteristics, channel routing, and the location of flood source areas within a relatively large watershed. It is noted that the nearest (to the outlet) or largest and the most distant or smallest subwatersheds do not necessarily generate the highest and lowest contribution to the flood peak at the outlet, respectively. Similarly, subwatersheds producing the highest and lowest discharges at their own outlet may not rank first and last in *FI* or *fi*. Subwatersheds' absolute and specific discharges are compared in (Fig. 4), whereas *FI*'s and *fi*'s are shown in (Fig. 5).

One can observe, from (Fig. 5), that the rankings of absolute discharge contribution (*FI*) generally differ from those of per unit area discharge contribution (*fi*). Subwatersheds 5 and 4 rank first and second in the unit area discharge contribution, whereas subwatershed 2 attains the lowest rank. Subwatershed 3, with the highest ranking in the absolute discharge contribution (*FI*), ranks

Table 3. Flood Index (*fi*) Matrix for Pairs of Subwatershed.

Subwatershed	1	2	3	4	5	6	7
1	0.568	0.439	0.426	0.593	0.596	0.558	0.472
2	0.439	0.193	0.366	0.499	0.474	0.436	0.273
3	0.426	0.366	0.403	0.456	0.448	0.450	0.396
4	0.593	0.499	0.456	0.645	0.649	0.585	0.481
5	0.596	0.474	0.448	0.649	0.659	0.580	0.456
6	0.558	0.436	0.450	0.585	0.580	0.523	0.399
7	0.472	0.273	0.396	0.481	0.456	0.399	0.283

fifth in the unit area contribution (*fi*). Use of flood index (*fi*) is recommended in the analysis of spatial flood source prioritization required for optimum planning flood control measures at subwatershed scale.

The effect of spatial aggregation of unit source areas could also be examined by removing a pair of subwatersheds at each simulation run. The flood index matrix is shown in Table 3. The *fi* values in nondiagonal cells, say jth row and kth column, correspond to removing the jth and kth subwatershed simultaneously. When $j = k$ in diagonal cells, the results correspond to the case when a single subwatershed j has been removed (as already reported in Table 2). Clearly, the combination of subwatersheds 4 and 5 accumulated the highest impact on outlet flood peak. Conversely, the combination of subwatersheds 7 and 2 indicates the lowest impact.

SUMMARY

A technique, abbreviated by UFR, was described in this chapter for mapping flood source areas within a watershed. Subsequent elimination of subwatershed units in the rainfall-runoff modeling process allows separation of the effect of individual watershed area. Thus, contribution of each subwatershed unit may be quantified and its priority determined. The technique can be effectively applied in flood source area mapping at the desired spatial scale.

The UFR technique was applied in a case study, and the map of a 50-yr flood index was prepared (Fig. 6). Based on the results of this case study, it may be concluded that because of the complex nature of flood hydrograph propagation within the stream network, use of the UFR approach can be considered as the optimal way for prioritization of flood source areas.

Another issue is that implementing flood abatement measures in subwatersheds with low flood index may actually result in delaying peak arrival of such areas and could cause a more synchronized response with other subwatersheds, which is the case with subwatershed 7 in the presented case study.

URBAN FLOODING

Ole Mark
Asian Institute of Technology
Hørsholm, Denmark

Flooding in urban areas is an inevitable problem in many cities, and it causes huge costs to the society in structural and nonstructural damage. The problems that arize from urban flooding range from minor ones such as water getting into the basement of a few houses, to major incidents, where large parts of cities are inundated for several days. Most modern cities in the industrialized part of the world usually experience smaller scale local problems due mainly to insufficient capacity in their sewer systems during heavy rainstorms. Cities in other regions, including those in South/Southeast Asia, often have more severe problems because of much heavier local rainfall and lower drainage standards. This situation is continuously getting worse because many cities in the developing countries are growing rapidly these days but do not have the necessary funds to extend and rehabilitate their existing drainage systems.

CAUSES OF URBAN FLOODING

Urban flooding may be caused by a river or by local rainfall over a city. *River-induced flooding* is flooding of a city due to high water levels in rivers adjacent to the city. River water flows to lower lying areas, and floods them. *Rainfall-induced flooding* is flooding of a city due to local rainfall in the built-up areas of the city. Examples of rainfall-induced flooding in Bangkok can be seen in Figs. 2 and 3. This may occur several times a year on various scales. Mainly, inadequate existing drainage paths and their improper operation and maintenance cause these floods.

An interaction often exists between the drainage capacity of an urban drainage system and the water level in a recipient. For example, Bangkok was flooded from local rainfall during October 2002 due to reduced drainage capacity from the city to the river. The condition in the river was caused by a combination of very high runoff from the upstream river basin and a spring tide in the Gulf of Thailand, resulting in a very high water level in the river and hence drastically reduced drainage capacity from Bangkok to the river. No drainage by gravity could take place, and only drainage to the river by pumping was feasible.

Figure 2. Flooding in Bangkok during a minor premonsoon rain in April 2002. (Photo by Dr. Ole Mark).

Figure 3. Flooding in Bangkok, 2002. (Photo by Mr. Ebbe Worm).

Individual streets in a city may flood due to numerous causes (1). Frequently, rainfall runoff starts as an overland flow on the street before entering the underground pipe system through catch pits. The water in the pipe system is then conveyed downstream but may return to the surface if the capacity of the pipes is exceeded. The duration of flooding on the street depends on the ground elevation, the intake capacity of the catch pits, and the capacity of the underground pipes. If the intake capacity of the catch pits is limited, large volumes of runoff will be transported along the surface during large rainstorms, even if there is sufficient capacity in the underground sewer network. Insufficient drainage capacity locally in the sewer system may then, in turn, cause surface flooding, even if the catch pit intake capacity is adequate.

THE EXTENT OF URBAN FLOODING

In Asian cities subject to regular flooding, people seem to have adjusted their daily lives to smaller flooding. However, major incidents have grave consequences. Jakarta, Indonesia, was flooded from an overnight rain during February 2002. During that flood, five people were killed and approximate 200,000 people were forced from their homes. Another urban flood occurred in Bangkok, Thailand, in 1983, which inundated the city for 6 months. The flood caused damage of approximately US$149 million. In 2000, an urban flood in Mumbai, India, claimed at least 18 lives, made hundreds of slum dwellers homeless, and plunged large areas of the city into darkness. In Dhaka City, Bangladesh, moderate rain can inundate parts of the city for several days. The situation was highlighted in

September 1996, when the residents of Dhaka experienced ankle to knee-deep water on the street (Fig. 1). Heavy traffic jams occurred because of stagnant water on the streets, and daily activities in parts of the city were almost paralyzed. At present, other major cities in Southeast Asia facing problems from regular urban flooding are Ho Chi Minh City, Hanoi, Vietnam, and Phnom Penh, Cambodia.

Examples of places outside South/Southeast Asia that suffer from urban flooding are Fukuoka and Tokyo, Japan (2); Playa del Gandia, Spain (3); and Houston, Texas, U.S.—where the storm "Allison" in June 2001 caused urban flood damage of the order of $2 billion at the Texas Medical Center in the Harris Gully watershed (4).

THE IMPACT OF URBAN FLOODING ON SOCIETY

The costs of urban flooding are often very difficult to estimate precisely. Urban flood damage may be divided into three groups (5):

- direct damage—typically material damage caused by water or flowing water
- indirect damage—traffic disruptions, administrative and labor costs, production losses, spreading of diseases
- social consequences—negative long-term psychological effects, due to decrease of property values in frequently flooded areas and slowed down economic development.

One way to quantify the cost of urban flooding from structural damage is to collect information about damage costs from insurance companies, as has been done in Norway (5). This process is not likely to be applicable to developing countries, where few families in flood-prone areas have insurance.

During urban floods in developing countries, it is often the poorer people who suffer the most, as they often live in areas of cheap or free land, which are more exposed to natural disasters and have no or only primitive drainage and a drinking water infrastructure. Open drains of insufficient capacity in such areas are often flooded causing material damage and danger of epidemics. The water depth in some inundated city areas may typically be up to the order of 40 to 70 cm, which creates considerable traffic congestion, infrastructure problems, and huge economic loss in production, as well as significant damage to property and goods.

Diseases spread when sewage is mixed with surface flood water which, in turn, may reach and contaminate local drinking water sources. This unfortunate interaction between drinking water, groundwater, and floodwater causes severe health problems and calls for an integrated water management policy. Examples of diseases are diarrhea or leptospirosis, which are spread by bacteria in the urine of rats. In the September 2000 flood in northeast Thailand, 6,921 cases of leptospirosis were reported; 244 of these resulted in loss of human life (6). Last, but not least, parasites seems to thrive when urban flooding occurs regularly. Moist soil provides a good environment for worm eggs to flourish, and flooded open drains spread eggs to new victims (1). Today, anthelmintica is available to kill parasites, but the parasites may gradually develop resistance to the drug and create new and more severe problems. The best way to manage parasite problems is to interrupt the life cycle of parasites, that is, to remove their natural environment by reducing the frequency and duration of flooding. For example, Moraes (7) found that reduced flooding decreased the prevalence of roundworm and hookworm by a factor of 2 and hookworm alone by a factor of 3.

WHAT CAN BE DONE TO UNDERSTAND AND REDUCE URBAN FLOODING?

The water-related infrastructure in cities consists of drinking water treatment facilities, water supply networks, sewer systems, and wastewater treatment plants. Many cities are old, and they have developed according to varying historical needs and visions. The sewer and drainage systems play the key role in efficient removal of storm water after rainstorms and prevention of urban flooding and its consequences. These systems, therefore, represent an important part of the urban infrastructure which was put in place through more or less continuous investments during the period of modern city development. This means that the layout and design of the infrastructure have gradually developed into rather complex systems. Inadequate planning and design as well as bad maintenance of these systems may cause severe economic and environmental damage in the cities, as many urban flooding cases prove. The problem is often aggravated if rainstorms coincide with high water levels in the sea or adjacent rivers during the monsoon season.

Many cities in the Western world manage local and minor flooding problems by using computer-based solutions. This involves building computer models of the drainage/sewer system, for instance, by using software such as MOUSE (8) and SWMM (9). Both of these software packages have been applied successfully to modeling major urban flooding events. The models are used to understand the often rather complex interaction between rainfall and flooding. Once the existing conditions have been analyzed and understood, alleviation schemes can be evaluated and the optimal scheme implemented.

At present, there are few studies on urban flooding that deal with both the conditions in the surcharged pipe network and extensive flooding on the catchment surface. However, it is feasible to model urban flooding based on the interaction between the pipe system and surface flooding, and this raizes new possibilities for managing urban flooding problems. Examples of this kind of modeling are Bangkok, Thailand (10); Dhaka City, Bangladesh (11); Fukuoka and Tokyo, Japan (2); Harris Gully, Texas, U.S. (4) and Playa del Gandia, Spain (3).

To model urban flooding, a hydrodynamic model must be applied, and the flow and water levels in the major system (the street network and surface storage between the houses) and the minor system (the pipe network) must be described accurately. The major and minor systems

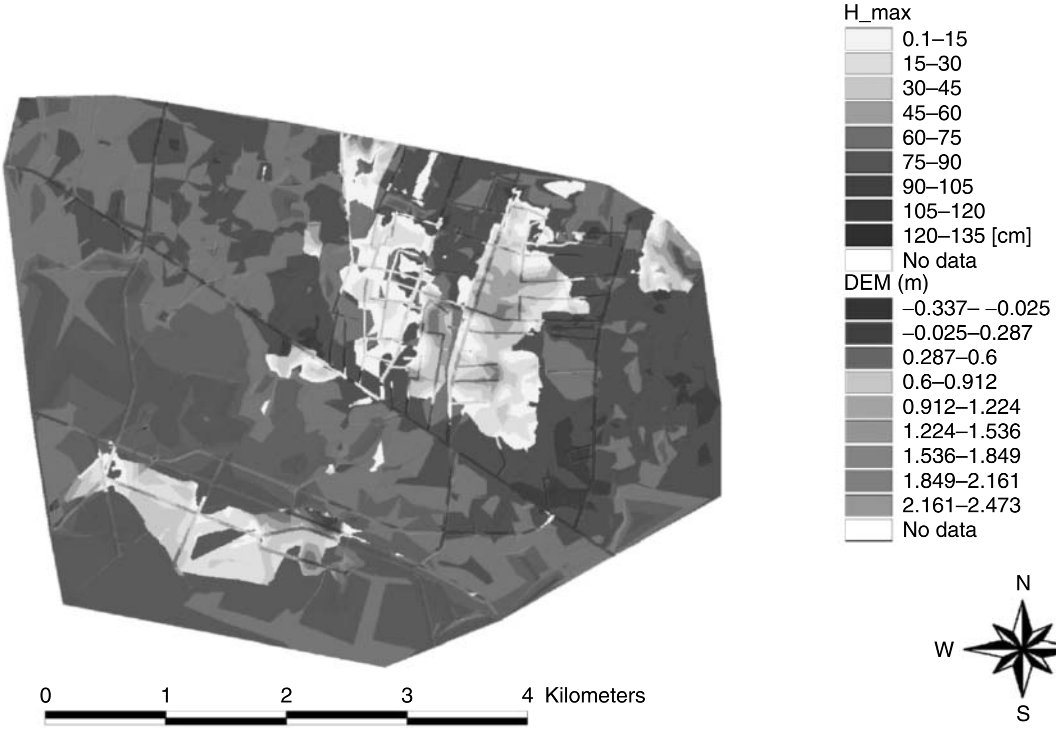

Figure 4. A flood inundation map for Bangkok (10).

route the rainfall runoff simultaneously in the pipes and on the streets. An exchange of water from the pipes to the streets (and vice versa) takes place, depending on the local hydraulic conditions in the catchment.

GIS plays a key role in data management for modeling urban flooding. A digital elevation model (DEM) is a powerful GIS tool for defining the catchment delineation and the storage of water on the surface. The DEM serves the dual purpose of input generation and result presentation of model simulations in terms of water depths in streets and between houses. An example of a flood inundation map for Bangkok (10) is shown in Fig. 4.

The handful of successful urban flood modeling applications carried out by computer models, which have traditionally been used to address local flooding problems in the industrialized part of the world, is very encouraging. The methodology is generic and can easily be transferred to other cities, if they have data available on the sewers and streets, as well as topographical maps.

FUTURE PERSPECTIVES AND CHALLENGES IN RELATION TO URBAN FLOODING

In 1997, the European Union (EU) passed a new and common set of directives, EN 752, for all EU member countries. This new standard calls for a new approach to the design of sewer systems in Europe. The old design criterion—design based on the return period of the rainfall—is replaced by a criterion based on the return interval of flooding. This new directive has boosted interest in understanding, research, and subsequent alleviation of urban flooding. Hence, it is foreseen that many urban flood applications will appear in the near future.

In the future, problems related to urban flooding will expand, as the cities in the developing countries are growing rapidly. So urban flooding must be seen in a broader perspective. An example is Dhaka City, which relies heavily (up to 97%) on groundwater for its water supply. During the last 25 years, the groundwater table has dropped by about 25 m (12). If this drop in the water table continues, it may generate problems for the city's water supply, and surface waters may need to be considered as additional resources. This is complicated by the growth of Dhaka City—areas that used to have permeable soils are being transformed into hard, impermeable surfaces. Such impermeable surfaces prevent replenishing groundwater storage and further aggravate groundwater problems. In turn, the runoff from the new impermeable surfaces generates additional surface runoff, which again increases the flooding in Dhaka City. Water supply pipes may be under low pressure during a period of flooding (e.g., due to power cuts), and polluted floodwater may enter the water supply network.

This poses an additional health risk to the population on top of the diseases spread by floodwater. In addition, there are considerable losses from the water supply network, so quite a large amount of drinking water is lost. This means that when dealing with urban flooding, one must remember that it involves not one problem, but a group of strongly interrelated problems, which have major impacts on the quality of life of people who live in flood-prone cities.

FLOODWATER SPREADING

Bahram Saghafian
Soil Conservation and
Watershed Management
Research Institute
Tehran, Iran

INTRODUCTION

Providing usable water resources, especially in arid and semiarid regions, is going to be one of the major challenges of the twenty-first century. Therefore, alternatives in water resources development must be studied thoroughly as population growth increases the pressure on renewable and nonrenewable water resources. Most of the precipitation and surface runoff in areas subjected to water scarcity usually occur in seasons that do not coincide with periods of high water demand. On the other hand, growth in drinking and irrigation water demand has caused overuse of more reliable resources, such as groundwater, and has degraded their quality.

Flood spreading is a practical water and soil conservation technique that, if designed and maintained properly, can address one or a combination of water-related issues on local scales. Such issues may involve reduction of flood damage downstream by diverting a portion of the flood volume, controlling sheet and gully erosion over the land by maintaining vegetation cover, storing water in the soil profile or in underground aquifers for future use, improving soil fertility through sediment deposition, leaching saline soils, and irrigating cultivated and cropped lands where the rainy period and the growing period nearly coincide. The suitability and success of a flood spreading system depends on the project objective(s), nature of the soil, amount and temporal distribution of precipitation, land topography, and water demand.

Although flood spreading has been practiced widely with diverse objectives, the aim of this article is to present an overview of flood spreading schemes designed mainly for groundwater recharge and/or flood irrigation. "Water spreading" and "flood spreading" are used interchangeably in most literature, and we focus mainly on systems designed to operate on spate floodwater.

BACKGROUND

According to the former Soil Conservation Service (USDA, undated): "Water spreading is a specialized form of surface irrigation accomplished by diverting flood runoff from natural channels or watercourses and spreading the flow over relatively level areas. The diversion and spreading is controlled by a system of dams, structures, dikes or ditches, or a combination of these, designed to accommodate a calculated rate and volume of flow." Bennett (1) believes that water spreading has been limited largely to arid and semiarid areas used for range rehabilitation and crop production. He considers flood spreading a simpler and less expensive irrigation method than indirect irrigation with the aid of water stored in reservoirs.

Stoddart et al. (2) reported that spreading water schemes helped to increase forage production in the U.S. Great Plains and Southwest. The schemes consist of dams and dikes to divert and convey water to the land where it is absorbed. Heady (3) considers water spreading systems for spreading floodwaters to irrigate land, reduce and store sediment, or store water underground. For irrigation, a 1:20–30 ratio of spreader land to watershed area was suggested based on the work in Israel on the basis of 15% runoff, an average annual rainfall of 100 mm, and a 400-mm crop water demand. The rainfall threshold to generate runoff is increased for larger watersheds, thus, favoring small spreader systems. But the sediment per square area of watershed tends to increase for smaller watersheds. Heady (3) indicates that many such systems have failed due to inadequate design and the lack of maintenance.

Gupta et al. (1995) studied different water harvesting and conservation techniques. Their findings indicate that the benefit of water harvesting is high and shows a considerable increase in total biomass, tree height, root mass, and water use efficiency compared with the control plot.

HISTORY

The origin of flood spreading systems is not transparent in the literature. Bennett (1) states that floodwater use for crop production probably originated in arid regions where river overflow was used to water crops planted in adjacent lands. Writings and remains of irrigation dikes show that western South America, Mexico, and southwestern United States were some of the places where floodwater was used for farming.

Hudson (5) provides an overview of the traditional use of runoff in areas where rainfall amount does not meet crop demand. In parts of Arizona where the annual rainfall is 300 to 400 mm, Indian tribes used runoff from sandstone outcrops to water crops such as maize, squash, and melons planted at the base of hills (6). The Hopi tribe also applied flood farming in southwest North America and still continues this practice in smaller areas (7).

Kovda (8) reported the use of natural runoff in arid areas of the former Soviet Union to crop on flood terraces of large rivers. The technique is called "kair" farming. "Khaki" farming practiced in Turkmenistan allows runoff from mountain slopes to inundate the plains. After the plains have dried out, the land is cultivated and planted. Carr (9) reported similar evidence in Ethiopia. In a mainly pastoral community in Kenya where annual rainfall is less than 200 mm, small patches of sorghum are grown using a variety of runoff farming (10). Farming on valley bottoms is an ancient practice in Tunisia and the Negev desert (5), where annual rainfall is low, and in the level pans of one to three hectares formed in broad valleys of gentle slopes in Colorado, United States, where rainfall is 400 mm (11).

Runoff farming on level fields surrounded by earth banks has been carried out in the Khost plain, Paktia province in Afghanistan, where the runoff from stony hills is collected and led down to the fields. In two experimental small-scale projects in Kenya, water from a catchment area is diverted into the cultivated area, partitioned by earth bunds, into gently sloped terraces to prevent erosion (5). Stone spillways are built into the bunds to pass water to lower terraces. Construction of large-scale inundation spreading schemes, called "ahars," have been reported in semiarid regions of India, namely, in Bihar and Uttar Pradesh. Runoff during monsoon season is retained on very gentle slopes by low earth bunds such that the moisture stored can support a 5-month crop grown following the end of monsoon. Weirs are built to allow excess storm water to pass. An advantage of this system is regular leaching of saline soil in semiarid areas. Other forms of inundation farming are also reported in the Jaisalmer district of Rajasthan (12), where an earth bund is constructed across the valley plain to store water from surrounding hills. The catchment ratio is at least 15:1 where annual rainfall is 165 mm.

In India and Pakistan, a canal that has an elevated bed compared to the river, may be excavated in the river bank with a flatter slope than that of the river (5). The canal is filled by the flood overflow and runs dry during low flow periods. Maintenance of the canal entry is necessary for removal of deposited sediment. The water carried by the canal is then distributed over irrigation fields.

Implementation of flood farming practices, both in large- and small-scale experiments, have been also reported in some parts of Sudan, Morocco, Syria, Yemen, Australia, Jordan, Brazil, and Iran. The FAO (13) reports that the irrigated area under floodwater harvesting (spate irrigation) totals about 2 million hectares in North Africa and the Middle East.

SUITABILITY CRITERIA FOR FLOOD IRRIGATION

Bennett (1) numbers a few criteria for the suitability of land in flood irrigation projects. The criteria include rich fertile soil that has favorable permeability, gentle and smooth slopes, and sufficient rainfall. Annual rainfall of less than 8 inches (200 mm), or rainfall less than 4 to 5 inches during the growing season, may preclude installation of flood spreading systems. Range forage or supplemental feed may be produced by using flood spreading schemes where rainfall ranges from 8 to 14 inches (200 to about 350 mm).

The moisture stored in the soil must be sufficient to supply the crops until the next rainy season. Therefore, soils of high storage capacity, ideally medium to moderately fine texture of sufficient depth are preferable. Coarsely texture soil is not suitable because of its high drainage rate and low water holding capacity. Prinz (14) suggests a range of annual rainfall between 150 and 600 mm and a catchment to spreading area ratio between 100:1 and 10,000:1 and more for flood irrigation. Land slopes between 1 and 2 percent are suitable, and the water should not carry a high sediment load.

FLOOD SPREADING FOR ARTIFICIAL RECHARGE

Storing water underground has the benefits of no or slight evaporation loss, large storage capacity and no need to construct structures, and less vulnerability to drought and contamination. Besides augmenting groundwater storage, one of the primary objectives of artificial recharge may be to conserve and dispose of floodwaters. As a major source of water, storm runoff and floods overflowing the river banks or diverted by canals may be spread and stored underground for future use. Water (flood) spreading is perhaps the most widely used man-made system of artificial groundwater recharge. Water is spread over the ground, so it infiltrates into the soil and recharges the aquifer. The efficiency of the spreading system depends on several factors such as the spreading area, duration of recharge, soil hydraulic properties, volume of spread water, and topography.

Todd (15) classifies water spreading methods into stream, ditch and furrow, pit, basin, and flooding, out of which the last two methods are briefly mentioned here. Basin, the most favored and widely practiced method, is formed by dikes or levees or by excavation. Water is normally diverted from a stream and led to a single or series of basins, where water spills to lower basins. Large lands with gentle slopes are required for basin spreading. Sedimentation and sealing is likely to occur when turbid water is used, so the upper basins act as settling areas.

Periodic scraping, disking, or scarifying may be performed to restore recharge rates.

In the flooding method, suitable for a low 1–3% gradient topography, water (flood) is diverted from a stream to the spreading area. Erosion must be avoided as the shallow water flows over the area. The preferable texture of the soil is as coarse as possible to allow a high recharge rate. The cost of construction and maintenance is usually low for this method, but sediment, evaporation, and high floods are major problems. The former problem decreases the system efficiency, and the latter causes damage to canals, embankments, and spillways. The flooding method applied for groundwater recharge is generally similar to the flood spreading systems designed for irrigation.

FLOOD SPREADING SCHEMES

Many different flood spreading systems have been constructed in different countries. Flood spreading systems, mainly for irrigation, may be divided into two types: flow type and detention type (16). Free drainage and flow of water occurs in the first category thanks to a gentle land slope, whereas water is retained in the second type systems for infiltration. The flow type system is further divided into syrup-pan, spreader ditch, and dike and bleeder. The detention type is also classified into manual inlet control and automatic inlet control. The following describes different flow type systems, as stated by Jensen (16).

In the syrup-pan flow system, a single spreader ditch at the upper end of the field picks up the water from the main watercourse. Water spills over the sides of the spreader into the field divided into some sections by contour dikes. While flowing down the field, it partly infiltrates and partly runs off to the next section downstream. Contour dikes are broken at one end to allow water to proceed to the next section. At the end of the last section, there is a waste way or a channel leading excess water, if any, back to the main channel. Figure 1 presents a typical sketch of the system. In Fig. 2, a spillway along a contour dike is shown during operation.

In a spreader ditch flow system, a number of ditches divert water from a stream. The slope of the ditches decreases toward the lower end. Dikes and bleeder flow systems are a modified type of a syrup-pan system. Water flows through dikes to lower sections of the fields via tubes or weirs installed at intervals along the dikes. Emergency waterways connect each section to the main stream in case the tubes are blocked. Detention type systems are designed to divert and spread long duration flows with control over the depth of water.

DESIGN FACTORS

Several factors must be considered in the design of flood spreading systems. The meteorology and hydrology of the watershed, which produces the runoff for spreading, is of particular importance. Flow duration curves as well as flood values and the sediment load are to be studied. The major factors considered in the design of efficient spreading systems are diversion sites, slope of the spreading land, soil infiltration and water holding capacity, the area available for spreading, and economic considerations such as maintenance costs. Although a standard and widely practiced procedure for design of spreading systems does not exist, some irrigation and soil and water conservation books may include a chapter for designing them (16).

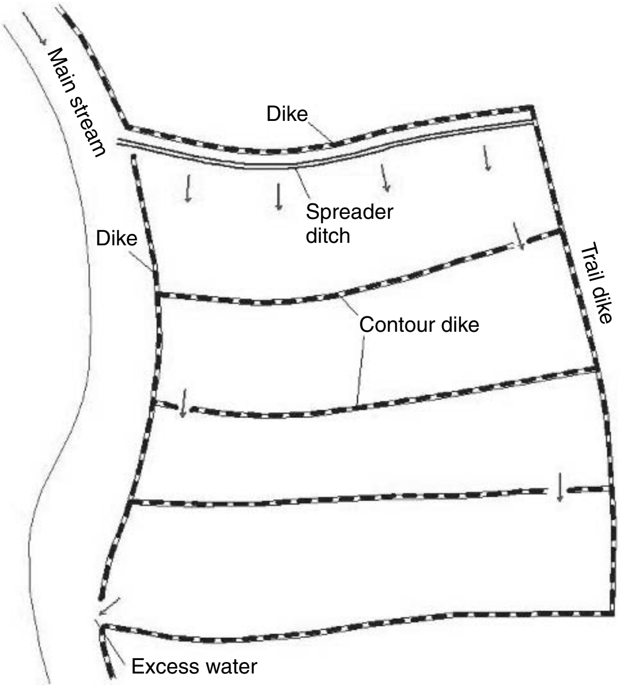

Figure 1. A typical syrup-pan flow system (modified from Reference 16).

Figure 2. A spillway along a contour dike during operation (Ghareh Baygon Flood Spreading Station, Fars Province, Iran).

ADVANTAGES AND PROBLEMS

Flood spreading systems have the advantages of generally low construction and maintenance costs and adaptability to rural areas because of their simple technology. By storing floodwater that would have been otherwise lost, local water demands can be partially met and flood damage downstream may be reduced. Other indirect benefits include environmental diversity, people migration control, and desert rehabilitation in arid areas.

The major problem of flood spreading projects is sedimentation. This decreases soil infiltration, which is a serious consequence in artificial recharge and flood irrigation systems. Efforts to maintain the efficiency of the system include growing vegetation, adding chemical soil conditioners, scarification, and leaving upper fields for siltation.

MINIMUM ENVIRONMENTAL FLOW REGIMES

Peyman Daneshkar Arasteh
Soil Conservation and
Watershed Management
Research Institute (SCWMRI)
Tehran, Iran

INTRODUCTION

A growing demand exists for water by humans that not only reduced the amount of water available for future industrial and agricultural development but also has a profound effect on aquatic ecosystems and their dependent species (1).

Every inland, coastal, fresh, or brackish water ecosystem has specific water requirements for the maintenance of ecosystem structure, function, and the dependent species. For river-dependent aquatic ecosystems, normally referred to as environmental water requirements (EWR), environmental flow, or a new branch of hydrology, ecohydrology, (1) there is no universal definition of environmental flows. Flow is the governing influence in rivers, controlling many aspects of the physical environment and significantly affecting the biota of a riverine system. It is essential that adequate water be provided for the purpose of protecting the physical and ecological processes and features. Such flows are defined as EWR (2).

EWR are also defined as: "The water regimes needed to sustain the ecological values of aquatic ecosystems at a low level of risk" (3). Given that some systems are overallocated and unable to provide the full EWR, negotiation between stakeholders leads to the establishment of flows for the purpose of environmental protection. Such flows are defined as environmental water provisions, meaning: "The part of EWR that can be met" (3).

An environmental flow is the water regime provided within a river, wetland, or coastal zone to maintain ecosystems, and their benefits, where competing water uses exist and where flows are regulated. Environmental flows provide critical contributions to river health, economic development, and poverty alleviation. They ensure the continued availability of the many benefits that healthy river and groundwater systems bring to society (4).

Balancing the needs of the aquatic environment and other uses are becoming critical in many of the world's river basins as population and associated water demands increase (1).

In order to sustain the ability of freshwater-dependent ecosystems to support food production and biodiversity, environmental flows must be established scientifically, made legitimate, and maintained.

In recent years, a number of local and global assessments of water resources, current and future water use, water and food security projections, and water poverty analyses have been completed (1,2,5–10). Assessment of water availability, water use, and water stress at the global scale has also been the subject of increasingly intensive research over the course of the past decades. However, the requirements of aquatic ecosystems for water have not been considered explicitly in such assessments (1).

OBJECTIVES OF ENVIRONMENTAL FLOW

The following environmental flow objectives apply specifically to the management of flow volumes in a river basin (5):

a. Maintain appropriate minimum environmental flows (MEF) during low flow periods.
b. Provide appropriate 'flushing flow' and 'high flow' regimes.
c. Maintain, enhance, or restore species diversity, population structure, and community assemblages of aquatic biota and associated wildlife dependent on the instream environment.
d. Ensure identified populations of significant biota are adequately protected through provision of appropriate environmental flows.
e. Maintain and improve aquatic habitat, river structure, riparian vegetation, and water quality through provision of adequate environmental flows.
f. Provide a flow regime that preserves and, where possible, reinstates important riffle and pool habitats.
g. Minimize sedimentation and smothering of aquatic habitats through protection, maintenance, and restoration of indigenous riparian vegetation.

METHODS OF DETERMINING EWR

A range of environmental flow determination techniques exist and have been variously applied all around the world (4,11,12). Possible methodologies for calculating environmental flow requirements include:

Hydrological Methods

These methods are based on historical records and are simplest and the least data intense for estimating instream flows. They include the look up tables and desktop analysis.

Habitats Methods

They require some fieldwork to quantify the relationship between the selected variables describing the physical habitat behaviors and the river discharge. These methods are based on hydraulic simulations and habitat rating or modeling.

Holistic Methods

They are discussion-based approaches. The approaches offer a structured framework to the setting of instream flow requirements, based on expert opinion and stakeholder requirements. Holistic approaches make use of teams of experts and may involve participation of stakeholders, so that the procedure is holistic in terms of interested parties as well as scientific issues. Where methods have the characteristic of being holistic, they clearly have the advantage of covering the whole hydrological-ecological-stakeholder system. The disadvantage is that it is expensive to collect the relevant data.

For a review of these methods, reading of Kinhill (13), Arthington and Pusey (14), Arthington and Zalucki (15), and Arthington et al. (16) articles are suggested. The determination of environmental flow requirements requires consideration of the entire flow regime. However, a key distinction in how environmental flow requirements are determined exists between low flows and high flows including floods.

When determining environmental flow requirements, it is important to understand the tolerance of stream biota to certain volumes, timing, and duration of flows, which can be achieved by comparing the current flow regime with the natural flow regime.

REQUIRED DATA

a. Physical description of basin
b. Water quality conditions in basin
c. Description of key biota or environmental values (fauna and flora)
    i. Fish
    ii. Other vertebrates
    iii. Aquatic macroinvertebrates
    iv. Vegetation
d. Water resource development and hydrology
    i. Licensed water use
    ii. System operation
    iii. Stream flows

SOME RECOMMENDATIONS

Harby et al. (17) used a river system simulator analysis to optimize the environmental flow requirement of regulated river Maana in central southern Norway. The analysis recommended an environmental flow release of around 345 MLD (million liters per day). Zampatti and Lieshke (18) recommended 1.5 MLD as MEF for Diamond Creek Catchment, Australia. Zampatti and Close (6) recommended a MEF of 130, 8, and 9 MLD for Kiewa River, Running Creek, and Yackandandah Creek, Australia, respectively. Lieschke et al. (5) recommended maximum MEF of Plenty River system about 1.5 MLD. MDNR (19) recommended a MEF of 380 MLD for Potomac River system, Maryland. Smakhtin et al. (1) estimated EWRs needed to maintain a fair condition of freshwater ecosystems range globally from 20–50% of the mean annual river flow in a basin. These MEFs have been determined on the bases of the habitat and hydrologic-hydraulic methods. Arasteh (20) recommended a volume of 3400 million cubic meters per year as the annual minimum volume of EWR to survive Hamoon, Iran-Afghanistan trans-boundary wetlands on the base of a simple water balance method.

FORENSIC HYDROGEOLOGY

LEO S. LEONHART
DAVID R. HARGIS
Hargis + Associates, Inc.
Tucson, Arizona

Forensic hydrogeology is a branch of environmental forensics, a relatively new discipline involving the use of environmental science to support litigation.

Forensics is derived from the Latin root *forensis*, meaning "of a forum," and is the study of formal debate. Accordingly, forensics involves arguing a position within any adversarial context. A legal context is not necessarily a requirement, but environmental forensics often support the interpretation or establishment of technical facts related to litigious matters. Generally, the product of a forensic hydrogeologic investigation is an opinion rendered in writing or orally via various legal vehicles such as affidavits, depositions, or trial testimony. The opinion may be direct or in rebuttal to an opinion proffered by an opposing expert. Due to the technical complexities of many legal matters pertaining to environmental issues, hydrogeologists often find themselves as members of interdisciplinary litigation support teams. These teams may comprise other experts in fields such as toxicology, chemistry, microbiology, engineering, industrial hygiene and safety, regulatory compliance, and industrial history and standards. Typical tasks for hydrogeologists include delineation of the source(s) and extent of contamination in subsurface soils and groundwater, interpretation of subsurface conditions controlling such flow and transport, analysis of groundwater flow and contaminant transport, determination of risk pathways toward potential receptors, and feasibility assessment of various remedial alternatives. The opinions rendered by the hydrogeology expert on these matters may be corroborated or supplemented by the opinion of the other experts involved.

There are also forensic applications in hydrogeology that involve litigation, but which do not involve contamination or toxic tort matters. Examples include settlement of damages between parties involving water supply issues, such as well interference or interruption of baseflow; flooding, such as watershed or hydrographic modifications resulting in increased runoff; or simply well drilling and design, involving poor yields or failures.

FORENSIC ISSUES IN HYDROGEOLOGY

There are a variety of legal issues whose resolution have required the support of forensic hydrogeologists. Recent cases have involved supporting determinations of allocation for environmental remediation costs among multiple responsible parties, circumstances "triggering" insurance policy coverage issues, environmental liabilities accompanying property transfers, and personal damages or tort claims from alleged exposure to contamination released from a site. Other claims have arisen over performance of contractors working on environmental cleanup or who were engaged in the construction or operations and maintenance of facilities that failed and allegedly resulted in contaminant releases.

Determination of fair and defensible cost allocation among parties potentially responsible for groundwater contamination is a complex undertaking. Various approaches involving allocation on the basis of area-, volume-, and mass-of-contamination, as well as weightings based on such factors, have been proposed (1,2). Additional approaches based on toxicity weighting have also been proposed for sites where multiple-groundwater contaminants are commingled. Such commingled plumes may also give rise to issues with regard to selecting alternative remedial technologies.

Depending on the period and type of coverage, exclusions, and various interpretations of what constitutes an occurrence, insurance claims involving liability for environmental damage may generate issues requiring input from hydrogeologists. For example, there may be matters related to the timing of releases relative to the timing of the policy coverage or to the enactment of certain "pollution exclusion" clauses within the policy. In such instances, the hydrogeologist may be able to opine on the likelihood that contamination occurred during the policy period and whether the contamination is persistent, requiring present-day remedial efforts.

Property transfer issues may be similar to the allocation and timing considerations considered earlier. Such matters require careful research of historical activities performed on the property. Hydrogeologists might use record searches, interviews, and review of historical photographic archives to reconstruct chronologies and thereby form opinions on the likelihood of certain operations as causes for contamination.

Tort claims are often the most complex issues and require extensive examination of risk factors from the source of the contamination, the transport pathway, and the point of exposure. Tort damages may not be limited to human exposure but may also extend to resource damage. In such matters, hydrogeologists might be able to help clarify the timing and fate of contamination from the source to the site of exposure using analytical or numerical models based on conceptualizations of the site hydrogeology.

TOOLS AND APPROACHES

In theory, the approach of hydrogeologists serving as experts in litigation is not fundamentally different from their serving in any other professional capacity. In other words, the tools of the trade are the traditional ones, and the approach involves traditional scientific methods of investigation. There are, however, issues that arise in contemporary forensic matters that are more interdisciplinary. In matters involving contaminant liabilities, environmental forensic specialists have been referred to as "industrial paleontologists," signifying their proficiency in unraveling the history of events leading to present-day conditions at a contamination site (3). Having been trained extensively in geology, hydrogeologists are particularly well suited for such "after-the-fact sleuthing."

As in any traditional investigation, forensic study is staged. The first stage is the acquisition and organization of pertinent data and information. This may involve simply compiling records, photoarchives, and searching databases, or it may include actual field data acquisition such as drilling, sampling, and analysis. At this stage, the hydrogeologist has various traditional and specialized tools available. For example, there are methods traditionally employed such as water level measurements and water and soil sample collection and analysis. Contaminant investigations may also incorporate isotopic analysis or chemical fingerprinting to assess timing or source issues to the extent materials released have a unique, detectable chemical signature. The basis for chemical fingerprinting might be weathering characteristics and composition of petroleum hydrocarbons, proprietary additives, alkyl-lead compounds, oxygenates, or isotopic ratios. Hydrogeologists might also consider the changing state of industrial technology. For example, much information has been gathered on the historical use of organic solvents (4). Some solvents were commercially available and in use at different times, as indicated in Table 1. Certain solvents were more prevalent in industrial use than others at different times. Other chemicals were banned for certain usages by regulatory agencies. A hydrogeologist who is knowledgeable about historical chemical usage/availability and can reconcile such information with chemical use and disposal history of the site can present informed opinions on the timing of releases. Using chemical associations in this manner and context is analogous to using index fossils in geochronology.

The next stage involves assessing and analyzing the data per the study objectives. This analysis is based on both the hydrogeologist's conceptualization or alternative conceptualizations of the hydrogeologic system and the impacts of site operations on the soil and groundwater. The hydrogeologist assembles information gathered to determine such things as the occurrence, flow direction,

Table 1. Year of First Commercial Availability of Selected Organic Chemicals[a]

and use of groundwater; interaction with surface water; geologic cross sections; distribution of contaminants in the soil and groundwater; and other factors related to the overall hydrogeologic conditions at and in the vicinity of the site. Current and past operational information can then be used to interpret the contaminant history of the site. The approach for this step can vary widely according to the skills and experience of the expert as well as the history of site operations and the type and availability of site records. In some cases, the hydrogeologist may want to apply various models to simulate or project groundwater flow and solute transport conditions. Other types of modeling that are less familiar to traditional hydrogeology, but which can support interpretations on timing of release, might include various geochemical models, degradation models of various fuels and components, and corrosion models (for tanks and pipeline leaks).

ETHICS AND STANDARDS

In the process of performing these services, extreme care must be taken to organize and document the information used and generated, considering the likely degree of scrutiny by both technical and legal adversaries. In general, this requires strict adherence to professional ethical standards and methods of analysis, systematic maintenance of records, traceability, and disclosure.

With specific regard to the admissibility of expert opinion in the courtroom, some courts use criteria or standards to determine the acceptability of expert testimony. One such precedent was set in the opinion of *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, which held that judges must function as gatekeepers in assuring that expert opinion proffered in the courtroom is valid and reliable (5). To this goal, the court suggested criteria based on the following questions:

1. Is the opinion testable and has it been tested?
2. Is the error rate associated with the technique or opinion acceptable?
3. Has the basis for the opinion survived peer review and has it been published?
4. Is it generally accepted among scientists in the pertinent field?

Other courts have simply applied a "general acceptance" criterion, which originated in the 1923 case of *Frye v. United States*, which dealt with admissibility of a polygraph-type examination. This court held that the scientific opinion must have achieved "general acceptance" in its particular field or context.

FORESTS AND WETLANDS

Theodore A. Endreny
Emera Bridger
SUNY-ESF
Syracuse, New York

Forests and wetlands are landscape features that play integral roles in the hydrological cycle. Within the landscape, forests and wetlands are inextricably linked. Wetlands may exist within forest ecosystems, or wetland ecosystems can be characterized as "forested." This article will outline the characteristics of both forests and wetlands and some implications for water resource management.

FORESTS

Forests cover an estimated area of 4.17×10^9 hectares, which is roughly 32% of Earth's surface (1). A forest can be defined as "a biotic community predominated by trees and woody vegetation that covers a large area" (1), whereas others define forests by its vegetative character irregardless of area. Forests serve social, economic, and ecological functions, which impact water resources in

Other types of modeling that are less familiar to traditional hydrogeology, but which can support interpretations on timing of release, might include various geochemical models, degradation models of various fuels and components, and corrosion models (for tanks and pipeline leaks).

ETHICS AND STANDARDS

In the process of performing these services, extreme care must be taken to organize and document the information used and generated, considering the likely degree of scrutiny by both technical and legal adversaries. In general, this requires strict adherence to professional ethical standards and methods of analysis, systematic maintenance of records, traceability, and disclosure.

With specific regard to the admissibility of expert opinion in the courtroom, some courts use criteria or standards to determine the acceptability of expert testimony. One such precedent was set in the opinion of *Daubert v. Merrell Dow Pharmaceuticals, Inc.*, which held that judges must function as gatekeepers in assuring that expert opinion proffered in the courtroom is valid and reliable (5). To this goal, the court suggested criteria based on the following questions:

1. Is the opinion testable and has it been tested?
2. Is the error rate associated with the technique or opinion acceptable?
3. Has the basis for the opinion survived peer review and has it been published?
4. Is it generally accepted among scientists in the pertinent field?

Other courts have simply applied a “general acceptance” criterion, which originated in the 1923 case of *Frye v. United States*, which dealt with admissibility of a polygraph-type examination. This court held that the scientific opinion must have achieved “general acceptance” in its particular field or context.

FORESTS AND WETLANDS

Theodore A. Endreny
Emera Bridger
SUNY-ESF
Syracuse, New York

Forests and wetlands are landscape features that play integral roles in the hydrological cycle. Within the landscape, forests and wetlands are inextricably linked. Wetlands may exist within forest ecosystems, or wetland ecosystems can be characterized as “forested.” This article will outline the characteristics of both forests and wetlands and some implications for water resource management.

FORESTS

Forests cover an estimated area of 4.17×10^9 hectares, which is roughly 32% of Earth’s surface (1). A forest can be defined as “a biotic community predominated by trees and woody vegetation that covers a large area” (1), whereas others define forests by its vegetative character irregardless of area. Forests serve social, economic, and ecological functions, which impact water resources in myriad ways. A salient economic use of forested land throughout the world is as a source of fuel and timber. The various hydrological functions that forests perform have substantial economic benefits as well, which ecologists and economists have tried to quantify in recent decades. These economic factors may be a driving force in forest and water resource management decisions.

DISTRIBUTION OF FORESTS

Forest types vary along temperature and moisture gradients. Forests generally occur in regions where the annual precipitation exceeds 38 cm, the frost-free period is at least 14 to 16 weeks in duration, and solar radiation is greater than 27 W/m^{-2} (1). Regional conditions, such as ocean currents and air mass circulation patterns, may also determine the range of forest types in a particular location.

Forested landscapes impact global hydrologic systems by vapor and gas exchange, and conversely, these hydrologic regimes impact the distribution and composition of forests. For instance, overharvesting of timber in semiarid regions may result in lower precipitation, thus further constraining the growth of vegetation (2). On a local scale, the composition of a forest will impact processes such as throughfall, residence time, chemical enrichment, litter characteristics, and soil characteristics (3).

FOREST STRUCTURE AND THE HYDROLOGIC CYCLE

Interception

Precipitation, or the deposition of liquid or solid water onto the Earth's surface, can fall directly onto the soil surface, be intercepted by vegetation or other surfaces, or flow to the ground via trunks and stems (4). The forest canopy plays a significant role in precipitation interception. It has been found that 10–20% of annual precipitation is removed by canopy interception, depending on climatic and vegetation characteristics (1).

Litter on the forest floor may also intercept and store water temporarily before it infiltrates into the soil. The leaching that occurs as water travels through the litter layer can have a substantial impact on the biogeochemistry of the site. The enrichment of precipitation intercepted by litter will vary among forest types because of differences in litter composition. On average, the litter layer in deciduous forests is thinner than in coniferous forests (3), therefore constituents (i.e., nitrogen, calcium) have been found to leach out in higher quantities at sites dominated by deciduous species as compared with conifer-dominated locations (3)

Evapotranspiration

A portion of the intercepted water may evaporate and return to the atmosphere. The rate of evaporation is determined by the amount of water present and the amount of solar energy available (5). Transpiration can also result in the loss of water vapor into the atmosphere. Transpiration is the process whereby water is released from plants' stomata on leaves and lenticels on stems. Transpiration rates can be a considerable output of water in a watershed depending on the type of vegetation and the age of the stand. On average, 95% of the water taken up by a plant's roots will be transpired, whereas the remaining 5% will be converted into biomass via photosynthesis (5). Chang (1) states "a mature forest can transpire as much as 1000 tons of water to produce 1 ton of wood," while noting that this figure can be even higher in some species. As a result of the difficulty of empirically differentiating the water lost by evaporation and that which is lost by transpiration, these two processes are discussed as single process called evapotranspiration.

Throughfall and Stemflow

Precipitation is also routed toward the forest floor by the processes of throughfall or stemflow. Throughfall is defined as the portion of the water that falls without being intercepted or that which was stored in the canopy that drops from the canopy to the forest floor (5). Stemflow is the water the travels along the stems of plants. Throughfall and stemflow are important processes because they influence the distribution of and quality of the water that reaches the soil surface, and thereby they have a "[significant] impact [on] forest biogeochemical cycles" (6). Leaching of nutrients from above ground biomass in deciduous hardwood forests can account for up to 20% of the annual nitrogen and potassium fluxes (6).

Despite its small volumetric contribution to the forest ecosystem, stemflow, in particular, has been found to have a significant impact on runoff generation, soil moisture patterns, and soil water chemistry (6). The rate and magnitude of stemflow has been found to be correlated with vegetation type and structure, storm event characteristics, and seasonality. In general, stemflow yields increase with the magnitude of a storm event (6). The chemical inputs from stemflow also vary based on seasonal variables. Concentrations of target constituents were found to be greater during the winter months than during the summer. Changes in canopy density, greater residence time in the bark, and the lower bark pH during the winter are some of the seasonal factors (6).

Infiltration and Runoff Mechanisms

The forest type, and its subsequent root system, plays an important part in soil genesis and structure, as well as the soil's infiltration capacity. In forest ecosystems, 40–70% of the total biomass is found below the soil surface. Therefore, root systems introduce a significant amount of organic material into the system, which facilitates the formation of aggregates, the organization of which determines soil structure The roots also remove soil moisture from the adjacent soil, which serves to increase soil aggregation (7).

In addition to the organic matter that is contributed by the forest root system, roots also move soil and form macropores that play an important role in infiltration and percolation. Woody plants can send their roots more than 5 m deep depending on the substrate (7). These roots often follow existing channels and voids, but as they grow, they expand these spaces. When roots die, these voids are left empty and can influence the hydraulic conductivity of the soil under certain conditions.

The type and structure of forests also affects the process of infiltration of water into the soil (1). The infiltration capacity is the "maximum rate at which precipitation can infiltrate into the soil" (5). In most forest systems, the infiltration capacity is generally high and infiltration excess overland flow does not generally occur and cannot be considered a significant runoff mechanism (5). That being said, surface conditions such as vegetation cover, roughness, crusting, soil temperature, and slope can determine the quantity of overland flow and its velocity (1).

The hydraulic conductivity is the ability of a soil to carry water or another liquid (5). The conductivity of a soil depends both on the properties of the soil as well as the properties of the liquid. The soil structure and the system of macropores will impact the conductivity. The water that firsts enters the soil after a storm event will follow preferential pathways. Typically, water infiltrating at the soil surface will follow the path of least resistance filling large pores, cracks, and animal burrows before the rest of the soil has been saturated. Forests, like was mentioned above, have a greater number of macropores because of root propagation and the decomposition of dead roots.

In addition, a healthy root system can reduce the amount of soil lost in overland flow events. Thus, soil stabilization and retention can prevent erosion and retard surface water pollution.

Management Implications

As a result of the integral relationship between forests and the hydrological cycle, the extent and quality of forested areas will have an impact on the water balance of the watershed. On average, peak flows of streams are generally lower in watersheds that have a high percentage of forested area (1). Activities that reduce forest cover, such as residential and industrial development, clearing for agricultural operations, and logging, may change the hydrological balance within a given watershed. According to Huber and Iroumé (8), intensive forest operations can have implications for water yield and quality. Removal of forest vegetation can impact soil moisture, infiltration capacity, and total water yield. A decrease in interception capacity, by removing or altering the forest canopy, can result in greater soil moisture.

For example, reduction of forest canopy area can cause an increase in snow accumulation on the ground. As the snow melts, an overall increase in water yield will occur because the storage capacity of the watershed has decreased. Also, an increase of impervious surfaces can decrease infiltration, contributing to a greater quantity of infiltration excess overland flow. Therefore, a greater quantity of water is released into streams.

WETLANDS

Wetlands are ecosystems inundated by water during the growing season, which produces soils dominated by anaerobic processes and in which the biota exhibits flood-tolerant adaptations (9). Wetlands cover approximately 4–5% of the Earth's surface. They exist in across a broad spectrum of climates from boreal peatlands to tropical mangrove forests (9). Although they make up a relatively small percentage of the total land area, wetlands can have disproportional affects on hydrological and biogeochemical cycles in local, regional, and continental contexts.

FORESTED WETLANDS

Forested wetlands are the dominant wetland type in the continental United States (10). These wetlands are of particular interest because they lie at the interface of upland and aquatic systems; these wetlands possess characteristics of both upland and aquatic systems while having distinctive properties found only in wetlands. This unique landscape position makes forested wetlands important to surface and groundwater quality as well as biodiversity. The forested wetlands of most interest to this discussion are swamps and riparian wetlands.

Swamps are wetlands that are dominated by trees rooted in hydric, mineral soils (9,11). Swamps have standing water through most or all of the growing season (11). Freshwater swamps, or deepwater swamps, have a broad geographic distribution ranging from the bald cypress-tupelo (*Taxodium distichum-Nyssa aquatica*) swamps that are found from the Midwest to the southern United States to the Atlantic white cedar (*Chamaecyparis thyoides*) swamps and red maple (*Acer rubrum*) swamps of the northeastern United States. The hydrogeology and landscape position of swamps will, in large part, determine the hydrologic and ecological functions that the wetland performs as well as the magnitude of these functions (11)

The riparian zone is the corridor of land on the banks of streams, rivers, and lakes. Riparian wetlands are found within the riparian zone, in areas that receive seasonal inputs of water through flooding of the adjacent body of water, but that do not have standing water throughout the growing season. Although riparian wetlands are not necessarily forested (i.e., wet meadows), they often are. Willows (*Salix* spp.), red alder (*Alnus rubra*), and green ash (*Fraxinus pennsylvanica*) are common bottomland species found in riparian wetlands. Riparian vegetation, particularly riparian forests, has a significant affect on stream geomorphology and ecology. It has been found that stream water temperatures, for example, are correlated with riparian soil temperatures. Riparian vegetation also provides allochthonous inputs that are used by aquatic biota as a source of carbon.

ROLE OF WETLANDS IN WATERSHED HYDROLOGY

Wetlands, especially forested wetlands, perform similar hydrologic functions to those performed by upland forests. Interception, evapotranspiration, throughfall, and stemflow are all processes that occur in wetlands. However, unlike upland forests, wetlands are more directly impacted by the hydrologic environment. The character of wetlands is directly affected by specific effects of hydrology (11). Hydrology leads to specialized vegetative communities; also, flow properties can determine productivity, and nutrient cycling is impacted by the hydrological characteristics of a wetland (11). Wetlands also provide important hydrological functions, including hydrological storage, biogeochemical cycling, and pollutant retention (9).

Hydrological storage includes flood attenuation, groundwater recharge, and in some cases, groundwater discharge. Wetlands attenuate flood waters by intercepting storm runoff and flood waters, storing the water for some period of time, and then releasing the water at a slower rate than if it had not been intercepted. Thus, wetlands reduce the peak flows and spread them out over time (11). The abatement of floods by wetlands has both economic and ecological implications. The reduction of peak flows also has water quality benefits. Wetlands reduce the velocity of the peak flows, which allows sediments and other pollutants to settle out from the water column. Flood reduction can also decrease scour of stream bed and banks, reducing the amount of material eroded from stream channels.

Wetlands contribution to groundwater is largely dependent on the geomorphology of the wetland. Groundwater dynamics can play an important role in some wetlands, but be negligible in others. Groundwater recharge is common in depression wetlands such as prairie potholes in the mid-western United States. These wetlands fill with water during the spring, and as the growing season progresses, water from the wetland infiltrates the soil and percolates into the aquifer. In other wetlands, such as fens, groundwater is discharged into the wetland and is the dominate source of water for the wetland. In other wetlands, neither significant groundwater recharge nor discharge occurs (11).

Biogeochemical cycling is another crucial function of wetlands. Wetlands specialized role in biogeochemical cycling is largely because of the alternative aerobic and anaerobic soil conditions throughout the year (11). When the wetland soils are saturated, they became anaerobic and a series of reduction reactions occur. The reduction of compounds can alter their bioavailability and prevent their introduction into surface and groundwaters. When the soil moisture decreases and aerobic activity again commences, these constituents can become available again. A large body of research has examined the removal of nitrates (NO_3^-) from subsurface water and phosphorous (P) from overland flow in riparian systems (12–15). The efficiency of these wetlands to remove nutrients and sediments is largely because of vegetation characteristics, preferential flow paths, and seasonality of inputs.

Wetlands are sometimes referred to as the "kidneys of the landscape" because they can remove nutrients, particularly nitrogen and phosphorus, pesticides, bacteria, heavy metals, and other potential pollutants from the surface or groundwater that they intercept. Similarly, researchers often conceptualize the landscape as a series of sources and sinks. Within this framework, wetlands are often thought of as sinks for pollutants. In reality, the relationship between the wetland and its watershed is often much more complex. At a certain point, wetlands may become saturated with a certain constituent and become a source rather than a sink (16). For example, when a high sediment yield exists in a watershed, wetlands may become a source of sediment. In large basins that have high upland yield, wetlands can actually account for 52–91% of the sediment discharged into streams. The role of wetlands as sources of sediment may be more variable in smaller watersheds, depending on the geomorphology and land use in the watershed (17).

The benefits of having wetlands throughout the watershed are now well known. Yet, anthropogenic disturbances as well as natural variation have contributed to the loss of wetlands throughout the world. It is estimated that, in the United States, the loss of 50% of the wetlands has occurred since European settlement (11). Wetlands are typically drained so that the land can be used for other uses, such as agricultural or residential development. The loss of wetlands from the watershed can translate to increased stream discharge, increased sediment yields, and eutrophication of surface waters.

Another anthropogenic disturbance that impacts riverine swamps and riparian wetlands is the reduction of flow in the stream channel or channel alteration. These disturbances impact the seasonal inputs of water from flooding and may cause changes in the composition and distribution of plant species. These changes may also impact the rate and magnitude of biogeochemical as well as hydrologic functions.

CONCLUSION

Although it may be helpful to look at forests and wetlands as two distinct ecosystems, it is important to understand the interconnections between them. Forest management regimes may determine the types of constituents as well as the amount of water that travels into bottomland areas by overland flow as well as subsurface flow paths. Subsequently, the condition of wetlands can have an effect on the storage and cycling of nutrients, sediments, and organic matter. The consideration of both of these ecosystems when making management decisions will enable managers to accentuate the ecosystem functions of one ecosystem without compromising the health of the other.

ROCK GLACIER

Alexander Brenning
Humboldt–Universität zu Berlin
Berlin, Germany

Active rock glaciers are the geomorphological expression of creeping mountain permafrost (Fig. 1). They consist of a debris–ice mixture that mechanically deforms and slowly moves downslope or downvalley and develop therefore a tongue-shaped or lobate landform with a front scarp and characteristic surface structures, such as furrows and ridges, as rheological expressions. Unlike "true" glaciers, rock glaciers do not present surface ice or exposed ice in general but contain only supersaturated ground ice.

Rock glaciers that do not move any longer but still contain ice are called inactive, and the sediment body that remains after a rock glacier has melted is called a relict (or fossil) rock glacier. Rock glaciers may become inactive for climatic or dynamic reasons. In the former case, the seasonally unfrozen block mantle has grown as a consequence of permafrost degradation. A dynamically inactive rock glacier, in contrast, may develop even in areas of continuous permafrost if it enters into flat terrain or if its thickness falls below a critical value. The front scarp of active rock glaciers generally reaches inclinations between 35° and up to 45°, but inactive ones show front slopes at or below the angle of repose, and the upper part of inactive front slopes is gentler than for activity. Relict rock glaciers can be recognized from their subdued appearance and irregular surface structure. Further classification criteria are presented in Table 1.

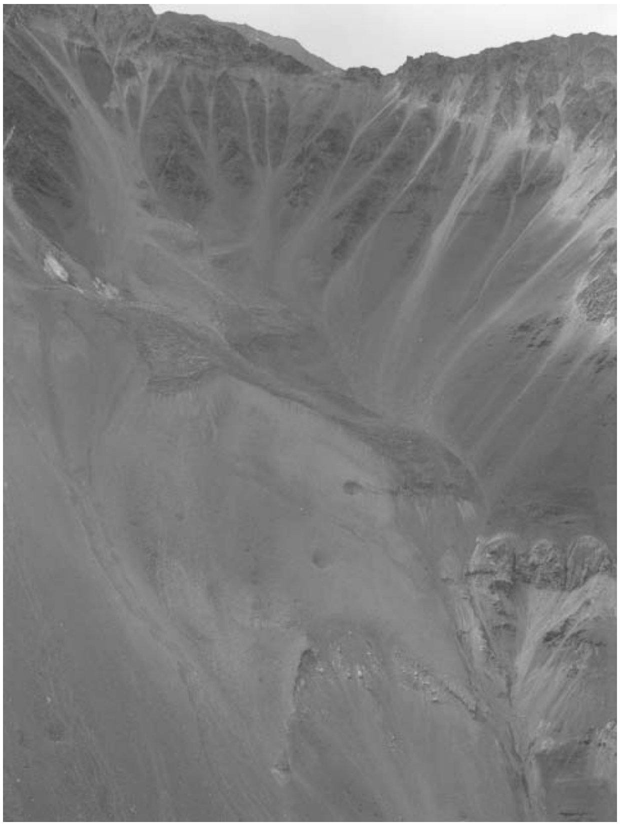

Figure 1. An active talus rock glacier in the Andes of Central Chile (Estero de las Yeguas Muertas, 33.5°S). (The crater-like depressions are produced by subrosion of gypsum).

In the 19th century, several authors already described rock glaciers, but only with the work of Wahrhaftig and Cox (1959) did modern and more comprehensive rock glacier research begin. However, until today, some confusion persists, mainly of the terminological kind concerning the precise differentiation of rock glaciers and glaciers (Table 1).

The development of rock glaciers is a consequence of the enrichment of debris with percolating snow meltwater, which freezes under permafrost conditions and forms interstitial and segregation ice. Therefore, rock glaciers are of periglacial origin. They may form out of talus accumulations (talus rock glaciers) or morainic debris (debris rock glaciers).

Rock glaciers contain between 40% and 60% of ice by volume and therefore constitute unsuspicious stores of water. In the Swiss Alps, rock glaciers contain only 0.03 km^3 of water equivalent per 1000 km^2 of mountain area, compared with 2.5 km^3 per 1000 km^2 stored within glaciers. In semiarid mountain areas, such as the Andes at 33°S, in contrast, the amount of water stored within rock glaciers is by one order of magnitude higher, while at the same time glacier sizes are smaller.

Table 1. Rock Glacier Taxonomy as Suggested by Barsch (1987)

Type	Talus rock glacier (material: talus) Debris rock glacier (morainic debris) Special rock glacier (other material)
Location	For talus rock glaciers: –Valley head, including cirques –Valley side walls –Footslope below cliff For debris rock glaciers: –Glacier terminus –Side of glacier
Connection to source area	Direct Not direct
Surface relief	Very well developed Subdued to well developed No furrows and ridges
Surface grain sizes	Earthy/blocky
Form	Singular/complex
Complexity	Multipart/multilobe/multiunit/multiroot
Shape	Tongue-shaped/lobate/transitional
Size (area)	Small ($<10^4$ m^2), medium, huge ($>10^5$ m^2)
Activity	Active/inactive/relict

Therefore, rock glaciers are important water resources in high mountain areas of continental semiarid and arid climates. In spite of this, little is known about their quantitative importance for river discharge.

The lower limit of rock glacier distribution is associated with the lower limit of discontinuous mountain permafrost, which is often attributed to the $-1\,^{\circ}$C to $-2\,^{\circ}$C isotherm of mean annual air temperature. Therefore, rock glaciers are considered good permafrost and climate indicators on a regional scale.

Concerning rock glacier movement, horizontal displacement rates range between a few centimeters and 1–2 m per year. Velocities are highest in the central lower part of the rock glacier and decrease laterally and toward the rock glacier's rooting zone. Furthermore, rock glaciers seem to move faster in summer than in winter.

The age of active rock glaciers may generally range between several thousand years and up to 10,000 years. Although several attempts have been made to obtain more precise data, absolute age determination has turned out to be extremely difficult. As climatically inactive rock glaciers are often situated at the lower limit of the distribution of active ones and up to 200 m below this limit, their inactivity probably developed since the Little Ice Age.

Recent rock glacier investigations focus increasingly on their physical properties. Geophysical methods, such as geoelectric soundings and refraction seismics, are being used in order to differentiate between permafrost and unfrozen ground along cross sections through the rock glacier. Furthermore, boreholes have been established in order to directly observe the internal structure of rock glaciers and monitor the change of deformation rates with depth. As the coarse boulder mantle of rock glaciers may strongly influence their energy balance, this issue is also being addressed within the more general framework of ground thermal regime in permafrost areas. At a regional scale, statistical methods are being applied in order to determine morphological and climatic controls on rock glacier formation.

GREAT LAKES

Theodore A. Endreny
SUNY ESF
Syracuse, New York

GEOLOGIC ORIGINS

Lakes Superior, Michigan, Huron, Erie, and Ontario comprise the five interior freshwater lakes that extend across a total area of 244,000 km^2 (0.16% of world land area), occupy parts of six states and two provinces in two nations, and contain nearly 20% of the world's freshwater supply (see Fig. 1). Glaciers, although frozen, are the only contiguous surface freshwater volume that contains more freshwater; they were the geologic forces that carved these lakes and the surrounding drainage area from the Precambrian rocks and overlying marine deposits from earlier inland seas that are now rocks classified by their Cambrian, Ordovician, Silurian, Devonian, Mississippian, and Pennsylvanian periods. The current Pleistocene Epoch of glacier activity, whose vertical heights were 2 km, compressed and scoured the area during numerous advances and retreats. During each icesheet retreat, the ice-excavated lake basins were filled by meltwater, and the absence of ice overload burden triggered areas of earth uplift and the creation of drainage outlets. Prior to the St. Lawrence drainage that followed the most recent

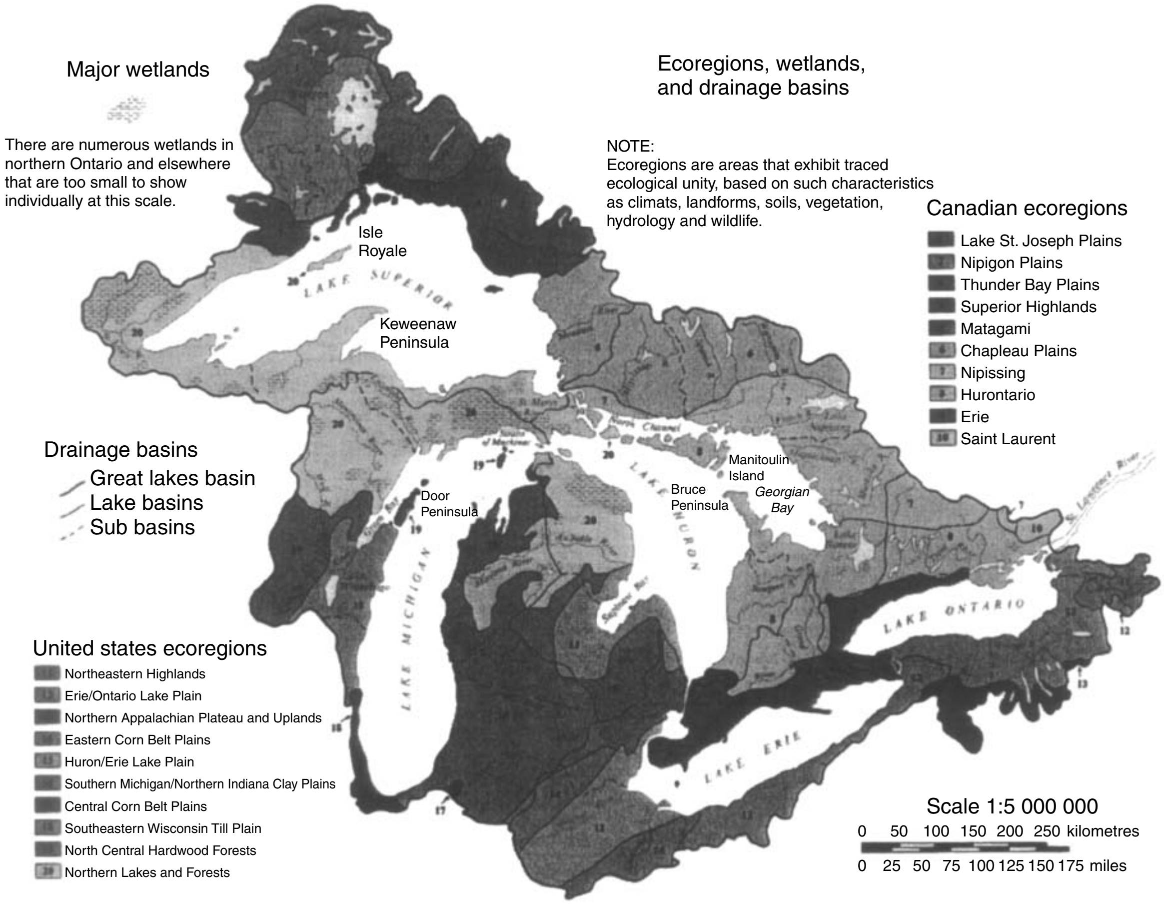

Figure 1. Great Lakes ecoregions, indicating unique features of the basin formed by geological forces, such as low-lying wetland areas.

Wisconsin icesheet retreat, lake drainage had spilled through Illinois River Valley toward the Mississippi, the Hudson River Valley, the Trent River, and the Ottawa River Valley. Uplift continues today, although more slowly.

Deposits from the glacial scour and retreat are largely poorly sorted mixtures of boulders, gravel, sand, silt, and clay, referred to as glacial drift and till. Exposed consolidated rocks of limestone, shale, sandstone, halite, and gypsum formed during the preglacial period of inland seas from sedimentary deposits are found in many river and glacial carved valleys; outcrops of igneous and other morph rocks are also revealed. Landforms include sand dunes; flat till plains; linear moraines; ramp shaped drumlins; and meltwater deposited eskers, kames, and outwash. Relatively low relief defines the drainage basin, but the lakes feature remarkable depth gradients, widths, and lengths, which are recorded in Table 1. It is apparent that extremes exist among the lakes; Erie and Superior have nearly a 350 m difference in maximum depth. The lakes are stunning, but the wetlands occupying the low gradient lands, as well as the isolated gorges and ravines carved by active rivers, also provide both ecological and geologic complexity.

HYDROLOGIC FLOWS AND CLIMATE

Great Lake flows are from Lake Superior and Michigan into Huron, Huron into Erie, and Erie into Ontario, which flows into the St. Lawrence Seaway through Canada and into the Atlantic. Numerous smaller inland lakes, rivers, and wetlands drain into the Great Lakes system, including some famous waterbodies such as the Finger Lakes, Lake Nipigon, Lake St. Clair, the Niagara River, and the Montezuma Wetlands of New York. Alterations to flow have occurred, such as diversions of Long Lac and Lake Ogoki to capture water from the Hudson Bay watershed, dams to drown the Lachine Rapids, and reversing the Chicago River to keep sewage from mixing with drinking water. Interesting dynamics of flow within the Great Lakes system include fall and spring turnover that breaks the Lake's thermocline strata and mixes hypolimnion and epilimnion waters, seiche, or sloshing of lake water height from shore to shore, an oscillation due to the large fetch of lake surface and strong winds piling water against the coast, and devastating surface waves caused by gale force winds. The Welland Canal, a unique man-made feature of the system, forms a navigable channel between Lakes Erie and Ontario, which are vertically separated by nearly 100 m, a drop that is dramatically illustrated by the Niagara Falls.

Surface water resources are enormous in volume and area; the precipitation, evaporation, and runoff components of the hydrologic cycle maintain this system that has a large flux rate, as shown in Table 2. Runoff into the lakes is smallest for Erie and Ontario, almost half that for Superior and Huron, but is augmented by the inflows from those same upper Great Lakes. The retention times follow a logarithmic decrease of 100-year intervals from the headwater Lakes of Superior and Michigan, which have large volumes and small inflows, to the yearly intervals for Erie and Ontario, which have enormous inflows and relatively small volumes. Fluctuation in lake levels has dramatic impacts on the internal and surrounding ecosystems and despite management efforts, is largely regulated by seasonal and annual (e.g., persistent) weather patterns. Groundwater reserves in the Great Lakes are present in multiple locations and at many different depths and flow rates. Besides their role in providing drinking water for numerous communities, they provide important base-flow release to keep the Lakes' feeder rivers perennial and flowing year-round.

Wetlands in the Great Lakes region are extensive and are represented by four distinct types classified as swamps, marshes, bogs, and fens. Swamps are distinguished by the presence of trees and shrubs and significant annual water cover. Marshes are known for their thick stands of aquatic plants rather than trees and like swamps, are most likely located in the southern Lake region. Bogs are most well known for their stagnant acidic water and slowly decaying, thick mats of sphagnum mosses; fens are filled by slowly moving, less acidic groundwater, dominated by sedges and grasses, but may have stunted shrubs and trees. Many of these wetlands are located along the coastal area, including the UNESCO Biosphere Reserve at Long Point on the north shore of Lake Erie.

Weather patterns and their long-term average condition known as climate have dynamic annual fluctuations in temperature and precipitation due to the Lakes' middle latitude location, which is a global meeting area for continental polar and maritime tropical air masses pushed by the jet stream. January mean daily air temperature ranges from −20 to 0 °C, and July mean daily air temperature ranges from 7.5 to 25 °C. Mean annual precipitation ranges from 600 to 1300 mm, and snowfall ranges from 150 to 350 mm. The mean annual frost-free period ranges from 220 days to a period less than 2 months north of Lake Superior. Rossby long waves perturbed by shortwave upper airflow patterns trigger the deepening of low-pressure systems, termed cyclogenesis, which results in open wave cyclones defined by the overrunning of warm fronts by cold fronts. Several such open wave cyclones can cover the Great Lakes region, and depending on the season, this can result in synoptic snowfall and rainfall as the cold, dry air mixes with the saturated Gulf Coast air.

Several other weather patterns are also familiar to the region. When the semipermanent Bermuda high-pressure system moves off the southeastern coast after autumn's first frost, the area may experience an Indian Summer as warmer Gulf Coast air is pushed north. Winter weather patterns common to this region include the severe lake effect snows, caused by cold air warming and absorbing lake water, and then cooling on the leeward shore and precipitating, and the northeastern (Nor'easter) winds caused by a strong high-pressure system in Quebec that bring Atlantic Ocean moisture into the region, with ice storms and wet snows. Spring weather is famous for its oscillation between extreme heat and cold, again as a result of the dynamic middle latitude looping of the Gulf Stream that can drag very warm spring Gulf Coast air northward or extremely cold, spring Hudson Bay air southward. Summer weather in the Great Lakes is moderated from extreme heat by the lake temperatures, which may set up lake–land breezes,

Table 2. Water Budgets for Great Lakes Water System ($m^3 s^{-1}$)

Category	Superior	Michigan	Huron	Erie	Ontario
Runoff to lake	14,000	11,000	14,000	7,000	9,000
Precipitation to lake	21,000	15,000	15,000	7,000	5,000
Evaporation from lake	15,000	10,000	13,000	7,000	3,000
Flow in by diversions	2,000	−1,000	0	−2,000	2,000
Flow in from upper lake	0	0	37,000	53,000	58,000
Flow out to lower lake/river	22,000	15,000	53,000	58,000	71,000
Retention time (yr)	191	99	22	2.6	6

as well as provide water vapor for convective afternoon thundershowers.

LAND AND WATER USE

Settlement in the Great Lakes extends back to Native American occupation following the Wisconsin icesheet retreat 10,000 years ago; the estimated population during the sixteenth century was between 60,000 and 117,000. The famous Iroquois confederacy of six tribes (Cayuga, Mohawk, Onondaga, Oneida, Seneca, and Tuscarora) occupied much of the New York lands draining into Lake Ontario. European settlers arrived in the early seventeenth century; boats were initially limited to the St. Lawrence Valley due to severe rapids. By 1680, French fur trading in Canada was well established and protected by army forts; by 1730, the British Fort Oswego protected colonies along the southern shore of Lake Ontario. The British captured many French forts by 1759, and the British retained control of the Great Lakes during the American Revolution, granting lands to nearly 40,000 loyalists who fled New England. The 2-year War of 1812 between America and Britain for the Great Lakes was claimed a victory by both sides; America secured the southern coast, and Canada retained its northern control.

Approximately 1 million people in the western Great Lakes region, who sowed crops, worked dairy, and built canals to ship exports and bring new products, firmly established an agricultural heritage for the region by the mid-1800s. Wetlands were drained, soils eroded by denuded lands, rivers were clogged by sediment, and many fish spawning habitats were destroyed. Soil conservation measures have helped stabilize soils, and chemical fertilizers, pesticides, herbicides and irrigation have been recommended for increasing production. Chemicals such as excess phosphorous and historic use of DDT, along with modern row crop monoculture and hormone disrupting chemicals, have significantly impacted the ecosystem. Agricultural production brings vital income and needed food to the region and occupies between 3 and 67% of basin land and upward of 33% of shoreline land, as reported in Table 3.

Logging and forestry occupy even greater amounts of land, from 21 to 91% in the basin (see Table 3), and commercially began in the 1830s by targeting the light and strong white pine, desired for ship and building construction. Forest industrial uses, primarily pulp and papermaking, but also tannins, created additional revenue and development of the region. Again, however, several negative environmental consequences of this industry, such as water pollution and extensive area, high grade, clear cutting have since been identified. Now it operates at lower volumes and uses best management practices to target sustainable operations. Commercial fisheries were also of major importance; in the late 1890s, harvests had grown by 20% per year since 1820, and annual harvests of 65,000 tonnes were recorded. Today, lake trout, sturgeon, and lake herring have largely been replaced by introduced species of smelt, alewife, splake, and Pacific salmon; average harvests have been around 50,000 tonnes. Recreation boating, swimming, and ecotourism along with sport fishing also represent significant uses and income on the Lakes.

Table 3. Basin and Shoreline Land Use Type (%)

Category	Superior	Michigan	Huron	Erie	Ontario

Commercial	n/a	12	32	12	8
Other	n/a	5	7	16	7

Industrial and commercial development cultivated along the shores of the Great Lakes provided waterpower and waterways for shipping, through which in the 1820s, the Erie Canal and Welland Canal were built. By 1960, water level controls allowed operation of the St. Lawrence Seaway, and the region's principal commodities, iron ore, coal, and grain, were heavily shipped between lakes and to the Atlantic Ocean. Industrial manufacturing, aggressively developed in this region, fostered the growth of many important cities such as Duluth, Marquette, Chicago, Detroit, Toledo, Hamilton, Cleveland, and some towns that had less waterborne commerce such as Rochester, Buffalo, and Toronto in Lake Ontario. Polluted discharges from these industrial centers caused a significant negative impact on the Great Lakes, further discussed in the next section. Episodes of cholera in 1854 and typhoid fever in 1891 were the impetus to reverse the flow of the sewage-spoiled Chicago River away from Lake Michigan, a drinking water source; Hamilton, faced with contaminated lakeshore water, installed deeper intakes into Lake Ontario.

Aquatic ecosystem resources and dynamics are extensive and complex. Driving the food web is sunlight, supplying energy for autotrophs such as phytoplankton, algae, and plants, which in turn feed the heterotrophs, from zooplankton to herbivore fish, which then feed the larger ecosystem carnivore and omnivore predators. Fish species for this region include alewife*, Atlantic salmon, bloater, bowfin, brook trout, brown trout*, burbot, carp*, Chinook salmon*, Coho salmon*, freshwater drum, lake herring, lake sturgeon, lake trout, lake whitefish, longnose sucker, muskellunge, northern pike, pink salmon*, pumpkinseed, rainbow smelt*, rainbow trout*, rock bass, round goby*, round whitefish, ruffe*, sea lamprey*, smallmouth bass, walleye, white bass, white perch*, white sucker, and yellow perch, where * indicates invasive species. This process continues upward to the amphibian, avian, and terrestrial herbivores and predators and is repeated in many adjoining wetlands and rivers. Popular avian and terrestrial animals in this region include cormorants, gulls, waterfowl, eagles, snapping turtles, whitetailed deer, moose, beaver, muskrat, fox, wolf, and black bear. Decomposition returns the organic nutrients to the mineral soil and inorganic system, an important process carried out by bacteria and fungal organisms. Natural and anthropogenic supplies of essential micro- and macronutrients are critical for the proper biological functioning of this food web, but the introduction of metals, industrial chemicals, and excess nutrients has caused problems, including bioaccumulation and biomagnification, some of them are discussed in the next section.

WATER RESOURCE MANAGEMENT

Pioneering international water resources management has been forged along the shores of the Great Lakes, possibly a challenge best met by two countries that have relatively stable political and economic systems. In 1909, the Boundary Waters Treaty established binational guidance on regulating water levels and flows, which have been the responsibility of the International Joint Commission (IJC), an agency of and for Canada and the United States interests. Separate legislation in 1972, called the Great Lakes Water Quality Agreement (GLWQA), established guidance on regulating water quality, again overseen by the IJC and implemented by numerous national, provincial, state, and small government agencies. Dams are operated on the St. Marys River, Niagara Falls, and the St. Lawrence and only directly affect Lake Superior water levels. These few control points prevent the IJC from dampening all fluctuation; municipal, manufacturing, and power production withdrawls (see Table 4) are affected by and affect levels. Weather exerts a larger control on water level variability, but the IJC has concluded that costs to engineer controls outweigh benefits. Beginning in 1973, the IJC has included erosion control within its water level management objectives of hydropower and navigation, and today the IJC has established new water level guidance to allow greater fluctuation, principally in Lake Ontario, for ecosystem health.

Water quality management under the GLWQA, signed in 1978, began with an analysis of the mass balance loading of phosphorous and other pollutants, leading the way for major subsequent advances in setting target loading limits and current total maximum daily load analysis. Nutrients and carcinogens have received the greatest research and management focus, but the initial analysis of hormone disrupting chemicals in the Great Lakes food chain has identified new concerns and represents a growing issue. An ecosystem approach was adopted by the GLWQA, which was implemented through more expansive Lakewide Management Plans (LaMPs), but areas of concern that contained extreme pollution were also targeted by Remedial Action Plans (RAPs). Innovative water resource management methods developed by the IJC and national agencies such as the Environmental Protection Agency and Environment Canada that encouraged citizen involvement in seeking and implementing solutions have since been studied and shared within the UNESCO Hydrology for the Environment Life and Policy (HELP) Initiative, a needs driven hydrology policy-management-science program to which Lake Ontario belongs. Advanced hydrologic research, such as remote sensing driven modeling and monitoring, coupled with consensus based watershed management, will ideally answer pressing water resource issues.

Table 4. Municipal, Manufacturing, and Power Production Water Withdrawals (10^6 m^3 yr^{-1})

Category	Superior	Michigan	Huron	Erie	Ontario
		Withdrawals			
Municipal	98	2,622	384	2,685	927
Manufacturing	1,133	8,608	2,158	9,820	2,935
Power production	740	12,131	4,852	12,791	13,282
		Consumptive Use			
Municipal	18	169	170	189	152
Manufacturing	71	785	89	1,409	125
Power production	9	214	62	178	174

New management issues have replaced the traditional water chemistry concerns and include the response to several invasive species. Of the many invasives, including crustaceans, fish, mollusks, and plants, some new introductions such as the spiny water flea and zebra muscle are wreaking havoc on industrial to recreational uses of the Great Lakes. Ballast dewatering operations of commercial shipping vessels have been identified as the major pathway for invasives, and U.S. Coast Guard regulations prohibiting this operation are in place. Other challenges include the restoration of coastal wetlands; many of them were destroyed by the removal of extreme peak and low water levels that are responsible for the killing back of monocrop grasses that outcompete the more complex ecosystems needed for proper fish spawning. Restoration of urban streams, including the separation of storm and sanitary sewers, will also be required to regain healthy tributary and headwater spawning areas for Lake species. Additionally greater management control is needed for agricultural, suburban, and urban management of nonpoint source runoff, currently the biggest source of sediment, nutrient, metal, organic, and chemical pollutant loading, now that point source discharges have largely been controlled. A final note must address the recent climate change analysis performed as part of the U.S. Global Change Research Program, which predicts a most likely scenario of lower lake levels due to the establishment of greater evaporation rates, which would potentially have devastating impacts on many recreational, commercial, industrial, navigational, and other Great Lakes activities.

GREENHOUSE GAS EMISSIONS FROM HYDROELECTRIC RESERVOIRS

Nathalie Barrette
Laval University
Québec, Canada

The presence of certain trace gases (e.g., CO_2 and CH_4) in the atmosphere is related to human activity (fossil fuel combustion, deforestation, and intensive agriculture), and to the biogeochemical processes that occur in natural environments (tropical and boreal forests and tundra). For many years now, scientists have been trying to determine the importance of natural environments as sinks for or sources of these trace gases (1–3). The terrestrial biosphere constitutes a major carbon sink (4); more than a third of the anthropic CO_2 emissions are fixed there (5). However, certain changes in land use (e.g., deforestation and the draining of marshes for agriculture) can lead to changes in the way greenhouse gases (GHGs) are produced or fixed by modifying the physicochemical characteristics of these soils. In the medium and long term, these changes are likely to invert the carbon sink capacity that has been attributed until now to certain natural environments (e.g., boreal regions). This article examines how one of these land-use changes, the creation of hydroelectric reservoirs, significantly modifies the carbon cycle in natural environments.

STATE OF RESEARCH

The scientific community's interest in GHG production by hydroelectric reservoirs originated, in part, from the controversy launched by the publication of a paper by Rudd et al. (6). In this publication, the authors concluded that "*. . .per unit of energy produced, greenhouse-gas flux to the atmosphere from some hydroelectric reservoirs may be significant compared to greenhouse-gas emission by fossil-fuelled electricity generation. . .*". This conclusion, based on a weak sampling of fluxes and a method of calculation described as inadequate by certain scientists, created keen interest among researchers (7,8) and the scientists affiliated with hydroelectric companies (9–11). Above and beyond the exercise of comparing energy production methods, one fact remains: that hydroelectricity can no longer be described "as clean energy" with respect to GHG emissions (12–17).

Boreal Reservoirs

One of the studies that has contributed greatly to furthering our knowledge focused on boreal reservoirs in central northern Québec (18).

It was initially assumed that CO_2 and CH_4 fluxes measured on the surface of the reservoirs came mainly from the degradation of organic material in the flooded soil (12). The first research endeavors to understand the processes involved were devoted to surface sampling of GHG emission. Parallel to sampling these surface fluxes, certain morphological parameters (depth of the water column, type of flooded soil), physicochemical (temperature of water), and meteorological data (wind speed, temperature) were also measured to determine their effects on the variability of these fluxes. Over the years, a significant amount of data was collected concerning GHG emissions from hydroelectric reservoirs in northern Québec. These data, as well as complementary work in microbiology, geochemistry, and other scientific fields, have made it possible to understand better the complex series of processes that control the annual carbon balance in the reservoirs. These processes include the production of GHGs through the degradation of flooded organic matter (soil and vegetation), the production/fixation of GHGs by bacteria and plankton in the water column, and the loss of GHGs to the atmosphere by diffusion, convection, and effervescence (production of gas bubbles) (19).

The processes responsible for producing GHGs in reservoirs and, in particular, production from the degradation of organic material in flooded soil are still being studied. Moreover, we can make no definitive qualitative or quantitative statements about the nature and importance of the various processes involved in producing CO_2 and CH_4. The original assumption about the origin of these gases supposed that the flooding that occurs when a hydroelectric reservoir is created starts significant bacterial activity that degrades the flooded terrestrial organic matter. This activity leads to mineralization of the organic matter and the liberation of CO_2 in the water column. There is likewise the creation of anoxic zones in the flooded soils or in the hypolimnion that supports methanogenesis (formation of CH_4). The carbon source at the origin of the reservoirs' GHG emissions is thus located mainly in the flooded soils (12).

A subsequent study by Weissenberger et al. (20) concerning the total quantity of submerged carbon versus the issue rates of CO_2 and CH_4 at the surface of the reservoirs anticipated that after 100 years, the submerged organic matter would be completely degraded. In practice, however, we are far from observing such a phenomenon. The Cabonga reservoir (central northern Québec), which is more than 70 years old, shows few signs of advanced degradation. A scuba diver observed that certain submerged conifers were still intact after being submerged all these years (9). Moreover, one statistical study by Duchemin et al. (17) showed that there was little difference in CH_4 fluxes for reservoirs of different ages and that there was only a very slight decrease (less than 1% per year) of CO_2 fluxes according to the age of the reservoirs. According to Weissenberger and collaborators (20), the degradation of organic material in the flooded soil cannot solely explain CO_2 and CH_4 fluxes observed at the surface of the reservoirs.

Migrating carbon (from the drainage basin) in transition in the reservoir seems to constitute another considerable source of the carbon involved in GHG production. In fact, new avenues of research suggest that GHG production initially comes from the degradation of organic material in the flooded soil. After a few years, GHG production seems to remain stable due to a major change in the trophic state of the reservoir. Reservoirs go from an autotrophic state (self-sufficient in terms of energy; photosynthetic production exceeds the loss due to respiration) to a heterotrophic or allotrophic state (dependency on an external source of energy, where photosynthetic production is lower than respiration). This change leads to the assimilation of migrating, allochthonous carbon by living organisms in the reservoir. The bacteria are probably responsible for transforming this carbon into GHGs, and the process seems to occur in the entire water column. All of this is still hypothetical and constitutes a new research project in itself (21).

With regard to the bacterial activity in the water column, experiments in microbiology by Duchemin and his collaborators allowed them to observe that a significant portion of the CH_4 was oxidized before it even reached the reservoir surface (12). The CH_4 is oxidized in the first 25–50 centimeters above the flooded soil. The rate of oxidation is significant in flooded peat bogs and very low in flooded podzols. According to Duchemin et al. (19), two conditions are necessary for methane oxidation: a dissolved oxygen concentration higher than $1\ \mathrm{mg\,L^{-1}}$ and a dissolved inorganic nitrogen concentration lower than $20\ \mu\mathrm{M}$. This process is at work mainly during the ice-free season because, the weak dissolved oxygen concentrations generated an anoxic zone in the winter which largely reduced methane oxidation. However, at the present time, very few observations are available to quantify the process of methane oxidation adequately.

Planktonic activity did not appear to be a determining factor in the GHG concentration of the hydroelectric reservoirs of central northern Québec. Though biological activity (fixation-respiration) had suggested that the maximum dissolved CO_2 concentration occurred at night, a study by Canuel et al. (1997) has shown that the maximum concentration actually occurs during the day. The authors thus deduced that the evolution of the GHG concentrations in the reservoir is controlled by processes other than planktonic activity.

Conversely, the processes responsible for transporting dissolved gases in the water column are relatively well understood. It is assumed that most of the transport occurs vertically, that is, there is little horizontal current and homothermy. The vertical transport of dissolved gases results from turbulent diffusion and convection. The turbulent diffusion is induced by mechanical forcing (e.g., wind) which acts in a stable density gradient. For its part, the convection occurs following density anomalies that cause an unstable profile. This can ensue from the deep absorption of solar radiation or from the loss of sensible heat or latent heat through evaporation or through ice melting. These two transport mechanisms (turbulent diffusion and convection) vary in intensity according to the period of the year and weather surface conditions. For example, in autumn, major convective movements are responsible for transporting a significant quantity of dissolved gas toward the reservoir surface due to the static instability generated by surface cooling (23). According to Duchemin and Levesque (24), effervescence (i.e., release by bubbles) constitutes another transfer mechanism of GHGs in a reservoir. However, the contribution of this mechanism is only significant for CH_4 in the very shallow parts of reservoirs (24). For CO_2, it is estimated that this transport mechanism contributes less than 1% of the total annual emissions (25).

Kelly et al. (26) conducted a study in northwest Ontario in which GHG emissions were measured before and after the controlled flooding of a peat bog and pond. It was observed that the flooding of the peat bog greatly modified the GHG emission balance. Before flooding, the peat bog constituted a CO_2 sink and a weak source of CH_4. After flooding, it became a significant source of CO_2 and CH_4. According to Kelly et al. (26), this CO_2 status inversion is partly caused by the death of almost all the vegetation in the natural environment, making it incapable of fixing CO_2, and by the decomposition of the submerged organic matter. Furthermore, the reinforcement of its status as a CH_4 source is due to an increase in the anoxic decomposition of the vegetation and to a reduction in the consumption of CH_4 (oxidation) by oxidizing bacteria. It would seem that the first mechanism is quantitatively more significant than the second.

Tropical Reservoirs

Reservoirs in tropical regions have also been studied. The first studies indicated that tropical reservoirs constitute even more significant GHG sources than northern reservoirs (15,16,24,27). According to Fearnside (27), the results obtained until now even call into question the idea that hydroelectricity in the Amazon region will produce less GHGs than the production of the same quantity of energy by other fossil fuels. According to Pearce (15), the Amazon basin brings together ideal conditions for producing methane; little dissolved oxygen, relatively high temperatures, and high concentrations of nutrients. This author also states that all the hydroelectric reservoirs of the world produce the equivalent of 7% of the total production of CO_2. Duchemin et al. (24) point out that Amazonian reservoirs produce ten times more CO_2 and three times more CH_4 than the hydroelectric reservoirs of northern Québec.

CONCLUSION

The biosphere and, in particular, the soils contain substantial carbon reserves. Flooding following the creation of a hydroelectric reservoir can therefore significantly modify this carbon reserve. The boreal regions and their soils have acted as a carbon sink since the last glaciation. This capacity can, however, be reversed. As for the tropical regions, their GHG emissions can be so significant as to call into question hydroelectric development.

From the point of view of the international effort to reduce GHGs, it would appear essential to compare the annual total GHG emissions arising from different energy forms; an exercise that has been carried out by several scientists (28–30). Duchemin (29) has shown that the boreal reservoirs have annual equivalent CO_2 emissions lower than those emitted by power stations fueled by coal or natural gas when producing an equivalent quantity of energy (see Fig. 1). On the other hand, he has also shown that certain tropical reservoirs can emit quantities

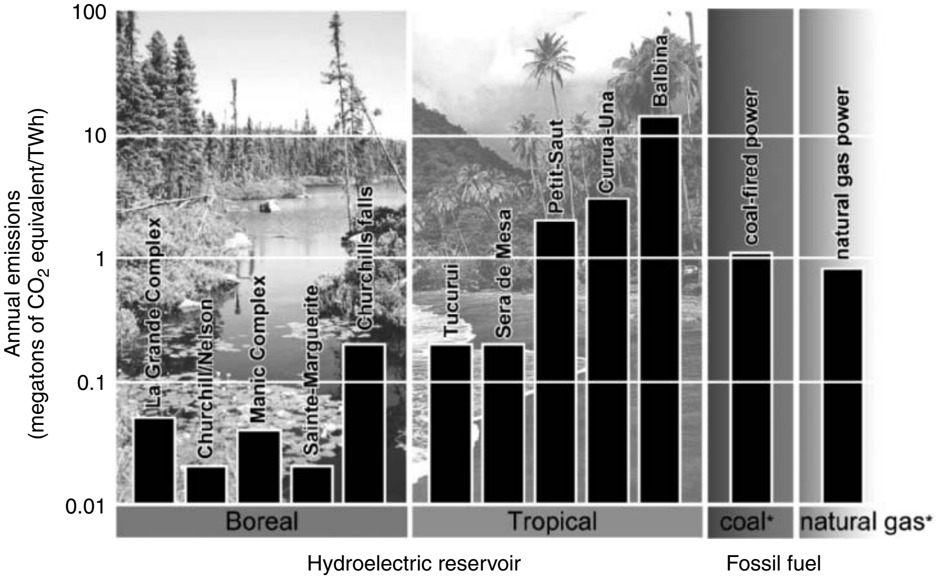

Figure 1. Greenhouse gas emissions from hydropower and fossil fuel power (29).

*average value

of equivalent CO_2 up to 14 times higher than the emissions from a coal-fired power station producing a comparable quantity of energy (see Fig. 1). It is particularly worth noting that shallow tropical reservoirs (6 m and less) emit up to two to three times more CO_2 per square meter than deep reservoirs (25 m and more). Thus, the site for constructing a hydroelectric reservoir in a tropical area can be a determining factor in its emission balance. The creation of hydroelectric reservoirs in zones of fairly flat topography should be avoided because the flooded surface areas will be substantial and will provide ideal conditions for developing the bacteria responsible for these emissions.

Duchemin insists that the current measurements of emissions in tropical reservoirs are still too limited to offer a clear answer to the question of energy choices. Moreover, he adds that future studies should introduce the concept of the net before-and-after-flooding balance to evaluate truly the changes in the carbon sink or source capacity of a given territory.

GULLY EROSION

Wayne D. Erskine
State Forests of New South Wales
Beecroft, New South Wales
Australia

Gullies have formed rapidly in many parts of the world during the last 300 years following the change from traditional agriculture or nomadic indigenous lifestyles to more intensive European-based agriculture. They are deeper erosion channels than rills, but their differentiation is often unclear and arbitrary because of a continuum between the two features. Rills are shallow, ephemeral erosion channels that can be obliterated by standard tillage, alternating cycles of freeze-thaw, or rain-impacted shallow overland flows.

DEFINITION

Brice (1) proposed that gullies are recently extended drainage channels that transmit ephemeral flow, have steep sides, a width > 0.3 m, a depth > 0.6 m, and terminate at a steeply sloping or vertical, upstream primary nickpoint (see next section for definition of within-gully features). Gregory and Walling (2) concluded that gullies are characterized by

- ephemeral streamflow,
- steep sidewalls and nickpoints,
- a depth greater than rills so that they cannot be eliminated by plowing, crossed by a wheeled vehicle, or restored in the short term,
- a V-shaped cross section in fine-grained, resistant subsoils,
- a U-shaped cross section where the soil and subsoil are equally erodible, and
- unconsolidated sediments in the sidewalls.

Attempts to differentiate between gullies and streams on the basis of flow frequency are difficult for two reasons. First, gullies are not restricted to specific climatic regions but have been described in arid, semiarid, subhumid, and humid areas (11). Second, flow regimes vary systematically based on drainage basin area and climate, (31) and gullying is not restricted to specifically sized basins nor to areas of ephemeral flow.

Brice (1) adopted a depth > 0.6 m as representative of a gully, but a depth of 0.3 m has been proposed by soil conservationists (3) and a depth of 0.5 m by Prosser and Winchester (4). Gullies need not be defined by the exceedance of a critical depth because the depth of incision, cross-sectional shape and longitudinal profile of gullies are all dependent on the materials into which the gully is eroded (5–7).

To overcome the above problems, the definition proposed by Schumm et al. (8) is adopted. A gully is a relatively deep, recently formed eroding channel that forms on valley sides and on valley floors where no well-defined channel previously existed. In contradistinction, incised streams form by the erosion of a preexisting river channel (8). Valley-side gullies result in an expansion of the drainage network due to erosion of soil, colluvium, and/or bedrock in hillside hollows. Valley-floor gullies may be either continuous or discontinuous and erode valley-fills of alluvium, swamp deposits, and/or bedrock. Arroyos, which have been the subject of much research in the American southwest, are valley-floor gullies that have steeply sloping or vertical walls of cohesive, fine sediments and flat and generally sandy floors (9).

GULLY EROSION PROCESSES

Gully erosion occurs by a number of erosional processes involving nickpoint or nickzone initiation and upstream retreat (Fig. 1), downstream progressing degradation, and sidewall erosion. Nickpoints are an abrupt change in bed profile that involve a substantial, local increase in slope and retreat by migrating upstream at a rate that declines exponentially over time (5,8). Primary nickpoints mark the upslope limit of gully erosion, whereas secondary nickpoints rework sediment temporarily stored in the gully bed (Fig. 1). Nickzones are steep sections at the headward limit of erosion cycles and also migrate upstream over time without maintaining a vertical face (8). The rotation of nickpoints into nickzones usually occurs when the eroded valley fill is not stratified (6) or when it is uniform, noncohesive material (5). During downstream progressing degradation, bed slope is reduced, the bed often becomes armoured or veneered with gravel, if present, and bed material discharge declines, approaching a minimum value consistent with upstream sediment supply (10). During the evolution of gullies, initial upstream nickpoint migration is often replaced by subsequent downstream progressing degradation, as upstream sediment supply declines due to the exhaustion of most of the stored sediment within the gully network. These erosion cycles can be repeated many times. Sidewall or bank erosion following incision occurs by many processes that operate at different rates (7,11) and can, in some cases, erode more sediment than the initial nickpoint erosion (12).

Gully Sediment Yields

Actively developing gullies generate very high sediment yields that have caused concern to land and river managers throughout the world. However, rates of gully erosion are not included in equations for standard erosion prediction (13). The author's data on sediment yields from gullies of different age in southeastern Australia have been combined with that of Prosser and Winchester (4) to produce Fig. 2. Erskine and Saynor's (14) detailed review of the available sediment yield data for Australian rivers showed that most rivers have yields less than 50 $\mathrm{t km^{-2} y^{-1}}$, and many are also less than 10 $\mathrm{t km^{-2} y^{-1}}$. High yields in excess of 120 $\mathrm{t km^{-2} y^{-1}}$ have been found only for basins that have been extensively disturbed by agriculture or significantly gullied. Figure 2 demonstrates that developing gullies less than 5 years old produce sediment yields greater than 2000 $\mathrm{t km^{-2} y^{-1}}$, but that these high yields rapidly decline during the next 20 years. Williams (15) reported the very high sediment yield of 93,750 $\mathrm{t km^{-2} y^{-1}}$ for a small developing gully in the seasonally wet tropics of northern Australia, where sediment yields are usually very low by world standards (8). Neil and Fogarty (17) used farm dams to determine sediment yields from continuous and discontinuous gullies in comparison to native forest in southeastern Australia. They found that discontinuous gullies, on average,

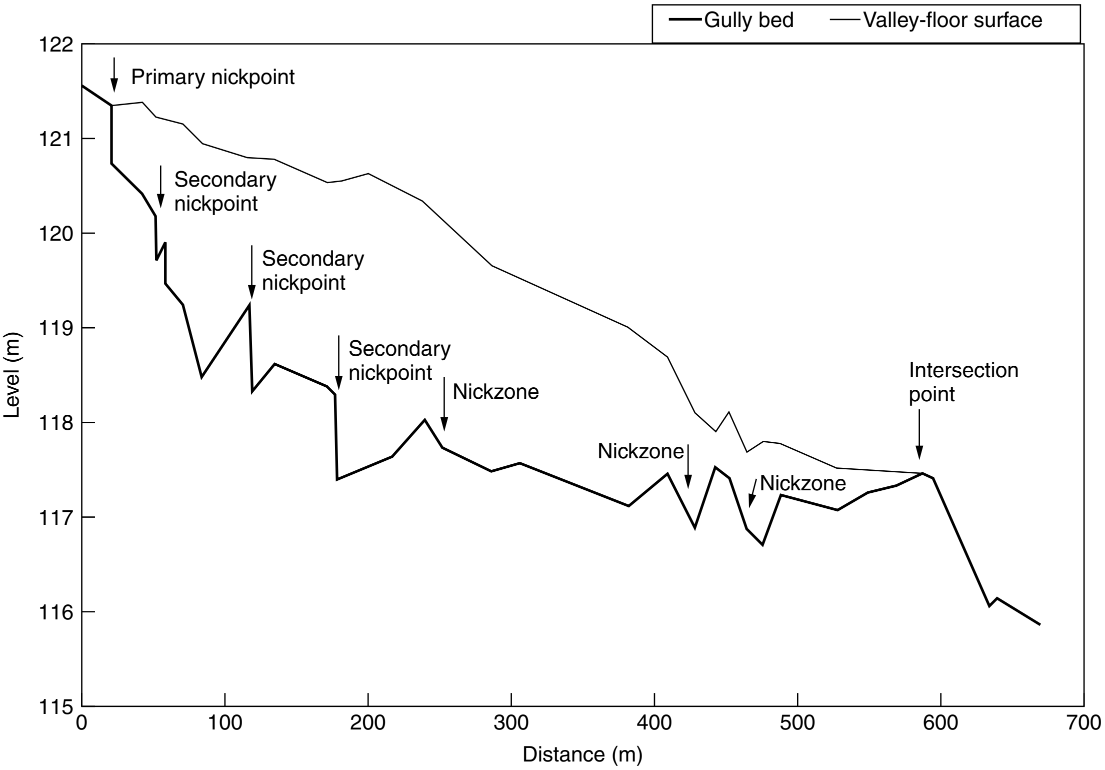

Figure 1. Longitudinal profile of the Dry Arm discontinuous valley-floor gully in the upper Wollombi Brook drainage basin in southeastern Australia, showing some of the main features.

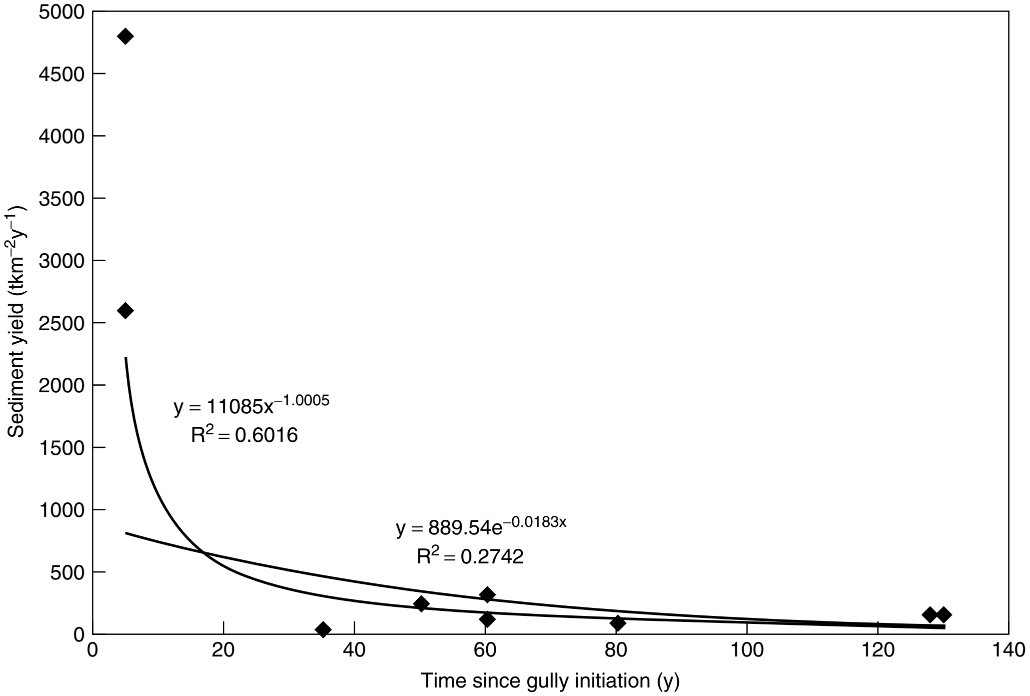

Figure 2. Variations in gully-derived sediment yields with time since gully initiation in southeastern Australia.

produced more than 11 times higher yields than native forests and that continuous gullies generated the highest yields at more than 73 times greater than native forests. Graf (18) demonstrated that an exponential decline in rates of gully erosion occurs in Colorado, consistent with relaxation following initial gully erosion. However, for the data in Fig. 2, a power function is a much better fit than an exponential function. Nevertheless, there is a rapid decline in sediment yield following the first 20 years after gully initiation.

Not all of the sediment generated by gully erosion is transported directly into higher order streams because significant amounts are often stored within the gully and immediately downstream. Melville and Erskine (19) found from detailed field measurements on a compound discontinuous gully system draining a 13.8 km^2 basin in southeastern Australia that 90% of the 190,000 m^3 eroded since European settlement was trapped in the gully bed and small floodplain within the gully as well as in the fan immediately downstream, without ever being exported from the basin. More recent research by the author on other discontinuous gullies in southeastern Australia accounted for all of the gully-eroded sediment which was entirely stored within the gully and the downstream fan. Similarly, Neil and Fogarty (17) estimated that as much as 60% of the material eroded from discontinuous gullies in southeastern Australia was deposited solely in the downstream fan and hence was not transported out of the basin.

Sediment movement in drainage basins is often restricted to clearly defined compartments that may be up to tens of kilometers long but are not linked to higher order streams (19,20). Therefore, gullying often results in reworking sediment from one temporary storage to another without a detectable impact on the sediment yields of large drainage basins (21).

CAUSES OF GULLY EROSION

Cooke and Reeves (9) proposed a deductive model of arroyo formation which maintains that a gully is initiated when the erosion potential of flows (erosivity) locally exceeds the resistance of the surficial materials (erodibility). Therefore, there are two fundamental changes, increased erosivity and increased erodibility, which either together or individually, can lead to gully initiation (9). Erosivity refers to the propensity for flows to detach and remove materials from a given area more rapidly than they are replaced from upstream and is a function of many interrelated hydraulic, channel form, and sediment load variables that are difficult to evaluate precisely (9). Nevertheless, recent research has demonstrated that grass is very important in increasing critical boundary shear stress for soil erosion (22,23). Erodibility is a measure of surficial sediment's resistance to erosion forces and is determined by soil texture, soil aggregation, soil coherence to wetting, soil organic matter content, and vegetative cover. However, there are many trigger mechanisms that can potentially lead to gully formation; they have been classified (Fig. 3) as natural geomorphic processes, gradational geomorphic thresholds, random climatic events, secular rainfall changes, and land use changes (9,24).

Figure 3 shows an expanded version of Cooke and Reeves's deductive model without the explicit links between specific trigger mechanisms and the induced changes in erosivity and/or erodibility. The reason for the omission of these explicit links is to show an uncluttered

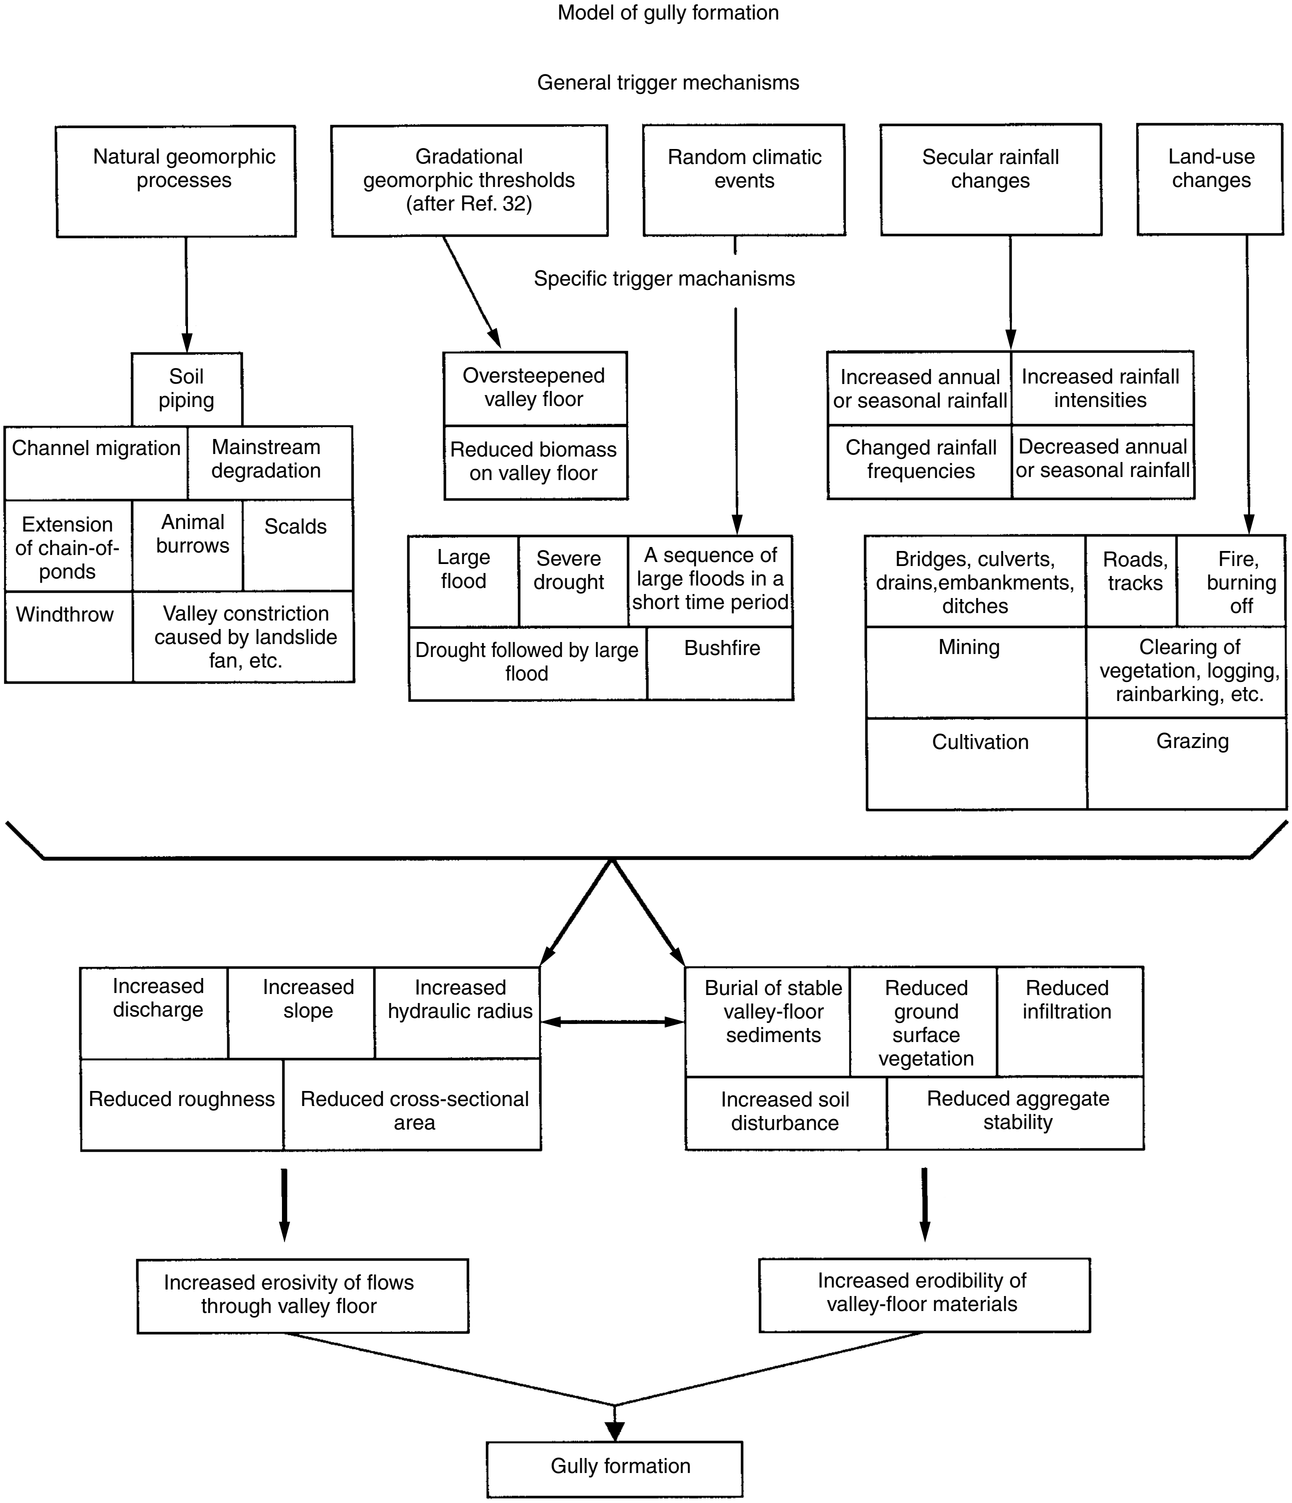

Figure 3. Deductive model of gully formation (modified from Refs. 9 and 24).

hierarchical representation of the interrelationships. Examples of the possible specific trigger mechanisms are outlined in the second tier, and the way they effect erosivity and erodibility is listed in the third tier of Fig. 3.

It is important to emphasize that the results of detailed investigations of gully initiation have found that apparently similar gullies can be formed in different areas as a result of different combinations of initial conditions and specific trigger mechanisms (9). For example, the author found that in upper Wollombi Brook, a 341 km^2 basin in humid southeastern Australia, for the period since first European settlement in the 1820s,

- the timing of valley-floor gully initiation was highly variable, ranging over at least 100 years and only rarely coincided with the period of peak agricultural productivity in the middle of the nineteenth century,
- most gullies were initiated at various times following long periods of sediment storage in valley segments without inflowing tributaries that eventually increased valley-floor slope until it exceeded a stability threshold (gradational geomorphic threshold in Fig. 3),
- some gullies were initiated by a catastrophic flood when up to 508 mm of rainfall were recorded in 12 hours in June 1949 (25) (random climatic event in Fig. 3),
- some gullies were initiated at various times by culvert construction, drains, and ditches in localized parts of valley floors (19) (land use changes in Fig. 3), and
- many valley floors remained ungullied despite extensive valley-floor forest clearing, high intensity agricultural activities involving repeated cultivation, extensive valley-floor roading, repeated high intensity wildfires, and intensive rural subdivision.

Figure 4 depicts the least-squares linear regression relationship between field-surveyed, mean valley-floor slope and basin area for 19 sites (nine ungullied and 10 gullied) in the upper Wollombi Brook basin. For the gullied sites, the valley-floor slope of the presumed initiation point of the gully was surveyed. As this is frequently buried by sand eroded from the upstream gully, multiple excavations were conducted to reveal the original valley-floor surface which was readily identified using the techniques outlined by Happ et al. (26). A locally steeper slope segment was found at the downstream end of each gully, as first reported elsewhere (27). The slope and constant of the regression equation are consistent with reported values elsewhere (13). The regression line effects a clear separation between gullied and ungullied sites (only one gullied site plots below and no ungullied sites plot above the line) and represents a gradational threshold slope for the initiation of gullying in this basin. Similar results have been reported elsewhere (8,13,27,28).

EFFECTS OF GULLY EROSION

The environmental, human, and economic effects of gully erosion documented by many authors (for examples, see Refs. 7–9, 13, 24, 26, 28–30) include all of the following:

1. high soil erosion rates and sediment yields
2. substantial loss of productive farmland
3. deterioration of downstream water quality
4. rapid and massive downstream sedimentation
5. replacement of a relatively stable, muddy substrate by very mobile sand
6. more peaked flood hydrographs
7. higher flow velocities due to decreased resistance to flow and greater flow depths
8. reduced baseflow persistence
9. reduced frequency of overbank flow
10. lower floodplain water tables
11. loss of valley-floor wetlands and seepage zones and their associated vegetation
12. reduced macroinvertebrate, reptile, amphibian and fish biodiversity and some local extirpations by the wholesale loss of aquatic habitats
13. severe farm access and management problems

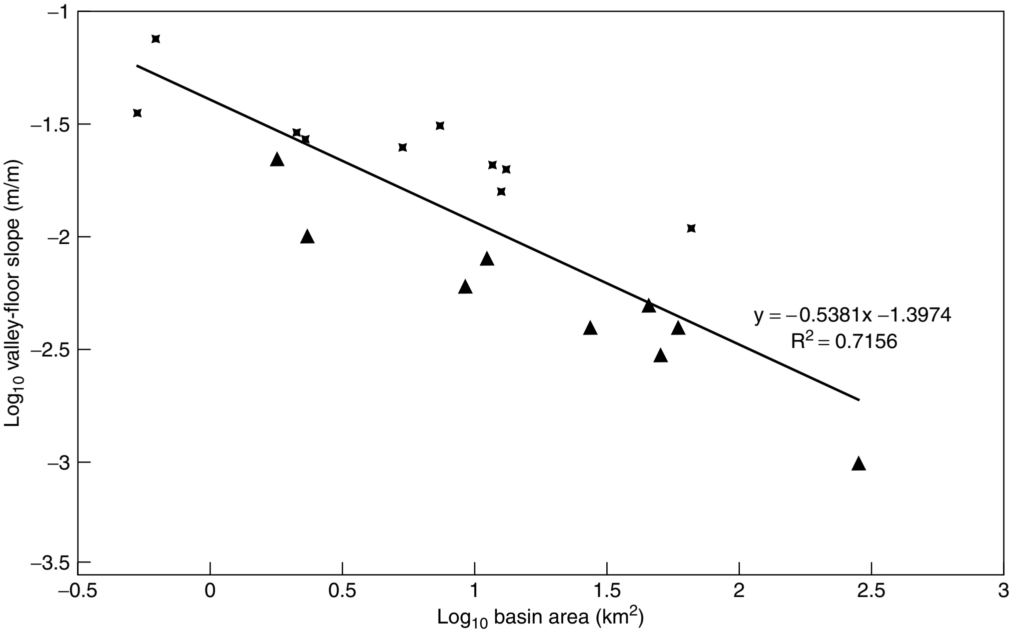

Figure 4. Bivariate plot of mean valley-floor slope versus drainage basin area for various gullied and ungullied sites in the upper Wollombi Brook drainage basin, southeastern Australia. The gullied sites are represented by crosses and the ungullied sites by triangles.

14. flooding of houses by soil-laden water
15. reduced farm incomes due to a decline in land productivity
16. disruption and dislocation of transport routes
17. damage to, and loss of, human structures, such as bridges, pipelines, pump sites and water intakes.

These effects have been recorded at the site of initial gully erosion as well as upstream and downstream (8,9).

POTENTIAL HEALTH ISSUES ASSOCIATED WITH BLUE-GREEN ALGAE BLOOMS IN IMPOUNDMENTS, PONDS AND LAKES

Barry H. Rosen
U.S. Fish and Wildlife Service
Vero Beach, Florida

INTRODUCTION

Cyanobacteria, also known as blue-green algae, are the most primitive group of algae. Although they are most closely related to other bacteria, they have the same pigment for photosynthesis that other algae and plants have. They are simple but remarkably successful organisms. Individually, they are microscopic; however, large clusters of cells are easily visible as a surface scum (a type of algal bloom) on any stable body of water. Some kinds of blue-green algae produce natural toxins. Unfortunately, no visual technique can distinguish between toxin-producing blue-greens and those that are harmless. Ingestion of these toxins has caused the poisoning of domestic animals, sometimes resulting in death. These include cattle, horses, sheep, hogs, ducks, dogs, and wildlife. Human exposure and toxicity, ranging from intestinal problems to liver damage and fatalities, has only recently been documented.

TOXINS TYPES

The toxins are generally of two types: hepatotoxins and neurotoxins. Hepatotoxins affect the liver, disrupting the important proteins that keep the liver functioning. They generally act more slowly, and a higher dose is needed before death occurs; however, they also may be tumor promoters at low doses. Microcystins, the most common and important family of hepatotoxins, have over 60 variations of a basic cyclic peptide structure. Most of these are hepatotoxins, however, their toxicity depends on the specific amino acids that are part of the basic structure (Fig. 1). Related compounds include nodularin, nodulapeptins, anabaenopeptins, and aeruginopeptin. Another increasingly important hepatotoxin is cylindrospermopsin.

Neurotoxins are normally fast-acting; ingestion of a large dose causes paralysis of skeletal and respiratory muscles which results in death. These compounds are potent alkaloids rather than cyclic peptides. The most common forms are anatoxin, anatoxin-a(S), saxitoxin, neosaxitoxin, and related compounds (Fig. 2).

All of these toxins are difficult to identify and quantify and require detailed laboratory analysis using techniques such as liquid chromatography and mass spectroscopy. Canada, Australia, and Great Britain have developed a guideline level of 1 microgram microcystin per liter of water, or 1 part per billion (1 ppb) for drinking water, and this standard has been adopted by the World Health Organization. During algal blooms, toxin levels can greatly exceed 1 ppb.

SOURCES OF TOXINS

Hundreds of kinds of blue-green algae are known from aquatic habitats; however, only a handful of these are of concern. Some common ones that are known toxin producers include species of *Aphanizomenon, Microcystis*, and *Anabaena* (Fig. 3). Others include species of *Planktothrix (Oscillatoria), Nostoc, Anabaenopsis, Nodularia, Cylindrospermum, Cylindrospermopsis, and Lyngbya.*

Blue-green algae blooms may appear like thick pea soup or grass clippings on the water and are most common in late summer, although blooms can happen in spring or year-round in the warmest latitudes. Pigments and toxins are produced inside the cells and stay there as long as they are alive. When cells break down, usually when a bloom begins to die, their pigments are released into the water and may look like green or blue paint. Bloom die-off also leads to oxygen depletion and associated fish kills in a waterbody. This results from bacterial decomposition of these dead algal cells, which consumes the oxygen. Generally, cooler weather, rainfall, and reduced sunshine will lead to the collapse of an algal bloom. Some blooms last a few weeks; others persist for a few months, depending on environmental conditions. Nutrient enrichment often increases the amount of blue-green algae and may also enhance the dominance of noxious forms.

Control of Blue-Green Algal Blooms

Reducing the load of nutrients from the watershed and/or preventing the release of nutrients from bottom sediments are the primary control measures. In most systems, phosphorus is the critical nutrient. Because in-lake controls treat mostly symptoms, reducing the input of nutrients from the watershed is preferable.

In-lake controls include physical methods such as aeration, circulation, dilution, flushing, and light-limiting

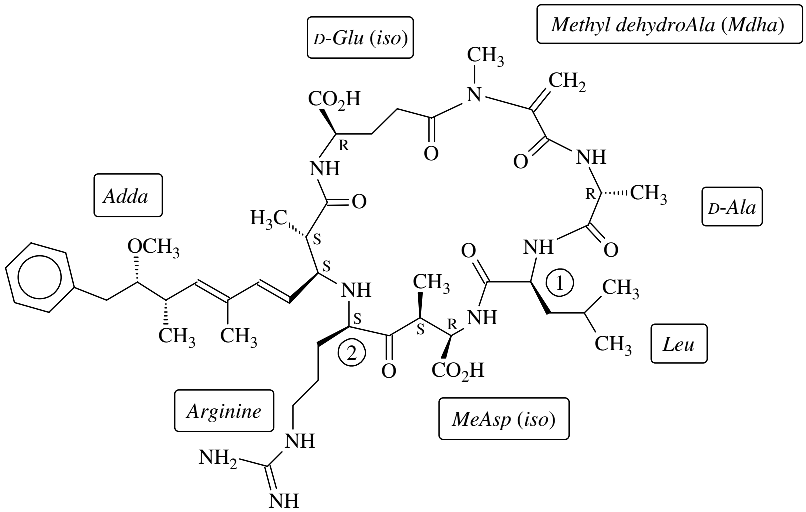

Figure 1. The generic structure of a microcystin. Amino acids substituted at positions 1 and 2 account for most of the variations in this family of compounds (e.g., microcystin-LR contains the amino acids leucine (L) and arginine (R) at positions 1 and 2, respectively) (courtesy of Dr. Gregory Boyer, SUNY-Syracuse).

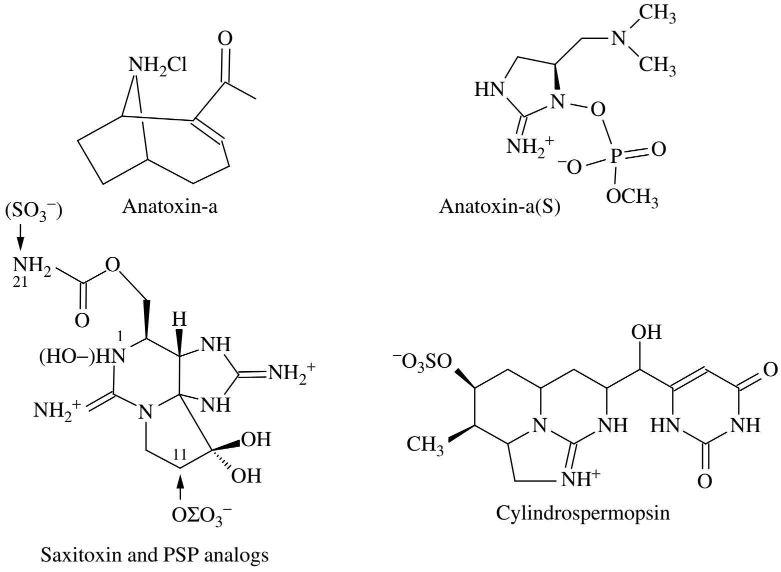

Figure 2. Structures of the alkaloid cyanobacterial toxins: anatoxin-a, anatoxin-a(S), saxitoxin, and cylindrospermopsin. Anatoxin-a, -a(S), and saxitoxin are neurotoxins. Cylindrospermopsin is a hepatotoxin. Saxitoxin is a representative of a large toxin family referred to as the paralytic shellfish poisons (courtesy of Dr. Gregory Boyer, SUNY-Syracuse).

dyes. Chemical controls include algicides and phosphorus inactivation. Biological controls include in-lake plantings and barley straw. All of these techniques have advantages and disadvantages that need to be addressed for controlling an algal bloom.

HEAT BALANCE OF OPEN WATERBODIES

Klaus Jöhnk
University of Amsterdam
Amsterdam, The Netherlands

INTRODUCTION

From a continuum–mechanical point of view, the heat balance or the thermodynamics of a lake, reservoir, or ocean is governed by three different types of processes: surface fluxes, those through the water surface and the sediment boundary of a water body; internal heat production; and external heat supply. Whereas surface fluxes are accounted for in boundary conditions, supply and production take place in the water volume and are described as additional production terms in the equation of heat (1). Turbulent diffusion and, to a much lesser degree, molecular diffusion lead to a certain temperature stratification, usually dividing a lake into a well-mixed, upper warm layer, the epilimnion, separated from it by a transition zone a colder hypolimnion. The temperature–depth distribution can be determined from the heat balance equation and boundary conditions describing the surface fluxes into the water. In contrast to this, in a well-mixed waterbody with a homogeneous temperature distribution, for example, a polymictic lake, all heat production and flux terms are lumped together in a net thermal energy flux. In this case, the heat production terms are treated as fluxes across the surface. Using such a simple system, one can determine the equilibrium temperature of the waterbody for a certain set of meteorologic conditions, that temperature to which the mixed waterbody is driven under the same prevailing meteorologic conditions. For a stratified lake or ocean, such an approach is only of limited use because it does not account for vertical transport of heat in the waterbody. But it can be a good approximation for the surface temperature when the stratification is strong, thus separating the hypolimnion from the well-mixed epilimnion.

The heat budget of a waterbody is determined mainly by the heat exchange across the water surface through long-wave (infrared) radiation, evaporation, and conduction, plus heat production through the absorption of short-wave radiation in the water column. To a far less extent, inflows (rivers, discharges) and outflows, precipitation, heat conduction across the bottom, and biogeochemical reactions alter the heat balance. These effects become relevant only in certain cases: in/outflow in reservoirs and lakes with short residence time (2); heavy precipitation by thunderstorms (3); sedimentary (or geothermal) heat flow in transparent shallow lakes (4); or in amictic or meromictic lakes, where the water body is decoupled from the atmosphere (5).

Special conditions occur in ice-covered lakes. Here, heat conduction and short-wave absorption through the snow and ice cover limit the heat entering the waterbody. The parameters describing these processes depend strongly on factors such as the type of ice, ice thickness, water inclusions, snow cover, and snow type (6). The description of the heat transfer across the air–ice interface down into the lake water thus needs to include additional formulations for snow and ice (7).

HEAT BALANCE

Meteorologic Driving Factors

Heat exchange across a water surface is related to the meteorologic conditions above the water surface and the water surface temperature itself. The main driving factors are air temperature, water vapor pressure, and wind speed above the water surface. They control conductive and evaporative heat transfer. Radiative heat fluxes are additionally influenced by clouds and atmospheric conditions. Usually only a limited set of meteorologic variables are known for calculating heat fluxes using empirical relations. These variables comprise air temperature T_a and relative humidity H, usually measured 2 m above ground level, wind speed U, cloud cover C, and global irradiance I. Instead of relative humidity, dew point temperature or water vapor pressure might be given. Wind speed drops significantly when measured nearer to the ground, so it has to be scaled to a fixed level, for example, 10 m above ground, using a logarithmic velocity profile depending on the roughness height of the terrain (8).

General Heat Balance Formulation

The main components of the net heat exchange Q_{net} between atmosphere and water can be divided into radiative and nonradiative terms. Radiative heat fluxes are distinguished according to their wavelengths. Short-wave radiation Q_s entering the water column has its major spectral parts in the range from 400–700 nm, whereas long-wave, infrared radiation is in a range of approximately 10 μm. In contrast to short-wave radiation, which penetrates the water column, infrared radiation from clouds and the atmosphere, Q_{lin}, is absorbed directly at the water surface. Depending on the surface temperature T_w of the waterbody, it behaves as a so-called blackbody and also emits infrared radiation, Q_{lout}. Nonradiative heat flux terms are due to evaporation or condensation Q_e and the sensible heat flux Q_c generated by conduction.

Omitting other less important heat fluxes such as geothermal heat flux or those by in/outflows, the general heat balance is given by

$$Q_{\mathrm{net}} = Q_s + Q_{\mathrm{lin}} + Q_{\mathrm{lout}} + Q_e + Q_c \tag{1}$$

The magnitudes of the different heat fluxes are shown in Fig. 1 for Lake Nieuwe Meer in The Netherlands.

Empirical Relations

The relations between meteorologic fields and heat fluxes are evaluated by empirical formulas. Usually they are derived from measurements at lakes or the ocean in certain climatic and/or geographic regions. One can find a multitude of parametric values for a certain empirical relation for different waterbodies. Thus, those relations cannot be generalized, and care must be taken in applying them to other settings. Collections of different formulations and parametric sets are described in the literature (e.g., 9–11). In the following, one set of these empirical relations is shown that exemplifies their structure. The heat flow direction is assumed here to be positive from the atmosphere into the waterbody.

Short-Wave Radiation. Solar irradiance at the water surface is partly reflected, depending on the solar zenith angle. The zenith angle Θ itself depends on latitude λ, the day of the year d, and daytime τ. In addition, the reflectivity r of the water depends on wave action, which

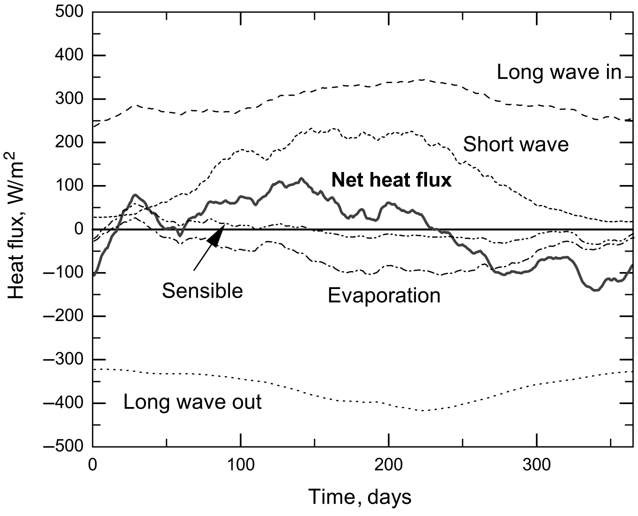

Figure 1. Heat fluxes for Lake Nieuwe Meer, The Netherlands, during the year 2002 (30-day running mean).

can be parameterized by the wind speed U across the water surface (12). If the global irradiance incident at the surface Q_{irr} is measured, the irradiance entering the water column is given by $Q_s = Q_{\text{irr}}[1 - r(\Theta, U)]$. If the irradiance is unknown, it can be calculated from the solar constant S and the angle of incident light at the location (13,14): $Q_{\text{irr}} = S \cos \Theta$. Obviously, this is an upper bound for a clear sky and must be modified for cloud cover by multiplying by an attenuation function $g_s(C)$ (9).

Short-wave radiation that penetrates into a waterbody decays with depth. In its simplest form, this process is described by the Lambert–Beer law: exponential decay $\exp(-kz)$ with depth z and vertical extinction coefficient k. More sophisticated models describing light extinction with depth that depend on water constituents, phytoplankton biomass, and spectral composition of the light can be found in Reference 14. In a well-mixed water column, the depth distribution of heat absorption does not affect the heat balance, as long as there is no significant heat flux into the sediment.

A simple formulation for heat flux into the water column generated by short-wave radiation is given below. Some effects such as the dependence of solar radiation on the Sun–earth distance, atmospheric attenuation, or local effects, for example, shading, are not included here.

Formulation. Earth's declination [day of year: d (days)]:

$$\delta = 23.45 \cdot \frac{2\pi}{360} \cdot \sin\left[\frac{2\pi}{365.25}(d + 283)\right] (\text{deg}) \tag{2}$$

Zenith angle [latitude: λ (deg); time: τ (hours)]:

$$\Theta = \arccos\left[\sin\delta \sin\lambda - \cos\delta \cos\lambda \cos\left(\frac{2\pi}{24}\tau\right)\right] (\text{deg}) \tag{3}$$

Refractive index air–water:

$$n_w = 1.33 \tag{4}$$

Snell's law [incidence angle: Θ; refraction angle: Θ_w (deg)]:

$$\sin\Theta_w = \frac{\sin\Theta}{n_w} \tag{5}$$

Reflection coefficient:

$$r = \frac{1}{2}\left\{\left[\frac{\tan(\Theta - \Theta_w)}{\tan(\Theta + \Theta_w)}\right]^2 + \left[\frac{\sin(\Theta + \Theta_w)}{\sin(\Theta + \Theta_w)}\right]^2\right\} (-) \tag{6}$$

Reflection coefficient depending on wind speed for large zenith angles (wind speed: U [m/s]):

$$r = 0.09[4.444 \exp(-0.17U) + 2.977]^{\left(\frac{180}{\pi}\Theta - 65.5\right)0.040816} (-),\quad \Theta > 65.5^\circ \tag{7}$$

Effect of cloudiness [Cloudiness: $C(-)$ range [0,1]]:

$$g_s = 1 - 0.65\, C^2 (-) \tag{8}$$

Solar constant (for the mean distance between the Sun and the earth)

$$S = 1353\ \text{W/m}^2 \tag{9}$$

Incident irradiance:

$$Q_{\text{irr}} = S \cos\Theta\ (\text{W/m}^2) \tag{10}$$

Heat flux of short-wave radiation entering the water column:

$$Q_s = (1 - r) g_s Q_{\text{irr}}\ (\text{W/m}^2) \tag{11}$$

Long-Wave Radiation from the Atmosphere and Clouds. Long-wave radiation from the atmosphere, clouds, and the water surface can be treated as blackbody radiation; thus, according to the Stefan–Boltzmann law, it is proportional to the fourth power of the body's surface temperature. For long-wave radiation into a lake, cloud cover increases the heat flux, which is taken into account by a quadratic expression for the cloudiness $g_l(C)$. The proportionality factor, emissivity ε_a, depends on a number of factors, such as air temperature, vapor pressure, and cloud height. A common expression for it is given (see e.g., Ref. 9) as a quadratic function of air temperature.

Formulation. Emissivity of the atmosphere [air temperature: T_a (°C)]:

$$\varepsilon_a = 0.919 \cdot 10^{-5}(T_a + 273)^2 (-) \tag{12}$$

Effect of cloudiness [cloudiness: $C(-)$ range (0, 1)]:

$$g_l = 1 + 0.17\, C^2 (-) \tag{13}$$

Stefan–Boltzmann constant:

$$\sigma = 5.6697 \cdot 10^{-8}\ \text{W m}^{-2}\ \text{K}^{-4} \tag{14}$$

Heat flux of long-wave radiation from the atmosphere and clouds:

$$Q_{\text{lin}} = \varepsilon_a \sigma g_l (T_a + 273)^4\ (\text{W/m}^2) \tag{15}$$

Long-Wave Radiation from a Water Surface. The emission of infrared radiation from a water surface takes the usual form for blackbody radiation at the temperature of the water surface, where the emissivity ε_w of water is constant. It yields the Stefan–Boltzmann law for long-wave radiation from a water surface, given below.

Formulation. Emissivity of water:

$$\varepsilon_w = 0.97 (-) \tag{16}$$

Heat flux of long-wave radiation from a water surface [water temperature: T_w (°C)]:

$$Q_{\text{lout}} = -\varepsilon_w \sigma (T_w + 273)^4\ (\text{W/m}^2) \tag{17}$$

Evaporation. Evaporation from a water surface, a heat loss term in evaporation and a source term for condensation, depends on the water temperature and the water vapor pressure above the water surface e_a (see, e.g., Reference 15). The latent heat of evaporation/condensation multiplied by the water's density $\rho_w L(T_w)$ describes the energy needed to evaporate a given volume of water. The amount of water per unit surface, the evaporation height, which evaporates per time, E, depends on the atmospheric conditions above the water column. It is proportional to the gradient of water vapor pressure, which can be approximated by the difference in saturated vapor pressure at ambient water temperature $e^{(\mathrm{sat})}(T_w)$ and the vapor pressure above the water column. The latter can be computed as the saturated vapor pressure at the dew point temperature T_{dew} or via the relative humidity H defined as the ratio of actual to saturated vapor pressure, depending on the meteorologic data available. The effect of wind speed on the evaporation $f_{\mathrm{wind}}(U)$ mixing the air above the water is often assumed to have a linear form (9,16). As humidity is increasing when moving downwind across a water surface, evaporation decreases slightly with the size of a lake (or the wind fetch). To correct for that effect, an additional factor $R_{\mathrm{size}}(A)$ dependent on lake size is applied (17,18).

Formulation. Latent heat of evaporation/condensation [air temperature: T_w (°C)]:

$$L = 2.5 \cdot 10^6 + 2365 T_w \ (\mathrm{J/kg}) \tag{18}$$

Saturated vapor pressure from the Clausius–Clapeyron equation [temperature: T (°C)]:

$$e^{(\mathrm{sat})}(T) = 1230 \exp\left[5362.97\left(\frac{1}{283} - \frac{1}{T+273}\right)\right] \ (\mathrm{Pa}) \tag{19}$$

Water vapor pressure in the air [dew point temperature: T_{dew}(°C); rel. humidity: $H(-)$]:

$$e_a = e^{(\mathrm{sat})}(T_{\mathrm{dew}}) = H e^{(\mathrm{sat})}(T_a) \tag{20}$$

Wind function [wind speed: U (m/s)]:

$$f_{\mathrm{wind}} = 1 + 0.59U(-) \tag{21}$$

Lake size scaling [surface area: A (km^2)]:

$$R_{\mathrm{size}} = \left(\frac{5}{A}\right)^{0.05} \ (-) \tag{22}$$

Evaporation rate:

$$E = 1.36 \cdot 10^{-11} f_{\mathrm{wind}} R_{\mathrm{size}} [e^{(\mathrm{sat})}(T_w) - e_a] \ (\mathrm{m/s}) \tag{23}$$

Density of water:

$$\rho_w = 1000 \ \mathrm{kg/m^3} \tag{24}$$

Heat flux by evaporation/condensation:

$$Q_e = -\rho_w L E \ (\mathrm{W/m^2}) \tag{25}$$

Sensible Heat. The sensible heat flux across a water surface depends on the temperature difference between the water and the overlying air. Assuming that the transport of heat in the atmosphere is similar to that of water vapor, the sensible heat flux due to conduction and convection can be modeled in parallel to the latent heat flux. The Bowen ratio B (19,20) relating these two fluxes can be approximated by the ratio of temperature differences and water vapor pressure differences across the surface and a linear dependence on air pressure p_a. Air pressure is either measured or approximated with a barometric height formulation to adapt for different elevations of the water surface.

Formulation. Bowen ratio [atmospheric pressure: p_a (Pa); air and water temperatures: T_a, T_w(°C)]

$$B = 0.61 \cdot 10^{-3} p_a \frac{T_w - T_a}{e^{(\mathrm{sat})}(T_w) - e_a}(-) \tag{26}$$

Sensible heat flux:

$$Q_c = B Q_e \ (\mathrm{W/m^2}) \tag{27}$$

HYDRAULICS

Stefano Pagliara
Pietro Chiavaccini
Universitá di Pisa
Pisa, Italy

INTRODUCTION

Hydraulics is the branch of physics that studies the equilibrium (hydrostatic) and the motion (hydrodynamics) of fluids. Fluids can be divided into gases and liquids. Hydraulics treats the liquid that generally are practically incompressible and occupies definite volumes.

THE PROPERTIES OF LIQUIDS

The density r is the mass per unit volume, and it is influenced both by the temperature and the pressure. For water at 4 °C, r = 1000 kg/m^3. The specific weight g is the weight of a unit volume of substance. For water, g = 9.813 kN/m^3. The viscosity m is the properties of a fluid that determine the resistance to a shearing force. For liquids, it decreases as the temperature increases, and for water at 20 °C, it is 1.14 10^{-3} kg/(m s). The surface tension is because of the molecular attraction and is responsible for the curvature of the fluid surface near the wall of vessels.

HYDROSTATIC FORCES

A liquid at rest in a vessel exerts a pressure on the base and on the wall. This pressure is called hydrostatic. If A is the area of the base, the force per unit area exerted is $p = W/A$, where W is the weight of the liquid in the vessel. Further, the pressure p applied to any horizontal plane passing through the liquid is $p = gh$, where h is the vertical distance of the plane below the free surface (Stevin's law). Besides, any external pressure applied to a fluid is transmitted undiminished throughout the liquid and onto the walls of the containing vessel (Pascal's principle), and the pressure at a given depth does not depend on the shape of the vessel containing the liquid or the amount of liquid in the vessel.

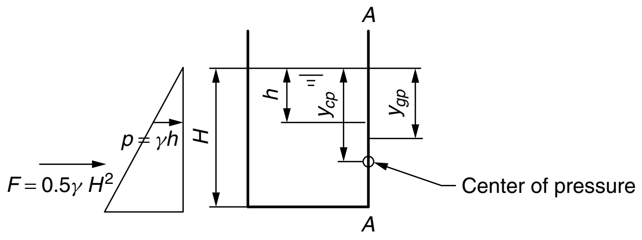

Figure 1. Pressure and resulting forces on the wall A–A of a vessel containing a liquid.

In a liquid at rest, viscous and shearing forces do not exist. The vertical distance h between any selected points in a liquid at rest and the free surface exposed to the atmosphere is called the head of the liquid.

The line of action of the resultant force passes through the center of pressure. This center of pressure lies below the centroid, which is an intuitive result, because pressure increases with depth.

It can be determined graphically or analytically using the following formula:

$$y_{cp} = \frac{I_{cg}}{y_{cg}A} + y_{cg} \tag{1}$$

where I_{cg} is the moment of inertia of the area A about its center of gravity axis and y_{cg} is the depth of the center of gravity below free surface (Fig. 1).

The horizontal component of the resulting force acting on any surface is equal to the normal force on the vertical projection of the surface and acts on the center of pressure for the vertical projection. Instead, the vertical component is equal to the weight of the liquid above the area, real or imaginary.

FLUID FLOWS

Fluid flow can be steady or unsteady, uniform or nonuniform. Steady flows occur if the velocity, pressure, and other fluid variables (density, viscosity) are constant with time. Uniform flow instead occurs when no variation in space exists. The two fundamental equations of fluid flows are the equation of continuity and the Bernoulli equation (or the momentum equation). The first expresses the principle of conservation of mass, and in steady conditions and for incompressible fluids becomes

$$A_1V_1 = A_2V_2 \tag{2}$$

where A_i and V_i are, respectively, the cross-sectional area and the average velocity at the generic section i.

The Bernoulli equation results from the application of the principle of conservation of energy, and in the direction of the flow is expressed as follows:

$$\frac{p_1}{\gamma} + z_1 + \frac{V_1^2}{2g} = \frac{p_2}{\gamma} + z_2 + \frac{V_2^2}{2g} + \Delta h \tag{3}$$

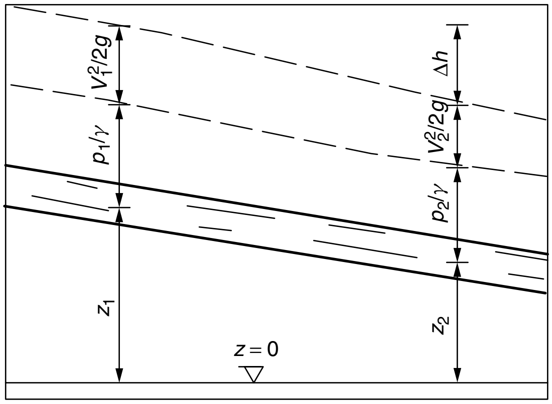

Figure 2. Graphical representation of Bernoulli equation.

where z_i is the height of the fluid above a reference level, p_i the pressure, V_i the velocity, g the acceleration because of gravity, and Dh the energy lost between the two sections. The term p/g represents the pressure head, z the geometric head, and $V^2/2g$ the velocity head, and their sum is the total energy. The graphical representation of the Bernoulli equation is illustrated in (Fig. 2).

FLOWS THROUGH ORIFICES AND WEIRS

For a tank with a hole with sharp edges (Fig. 3a) flowing in the atmosphere, the discharge Q through the orifice of area A can be obtained applying Bernoulli's equation:

$$Q = \mu A\sqrt{2gh} \tag{4}$$

where h is the water depth above the center of the orifice and m is a coefficient that takes into account the effect of friction and the contraction of the flow and is equal to 0.61–0.62.

A weir is a wall built in a channel cross section, over which the water flows from one level to another in a controlled way (Fig. 3b). The relationship that links the characteristics of a rectangular weir to the discharge, in the hypothesis that the velocity of the fluid approaching is small so that kinetic energy can be neglected, is:

$$Q = \mu' Bh\sqrt{2gh} \tag{5}$$

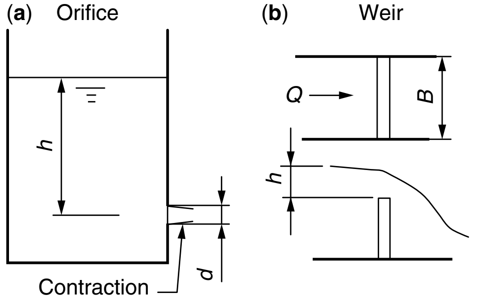

Figure 3. Flow through orifices (**a**); and weir (**b**).

where B is the width of the weir, h is the hydraulic depth over it, and m' is a coefficient (0.42 in case of sharp edge and 0.385 for a wide-crested weir).

FLOWS IN PIPES

Flow in pipes can be laminar or turbulent (1,2). In the first case, the fluids move in parallel layers. In the second one, the particles move in all directions, causing a complete mixing of the fluid. If the flow is laminar or turbulent, it can be evaluated with the Reynolds number, which expresses the ratio between inertial and viscosity forces:

$$\mathrm{Re} = \frac{\rho V d}{\mu} \tag{6}$$

where d is the diameter of the pipe. When Re<2000, flow is in laminar condition, whereas for values greater than 2000, it starts to be turbulent.

If a flow is laminar, the head losses Dh can be determined using the Hagen–Poiselle formula:

$$\Delta h = \frac{64}{\mathrm{Re}}\frac{L}{d}\frac{V^2}{2g} \tag{7}$$

where L is the distance between two sections.

For turbulent flow, the lost head can be given by means of the Darcy–Weisbach formula:

$$\Delta h = f\frac{L}{d}\frac{V^2}{2g} \tag{8}$$

where f is the friction factor, which depends on the values of Re and on the roughness of the wall of the pipe. According to Colebrook and White, f is expressed as:

$$\frac{1}{\sqrt{f}} = -2\log\left[\frac{(\varepsilon/d)}{3.71} + 2.51\frac{\mathrm{Re}}{\sqrt{f}}\right] \tag{9}$$

where e is the dimension of the roughness.

The head losses can also be because of singularity inserted in the pipes (curves, valves, entrance and exiting connections, etc.), and they are expressed as

$$\Delta h = k\frac{V^2}{2g} \tag{10}$$

where k is a coefficient depending on the characteristics of the singularity.

OPEN CHANNEL FLOWS

An open channel is a conduit in which the liquid flows with a free surface subjected to atmospheric pressure (3). For steady and uniform flow, the energy grade line is parallel to the liquid surface (which represents the hydraulic grade line). Define with S the slope of the channel and with R the hydraulic radius, the velocity of the flow can be determined with the Chezy formula:

$$V = C\sqrt{RS} \tag{11}$$

where C is a coefficient depending on the wall roughness determined with the following expression (Bazin):

$$C = \frac{87}{1 + m\sqrt{R}} \tag{12}$$

The coefficient m is given in Table 1.

The hydraulic radius represents the ratio between the wetted area and the wetted perimeter. For a rectangular channel, $R = Bh/(B + 2\,h)$ where B is the width and h the water depth.

Another expression to determine the hydraulic characteristic of open channel flow is the Manning equation:

$$V = \frac{1}{n} R^{2/3} \sqrt{S} \tag{13}$$

where n is the Manning coefficient (Table 2).

In open channel flow, the specific energy can be introduced as

$$E = y + \frac{V^2}{2\,g} \tag{14}$$

It represents the sum of water depth and velocity head, and in terms of unit discharge $q = Q/B$, it is

$$E = y + \frac{q^2}{2\,gy^2} \tag{15}$$

For a constant value of q and for rectangular channel, the specific energy has a minimum for a water depth

$$y_c = \sqrt[3]{\frac{q^2}{g}} \tag{16}$$

This water depth is called critical depth. For a given value of specific energy, it corresponds to the maximum unit discharge.

Table 1. Values for Bazin's Roughness Coefficient

Type of Channel	Bazin's m
Cement: planed wood	0.109
Planks: brick, cut stones	0.290
Roubble masonry	0.833
Earthen channel: very regular	1.54
Earthen channel: in ordinary condition	2.35
Earthen channel: very rough or weed grown	3.17

Table 2. Values for Manning Coefficient

Type of Channel	n
Natural stream: Clean and Straight	0.030
Natural stream: Major Rivers	0.035
Natural stream: Sluggish with Deep Pools	0.040
Excavated Earth Channels: Clean	0.022
Excavated Earth Channels: Gravelly	0.025
Excavated Earth Channels: Weddy	0.030
Floodplains: Pasture, Farmland	0.035
Smooth Steel	0.012
Smooth Steel	0.022

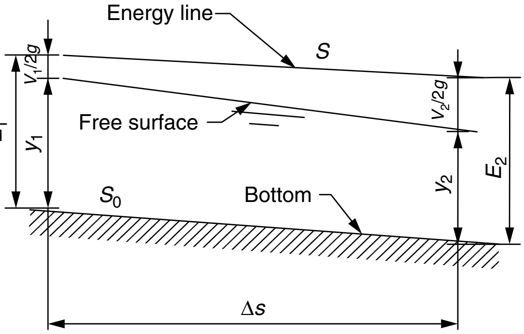

Figure 4. Nonuniform flow condition.

Flows occurring at depth below and above the critical depth are classified as supercritical and subcritical, respectively.

In steady, nonuniform flow conditions, the water depth varies with the distance. These conditions can usually be studied using Bernoulli's theorem and dividing the problem into lengths of approximately uniform condition. For each reach of length DS, the energy equation becomes

$$\Delta S = \frac{E_2 - E_1}{S_0 - S} \tag{17}$$

where E_2 and E_1 are the specific energies downstream and upstream, respectively, S_0 is the bottom slope, and S is the slope of the energy line (Fig. 4).

CONCLUSION

A compacted summary of the fundamental principles of hydraulics is presented in this paper. Aspects of hydrostatic and of the motion of fluids have been described from an engineering point of view.

HYDRAULICS OF PRESSURIZED FLOW

Xing Fang
Lamar University
Beaumont, Texas

Hydraulics is a branch of fluid mechanics specifically dealing with water as a major fluid in many engineering systems. It is safe to consider water as an incompressible fluid for typical engineering applications. Pressurized flow usually refers to the flow in closed conduits. Hydraulics of pressurized flow involves three basic equations: continuity, energy, and momentum equations. Head loss is important in hydraulics of pressurized flow regardless of system design or flow analysis. Darcy-Weisbach and Hazen and Williams equations typically estimate friction head loss. The friction factor depends on Reynolds number and relative roughness of the pipe. Total head loss includes friction head loss caused by fluid viscosity and local head losses at changes in the cross section, bends, and various pipe fittings. A pump provides energy head to, and a water turbine takes energy head from, the pipe system.

Fluid mechanics is the study of behavior of liquids and gasses at rest or in motion subjected to various forces. Hydraulics is a branch of the fluid mechanics specifically dealing with water as a major fluid in many engineering systems. The way water behaves under various conditions depends primarily on its fundamental chemical and physical properties. The bulk modulus of water, which is a measure of its elasticity (or volume reduction under pressure), is about 2.2×10^9 N/m^2 under normal pressure. Therefore, it is safe to consider water as an incompressible fluid for practical purposes. An incompressible fluid does not change its density (ρ) with respect to pressure; therefore, it is also independent of location if no changes of temperature occur in the study area. Pressurized flow usually refers to the flow in closed conduits, e.g., in a water supply pipe system, where the flow is under pressure and full-pipe flow (Fig. 1), whereas pressure could be above or under the local atmospheric pressure.

Hydraulics of pressurized flow involves three basic equations: continuity, energy, and momentum equations. The equation of continuity is a mathematical statement of the Law of Conservation of Mass (water). Along a conduit, inflow rate at the upstream cross section 1 (Q_1) equals the outflow rate at the downstream cross section 2 (Q_2):

$$Q_1 = Q_2 \quad \text{or} \quad V_1 A_a = V_2 A_2 \tag{1}$$

where V_1 and V_2 are the average velocities at the cross sections 1 and 2 and A_1 and A_2 are the cross-sectional areas. When the branch pipe system is involved, the equation of continuity states that the sum of inflow equals the sum of outflow in the control volume system. The energy equation for incompressible fluid under no heat exchange can be expressed as

$$Z_1 + \frac{p_1}{\gamma} + \frac{V_1^2}{2g} = Z_2 + \frac{p_2}{\gamma} + \frac{V_2^2}{2g} + HL_{12} + H_p - H_t \tag{2}$$

Each term in Eq. 2 has units of length (e.g., meter or feet). The first three terms ($z, p/\gamma, V^2/2g$) are the energy per unit weight of water caused by its elevation, pressure, and velocity, respectively, and they are called elevation head, pressure head, and velocity head. Subscripts 1 and 2 stand for upstream and downstream cross sections 1 and 2, and g is the acceleration of gravity (9.81 m/s^2 or 32.2 ft/s^2). HL_{12} is energy loss per unit weight of water from the cross section 1 to 2 and is called total head loss. H_p and H_t are energy heads provided by a water pump or taken by a water turbine to/from the pressurized flow system:

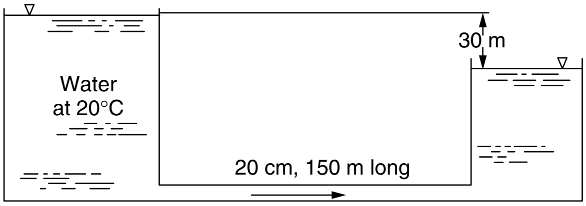

Figure 1. Pressurized pipe flow between two reservoirs.

$$H_p = \frac{P_E \eta}{\gamma Q} \quad \text{or} \quad H_t = \frac{P_T}{\eta \gamma Q} \tag{3}$$

where P_E is the electric power provided to a pump, P_T is the electric power generated by a turbine, η is overall efficiency, γ is specific weight of water, and Q is discharge through a pump or turbine. Some applications may not have pumps or turbine in the system (e.g., in Fig. 1). Head loss is an important term in hydraulics of pressurized flow regardless of system design or flow analysis. Total head loss includes friction head loss caused by fluid viscosity and local head losses at changes in the cross section, bends, and various pipe fittings. Friction head loss (HL_f) is usually determined from the Darcy–Weisbach equation:

$$HL_f = f \frac{L}{D} \frac{V^2}{2g} \tag{4}$$

where f is the friction factor, L is the pipe length between the cross section 1 and 2, D is the pipe diameter, and V is the mean velocity (Q/A). For a noncircular conduit, D is replaced by four times the hydraulic radius that is the flow area divided by wetted perimeter. The friction factor is a function of the Reynolds number (Re) and the relative roughness of a conduit (absolute roughness ε over diameter D). Absolute roughness for concrete, welded-steel and cast iron pipe are 0.3 to 3.0 and 0.12 and 0.25 mm, respectively, and it is a function of pipe material. For laminar flow, f is equal to 64/Re. For turbulent flow, the Moody diagram presented in many textbooks (1–3) can be used, and Swamee and Jain (4) also suggested an explicit formula in replace of the Moody diagram with restrictions:

$$f = \frac{1.325}{\left[\ln\left(\frac{\varepsilon}{3.7D} + \frac{5.74}{\mathrm{Re}^{0.9}}\right)\right]^2} \tag{5}$$

for $10^{-6} < \varepsilon/D < 10^{-2}$ and $5000 < \mathrm{Re} < 10^8$. For water supply engineering applications, the Hazen and Williams equation is typically used to estimate friction head loss as

$$HL_f = L \frac{4.727 Q^{1.852}}{C^{1.852} * D^{4.8704}} \quad \text{in English units} \tag{6a}$$

$$HL_f = L \frac{10.675 Q^{1.852}}{C^{1.852} * D^{4.8704}} \quad \text{in the international system of units} \tag{6b}$$

where C is a coefficient given in Table 1 for various types of conduit surface. Local head loss (HL_L) is typically expressed as function of velocity head:

$$HL_L = K \frac{V^2}{2g} \tag{7}$$

Table 1. Values of C for the Hazen–Williams formula [from Khan (1)]

Type of Pipe	C	Type of Pipe	C
Asbestos cement	140	Brass	130–140
Cast Iron		Concrete	
New, unlined	130	Steel forms	140
Old, unlined	40–120	Wooden forms	120
Cement lined	130–150	Centrifugally spun	135
Bitumastic, enamel-lined	140–150		
Tar-coated	115–135		
Copper	130–140	Galvanized iron	120
Lead	130–140	Plastic	140–150
Steel (riveted)	110	Steel (new, unlined)	140–150

Velocity V is typically taken from just downstream of the local fitting. K is the local head loss coefficient and typically determined by experiments. For example, perpendicular square entrance, $K = 0.5$; exit to a reservoir, $K = 1.0$; standard tee entrance, $K = 1.8$; globe valve when fully open, $K = 10$; and close return bend, $K = 2.2$. Many other local head loss coefficients are given in textbooks (1–3). Local head losses from various fittings are also represented as equivalent pipe lengths in many application fields. Therefore, the total head loss can be calculated by Darcy–Weisbach and Hazen–Williams equations alone when length (L) as the sum of equivalent pipe lengths from fittings and actual pipe length is used.

The fluid momentum equation can analyze forces required to keep a pipe bend and a vertical tee in place (Fig. 2). Fluid momentum equation is derived from the Newton's second law of motion as

$$\sum F = \dot{M}_o - \dot{M}_I \tag{8}$$

It means that the sum of all external forces applied on the control volume equals the difference of the rate change of momentum leaving (outflow) and entering (inflow) the control volume. It is easier to arrange the momentum equations in the direction of three rectangular axes x, y, and z.

Energy Eq. 2 can determine what flow rate the pressurized cast iron pipe in Fig. 1 can carry:

$$HL_{12} = f\frac{L}{D}\frac{V^2}{2g} = Z_1 - Z_2 = 30\ m = f\frac{150}{0.2}\frac{V^2}{2 * 9.81} \tag{9}$$

The cross sections 1 and 2 are located at the surface of upstream and downstream reservoirs, so pressure head and velocity head at the cross sections 1 and 2 are all zero. H_p and H_t are zero as no pump and turbine are in the system. The relative roughness (ε/D) of the cast iron pipe is 0.25 mm/20 cm = 0.00125; and by assuming that the Reynolds number is very large first, the friction factor can be estimated from Eq. 5 as 0.02. Therefore, flow velocity V can be calculated from Eq. 9 as 6.26 m/s. Now one needs to recheck the Reynolds number and recalculate friction factor and velocity:

$$\mathrm{Re} = \frac{VD}{\nu} = \frac{6.26\ m/s * 0.2\ m}{1.007 \times 10^{-6}} = 1.24 \times 10^6 \tag{10a}$$

$$f = \frac{1.325}{\left[\ln\left(\dfrac{0.25}{3.7 * 200} + \dfrac{5.74}{(1.24 \times 10^6)^{0.9}}\right)\right]^2} = 0.02 \tag{10b}$$

where ν is the kinematic viscosity of water at 20 °C. Because the friction factor is still 0.02, the final velocity is the same as the first trial, and the flow rate in the pipe is

$$Q = VA = 6.26\ \mathrm{m/s} * (\pi/4 * 0.2^2) = 0.196\ \mathrm{m^3/s} = 6.95\ \mathrm{ft^3/s} \tag{11}$$

where local head losses (entrance and exit) are relatively small and ignored in the above calculation. For fully turbulent conditions at high Reynolds numbers, discharge for a pressurized pipe flow can be calculated as

$$Q = \left[\frac{\pi}{4}\sqrt{2g}\left(1.14 - 0.86\ln\frac{\varepsilon}{D}\right)D^{2.5}\right]\left(\frac{HL_f}{L}\right)^{1/2} \tag{12}$$

HYDROELECTRIC POWER

Sharad K. Jain
National Institute of Hydrology
Roorkee, Uttranchal, India

INTRODUCTION

Hydropower generation follows a simple concept: water falling from the force of gravity turns the blades of a turbine, which is connected to a generator. The rotating generator produces electricity. Prehistoric man was aware of the energy contained in falling water. One of the earliest devices to use this energy was the water wheel. The Romans used the energy of falling water to do many useful things. They constructed paddle wheels that turned with river flow and lifted water to troughs built higher than river level. The Egyptians and Greeks harnessed the power of river currents to turn wheels and grind grain before 2000 B.C. In the Middle Ages, more efficient water wheels were built for milling grain.

In the nineteenth century, the water turbine gradually replaced the water wheel, and dams were built to control the flow of water. Since then, the hydroelectric potential of rivers continued to be developed. The first modern turbine design was developed in 1849 by James Francis. According to estimates, hydroelectric power production has now risen to 2,000 billion kilowatt hours worldwide.

DAMS AND HYDROPOWER

As a dam holds back water in its reservoir, the water level rises creating a reservoir of potential power. This water is allowed to pass through the turbines of a hydroelectric power plant in conduits called penstocks. The water turns the turbines which are coupled with generators to produce electricity. This electricity passes through a transformer and reaches factories, shops, and homes on transmission lines. The principle and the technique to generate electricity from water remain the same regardless of the size of the project. A plant may serve a small community or a country. For example, many communities in remote areas of Nepal are not connected to the national grid and get electricity from mini/micro hydropower (size <2 MW) plants. The largest hydroelectric complex in the world now is on the Parana River between Paraguay and Brazil. It is known as the Itaipu Dam, and its 18 turbines produce 12,600 megawatts (MW) of electricity. The Itaipu Dam supplies about 80% of the entire electricity demand in Paraguay and 25% of the demand in Brazil. Even this will be surpassed by the hydropower plant at the Three Gorges Dam (under construction) across the Changjiang River (China) whose installed capacity will be about 18,000 MW!

QUANTITATIVE HYDROPOWER FACTS

Hydropower is the world's most important and cleanest source of renewable energy. It can be seen from Table 1 that nearly 17.5% of the world's electricity is produced by hydropower.

Canada is the world's biggest producer of hydropower, generating 350 TWh/year (nearly 62% of the country's total electricity production). Canada produces more than 13% of the global output of hydropower and is the world's second largest exporter of electricity after France.

Europe and North America have developed more than 60% of their hydropower (see Table 2), most of it during the twentieth century. In contrast, many countries in Asia, South America, and Africa currently use only a small portion of their potential hydropower, and a large hydropower potential still remains unexploited.

The electricity supplied by hydropower far exceeds the capacity of any other renewable energy resource. Norway meets virtually its entire (99.6%) electricity demand by hydropower. Twenty-five countries worldwide depend on hydropower for more than 90% of their electricity needs. Though fossil fuels are dominant in electricity generation, worldwide, more than 60 countries currently use hydropower for half or more of their electricity needs. Most of the installed hydroelectric capacity is in North America, Brazil, Russia, China, and Europe. The amount of hydropower generation by major producers is shown in Table 3.

ADVANTAGES OF HYDROPOWER

Hydroelectric power is a clean, renewable energy source. In contrast to other renewable sources of electricity, hydropower can supply a significant portion of the world's electricity needs, year after year. Because it can respond quickly to changes in electricity demand by controlling the release of water, hydropower can augment other energy sources, such as solar and wind energy. Besides, hydropower generation is better suited to meet demands for peak loads compared to thermal units.

These are some other advantages of hydropower generation

- Hydropower has furnished electricity to the world for more than a century, making it a time-tested, reliable technology of known costs and benefits.
- This is the most important renewable source of energy in the world. The Sun is the prime mover of the water cycle, and power can be produced as long as the rain/snow falls and rivers flow.
- As the raw material is virtually free, generating cost is almost free from inflation.
- Hydropower plants do not require much outlay on account of operation and maintenance and have long lives.
- Hydropower generation does not pollute the environment; no heat is produced, and no harmful gases are released.
- Hydropower power plants work at very high efficiency compared to the other major source (thermal power).
- Reservoirs can store water during times of low demand and can quickly start power generation. Thermal power plants take much longer to start up than hydropower plants.
- In multipurpose projects, generation of hydroelectric energy is combined with other uses such as irrigation, water supply, and flood control, resulting in tremendous savings of money and other resources.
- Small, mini-, and microscale hydropower projects can be tailor-made to provide power and minimize adverse environmental and social impacts.
- As a result of developments in turbine technology, efficient turbines whose capacities vary from several hundreds of MW to a few MW have been developed.

If waterpower is used to generate electricity in place of fossil fuels, emission of greenhouse gas can be substantially reduced. However, the creation of large reservoirs and accompanying infrastructures is being resisted by many local communities. Often, small hydropower projects built with the involvement of local communities provide an acceptable solution to electricity problems and the least harm to the environment. Many regions, particularly Asia, Europe, and North America, have developed substantial hydroelectric resources using small plants of <10 MW capacity.

DISADVANTAGES AND ISSUES IN HYDROPOWER GENERATION

The development of hydropower in many countries is not at desired rates for several reasons. Major hydropower projects have large initial costs and long gestation periods. Of late, these projects are being opposed because of harm that they can do to the environment. The reservoirs inundate forests, disturb wild life, and the local population may be displaced causing social tensions.

Careful planning and operation of hydropower facilities can minimize environmental damage, but environmental costs may hinder the development of hydropower in some areas. Another problem is the adverse effect of dams on river ecosystems. After construction of a dam, the river flow downstream is considerably reduced leading to significant changes in river ecology. The construction of a dam also restricts fish movement.

Proponents of these projects argue that many of the adverse impacts are temporary: they arise mainly during the construction phase. Problems such as forest submergence can be tackled by compensatory afforestation. The acceleration in regional development as a result of these projects can more than offset the harmful effects. Most problems are not insurmountable and can be largely overcome by careful planning and involving all stakeholders in decision-making.

COMPONENTS OF HYDROPOWER PROJECTS

In a storage project, the reservoir behind the dam stores water that generates electric power. The portion of the reservoir that is immediately upstream of the intake structure is known as the forebay. A penstock is a conduit to carry water from the forebay to turbines and gates, and valves are installed to control the flow of water. A surge tank is constructed to handle the problems of water hammer. The turbines and generators are installed in a powerhouse. The water comes out of the turbines through the draft tube and joins the tail water.

The term "static head" (see Fig. 1) denotes the difference between the water surface elevation in the forebay and the tail water level (TWL). The 'net head'

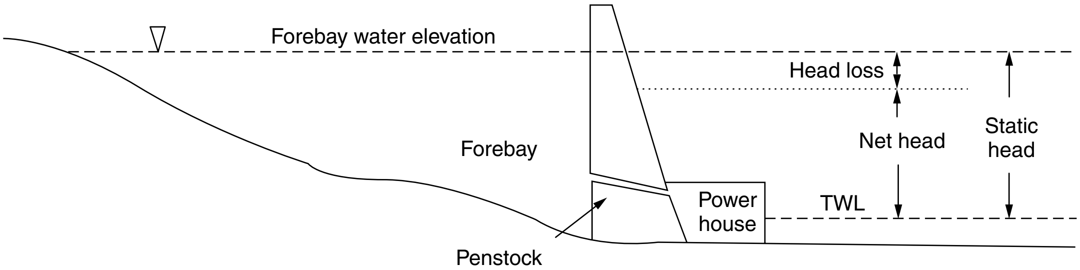

Figure 1. Terms related to head in a hydropower plant.

is the static head less losses in the penstock:

$$\begin{aligned}\text{Net head} &= \text{Static head} - \text{Losses}\\ &= \text{Water surface elevation in forebay}\\ &\quad - \text{TWL-Penstock losses} \qquad (1)\end{aligned}$$

Although the head is related to the height of the dam, a low dam can yield a high head if the powerhouse is located some distance downstream from the dam. The amount of hydropower generated is a function of the discharge and the hydraulic head:

$$P = 9.817QH\eta \qquad (2)$$

where P is electric power in kW, Q is the discharge through the power plant in m^3/s, and H is the net head in m. Further, η is the overall efficiency of the power plant expressed as a ratio (usually about 0.85) obtained by multiplying the turbine efficiency by the generator efficiency. Note that hydroelectric power generation depends on the rate of flow through the turbines and the effective head. Thus, power output can be controlled by releasing more water at a low head or less water at a high head. Most hydropower plants are constructed in hilly areas where steep slopes provide high heads.

TYPES OF HYDROPOWER PROJECTS

There are four major classifications of hydroelectric projects with respect to types of site development: storage, barrages, run-of-river, and pumped storage. Storage plants usually have heads in the medium to high range (greater than 25 m) and can store relatively large volumes of water during periods of high stream flow to provide supply for power generation during periods of low stream flow. The power plant is commonly located at the toe of the dam, though it might also be away from the dam. Peaking operation is frequently associated with storage projects, and this requires large and sometimes rapid fluctuations in releases of water. It is often necessary to provide facilities to even out the fluctuations in the discharge, if rapid changes in water levels below the project are not tolerable.

A barrage, also known as pondage, has a very small storage capacity. It can't effectively regulate flow and generates power according to the variation of load. Run-of-river plants have little or no storage and, therefore, must generate power from stream flow as it occurs with little or no benefit from at-site regulation. Run-of-river projects generally have productive heads in the low to medium range (5 to 30 m) and are frequently associated with navigation or other multipurpose developments. For a base-load run-of-river project to be feasible, the stream must have a relatively high baseflow. Falls in irrigation canals are sometimes used to generate energy.

PUMPED STORAGE SCHEMES

A significant and growing portion of the hydroelectric capacity worldwide is devoted to pumped storage facilities that are designed solely to provide power during peak loads. These projects depend on pumped water as a partial or total source of water. Pumped storage projects consist of a high level forebay where inflow or pumped water is stored until needed and a low level afterbay where the power releases are stored. Pumping and generation are done by units composed of reversible pump turbines and generator motors connecting the forebay and afterbay. During off-peak hours, excess electricity produced by conventional power plants is used to pump water from lower to higher level reservoirs. During periods of high demand, water is released from the upper reservoir to generate electricity. Such projects derive their usefulness because the demand for power is generally low at night and on weekends, and therefore, pumping energy at a very low cost will be available from idle generating facilities. The feasibility of pumped storage developments arises from the need for relatively large amounts of peaking capacity, the availability of pumping energy at a cheap rate, and a sufficiently long off-peak period. It results in large cost savings through more efficient use of base-load plants.

There are three types of pumped storage development: diversion, off-channel, and in-channel. In the diversion type of development, water is released through generating units into an afterbay in an adjacent basin. The off-channel type of pumped storage development is most suitable when a forebay site exists on a hill above a stream where an afterbay can be constructed. The head differential should be large, and the forebay site should be close to the afterbay to avoid head loss and reduce construction costs. The water requirement in this scheme is not large after the initial supply has been provided.

In the in-channel type of scheme, the reservoir of a conventional power project is used as a forebay. The afterbay could be a reservoir from a downstream project or a reservoir provided solely to serve as an afterbay. This scheme is more attractive if the cost of the afterbay is shared with other purposes.

LOAD OF HYDROPOWER PROJECTS

The demand for electrical energy is known as load. The ratio of the average power demand to peak power demand for the time period under consideration is known as the load factor, and it is computed daily, weekly, monthly, or annually. Thus,

$$\text{Load factor} = \frac{\text{Average power demand}}{\text{Peak power demand}} \tag{3}$$

With respect to the type of load served, hydropower projects can be classified in two categories: base-load plants and peaking plants. Base-load plants are projects that generate hydroelectric power to meet the base-load demand (the demand that exists 100% of the time).

Peaking plants generate power to supplement base-load generation during periods of peak demands. These plants must have sufficient capacity to satisfy peak demands, and enough water should be available. In general, a peaking hydroelectric plant is desirable in a system that has thermal generation units to meet base-load demands.

ESTIMATING HYDROPOWER POTENTIAL

Hydroelectric power potential is determined on the basis of the critical period, as indicated by the historical stream flow record. If a project serves more than one purpose and if, while serving another purpose, some of the storage or stream flow is not available for power production, the stream flow data should be adjusted to reflect the “loss.” Losses such as evaporation and leakage must also be deducted from the available flow. The amount of power generated over a time, or energy, is expressed in kilowatt-hour (kWh):

$$\text{kWh} = 9.817QHT\eta \tag{4}$$

in which kWh is the hydropower generated during the period (kWh) and T is the number of hours in the period. Two methods are used to estimate the hydropower potential at a given site: the flow duration curve method and the sequential stream flow routing (SSR) method. In the first method, the flow duration curve developed at the site using the stream flow data is the basic input. The net head for various discharges is estimated, and the hydropower equation is used to estimate the power generated at many points on the flow duration curve. In this way, a power duration curve is developed. The average annual energy and dependable capacity can now be calculated. This method is simple and fast, but it cannot take into account the installed capacity and key project features, such as power plant characteristics.

In the SSR method, the time step size and period of analysis are chosen, and the operation of the reservoir is simulated. For each time period, the reservoir outflow is computed, and the amount of energy generated is calculated using Equation 4. The process is repeated for all the time steps. Now the average annual, monthly, etc., generation as well as firm power can be computed. This method can take into account the reservoir and power plant characteristics. The results of this method are more realistic compared to the flow duration curve method.

OPERATION OF HYDROPOWER RESERVOIRS

Hydropower reservoirs store water to ensure supply as well as hydraulic head. During the filling season, the aim usually is to end the season with as much energy (as water) as possible in store in the system. The water stored in an upper reservoir (higher elevation) has higher potential energy, so upper reservoirs in a series should be filled first. After generating energy at an upper reservoir, the water can be captured in a downstream (lower) reservoir where energy can be generated again. The same logic also holds for any spill from an upper reservoir. Of course while storing water, one also has to examine the compatibility of hydropower use with the other uses of water.

During the drawdown, the objective is to maximize hydropower production for a given total storage amount vis-à-vis the demands. Recall that a system can generate the maximum amount of power when all reservoirs are full (the hydraulic heads will be the highest). If the available water is limited, it should be allocated among the reservoirs to maximize hydropower production. The governing variables are the storage and power generating capacities of reservoirs, the inflows, and the efficiencies of power plants. Note that in smaller reservoirs, the rate of increase of head per unit volume of additional water is higher compared to a large reservoir (that has more surface area). Referring to Fig. 2, the volume of water needed to increase the head by **x** units in a smaller reservoir (V_1) is less than the volume needed (V_2) to increase the head in a larger reservoir by the same increment.

The combination of the important variables in hydropower production, reservoir capacity, volume of inflows, and efficiency of power plant determines the ranking of the reservoirs to produce power. When reductions in storage are necessary, they are made from reservoirs that are least able to produce power. Conversely, an increase

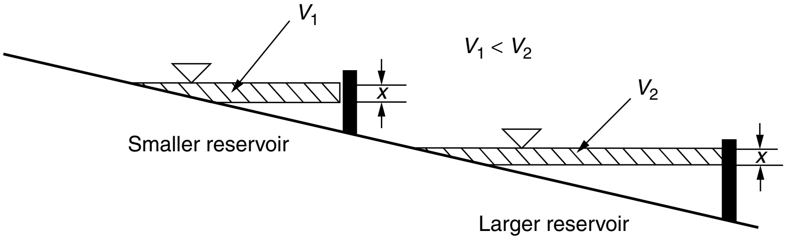

Figure 2. Change in head as capacities vary (after Reference 2).

in storage should be in reservoirs that have the greatest ability to produce power. The following reservoir ranking ratio can be used (2):

$$V_i = a_i e_i \left(\sum_{j=1}^{i} I_j \right) \quad (5)$$

where V_i is the increased power production per unit increase in storage, a_i is unit change in hydropower head per unit change in storage, and e_i is the power generation efficiency, all for reservoir i, and I_j is direct inflows and releases into reservoir j, for all reservoirs upstream of reservoir i. Note that reservoir 1 is the uppermost reservoir in the series. The reservoirs are ordered according to V_i values, and filling begins at the highest value of V_i and proceeds in descending order.

A number of software packages are available to analyze reservoir operation for hydropower generation. See HEC (3), McMahon and Mein (4), and Wurbs (5) for further details.

OVERVIEW

The ever-increasing demand for energy over the recent development of societies has spurred the construction of hydroelectric facilities. Since dams were first used to generate hydropower around 1890, their construction rate increased tremendously to peak during the 1950s and the 1980s (1). Today, about 25% of the 33,105 large dams (≥ 15 m height) listed by the International Commission on Large Dams (ICOLD) are used for hydropower generation (2) and currently provide 19% of the world's electricity supply (1). Although over 150 countries operate hydroelectric plants, Brazil, China, Canada, Russia, and the United States produce more than 50% of the world's hydropower (1). According to data from 1996, hydroelectric reservoirs worldwide cover an estimated 600,000 km^2 (3).

Apart from the benefits they provide, hydroelectric reservoirs entail several social and environmental drawbacks such as the loss of lands and displacement of peoples (1,4), downstream hydrological alterations (5–8), elevated methylmercury burdens in fish and human consumers (8–11), as well as the loss of biodiversity (1,8). Recently, they also proved to be nonnegligible sources of greenhouse gases (GHG) like carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O) (12–31). Owing to their implication in climate change (32–35), hydroelectric reservoirs have raised a sustained interest among both the scientific and political communities. Research during the last decade has brought valuable insights into the biogeochemical impacts stemming from their creation. Although it is now recognized that impoundment leads to both the disappearance of a GHG sink and the creation of a new anthropogenic GHG source (8,34), the duration of anthropogenic GHG emissions from these water bodies remains a matter of current debate (36).

ESTIMATES OF GHG EMISSIONS FROM HYDROELECTRIC RESERVOIRS WORLDWIDE

Table 1 provides statistical parameters for GHG fluxes at the surface of hydroelectric reservoirs. Spatial variability is an important issue that may interfere with regional estimates of GHG fluxes (31,33,35,36). Nevertheless, several data sets shown in Table 1 are normally distributed and mean values can therefore be used to estimate GHG fluxes on a latitudinal basis.

Exceptions are tropical CH_4 diffusive fluxes, which are not normally distributed, and N_2O diffusive fluxes for which data are too scarce. Likewise, bubbling fluxes are marred by either failure to comply with normality or insufficiency of data. In all of these cases, mean values must be used with caution as they poorly reflect the actual situation.

Generally speaking, tropical hydroelectric reservoirs possess the highest mean GHG fluxes, whereas the lowest mean fluxes are observed in temperate ones. A striking characteristic is the presence of CO_2 influxes in some temperate hydroelectric reservoirs from arid and semiarid regions (31). These distinctive GHG emission regimes are caused mainly by particular environmental conditions, such as temperature, which can influence GHG production processes (22,33,36). To a lesser extent, important differences in the mean age of hydroelectric reservoir sets in Table 1 may also intervene (33,35,36).

[a] Hydroelectric reservoirs that have been sampled multiple times are considered as seperate water bodies.

GHG DYNAMICS IN HYDROELECTRIC RESERVOIRS

GHG emissions are common in natural freshwater ecosystems (39–42). However, hydroelectric reservoirs differ from these natural ecosystems in several fundamental aspects (43–45) and therefore cannot be directly compared. Typically, these man-made water bodies are created by damming rivers or lakes. Consequently, the first outcome of hydroelectric reservoir creation is the flooding of terrestrial ecosystems and the subsequent death of the associated vegetation (10,13,33). Overall, this event likely corresponds to the permanent loss of a potential carbon sink (10,33,46), as exemplified by data in Table 2. The second outcome attributable to hydroelectric reservoirs is the creation of a net source of GHG through perturbations that are not observed in steady, natural aquatic ecosystems. These perturbations are highlighted by the GHG emission regimes of hydroelectric reservoirs, which generally overwhelm, at least temporarily, those of natural water bodies (10,13,15,16,21–23,33,35,56).

Emissions that would not have existed without the perturbations brought about by hydroelectric reservoirs are referred to as “anthropogenic GHG emissions.” Consequently, when evaluating these emissions, the following issues must be taken into account. First, the establishment of a valid reference state must be based on a comparison with GHG fluxes prior to flooding because of the major impacts of impoundment on terrestrial ecosystems (13,36). Second, the altered GHG dynamics following the impoundment phase as well as its temporal evolution must be considered (36).

Figure 1 summarizes the current knowledge on GHG dynamics in hydroelectric reservoirs. GHG emissions result from the superposition of short- and long-term

Table 2. Examples of Preimpoundment Carbon Fluxes from Terrestrial Ecosystems Commonly Flooded for the Creation of Hydroelectric Reservoirs[a]

Terrestrial Ecosystem	Study Site	Flux (g C·$\mathrm{m^{-2}{\cdot}y^{-1}}$)[b]	Reference

Temperate pine (*Pinus tæda*) forest, CO_2 only	United States	−69	52
Temperate Mediterranean alpine grassland, CO_2 only	United States	+29 to −132	53
Tropical mesic savanna, considering/not considering bush fires	Australia	−100/−300	54
Tropical rain forest, mature	Brazil	+80 to −390	55
Natural lakes, worldwide average, CO_2 only	many countries	+70	40

[a] Carbon storage capacity of terrestrial ecosystems depends on several factors, such as their type, maturity level, and disturbance history, as well as climatic conditions (9,14,36,49–51).

[b] Positive sign indicates a carbon source; negative sign indicates a carbon sink.

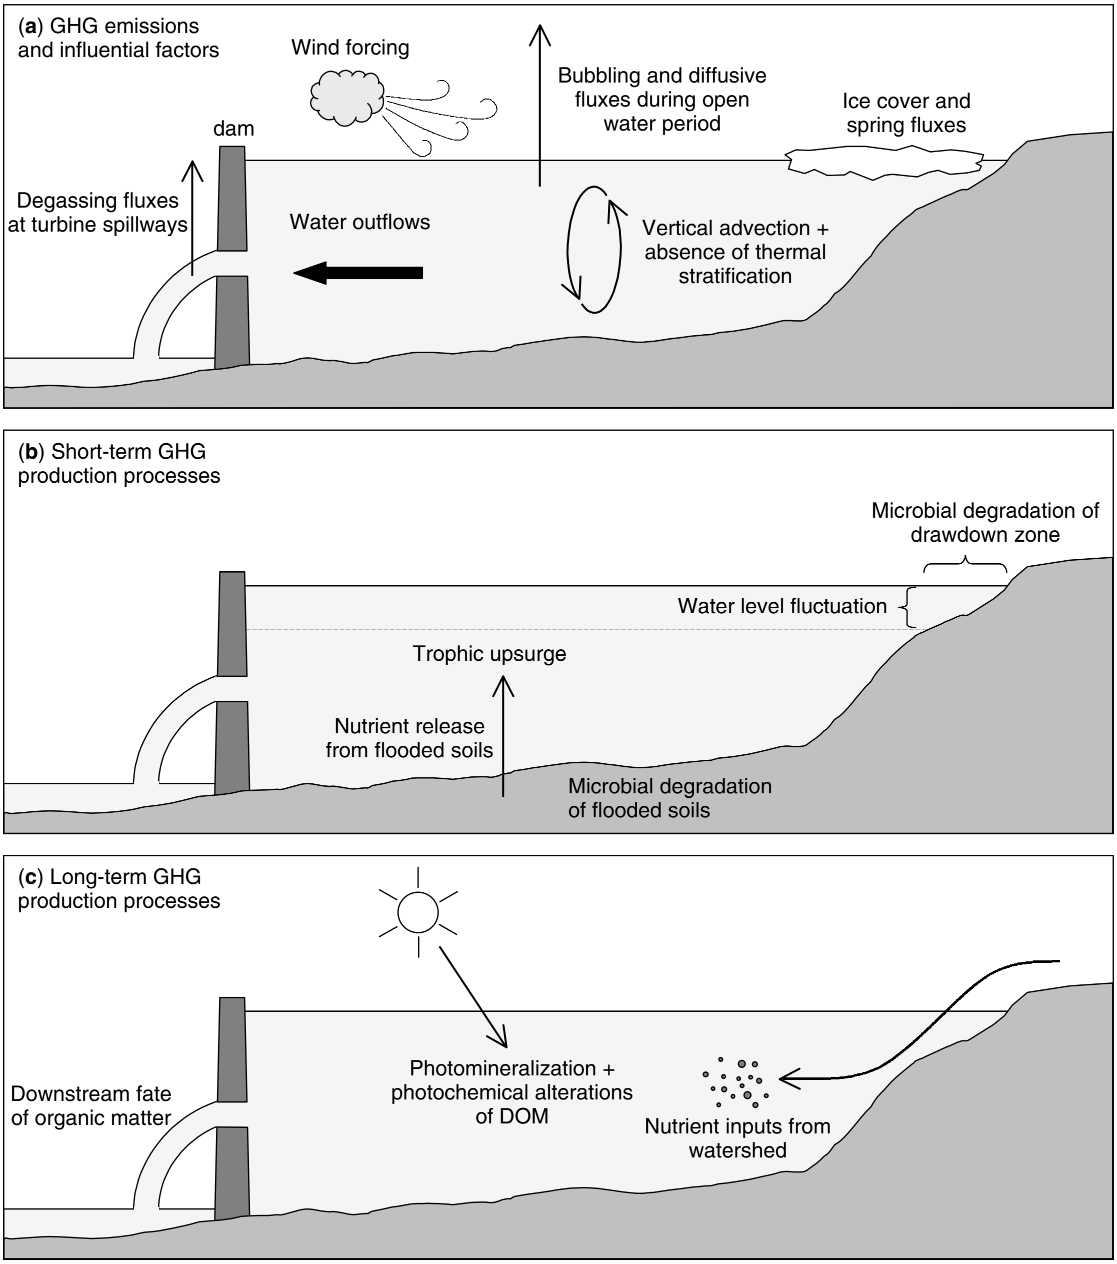

Figure 1. Dynamics of GHG in hydroelectric reservoirs. GHG emissions (**a**) are the result of short-term (**b**) and long-term (**c**) production processes.

production processes. Fundamental mechanisms involved in the production and emission of GHG are exhaustively described in limnology handbooks (57,58). Therefore, only the characteristics of hydroelectric reservoirs that lead to anthropogenic GHG emissions are hereafter described.

GHG Emission Processes and Influential Factors in Hydroelectric Reservoirs

GHG Fluxes at the Air/Water Interface During the Open Water Period. During the open water period, a fraction of GHG escapes from hydroelectric reservoirs through vertical advection (bubbling fluxes) (59) and molecular diffusion (diffusive fluxes) (60,61). GHG emission levels at the air/water interface may vary widely both within and between hydroelectric reservoirs, depending on the factors presented in Table 3.

Hydrometeorological forcings induce a particular hydrodynamic within hydroelectric reservoirs that enhance air/water interface GHG fluxes (36,43). For instance, wind generates surface waves and the vertical advection (Langmuir circulation) of water masses (43), thereby promoting gas transfer velocity across the air/water interface (61,62). For hydroelectric reservoirs with relatively extended surface areas and large fetches, wind leverage can be substantial (14,22,63,64). The operation regime of hydroelectric reservoirs also contributes to hydrodynamic features, which augment

Table 3. Main Factors Identified to Be Responsible for Inter- and Intra-Reservoir Variations in GHG Emission Levels at the Air/Water Interface (16,21,22,27,31,36)

Inter-Reservoir Variability	
Internal factors(pertaining to hydroelectric reservoir)	age of impoundment surface area morphometry and bathymetry physicochemistry operation regime
Regional factors(pertaining to watershed)	type of ecosystems flooded climatic feature pedology and geological basement ecological features
Intra-Reservoir Variability	
Spatial heterogeneities	water column depth water column temperature presence or absence of macrophytes hydrodynamics (main channel vs. protected coves) exposure to meteorological forcings (wind and sun)
Temporal heterogeneities	interannual (age, variations in climate and operation regime) season cycle (water level, biology, ice cover if applicable) day-night cycle (biology, especially photosynthesis)

GHG emissions. Intermittent huge water outflows for hydropower generation enable vertical advection and impede thermal stratification of the water column (43). This frequent situation in hydroelectric reservoirs (23,26,31,45) allows hypolimnetic water to mix with the upper layers, thereby promoting GHG evasion to the atmosphere.

GHG Fluxes at the Air/Water Interface During Spring. During wintertime, ice covers boreal and some temperate freshwater bodies. As GHG are still being produced throughout this period (26), gas bubbles accumulate under the ice. When the ice melts in the spring, GHG evade to the atmosphere at greater rates than during the open water period (22,26). However, as most studies on hydroelectric reservoirs are conducted in summer, spring GHG fluxes are often overlooked.

Degassing Fluxes at Turbine Spillways. GHG also escape from the water column at turbine spillways when hydropower is produced. Such degassing fluxes are caused by the sudden change in pressure as well as the increased air/water exchange surface (17,19) and strongly depend on the volume of outflows, the GHG concentrations within the water column, and the depth of water outlets on the dam. Although an important term of the GHG budget of hydroelectric reservoirs (36), degassing fluxes have seldom been assessed (19,31,46).

GHG Production Processes in Hydroelectric Reservoirs

Flooded Soils and Drawdown Zones. Hydroelectric reservoirs create a new interface between water and soils, thereby triggering the onset of major biogeochemical perturbations. Following impoundment, the physicochemical features of flooded soils promote the production of GHG through microbial degradation of organic matter (10,13). Biomass degradation is generally associated with oxygen depletion at the bottom of tropical hydroelectric reservoirs (19,23,28,65), a phenomenon that seems to be transient or inexistent in boreal and temperate ones (16,26,31,66).

Drawdown zones refer to the extended portion of hydroelectric reservoir banks that are periodically flooded by fluctuating water levels that occur during the operation phase. These zones act as intermittent water/soil interfaces and also constitute favorable sites for the production of GHG (67).

Typically, flooded organic matter undergoes an initial phase of rapid decomposition of labile compounds, followed by the slower decomposition of more recalcitrant compounds (13,28). Microbial degradation of flooded soils thus decreases with time and, according to studies on both carbon loss and isotopic tracers (δ^{13}C), appears to be limited to approximately ten years (68,69).

Trophic Upsurge. Following impoundment, a fraction of compounds from flooded soils and drawdown zones are released into the water column of hydroelectric reservoirs (28,68,70). This nutrient (C, N, P) pulse increases water turbidity, alters feeding habits as well as trophic levels of the planktonic community, and ultimately disrupts its initial photosynthesis:respiration ratio (22,69–73). Overall, these drastic shifts within the planktonic community structure provoke the transition of the aquatic system to a more allotrophic state (trophic upsurge) (74). Consequently, respiration overwhelms photosynthesis, thus enhancing the production of GHG in the water column.

Figure 2 illustrates the temporal progression of bacterioplankton in hydroelectric reservoirs. After the impoundment phase, bacterial biomass increases sharply (Fig. 2a). Then, as nutrient inputs from flooded soils gradually decrease, physicochemical parameters within the

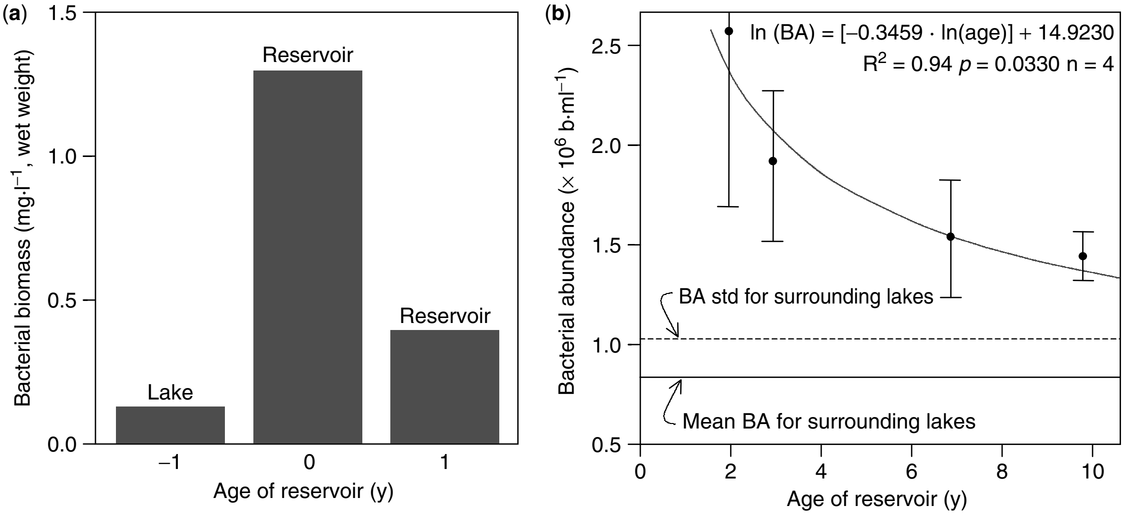

Figure 2. Temporal progression of bacterioplankton in reservoirs. Year "0" corresponds to the impoundment event. (**a**) Bacterioplankton biomass before and after the impoundment of a experimental reservoir created from a small boreal lake (70). (**b**) Evolution of bacterioplankton abundance (BA) following the impoundment of the boreal hydroelectric reservoir Laforge-1 (22,38,75). Error bars are standard deviation.

water column tend to evolve toward natural conditions (66,76,77). In accordance with the bottom-up theory, bacterial abundance also declines (65,70), but, as suggested in (Fig. 2b), a substantial time lag exists between the depletion of flooded nutrients and the anticipated onset of an equilibrium state within the bacterioplanktonic population.

Allochthonous Inputs from the Watershed. The actual contribution of allochthonous organic matter to anthropogenic GHG emissions from hydroelectric reservoirs is unclear (36). Nevertheless, the fact that long-term GHG emissions from certain hydroelectric reservoirs still overwhelm those of natural water bodies (33,35) and do not stem from the degradation of flooded soils (68,69) supports the hypothesis that these anthropogenic emissions are fueled by inputs from the watershed (22,36,56,78). If so, allochthonous inputs would only contribute to anthropogenic GHG emissions from hydroelectric reservoirs if they are mineralized to a greater extent than in natural ecosystems.

Two phenomena may account for such a case. On the one hand, photochemical reactions play a key role in the carbon cycle of aquatic systems (79–84) through both direct photomineralization of dissolved organic matter (DOM) into CO_2 (85–89) and molecular alterations that modify the bioavailability of DOM to bacteria (90,91). Empirical data suggest that these mechanisms play a greater role in hydroelectric reservoirs than in natural water bodies. For instance, a study conducted on a boreal hydroelectric reservoir has indicated that DOC photoreactivity exceeded that of boreal and temperate natural lakes significantly (94). This situation is not due to qualitative aspects of DOM, but rather to differences in age of water, as well as iron and manganese concentrations (92).

On the other hand, hydroelectric reservoirs disrupt natural streamflows and increase the water residence time (7,8,36,93), thereby retaining organic matter and hypothetically allowing for increased degradation. It is thus likely that hydroelectric reservoirs modify the mineralization pattern of organic matter at the scale of the watershed. However, this important issue has yet to be addressed.

DURATION OF ANTHROPOGENIC GHG EMISSIONS FROM HYDROELECTRIC RESERVOIRS

As shown in (Fig. 3) and elsewhere (14,33,35), GHG emissions significantly decline with the age of hydroelectric reservoirs. The duration of anthropogenic GHG emissions is closely related to the perturbations caused by their creation and operation. As these perturbations occur at different time scales (Fig. 1), anthropogenic GHG emissions from hydroelectric reservoirs may last for decades (33,35).

The duration of anthropogenic GHG emissions from hydroelectric reservoirs can be grossly estimated through a heuristic comparison with natural lakes. Higher GHG emission levels from the former likely indicate that certain biogeochemical perturbations still intervene. (Fig. 3) suggests that CO_2 diffusive fluxes exceeding the mean of natural lakes worldwide (704 mg $CO_2 \cdot m^{-2} \cdot d^{-1}$) (40) can last up to 70 years. However, weak regression coefficients (R^2) between the magnitude of GHG fluxes and the age of hydroelectric reservoirs, in (Fig. 3) and in previous literature reviews (33,35), indicate that the latter parameter poorly explains the decline of GHG fluxes. Ultimately, the accurate determination of the duration of anthropogenic GHG emissions will depend on an exhaustive appraisal of the mechanisms involved in the production of GHG.

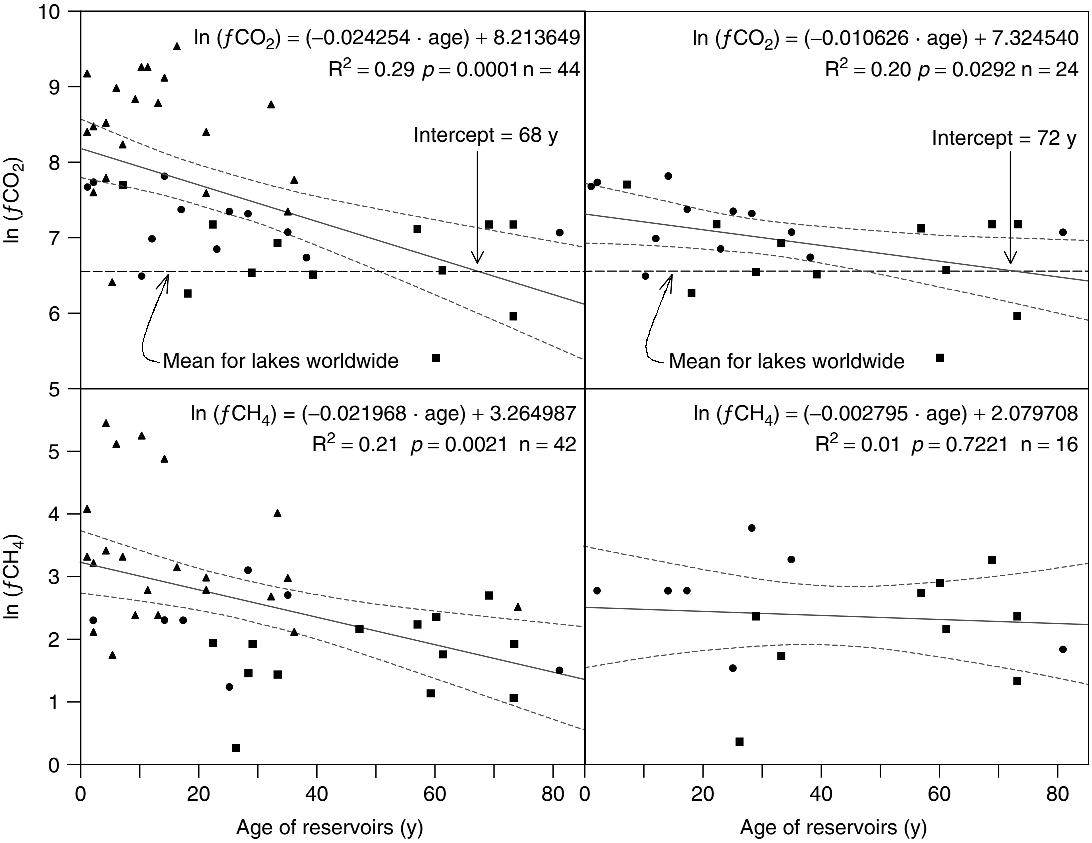

Figure 3. Temporal evolution of CO_2 and CH_4 diffusive fluxes from hydroelectric reservoirs during the open water period (12,14–16,19–29,31,37,92). Left panel: Includes hydroelectric reservoirs from all climatic zones (boreal, temperate, and tropical). Right panel: Boreal and temperate hydroelectric reservoirs only. Hydroelectric reservoirs with CO_2 influxes have been discarded and those that have been sampled during different years are considered as seperate water bodies. Circles = boreal; squares = temperate; triangles = tropical. Dashed curved lines represent the 95% confidence intervals.

POLITICAL ASPECTS

As a result of the threat of climate change, anthropogenic GHG emissions have become of major concern for political entities. In 1990, the Intergovernmental Panel on Climate Change's (IPCC) First Assessment Report set the basis for the United Nations Framework Convention on Climate Change (UNFCCC), which was further implemented by the Kyoto Protocol in 1997 (34). The UNFCCC establishes an overall international structure to deal with climate change. Its mandate is to require signatory countries to gather relevant information on GHG emissions (national GHG inventories) as well as to develop strategies to prevent or mitigate these emissions (94).

From this perspective, the energy sector represents an area where GHG abatements are possible through strategies such as the "clean development mechanism" (CDM). As defined by the Marrakesh Accords, a project is considered a CDM provided that it substitutes a higher GHG-emitting option (95) [for instance, building hydropower plants instead of thermal ones, the latter being commonly recognized as emitting more GHG (28,33,35)]. Certificates of GHG emission reduction can then be acquired through the World Bank's Prototype Carbon Fund (PCF) (96).

Within the framework of the CDM, anthropogenic GHG emissions from hydroelectric reservoirs cannot be ignored. However, their inclusion into national GHG inventories is a prerogative that has yet to be achieved. To date, only GHG emissions produced by the degradation of flooded soils are considered as anthropogenic by IPCC (97). Nevertheless, the eventual part of GHG emissions stemming from allochthonous inputs should also be considered in the next IPCC guidelines, provided that enough evidence exists to substantiate such a situation. In any case, the inclusion of hydroelectric reservoirs into national GHG inventories is planned for the second commitment under the Kyoto Protocol, effective as of 2012. Countries that are characterized by large surface areas covered by hydroelectric reservoirs should then observe a significant increase in their national GHG inventories.

HYDROLOGIC PERSISTENCE AND THE HURST PHENOMENON

DEMETRIS KOUTSOYIANNIS
National Technical University
Athens, Greece

INTRODUCTION

Unlike common random series like those observed, for example, in games of chance (dice, roulette, etc.), hydrologic (and other geophysical) time series have some structure, that is, consecutive values of hydrologic time series depend on each other. It is easy to understand that, for instance, in a monthly river flow series, a month of very high flow is likely to be followed by a month of high flow, too. River flow is interrelated to groundwater storage, so high flow indicates that groundwater storage will be high, too, and given that the groundwater flow is a slow process, it is expected that its contribution to river flow in the next month can be significant. This explains the dependence of consecutive values of hydrologic time series, which have been known as *short-range* (or *short-term*) *dependence, persistence, or memory*.

Interestingly, however, there is another kind of dependence observed on larger timescales, known as *long-range* (or *long-term*) *dependence, persistence, or memory*. This was discovered by Hurst (1), while investigating the discharge time series of the Nile River in the framework of the design of the Aswan High Dam, and was found in many other hydrologic and geophysical time series. This behavior is the tendency of wet years to cluster into multiyear wet periods or of dry years to cluster into multiyear drought periods. The terms “Hurst phenomenon” and “Joseph effect”, due to Mandelbrot (2) from the biblical story of the “seven years of great abundance” and the “seven years of famine,” have been used as alternative names for the same behavior. Since its original discovery, the Hurst phenomenon has been verified in several environmental quantities such as (to mention a few of the more recent studies) in wind power (3); global or point mean temperatures (4–6); flows of several rivers such as the Nile (7,8); the Warta, Poland (9), Boeoticos Kephisos, Greece (5), and the Nemunas, Lithuania (10); inflows of Lake Maggiore, Italy (11); indexes of North Atlantic oscillation (12); and tree-ring widths, which are indicators of past climate (8). In addition, the Hurst phenomenon has gained new interest today due to its relation to climate changes (5,13–15).

The possible explanation of long-term persistence must be different from that of short-term persistence discussed above. This will be discussed later. However, its existence is easy to observe even in a time series plot, provided that the time series is long enough. For example, in Fig. 1 (up) we have plotted one of the most well-studied time series, that of the annual minimum water level of the Nile River for the years 622–1284 A.D. (663 observations), measured at the Roda Nilometer near Cairo (16, pp. 366–385; 17). In addition to the plot of the annual data values versus time, the 5-year and 25-year averages are also plotted versus time. For comparison, in the lower panel of Fig. 1, we have also plotted a series of white noise (consecutive independent identically distributed random variates) with statistics the same as those of the Nilometer data series. We can observe that the fluctuations in the aggregated processes, especially of the 25-year average, are much greater in the real-world time series than in the white noise series. Thus, fluctuations in a time series on a large scale distinguish it from random noise.

STOCHASTIC REPRESENTATION OF THE HURST PHENOMENON

Quantification of long-term persistence is better expressed mathematically using the theory of stochastic processes. Let X_i denote a stochastic representation of a hydrometeorologic process where $i = 1, 2, \ldots,$ denotes discrete time with a time step or scale which for the purposes of this article is annual or multiannual. It is assumed that the process is stationary, a property that does not hinder exhibiting multiple scale variability. The stationarity assumption implies that its statistics are not functions of time. Therefore, we can denote its statistics without reference to time, that is, its mean as $\mu := E[X_i]$, its autocovariance as $\gamma_j := \mathrm{Cov}[X_i, X_{i+j}] (j = 0, \pm1, \pm2, \ldots)$, its autocorrelation $\rho_j := \mathrm{Corr}[X_i, X_{i+j}] = \gamma_j/\gamma_0$, and its standard deviation $\sigma := \sqrt{\gamma_0}$. Further, we assume ergodicity, so that these statistics can be estimated from a unique time series substituting time averages for expected values.

Let k be a positive integer that represents a timescale larger than the basic timescale of the process X_i. The aggregated stochastic process on that timescale is denoted as

$$Z_i^{(k)} := \sum_{l=(i-1)k+1}^{i\,k} X_l \tag{1}$$

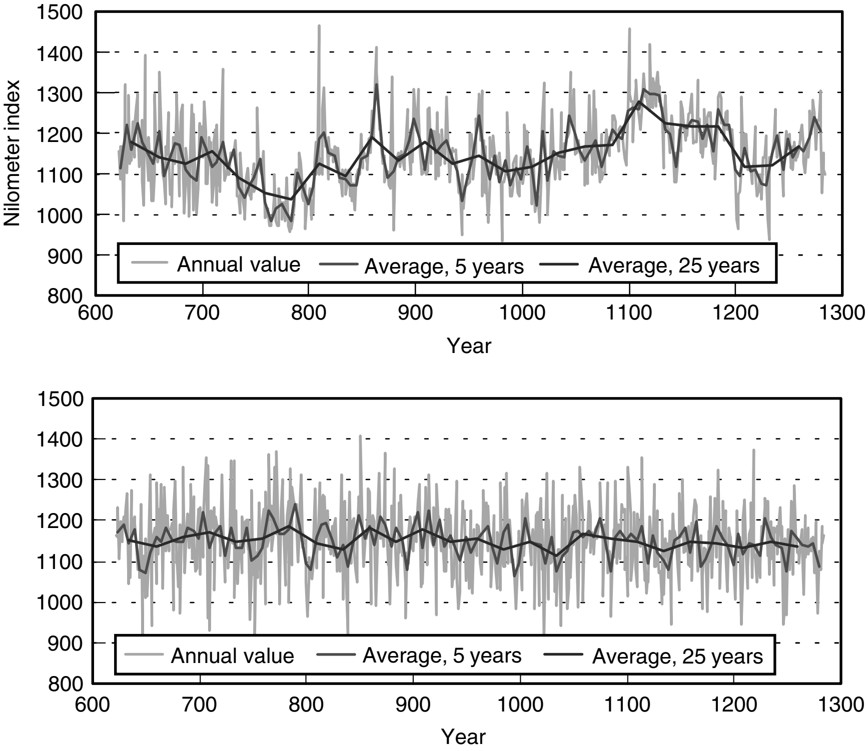

Figure 1. (Up) Plot of the Nilometer series indicating the annual minimum water level of the Nile River for the years 622–1284 A.D. (663 years); (down) a white noise series with same mean and standard deviation, for comparison.

The statistical characteristics of $Z_i^{(k)}$ for any timescale k can be derived from those of X_i. For example, the mean is

$$E[Z_i^{(k)}] = k\ \mu \tag{2}$$

and the variance and autocovariance (or autocorrelation) depend on the specific structure of γ_j (or ρ_j). In a process that exhibits the Hurst phenomenon, the variance $\gamma_0^{(k)}$ for timescale k is related to that of the basic scale γ_0 by

$$\gamma_0^{(k)} := \mathrm{Var}[Z_i^{(k)}] = k^{2H}\gamma_0 \tag{3}$$

where H is a constant known as the Hurst coefficient whose values are in the interval [0.5, 1]. The value $H = 0.5$ corresponds to random noise, whereas values in the interval [0, 0.5] are mathematically possible but without interest in hydrology. Consequently, the standard deviation is a power law of the scale or level of aggregation k with exponent H, that is,

$$\sigma^{(k)} := (\gamma_0^{(k)})^{1/2} = k^H\sigma \tag{4}$$

This simple power law can be easily used for detecting whether a time series exhibits the Hurst phenomenon and for determining the coefficient H, which is a measure of long-term persistence. Equation 4 calls for a double logarithmic plot of standard deviation $\sigma^{(k)}$ of the aggregated process $Z_i^{(k)}$ versus timescale k. In such a plot, called an aggregated standard deviation plot, Hurst behavior is manifested as a straight line arrangement of points corresponding to different timescales, whose slope is the Hurst coefficient. An example is depicted in Fig. 2 for the Nilometer series of Fig. 1. Clearly, the plot of the empirical estimates of standard deviation is almost a straight line on the logarithmic diagram of slope 0.85. For comparison, we have also plotted the theoretical curve for the white noise of slope equal to 0.5, significantly departing from historical data.

By virtue of Eq. 3, it can be shown that the autocorrelation function, for any aggregated timescale k, is independent of k and is given by

$$\rho_j^{(k)} = \rho_j = (1/2)(|j+1|^{2H} + |j-1|^{2H}) - |j|^{2H}$$
$$\approx H(2H-1)|j|^{2H-2} \tag{5}$$

which shows that autocorrelation is a power function of the lag. Consequently, the autocovariance $\gamma_j^{(k)} = \gamma_0^{(k)}\rho_j^{(k)}$ is a power law of both the scale k (with exponent $2H$) and the lag j (with exponent $2H - 2$).

The power spectrum of the process,

$$s_\gamma^{(k)}(\omega) := 2\sum_{j=-\infty}^{\infty} \gamma_j^{(k)}\cos(2\pi j\omega) \tag{6}$$

is given approximately by

$$s_\gamma^{(k)}(\omega) \approx 4\ (1\text{—}H)\gamma_0^{(k)}(2\ \omega)^{1-2H} \tag{7}$$

which is a power law of both the scale k (with exponent $2H$) and the frequency ω (with exponent $1 - 2H$).

The power law Eqs. 5 and 7 can be used, in addition or alternatively to Eqs. 3 and 4, to detect the Hurst behavior of a time series. Note that Hurst's (1) original formulation to detect this behavior was based on another quantity, the so-called rescaled range, which corresponds to the cumulated process of inflow minus outflow of a hypothetical infinite reservoir.

Equations 3–7 describe the second-order properties of the process $Z_i^{(k)}$. A generalization is possible, if we assume that the process of interest exhibits scale invariant properties in its (finite-dimensional joint) distribution function:

$$(Z_i^{(k)} - k\ \mu) \overset{\mathrm{d}}{=} \left(\frac{k}{l}\right)^H (Z_j^{(l)} - l\ \mu) \tag{8}$$

where the symbol $\overset{\mathrm{d}}{=}$ stands for equality in distribution. In this case, Eq. 3 can be obtained from Eq. 8 by setting $i = j = l = 1$ and taking the variance of both sides. Equation 8 defines X_i and $Z_i^{(k)}$ as stationary increments of a self-similar process. If, in addition, X_i (and hence $Z_i^{(k)}$) follows the normal distribution, then X_i (and $Z_i^{(k)}$) is called fractional Gaussian noise (FGN; (18)). Our interest here includes processes that may be not Gaussian, so we will limit the scaling property of Eq. 8 to second-order properties only and call the related process a *simple scaling signal* (SSS).

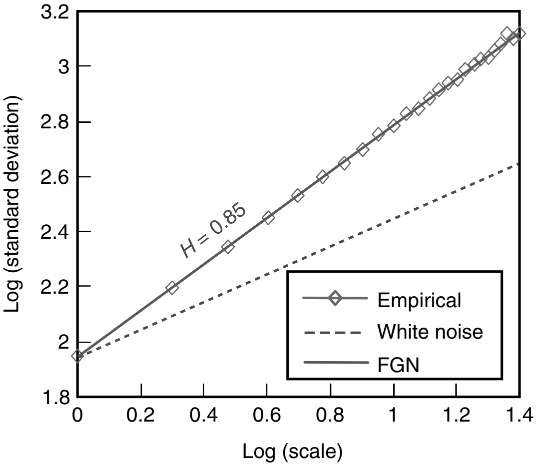

Figure 2. Aggregated standard deviation plot of the Nilometer series.

PHYSICAL EXPLANATIONS OF THE HURST PHENOMENON

As described in the Introduction, the concept of short-term persistence in hydrologic processes is easy to explain, whereas long-term persistence and the Hurst phenomenon are more difficult to understand. Mesa and Poveda (19) classify the Hurst phenomenon as one of the most important unsolved problems in hydrology and state that "something quite dramatic must be happening from a physical point of view." However, several explanations have been proposed. These can be classified in two categories, physically based and conceptual.

Klemeš (20) proposed an explanation that may be classified in the first category. According to this, the Hurst behavior of hydrologic records can be explained by representing the hydrologic cycle by a "circular cascade of semi-infinite storage reservoirs" where the output from one reservoir constitutes an essential part of input into the next. He showed that, even with an originally uncorrelated Gaussian forcing, the outputs grew progressively more Hurst-like as the complexity of the system increased, for example, the number of reservoirs in the cascade. Another example of such a hydrologic system was suggested in Klemeš (21).

Beran (17, pp. 16–20) describes two physically based model types that lead to system evolution (in time or space) with long-range dependence. The first model type applies to critical phenomena in nature such as phase transition (transition from a liquid to a gaseous phase or spontaneous magnetization of ferromagnetic substances). For some critical system temperature, the correlation of the system state at any two points decays slowly to zero, so the correlation in space can be represented by Eq. 5. The second type is related to models based on stochastic partial differential equations, which, under certain conditions, result in solutions with long-range dependence. These models provide sound links of long-range dependence with physics but are very complex.

A simple model of this category was studied by Koutsoyiannis (6). This model assumes a system with purely deterministic dynamics in discrete time, which, however, results in a time series with an irregular appearance exhibiting the Hurst phenomenon. The system dynamics is based on the simple map

$$x_i = g(x_{i-1}; \alpha) := \frac{(2-\alpha)\min(x_{i-1}, 1-x_{i-1})}{1-\alpha\min(x_{i-1}, 1-x_{i-1})} \tag{9}$$

where x_i is the system state, assumed to be scalar, at time i and $\alpha < 2$ is a parameter. This map, known as a generalized tent map, has been used in the study of dynamic systems. For example, the map approximates the relation between successive maxima in the variable $x(t)$ from the Lorenz equations that describe climatic dynamics (22, p. 150). Koutsoyiannis (6) demonstrated that this model can describe a system subject to the combined action of a positive and a negative feedback. If the parameter α is assumed to vary in time following the same map, $\alpha_i = g(\alpha_{i-1}; \lambda)$, then we obtain the double tent map,

$$u_i = G(u_{i-1}, \alpha_{i-1}; \kappa, \lambda) := g(u_{i-1}; \kappa\ \alpha_{i-1}) \tag{10}$$

Both parameters κ and λ should be < 2, whereas the domain of u_t is the interval [0, 1]. If the system domain is the entire line of real numbers, we can apply an additional transformation to shift from [0, 1] to $[-\infty, \infty]$:

$$x_t = \ln[u_t/(1-u_t)] \tag{11}$$

The model behavior with respect to parameters κ and λ is depicted in Fig. 3. We observe that for small values of the parameter κ, the time series synthesized by the model exhibits short-range dependence with a Hurst coefficient around 0.5. For large values of κ, the model yields runaway behavior. However, in between the two noninteresting areas, there is an area of parameter values, shaded in Fig. 3, in which the resulting time series exhibits long-range dependence. All three types of behavior are observed for negative values of λ (not shown in Fig. 3), whereas for $\lambda > 1$, only the runaway behavior is observed, regardless of the value of κ.

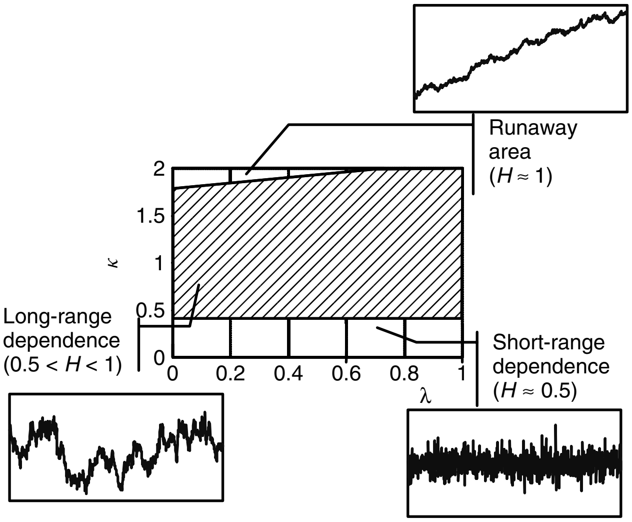

Figure 3. Schematic of the general behavior of the double tent map in terms of the ranges of its parameters κ and λ.

The second category, labeled here "conceptual," does not aim at explaining the physical mechanism leading to Hurst behavior of historical records of some natural or other processes but examines different stochastic mechanisms that might produce realizations resembling the patterns of the observed empirical time series. For example, Klemeš (20) analyzed several variants of the "changing mean" mechanism which assumes that the mean of the process is not a constant determined by the arithmetic mean of the record but varies through time. Specifically, he performed numerical experiments with the following Gaussian random processes:

1. a process with the mean alternating periodically between two values after constant time intervals called "epochs";
2. a process with a monotonic linear trend in the mean, throughout the entire series length;
3. a process similar to 1 but with epoch lengths taking two different values with probabilities p and $1 - p$; and
4. a process with a Gaussian-distributed mean randomly varying from epoch to epoch, the epoch length also varying randomly and following either a uniform, exponential, or (single parameter) Pareto distribution.

The processes behaved increasingly Hurst-like as their structure changed from 1 to 4. This behavior was most influenced by the distribution of epoch lengths, whereas the distribution of the mean itself had little effect.

The effect of periodical patterns, which are extensions of those of model 1, have been thoroughly studied by Montanari et al. (23), who, however, noted that such patterns are unusual in real data. The effect of monotonic deterministic trends, which are extensions of model 2, was studied by Bhattacharya et al. (24), who showed mathematically that a trend of the form $f(t) = c\,(m + t)^{H-1}$, where t denotes time, c a nonzero constant, m a positive constant, and H a constant in the interval [0.5, 1], results in time series exhibiting the Hurst phenomenon with a Hurst coefficient precisely equal to H. We may note, however, that this kind of nonstationarity with a monotonic deterministic trend spanning the whole length of a time series can hardly represent a long time series of real data, even though in short time series it seems to be realistic. For example, to refer to the Nilometer series of Fig. 1, if one had available only the data of the period 700–800, one would detect a "deterministic" falling trend of the Nile level; similarly, one would detect a regular rising trend of the Nile level between the years 1000–1100. However, the complete picture of the series suggests that these trends are parts of large-scale random fluctuations rather than deterministic trends.

Based on this observation, Koutsoyiannis (8) proposed a conceptual explanation, which can be regarded as an extension of Klemeš's model 4 and is also similar to other proposed conceptual models, as will be discussed later. More specifically, Koutsoyiannis (8) demonstrated that superimposition of three processes with short-term persistence results in a composite process that is practically indistinguishable from an SSS process.

This demonstration is reproduced here in Figs. 4–5. It starts by assuming a Markovian process U_i, like that graphically demonstrated in Fig. 4a, where mean $\mu := E[U_i]$, variance γ_0, and lag one autocorrelation coefficient $\rho = 0.20$. The specific form of this process is an AR(1) one, $U_i := \rho\, U_{i-1} + E_i$, where E_i is white noise, and its autocorrelation is

$$\mathrm{Corr}[U_i, U_{i+j}] = \rho^j \tag{12}$$

The autocorrelation function is shown in Fig. 5a along with the autocorrelation function of SSS with the same lag one autocorrelation coefficient (0.20). We observe the large difference of the two autocorrelation functions: that of the Markovian process practically vanishes at lag 4, whereas that of SSS has positive values for lags as high as 100.

In the next step, a second process V_i is constructed by superimposing another Markovian process M_i:

$$V_i = U_i + M_i - \mu \tag{13}$$

Here the process M_i is constructed in a different way, rather than using the AR(1) model, yet without loosing its Markovian behavior, so that its autocorrelation is

$$\mathrm{Corr}[M_i, M_{i+j}] = \varphi^j \tag{14}$$

for $\varphi > \rho$. More specifically, a continuous time process M (see explanatory sketch in Fig. 4b) with the following properties was assumed: (1) it has mean μ and some variance Var[M], (2) any realization m of M lasts N years and is independent of previous realizations, and (3) N is a random variable exponentially distributed with mean $\lambda = -1/\ln\,\varphi$. (This means that N can take nonintegral values). In other words, M takes a value $m_{(1)}$ that lasts n_1 years, then it changes to a value $m_{(2)}$ that lasts n_2 years, etc. (where the values $m_{(1)}$, $m_{(2)}$, ... can be generated from any distribution). The exponential distribution of N indicates that the points of change are random points in time. If we denote M_i the instance of the M process at discrete time i, it can be shown that M_i is Markovian with lag one autocorrelation φ. This way of constructing M_i allows us to interpret V_i as a process similar to U_i but with mean M_i that varies randomly in time (rather than being constant, μ) shifting among randomly determined values $m_{(1)}, m_{(2)}, \ldots$, each lasting a random time period with average λ. It can be easily shown from Eq. 13 that the autocorrelation of V_i for lag j is

$$\mathrm{Corr}[V_i, V_{i+j}] = (1 - c)\rho^j + c\,\varphi^j \tag{15}$$

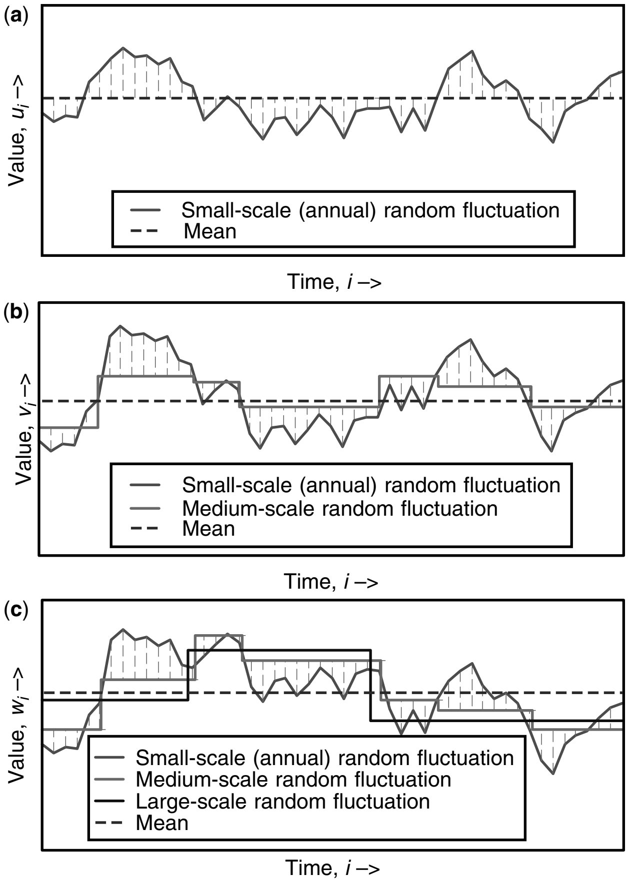

Figure 4. Illustrative sketch of multiple timescale random fluctuations of a process that can explain the Hurst phenomenon: (**a**) a time series from a Markovian process with constant mean; (**b**) the same time series superimposed on a randomly fluctuating mean on a medium timescale; (**c**) the same time series further superimposed on a randomly fluctuating mean on a large timescale (from Reference 8).

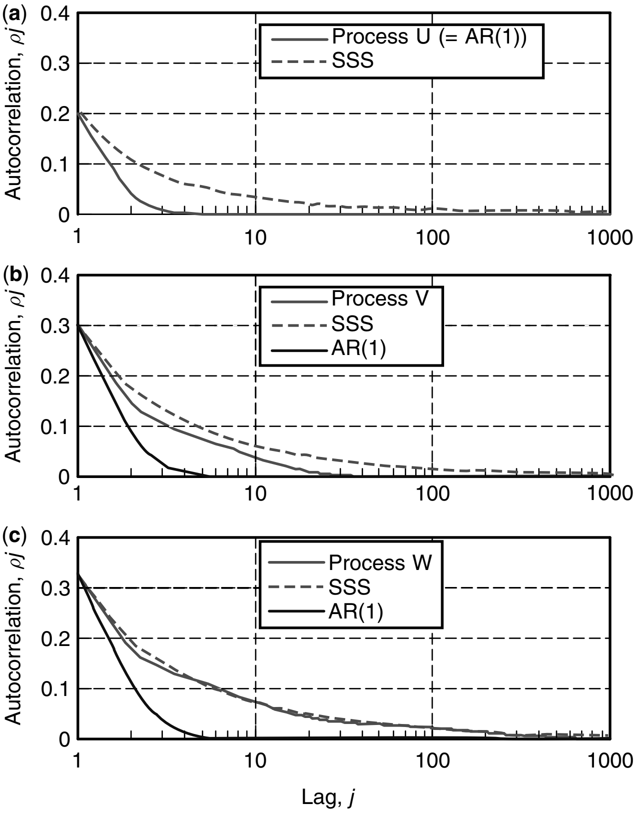

Figure 5. Plots of the example autocorrelation functions of (**a**) the Markovian process U with constant mean; (**b**) the process U superimposed on a randomly fluctuating mean on a medium timescale (process V); (**c**) the process V further superimposed on a randomly fluctuating mean on a large timescale (process W). The superimposition of fluctuating means increases the lag one autocorrelation (from $\rho_1 = 0.20$ for U to $\rho_1 = 0.30$ and 0.33 for V and W, respectively) and also shifts the autocorrelation function from the AR(1) shape (also plotted in all three panels) toward the SSS shape (also shown in all three panels) (from Reference 8).

where $c := \mathrm{Var}[M_i]/(\mathrm{Var}[M_i] + \mathrm{Var}[U_i])$. Setting, for instance, $\lambda = 7.5$ years ($\varphi = 0.875$) and $c = 0.146$, we get the autocorrelation function shown in Fig. 5b, which has departed from the AR(1) autocorrelation and approached the SSS autocorrelation.

In a third step, another process W_i is constructed by superimposing on V_i a third Markovian process P_i:

$$W_i = V_i + P_i - \mu = U_i + M_i + P_i - 2\,\mu \tag{16}$$

P_i is constructed in a way identical to that of M_i, but with lag one autocorrelation $\xi > \varphi$, so that the mean time between changes of the value of P is $\nu = -1/\ln \xi$. Working as in the previous step, we find

$$\mathrm{Corr}[W_i, W_{i+j}] = (1 - c_1 - c_2)\rho^j + c_1\varphi^j + c_2\xi^j \tag{17}$$

where c_1 and c_2 are positive constants (with $c_1 + c_2 < 1$). Setting, for instance, $\lambda = 7.5$ years ($\varphi = 0.875$), $\nu = 200$ years ($\xi = 0.995$), $c_1 = 0.146$, and $c_2 = 0.036$, we get the autocorrelation function shown in Fig. 5c, which has now become almost indistinguishable from the SSS autocorrelation for time lags from 1 to 1000.

In conclusion, a Markovian underlying process can result in a nearly SSS process if there occur random fluctuations of the mean of the process on two different scales (e.g., 7.5 and 200 years), yet the resulting composite process is stationary. If we consider that fluctuations occur on a greater number of timescales, the degree of approximation of the composite process to the SSS process will be even better and can cover time lags greater than 1000 (although the extension to lags beyond 1000 may not have any practical interest in hydrology). In conclusion, the *irregular* changes of climate that, according to the National Research Council (25, p. 21), occur on all timescales can be responsible for and explain the Hurst phenomenon.

This demonstration bridges several ideas that had been proposed to explain the Hurst phenomenon, rather than being a novel explanation. As already discussed, it is similar to Klemeš's model 4, except for the setting of multiple timescales for the fluctuation of the mean and the emphasis on the stationarity of the composite process. Here, note that Klemeš referred to all his "changing mean" models as models with nonstationarity in their mean, even though this is strictly true only for models 1 and 2. He did point out that his final models in group 4 were in fact stationary and that he kept the term "nonstationary" for all changes in the mean to communicate the fact (elaborated in more detail in Ref. 26) that one cannot tell the difference from the pattern of a single "nonstationary-looking" time series (which even a stationary model is designed to mimic), but his explanation has sometimes been missed and led to a misconception about his work by some authors (including this one, who expresses his apology).

The idea of irregular sporadic changes in the mean of the process appeared also in Salas and Boes (27) but not in connection with SSS and not in the setting of multiple timescales. The idea of composite random processes with two timescales of fluctuation appeared in Vanmarcke (28, p. 225). The idea of an explanation of the Hurst phenomenon as a mixture of scales appears in Mesa and Poveda (19). The idea of representing SSS as an aggregation of short-memory processes is the principle of the well known fast fractional Gaussian noise algorithm (FFGN, 29) and is also studied as a possible physical explanation of the Hurst phenomenon by Beran (17, p. 14). The difference in the above described explanation is the aggregation of only three short-memory processes.

IMPORTANCE OF THE HURST PHENOMENON

The presence of the Hurst phenomenon increases dramatically the uncertainty of climatic and hydrologic processes. If such a process were random and our information on this were based on a sample of size n, then the uncertainty in the long term, which can be expressed in terms of the variance of the estimator of the mean, $\overline{X}$, would be

$$\mathrm{var}[\overline{X}] = \frac{\sigma^2}{n} \tag{18}$$

This offers good approximation for a process with short-term persistence, as well, but it is not valid for a process with long-term persistence. Instead, the following relation holds (5;17, p. 54; 30):

$$\mathrm{var}[\overline{X}] = \frac{\sigma^2}{n^{2-2H}} \tag{19}$$

The difference between Eqs. 18 and 19 becomes very significant for large values of H. For example, in a time series of $n = 100$ years of observations and standard deviation σ, according to the classical statistics (Eq. 18), the standard estimation error, the square root of $\mathrm{var}[\overline{X}]$, is $\sigma/10$. However, for $H = 0.8$, the correct standard error, given by Eq. 19, is $\sigma/2.5$, four times larger. To have an estimation error equal to $\sigma/10$, the required length of the time series would be 100,000 years! Obviously, this dramatic difference induces substantial differences in other common statistics as well (5).

A demonstration of the difference in estimates related to climate is given in Fig. 6. Here, a long climatic time series (992 years) was used that represents the Northern Hemisphere temperature anomalies with reference to the 1961–1990 mean (Fig. 8, up). This series was constructed using temperature sensitive palaeoclimatic multiproxy data from 10 sites worldwide that include tree rings, ice cores, corals, and historical documents (31,32). The time series was studied in relation to the Hurst phenomenon by Koutsoyiannis (5), and it was found that the estimate of the Hurst coefficient is 0.88. In the upper panel of Fig. 6, the point estimates and the 99% confidence limits of the quantiles of the temperature anomalies have been plotted for the probability of nonexceedance, u, ranging from 1 to 99%, assuming a normal distribution, as verified from the time series, and using the classical statistical estimators. This is done for two timescales, the basic one ($k = 1$) that represents the annual variation of temperature anomaly and the 30-year timescale, which typically is assumed to be sufficient to smooth out the annual variations and provide values representative of the climate. (For the latter, the averaged rather than aggregated time series, i.e., $z_i^{(30)}/30$, has been used.)

If classical statistics is used (Fig. 6, upper panel), then it is observed that, due to the large length of the series, the confidence band is very narrow and the point estimates for the basic and the aggregated timescale differ significantly. The variability of climate, as expressed by the distribution of the average at the 30-year timescale, is very low, despite much higher variability on the annual scale. This justifies the saying "Climate is what you expect, weather is what you get." Things change dramatically, if the statistics based on the hypothesis of long-term persistence (5) are used with $H = 0.88$. This is depicted in the lower panel of Fig. 6, where it is observed that the variation in the 30-year average is only slightly lower than that of the annual values and the confidence band has dramatically widened for both timescales. This could be expressed by paraphrasing the above proverb to read "Weather is what you get, climate is what you get—if you keep expecting for many years." The consequences of these differences in estimating climatic uncertainty due to natural variability are obviously very significant.

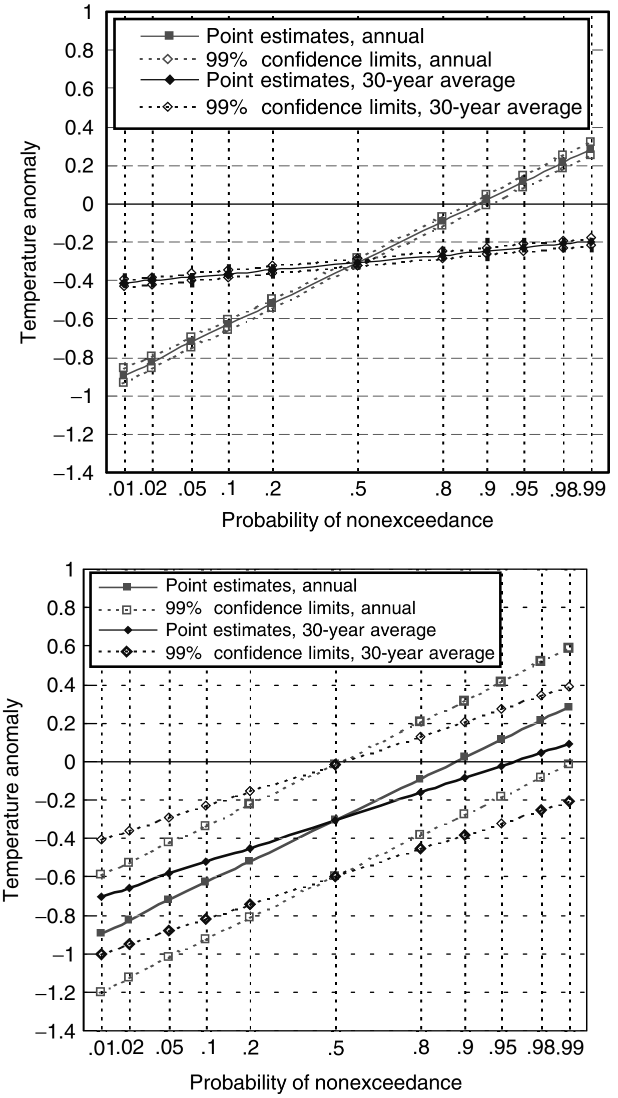

Figure 6. Point estimates of quantiles and 99% confidence limits thereof on the basic timescale (annual values, $k = 1$) and the 30-year timescale (30-year averages, $k = 30$), for the Jones's time series of the Northern Hemisphere temperature anomalies: (up) using classical statistics; (down) using adapted statistics.

The consequences in water resources engineering and management are even more significant. Particularly, because the notion of climate implies long timescales, it is to be expected that the practical importance of the Hurst phenomenon increases in projects whose operating cycles span long periods of time. A typical example may be large reservoirs with multiyear flow regulation (33; see also article SW-776, Reliability Concepts in Reservoir Design). For small-to-middle range reservoirs, it is generally regarded that the effect of the Hurst phenomenon appears to be within the margin of error of hydrologic data used for their design and operation. However, even in hydrosystems with small reservoirs or no reservoirs at all, as becomes obvious from the previous discussion, the effect on the Hurst phenomenon is significant if the uncertainty (not only the expected value) of water availability is to be assessed.

SIMPLE ALGORITHMS TO GENERATE TIME SERIES REPRODUCING THE HURST PHENOMENON

Several algorithms have been developed to generate time series that reproduce the Hurst phenomenon. Among these, we discuss here the simplest ones that can be applied, even in a spreadsheet. These are based on the previously discussed properties of SSS and can be used to provide good approximations of SSS for practical hydrologic purposes.

A first, rather "quick and dirty" algorithm can be very easily formulated based on the deterministic double tent map (Eqs. 10 and 11). The problem with the resulting time series is that consecutive generated values are too regularly and smoothly related. This can be avoided by discarding some of the generated values x_i and holding only the values $x_{\nu j}$, for some $\nu > 1$ and for $j = 1, 2, \ldots, n$, where n is the required series length. Figure 7 depicts the attained Hurst coefficient in a time series generated from the double tent map (Eq. 10) either untransformed or transformed (Eq. 11) for $\nu = 1$ and 4. This figure can serve as a tool to estimate the parameter κ required to achieve a certain Hurst coefficient H (assuming $\lambda = 0.001$). A time series so generated can then be transformed linearly to acquire the required mean and standard deviation.

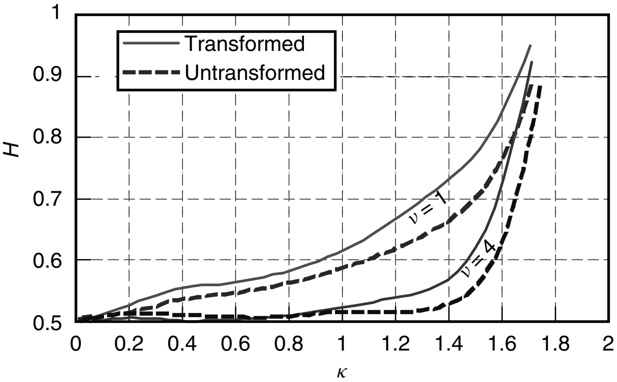

Figure 7. Hurst coefficient of a time series generated from the double tent map (Eqs. 10 and 11) for parameter values $\lambda = 0.001$, κ ranging from 0 to 2, and $\nu = 1$ and 4. For κ approaching 2, the double tent map has runaway behavior.

By appropriately choosing the initial values α_0 and u_0, one can obtain a time series that can have a presumed general shape; this requires applying a random search optimization technique. An example of the application of this algorithm to the Jones data set already discussed is depicted in Fig. 8.

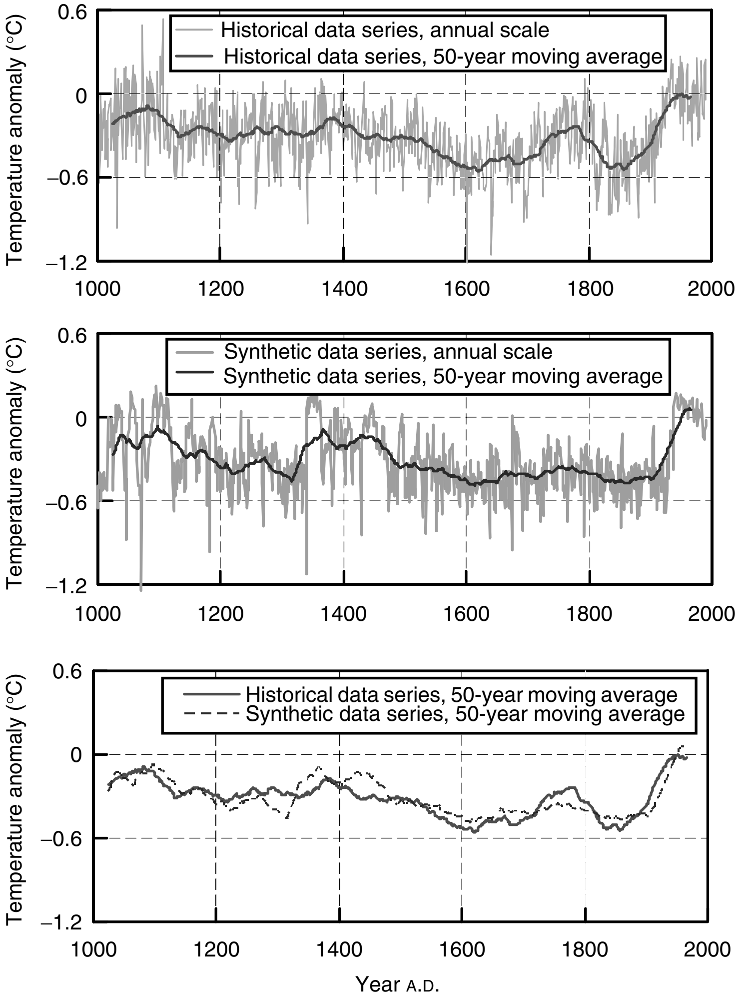

Figure 8. (Up) Plot of the Jones data series indicating Northern Hemisphere temperature anomalies with reference to the 1961–1990 mean; (middle) a synthetic time series generated by the double tent map fitted to the Jones data set and assuming $\nu = 4$; (down) comparison of the synthetic and original time series in terms of their 50-year moving averages.

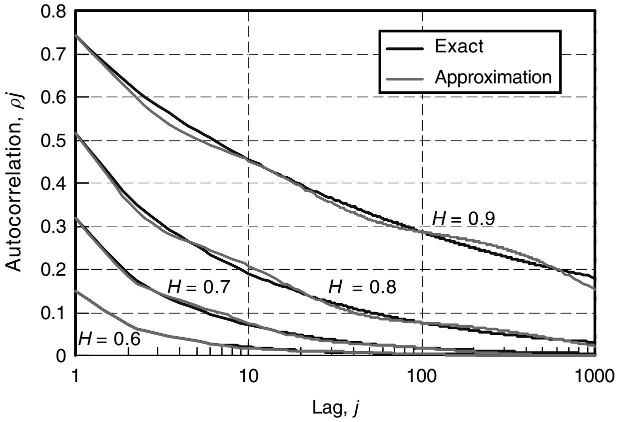

Figure 9. Approximate autocorrelation functions based on Equations 17 and 20–21 vs. the exact SSS autocorrelation functions (Eq. 5) for various values of the Hurst exponent H (from Reference 8).

As we saw earlier, the weighted sum of three exponential functions of the time lag (Eq. 17) can give an acceptable approximation of the SSS autocorrelation function on a basic timescale. This observation leads to an easy algorithm to generate SSS. The following equations (from Reference 8) can be used to estimate the parameters ρ, φ and ξ:

$$\rho = 1.52\ (H - 0.5)^{1.32}$$
$$\varphi = 0.953 - 7.69\ (1 - H)^{3.85} \tag{20}$$

$$\xi = \begin{cases} 0.932 + 0.087\,H & H \leq 0.76 \\ 0.993 + 0.007\,H & H > 0.76 \end{cases} \tag{21}$$

The remaining parameters c_1 and c_2 can then be estimated so that the approximate autocorrelation function (Eq. 17) matches the exact function (Eq. 5) for two lags, for example, lags 1 and 100. (Their values are obtained by solving two linear equations). Comparison plots of approximate autocorrelation functions based on Equations 17 and 20–21 versus the exact SSS autocorrelation functions (Eq. 5) for various values of the Hurst exponent H are shown in Fig. 9. Equations 16 and 17 may be interpreted as representing the sum of three independent AR(1) processes, with lag one correlation coefficients ρ, ϕ, and ξ, and variances $(1 - c_1 - c_2)\ \gamma_0$, $c_1\gamma_0$, and $c_2\gamma_0$, respectively. Thus, the generation algorithm is as simple as the generation of three AR(1) series and their addition.

The simple expressions of the statistics of the aggregated SSS process make possible a disaggregation approach for generating SSS (8). Specifically, let us assume that the desired length n of the synthetic series to be generated is 2^m where m is an integer (e.g., $n = 2, 4, 8, \ldots,$); if not, we can increase n to the next power of 2 and then discard the redundant generated items. We first generate the single value of $Z_1^{(n)}$ knowing its variance $n^{2H}\gamma_0$ (from Eq. 3). Then we disaggregate $Z_1^{(n)}$ into two variables on the timescale $n/2$, $Z_1^{(n/2)}$ and $Z_2^{(n/2)}$, and we proceed this way until the series $Z_1^{(1)} \equiv X_1, \ldots, Z_n^{(1)} \equiv X_n$ is generated (see explanatory sketch in Fig. 10).

We consider the generation step in which we disaggregate the higher level amount $Z_i^{(k)} (1 < i < n/k)$ into two lower level amounts $Z_{2\,i-1}^{(k/2)}$ and $Z_{2\,i}^{(k/2)}$ so that

$$Z_{2\,i-1}^{(k/2)} + Z_{2\,i}^{(k/2)} = Z_i^{(k)} \tag{22}$$

Thus, it suffices to generate $Z_{2\,i-1}^{(k/2)}$ and then obtain $Z_{2\,i}^{(k/2)}$ from Eq. 22. At this generation step, we have available the already generated values of previous lower level time steps, $Z_1^{(k/2)}, \ldots, Z_{2\,i-2}^{(k/2)}$, and of next higher-level time steps, $Z_{i+1}^{(k)}, \ldots, Z_{n/k}^{(k)}$ (see Fig. 10). Theoretically, it is necessary to preserve the correlations of $Z_{2\,i-1}^{(k/2)}$ with all previous lower level variables and all next higher level variables. However, we can get a very good approximation if we consider correlations with only one higher level time step behind and one ahead. Under this simplification, $Z_{2\,i-1}^{(k/2)}$ can be generated from the linear relationship,

$$Z_{2\,i-1}^{(k/2)} = a_2\, Z_{2\,i-3}^{(k/2)} + a_1\, Z_{2\,i-2}^{(k/2)} + b_0\, Z_i^{(k)} + b_1\, Z_{i+1}^{(k)} + V \tag{23}$$

where a_2, a_1, b_0 and b_1 are parameters given by

$$\begin{bmatrix} a_2 \\ a_1 \\ b_0 \\ b_1 \end{bmatrix} = \begin{bmatrix} 1 & \rho_1 & \rho_2 + \rho_3 & \rho_4 + \rho_5 \\ \rho_1 & 1 & \rho_1 + \rho_2 & \rho_3 + \rho 4 \\ \rho_2 + \rho_3 & \rho_1 + \rho_2 & 2(1 + \rho_1) & \rho_1 + 2\rho_2 + \rho_3 \\ \rho_4 + \rho_5 & \rho_3 + \rho_4 & \rho_1 + 2\rho_2 + \rho_3 & 2(1 + \rho_1) \end{bmatrix}^{-1} \bullet \begin{bmatrix} \rho_2 \\ \rho_1 \\ 1 + \rho_1 \\ \rho_2 + \rho_3 \end{bmatrix} \tag{24}$$

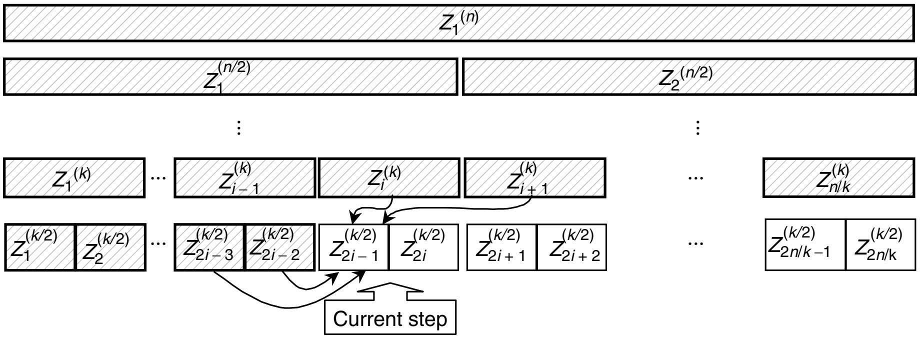

Figure 10. Explanatory sketch of the disaggregation approach for generating SSS. Gray boxes indicate random variables whose values have been already generated prior to the current step, and arrows indicate the links to those of the generated variables that are considered in the current generation step (from Reference 8).

with ρ_j given by Eq. 5 and V is an innovation with variance,

$$\mathrm{Var}[V] = \gamma_0^{(k/2)}(1 - [\rho_2, \rho_1, 1+\rho_1, \rho_2+\rho_3][a_2, a_1, b_0, b_1]^T) \tag{25}$$

where the superscript T denotes the transpose of a vector.

All parameters are independent of i and k, and therefore they can be used in all steps. When $i = 1$, there are no previous time steps, and thus the first two rows and columns of the above matrix and vectors are eliminated. Similarly, when $i = n/k$, there is no next time step, and thus the last row and column of the above matrix and vectors are eliminated.

The power law of the power spectrum of SSS allows generating an SSS time series X_i by filtering a series of white noise V_i using the symmetrical moving average (SMA) scheme (34):

$$X_i = \sum_{j=-q}^{q} a_{|j|}\, V_{i+j} = a_q\, V_{i-q} + \cdots + a_1\, V_{i-1} + a_0\, V_i + a_1\, V_{i+1} + \cdots + a_q\, V_{i+q} \tag{26}$$

where q theoretically is infinity but in practice can be restricted to a finite number, as the sequence of weights a_j tends to zero for increasing j. Koutsoyiannis (8) showed that the appropriate sequence of a_j is

$$a_j \approx \frac{\sqrt{(2-2H)\gamma_0}}{3-2H}(|j+1|^{H+0.5} + |j-1|^{H+0.5} - 2|j|^{H+0.5}) \tag{27}$$

The sequence length q must be chosen at least equal to the desired number of autocorrelation coefficients m that are to be preserved. In addition, the ignored terms a_j beyond a_q must not exceed an acceptable tolerance $\beta\sigma$. These two conditions result in

$$q \geq \max\left[m, \left(\frac{2\beta}{H^2 - 0.25}\right)^{1/(H-1.5)}\right] \tag{28}$$

Thus, q can be very large (on the order of thousands to hundreds of thousands) if H is large (e.g., > 0.9) and β is small (e.g., < 0.001). Approximate autocorrelation functions based on Eqs. 26 and 27 versus the exact SSS autocorrelation functions (Eq. 5) for various values of H and q are shown in Fig. 11.

This method can also generate non-Gaussian series with skewness ξ_X by appropriately choosing the skewness of the white noise ξ_V. The relevant equations for the statistics of V_i, which are direct consequences of Eq. 26, are

$$\left(a_0 + 2\sum_{j=1}^{s} a_j\right) E[V_i] = \mu,$$

$$\mathrm{Var}[V_i] = 1,$$

$$\left(a_0^3 + 2\sum_{j=1}^{q} a_j^3\right) \xi_V = \xi_X \gamma_0^{3/2} \tag{29}$$

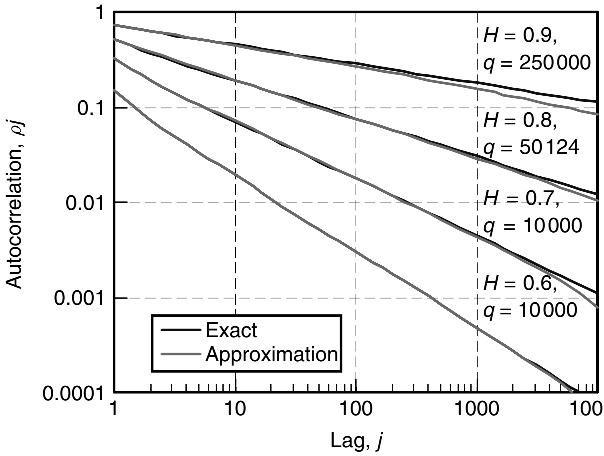

Figure 11. Approximate autocorrelation functions based on Equations 26 and 27 vs. the exact SSS autocorrelation functions (Eq. 5) for various values of the Hurst exponent H and of the number of weights q (from Reference 8).

CONCLUDING REMARKS

More than half a century after its discovery, the Hurst phenomenon has been verified as almost omnipresent in several processes in nature (e.g., hydrology), technology (e.g., computer networks), and society (e.g., economics). However, its consequences are still not widely understood or are ignored; to quote Klemeš (20), it is still regarded by many as “a ghost to be conjured away.”

For example, in stochastic hydrologic simulations that are used in hydrosystem modeling, the Hurst phenomenon is generally not reproduced. The most widespread stochastic hydrology packages have not implemented any types of models that reproduce the Hurst phenomenon. However, today methodologies exist, implemented in software packages, which can reproduce the Hurst phenomenon even in complicated situations, such as a multivariate setting with multiple timescales and asymmetric probability distributions (15,34,35). In addition, as described before, reproducing the Hurst phenomenon in univariate problems is quite simple.

In hydrologic analysis, it has been a common practice to detect falling or rising monotonic “trends” in available records, assume that these are deterministic components, and then “subtract” them from the time series to obtain a “detrended” time series, which is finally used in subsequent analyses. This common technique, which is described in several hydrologic texts, obviously contradicts the Hurst phenomenon. The “trends” are large scale fluctuations, the basis of the Hurst phenomenon. They could be regarded as deterministic components if a sound, physically based model could capture them and also predict their evolution in the future. This, however, is not the case. The a posteriori fitting of a regression curve (e.g., a linear equation) on historical data series has no relation to deterministic modeling. The subtraction of the “trends” from the time series results in a reduction of the standard deviation, an artificial decrease of uncertainty. This is exactly opposite to the real meaning of the

Hurst phenomenon, which, as analyzed before, increases uncertainty substantially.

Even without adopting this “detrending” technique, hydrologic statistics, the branch of hydrology that deals with uncertainty, in its current state is not consistent with the Hurst phenomenon. Typical statistics used in hydrology such as means, variances, cross- and autocorrelations and Hurst coefficients, and the variability thereof, are based on classical statistical theory, which describe only a portion of natural variability, and thus its results may underestimate dramatically the natural uncertainty and the implied risk.

The situation is even worse in climatology, which again uses the classical statistical framework but on longer timescales (e.g., 30 years). As demonstrated before, the consequences of the Hurst phenomenon for natural variability increase as the timescale increases. Recently, many researchers are involved in detecting anthropogenic climatic changes mostly using classical statistical tests, without taking into account the Hurst phenomenon. If statistical estimators consistent to the Hurst phenomenon are used, a choice more consistent with nature, it is more unlikely that such tests will result in statistically significant changes.

Acknowledgments
The enlightening general discussions of Vit Klemeš about the nature of the Hurst phenomenon and related issues, as well his detailed suggestions and comments on this particular article are gratefully appreciated.

UNIT HYDROGRAPH

Christophe Cudennec
Ecole Nationale Supérieure
Agronomique
Rennes, France

On the scale of a hydrologic event, a river basin schematically has two influences. The first is the yield of rainfall transformed into effective rainfall (in terms of runoff production), and the second is the transfer of runoff flows generated all over the basin territory to the unique outlet. The concept assumes that all transfer processes of the whole basin can be synthesized in a single linear function, called the unit hydrograph of the basin considered (1). It is at the root of the idea of the transfer function and is a kind of functional signature of the basin (2). This means that a characteristic function can be identified for a given basin. It is assumed that this function underlies any rainfall–runoff event and synthesizes all relevant hydrologic processes and geographic influences on the temporal scale of the event and the spatial scale fixed by the basin territory. Furthermore this means that the unit hydrograph should really be the hydrograph at the outlet, following an average impulse unit effective rainfall input, and that the response of the basin to any actual effective rainfall chronicle can be simulated through the sum of successive elementary affinities of the unit hydrograph. Such a holistic purpose necessarily faces problems of simplifying the natural complexity and of identifying the unit hydrograph itself.

The mathematical translation of the unit hydrograph concept is based on the following assumptions and analytical proposals:

- One considers a 1-unit height of effective rainfall generated uniformly over the basin territory during a time-unit duration.
- The response at the outlet of the basin is the characteristic unit hydrograph $u(t)$ during time t.
- This analytical function is used as a linear operator, which means that it respects the affinity and additivity properties. The response to any height of uniform unit effective rainfall is proportional to the unit hydrograph. The response to two following unit effective rainfalls is the sum of two following unit hydrographs. These two properties allow calculating the discharge chronicle $Q(t)$ generated by a chronicle of effective rainfall $\overline{R_{\mathrm{eff}}}(t)$:

$$Q(t) = \frac{S}{\Delta t} \cdot \sum_{\tau=1}^{\min(t,\theta)} \overline{R_{\mathrm{eff}}}(t-\tau+1)u(\tau) \qquad (1)$$

where Δt: the discrete time pace;
$Q(t)$: the mean discharge during the time step $[t-\Delta t; t]$;
$\overline{R_{\mathrm{eff}}}(t)$: the height of effective rainfall, average in space, during the time step $[t-\Delta t; t]$;
$u(t)$: the value of the unit hydrograph during the time step $[t-\Delta t; t]$;
S: the basin surface area;
θ: the length of the unit hydrograph;
τ: the time abscissa of the unit hydrograph.

If one considers Δt close to zero, the effective rainfall input is similar to a Dirac function, and the consequent unit hydrograph is then called an instantaneous unit hydrograph. Equation 1 can than be expressed continuously as a convolution:

$$Q(t) = S\overline{i_{\mathrm{eff}}}(t) * u(t) \qquad (2)$$

$$\Leftrightarrow Q(t) = S\int_0^t \overline{i_{\mathrm{eff}}}(t-\tau)u(\tau)d\tau \qquad (3)$$

where $\overline{i_{\mathrm{eff}}}(t)$ is the intensity of the effective rainfall, average in space, at time t. $u(t)$ is then the kernel function of the convolution.

The initial unit hydrograph concept strongly simplifies the complexity of basin hydrology:

- Its globality does not easily allow accounting for space heterogeneities and variabilities.
- It applies only to rapid components of runoff.
- Its linearity and stationarity can be criticized because actual hydrologic events are nonlinear.
- The claim of describing all transfer processes within a basin is strong regarding the differences between hillslope and channel processes.

But these problems have been studied through different proposals for identifying it.

The analytical expression for the unit hydrograph can be deduced from a comparison of actual rainfall and discharge gauging (3,4). It can also be deduced from conceptual assumptions, based mostly on the concepts of linear reservoir and linear channel (3). The most famous conceptual proposal is Nash's model (5,6), based on an analogy between a basin and n identical linear reservoirs in series. The unit hydrograph obtained is the following gamma law:

$$u(t) = \frac{1}{k(n-1)!}\left(\frac{t}{k}\right)^{n-1} e^{-\frac{t}{k}} \quad (4)$$

where the parameters n and k have to be calibrated, but where it is a priori assumed that the gamma law is the shape of the unit hydrograph.

To show the influence of basin geomorphology on unit hydrograph identification, a theory has been proposed by Rodriguez-Iturbe and Valdès (7). They define the unit hydrograph as the probability density function of the water travel time to the outlet. They estimate it by combining the probabilities of paths through the Strahler states and the probabilities of residence times in the different Strahler states of the river network. The result is called the geomorphological unit hydrograph.

Parallel to this, some models are based on the isochrone notion. It is already the case for the rational method used since the nineteenth century (8) and is coming back in models based on the geomorphological area and width functions because they are easily available from geographic databases and GIS processing (9,10). This geomorphological basement of the unit hydrograph identification opens, today, new prospects because it allows splitting transfers through hillslopes and through a river channel (11), considering nonlinear transfer processes through a stable geometric structure (8), and accounting for variability of effective rainfall input along the isochrone areas (12).

HYDROLOGICAL PROCESSES

Hydrological processes involved in the circulation of water between the atmosphere, the land surface, and underground and its return back to the atmosphere is know as the hydrologic cycle (Fig. 1). In the circulation process, water vapors are transported by winds and air currents through the atmosphere (1). When the air mass cools sufficiently, the water vapor condenses into clouds, and a portion falls to the ground as precipitation in the form of snow, rain, sleet, or hail. Water that falls to the ground as precipitation follows many paths on its way back to the atmosphere. The water may be intercepted and taken up by the plants; it may be stored in small depressions or lakes; it can infiltrate the soil; or it can flow over the surface to a nearby stream channel. The sun may cause the water to evaporate directly back into the atmosphere, or the force of gravity may pull it down through the pores of the soil to be stored for years as slowly moving groundwater. Some of the water flowing through the ground returns to the surface to supply water to springs, lakes, and rivers. Water on the ground surface, in streams, or in lakes can return to the atmosphere as vapor through the process of evaporation. Water used by plants may return to the atmosphere as vapor through transpiration, which occurs when water passes through the leaves of plants. Collectively known as evapotranspiration, both evaporation and transpiration occur in greatest amounts during periods of high temperatures and wind, dry air, and sunshine.

This movement of water supports life on the earth and is mainly governed by the energy of the sun, the force of gravity, land use/land cover pattern, soil type, and geological characteristics. The quantities of water in the atmosphere, soils, groundwater, surface water, and other components are constantly changing because of the dynamic nature of the hydrological processes. The magnitude of various storage components including soil water, snow packs, lakes, reservoirs, and rivers can be altered by human activities. With the water

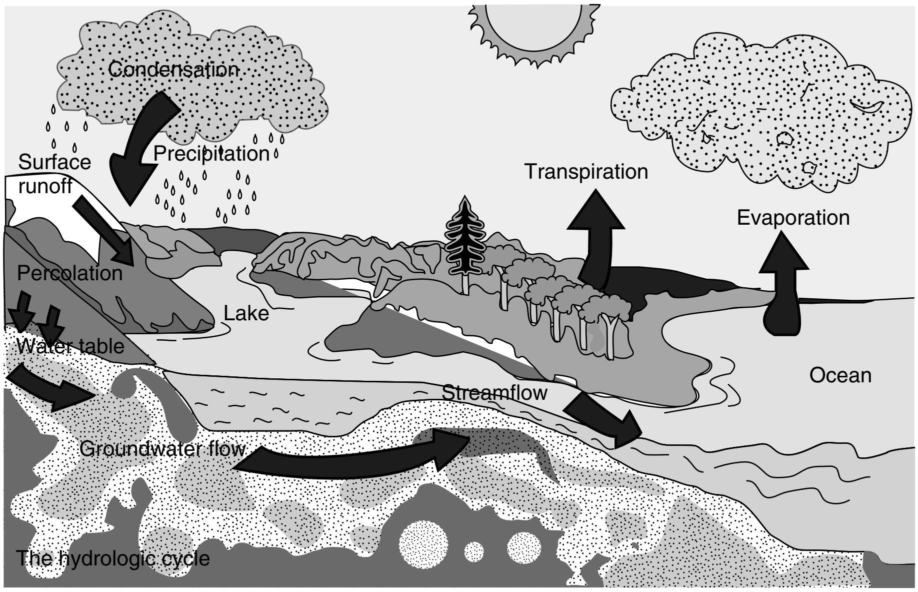

Figure 1. Circulation of water—the hydrologic cycle.

budget approach, experts can examine existing watershed systems, quantify the effects of management impacts on the hydrologic cycle, and, in some cases, predict or estimate the hydrologic consequences of proposed activities. Further, the budget can be estimated in a simplified manner, if components are categorized into input, output, and storage (2). Based on the principle of conservation of mass, inputs such as rainfall, snowmelt, and condensation must balance with changes in storage and outputs, which include stream flow, groundwater seepage, and evapotranspiration (outflow subtracted from the inflow is equal to change in storage). This hydrologic balance, or water budget, is an application of the conservation of mass law expressed by the equation of continuity:

$$I - O = \Delta S \tag{1}$$

where $I = \text{inflow}$, $O = \text{outflow}$, and $\Delta S = \text{change in storage}$.

It is to be noted that Eq. 1 does not consider the quality aspects in water budgeting using conservation of mass theory. As a result of increasing population, growth steady rise in irrigation activities, rapid expansion of industries, urbanization, and modern ways of living, tremendous pressure on the available water has been exerted, which is highly uneven in its spatial and temporal distribution both in quantity and quality. Therefore, the water pollution is a major environmental concern all over the world. In the following section, pollutant loads in hydrological variables generated and altered because of human activities have been presented.

MEASURED POLLUTANT LOADS

It is essential for water resources planners and managers to look for water pollution generated in different variables of hydrologic cycle because of human activities. It has been found that among various hydrological variables, rainfall, runoff (including snowmelt runoff), seepage, and groundwater flow are affected, and the water quality has been degraded beyond permissible limits in many instances.

Pollution Measurement in Rainfall

Acids are the main source of pollution in the rainfall. They occur naturally or because of human activities. Both the phenomena are discussed in the following section.

Pollution Because of Natural Phenomena. Natural sources of acids exist, such as volcanoes, natural geysers, and hot springs. Nature has developed ways of recycling these acids by absorbing and breaking them down. These natural acids contribute to only a small portion of the acidic rainfall in the world today. In small amounts, these acids actually help dissolve nutrients and minerals from the soil so that trees and other plants can use them for food. The large amounts of acids produced by human activities overload this natural acidity.

Pollution Because of Human Activities. On a daily basis, human activities (industrial, agricultural, and residential) cause vast quantities of natural and synthetic chemicals to be emitted into the atmosphere. Once released, the substances are dispersed throughout the globe by air currents.

Scientists have discovered that air pollution from the burning of fossil fuels is the major cause of acid rain (Fig. 2). Power plants use coal and oil to produce the electricity we need to heat and light our homes and to run our electric appliances. Natural gas, coal, and oil are burnt to heat homes. Cars, trucks, and airplanes use gasoline, another fossil fuel. The smoke and fumes from burning fossil fuels rise into the atmosphere and combine with the moisture in the air to form acid rain (3).

When water droplets form and fall to the earth, they pick up particles and chemicals that float in the air. Even

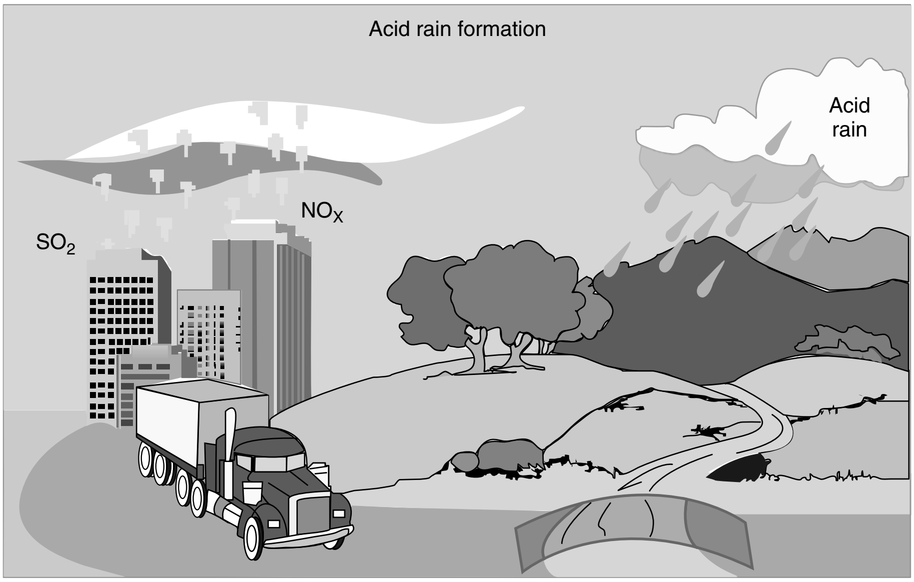

Figure 2. Acid rain formation.

clean, unpolluted air has some particles such as dust or pollen. Clean air also contains naturally occurring gases such as carbon dioxide. The interaction between the water droplets and the carbon dioxide in the atmosphere gives rain a pH of 5.6, making even clean rain slightly acidic. Other natural sources of acids and bases in the atmosphere may lower or raise the pH of unpolluted rain. However, when rain contains pollutants, especially sulfur dioxide and nitrogen oxides, the rain water can become very acidic.

The main chemicals in air pollution that create acid rain are sulfur dioxide and nitrogen oxides. Acid rain usually forms high in the clouds where sulfur dioxide and nitrogen oxides react with water, oxygen, and oxidants, which forms a mild solution of sulfuric acid and nitric acid. Sunlight increases the rate of most of these reactions. Rainwater, snow, fog, and other forms of precipitation containing those mild solutions of sulfuric and nitric acids fall to the earth as acid rain with a consequent decrease of water pH (pH below 5.5–5.6). Figure 3 depicts the acid rain formation in the atmosphere.

Effects of Acid Rain. Acid rain does not account for all of the acidity that falls back to earth from pollutants. About half the acidity in the atmosphere falls back to the earth through dry deposition as gases and dry particles. The wind blows these acidic particles and gases onto buildings, cars, homes, and trees. In some instances, these gases and particles can eat away the things on which they settle. Dry deposited gases and particles are sometimes washed from trees and other surfaces by rainstorms. When that happens, the runoff water adds those acids to the acid rain, making the combination more acidic than the falling rain alone. The combination of acid rain plus dry deposited acid is called acid deposition.

Acid rain can contaminate drinking water, damage vegetation and aquatic life, and erode buildings and

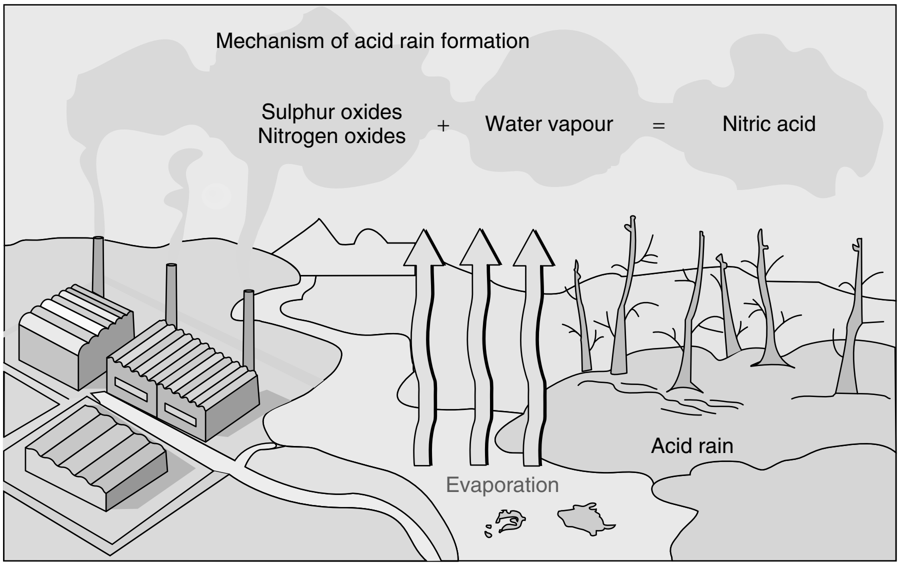

Figure 3. Acid rain formation in the atmosphere.

monuments. The water bodies most susceptible to change because of acid precipitation are those whose catchments have shallow soil cover and poorly weathering bedrock, e.g., granite and quartzite. These soil types are characterized by the absence of carbonates that could neutralize acidity. The runoff water from such areas is less buffered than from areas such as limestone catchments, with an adequate level of carbonate. Such catchments and waters are termed acid-sensitive (poorly buffered), and can suffer serious ecological damage because of artificially acidified precipitation from air masses downwind of major emissions.

Numerous studies show that acid precipitation damages forests and may cause significant decreases in productivity. Acid precipitation causes foliar damage to birch and pines, impairs seed germination of spruce seeds, erodes protective waxes from oak leaves, and leaches nutrients from plant leaves. Scientists believe that damage to trees may increase the likelihood of avalanches and landslides because trees help retain snow cover and soil cover on steep mountainsides.

Concern for agriculture has also been raised by numerous researchers. Acid precipitation is particularly harmful to buds; therefore, acids falling on plants in the spring might impair growth. Acids may also damage plants by altering the soil. For example, acid rain may leach important elements from the soil, resulting in lower yield and reduced agricultural output. Acidification of soils may also impair soil bacteria and fungi that play an important role in nutrient cycling and nitrogen fixation, both essential to normal plant growth.

The toxic action of acidity is most pronounced in its effect on the fish and macroinvertebrate fauna of streams and lakes. Dissolved aluminium concentrations as low as 0.05–1 mg can kill such organisms, whereas lower levels may have nonlethal effects such as respiratory difficulty, impaired growth, and reproductive ability, which, in the long term, may lead to their elimination.

Pollution Measurement in Runoff

The portion of water that does not infiltrate the soil but flows over the surface of the ground to a stream channel is called surface runoff. Water always takes the path of least resistance, flowing downhill from higher to lower elevations, eventually reaching a river or its tributaries. Runoff is the greatest source of water pollution, contributing from 50–60% of the pollutant load. As this water flows over agricultural lands, urban areas, hills, and forest land, it picks up different types of pollutants such as silt particles, microbial contaminants, pesticides, fertilizer, pet waste, litter, industrial wastes, urban wastes, and oil.

Natural Sources of Runoff Pollution. Heavy rain falling on exposed soil can cause substantial leaching of nitrate, some of which goes directly into rivers, but most of which percolates into the groundwater from where it may eventually reach the rivers if no natural denitrification occurs. Assessment of trends in nitrate concentrations should be undertaken on a long-term basis (i.e., frequent sampling for more than 10 years' duration).

In regions of high erosion (e.g., steep slopes, heavy rainfall, highly erodible rocks) where natural total suspended solids (TSS) already exceed 1 gm per litre, intensive agriculture aggravates the natural erosion rates.

Increased mineral salts in rivers may develop from potash mines, salt mines, iron mines, and coal mines. Mining wastes result in increases in specific ions only, such as Cl^- and Na^+ from potash and salt mines, and SO_4^{2-} from iron and coal mine wastes. The changes in ionic contents and the ionic ratio of waters are very often linked to pH changes. Mine wastewaters are generally very acidic ($pH \leq 3$), whereas industrial wastes may be basic or acidic.

Increased evaporation and evapotranspiration in the river basin (mainly in arid and subarid regions) also increase minerals. Evaporation affects all ions and as calcium carbonate reaches saturation levels, calcium sulphate-rich waters or sodium chloride-rich waters are produced. Increased evaporation and evapotranspiration in the river basin (mainly in arid and subarid regions) also increase minerals. Salinization resulting from evaporation usually leads to more basic pH levels.

In colder regions where snowmelt has a significant hydrological influence, the accumulated acidic deposition in the snow may be released when it melts. Melting snow during spring releases its acid in a sudden torrent, quickly elevating the acidity of lakes and streams. This surge of acids coincides with the sensitive reproductive period for many species of fish. The first 30% of the melt water contains virtually all of the acid and typically has a pH of 3 to 3.5, which is toxic to eggs, fry, and adult fish as well, which can cause a sudden acid pulse, which may be more than one pH unit lower than normal (4).

Runoff Pollution Because of Human Interference. There are many causes for water pollution, but two general categories exist: direct and indirect contaminant sources (Fig. 4). Direct sources include effluent outfalls from factories, refineries, waste treatment plants, etc. that emit fluids of varying quality directly into water supplies.

Indirect sources include contaminants that enter from soils/groundwater systems and from the atmosphere via rain water. Soils and groundwater contain the residue of human agricultural practices (fertilizers, pesticides, etc.) and improperly disposed of industrial wastes (5). Atmospheric contaminants are also derived from human practices (such as gaseous emissions from automobiles,

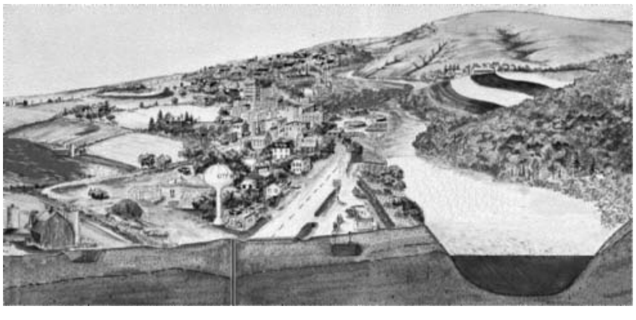

Figure 4. Representation of direct and indirect sources of pollution.

Table 1. Nonpoint Sources Pollution and Pollutants

Category of Nonpoint Source	Pollution Causing Activities	Principal Pollutants
Agriculture	Crop production, animal production, farm production	Nutrients, salts, fertilizer, pesticides, organic matters
Forestry	Access road construction and operation, harvesting systems, logging, crop regeneration, other silvicultural processes	Nutrients, pesticides, organic pollutants
Mining	Exploration, construction of facilities, mine operation, mine abandonment	Nutrients, waters, dissolved minerals, salinity
Construction	Land development, transportation and communication networks, water resources facilities	Chemicals, biological materials
Urban runoff	Precipitation discharges containing pollutants, accelerated and concentrated by urban surfaces and collection system	Organic materials, coliform bacteria, pesticides, nutrients, heavy metals
Hydrologic modifications	Channel modifications, farm drainage, dams, resource recovery, and related activities	Nutrients, pesticides, thermal chemicals, micro-organisms
Residual wastes	Foregoing categories create residual waste not discharged to water but conveyed by runoff and infiltration	Both hazardous and nonhazardous

factories, and even bakeries as discussed earlier). Table 1 reflects the pollution causing activities and their principal pollutants of nonpoint sources of water pollution.

Many physical, chemical, and biological parameters are measured to determine the overall quality of water. However, the quality of water is based not only on the concentration of substances but also on the intended use of the water. A person using water for drinking would have a different set of criteria for determining the water quality compared with a person using the water for swimming. In Tables 2, 3, and 4, the water quality criteria based on the use of water (such as drinking, bathing, and irrigation) is presented (8).

Pollutant Loads in Groundwater

Where water infiltrates the ground, gravity pulls the water down through the pores until it reaches a depth in the ground where all of the spaces are filled with water (Fig. 5). At this point, the soil or rock becomes saturated, and the water level that results is called the water table. The water table is not always at the same depth below the land surface. During periods of high precipitation, the water table can rise. Conversely, during periods of low precipitation and high evapotranspiration, the water table falls. The area below the water table is called the saturated zone, and the water in the saturated zone is called groundwater. The area above the water table is the unsaturated zone.

Groundwater is found in aquifers, which consist of soil or rock in the saturated zone that can yield significant amounts of water. In an unconfined aquifer, the top of the aquifer is defined by the water table. Confined aquifers are bound on the top by impermeable material, such as clay. Water in a confined aquifer is normally under pressure and can cause the water level in a well to rise above the water table. If the water rises above the ground surface, it is designated a flowing artesian well. A perched water table occurs when water is held up by a low permeability material and is separated from a second water table below by an unsaturated zone. In the saturated zone, groundwater flows through the pores of the soil or rock both laterally and vertically.

Water moving from an aquifer and entering a stream or lake is called groundwater discharge, whereas any water entering an aquifer is called recharge. An aquifer may receive recharge from these sources, an overlying aquifer, or more commonly from precipitation followed by infiltration. The pollutants present in soil also move along the water entering the aquifer and pollute the groundwater.

How We Contaminate Groundwater. Any addition of undesirable substances to groundwater caused by human activities is considered to be *contamination* (9). It has often been assumed that contaminants left on or under the ground will stay there. This assumption has been shown to be wishful thinking. Groundwater often spreads the effects of dumps and spills far beyond the site of the original contamination. Groundwater contamination is extremely difficult, and sometimes impossible, to clean up.

Groundwater contaminants come from two categories of sources: point source and distributed, or nonpoint source. They are as follows:

Point sources

The main sources are:

- On-site septic systems
- Leaky tanks or pipelines containing petroleum products
- Leaks or spills of industrial chemicals at manufacturing facilities
- Underground injection wells (industrial waste)
- Municipal landfills
- Livestock wastes
- Leaky sewer lines
- Chemicals used at wood preservation facilities
- Mill tailings in mining areas
- Fly ash from coal-fired power plants
- Sludge disposal areas at petroleum refineries
- Land spreading of sewage or sewage sludge
- Graveyards
- Road salt storage areas

Table 2. General Quality Criteria for Raw Waters Used for Organized Community Water Supplies (Surface and Groundwater)

(a) Primary parameters (frequency of monitoring may be daily and/or even continuous using automatic instruments for few parameters like pH, DO, and Conductivity)

Parameter	Range/limiting value		Note
	Use with Only Disinfection	Use After Conventional Treatment	
pH	6.5–8.5	6–9	To ensure prevention of corrosion in treatment plant and distribution system and interference in coagulation and chlorination
Color, Pt scale, Hz units	<10	10–50	Color may not get totally removed during treatment (not applicable in monsoon period)
Total suspended solids, mg/l	<10	10–50	High SS may increase the cost of treatment
Odor, dilution factor	<3	3–10	May not be easily tackled during treatment to render water acceptable
Dissolved oxygen, (% saturation)	90–110	80–120	
Biochemical oxygen demand, mg/l	<3	3–5	Could cause problems in treatment, larger chlorine demands, and residual taste and odor problems.
Total Kjeldahl' Nitrogen, mg/l	<1	1–3	Same as above
Ammonia, mg/l	<0.05	0.05–1.5	Same as above
Fecal coliform, MPN/100 ml	<200	200–2000	The criteria world be satisfied if, during a period of one week, not more than 5% samples show greater than 20,000 MPN/100 ml, and not more than 20% of samples show greater than prescribed limit
Conductivity, umhos/cm	<1000	1000–2000	High conductivity may cause unpalatable mineral taste and physiological disorders
Chloride, mg/l	<200	200–300	May cause physiological impact and unpalatable mineral taste
Sulphates, mg/l	<100	100–250	May cause digestive abnormality on prolonged consumption
Phosphates, mg/l	<0.1	0.1–0.3	May interfere with coagulation
Nitrate, mg/l	<30	30–50	High nitrate/nitrite may cause methamoglobinemia
Fluoride, mg/l	<1.0	1.0–1.5	Prolonged consumption of water containing high F may cause fluorosis
Surfactants, mg/l	<0.1	0.1–0.2	May impair treatability and cause foaming

Note: There should not be any significant wastewater discharge in the upstream (up to 5 km) of the water intake point.

(b) Additional Parameters for Periodic (Say Monthly/seasonal) Monitoring

Parameters	Desirable	Acceptable	Note
Dissolved iron, mg/l	<0.3	3–5	Higher iron affects the taste of beverages and causes stains
Copper, mg/l	<0.5	0.5–1.0	May result in damage of liver
Zinc, mg/l	<0.1	<5.0	May cause bitter stringent taste
Arsenic, mg/l	<0.002	0.002–0.05	Can cause hyperkertosis and skin cancer in human beings
Cadmium, mg/l	<0.001	0.001–0.005	Toxic to man
Total-Cr, mg/l	<0.05	<0.05	Toxic at high doses
Lead, mg/l	<0.05	0.04–0.05	Irreversible damage to the brain in children, anaemia, neurological disfunction, and renal impairment
Selenium, mg/l	<0.01	<0.01	Toxic symptoms similar to arsenic
Mercury, mg/l	<0.0002	0.0002–0.0005	Deadly, poisonous, and carcinogenic
Phenols, mg/l	<0.001	<0.001	Toxic and carcmogenic; may also cause major problem of taste and odor
Cyanides mg/l	<0.05	<0.05	Larger consumption may lead to physiological abnormality
Any Polycyclic Aromatic hydrocarbons, mg/l	<0.0002	<0.0002	Carcinogenic
Total Pesticides, mg/l	<0.001	<0.0025	Tend to bioaccumulate and biomagnify in the environment; toxic and carcinogenic

Note: The parameters mentioned need to be examined only when (i) there are known natural sources in the upstream basin region likely to contribute, (ii) there are known problems in respect to the parameter, (iii) there are other well-founded apprehensions.

- Wells for disposal of liquid wastes
- Runoff of salt and other chemicals from roads and highways
- Spills related to highway or railway accidents
- Coal tar at old coal gasification sites
- Asphalt production and equipment cleaning sites

Among the more significant point sources are municipal landfills and industrial waste disposal sites. When either

Table 3. Quality Criteria for Waters of Mass Bathing Reaches

Parameter	Desirable	Acceptable	Note
Fecal coliform, MPN/100 ml	<100	100–1000	If MPN of fecal coliform is noticed to be more than 100/100 ml, then regular tests should be carried out. The criteria would be satisfied if, during a period, not more than 5% samples show greater than 5000 MPN/100 ml, and not more than 20% of samples show greater than 1000/100 ml
pH	6–9	6–9	
Color Pt scale Hz units	No abnormal color	No abnormal color	No color of anthropogenic origin
Mineral oil, mg/l	No film visible	No film visible	
Methylene blue active substances, mg/l	<0.3	0.3–1.0	Skin problem likely
Phenols, mg/l	<0.005	0.005–0.01	Skin problems and odor problem
Transparency (Sechhi depth)	>2 m	0.5–2 m	
Biochemical oxygen demand, mg/1	<5	5–8	High organic matter may be associated with coliform pathogens
Dissolved oxygen, % saturation	80–120	60–140	–
Floating matter of any type	Absent	Absent	

Note: No direct or indirect discharge of untreated domestic/industrial wastewater within 5 km upstream.

Table 4. General Water Quality Criteria for Irrigation Waters (6,7)

Parameter	Generally Acceptable	Relaxation for Special Planned (Exceptional Notified) Cases	Note
Conductivity, umhos/cm	<2250	2250–4000	The irrigation water having conductivity more than 2250 µs/cm at 25 °C may reduce vegetative growth and yield of the crops. It may also increase soil salinity, which may affect its fertility
Fecal coliform, MPN/100 ml	<5000	No limit	No limit for irrigating crops not eaten raw
pH	6–9	5–9.5	Soil characteristics important
Biochemical oxygen demand, mg/l	<100	No limit	Land can absorb organic matter faster than water; however, the conditions of water logging should be avoided. Stagnant water should not persist for more than 24 hours
Floating materials such as wood, plastic, rubber, etc.	Absent	No limit	May inhibit water percolation
Boron, mg/l	<2	<2	Boron is an essential nutrient for plant growth; however, it becomes toxic beyond 2 mg/l
SAR	<26	No limit	SAR beyond 26 may cause salinity and sodicity in the soil. When it exceeds the limit, method of irrigation and salt tolerance of crops should be kept in mind
Total heavy metals mg/l	< 5.0	5.0–15.0	

of these occur in or near sand and gravel aquifers, the potential for widespread contamination is the greatest. Other point sources are individually less significant, but they occur in large numbers all across the country. Some of these dangerous and widespread sources of contamination are septic tanks and leaks and spills of petroleum products and of dense industrial organic liquids.

Septic systems are designed so that some of the sewage is degraded in the tank and some is degraded and absorbed by the surrounding sand and subsoil. Contaminants that may enter groundwater from septic systems include bacteria, viruses, detergents, and household cleaners, which can create serious contamination problems. Despite the fact that septic tanks and cesspools are known sources of contaminants, they are poorly monitored and studied very little.

Nonpoint (Distributed) Sources

Nonpoint sources comprise the other type-generalized discharges of waste whose location cannot be identified. The main sources are agriculture, forestry, mining, construction, urban runoff, hydrologic modifications, and residual wastes. Table 1 reflects the pollution-causing activities and their principal pollutants of nonpoint sources of water pollution.

Contamination can render groundwater unsuitable for use. Scientists also predict that, in the next few decades, more contaminated aquifers will be discovered, new contaminants will be identified, and more contaminated groundwater will be discharged into wetlands, streams, and lakes.

Once an aquifer is contaminated, it may be unusable for decades. The residence time, as noted earlier, can be

Figure 5. Infiltration of surface water.

anywhere from two weeks to 10,000 years. Furthermore, the effects of groundwater contamination do not end with the loss of well water supplies. Several studies have documented the migration of contaminants from disposal or spill sites to nearby lakes and rivers as this groundwater passes through the hydrologic cycle, but the processes are not as yet well understood. In Canada, pollution of surface water by groundwater is probably at least as serious as the contamination of groundwater supplies. Preventing contamination in the first place is, by far, the most practical solution to the problem. Prevention can be accomplished by the adoption of effective groundwater management practices by governments, industries, and all individuals. Although progress is being made in this direction, efforts are hampered by a serious shortage of groundwater experts and a general lack of knowledge about how groundwater behaves.

HYDROLOGIC THRESHOLDS

Bellie Sivakumar
University of California
Davis, California

INTRODUCTION

Hydrologic science has witnessed an exponential growth in the last century, thanks to sheer necessity (or even mere curiosity) and technological advances. Population growth and lifestyle changes have contributed (both positively and negatively) to hydrologic science, in terms of water resources availability, planning, and management. Invention of powerful computers, remote sensing, geographic information systems, worldwide networking facilities, and many other technologies have, in one way or another, allowed better hydrologic data collection, analysis, and sharing, which, in turn, facilitated more effective and efficient water resources planning and management. Despite these developments, our lack of ability to adequately plan and manage our water resources continues to be a matter of grave concern.

Setting aside, for the present discussion, the population growth and the socio-politico-economic scenarios, our inability to adequately plan and manage our water resources may largely be attributed to two factors:

1. our inability to collect all the relevant data for the system of interest; and
2. our inability to understand the past, model the present, and forecast the future, even with collected data; in other words, our inability to accurately “replicate and extrapolate” the data.

In regard to 1, we may take some solace by our experience, albeit limited, that often only a few processes dominate responses in a given hydrologic system and, therefore, may focus on collecting more reliable data relevant only to these dominant processes (1). This concept, fittingly termed by Grayson and Blöschl (1) as the "Dominant Processes Concept" (DPC), has been receiving increasing attention among hydrologists in one way or another (2–4). More recently, Sivakumar (5) presented a new proposal for moving forward with the DPC, emphasizing on integration of theoretical concepts and practical knowledge for more effective and efficient data collection and analysis procedures.

As for 2, notwithstanding data quantity and quality issues, our inability to accurately replicate and extrapolate the data may largely be because of the inherent limitations of our modeling and forecasting procedures and the inappropriate selection of data sets used therein for "training" (learning or calibration) and "testing" (verification or validation), respectively. Sivakumar (6) points out this "data handling" problem in a rather different and multifaceted manner, by reviewing sample studies on recent data modeling and forecasting techniques in hydrology, including artificial neural networks and chaos theory. More specifically, Sivakumar (6) argues that any bias resulting in our extrapolations is in line with the procedural or data bias in our learning, which is chosen to capture (the statistics of) our desired "extreme" or "average" extrapolations. To overcome this problem, he suggests the use of different models for different ranges of data, rather than a single model for the entire data range, as is commonly used. Deriving an analogy between humans and catchments, and emphasizing their internal characteristics and responses to external events, Sivakumar (6) discusses the usefulness of "thresholds" in identifying these data ranges. Reiterating that the "threshold" concept is already in wide use in different implicit forms in hydrology, he stresses the need for bringing these implicit forms under one common umbrella, and explicitly termed as "thresholds," for everyone to understand.

In the spirit of the proposal by Sivakumar (6), this article presents further ideas as to the potential role of thresholds in hydrology. Specifically, it aims to launch the threshold concept at a much wider spectrum than the narrow time-series/parameter-optimization spectrum presented by Sivakumar (6), which is attempted by discussing three important issues: (a) relevance of thresholds in hydrology; (b) challenges in the identification and quantification of thresholds; and (c) importance of interdisciplinary efforts on threshold research.

THRESHOLDS IN HYDROLOGY

Simply put, thresholds are "critical" points separating different states (or phases) that exist or are possible in a given system. These points are critical because they are the "enablers" or "barriers" for transitions between states that may have enormous differences in their properties (e.g., physical, chemical, and biological). As these transitions are often "catastrophic", thresholds are generally defined as points separating "average" and "extreme" events.

The relevance of thresholds in hydrology should be evident even from our simple observations of "average", "high", and "low" rainfall periods, which often lead to "normal", "flood", and "drought" periods, respectively. Whether it is rainfall, runoff, or any other hydrologic phenomenon, transitions between different states are essentially the result of the underlying physical mechanisms. These physical mechanisms are, in turn, governed by the characteristics of the land, ocean, and atmosphere. As natural and man-made changes to land, ocean, and atmosphere occur, even within their individual realms, so do changes to the underlying physical mechanisms and transitions from one state to another. When such changes occur across these domains, the "probability" of changes to physical mechanisms and transitions between states increases, because a much more complex coupled land-ocean-atmospheric system is in effect.

The land-ocean-atmospheric system as a whole is a "network" composed of interconnected parts, which in themselves are "networks" (e.g., hydrologic system) composed of their own interconnected parts, and so on. In this network(s), the relationships between the parts are circular (in an abstract, but not necessarily spatial, sense), which causes "feedback" because the actions of each component "feeds back" on itself (e.g., rainfall-evaporation-rainfall or rainfall-runoff-evaporation-rainfall). This feedback mechanism can be either positive or negative, but both types are relevant and important; a negative feedback stabilizes the system, whereas a positive feedback often destabilizes the system.

Feedbacks are not only inherent in hydrologic systems but are also inherently nonlinear in their nature. The nonlinear nature of the feedbacks, when combined with the complex nature of the hydrologic systems, may cause bifurcations, i.e., rapid, unpredictable, and often catastrophic transitions to new states, occurring at critical points or thresholds. One state that can develop at a bifurcation is chaos, which demonstrates sensitive dependence to initial conditions or "butterfly effect" [e.g., (7,8)]. This effect, i.e., infinitesimal changes in inputs leading to enormous differences in outcomes, amplifies uncertainty and limits predictability. In fact, the most complex behavior in hydrologic systems (and other networks) often occur at the edge of chaos, i.e., at a transition from chaos to order or vice-versa. A particular signature of this state is the presence of fractals, i.e., patterns in space and/or time that are self-similar on many scales [e.g., (9)].

A related property of a feedback, nonlinear, chaotic, and fractal system is self-organization, which refers to the spontaneous development (organization) of the system and its evolution to different and more complex states. Self-organizing systems demonstrate the "emergence" of properties. The emergent properties are not inherent in any of the parts of the system examined in isolation, but emerge only as a result of the interactions between the parts that characterize the system as a whole. Self-organization is particularly relevant for hydrologic systems. For example, a river exists as an interaction between the flow of water, the materials making up the riverbank and channel, the elevation and terrain of the land, the climate, temperature and rainfall, the law of gravity, the forces of turbulence, and more. Although it is possible to understand each component of the river by reduction, this is not adequate for understanding the river as a whole, because the emergent properties and evolution of the river are governed by the interactions among the components, which stretch beyond the domain of any one single component.

IDENTIFICATION AND QUANTIFICATION OF THRESHOLDS

With the relevance and importance of thresholds in understanding hydrologic systems evident, the immediate question is how to identify and quantify them. In this regard, knowledge of general system characteristics (e.g., climatic condition, geography, land use, wet or dry state) and system evolution (i.e., history of changes to the system and the associated changes to hydrologic events, such as rainfall amounts, frequency of floods and droughts) may provide some basic information on the types of thresholds (i.e., identification) and their levels (i.e., quantification). With this information, additional threshold criteria may be established using methods and tools, available at our disposal, based on traditional linear and reductionistic approaches.

We may be able to achieve some success with the above; however, it will only be partial, because linear and reductionistic approaches only study the system components in parts and attempt to estimate important statistics, whereas hydrologic systems are governed by nonlinear feedbacks, bifurcations, chaos, fractals, and emergent properties that run across the individual component parts and require a nonlinear and holistic approach(es).

As much as the concept of a nonlinear and holistic approach is exciting, the following point is noteworthy. Although a nonlinear and holistic approach may be *the* approach for the system as a whole, it may *not* be the one for the individual component parts after all, for which a linear and reductionistic approach may perform better. As a “complete” explanation of a system requires accurate analysis of the parts (reductionism) AND the whole system complexity (holism), a coupled reductionistic-holistic approach may work, in all probability, better than either of the two approaches when adopted independently. The impending challenge, therefore, is to devise such a coupled approach that would provide equal importance to the whole system as well as to its parts.

New theoretical developments and methodological advancements may indeed be needed to address this challenge. To what extent will we give priority to this challenge and how quickly will we be successful in formulating a reliable coupled reductionistic-holistic approach remain to be seen. Although we must start laying the foundation for this task, sooner rather than later, we must also find ways to understand, use, interpret, and even integrate the existing theories and methods better than we have thus far, because the latter may provide some important information that may, subsequently, become significant in implementing the former.

An examination of hydrologic literature clearly reveals the opportunities and possibilities in this regard, as evident from the following two examples. Sivakumar (12), through a discussion of three fundamental ideas of chaos theory (maybe less popular among hydrologists), presents an interpretation of “chaos theory as a bridge between our popular views of determinism and stochasticity”. Addressing the Dominant Processes Concept, Sivakumar (5) proposes an integration of ideas from nonlinear dynamic theory, expert system, and optimization technique, whose usefulness may be viewed at a much broader spectrum of model simplification.

The fact that interpretation and integration of existing theories and development of new ones often require knowledge of not only hydrology but also other fields, including atmospheric and ocean sciences, ecology, geomorphology, mathematics, and physics, our ability to succeed in identifying and quantifying thresholds mainly lies in our ability to perform collaborative work with researchers in these fields. This topic is discussed next.

INTERDISCIPLINARY RESEARCH ON THRESHOLDS

Thresholds are problem-dependent. Although a connection between thresholds of inputs (e.g., rainfall) and outputs (e.g., runoff), often exists a threshold for an input does not automatically lead to a corresponding threshold in an output. For example, in a rainfall-runoff-sediment transport scenario, the threshold for erosion (a result of runoff) may be different from that for runoff (a result of rainfall), which, in turn, may be different from that for rainfall (a result of atmospheric mechanisms). Similarly, thresholds are also scale-dependent. Although scale-invariance in space and time exists in hydrologic systems and phenomena, different thresholds may exist at different scales, depending on the dominant catchment parameter at the given scale (e.g., slope, land use) and the dominant catchment mechanism (e.g., erosion, interception, evapotranspiration).

These observations indicate the complications involved in even arriving at a definition for thresholds for a given hydrologic system. Also, hydrologic systems play different roles with respect to other related systems (e.g., atmospheric, ecologic, environmental, and geomorphic systems) and vice-versa, which makes the problem even more difficult. Further complications develop when consideration of a one-to-one system scenario or a multiple-system scenario is needed. In view of these, the only hope we can have is to approach the problem from an interdisciplinary view, and multidisciplinary to be more specific, involving researchers from as many related fields as possible.

Establishing interdisciplinary collaborations is not an easy task, particularly at a time we, hydrologists, ourselves seem to be moving away from each other, with our emphasis on specific data analysis techniques rather than common hydrologic problems (6). There is encouraging news, however, as efforts are already being made to address the threshold problem from an interdisciplinary perspective. For instance, the Environmental Hydroscience Discipline Group of the University of Western Australia is working toward the organization of a multidisciplinary workshop entitled “Thresholds and Pattern Dynamics—A New Paradigm for Predicting Climatic Driven Processes,” which is planned to be held July 4–7, 2005 (13). The purpose is to bring together researchers from different disciplines, including seismology, hydrology, ecology, geomorphology, and economics. A session on introduction of threshold concepts in these disciplines is also planned, an important focus of which is "learning each other's problems and language," a point also highlighted by Sivakumar (6) in his proposal of "thresholds" for its simplicity and generality. We will need to make continued efforts in this direction to be successful in solving the threshold "conundrum."

CONCLUDING REMARKS

Following up on a recent initiation for "thresholds" in hydrology (6), this article discussed their relevance, identification and quantification, and the importance of interdisciplinary research. The discussion points to the need for a new paradigm, or at least a major paradigm shift, for studying thresholds. As thresholds play crucial roles in future predictions and risk assessment, for both the whole system and its component parts, only a (new) coupled reductionistic-holistic approach seems appropriate. Formulation of such an approach, however, may benefit from existing theories and methods, particularly their integration. Interdisciplinary efforts would significantly help in these directions. Hope certainly exists with the availability and advancement of technology, communication facilities, and human resources.

GANGA RIVER, INDIA

Sharad K. Jain
National Institute of Hydrology
Roorkee, Uttranchal, India

The Himalayas, the great mountain chain of Asia are the source of three major river systems of the world, the Indus, the Ganga (or the Ganges), and the Brahmputra. The large and fertile plains of the Indus and Ganga in the subcontinent of Northern India have been the cradles of one of the greatest ancient civilization, the Indus Valley Civilization. The River Ganga which occupies nearly one-third of the geographical area of India is the most important and sacred river of India.

So legendary has been the socioeconomic, cultural, and religious saga of this great river that the Indian mythology and history are full of stories and incidents woven around the river and numerous pilgrim spots along its course like Rishikesh, Hardwar, Allahabad, Varanasi, and Patna.

DESCRIPTION OF GANGA BASIN

The catchment area of the Ganga falls in four countries, India, Nepal, Tibet (China), and Bangladesh. Many important tributaries of the Ganga originate in the Himalayas in India and Nepal; Bangladesh lies in the deltaic region. The total length of the river is 2525 km which makes it the fifteenth longest river in Asia and the thirtyninth longest in the world. The combined basin of the Ganga, Brahmaputra, and Meghna rivers in India, Nepal, and Bangladesh is also known by the name *Greater Ganga Basin*. The major part of the geographical area of Ganga Basin lies in India.

Though the headwaters region of the Ganga in the Himalayas is dotted by a number of mighty tributaries, the Bhagirathi river that rises from the Gangotri glacier near Gomukh at an elevation of about 7010 m above mean sea level is traditionally considered the source of River Ganga.

The other main stream that originates in the Uttranchal state of India is the Alakhnanda. Flowing downhill, Bhagirathi and Alakhnanda are joined by a number of streams such as the Mandakini, the Dhuli Ganga, and the Pindar. These two rivers (Bhagirathi and Alakhnanda) meet at a place called Devprayag and thereafter, the combined flow is known by the name Ganga. The River Ganga enters into plains at the pilgrimage center at Haridwar, and from there it flows in a south/southeasterly direction. Yamuna is the most important tributary of the Ganga that joins it on the right bank at Allahabad. The total length of the Yamuna from its origin to Allahabad is 1,376 km, and the drainage area is 366,223 sq. km. The Yamuna is a mighty river in itself and has a number of tributaries such as the Chambal, the Sind, the Betwa, the Ken, and the Tons. After confluence with Yamuna, the Ganga River flows east and is joined by a number of tributaries such as the Ramganga, the Gomti, the Ghaghra, the Gandak, the Bagmati, the Kosi, the Sone and the Damodar.

The Ganga delta is said to begin at a place known as Farakka where a barrage has been constructed to control river flow. At about 40 km downstream from Farakka, the river splits into two arms. The right arm called River Bhagirathi flows south and enters the Bay of Bengal about 150 km downstream from Calcutta. The left arm, known as Padma, turns east and enters Bangladesh. While flowing in Bangladesh, the Padma meets the River Brahmputra at a place known as Goalundo. The combined flow, still known as Padma, is joined by another mighty river Meghna at Chandpur, 105 km downstream from Goalundo. Further down, the river ultimately flows into the Bay of Bengal. The delta of the Greater Ganga Basin, one of the largest in the world, is known by the name Sunderbans.

For hydrologic studies, the entire stretch of the Ganga River in India can be divided into three stretches or reaches. The upper reach extends from the origin to Narora, the middle reach from Narora to Ballia, and the lower reach from Ballia to its delta.

An index map of the basin is given in Fig. 1.

HYDROLOGY OF THE GANGA BASIN

The Ganga Basin extends across an area of 1,086,000 sq. km. The drainage area of the basin lying in India is 861,452 sq. km, nearly 26.2% of the geographical area of the country and 79.32% of the Ganga Basin. Some tributaries such as the Ghagra, the Gandak, and the Kosi drain areas in Nepal amounting to 190,000 sq. km. The delta of the Greater Ganga Basin covers an area of 56,700 sq. km. The headwater reaches of the river receive a considerable part of the precipitation as snow, and some peaks are permanently snow covered. The average annual rainfall in the basin varies from 35 cm at the western end to nearly 200 cm near the delta.

The average annual discharge of the Ganga, the Brahmaputra, and the Meghna rivers is 16.65, 19.82, and 5.1 thousand m^3/s, respectively. The average annual flow of the Ganga at Farraka is about 525×10^9 m^3. There are large variations in the flow of the Ganga with time. Snow and glacier melt during the hot months (March to June) give large summer flows in Himalayan rivers such as the Ganga and its tributaries. The maximum discharge in these rivers is observed during monsoon months (June to September). At Goalundo, the average annual flow of the river is 11,470 m^3/s. The maximum and minimum flow at this site is 70,934 and 1161 m^3/s (1). The peak flow at Farakka in 1971 was estimated at 70,500 m^3/s.

The surface water resource potential of the Ganga and its tributaries in India has been assessed at 525×10^9 m^3 out of which 250×10^9 m^3 is considered useable NCIWRD (1). Based on the 1991 census, the per capita water availability was near 1471 m^3 per year. Though the Ganga Basin is bestowed with an abundant water resource, its occurrence/availability both in quantity and quality is not uniformly distributed either spatially or temporally. More than 75% of the annual rainfall occurs in the monsoon months of June to September. As a result, large areas are subjected to floods on one hand and droughts on the other.

The storage potential of the Ganga Basin in India has been identified at 84.46×10^9 m^3. However, till 1995, a total of only 36.8×10^9 m^3 of storage space was created. Water resources development schemes to create storage of 17.06×10^9 m^3 are under construction, and projects to provide another 29.56×10^9 m^3 of storage are in the pipeline. The total replenishable ground water resource of the Ganga Basin is estimated at 171.0×10^9 m^3, of which about 48.6×10^9 m^3 was being used by 1999. The River Ganga carries one of the world's highest sediment loads, equal to nearly 1451 million metric tons per annum.

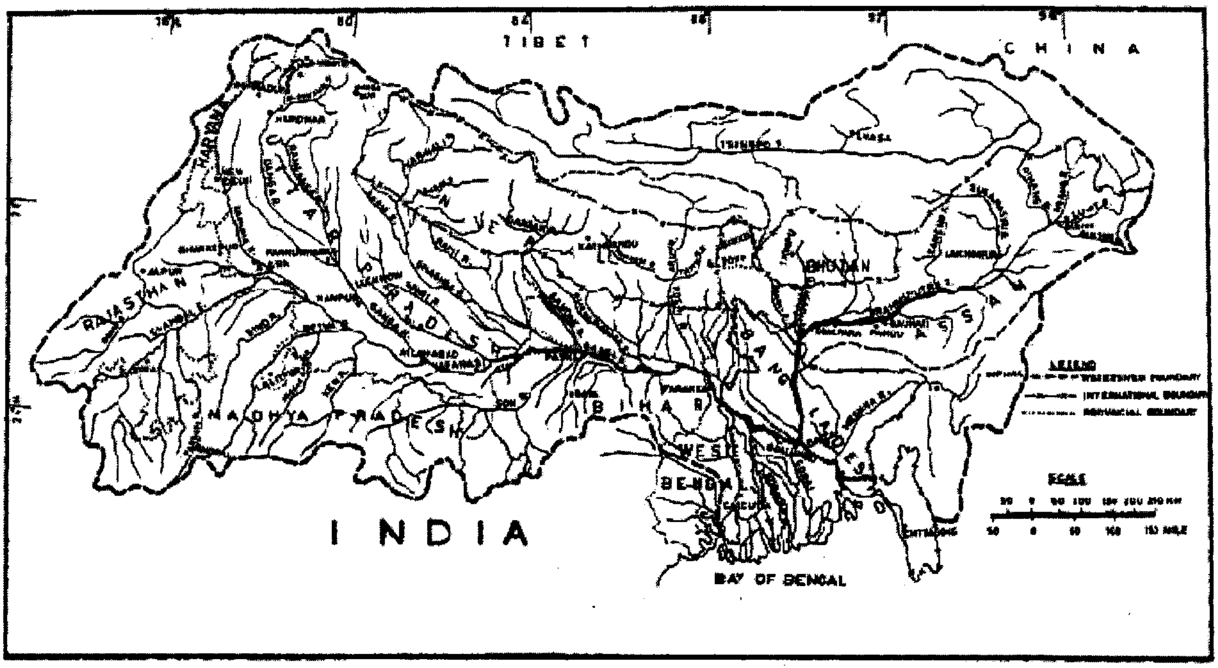

Figure 1. Index map of the Greater Ganga Basin (2).

The Ganga Basin is the largest basin in India, both catchmentwise and populationwise. The total population in the Basin per the 1991 census has been estimated at 356.8 million, which is 42% of India as a whole. The average population density in the Basin was 414 persons per sq. km as against 267 for all of India. Per the 1991 census, the Basin had 111 urban centers that had populations of more than 0.1 million, and of these, seven cities had populations exceeding a million.

The Ganga and its tributaries have formed a large flat and fertile plain in North India. The availability of abundant water resources, fertile soil, and a suitable climate have given rise to a highly developed agriculture-based civilization and one of the most densely populated regions of the world. The net sown area in the Ganga Basin in India is around 44 million hectares (M-ha), and the net irrigated area is 23.41 M-ha.

The hydroelectric potential of the Ganga Basin has been assessed as 10,715 MW at a 60% load factor. Of the 142 identified schemes in the Basin, 22 schemes that have a total installed capacity of 2437 MW are operating and 12 schemes whose installed capacity is about 2716 MW are in various stages of construction.

WATER RESOURCES DEVELOPMENT PROJECTS IN GANGA BASIN

The development of water resource projects in the Ganga Basin has a long history. One of the most remarkable of these works which includes many great civil engineering structures is the Upper Ganga Canal system whose construction was commenced by the then British government in the 1840s to ward off drought and famine in the western part of Uttar Pradesh state. Completed in 1854, the Upper Ganga Canal was to irrigate 0.7 million ha area. The canal takes off from the Ganga at Bhimgoda weir near Hardwar. The main canal is 230 km long and is one of the most exquisitely constructed structures. To expand the command area, the discharge capacity of the canal was recently augmented to nearly 297 m^3/s. The command area of the canal is about 0.924 million hectares.

The Madhya Ganga Canal takes off from Ganga at Raoli barrage near Bijnor. The capacity at the head of this 115 km long canal is 234 m^3/s. It is operated to provide irrigation to paddy crops in 114,000 hectares as well as to augment the supply to the Upper Ganga Canal system. The Lower Ganga Canal takes off from the Narora weir across the Ganga and was constructed in 1879. The main canal is 100 km long and irrigates 0.5 million ha. Near the Indo–Bangladesh border, a barrage has been constructed at Farakka to divert water to the river Hooghly to increase and maintain adequate depths of flow for navigation and operation of the Calcutta port.

The Yamuna river emerges from the hills near Tajewala where the water is taken off by the western and eastern Yamuna canals. It flows a further 280 km down to Okhla near Delhi from where the Agra Canal takes off. Chambal river is an important tributary of the Yamuna whose catchment area is 139,468 sq. km. Three important storages constructed in the basin include Gandhisagar, Jawahar sagar, and Rana Pratap Sagar cascade, which provide live storage of 8,500 million cubic m. The barrage at Kota diverts water into canals on either side that irrigate a 0.57 million ha agricultural area.

The Ramganga dam on the tributary of the same name has created a reservoir at Kalagarh that has a live storage capacity of 2,190 million m^3. A feeder channel takes off from the dam to provide extra supplies of water to the upper and lower Ganga canal and the Agra canal, besides direct irrigation. A 666,000 ha cropped area will be irrigated by this project. A system of reservoirs in the Damodar valley, Konar, Tilaiya, Tenughat, Maithon, and Panchet dam and Dugapur barrage have largely controlled floods in this subbasin. The Damodar Valley Corporation is responsible for the integrated regulation of most of these dams.

Some other important projects on the tributaries of the Ganga include Matatila on Betwa, Sarda sagar on the Sarda, Obra and Rihand on the Rihand river, and Mayurakshi on the Mayurakshi River. The Sarda canal provides protective irrigation to a nearly 0.6 million ha area. The Tehri dam on Bhagirathi (under construction) will provide live storage capacity of 2,613 million cubic m to be used for power generation and irrigation. Some other major projects under construction are Rajghat on the Betwa, Bansagar on the Sone, and Lakhwar-Vyasi on the Yamuna. A few projects are also being planned in collaboration with the government of Nepal. To boost the use of waterways, some segments of the Ganga River have been declared national waterways.

PROBLEMS IN WATER RESOURCE DEVELOPMENT OF THE GANGA BASIN

The basic problem in using water resources in the Ganga Basin is that in relation to the relatively large annual flow in the Basin, the storage capacity of existing and foreseeable reservoirs in India is not large enough to permit conservation of flows during the high flow season. The live storage capacity of all reservoirs in the Ganga Basin is less than one-sixth of the annual flow, which does not permit the desired degree of flow regulation. The majority of the good storage sites of the Basin are in Nepal, and this is leading to a delay in constructing dams. Lean season flows in the basin without adequate storage backup are not sufficient to meet the requirements for various demands. Besides, monsoon flows in the basin are so high that the Ganga and its tributaries remain in spate almost every year.

In the Ganga Basin, the flooding problem is confined mainly to the middle and terminal reaches. In general, the severity of the problem increases from west to east and from south to north. The worst flood-affected states in the Ganga Basin are Uttar Pradesh, Bihar, and West Bengal. In Uttar Pradesh, flooding is largely confined to the eastern districts; the rivers that cause flooding include the Sarada, the Ghagra, the Rapti, and the Gandak. The major causes of flooding here are drainage congestion and bank erosion. North Bihar is in the grip of floods almost every year due to spillage of rivers. In West Bengal, floods are caused by drainage problems as well as tidal effects. The Ganga

Flood Control Commission was set up by the government of India for flood management in the Ganga Basin.

WATER QUALITY CONSIDERATIONS

The numerous cities located in the Ganga Basin generate and discharge huge quantities of wastewater; a large portion eventually reaches the river through the natural drainage system. Industrial complexes which have sprung up along the rivers also dump considerable pollution loads into the river. Over the years, the Ganga and its tributaries have become the channels of transport of industrial effluents and the drains for the wastewater of cities. It is estimated that some 900 million liters of sewage is dumped into the Ganga every day; three-fourths of the pollution in the Ganga is from untreated municipal sewage. In particular, the middle reach of the basin between Kanpur and Buxar is the most urbanized and industrialized and also the most polluted segment of the Basin. Municipal and industrial wastes in dangerous concentrations enter the watercourse in this segment and pose a grave threat. Murti et al. (3) repeat results of a detailed study on Ganga River.

The pollution load dumped in the river by humans is a serious health hazard to the dense population of the Basin. Recognizing the magnitude of this problem and realizing the importance of water quality as a cardinal element of river management, the government of India started the planning and execution of several programs to check the pollution of the River Ganga and its tributaries. An ambitious program, known as the Ganga Action Plan (GAP), was initiated in 1985. Pollution abatement works for the River Ganga had been taken up in 25 class I towns (population above 1,00,000) along the main River Ganga under the three basin states of Uttar Pradesh, Bihar, and West Bengal. The main objectives of the GAP were

1. reduction of the pollution load on the river and improving the water quality as a result thereof, and
2. establishment of domestic/municipal wastewater treatment systems emphasizing resource recovery to make such systems self-sustainable as far as possible.

In addition, GAP was to serve as a model to demonstrate the methodology of improving the water quality of the other polluted rivers and waterbodies of the country to their designated best use class. A multipronged approach was adopted to achieve the objectives of the GAP. Similar other plans are in various stages of implementation in some tributaries of the Ganga.

The task of restoring the Ganga to its pristine glory will not be easy. Nevertheless, it will be worth the trouble because the sustainable development of a large geographical area and population crucially depends on it.

INTERCEPTION

Hubert H.G. Savenije
Delft University of Technology
The Netherlands

Interception is a key process in hydrology that is receiving relatively little attention. It is the first process of the hydrological cycle that a raindrop experiences after falling from the sky, and hence, all subsequent processes depend on it. Neglect of the interception process can lead to serious modeling mistakes. Interception is defined as the evaporative process that feeds moisture back to the atmosphere shortly after the rainfall has ceased (within approximately 1 day). It is the evaporation from all surfaces that have been moistened by precipitation, including leaves, soil, mulch, rock, paved, and build-up surfaces. Evaporation from interception can amount to a considerable part of all terrestrial evaporation, depending on the climate and region. The interception process behaves differently at different time scales. Formulas are presented for the computation of interception at short, daily, and monthly time scales.

INTRODUCTION

To hydrologists who focus on the terrestrial part of the hydrological cycle, precipitation is generally seen as the starting point of the water cycle. Although one could start with any other point in the cycle as well, e.g., advection of moisture to the land or evaporation from the oceans, it is common to begin the terrestrial water cycle with the rainfall, probably because rainfall is more easily measurable than are other incoming fluxes. This cycle involves many interconnected processes (fluxes), separation points, feedback loops, and stocks where the water resides over longer or shorter periods of time. Starting from the rainfall, the first process that comes into view is interception. It retains the water before it can continue its path in the water cycle, and it allows for a direct feedback loop to the atmosphere. Depending on the precise definition of this process, interception can be understood to mean different things.

First, it is important to decide whether we consider interception as a stock or a flux, or as the combination of both. If we consider it a stock, then it is the amount of rainfall that can be temporarily stored on the land (with its natural and manmade cover) to be evaporated shortly after (or during) the rainfall event. Here, we actually mean the interception capacity. If we consider interception as a flux, then it is the evaporation from intercepted water, which we express in millimeters per unit of time. If we consider interception as an integrated process, then it is the sum of the rate of change of intercepted water and its evaporation:

$$I = \frac{dS_I}{dt} + E_I \qquad (1)$$

where I is the interception process (mm/d), S_I is the interception storage (mm), and E_I is the evaporation from interception (mm/d). The interception I is the part of the rainfall that is intercepted and, after a short period of time, turns into the evaporative flux E_I. For a time scale in the order of 1 day, it is safe to assume that $I = E_I$.

Next, it is important to define the location of the interception process in the hydrological cycle. The most logical place is between the atmosphere and the first separation point where the rainfall splits into interception, surface runoff, and infiltration (see Fig. 1). The interception stock (S_I) is located at the first separation point. In this definition, the interception process includes evaporation from wet leaves, wet land cover (included manmade structures and roads), wet mulch, wet forest floor, and even wet soil. In short, it is the fast evaporation mechanism that dries moist land cover during and directly after the rain.

A more narrow definition of interception, often used, is the difference between rainfall and "throughfall," the rain that falls through the leaves of, e.g., a tree. In this definition, interception is merely the amount of water retained by the leaves of a tree. This definition is not workable for hydrologists because it leaves evaporation from land surface not catered for. Hydrologists who do use this definition, however, combine wet surface evaporation with all other evaporative fluxes and call it evapotranspiration, which is not really a process, but rather a combination of different evaporation processes with different time scales and characteristics (1).

The total evaporation E in a catchment is the sum of several different processes: interception I, transpiration T, surface evaporation E_s, and open water evaporation E_o (2). In the broader definition of interception, we combine evaporation from leaf interception with wet surface evaporation occurring on the same day as the rainfall. The amount of interception thus defined is larger than the amounts quoted in the literature based on the difference between rainfall and throughfall.

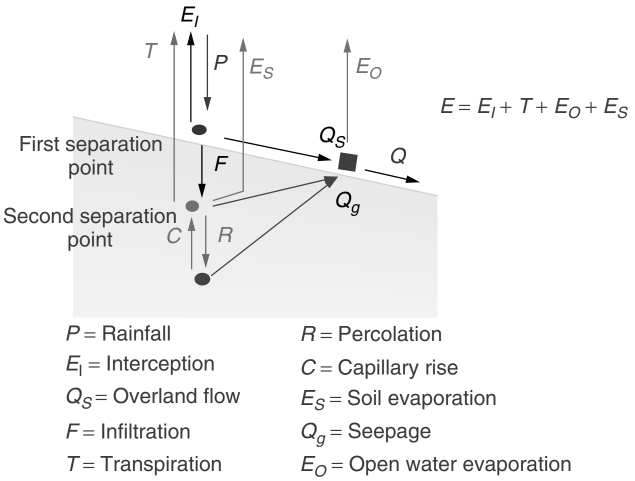

Figure 1. Separation points at the landscape interface.

THE IMPORTANCE OF INTERCEPTION

Interception is one of the most underrated, and underestimated, processes in rainfall–runoff analysis. One could call interception the "Cinderella of Hydrology." She may be beautiful and rather straightforward but apparently not interesting enough to be adequately represented in hydrological models. Some models even disregard interception completely [particularly event-based models, based on the simplified catchment model of Dooge (3, 4)], the argument being that it is generally a small proportion of the total evaporation. This disregard is a mistake, for several reasons.

First, the amount of interception is not small. Beven (5) states that evaporation from intercepted water on leaf surfaces in rough canopies can be efficient and a significant component of the total water balance in some environments. Calder (6) shows that in the upland forest catchments of Britain, evaporation from interception amounts to 35% in areas with an annual rainfall of more than 1000 mm/a, but that it is higher in areas with lower rainfall, amounting to about 40–50% in areas with 500–600 mm/a. In Calder's definition, however, interception is merely the difference between rainfall and throughfall. But if we use the broader definition presented above, interception is considerably larger. After a rainfall event, not only the leaves of vegetation are wet, but also the surface underneath (rock, soil, mulch layer, roads, build-up area, etc.), which becomes dry within the same day, particularly in warm climates. Moreover, many stagnant pools continue to evaporate until a day after the event. The additional wet surface evaporation can be as much as the interception by leaves, particularly in dry climates. These interception processes are fast, having an average residence time in the order of 1 day.

Note that the wetted soil surface should not be considered part of the soil moisture that feeds the transpiration process. The wet surface (extending to several millimetres of soil depth) feeds back the intercepted water through direct evaporation and not via a delayed transpiration process. Even a stretch of dry sand, without vegetation, can intercept water. After a rainfall event, a wet "crust" of soil is formed, underlain by dry sand, which dries out again within a day. This soil can intercept several millimeters of rainfall.

Transpiration is different. First, it is a physiological process intimately tied to CO_2 assimilation. The time scale of transpiration is determined by the soil moisture stock, which makes the time scale of the process much longer (average residence times varying between weeks and months depending on the soil depth). Finally, the process of transpiration does not change the isotope composition of the evaporated moisture, whereas evaporation of a water surface does. One can distinguish fast transpiration and delayed transpiration. Fast transpiration is from shallow rooted plants (typically grass and annual crops) with a time scale of less than a month; delayed transpiration is from deeply rooted plants (trees, shrubs, perennial crops), which have a time scale longer than a month. Fast transpiration only draws on the upper soil layer (until 50 cm depth), whereas delayed transpiration draws on deeper soil layers. Open water evaporation can be considered separately, when necessary, and is identifiable relatively simply.

DETERMINING EVAPORATION FROM INTERCEPTION

Computation of interception on an instantaneous basis is done by a Rutter model (7), based on Equation 1. For practical purposes, however, and in view of the typical time scale of the process where wetness caused by a rainfall event evaporates within a time span of a day, interception is well captured on a daily time scale. The daily process of interception is conveniently described as a threshold process, with a daily threshold D (mm/d). Daily interception (mm/d) is then computed as

$$I = \min(P,D) \tag{2}$$

which implies that if the rainfall is less than the threshold, the interception is equal to the rainfall and otherwise it is equal to the threshold value.

Monthly evaporation from interception can be determined efficiently, even for poorly gauged catchments through De Groen's method. De Groen (8) developed an analytical model for the computation of monthly interception based on the Markov property of daily rainfall[1] and using a daily interception capacity D.

$$I_m = P_m\left(1 - \exp\left(-\frac{n_r D}{P_m}\right)\right) \tag{3}$$

where I_m is the monthly evaporation from interception (mm/month), P_m is the monthly rainfall (mm/month), and n_r is the number of raindays per month (d/month). She demonstrated that, as a result of the Markov property of daily rainfall, the number of raindays in a month is a function of the monthly rainfall.

$$n_r = \frac{30p_{01}}{1 - p_{11} + p_{01}} \tag{4}$$

where p_{01} is the probability of a rainday after a dry day and p_{11} is the probability of a rainday after a rainday. These probabilities appear to be power functions of monthly rainfall. These power functions can be derived from time series analysis of selected raingauges with daily observations. De Groen (9) demonstrated that the coefficients of the power functions are representative for larger areas and can be interpolated between rainfall stations, similar to the regional distribution of monthly rainfall, which is surprising, because daily rainfall is known to have a very small spatial correlation (a few kilometer), but apparently the Markov property has a high one, of the same order of magnitude as monthly rainfall (100–1000 km).

Figure 2 shows the relative contributions of monthly interception (I) and transpiration (T) to total evaporation (E) in the Mupfure catchment. The Mupfure river, at Beatrice in Zimbabwe, drains a small catchment of 1215 km^2. It has an annual rainfall of about 800 mm/year. There is no substantial open water. The plots are based on monthly values over the period 1970–1979. The monthly interception has been computed by De Groen's formula with a threshold value of 4 mm/day. This threshold, may seem large but it caters to more than the difference between rainfall and throughfall (including wet surface evaporation) and there is generally more than one rainfall event per day, each of which contributes to evaporation from interception. Pitman (10) argues that interception in Southern Africa can be as much as 8 mm/day in forests. De Groen (8) considers 2–5 mm/day appropriate, depending on the land use, but the true value is not exactly known. The use of a higher or lower value of D changes the partitioning between I and T. The transpiration is computed as the difference between the interception and the total evaporation, which was determined on the basis of a monthly water balance. As a result, Fig. 2 gives an impression of how interception and transpiration relate and their order of magnitude, for different amounts of monthly rainfall.

As an aside, in Fig. 2, one can distinguish scatter dots and dots that appear to follow a pattern (the drawn lines). The scatter dots that occur in the low rainfall months are the result of transpiration from soil moisture stocks built-up during the wet season, which are accessed by deeply rooted vegetation. The scatter dots in the months with high rainfall are caused by limited solar radiation constraining evaporation. The drawn curves represent the contributions of interception and transpiration to the fast evaporation, occurring within 1 month, i.e., interception and fast transpiration.

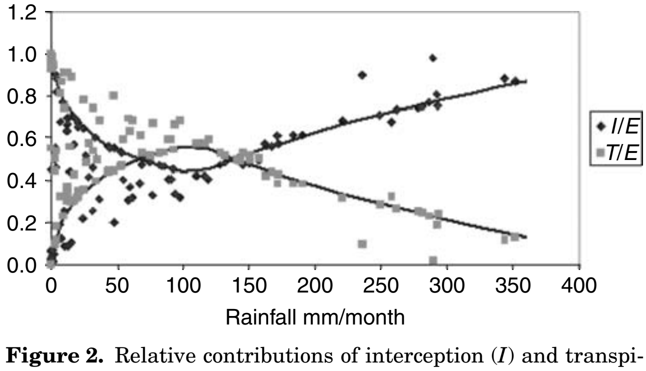

Figure 2. Relative contributions of interception (I) and transpiration (T) to monthly evaporation (E) in the Mupfure catchment in Zimbabwe, with $D_d = 4$ mm/day.

---

[1] The Markov property implies that the probability that a certain day is a rainday depends purely on whether the previous day was a wet or a dry day.

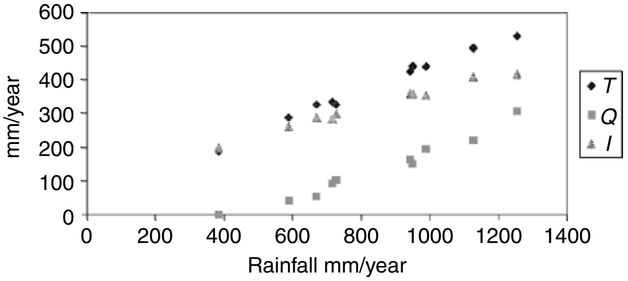

Figure 3. Annual rainfall partitioning into runoff (Q), interception (I), and transpiration (T), Mupfure basin at Beatrice, with $D_d = 4$ mm/day.

It can be seen that, overall in the Mupfure catchment, evaporation from interception is as significant as transpiration, and that in the wet months, transpiration is dominated by fast transpiration (the drawn curve), as there is no moisture deficit and the soil moisture stock is being replenished. More importantly, interception is dominant in wet months. Fig. 3 shows the annual partitioning of rainfall into transpiration (T), runoff (Q), and interception (I), indicating that interception comprises a considerable amount of the annual rainfall, with a tendency for interception to dominate in very dry years.

Besides interception forming a considerable part of monthly evaporation, it is crucial for determining antecedent conditions in rainfall–runoff modeling. It is often said that during storm events, evaporation from interception is negligible as compared with other fluxes. This may be true during the event, which is of short duration, but it is untrue in relation to the build-up of the antecedent conditions. It is widely recognized that the success of event-based modeling depends to a large extent on the antecedent conditions, particularly the distribution of the soil moisture in the unsaturated soil. If we want to get that right, it is important to split the rainfall into the effective part that contributes to soil moisture (and hence the rainfall–runoff process) and the ineffective part that does not, i.e., interception.

Finally, evaporation from interception is the most important process in moisture recycling to support continental rainfall. Figure 2 illustrates this. It shows that in months with high rainfall (i.e., the wet season), interception is an important mechanism. In dry months, transpiration is often dominant, but in these months (typically after the wet season), there are hardly any rainfall generating mechanisms to benefit from this feedback. Shuttleworth (2) observed that half the evaporation from interception occurs during the storm, which provides instant moisture feedback. Hence the moisture feedback to the atmosphere, which is such an important mechanism to support continental rainfall in the Sahel, and the Amazon (11,12), relies primarily on interception. The reason why transpiration is relatively small in wet months is because part of the energy available for evaporation is consumed by the interception process, which precedes transpiration, and because solar radiation is inhibited by clouds in wet months.

CONSEQUENCES OF UNDERESTIMATING INTERCEPTION

The picture of the Mupfure basin may not be representative for other climatic regions, but it serves to make a point. Interception is an important mechanism that cannot be simply neglected or lumped with other evaporation mechanisms. Disregarding or underestimating interception can lead to serious modeling mistakes, particularly when one uses automated calibration techniques. If interception is modeled incorrectly, the error will be compensated by other parameters, to satisfy the goodness-of-fit criterion. If a range of interception thresholds is tested, then one may find a correlation between interception and other soil and groundwater parameters. Clearly such relations are spurious.

The most common mistake of lumping interception with transpiration leads to an overdimensioning of the soil moisture stock, which can be seen easily. If the interception is forced through the transpiration process, a correct representation of the total flux and time scale in the model can only be achieved if the soil moisture stock is overdimensioned. If transpiration and interception are of the same order of magnitude, then the modeled soil moisture stock should be double its "real" value.

KINEMATIC SHOCK

Vijay P. Singh
Louisiana State University
Baton Rouge, Louisiana

Kinematic shocks form due to a variety of factors, including spatial and temporal variability of inflow, systems geometry, and initial and boundary conditions. This study provides a short overview of the formation, propagation, tracing, and fitting of shocks in hydrologic modeling, in particular, referring to rainfall–runoff modeling.

INTRODUCTION

The kinematic shock is a discontinuity representing a sudden rise or surge in flow depth. For example, flood waves have an intrinsic tendency to steepen as they propagate downstream due to lateral inflow or geometric constriction and eventually form a shock. The discontinuity can also represent a sudden decrease in flow depth. For example, when flow advances over a porous bed, there comes a time when the flow rate is not sufficient to satisfy the infiltrating demand of the bed and is, therefore, suddenly absorbed by the bed. This phenomenon is observed in ephemeral streams and irrigation borders and furrows. Discontinuities in flow are also observed in geologic formations due to fracture, fissures, and sudden changes in porous media properties. Shocks are also observed in landscape evolution and formation of deltas, river bed profiles, and river junctions.

Documented evidence of the occurrence of shocks is hard to find, but shocks have been observed in numerical solutions (1). Shocks lead to physically unrealistic multiple-valued and nonconvergent solutions (2). Therefore, proper consideration of shocks in hydrologic and hydraulic modeling is needed. There are four aspects of shocks that need consideration: (1) formation, (2) propagation, (3) tracing of the shock path, and (4) shock fitting. From a numerical standpoint, two main issues need to be addressed: (1) the physical relevance of kinematic shocks and (2) the adequacy of numerical schemes in the presence of shocks. In many kinematic cascade models, numerical schemes, such as the Lax–Wendroff scheme, do not exhibit multiple-valued solutions, and therefore, the presence of shocks goes unnoticed. This may partly be due to smoothing out of shocks by the numerical schemes. For many engineering problems, this may be acceptable if shocks are small and of short duration. However, these schemes may yield unrealistic or undesirable multiple hydrographs. Then, kinematic shocks warrant proper consideration.

SHOCK FORMATION

A range of factors leads to shock formation. These factors can be classified into three groups. In the first group are initial and boundary conditions. Lateral inflow and outflow form the second group. System geometric characteristics, such as surface roughness, geometric shape, and surface slope, are in the third group. It is, however, difficult to single out the contribution of each individual factor. Ponce and Windingland (3) attempted to determine flow and channel characteristics that either tend to promote or inhibit development of a kinematic shock. The flow and channel characteristics considered by them were the inflow hydrograph peak, the Froude number, the time to peak, the base-to-peak-flow ratio, the kinematic roughness parameter, and the kinematic exponent. The inflow hydrograph was represented by a gamma distribution. Of all the parameters, the size of the wave was the most important in the occurrence or nonoccurrence of the shock. They concluded that a kinematic shock is most likely to occur when there are a low base-to-peak-flow ratio, a high Froude number, and a wide and sufficiently long channel. A flood wave traveling in a steep, initially dry channel would be a potential candidate for shock formation.

ORDER OF DISCONTINUITY

Two kinds of discontinuities occur in hydrology. A discontinuity of the first kind (or first order) represents a sudden, finite change in flow depth. In that case, the differential equation of continuity no longer applies. The partial derivatives cease to be defined so that some additional condition is needed. This condition may be derived using the theory of weak solutions replacing the differential equation by an integral equation or by multiplying the conservation of mass to a frame comprising the shock (4). Both methods yield the same result in the form of a jump condition. According to the second method, the differential continuity equation is replaced by an equation stating that the flow into one side of the shock equals the flow out on the other side. Mathematically, this can be expressed as

$$U = \frac{Q_2 - Q_1}{h_2 - h_1} = \frac{\Delta Q}{\Delta h} \tag{1}$$

where subscripts 1 and 2 denote the variables calculated in front of and behind the moving shock, U is the shock velocity which must be between the characteristic velocities on either side of the shock (5), h is the flow depth, and Q is the flow discharge.

A discontinuity of the second kind (or second order) is a small change in flow depth h. If $h_2 - h_1 = dh$ is small, the expression for U reduces to

$$U = \frac{dQ}{dh} = c(h) \tag{2}$$

where c is the velocity of the discontinuity between flow depths h and $h + dh$. A small change in flow depth, dh, if maintained, is propagated through a flow depth h at velocity U. A line of constant depth in the $x - t$ diagram, therefore, describes the motion of the boundary between flows of depth h and $h + dh$, such that its slope is necessarily equal to the flow wave celerity, c.

For flows where the depth (h) increases downstream, the condition for forming a discontinuity of the first kind can be expressed in the following equivalent terms: (1) The lines of constant depth in the x–t diagram, if continued away from the t axis or x axis, would intersect; (2) the wave celerity, c, increases with depth of flow; and (3) the $Q - h$ curve is concave to the h axis. If these conditions are not satisfied, a first-order discontinuity is not formed. This can be illustrated in terms of second-order discontinuity. If c increases with h, small depth changes in higher flow regions upstream will move faster downstream than those in lower order flow regions and overtake them. This means that the depth gradient increases until a first-order discontinuity is formed. If c decreases with h, the reverse takes place; the depth gradient decreases, and any discontinuity is dispersed.

Three types of first-order shocks can be identified. To that end, we consider an x–t diagram which has two types of characteristics: A and B, as shown in Fig. 1. The A characteristics originate from the x axis and therefore depend on the initial condition. The B characteristics originate from the t axis and therefore depend on the boundary condition. These two types of characteristics are separated by a bounding or limiting characteristic that originates from the origin. The first kind of shock (or discontinuity) forms when two A characteristics intersect. This kind of shock does not occur in overland flow on an initially dry plane where effective rainfall depends only on time. The second kind of shock is designated as mixed shock and is formed by the intersection of one A characteristic and one B characteristic. Clearly, the limiting characteristic plays a major role in this case. The third kind of shock is boundary dependent and forms when two characteristics intersect.

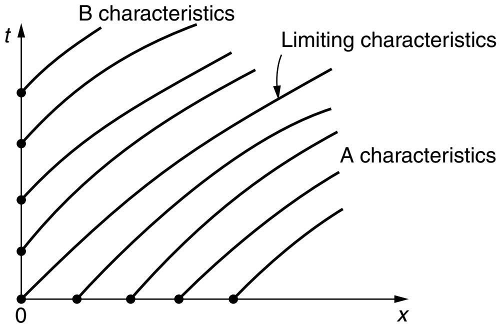

Figure 1. Characteristics of a plane in the (x, t) space.

It may be interesting to consider some possible cases of boundary-dependent shock formation. When rainfall increases with time and c increases with h, a shock will be formed by the intersection of the B characteristics, as shown in Fig. 2a. This can be prevented only by stopping it at the discontinuity. The shock is small and is fed by the characteristics running into it. Another example is when the initial region of varying h is small and there is effectively an initial discontinuity that is propagated along the line of discontinuity, as shown in Fig. 2b. Again, the discontinuity is small and is fed by lines running into it.

Another case is a sudden rise in rainfall at a given time within a small region of rapid change. A shock is

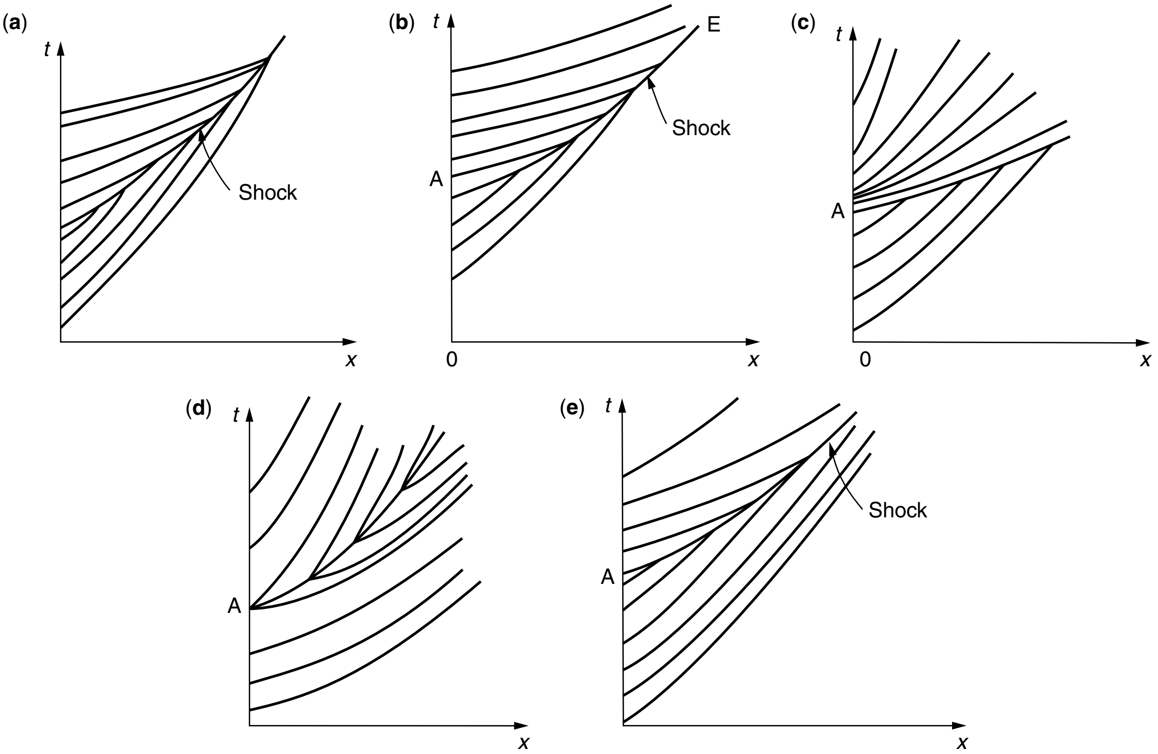

Figure 2. (**a**) Rainfall increases continuously with t; (**b**) rainfall increases over a short time; (**c**) rainfall suddenly increases at A in the limit; (**d**) rainfall increases, but without limit; and (**e**) rainfall increases to a limit and then decreases.

formed and occupies a region. It is fed by characteristics running into its lower boundary, as shown in Fig. 2c. This assumption is waived in Fig. 2d. Still another case occurs when rainfall increases to a limit and then decreases. In this case also, the shock occupies a region, as shown in Fig. 2e.

SHOCKS IN PLANAR FLOWS

For constant effective rainfall, r, the B characteristics are given by (6)

$$h(t, t_0) = h_1(t_0) + r(t - t_0) \tag{3}$$

$$x(t, t_0) = \frac{\alpha}{r}[h_1(t_0) + r(t - t_0)]^n - \frac{\alpha}{r}h_1^n(t_0) \tag{4}$$

where $t_0 (0 \leq t_0 \leq \infty)$ is the time when a B characteristic intersects the t axis, h_1 is the flow depth at the boundary $x = 0, n$ is the kinematic flow exponent, and α is the kinematic roughness coefficient. A shock may occur if $\partial x(t, t_0)/\partial t_0 > 0$, and the derivative can be obtained by differentiating Eq. 4. The region of intersecting characteristics can be obtained by taking the derivative of Eq. 4 with respect to t_0 and equating them to zero. Then, these two derivative equations can be solved to yield the coordinates of points on the characteristic envelope. The smallest values of these coordinates define the first point in the region of B characteristics where the formation of the kinematic shock is initiated, as shown in Fig. 3.

SHOCKS IN A KINEMATIC CASCADE

The mathematical properties of a kinematic cascade were investigated by Kibler and Woolhiser (1,7). A cascade is a representation of a watershed or a portion thereof by a series of planes discharging into a channel. Thus, the outflow of one plane forms the upper boundary condition of flow for the next. They developed a criterion, based on the properties of adjacent flow-plane pairs, to predict when a shock occurs in a cascade. They modified their Lax–Wendroff solution by placing instantaneous jumps in the output hydrograph corresponding to the arrival of shocks. They found that the Lax–Wendroff scheme effectively smoothed out shocks but was adequate when corrected for known shocks for solving the kinematic cascade. Schmid (8) derived a generalized shock formation criterion for infiltrating cascades that also encompasses the cascades with time-dependent rates of effective rainfall. On an infiltrating surface, the time to ponding marks the onset of overland flow. Ponding time can be computed by using the hydraulic properties of soils, and it strongly influences shock formation. For an infiltrating cascade, the ratio of respective ponding times of two adjacent, infiltrating planes is of major importance.

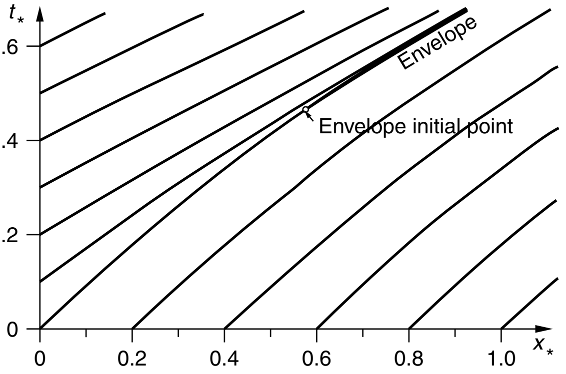

Figure 3. Intersection of characteristics in the (x, t) plane.

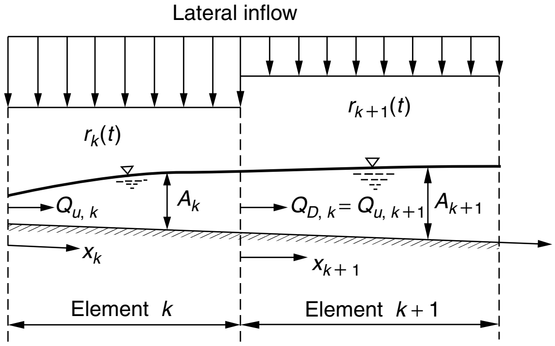

Figure 4. Two geometric elements in series, each has spatially uniform lateral inflow and topographic characteristics.

In a kinematic cascade, the criterion for shock formation is when the time to ponding of the upper plane is less than the time to ponding of the lower plane. If a cascade has two planes and overland flow starts on the upper plane rather than on the lower plane, a shock will form as soon as the rate of effective rainfall on the upper plane becomes nonzero, as shown in Fig. 4. Shocks can also occur when the time to ponding on the upper plane is greater than that on the lower plane (6).

SHOCKS ON CURVED SURFACES

A curved surface, where the slope continuously varies, can be considered a generalization of the kinematic cascade. Harsine and Parlange (9) dealt with kinematic shocks on curved surfaces. If the kinematic roughness coefficient varies in space or is a function of x, then one condition for the shock to occur is when $d\alpha_0/dx_0$ is a maximum. When $x = x_0$, the points where the B characteristics originate from the x axis, at that point α is α_0. Similarly, the effect of spatial variations on other surface geometric features can be derived.

SHOCK FITTING

Due to the spatial and temporal variability of rainfall and watershed characteristics, innumerable shocks may develop when the kinematic wave theory is applied to rainfall–runoff modeling, flow through unsaturated media, flow over porous beds, and dam break modeling. Because shock formation is intrinsic to the theory, approximate methods of shock fitting have been developed and are employed. In general, shock fitting entails (1) determining the characteristics intersecting each other on the shock path, (2) locating the points of intersection or determining the shock path, and (3) shock fitting.

It is assumed that a shock or discontinuity in h occurs first at the initial point on the characteristic envelope, and then the location of this moving shock is traced in the $x-t$ plane as the solution of the kinematic wave equations is generated. Across this discontinuity, however, the differential form of the continuity equation does not hold, but a control-volume form of this equation does, which leads to Eq. 1. In this equation, discharge is expressed by the kinematic depth–discharge relation. Thus,

$$\frac{dx_s}{dt} = \alpha \frac{h_2^n - h_1^n}{h_2 - h_1} \tag{5}$$

where x is the x coordinate of the discontinuity. The path of this moving shock in the x–t plane results from the solution of Eq. 5:

$$x_s(t) = x_0 + \alpha \int_{t_0}^{t} \frac{h_2^n - h_1^n}{h_2 - h_1} \tag{6}$$

where (x_0, t_0) are the coordinates of the initial point on the envelope. An iterative numerical solution of Eq. 6 is straightforward.

Borah et al. (10) developed an approximate procedure for shock fitting in unsteady-state flow routing. This method avoids finding the exact location of the shock origin by discretizing the upstream hydrograph, and it preserves the effect of shocks by routing them as they appear. It permits the use of the same numerical scheme to route both characteristic and shock waves. The procedure is particularly efficient when the initial condition represents a dry or uniform flow condition and only the outflow hydrograph is desired.

KINEMATIC WAVE METHOD FOR STORM DRAINAGE DESIGN

TOMMY S.W. WONG
Nanyang Technological University
Singapore

INTRODUCTION

Ever since Lighthill and Whitham showed that the main body of a natural flood wave moves as a kinematic wave, there has been continual interest in applying the kinematic wave theory to drainage design. A drainage design method based on the kinematic wave theory has several inherent advantages: physically based parameters, facility for hydrograph prediction, and feasibility of obtaining analytical solutions for certain idealized basin and channel conditions. In this article, based on the theory, a drainage design method is developed for estimating the design discharge for a series of overland planes and for a V-shaped basin.

APPLICABILITY OF KINEMATIC WAVE THEORY

The applicability of the kinematic wave theory to overland and open channel flow of with sufficient accuracy compared to the solution from the Saint-Venant equations has been investigated by several researchers (1–3). For overland flow, the applicability of the theory can be defined by the Morris and Woolhiser (13) criterion,

$$kF_o \geq 5 \tag{1}$$

where k is the kinematic flow number and F_o is the Froude number at the end of the plane at equilibrium. The parameter kF_o can be related to the physical characteristics of an overland plane and the rainfall intensity as follows (4, p. 66):

$$kF_o = 8586 \frac{S_o^{1.3} L_o^{0.4}}{n_o^{0.6} i_n^{0.6}} \tag{2}$$

where S_o is the slope of the overland plane, L_o is the length of the overland plane, n_o is Manning's roughness coefficient of a plane surface, and i_n is the net rainfall intensity. The units are m m^{-1} for S_o, m for L_o, and mm h^{-1} for i_n.

For open channel flow, the applicability of the theory can be defined by the Ponce et al. (2) criterion,

$$\tau = \frac{TS_c u_c}{y_c} > 83 \tag{3}$$

where τ is the dimensionless wave period, T is the wave period that can be taken as twice the time-of-rise of the flood wave (5), S_c is the channel bed slope, u_c is the steady-state, uniform, channel flow mean velocity, and y_c is the steady-state uniform flow depth in the channel. The units are s for T, m m^{-1} for S_c, m s^{-1} for u_c and m for y_c. As a rule of thumb, the American Society of Civil Engineers (6, p. 58; 7, p. 87) simplified the criterion to

$$S_c > 0.002 \tag{4}$$

In general, the theory is applicable to overland flow and most open channel flow where the backwater effect is not significant (8, p. 42).

RAINFALL INTENSITY–DURATION RELATIONSHIP

To estimate the design discharge of a desired recurrence interval, the rainfall intensity–duration curve of the same recurrence interval is used. Analyses of the total rainfall curves show that, for a given recurrence interval, the rainfall intensity varies inversely with the rainfall duration and can be mathematically described by (9; 10, p. 71)

$$i = a/(c + t_r)^b \tag{5}$$

where i is the rainfall intensity, t_r is the rainfall duration; and a, b, and c are constants. To facilitate the derivation of an explicit expression for design discharge, Eq. 5 is reduced to (11, p. 20)

$$i = a{t_r}^{-b} \tag{6}$$

Using Eq. 6 with a single set of a and b values cannot fit the entire rainfall intensity-duration curve, but Chen and Evans (12) showed that by dividing the rainfall curve into segments, it is possible to fit the entire rainfall curve using different values of a and b for each segment.

Further, the effect of abstraction losses such as initial and infiltration losses can be incorporated into Equation 6 by substituting the net intensity, i_n, for rainfall intensity, i, and the net duration, t_n, for rainfall duration, t_r:

$$i_n = a_n {t_n}^{-b_n} \tag{7}$$

where a_n and b_n are constant within one segment of the rainfall curve but vary from segment to segment. The relationship between the net intensity, i_n, the rainfall intensity, i, and the rate of infiltration, f, is

$$i_n = i - f \tag{8}$$

and the relationship between the net duration, t_n, the duration, t_r, and the initial loss, I, is

$$t_n = t_r - \left(\frac{60I}{i}\right) \tag{9}$$

The units for Eqs. 6–11 are mm h^{-1} for i, i_n, and f; min for t_r and t_n; and mm for I. Typical values of initial loss and uniform infiltration rates for various surface types are reported by Stephenson and Meadows (4, p. 57).

TIME OF CONCENTRATION FOR A SERIES OF PLANES

Based on the kinematic wave theory, Wong (13) showed that the time of concentration, t_o, for a series of planes, is

$$t_o = \sum_{j=1}^{N} 7L_{oj} \times \left(\frac{n_{oj}}{\sqrt{S_{oj}}}\right)^{3/5} \left\{ \frac{\left[\sum_{r=1}^{j}(i_{nr}L_{or})\right]^{3/5} - \left[\sum_{r=1}^{j-1}(i_{nr}L_{or})\right]^{3/5}}{\sum_{r=1}^{j}(i_{nr}L_{or}) - \sum_{r=1}^{j-1}(i_{nr}L_{or})} \right\} \tag{10}$$

where N is the number of planes, j is the jth plane under consideration in the direction of flow for calculating the time of concentration, and r is the rth plane under consideration in the direction of flow for calculating the equilibrium inflow and outflow of the jth plane. The units are min for t_o, m for L_o, m m^{-1} for S_o, and mm h^{-1} for i_n. Equation 10 is applicable to a series of planes in which each plane has uniform slope and roughness, is subject to uniform net rainfall intensity, and has a turbulent or nearly turbulent flow regime. Within this condition, it can be applied to a cascade of planes, to planes of different roughness, to planes of different soil types resulting in different net intensities, to planes subject to different rainfall intensities, and to planes that combine all these variables. In the application of Eq. 10, the values of n_o may be selected from the recommended values of Engman (14), the Institution of Engineers, Australia (15, p. 300), or the American Society of Civil Engineers and Water Environment Federation (10, p. 88).

If the net intensity is the same for all planes, Eq. 10 reduces to

$$t_o = \sum_{j=1}^{N} \frac{7}{{i_n}^{2/5}} \left(\frac{n_{oj}}{\sqrt{S_{oj}}}\right)^{3/5} \left[\left(\sum_{r=1}^{j} L_{or}\right)^{3/5} - \left(\sum_{r=1}^{j-1} L_{or}\right)^{3/5} \right] \tag{11}$$

If there is only one plane, both Eqs. 10 and 11 reduce to (1)

$$t_o = \frac{7}{{i_n}^{2/5}} \left(\frac{n_o L_o}{\sqrt{S_o}}\right)^{3/5} \tag{12}$$

DESIGN DISCHARGE FOR A SERIES OF PLANES

For a homogenous, rectangular plane, Stephenson and Meadows (4, pp. 49–51) and Chen and Wong (16) showed that the maximum peak discharge for the plane may occur under the condition of full-area or partial-area contribution. Chen and Wong (17) and Wong (18) further showed if the maximum discharge occurs under the condition of partial-area contribution, the maximum discharge is related to the rainfall by $b_n = 1$ in Equation 7. However, this condition may not apply to a series of planes that are heterogeneous. A trial and error process is required to determine the maximum discharge for the series of planes. The maximum discharge is the design discharge for the planes.

For planes subject to uniform net rainfall intensity and for full-area contribution, an explicit expression for the peak discharge can be derived by equating the time of concentration of the planes to the net rainfall duration. This expression can also be used to estimate the peak discharge from the downstream portion of the series of planes. For full-area contribution, the peak discharge per unit width of plane, q_o, is related to the design rainfall intensity, i_o, as follows:

$$q_o = \frac{i_o \sum_{j=1}^{N} L_{oj}}{3.6 \times 10^6} \tag{13}$$

The units are m^2 s^{-1} for q_o, mm h^{-1} for i_o, and m for L_o. Equating t_n Eq. 7 to t_o Eq. 11 to obtain the design rainfall intensity, i_o, and substituting it into Eq. 13 results in the following explicit expression for the peak discharge q_o:

$$q_o = \frac{\sum_{j=1}^{N} L_{oj}}{3.6 \times 10^6} \left\{ \frac{{a_o}^{1/b_o}}{\sum_{j=1}^{N} 7\left(\frac{n_{oj}}{\sqrt{S_{oj}}}\right)^{3/5} \times \left[\left(\sum_{r=1}^{j} L_{or}\right)^{3/5} - \left(\sum_{r=1}^{j-1} L_{or}\right)^{3/5}\right]} \right\}^{b_o/[1-(2b_o/5)]} \tag{14}$$

where a_o and b_o are the respective values of a_n and b_n in Eq. 7 for $i_n = i_o$ and $t_n = t_o$. The units are $\mathrm{m^2\,s^{-1}}$ for q_o, m for L_o, and $\mathrm{m\,m^{-1}}$ for S_o.

If there is only one plane, Eq. 14 reduces to

$$q_o = \frac{1}{3.6\times10^6} \left\{ \frac{{a_o}^{1/b_o} {L_o}^{(1-b_o)/b_o}}{7\left(\frac{n_o}{\sqrt{S_o}}\right)^{3/5}} \right\}^{b_o/[1-(2b_o/5)]} \tag{15}$$

TIME OF TRAVEL IN A CHANNEL

For a drainage basin that comprises overland planes and drainage channels, the time of concentration for the basin is the summation of the overland time of concentration and the time of travel in the channel (8, p. 90). Yen (19) asserted that these two flow components should be evaluated separately, as they are really two separate, sequential systems. Further, Kibler and Aron (20) showed that time of concentration methods that consider the two flow components separately give better estimates.

Based on the kinematic wave theory, Wong (21) and Wong and Zhou (22) showed that for channels that have a negligible backwater effect subject to uniform lateral inflow and constant upstream inflow, the times of travel in these channels for seven different cross sections are as follows:

1. Wide rectangular channel

$$t_t = 0.0167 \left(\frac{n_c}{\sqrt{S_c}}\right)^{3/5} L_c B^{2/5} \left(\frac{{Q_d}^{3/5} - {Q_u}^{3/5}}{Q_d - Q_u}\right) \tag{16}$$

2. Square channel

$$t_t = 0.0289 \left(\frac{n_c}{\sqrt{S_c}}\right)^{3/4} L_c \left(\frac{{Q_d}^{3/4} - Q_u^{3/4}}{Q_d - Q_u}\right) \tag{17}$$

3. Deep rectangular channel

$$t_t = 0.0265 \left(\frac{n_c}{\sqrt{S_c}}\right) \frac{L_c}{B^{2/3}} \tag{18}$$

4. Triangular channel

$$t_t = 0.0236 \left(\frac{n_c}{\sqrt{S_c}}\right)^{3/4} L_c \left(\frac{z^2+1}{z}\right)^{1/4} \times \left(\frac{{Q_d}^{3/4} - {Q_u}^{3/4}}{Q_d - Q_u}\right) \tag{19}$$

5. Vertical curb channel

$$t_t = 0.0198 \left(\frac{n_c}{\sqrt{S_c}}\right)^{3/4} L_c \left(\frac{1+\sqrt{z^2+1}}{\sqrt{z}}\right)^{1/2} \times \left(\frac{{Q_d}^{3/4} - {Q_u}^{3/4}}{Q_d - Q_u}\right) \tag{20}$$

6. Parabolic channel

$$t_t = 0.0272 \left(\frac{n_c}{\sqrt{S_c}}\right)^{9/13} L_c B^{2/13} \left(\frac{{Q_d}^{9/13} - {Q_u}^{9/13}}{Q_d - Q_u}\right) \tag{21}$$

7. Circular channel

$$t_t = 0.0290 \left(\frac{n_c}{\sqrt{S_c}}\right)^{4/5} \frac{L_c}{B^{2/15}} \left(\frac{{Q_d}^{4/5} - {Q_u}^{4/5}}{Q_d - Q_u}\right) \tag{22}$$

where t_t is the time of travel in the channel, n_c is Manning's roughness coefficient of the channel surface, S_c is the channel bed slope, L_c is the channel length, B is the dimension defined in Fig. 1, Q_d is the constant downstream

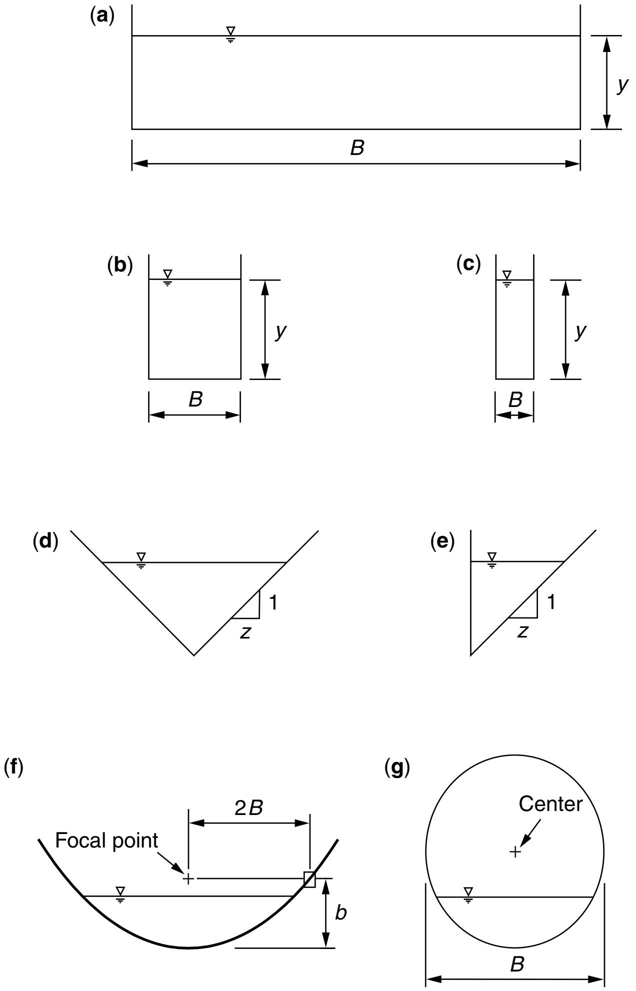

Figure 1. Channels of different cross section: (**a**) wide rectangular ($B \gg y$); (**b**) square ($B = y$); (**c**) deep rectangular ($B \ll y$); (**d**) triangular; (**e**) vertical curb; (**f**) parabolic; (**g**) circular.

outflow from the channel, and Q_u is the constant upstream inflow to the channel.

Further, Wong (23) showed that the time of travel in a general rectangular channel (i.e., a rectangular channel that has any flow depth) is

$$t_t = 0.0167\left(\frac{n_c}{\sqrt{S_c}}\right)^{3/4} L_c\left[\frac{(1+2\mu)^2}{\mu}\right]^{1/4}\left(\frac{{Q_d}^{3/4}-{Q_u}^{3/4}}{Q_d-Q_u}\right) \tag{23}$$

where μ is a parameter relating flow depth y to channel breadth B as follows:

$$\mu = \frac{y}{B} \tag{24}$$

Based on Manning's equation, the value of μ can be determined from

$$\left[\frac{\mu^5}{(1+2\mu)^2}\right]^{1/3} = \frac{n_c Q}{B^{8/3}\sqrt{S_c}} \tag{25}$$

where Q is the discharge in the channel. Equation 8 can be applied only to channels where the variation in μ is small. For channels that have a large variation in μ, the channel can be divided into longitudinal segments, and the time of travel is determined for each segment.

The units for Eqs. 16–25 are min for t_t; m m^{-1} for S_c; m for L_c, B, and y; and m^3 s^{-1} for Q_d, Q_u, and Q. In the application of Eqs. 16–23, the values of n_c may be selected from those recommended by Chow (24, pp. 110–113) or Acrement and Schneider (25).

DESIGN DISCHARGE FOR A V-SHAPED BASIN

Consider a V-shaped basin comprised of two identical overland planes and a drainage channel, as shown in Fig. 2. The two planes are subject to a uniform intensity i_n, and the runoff from the planes becomes the lateral inflow to the channel. The time of concentration for the basin, t_b, is the summation of the overland time of concentration, t_o, and the time of travel in channel, t_t, as follows (8, p. 90)

$$t_b = t_o + t_t \tag{26}$$

The overland time of concentration, t_o, is given by Eq. 12. Based on Eqs. 16–23, the times of travel in the channel, t_t, are as follows:

1. Wide rectangular channel

$$t_t = 7\left(\frac{B}{2i_n L_o}\right)^{2/5}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{3/5} \tag{27}$$

2. Square channel

$$t_t = \frac{1.26}{(2i_n L_o)^{1/4}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{3/4} \tag{28}$$

3. Deep rectangular channel

$$t_t = \frac{0.0265}{B^{2/3}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right) \tag{29}$$

4. Triangular channel

$$t_t = \frac{1.03}{(2i_n L_o)^{1/4}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{3/4}\left(\frac{z^2+1}{z}\right)^{1/4} \tag{30}$$

5. Vertical curb channel

$$t_t = \frac{0.863}{(2i_n L_o)^{1/4}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{3/4}\left(\frac{1+\sqrt{z^2+1}}{\sqrt{z}}\right)^{1/2} \tag{31}$$

6. Parabolic channel

$$t_t = \frac{2.84B^{2/13}}{(2i_n L_o)^{4/13}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{9/13} \tag{32}$$

7. Circular channel

$$t_t = \frac{0.594}{B^{2/15}(2i_n L_o)^{1/5}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{4/5} \tag{33}$$

8. General rectangular channel

$$t_t = \frac{0.726}{(2i_n L_o)^{1/4}}\left(\frac{n_c L_c}{\sqrt{S_c}}\right)^{3/4}\left[\frac{(1+2\mu)^2}{\mu}\right]^{1/4} \tag{34}$$

The units are min for t_t; mm h^{-1} for i_n; m for L_o, L_c, B, and y; and m m^{-1} for S_c.

For the V-shaped basin, the maximum peak discharge may occur under the condition of full-area or partial-area contribution. The maximum discharge is the design discharge for the basin. For planes subject to uniform net rainfall intensity and for full-area contribution, the design rainfall intensity, i_b, can be derived by equating the time of concentration of the basin, t_b, Eq. 26 to the net rainfall

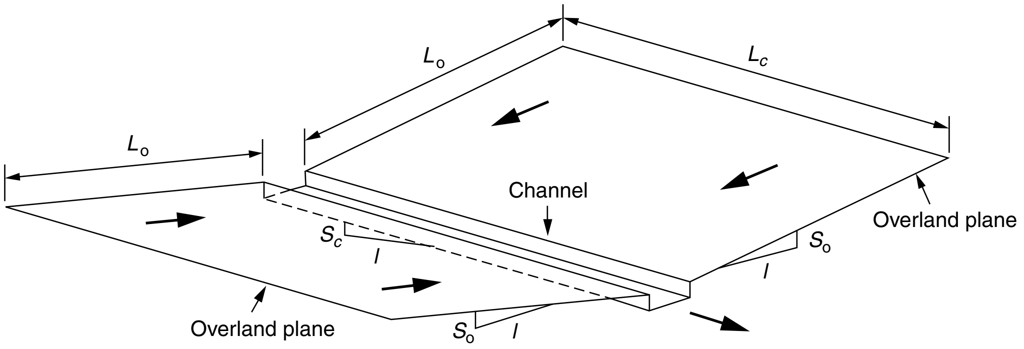

Figure 2. A V-shaped drainage basin.

duration, t_n Eq. 7. The peak discharge for the basin, Q_b, is then derived from i_b as follows:

$$Q_b = \frac{2 i_b L_o L_c}{3.6 \times 10^6} \tag{35}$$

The units are $\mathrm{m^3\ s^{-1}}$ for Q_b, $\mathrm{mm\ h^{-1}}$ for i_b, and m for L_o and L_c. Equation 35 can also be used to estimate the peak discharge under the partial-area contribution (i.e., only from the downstream portion of the basin).

Further, for a V-shaped basin that has a wide rectangular channel, an explicit expression for the peak discharge can be derived. The design rainfall intensity, i_b, can be obtained by substituting Eqs. 12 and 27 in Eq. 26 to obtain t_b and equating it to t_n Eq. 7. Substituting i_b in Eq. 35 results in the following explicit expression for the peak discharge Q_b:

$$Q_b = \frac{2L_oL_c}{3.6 \times 10^6} \left\{ \frac{{a_b}^{1/b_b}}{7\left[\begin{array}{c} \left(\dfrac{n_oL_o}{\sqrt{S_o}}\right)^{3/5} \\ + \left(\dfrac{B}{2L_o}\right)^{2/5} \left(\dfrac{n_cL_c}{\sqrt{S_c}}\right)^{3/5} \end{array} \right]} \right\}^{b_b/[1-(2b_b/5)]} \tag{36}$$

where a_b and b_b are the respective values of a_n and b_n in Eq. 7 for $i_n = i_b$ and $t_n = t_b$. The units are $\mathrm{m^3\ s^{-1}}$ for Q_b; m for L_o, L_c, and B; and $\mathrm{m\ m^{-1}}$ for S_o and S_c.

KINEMATIC WAVE AND DIFFUSION WAVE THEORIES

Vijay P. Singh
Louisiana State University
Baton Rouge, Louisiana

A wide range of phenomena, natural as well as man-made, in physical, chemical, and biological hydrology exhibit characteristics similar to those of kinematic or diffusion waves. The wide range of phenomena suggests that these waves are very pervasive. This study presents theories that are considered fundamental to advancing the state of the art of hydrology.

INTRODUCTION

The term "wave" implies a disturbance traveling upstream, downstream, or remaining stationary. We can visualize a water wave propagating where the water itself stays very much where it was before the wave was produced. We witness other waves that travel as well, such as heat waves, pressure waves, and sound waves. There is obviously the motion of matter, but there can also be the motion of form and other properties of matter.

Flow phenomena, according to the nature of particles composing them, can be classified into two categories: (1) flows of discrete noncoherent particles and (2) flows of continuous coherent particles. Examples of flows in the first category include traffic flow; transport of sand and gravel in pipes, flumes, and rivers; evolution of ripples, dunes, and bars on a river bed; settlement of sediment particles in a tank; and movement of microbial organisms. Exemplifying flows in the second category are overland flow, flood movement, baseflow, snowmelt, movement of glaciers, infiltration, evaporation, solute transport, ion exchange, and chromatographic transport. Because of their wave-like behavior, these flow phenomena can be described by the hydrodynamic wave theory or one of its variants, including the kinematic wave theory, diffusion wave theory, gravity wave theory, and linear wave theory.

A survey of geophysical literature reveals that the kinematic and diffusion wave theories have been applied to a wide spectrum of problems, including watershed runoff modeling, flood routing in rivers and channels, movement of soil moisture, macropore flow, subsurface storm flow, erosion and sediment transport, debris flow, solute transport, ion exchange, chromatography, sedimentation, glacial motion, movement of snowmelt water, flow over porous beds in irrigation borders and furrows, river-ice motion, vertical mixing of coarse particles in gravel-bed rivers, to name but a few. Other fields outside the realm of geophysics that apply the kinematic and diffusion wave theories include traffic flow, movement of agricultural grains in a bin, and blood circulation. It can be argued that within certain limitations a wide range of hydrologic phenomena can be approximated quite closely by kinematic and diffusion wave theories. Outside of these limitations, the theories provide only a crude approximation and the full hydrodynamic wave theory or one of its higher order variants may be needed.

Before presenting the theories, one may ask, What is meant by kinematic and diffusive? Although papers and textbooks in hydrology define kinematic and diffusive waves mostly from an approximation of the momentum equation and occasionally from defining flux laws, a comprehensive account of these terms is lacking in literature. Therefore, a short discussion to that end is in order.

WHAT IS KINEMATICS?

The term "kinematic" involves consideration of such macroscopic properties of a flow phenomenon as velocity, discharge, concentration, and time of travel. It does not involve consideration of forces and mass. Thus, the connotation of "kinematic" is that it is phenomenological and less physical, but its representation may be derived from or related to dynamic considerations involving forces, mass, momentum, and energy.

Although studies based on kinematics existed long before the development of Greek science, Ampere (1) is credited with introducing the term "kinematics" for the study of motion in his famous essay on the classification of sciences. His intent was to create a discipline for the study of motion without regard to the forces involved. Thus, kinematics is defined as the science that deals with the study of motion in the most general way. The motion can be translatory, dilatational, or rotational (angular) (2).

It may be instructive to view kinematics in the context of geometry and dynamics. From the standpoint of dimensions, geometry implies only length, whereas kinematics involves length and time, and dynamics considers length, mass, and time. Thus, kinematics is somewhere between geometry and dynamics, perhaps closer to the latter. Although kinematics is related to geometry, it can also be studied without geometry by means of numerical description of the functions as the Babylonians seem to have done it—a precursor to curve fitting. In kinematics, we are concerned with the position of a point at a certain time and also with the displacement accomplished and the distance traversed in a certain time interval. Other functions of time such as velocity and acceleration can be introduced. Even higher derivatives such as the rate of change of acceleration, called jerk, and even higher order derivatives can be included.

It should be noted that the introduction of mass does not necessarily make some motions strictly dynamic; they may remain strongly and functionally kinematic. For instance, the formulation of equations for conservation of volume in fluid mechanics is very much in the realm of kinematics. When the equations for conservation of mass are formulated, they are still in the same domain; the two treatments are very similar. Even the discussion of momentum flux and kinetic energy flux are fundamentally kinematic. In general, there are terms in the equations of dynamics that are essentially kinematic. The difference between kinematics and dynamics thus requires close scrutiny.

KINEMATIC WAVE THEORY

In a seminal contribution, in 1955, Lighthill and Whitham developed the kinematic wave theory, and they gave a full account of the theory for describing flood movement in long rivers and traffic flow on long crowded roads (3,4). The theory is comprised of three components: (1) the theory of kinematic continuous waves, (2) the theory of shock waves, and (3) the theory of the formation of shock waves from continuous waves. Iwagaki (5) developed a approximate method of the characteristics for routing steady-state flow in open channels of any cross-sectional shape that have nearly uniform lateral flow and proposed that the method would be applicable to the hydraulic analysis of runoff estimates in river basins. Implicit in his method was the kinematic wave assumption. Thus, Iwagaki (1955) can also be credited with independently conceiving of the kinematic wave concept and developing the method of kinematic wave routing.

Following Lighthill and Whitham (3,4), kinematic waves exist if it can be assumed with sufficient accuracy that there is a functional relationship between flux, concentration, and position. Thus, the kinematic wave theory is mathematically expressed by the law of conservation of mass through the continuity equation and a flux–concentration relation. The coupling of these two equations leads to a first-order partial differential equation that has only one system of wave characteristics. The essence of this is that the wave property is derived from the continuity equation alone. The governing equation (or continuity equation) is only of the first order, so kinematic waves possess only one system of characteristics. This would also imply that kinematic waves travel only in a downstream direction and that the kinematic wave theory cannot accommodate waves that travel in the upstream direction as in backwater flow. In the absence of any lateral inflow and/or outflow, the flux along the characteristics is constant, and the kinematic waves are nondispersive and nondiffusive. However, the waves are dispersive and diffusive when there is lateral inflow and/or outflow, as, for example, in rainfall runoff.

Continuous Waves

If the volume of a quantity passing a given point x in unit time is denoted by flux F and the concentration C is defined as the volume of the quantity per unit distance, then for a one-dimensional flow system without any lateral sources and sinks, the continuity equation or the mass conservation law is

$$\frac{\partial C}{\partial t} + \frac{\partial F}{\partial x} = 0 \tag{1}$$

Equation 1 is first order and states that the volume of the quantity in a small element of length changes at a rate equal to the difference between the rates of inflow and outflow.

Fundamental to the development of the kinematic wave theory is the development of a flux–concentration relation. A general flux–concentration relation can be assumed as

$$F = F(C, x) \tag{2}$$

Equations 1 and 2 have two unknowns, F and C, and can therefore be combined into one equation having one unknown. Multiplying Eq. 1 by

$$c = \left(\frac{\partial F}{\partial C}\right)_{x\,\text{constant}} = c(C, x) \tag{3}$$

one obtains

$$\frac{\partial F}{\partial t} + c\frac{\partial F}{\partial x} = 0 \tag{4}$$

Equation 4 is the kinematic wave equation. The quantity c has various names. In hydraulics, it is called wave velocity or celerity, and it is referred to as mobility in vadose zone hydrology. It is the slope of the flux–concentration relation at a fixed x. This is not the same as the mean velocity u which is expressed as

$$u = F/C \tag{5}$$

The relation between c and u is thus obvious:

$$c = \frac{d}{dC}(uC) = u + C\frac{du}{dC} \tag{6}$$

Equation 6 shows that c is greater then u, if u increases with C as in river flow; it is less than u if u decreases with C as in sedimentation; and it is equal to u if u does not change with C. Equation 4 states that F is constant in waves traveling past a point whose celerity c is given by Eq. 3. The kinematic wave equation 4 has one system of characteristics traveling only in the downstream direction, given by $dx = c\,dt$, and along each of these characteristics, F is fixed.

Although Eq. 3 constitutes the basic building block of the kinematic wave theory, a more popular, but more restrictive, derivation of the theory in hydrology is obtained by assuming that the local acceleration, convective acceleration, and pressure gradient (or concentration gradient) in the momentum equation are negligible. This assumption states an equivalence between frictional and gravitational forces. When only the local and convective acceleration terms are assumed negligible, the remainder of the momentum equation (i.e., the pressure gradient equaling the difference between gravity and frictional slopes) leads, in conjunction with the continuity equation, to diffusion wave theory. When the full momentum equation is used jointly with the continuity equation, the result is the dynamic wave theory. In general, the local acceleration and the convective acceleration are of the same order of magnitude but are opposite in sign, thus counteracting each other. In a wide range of problems in hydrology, the frictional and gravitational terms are dominant, and this is one of the reasons for the popularity of the kinematic wave theory.

Formation of Kinematic Shocks

A kinematic shock is a discontinuity representing a sudden rise or surge in flow depth. For example, during wave movement, faster moving waves overtake slower moving waves, and at a fixed position, there will be an increase in flux and concentration as functions of time, leading to shock formation. Thus, flood waves have an intrinsic, nonlinear tendency to steepen as they propagate downstream, eventually forming a shock. In the characteristic plane, shock formation results from the intersection of characteristics. After some time, the shock weakens and dissolves into a region of uniform flow. Shocks arise in a variety of hydrologic processes. A short but general discussion of shocks is relevant, however, and is given here. Shocks or discontinuities are of first or second order. A discontinuity of the first kind in the concentration is defined by a sudden change of concentration at a certain level. In such a case, the differential equation of continuity (Eq. 4) no longer applies;

instead, it is replaced by an equation stating that the flow of mass into one side of the shock is equal to that on the other side of the shock. Denoting the velocity of discontinuity by U, mass conservation leads to

$$U = \frac{F_2 - F_2}{C_2 - C_1} \tag{7}$$

where subscripts 1 and 2 denote the quantities ahead and behind the shock. Equation 7 shows that, in general, the discontinuity is not at rest but moves with velocity U which is the slope of the chord joining the points (F_1, C_1) and (F_2, C_2) on the F–C diagram.

A discontinuity of the second kind is represented by a very small change in concentration. If $C_2 - C_1 = dC$ is small, the expression for U becomes $dF/dC = c$, the celerity. In this case the velocity of a discontinuity between concentrations C and $C + dC$ is the same as the celerity c. A small change, if maintained, is propagated through the medium of concentration C at velocity c similarly to the propagation of sound through air at a definite velocity. A line of constant concentration, therefore, describes the motion of a boundary between media of concentrations C and $C + dC$ so that its slope is necessarily equal to c. The complete modification of concentration at a position as well as its profile can be characterized as a series of small discontinuities propagated through the medium.

Determination of Kinematic Shocks

Many factors affect the formation of shocks, and these factors can broadly be distinguished as of three types: (1) initial and boundary conditions, (2) lateral inflow and outflow, and (3) watershed geometric characteristics. A full account of the theory of shock formation was given by Lighthill and Whitham (3,4), and a mathematical treatment of the formation and decay of shocks was given by Lax (6).

Carrier and Pearson (7) developed a method for determining the enveloping curve for any region of intersecting characteristics. Croley and Hunt (8) analytically determined boundary-dependent shocks in planar flow. Hairsine and Parlange (9) dealt with kinematic shocks on curved surfaces. Kibler and Woolhiser (10) investigated geometry-dependent shocks using a kinematic cascade. They derived the mathematical properties of a kinematic cascade and developed a criterion, based on the properties of adjacent flow-plane pairs, to predict when a shock would occur in a cascade. They also developed a numerical procedure for shock fitting. General properties of shock waves along with continuous kinematic waves were discussed. Full equations of motion were employed to investigate the structure of the kinematic shock.

Building on the work of Kibler and Woolhiser (10), Schmid (11) investigated the effect of lateral inflow and outflow as well as geometry on the development of shocks. He derived a generalized criterion for shock formation in an infiltrating cascade that also encompasses cascades that have time-dependent rates of effective rainfall. Using simulated conditions, Ponce and Windingland (12) determined flow and channel characteristics that either tend to promote or inhibit development of kinematic shocks. Borah (13) and Borah et al. (14) developed approximate but efficient numerical methods for determining the shock path and shock fitting.

DIFFUSION WAVE THEORY

The diffusion wave theory is comprised of (1) the formation of continuous waves, (2) the formation of shocks, and (3) the propagation of shock waves. The diffusion wave formulation is obtained from the continuity equation and a diffusive flux law. In surface water hydrology, the diffusive flux law is obtained by neglecting the inertial terms in the momentum equation, whereas in groundwater and subsurface water hydrology, it is expressed by Darcy's law. When the two equations are combined, the result is a second-order partial differential equation. The second-order differential term is associated with a coefficient expressed in terms of what is referred to as diffusivity. This term introduces diffusion. The first-order spatial derivative and the coefficient associated with it together lead to steepening or breaking of waves. Clearly, theses two terms have opposite tendencies of nonlinear wave steepening and diffusion. The diffusivity term is always positive.

When a shock is formed, it can be discontinuous or continuous. If the diffusivity is small, the shock is a rapid but continuous increase in flow concentration over a narrow range. Breaking due to nonlinearity is balanced by diffusion in the narrow range to yield a steady-state profile. The sign of the derivative of the concentration plays an important role in determining whether the shock will break forward or backward.

FLUX LAWS

The term "flux" is defined in two ways in hydraulics. First, flux denotes a volume of any quantity per unit area per unit time. Thus, its dimensions are L/T if the quantity is, say, runoff. Second, flux is defined as any quantity per unit time. For example, volume flux is the volume of a quantity per unit time as exemplified by discharge, mass flux is mass per unit time, momentum flux (it has the same dimensions as force) is momentum per unit time, energy flux (kinetic energy flux has the same dimensions as power) is energy per unit time, and so on. Both definitions are used in water and environmental engineering.

Flux laws are fundamental to the development of transport theories. The flux laws most common in environmental and water sciences are of two types: (1) power laws and (2) gradient laws. Kinematic wave flux laws are the most popular flux laws of the power type, and Darcy's law and the Darcy–Buckingham law are the most popular gradient type flux laws. Generalized flux laws that specialize into power and gradient laws are also used. An example of a generalized flux law is Burgers' law or a generalized version thereof (15). Power type flux laws lead to kinematic wave equations, whereas the gradient type flux laws lead to diffusion waves governed by elliptical or parabolic partial differential equations.

Algebraic Laws

A general expression for the flux–concentration relation is given by Equation 2. One of its special forms is the popular kinematic wave flux law expressed as

$$F = \alpha C^n \tag{8}$$

where α is a parameter and n is an exponent. The meaning and interpretation of α and n may vary with the problem to which Eq. 8 is applied. Equation 8 leads to the famous Chezy and Manning equations which are popular in studies of overland flow and flood routing in open channels and rivers. At a fixed location x, $(\partial F/\partial C)$ defines the wave celerity $c : c = (\partial F/\partial C)|_{x\,\text{fixed}}$ which is not the same as the average velocity of flow. When $n = 1$, Eq. 8 becomes

$$F = \alpha C \tag{9}$$

This is a linear flux–concentration law used to describe the movement of meltwater runoff from snowpack.

Beven (16) employed two somewhat uncommon three-parameter forms of the flux–concentration relation for his channel network routing model:

$$F = \frac{C(a + bk) - k}{1 - bC} \tag{10}$$

and

$$\frac{F}{a(1 - \exp(-kF)) + bF} = C \tag{11}$$

where a, b, and k are parameters.

Another flux law is defined as

$$F = \alpha C^2(C_o - C) \tag{12}$$

where C_o is the maximum value of C and α is a parameter. Equation 12 is used to describe the settlement of particles in a dispersion. Still another flux law used to describe the movement of sediment in flumes and pipes is

$$F = u_0 C\left(1 - \frac{C}{C_0}\right) \tag{13}$$

where u_0 is the velocity of a single particle when there are no other particles in the flow. All of these flux laws lead to kinematic waves.

Gradient Laws

The gradient-type flux law is expressed as

$$F = G(\partial C/\partial x) \tag{14}$$

where G is some function. As an example,

$$F = \beta(\partial C/\partial x)^m \tag{15}$$

where β is a parameter and m is an exponent. Equation 15 is a nonlinear version of Darcy's law. When $m = 1$, Eq. 15 becomes

$$F = \beta(\partial C/\partial x) \tag{16}$$

Equation 16 is Darcy's law, where β describes the negative of the saturated hydraulic conductivity and C the hydraulic head.

A more general form of Eq. 16 arises when β depends on C:

$$F = \beta(C)\partial C/\partial x \tag{17}$$

Equation 17 is the Darcy–Buckingham law where C describes the hydraulic head and β the negative of the unsaturated hydraulic conductivity which varies with moisture content. When a gradient flux law is coupled with the continuity equation, the resulting partial differential equation turns out to be of parabolic type under transient flow conditions and of elliptical type under steady-state conditions.

Generalized Flux Laws

A generalized flux law is obtained by combining the power and gradient-type flux laws. In general,

$$F = G(C, \partial C/\partial x, x) \tag{18}$$

where G is some function and its argument is defined by C, $\partial C/\partial x$, and x. One form of Eq. 18 is

$$F = \alpha C^n + \beta(\partial C/\partial x)^m \tag{19}$$

where m and n are exponents. Equation 19 specializes into (15)

$$F = \alpha C^n + \beta(\partial C/\partial x) \tag{20}$$

and

$$F = \alpha C + \beta \partial C/\partial x \tag{21}$$

Equation 21 is Burgers' flux law (17) used in turbulence modeling; when used in the continuity equation, the resulting partial differential equation is Burgers' equation. Equations 19 and 20 have been employed to rout flows in open channels (15).

VALIDITY OF KINEMATIC AND DIFFUSION WAVE THEORIES

Lighthill and Whitham (3) have shown that, for Froude numbers below 1 (appropriate to flood waves), dynamic waves are rapidly attenuated and kinematic waves become dominant. Using a dimensionless form of the Saint-Venant (SV) equations, Woolhiser and Liggett (18) obtained the kinematic wave number, K, as a criterion for evaluating the adequacy of the kinematic wave (KW) approximation. For K greater than 20, the kinematic wave approximation was considered an accurate representation of the SV equations in modeling overland flow. Morris and Woolhiser (19) modified this criterion by explicitly including a Froude number corresponding to normal flow, F_O, and showed, based on numerical experimentation, that $F_O^2 K \geq 5$ is a better indicator of the adequacy of the kinematic wave approximation.

Using a linear perturbation analysis, Ponce and Simons (20) derived properties of the kinematic wave, diffusion wave, and dynamic wave representations in modeling open channel flow. Menendez and Norscini (21) extended the work of Ponce and Simons (20) by including the phase lag between the depth and velocity of flow. Based on the propagative characteristics of a sinusoidal perturbation, they derived criteria to evaluate the adequacy of kinematic wave and dynamic wave approximations. Daluz Vieira (22) compared solutions of the SV equations with those of the kinematic wave and dynamic wave approximations for a range of F_O and K and defined regions of validity of these approximations in the $K - F_O$ space. Fread (23) developed criteria for defining the application range of the kinematic wave and dynamic wave approximations. Ferrick (24) defined a group of dimensionless-scale parameters to establish the spectrum of river waves, using continuous transitions between wave types and subtypes.

It is possible to make inferences about the diffusion wave theory using the Vedernilkov number, N, which is the ratio of relative celerity of kinematic waves to the relative celerity of diffusive waves. If N is less than one, flow is stable, and if N is greater than one, it is unstable. Thus, $N = 1$ gives the condition of neutral stability. Clearly, a surface disturbance attenuates in stable flow, amplifies in unstable flow, and undergoes no change in neutral stable flow.

The comparative studies cited before, show that many cases satisfy the conditions for the validity of kinematic wave theory and that in surface water hydrology, kinematic waves dominate in such cases. Other wave types may exist but they are either short-lived or play a minor role. This is further elaborated by considering two special cases: (1) uniform, unsteady-state flow and (2) steady-state, nonuniform flow.

Unsteady-State Uniform Flow

Using simplified conditions, Singh (2,25–30) derived error equations specifying error as a function of time for the kinematic wave approximation of space-independent flows. He considered four different types of scenarios depending upon the presence of lateral inflow or rainfall and infiltration: (1) Lateral inflow is constant, and there is no infiltration; if there is, it is included in lateral inflow. (2) Both lateral inflow and infiltration are considered constant. (3) Both lateral inflow and infiltration are included, but their difference is zero. (4) There is no lateral inflow, but infiltration is included. These scenarios were analyzed under two types of initial conditions: (1) the plane or channel is initially wet, and (2) the plane or channel is initially dry. In all, 18 cases were analyzed.

For space-independent flow, the continuity equation takes the form,

$$\frac{dh}{dt} = i - f \tag{22}$$

and the momentum equation takes the form,

$$\frac{du}{dt} = g(S_0 - S_f) - \frac{iu}{h} \tag{23}$$

where g is the acceleration of gravity, i is the lateral inflow (or rainfall intensity), f is the infiltration rate, S_0 is the bed slope, and S_f is the slope of the energy line. For a kinematic wave approximation, Eq. 23 becomes

$$S_0 = S_f \tag{24}$$

which can be expressed as

$$u = \left(\frac{S_0}{\beta}\right)^{0.5} h^{0.5} \tag{25}$$

where β is a parameter. Singh (2,26,27,29,30) derived error equations for all cases which turned out to be Riccati equations of the form,

$$\frac{dE}{d\tau} = C_0(\tau) + C_1(\gamma,\tau)E + C_2(\gamma,\tau)E^2 \tag{26}$$

where E is the error defined as (kinematic wave solution-dynamic wave solution)/dynamic wave solution, τ is dimensionless time, γ is a dimensionless parameter, and $C_i, i = 1$, 2, and 3, are Riccati coefficients. The parameter γ is analogous to a kinematic wave parameter and is defined as

$$\gamma = \frac{4g^2\beta S_0 h_0}{{i_0}^2} \tag{27}$$

or

$$\gamma = 4\beta g S_0 \tag{28}$$

depending upon whether or not lateral inflow (i_0) is included. In general, the kinematic wave approximation is very good if γ is equal to or greater than 10. As time progresses, that is, $\tau \geqslant 10$, the kinematic wave approximation converges to the dynamic wave solution.

Steady-State Nonuniform Flow

Steady-state nonuniform flows are encountered in a variety of natural situations. In overland flow, the steady state is attained for constant rainfall after the flow depth at the outlet has reached equilibrium. This same is true for channel flow subject to constant lateral inflow. For a channel receiving a constant inflow of long duration at its upstream boundary, the flow at the downstream end would reach equilibrium. The steady-state solution aids in understanding the nature of the surface water profile. It may help define the condition for use of zero depth in place of zero influx at the upstream boundary. When the rainfall duration is much longer than the time of equilibrium, steady-state surface water profiles are very useful. Pearson (31) examined the criteria for using the kinematic wave approximation of the SV equations for shallow water flow. For steady-state one-dimensional flow over a plane, he derived a new criterion as $K \geqslant 3+5/F_O^2$, where K is the kinematic wave number and F_O is the Froude number corresponding to normal flow.

Govindaraju et al. (32,33) provided a comprehensive discussion of the DW theory for steady-state nonuniform flow. They presented both numerical and analytical results for flux-type downstream boundary conditions and using zero inflow at the upstream boundary. Parlange et al. (34) investigated errors in the KW and diffusion wave (DW) approximations by comparing their predictions with the numerical solution of the SV equations under steady-state conditions. They suggested splitting the solution into two regions, one near the downstream end of the plane and the other covering most of the plane. Singh and Aravamuthan (35–38) derived errors in the kinematic and diffusion wave approximations under four conditions: (1) zero flow at the upstream boundary, (2) finite depth at the upstream boundary, (3) critical flow depth at the downstream end, and (4) zero-depth gradient at the downstream boundary. For economy of space, only the KW case will be discussed. Depending on the inclusion of lateral inflow and infiltration, 21 cases were analyzed for the four different scenarios mentioned before. By comparing the kinematic wave solution with the dynamic wave solution, error equations were derived for all cases. For time-independent flow, the governing equations are

$$\frac{dh}{dx} = i - f \tag{29}$$

and

$$\frac{d}{dt}\left(\frac{1}{2}u^2 + gh\right) = g(S_o - S_f) - \frac{iu}{h} \tag{30}$$

The error equations were generalized Riccati type equations:

$$\frac{dE}{dx} = C_0E + C_1E^2 + C_2E^3 + C_3E^4 + C_4E^5 \tag{31}$$

where the parameters, $C_i, i = 1, 2, 3$, and 4, are nonlinear functions of x, h, K, and F_O which are as defined before. In most cases, it was found that the downstream boundary exercised significant influence on the adequacy of the kinematic wave approximation. Away from the boundaries, that is, $0.1 \leqslant x/L \leqslant 0.9$, where L is the length of the plane, the kinematic wave approximation was a good approximation (39).

KINEMATIC WAVE FLOW ROUTING

VIJAY P. SINGH
Louisiana State University
Baton Rouge, Louisiana

Flow routing on planes, in channels, and in storm sewers using the kinematic wave theory is quite popular, especially for urban drainage design and planning. The small watershed sizes and the often fairly steeper prismatic conduits in an urban environment are well suited for application of the theory. Little or no streamflow data are required to develop the kinematic wave routing method. In nonurban environments, the kinematic routing wave method, corrected for dynamic effects, is also becoming increasingly popular.

KINEMATIC WAVE FORMULATION FOR CHANNEL FLOW ROUTING

The kinematic wave equation is derived from the continuity equation,

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = 0 \tag{1}$$

and can be expressed in terms of the discharge, Q, as the dependent variable for a channel:

$$\frac{1}{c}\frac{\partial Q}{\partial t} + \frac{\partial Q}{\partial x} = 0, \quad 0 \le x \le L \tag{2}$$

where A is the area of flow cross section, c is the travel speed of the flood wave called the kinematic wave speed and may, at a particular cross section and for a given Q, be evaluated from the Kleitz–Seddon law,

$$c = \frac{dx}{dt} = \left(\frac{dQ}{dA}\right)\bigg|_{x\,\text{fixed}} = \frac{1}{B}\left(\frac{dQ}{dh}\right)\bigg|_{x\,\text{fixed}} \tag{3}$$

where B is the channel flow width, h is the depth of flow, and A is the flow cross-sectional area. When c is constant, Eq. 2 becomes linear and will have a translatory solution. For a variable c, it is a nonlinear equation. In practice, c is usually estimated from a rating curve relating discharge to depth of flow, expressed in general by the Chezy or Manning formula:

$$Q = CAR^m S_f{}^{0.5} \tag{4}$$

where R is the hydraulic radius, C is an empirical resistance coefficient, S_f is the frictional slope = bed slope, S_o, and m is an exponent. Because R depends on A, Eq. 4 is usually written as

$$Q = \alpha A^n, \alpha = C(S_f)^{0.5}, n \in [1, 3] \tag{5}$$

where α is the resistance parameter and n is an exponent. Therefore,

$$c = n\alpha A^{n-1} = n\frac{Q}{A} = nu\left(\frac{Q}{\alpha}\right)^{(n-1)/n} \tag{6}$$

where u is the mean flow velocity.

To solve Eq. 2, the initial and boundary conditions are usually assumed as

$$Q(x, 0) = Q_0(x) \tag{7}$$

$$Q(0, t) = Q_u(x), Q_u(0) = Q_0(0) \tag{8}$$

If $Q_0(x) = 0, 0\langle x\langle L$, then the channel is initially dry. $Q_u(t)$ is such that an analytical solution is not tractable except when $Q_u(t) = Q_u =$ constant. Therefore, numerical solutions with attendant discretization of the solution domains are employed. A number of numerical schemes have been proposed to solve the kinematic wave equations (1). Figure 1 shows a finite-difference grid for a computational cell in (x, t) space. The discretization, however, has its own flaws. It is known that numerical solutions of Eq. 2 introduce variable amounts of numerical diffusion, and the solution resembles a diffusion wave rather than a kinematic wave (2). In first-order numerical schemes, the numerical diffusion is uncontrolled, making the solution depend on the grid size. In second-order schemes, the numerical diffusion vanishes, but a certain amount of numerical dispersion (of the third order) exists (3). Some workers (4) argue that a small amount of numerical diffusion should be welcome, for the kinematic wave solution

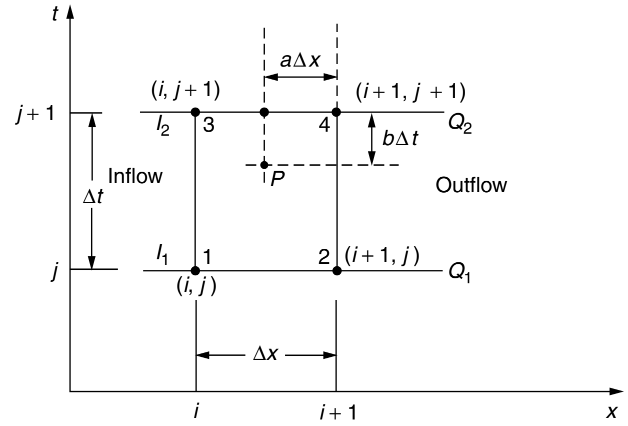

Figure 1. Finite-difference grid for a computational cell in the (x, t) space; a and b are weighting factors in space and time, respectively.

stands to benefit from it and is then applicable to a wider class of problems. Therefore, complete elimination of diffusion may not be desirable from a practical standpoint, for natural diffusion is inherent in physically realistic flows. Thus, one way to accomplish the twin objective of achieving a kinematic wave solution and an acceptable amount of diffusion is to match physical and numerical diffusion judiciously. This procedure has been successfully used for stream-flow routing (5–7). Three possible fully off-centered schemes, which are frequently used, are shown in Fig. 2. The stability depends on the scheme used.

GENERALIZED METHOD FOR A NUMERICAL SOLUTION

A fairly general and flexible finite-difference formulation of the kinematic wave model given by Eq. 2 can be developed, and it can be shown that several existing models are special cases of this formulation. To that end, we employ a rectangular $x - t$ grid, as shown in Fig. 1, where a $(0 \leq a \leq 1)$ and b $(0 \leq b \leq 1)$ are the weighting factors in space and time directions, respectively. Let p be a point in the x–t grid around which the finite-difference approximation is attained. If $W(x, t)$ is any variable denoting either $A(x, t)$ or $Q(x, t)$, then,

$$\frac{\partial W}{\partial x} = \frac{\Delta W}{\Delta x} = \frac{1}{\Delta x}[(1-b)(W_{i+1}^{j} - W_{i}^{j}) + b(W_{i+1}^{j+1} - W_{i}^{j+1})] \tag{9}$$

and

$$\frac{\partial W}{\partial t} = \frac{\Delta W}{\Delta t} = \frac{1}{\Delta t}[(1-a)(W_{i+1}^{j+1} - W_{i+1}^{j}) + b(W_{i}^{j+1} - W_{i}^{j})] \tag{10}$$

where subscript i denotes the space coordinate x and j denotes the time coordinate t.

Similar to Eqs. 9 and 10, Eq. 1 can be written in finite difference around a point p as,

$$\frac{1}{\Delta t}[(1-a)(A_{i+1}^{j+1} - A_{i+1}^{j}) + a(A_{i}^{j+1} - A_{i}^{j}) + \frac{1}{\Delta x}[(1-b)(Q_{i+1}^{j} - Q_{i}^{j}) + b(Q_{i+1}^{j+1} - Q_{i}^{j+1})] = 0 \tag{11}$$

Depending on the values of a and b, point p may lie anywhere within or on the boundaries of the rectangular grid element. Usually Q_{i+1}^{j+1} and A_{i+1}^{j+1} are unknowns, and these at previous points (i, j), $(i + 1, j)$, and $(i, j + 1)$ are known. Arranging the unknowns on the left side and knowns on the right side, Eq. 11 can be written as

$$bQ_{i+1}^{j+1} + (1-a)A_{i+1}^{j+1}\frac{\Delta x}{\Delta t} = bQ_{i+1}^{j} + (1-a)A_{i+1}^{j}\frac{\Delta x}{\Delta t} - Q_{i+1}^{j} - bQ_{i}^{j} + aA_{i}^{j}\frac{\Delta x}{\Delta t} + bQ_{i}^{j+1} - a\frac{\Delta x}{\Delta t}A_{i}^{j+1} \tag{12}$$

The kinematic wave assumption requires a unique relation between Q and A as in Eq. 5. Hence, there remains actually only one unknown on the left side of Eq. 12. Let

$$f(Q_{i}^{j}) = bQ_{i}^{j} - aA_{i}^{j}\frac{\Delta x}{\Delta t} \tag{13}$$

and

$$g(Q_{i}^{j}) = bQ_{i}^{j} + (1-a)A_{i}^{j}\frac{\Delta x}{\Delta t} \tag{14}$$

Taking advantage of Eqs. 13 and 14, Eq. 12 can be expressed as

$$g(Q_{i+1}^{j+1}) = g(Q_{i+1}^{j}) + f(Q_{i}^{j+1}) - f(Q_{i}^{j}) + Q_{i}^{j} - Q_{i+1}^{j} \tag{15}$$

Using the knowledge of the Q–A relationship, functions $f(Q)$ and $g(Q)$ can be computed. First, the right side of Eq. 15 is evaluated. Then, Q_{i+1}^{j+1} is evaluated by using the Q–A relationship. Thus, calculations can proceed either in the x direction or the t direction. The generalized scheme is stable for $a/b \leq c_n \leq (1-a)/(1-b)$, where c_n is the Courant number $= c\Delta t/\Delta x$. When $a = b = 0.5$, the scheme is second-order accurate. This means that point p is centrally located in the rectangular grid. As p departs from the center or as a and b depart from the value of 0.5, truncation errors of the order $O(\Delta x)$ and $O(\Delta t)$ increase,

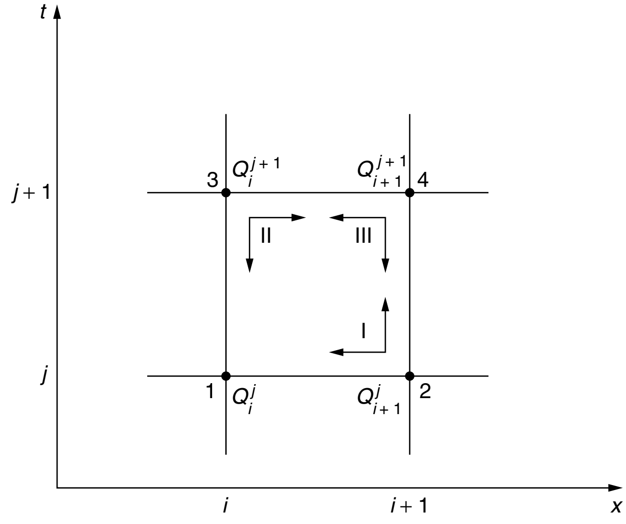

Figure 2. Three fully off-centered numerical schemes for solving kinematic wave equations.

respectively and independently. This truncation is the cause of the numerical diffusion encountered in numerical kinematic channel flow routing. Thus, the desired level of numerical diffusion can be achieved by an appropriate choice of a and b values. A more complete account of the stability and convergence properties of the generalized scheme is given by Smith (8), who showed that several flood routing models are special cases of Eq. 15.

Reservoir Flow Routing

The routing of flow through a reservoir involves a volume balance and the assumption that reservoir storage is controlled by outflow. The volume balance can be expressed as

Rate of change of storage = inflow − outflow,

$$(A^{j+1}_{i+1} - A^{j}_{i+1})\frac{\Delta x}{\Delta t} = \frac{1}{2}(Q^{j}_{i} + Q^{j+1}_{i}) - \frac{1}{2}(Q^{j}_{i+1} - Q^{j+1}_{i+1}) \quad (16)$$

By rearranging Equation 16 and comparing Eq. 12, one gets

$$0.5Q^{j+1}_{i+1} + A^{j+1}_{i+1}\frac{\Delta x}{\Delta t} = 0.5Q^{j}_{i+1} + A^{j}_{i+1}\frac{\Delta x}{\Delta t} - Q^{j}_{i+1} - 0.5Q^{j}_{i} + Q^{j}_{i} + 0.5Q^{j+1}_{i} \quad (17)$$

Equation 17 is a special case of Eq. 12 where $a = 0$ and $b = 0.5$.

Muskingum Method

Flow routing in channels, using the Muskingum method, is based on Eq. 16 and a relation between storage (S), inflow (I), and outflow (Q) (9):

$$S = K[x_m I + (1 - x_m)Q] \quad (18)$$

where x_m ($0 \leq x_m \leq 1$) is a weighting factor and K is travel time. The right side of Eq. 18 defines prism storage and wedge storage; the latter depends on the amount by which inflow exceeds outflow. Using Eq. 3,

$$K = \frac{\Delta x}{c} = \Delta x\left(\frac{dA}{dQ}\right) = \frac{\Delta x \Delta A}{\Delta Q} \quad (19)$$

In the Muskingum method, c is considered constant for a channel reach. Then,

$$KQ = \Delta x Q\frac{\Delta A}{\Delta Q} = \Delta x\frac{Q}{u} = \Delta x\frac{Q}{c} = \Delta x A \quad (20)$$

Equations 18–20 can be combined with the volume balance equation and then written in finite-difference form, similar to Eq. 12, as

$$0.5Q^{j+1}_{i+1} + (1 - x_m)A^{j+1}_{i+1}\frac{\Delta x}{\Delta t} = 0.5Q^{j}_{i+1} + (1 - x_m)A^{j}_{i+1}\frac{\Delta x}{\Delta t} - Q^{j}_{i+1} - 0.5Q^{j}_{i} + x_m A^{j}_{i}\frac{\Delta x}{\Delta t} + Q^{j}_{i} + 0.5Q^{j+1}_{i} - x_m A^{j+1}_{i}\frac{\Delta x}{\Delta t} \quad (21)$$

If $a = x_m$ and $b = 0.5$, Eq. 21 is a special case of Eq. 12. A nonlinear Muskingum method is discussed by Koussis and Osborne (10) and Singh and Scarlatos (11).

Brakensiek's Models

Brakensiek (12) employed the kinematic wave method for flood routing in prismatic channels. He used three numerical schemes which are special cases of Eq. 12 for

$a = 0.5$ and $b = 0.5$ Model I (centered)
$a = 0.5$ and $b = 1.0$ Model II (implicit)
$a = 0.5$ and $b = 0.0$ Model III (explicit)

His flood routing results were sensitive to model type. The first two schemes were more stable than the explicit scheme. The use of an implicit scheme did not require simultaneous solution of Q and A at a new point.

HYMO Model

Williams (13) developed a hydrologic modeling method, called HYMO, using a variable travel time routing procedure. The routing employs the volume balance using arithmetic averages to define discharges over a time increment and end areas over a distance increment. This amounts to using $a = b = 0.5$. A distinguishing feature of HYMO is said to be the variable travel time as a function of the unknown discharge, and therefore it involves an iterative calculation. Smith (8), however, has shown that the travel time has to be a constant. The travel time, T, is calculated in HYMO as

$$T = \frac{\text{reach length}}{\text{average velocity}} = \frac{2S}{I + O} \quad (22)$$

where S is the storage based on end areas, I is the inflow, and Q is the outflow. The wave velocity c, therefore, is

$$c = \frac{L}{T} = \frac{1}{2}\frac{I + O}{A_{\text{av}}} = \frac{Q^{j}_{i} + Q^{j}_{i+1}}{A^{j}_{i} + A^{j}_{i+1}} \quad (23)$$

This implies that

$$c = \frac{dQ}{dA} = \frac{Q}{A} \quad (24)$$

This means that the wave velocity in HYMO is defined by the $Q - A$ chord rather than by the tangent. This is true only for a linear channel where

$$u(x) = \frac{Q}{A} = f(x) \quad (25)$$

This implies that the velocity, u, will be independent of discharge or storage and travel time must necessarily be a constant.

SSARR Model

The U.S. Army Corps of Engineers (14) uses a continuous-time, stream-flow simulation and reservoir regulation model, called SSARR. The model represents a channel by a number of reaches through each of which storage is essentially routed. This amounts to using Eq. 12 where $a =$

0.0 and $b = 0.5$ for each reach. Flood wave modification, therefore, depends on the number of reaches employed.

SWMM Model

The storm water management model (SWMM), developed by the U.S. Environmental Protection Agency (15), is widely used in the United States for urban storm water analysis. In the channel routing phase, a finite-difference form of the continuity equation is employed using weighting coefficients, w_x and w_t, respectively, in space and time, which essentially are $w_x = 1 - a$, and $w_t = b$. When convective acceleration terms are included in the model, then $a = 0.45$ and $b = 0.55$ are used.

MUSKINGUM–CUNGE METHOD

Cunge (2) proposed an explicit finite-difference scheme for solving Eq. 2, which may also be a basis for a generalized treatment of kinematic wave models. The scheme centers the time derivative by taking $b = 0.5$ and retains the weighting coefficient a in space. The celerity, c, is taken as an average constant value for the reach or computational cell. Equation 2 can be written in finite-difference form as

$$\frac{1}{c\Delta t}[(1-a)(Q_{i+1}^{j+1} - Q_{i+1}^{j}) + a(Q_i^{j+1} - Q_i^j)] + \frac{1}{2\Delta x}(Q_{i+1}^j - Q_i^j + Q_{i+1}^{j+1} - Q_i^j) = 0 \tag{26}$$

By solving for Q_{i+1}, Eq. 26 can be written as the classical Muskingum equation:

$$Q_{i+1}^{j+1} = C_1 Q_i^j + C_2 Q_i^{j+1} + C_3 Q_{i+1}^j \tag{27}$$

or

$$Q_4 = C_1Q_1 + C_2Q_2 + C_3Q_3$$

where

$$C_1 = \frac{\Delta t + 2aK}{2K(1-a) + \Delta t} \tag{28}$$

$$C_2 = \frac{2K(1-a) - \Delta t}{2K(1-a) + \Delta t} \tag{29}$$

$$C_3 = \frac{\Delta t - 2aK}{2K(1-a) + \Delta t} \tag{30}$$

and

$$K = \frac{\Delta x}{c} \tag{31}$$

$$C_1 + C_2 + C_3 = 1 \tag{32}$$

The unit of K is time, and it has the connotation of storage-delay time, travel time, translation time, or lag time. It can be estimated from either the Kleitz–Seddon law, hydrographic analysis, or observations.

Cunge (2) showed that Eqs. 26–32 constitute a second-order approximation of the diffusion wave equation if the weighting coefficient a is evaluated as

$$a = \frac{1}{2}\left(1 - \frac{Q}{BS_o\Delta x}\right) \tag{33}$$

where S_0 is the channel bed slope. Cunge derived Eq. 23a from a Taylor series expression of $Q(x + \Delta x, t + \Delta t)$ in the finite-difference form of Eq. 2 and a comparison with the coefficients of the diffusion wave equation for regular channels.

Equation 33 specializes to the equation of Kalinin and Milyukov (16) for $a = 0$:

$$\Delta x = \frac{Q}{S_oBc} = \frac{Q}{S_o(dQ/dh)} \tag{34}$$

where h is the flow depth. Equation 34 can be used to compute the length of subreaches for flow routing in a channel reach.

In the traditional Muskingum method, a single value of a or Δx is used for the entire duration of routing. That can be accomplished by evaluating Eq. 33 or 34 for a representative value of Q and corresponding values of B and c, or dQ/dh. In irregular channels, the average values of these parameters for the subreach should be used. The value of a, it is found, depends on Δx.

Ponce (17) proposed a simplified Muskingum routing equation by taking $\Delta t/K$ and a in Eqs. 26–31 as

$$\frac{\Delta t}{K} = 1, a = 0 \tag{35}$$

Then, it follows that

$$C_1 + C_2 + C_3 = \tfrac{1}{3} \tag{36}$$

leading to the simplified Muskingum routing equation,

$$Q_{i+1}^{j+1} = \tfrac{1}{3}[Q_i^j + Q_i^{j+1} + Q_{i+1}^j] \tag{37}$$

Physically, Eqs. 35 and 36 fix Δt and Δx, and K is the time taken by a flood wave traveling a distance Δx at celerity c given by Eq. 31. Therefore, the Courant number c_N is

$$c_N = \frac{c\Delta t}{\Delta x} = 1 \tag{38}$$

implying equality between flood-wave celerity c and grid celerity $\Delta x/\Delta t$.

Ponce (17) defined a grid Reynolds number R_g (the ratio of physical or hydraulic diffusivity to numerical diffusivity) from Eqs. 33 and 36 or Eq. 34 as

$$R_g = \frac{Q}{BS_oc\Delta x} = 1 \tag{39}$$

which states that the channel diffusivity $Q/(2BS_o)$ is equal to the grid diffusivity $c\Delta x/2$. In Ponce's method,

Δx and Δt can be computed from flow variables by using Eqs. 35 and 39. For example, Δx is given by Eq. 34 or

$$\Delta x = \frac{q}{cS_o} \tag{40}$$

and Δt by Eq. 39,

$$\Delta t = \frac{\Delta x}{c} = \frac{q}{S_o c^2} \tag{41}$$

where q is the unit-width discharge. For natural (nonprismatic) channels, Eq. 37 relates the channel friction to cross-sectional shape and expresses the steady-state discharge relation. Using Eq. 38 in Eq. 40 yields

$$\Delta x = \frac{A}{nBS_o} \tag{42}$$

and

$$\Delta t = \frac{\Delta x}{c} = \frac{A^{2-n}}{\alpha n^2 BS_o} \tag{43}$$

The routing coefficients C_1, C_2, and C_3 can be expressed in terms of c_N and R_g by using Eqs. 31, 33, 38, and 39:

$$C_0 = 1 + c_N + R_g \tag{44}$$

$$C_1 = \frac{1 + c_N - R_g}{C_o} \tag{45}$$

$$C_2 = \frac{-1 + c_N + R_g}{C_o} \tag{46}$$

$$C_3 = \frac{1 - c_N + R_g}{C_o} \tag{47}$$

where c_N and R_g are expressed in terms of $B, c, \Delta x, \Delta t$, and Q.

If there is lateral inflow q_L, the Muskingum equation 27 can be modified as

$$Q_{i+1}^{j+1} = C_1 Q_i^j + C_2 Q_i^{j+1} + C_3 Q_{i+1}^j + Q_L \tag{48}$$

in which

$$Q_L = \frac{2cq_L \Delta t}{(\Delta t/K) + 2(1-a)} \tag{49}$$

where q_L is the unit-width lateral inflow. Because $c = \Delta t/K$ and if $K = \Delta t$ and $a = 0$, Eq. 50 reduces to

$$Q_L = \frac{2q_L \Delta x}{3} \tag{50}$$

It is pertinent at this point to comment on the role of the bed slope S_o and the frictional slope S_f in the Muskingum–Cunge method. In prismatic channels, S_o is used as one of the main channel parameters. Under steady-state, uniform conditions, it is known that $S_o = S_f = S_e$, where S_e is the energy slope. Under steady-state but nonuniform conditions, $S_o \neq S_e = S_f$. In the Muskingum–Cunge method, linearization (or the Taylor series approximation) of the flow is performed around the steady-state uniform or equilibrium flow condition represented by Q_o which permits using S_o in Eq. 33 or 34. In actual practice, however, S_o is not often readily determined, owing largely to local channel bed irregularities. For such channels, S_f is more readily obtained from a given value of Manning's roughness coefficient. Thus, it is more convenient to use S_f as an estimator of S_o. Ponce (18) used S_f in lieu of S_o in his work on linearized diffusion wave modeling.

MUSKINGUM–CUNGE METHOD WITH VARIABLE PARAMETERS

Ponce and Yevjevich (6) considered the space–time variation of K and a as the flow varied. In this case, Δt is usually fixed, and Δx and S_o are specified for each computational cell comprising four grid points. This requires determining flood wave celerity c and the unit-width discharge q for each computational cell. The Muskingum–Cunge method requires calculating the average values of Q and c for each computational cell to compute K and a. Ponce and Yevjevich (6) state three ways of determining c and q for use in computing C_N and R_g: (1) using a two-point average of values at grid point (i,j) and $(i+1,j)$; (2) using a three-point average of values at grid points (i,j), $(i+1)$, and $(i,j+1)$; and (3) using a four-point average calculation by iteration. The average values for a four-point scheme can be expressed bt taking the average at four points (19). Holden and Stephenson (19) showed through numerical experiments that parameter a is virtually independent of grid spacing. Furthermore, the lower the value of a, the greater the attenuation in flood peak. This means that the closer a is to zero, the greater attenuation occurs as numerical diffusion. Although the values of a found are close to 0.5 for many flow conditions, the value of a drops significantly lower for river channels because more gentle bed slopes lead to higher attenuation of a flood hydrograph. The implicit formation of the Muskingum–Cunge method has no particular advantage over the explicit one, and hence the latter may be preferable.

KOUSISS MODEL

Koussis (20) proposed a generalized numerical solution of Eq. 2 in which discretization was carried out only in space and continuous functions for time derivatives were retained. Considering c as an average value for the computational cell, Eq. 2 was written as an ordinary differential equation in Q_{i+1}. Subject to the initial condition $Q_{i+1}(0) = Q_i(0) = Q(x, t = 0)$, the resulting equation was solved by assuming a linear variation of $Q_j(t)$ over Δt and then expressing it in the form of the Muskingum equation.

MODEL PARAMETERS

Four parameters are involved in the previous kinematic wave models: Δx, Δt, a, and c. These parameters are used to compute the routing coefficients. The parameters can be constant (linear case) or variable (nonlinear case).

Spatial Grid Spacing

A single-valued storage function cannot be prescribed for long river reaches, and floods should be routed by dividing the reach length L into N subreaches of length Δx. Laurenson (21,22) has shown that Δx and the weighting parameter a are not independent of each other in that a decreases with Δx or as storage becomes less distributed. Because a cannot be negative, Δx must have a lower limit, or N must have a finite upper limit. Nash (23) argued that unrealistic negative outflows at the start of the outflow hydrograph were the result of applying the Muskingum method to distributed storages ($a \neq 0$). Weinmann and Laurenson (1) showed that these negative outflows can be ignored under certain conditions.

Temporal Grid Spacing

If Δt is much smaller than $\Delta x/c$, then the disturbance might not have traveled distance Δx. For $a \neq 0$, computation of variables at the current section may lead to unrealistic results such as a dip in the outflow hydrograph or negative outflows for an initially dry channel. The best time step for the kinematic wave model can be taken as $\Delta t = \Delta x/c$.

Weighting Factor, *a*

Strictly speaking, a can take on any value from zero to one. The value $a > 0.5$ results in amplifying flood waves and is therefore not important in flood routing. The value $a = 0.5$ for all values of $\Delta x/\Delta t$ results in pure translation of a flood wave (2), corresponding to fully distributed storage. The values $a < 0.5$ introduce numerical diffusion resulting in wave attenuation. For the extreme case, $a = 0$ corresponds to fully concentrated storage or a reservoir that has an instantaneous response and attenuating inflow peak. This discussion then shows that when Δx and Δt are chosen within prescribed limits, a flood wave can be both attenuated and translated by an appropriate choice of a. This is similar to what is done by using lag and route models that treat translation and attenuation separately. Translation can also be achieved by choosing $a = 0$ and an appropriate value of N, when concentrated storages are arranged in series, as in the Kalinin–Milyukov model. Frequently, a constant value of a will be sufficient, unless it varies greatly.

Wave Celerity, *c*

In kinematic wave models, c for a given reach is a function only of flow depth, for the rating curve is a single-valued function. In the coefficient representation of these models, a flood wave is attenuated by taking $a < 0.5$. Similar to kinematic wave models, the storage routing models commonly employed in hydrology use a single-valued storage–discharge curve. Koussis (5,20,24,25), Williams (13), and Ponce (4), amongst others, included a looped rating curve in kinematic wave models and thereby corrected them for dynamic effects.

To determine the average reciprocal wave celerity, the channel reaches should be selected as morphologically similar. For natural rivers, the variations in channel cross sections, bed slope, and roughness may be so great that it may not suffice to use only two $A(Q)$ curves at i and $(i + 1)$ cross sections, unless Δx is quite small. Nevertheless, it is reasonable to compute the average reciprocal wave celerity from steady flow $A(Q)$ curves at several cross sections. In prismatic channels, this may be computed from the slope of the $A(Q)$ curve for unsteady-state flow at i and $(i + 1)$ cross sections.

RELIABILITY CONCEPTS IN RESERVOIR DESIGN

Demetris Koutsoyiannis
National Technical University

INTRODUCTION

The reliability of a system is defined as the probability that the system will perform the required function for a specified period of time under stated conditions. Reliability is the complement of the probability of failure (or risk), the probability that the "loading" will exceed the "capacity." Denoting α as the reliability, β the probability of failure, and $P[\omega]$ the probability of an event ω, the mathematical expression of this definition is

$$\alpha := P[L(t) < C(t); t \in \Pi] =: 1 - \beta \tag{1}$$

where $L(t)$ and $C(t)$ represent the loading and capacity, respectively, at time t, within a certain time period Π (e.g., a year). The failure of a system can be classified as *structural failure* or *performance failure*. Structural failure involves damage of the structure or facility, hindering its ability to function as desired in the future, whereas performance failure does not necessarily involve structural damage but rather inability of the system to perform as desired at some time within the period of interest, which results in temporary unfavorable consequences.

RESERVOIR DYNAMICS

A reservoir's function is to regulate natural inflows, which vary irregularly, to provide outflows at a more regular rate that is determined by water demand for one or more uses (water supply, irrigation, hydropower), temporarily storing the surplus, when inflows exceed outflows. Reservoir dynamics are more conveniently expressed in discrete rather than continuous time.

The quantities that are necessary to describe dynamics are the following:

Storage S_t. More precisely known as *active storage,* it is the volume of water stored, at time t, above the minimum level, which is determined either technically (i.e., as the level of the lowest valve of off-take) or legally by a decree imposing rules for a reservoir's operation. Active storage S_t ranges between zero and a maximum value c imposed by the reservoir size, which corresponds to the level of the spillway crest (or some specified level above it when the sluice gates are constructed over the spillway). During floods, excess water is routed through the spillway, which causes temporary storage above the normal limit c. This is known as flood control storage. Water storage below the minimum level, known as *dead* or *inactive storage,* serves two main purposes: It provides volume for sediment accumulation and environmental protection, as it protects the habitat of the reservoir during dry periods by hindering complete emptying. Associated with the last function is also conservation of the quality of the landscape. This article is focused on the design of the active storage of a reservoir; some notes on additional storage zones are contained in the last section of the article.

Net Inflow X_t. It is the algebraic sum of cumulative inflows to the reservoir from time $t-1$ to time t, minus the losses during the same time period. Inflows include runoff from the catchment upstream of the reservoir (typically, the main component of inflows), rainfall on the surface area of the reservoir, and, possibly, water artificially conveyed from other sources (e.g., interbasin transfers through tunnels or pipelines). Losses include evaporation from the surface area of the reservoir, possibly seepage to groundwater, and leakage under or through the dam.

Water Demand, δ_t. It is the sum of all water requirements for the different water uses served by the reservoir for the time period $(t-1, t)$. The demand may vary with time (e.g., due to seasonal agricultural demand or due to some rule, usually based on the quantity of water in the reservoir).

Release, R_t. Also known as draft, withdrawal, or outflow, it is the actual amount of water taken from the reservoir to satisfy water demand during the time period $(t-1, t)$. When there is a sufficient amount of water in the reservoir, R_t equals demand δ_t; otherwise $R_t < \delta_t$.

Spill, W_t. It is the excess water that, during times of floods and simultaneously high reservoir storage, cannot be stored in the reservoir due to the upper reservoir storage limit c.

Reservoir dynamics are easily expressed by the law of mass conservation, or equivalently, the water balance equation. Considering that S_t is limited between 0 and c, the water balance equation is easily formulated as

$$S_t = \max(0, \min(S_{t-1} + X_t - \delta_t, c)) \tag{2}$$

In addition, the release is determined as

$$R_t = \min(S_{t-1} + X_t, \delta_t) \tag{3}$$

and the spill as

$$W_t = S_{t-1} - S_t + X_t - R_t = \max(0, S_{t-1} + X_t - \delta_t - c) \tag{4}$$

Equations 2–4 apply when the inflow and withdrawal occur at constant rates throughout the period $(t, t-1)$—this could be called the "steady" model. A simple

INTRODUCTION

The reliability of a system is defined as the probability that the system will perform the required function for a specified period of time under stated conditions. Reliability is the complement of the probability of failure (or risk), the probability that the “loading” will exceed the “capacity.” Denoting α as the reliability, β the probability of failure, and $P[\omega]$ the probability of an event ω, the mathematical expression of this definition is

$$\alpha := P[L(t) < C(t); t \in \Pi] =: 1 - \beta \qquad (1)$$

where $L(t)$ and $C(t)$ represent the loading and capacity, respectively, at time t, within a certain time period Π (e.g., a year). The failure of a system can be classified as *structural failure* or *performance failure*. Structural failure involves damage of the structure or facility, hindering its ability to function as desired in the future, whereas performance failure does not necessarily involve structural damage but rather inability of the system to perform as desired at some time within the period of interest, which results in temporary unfavorable consequences.

RESERVOIR DYNAMICS

A reservoir’s function is to regulate natural inflows, which vary irregularly, to provide outflows at a more regular rate that is determined by water demand for one or more uses (water supply, irrigation, hydropower), temporarily storing the surplus, when inflows exceed outflows. Reservoir dynamics are more conveniently expressed in discrete rather than continuous time.

The quantities that are necessary to describe dynamics are the following:

Storage S_t. More precisely known as *active storage,* it is the volume of water stored, at time t, above the minimum level, which is determined either technically (i.e., as the level of the lowest valve of off-take) or legally by a decree imposing rules for a reservoir’s operation. Active storage S_t ranges between zero and a maximum value c imposed by the reservoir size, which corresponds to the level of the spillway crest (or some specified level above it when the sluice gates are constructed over the spillway). During floods, excess water is routed through the spillway, which causes temporary storage above the normal limit c. This is known as flood control storage. Water storage below the minimum level, known as *dead* or *inactive storage,* serves two main purposes: It provides volume for sediment accumulation and environmental protection, as it protects the habitat of the reservoir during dry periods by hindering complete emptying. Associated with the last function is also conservation of the quality of the landscape. This article is focused on the design of the active storage of a reservoir; some notes on additional storage zones are contained in the last section of the article.

Net Inflow X_t. It is the algebraic sum of cumulative inflows to the reservoir from time $t-1$ to time t, minus the losses during the same time period. Inflows include runoff from the catchment upstream of the reservoir (typically, the main component of inflows), rainfall on the surface area of the reservoir, and, possibly, water artificially conveyed from other sources (e.g., interbasin transfers through tunnels or pipelines). Losses include evaporation from the surface area of the reservoir, possibly seepage to groundwater, and leakage under or through the dam.

Water Demand, δ_t. It is the sum of all water requirements for the different water uses served by the reservoir for the time period $(t-1, t)$. The demand may vary with time (e.g., due to seasonal agricultural demand or due to some rule, usually based on the quantity of water in the reservoir).

Release, R_t. Also known as draft, withdrawal, or outflow, it is the actual amount of water taken from the reservoir to satisfy water demand during the time period $(t-1, t)$. When there is a sufficient amount of water in the reservoir, R_t equals demand δ_t; otherwise $R_t < \delta_t$.

Spill, W_t. It is the excess water that, during times of floods and simultaneously high reservoir storage, cannot be stored in the reservoir due to the upper reservoir storage limit c.

Reservoir dynamics are easily expressed by the law of mass conservation, or equivalently, the water balance equation. Considering that S_t is limited between 0 and c, the water balance equation is easily formulated as

$$S_t = \max(0, \min(S_{t-1} + X_t - \delta_t, c)) \qquad (2)$$

In addition, the release is determined as

$$R_t = \min(S_{t-1} + X_t, \delta_t) \qquad (3)$$

and the spill as

$$W_t = S_{t-1} - S_t + X_t - R_t = \max(0, S_{t-1} + X_t - \delta_t - c) \qquad (4)$$

Equations 2–4 apply when the inflow and withdrawal occur at constant rates throughout the period $(t, t-1)$—this could be called the “steady” model. A simple modification of the equations allows for the case where the inflow (or withdrawal) is highly seasonal and can (in the limit) be modeled as a sudden occurrence; this could be called the “sudden” model. These two models, called “simultaneous” and “staggered” by Pegram (1), bound all the behavior observed in real reservoirs.

DEFINITION OF RELIABILITY APPLIED TO A RESERVOIR

Now, the previously stated general definition of reliability [also known as dependability; e.g., (2) p. 312] can be applied to a reservoir. It is observed that the failure of a reservoir's function is a performance failure, a failure to meet the water demand. At time t, the loading is the water demand δ_t, and the capacity is the sum of S_{t-1} (storage at time $t-1$) and X_t (inflow from time $t-1$ to t). Thus, application of Equation 1 yields

$$\alpha = 1 - \beta = P[\delta_t < S_{t-1} + X_t] \tag{5}$$

Considering Equations 2 and 3, the following equivalent and more convenient expressions are found:

$$\alpha = P[S_t > 0], \beta = P[S_t = 0] \tag{6}$$

and

$$\alpha = P[R_t = \delta_t], \beta = P[R_t < \delta_t] \tag{7}$$

In this context, the demand δ_t is regarded as a known quantity at any time instant t. All other quantities involved, namely, S_t, X_t, R_t, and W_t, are regarded as random variables. Given the storage capacity c, the demand δ_t, and the probability distribution and autocorrelation functions of the input X_t, in theory, the probability distributions of output variables S_t, R_t, and W_t can be determined in terms of that of X_t; this, however, is not an easy task due to the nonlinearity of the dynamics expressed in Equations 2–4. Theoretically, once the distribution function of S_t or R_t has been determined, the reliability α is obtained directly from Equation 6 or 7, respectively. However, although the theoretically based calculations unavoidably involve complete knowledge of the distribution function of S_t and R_t, the reliability α can be determined in an alternative, much simpler, manner. Under the assumptions of stationarity and ergodicity, α can be estimated from a historical (for an existing reservoir) or synthesized (via simulation) time series of storage s_t or release r_t of adequate length n. (Here lower case symbols were used for values of the random variables S_t and R_t.) Specifically, the estimate of α based on Equation 6 is

$$\alpha = \frac{1}{n}\sum_{t=1}^{n}[1 - U(-s_t)] \tag{8}$$

where $U(x)$ is Heaviside's unit step function, where $U(x) = 1$ for $x \geq 0$ and $U(x) = 0$ for $x < 0$. Correspondingly, the estimate of α based on Equation 7 is

$$\alpha = \frac{1}{n}\sum_{t=1}^{n} U(r_t - \delta_t) \tag{9}$$

The purpose of the sum in Equation 8 (or 9) is to count the periods when storage is not zero (or release r_t equals the demand δ_t). Thus, reliability is expressed as the proportion of time steps when the system performs as desired. For this reason, α has also been termed *time-based* reliability. Here, it must be observed that although Equations 5–7 are mathematically equivalent to each other, as are Equations 8 and 9, when applied to historical time series, they may result in different estimates. For example, a city's water supply may not be allowed to empty, as restrictions on releases are applied before this situation is reached. In such a case, Equation 8 may result in the erroneous estimate $\alpha = 1$, whereas Equation 9 will estimate the reliability correctly if the desired demand, before restrictions, is entered into the calculations. Thus, Equation 9 is preferable when dealing with historical time series, but both are equivalent in synthetic simulations; moreover, application of Equation 8 is faster as it does not require simulating releases at all (only Equation 2 needs to be applied).

The stationarity assumption that was inherent in the previous analysis is satisfactory when the time step is a year (either calendar or hydrologic). However, the annual time step is usually too large and hides the variation of both inflows and demand within a year, which may result in a failure some time within the year that is recovered at the end of the year. Therefore, a smaller time step (e.g., monthly) is usually chosen, so that one year corresponds to $k > 1$ (e.g., 12) time steps. On this finer timescale, all processes depend on the time step in a periodic manner, that is, they are cyclostationary. Yet, the reliability and failure probability are usually expressed on the annual scale, in which stationarity is redeemed. To shift from the finer scale to the annual scale, the rule adopted is that a failure occurring in one or more finer scale time steps is regarded as a failure for the year. Using this rule, Equation 6 becomes

$$\alpha' = P\left[\bigcap_{i=1}^{k}(S_{t-i} > 0)\right], \beta' = P\left[\bigcup_{i=1}^{k} S_{t-i} = 0\right] \tag{10}$$

where the symbols α' and β' were used instead of α and β to distinguish from time-based reliability, whereas the symbol ‘$\bigcap$’ indicates that all of the following events should occur simultaneously and ‘$\bigcup$’ indicates that any of the following events should occur. Similarly, Equation 7 becomes

$$\alpha' = P\left[\bigcap_{i=1}^{k}(R_{t-i} = \delta_{t-i})\right], \beta' = P\left[\bigcup_{i=1}^{k} R_{t-i} < \delta_{t-i}\right] \tag{11}$$

or alternatively,

$$\alpha' = P\left[\sum_{i=1}^{k} R_{t-i} = \sum_{i=1}^{k}\delta_{t-i}\right], \beta' = P\left[\sum_{i=1}^{k} R_{t-i} < \sum_{i=1}^{k}\delta_{t-i}\right] \tag{12}$$

Likewise, Equations 8 and 9 become

$$\alpha' = \frac{k}{n}\sum_{p=1}^{n/k}\min\{[1 - U(-s_t)]; t = k(p-1)+1, \ldots, kp\} \tag{13}$$

$$\alpha' = \frac{k}{n}\sum_{p=1}^{n/k}\min\{U(r_t - \delta_t); t = k(p-1)+1, \ldots, kp\} \qquad (14)$$

respectively. The sums in Equations 13 and 14 count the number of years in which no failure has occurred. Apparently, α' and β' provide information on the occurrence of a failure within a year and not in the time period during which the failure lasted. Therefore, they have been known as *occurrence-based* reliability and failure probability, respectively. An overall indication of the duration of failures within an average year can be obtained by applying Equation 8 or 9 and estimating β, the time-based probability of failure.

Apart from occurrence-based and time-based reliability, an additional reliability measure has been often used, which is not expressed in terms of probability (and thus, literally does not comply with the general definition of reliability). This is the so-called *volumetric* or *quantity-based* reliability, expressed as the ratio of the average release to demand:

$$\alpha_V = 1 - \beta_V = E\left[\sum_{i=1}^{k} R_t\right] \bigg/ \sum_{i=1}^{k} \delta_t \qquad (15)$$

Given that a failure that occurs in a year does not extend over the whole year, and, in addition, the release during the failure is not necessarily zero but some positive quantity smaller than demand, it is easily concluded that

$$\alpha' \leq \alpha \leq \alpha_V \qquad (16)$$

Among the three measures of reliability, the most important and most frequently used is the severest, the occurrence-based reliability α'. Another means for expressing virtually the same concept is the return period or recurrence interval of emptiness, T. This is the mean time between two consecutive empty states of the reservoir, and it is none other than the reciprocal of the probability of failure β' (1):

$$T := 1/\beta' = 1\ (1 - \alpha') \qquad (17)$$

which is expressed in years (given that α' and β' are expressed on an annual timescale). The concept of the return period of emptiness of a reservoir is similar to that typically used for design floods. The difference is that in design floods, failure is the exceedance of the magnitude of the design flood, whereas failure in a reservoir is emptying of the reservoir. Typical design values of reliability and return period for reservoir design are $\alpha' = 99\%$ ($T =$ 100 years) for municipal water supply reservoirs, $\alpha' = 70 - 85\%$ ($T = 3.3 - 6.7$ years) for irrigation reservoirs in subhumid climates, and $\alpha' = 80 - 95\%$ ($T = 5 - 20$ years) for irrigation reservoirs in arid climates (2, p. 313).

TRADITIONAL RESERVOIR DESIGN PROCEDURES

Most hydraulic structures, such as flood protection works and drainage networks, whose load varies randomly, have been designed on a probabilistic basis, adopting a certain reliability level or, equivalently, a certain return period for the design flood. Traditionally, however, this has not been the case in reservoir design, which has rarely been based on sound probability. This is obvious even from the terminology traditionally used. For example, the use of the term *firm yield* implies a nonprobabilistic, or failure-free concept. Specifically, the firm yield of a reservoir has been defined as the draft or withdrawal that lowers the water content in a reservoir from a full condition to its minimum allowable level just once during a critical historical drought. (3, p. 27.8; 4, p. 534). It has been characterized as essentially the no-failure yield (3, p. 27.8). In a probabilistic context, however, any draft has a nonzero probability of failure (unless the demand is less than the hypothetical lower bound of the inflow distribution, which can be plausible only for perennial streams; this is unusual).

Several procedures have been widely used in reservoir design, which are rather deterministic and not consistent with the reliability concept. The most common has been *mass curve analysis* and its variations. A mass curve is a plot of cumulative inflow volumes (typically based on historical discharge records) as a function of time. Using this plot, the firm yield, as well as the required reservoir storage to attain this firm yield, can be determined graphically. In addition, the method can determine the required storage for a smaller target release. This graphical method was developed 120 years ago (5) and has been widely used until now, although criticized (6) for not providing information on the probability of failure and for the fact that the reservoir capacity determined by this method increases as the arbitrary length of available observed inflow data increases. As shown by Feller (7), this increase is asymptotically proportional to the square root of the length of the record.

A first variation of the method is its application using synthetic, rather than observed, data (6). This eliminates the drawback of the arbitrary length of the record and also provides some measure of uncertainty by applying the same procedure using different generated synthetic series. However, this kind of description of uncertainty is not consistent with a rational definition of reliability (e.g., that of the previous section).

A more theoretical flavor for the method has been given by the so-called *range analysis*, commenced by the work of Hurst (8; see also 9, p. 184). Range is essentially the algebraic difference of the maximum and minimum departures of the mass curve from the straight line that joins its starting and ending points. The range concept has greatly contributed to the understanding and description of the so-called Hurst phenomenon in hydrology, climatology, and other geophysical sciences. Applied to a reservoir, the range represents the required storage of a reservoir operating without any spill or other loss and providing a constant outflow equal to the mean flow. Obviously, this is an oversimplification of a real reservoir. On the other hand, the range concept involves complexity in estimation, and simpler and more efficient methods have been proposed that can be used instead of range analysis (10).

An additional design method is the so-called *sequent-peak analysis* (11, p. 274; 12, p. 400). Essentially, it is a tabulated version of mass-curve analysis and can also incorporate in the calculations, apart from runoff, the effects of precipitation, evaporation, and leakage. The method does not involve the reliability concept, nor does it consider spills from the reservoir.

SIMPLIFIED RELIABILITY-BASED PROCEDURES FOR RESERVOIR DESIGN

As already mentioned, the analytical determination of reliability in the general case of a reservoir fed by inflows with seasonality, that have arbitrary probability distribution, and autocorrelation functions is a very difficult, if not impossible, task (1). Therefore, existing analyses have been based on several simplifications. However, the results of such analyses are very useful, at least for the initial stage of reservoir design. The typical simplifying assumptions are to

- neglect secondary inflows (precipitation) and losses (evaporation, leakage);
- neglect seasonality by the adoption of an annual time step;
- neglect autocorrelation and assume that inflows are independent in time;
- use a specific distribution function for inflows, typically two-parameter such as normal, lognormal, or gamma.

The objective of such probability-based theoretical analyses is to determine the relation of the following three quantities:

- reservoir size c; it is usually standardized as $\kappa := c/\sigma$, where σ is the standard deviation of annual net inflow X_t;
- demand δ, which is assumed constant for all years; it is usually standardized as $\varepsilon := (\mu - \delta)/\sigma$, where μ is the mean of annual net inflow X_t; ε has been termed the standardized inflow (8; 3, p. 27.7) or the *drift* (1);
- probability, expressed either as reliability α, probability of failure β, or return period T; because of the annual time step used, time-based reliability (Equations 6, 7) is identical to occurrence-based reliability (Equations 10–12).

The first among the probabilistic approaches used in such analyses is discretization of reservoir storage into several zones, each representing a certain state, and the use of a Markov chain model to represent transitions from state to state (13,14; see also 9, p. 264).

A second method is stochastic (Monte Carlo) simulation, in which a long synthetic series of inflows is generated from the appropriate distribution function and then transformed into a series of storage values using Equation 2; reliability is then easily determined from the storage time series using Equation 8. Gould (15) used this method to propose a reservoir size–yield–reliability formula, fitted to 240 sets of Monte Carlo simulations for various combinations of demand, reservoir size, and skewness of gamma distributed inflows:

$$(\varepsilon + 0.15)[\kappa + d_1(\alpha, \gamma)] = d_2(\alpha, \gamma) \quad (18)$$

where d_1 and d_2 are coefficients depending on reliability α and skewness γ and are given by nomographs (see also 2, p. 323). McMahon and Mein (16) adapted this formula to indicate reliability more explicitly; this can be estimated from the standardized normal variate z_α corresponding to α, using the equation

$$z_\alpha = 2\sqrt{\varepsilon(\kappa + d(\alpha)\sigma/\mu)} \quad (19)$$

where d is a coefficient depending on reliability α and is given by a table (see also 3, p. 27.14).

A more accurate and rigorous theoretical methodology to estimate the reservoir size–yield–reliability relationship was developed by Pegram (1). This was based on finite-difference and integral equations, which employ reservoir dynamics (Equation 2) in a probabilistic context to determine the return period of emptiness. Pegram applied his methodology for normal, lognormal, and discrete inputs both independent and serially correlated. His results, when compared to those of the Gould method (Equations 18–19) indicate that the latter underestimates the reservoir size required to attain a certain reliability level. Using Pegram's results for normally distributed inflows, which were verified and expanded here with extended simulations, the following approximate relationship has been established:

$$\ln(T - 1) = 2(\varepsilon + 0.25)(\kappa + 0.5)^{0.8} \quad (20)$$

This is valid for $T > 2 (\alpha > 0.5)$ and can be alternatively written as

$$\begin{aligned}\ln(T - 1) &= -\ln(1/\alpha - 1) \\ &= (2/\sigma^{1.8})(\mu + 0.25\sigma - \delta)(c + 0.5\sigma)^{0.8} \quad (21)\end{aligned}$$

For known mean μ and standard deviation σ of inflows, Equation 21 can directly yield either the reliability α for a known reservoir size and demand, the reservoir size c for a given demand and reliability, or the demand δ that can be met at a given reliability for a known reservoir size. Equation 20 is graphically depicted in Fig. 1 in comparison with Pegram's exact results. This equation is suggested for preliminary estimates, but it should be applied with caution for the reasons explained in the next section.

Effects of Inflow Characteristics on Reservoir Size

As explained earlier, simplified design procedures such as that using Equation 20 are based on a number of abridging assumptions about inflows. Significant differences may appear if these assumptions are not valid. More specifically, what may cause significant departures from Equation 20 are hydrologic persistence, especially long-term, and the seasonal distribution of inflow and demand. Less significant differences are caused by the skewness of inflows and secondary inflows and losses.

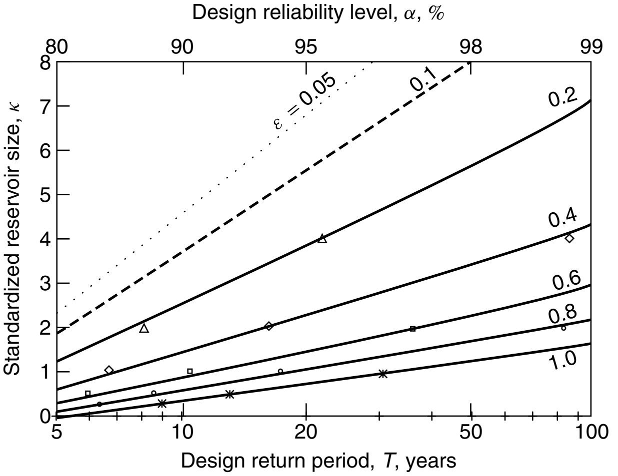

Figure 1. A simple representation of reservoir size–yield–reliability: Standardized reservoir size ($\kappa = K/\sigma$) required to achieve a certain drift ($\varepsilon = (\mu - \delta)/\sigma$) at a certain reliability level for independent inputs normally distributed. Lines are constructed from Equation 20, whereas plotted points are theoretical results by Pegram (1) for $\varepsilon = 0.2$ (triangles), 0.4 (diamonds), 0.6 (squares), 0.8 (circles), and 1.0 (stars).

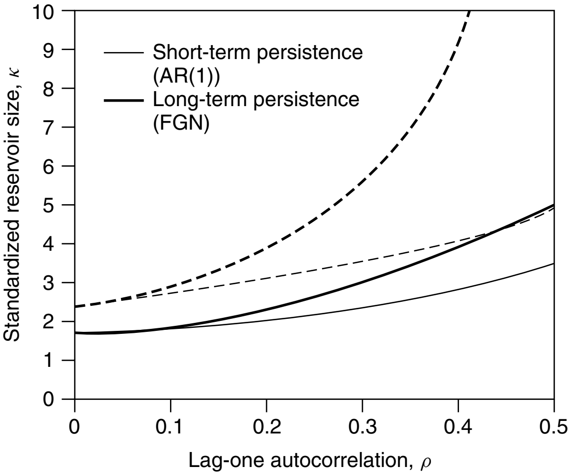

Figure 2. Effects of short-term and long-term hydrologic persistence of inflows on the standardized reservoir size κ required to achieve a drift $\varepsilon = 0.8$ at a reliability level $\alpha = 98\%$ (continuous lines) and a drift $\varepsilon = 0.2$ at a reliability level $\alpha = 90\%$ (dashed lines). Results are obtained by simulation.

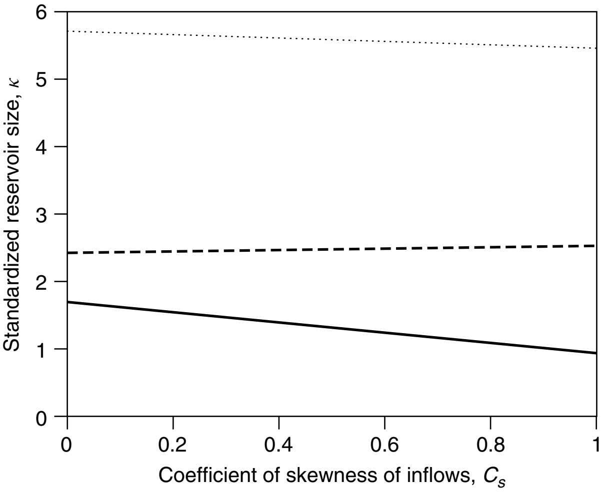

Figure 3. Effect of the skewness of inflows on the standardized reservoir size κ required to achieve a drift $\varepsilon = 0.8$ at a reliability level $\alpha = 98\%$ (continuous line), a drift $\varepsilon = 0.2$ at a reliability level $\alpha = 90\%$ (dashed line), and a drift $\varepsilon = 0.2$ at a reliability level $\alpha = 98\%$ (dotted line). Results are obtained by simulation using independent two-parameter gamma distributed inflows.

The effect of hydrologic persistence is demonstrated in Fig. 2, which depicts the standardized reservoir size κ required to achieve two combinations of drift and reliability ($\varepsilon = 0.8, \alpha = 98\%$ and $\varepsilon = 0.2, \alpha = 90\%$) versus the lag-one autocorrelation coefficient, ρ. Two cases of hydrologic persistence have been examined, short-term and long-term. In short-term persistence, it was assumed that the inflows follow the autoregressive process of order 1 [AR(1) or Markov], whereas in long-term persistence, it was assumed that they follow the fractional Gaussian noise (FGN) process with Hurst exponent $H = \ln(2 + 2\rho)/\ln 4$. Obviously, the effect of persistence is very significant, especially for long-term persistence and high demand (low drift ε). Thus, the required reservoir size for $\varepsilon = 0.2$ and $\alpha = 90\%$ is $c = 2.4\sigma$ when $\rho = 0$ ($H = 0.5$) and becomes 4 times larger ($c = 9.6\sigma$) when $\rho = 0.4$ ($H = 0.74$).

To quantify the effect of seasonal variation of inflow and demand, it is observed that in the worst case, the total annual inflow comes before the beginning of withdrawal (the "sudden" model). The reservoir dynamics in Equation 2 assumes that inflow and withdrawal are distributed evenly during a year (the "steady" model). If inflow precedes withdrawal, Equation 2 should be modified to read $S_t = \max[0, \min(S_{t-1} + X_t, c) - \delta_t]$. It is then easily determined that extra storage equal to δ is required in addition to that estimated from Equation 21. This worst case, however, is not very realistic, except in arid regions. In the real world, the extra storage capacity required (in addition to that estimated from Equation 21) is a percentage of δ. This can be as high as 50% for water supply reservoirs and 80% for irrigation reservoirs in semiarid regions.

The effect of the skewness of inflows is demonstrated in Fig. 3, which depicts the standardized reservoir size κ required to achieve three combinations of drift and reliability ($\varepsilon = 0.8, \alpha = 98\%$; $\varepsilon = 0.2, \alpha = 90\%$; and $\varepsilon = 0.2, \alpha = 98\%$) versus the coefficient of skewness, C_s. It can be observed that the effect of skewness is not significant; for low draft (high drift ε), this effect can be beneficial (lowering of required storage), but for high draft, the required storage is practically insensitive to skewness.

GENERALIZED SIMULATION PROCEDURE FOR RELIABILITY-BASED RESERVOIR DESIGN

The simplest general procedure for estimating the reservoir size–yield–reliability relationship in an accurate and detailed manner and for any arbitrary inflow characteristics is stochastic (Monte Carlo) simulation. A simplified simulation procedure is outlined as follows:

1. Generate a series of inflows X_t at an appropriate timescale (e.g., monthly) using an appropriate stochastic model (e.g., 17, 18; see also the entry Stochastic Simulation of Hydrosystems).
2. Assume a reservoir size c.
3. Calculate a series of reservoir storages using Equation 2.
4. Estimate the reliability using Equation 13.
5. Repeat steps 3–4 for different reservoir sizes.

This procedure is very simple to execute even in a tabulated form on a spreadsheet.

The drawback of stochastic simulation is that it requires a vast simulation length to find accurate results. It can be shown that the required number of simulated time steps (e.g., months) to estimate the occurrence-based failure probability β' at an acceptable error $\pm\varepsilon\beta'$ and confidence γ is

$$n = k(z_{(1+\gamma)/2}/\varepsilon)^2(1/\beta' - 1) \tag{22}$$

where k is the number of time steps per year and z_p is the p-quantile of the standard normal distribution. For instance, for $k = 12, \gamma = 95\%$ $(z_{(1+\gamma)/2} = 1.96), \varepsilon = 10\%$, and $\beta' = 0.01$, this yields $n = 456,000$ months (38,000 years). Today, this is not a major problem as the required computer time for such a simulation length can be less than one second in a common PC.

The simplified procedure described can be extended to a detailed simulation procedure, which includes, in addition to runoff, the precipitation, evaporation, and leakage of the reservoir. In this case, level–area–volume and level–leakage relationships are required to establish the functions $a(S)$ and $l(S)$ which yield reservoir area a and leakage l for any storage S (usually using interpolation from arrays of tabulated values). In this case, the runoff Q, has to be expressed in equivalent depth units, as are precipitation P and evaporation E. If f is the catchment area, the net inflow becomes

$$X_t = Q_t[f - a(S_{t-1})] + (P_t - E_t)a(S_{t-1}) - l(S_{t-1}) \tag{23}$$

where it was implicitly assumed that variations in the reservoir area and leakage within a time step are not large, so that $a(S_{t-1})$ and $l(S_{t-1})$ can be assumed representative of the entire period within a time step. When the detailed simulation procedure is employed, three time series, instead of one, have to be synthesized. Obviously, Q_t and P_t are cross-correlated, and therefore they cannot be generated independently of each other; a bivariate stochastic model is needed in this case. On the other hand, E_t can be generated independently of the other two series.

Obviously, the simulation procedure, either simplified or detailed, can be applied directly using historical, rather than synthesized inputs. However, due to short record length, the accuracy of results will not be satisfactory.

Extension of the simulation method, combined with optimization, for a multiple reservoir system can be found in References 19 and 20.

DESIGN OF ADDITIONAL STORAGE ZONES OF A RESERVOIR

The design of flood control storage is typically reliability-based but in a very different context from that described for active storage. A failure of the flood routing function of a reservoir is not a performance failure but a structural one: an overtopping of the dam due to a severe flood can result in collapse of the dam. Therefore much lower levels of probability of failure are adopted, of the order of $10^{-3} - 10^{-6}$. The typical steps here are (1) estimation of a design storm, based on statistical analysis of rainfall, for an appropriate return period ($10^3 - 10^6$ years); (2) estimation of the inflow hydrograph using an appropriate rainfall–runoff model; and (3) routing this hydrograph through the spillway and estimation of the outflow hydrograph and the maximum water level. Implicit assumptions in the entire procedure, like the assumption that the reservoir is full at the beginning of the flood, decrease the risk further. It must be noted that several procedures have been proposed that are supposedly risk-free. These are based on the so-called probable maximum precipitation concept. However, it has been argued that a risk-free procedure is an illusion and the value of probable maximum precipitation can be exceeded by a certain probability (e.g., of the order of 10^{-5}; 21).

The sizing of dead storage has been typically based on the expected sediment accumulation in the reservoir for a certain design period (e.g., of the order of 10^2 years). Because of the large design period and the accumulative character of this process, the approach to this problem is very different. Expected values, rather than probabilities, are involved in the calculations. The additional objectives that the dead storage serves, environmental protection (protection of the habitat of the reservoir during dry periods) and conservation of the quality of the landscape, have not been given special attention, until now, and have not been considered in the design procedure. One would expect that, some years after construction, these additional objectives would not be served adequately because the water in the dead volume would be reduced due to sediment accumulation. Fortunately, however, this has not been the case: the implicit assumption that sediments will reach the bottom of reservoir near the dam is not verified. Thus, in large reservoirs, sediment accumulation occurs mainly in the active zone of reservoir (near the entrance of the river to the reservoir) and much less in dead storage. The unfavorable consequence is the reduction of active storage. These problems need to be further investigated in future reservoir designs.

LAKES

WALTER GELLER
UFZ-Centre for Environmental Research
Magdeburg, Germany

Lakes are waterbodies of considerable size that are larger than ponds. *Shallow lakes* are mixed by the wind from the surface to the ground, and the daylight reaches the bottom. *Stratified lakes* are deep enough to be vertically divided into a lighted surface-near *euphotic* zone, where photosynthesis of green plants is possible, and a deep-water *aphotic* zone, which is too dark for photosynthetic activities. In many lakes, thermal vertical stratification is observed as a warm layer near the surface, the epilimnion, and a colder layer below, the hypolimnion. The epilimnion is wind-exposed and well mixed, whereas the deep water layer of the hypolimnion is not included in the mixis process. Introductions to the ecology, hydrology, and limnology of lakes are available in textbooks, handbooks (1,2), and reviews (3–9).

ORIGIN OF LAKE BASINS

Lake basins containing standing waterbodies were formed by different processes; tectonic forces; volcanic, glacial, fluviatile activities; or by solution of easily dissolvable rock such as limestone. Hutchinson (1) ordered the lakes by their mode of origin into about 80 categories. Typical examples are listed by Meybeck (8,10), who also gives numbers of the types of origin, of size, and of age.

Tectonic lakes are found in geological rift valleys; the deepest are Lake Baikal (11) and Tanganyika (12). The Caspian Sea and the Aral Sea (13) are rest areas of the ancient Thetis Sea which was closed by tectonic movements, and they are the largest inland waters in area (374,000 km^2, 64,500 km^2). The oldest inland waters are found among tectonic lakes, some of these, it is estimated, are older than 20 to 30 million years.

Volcanic processes led to the origin of different lake types. *Maar lakes* emerged after singular volcanic events (steam explosions in contact zones of magma and groundwater). Lava dams or emerging volcanoes resulted in reservoir-like lakes, such as L. Kivu and Laguna del Laja (Chile). Large lakes were formed on lava plateaus (L. Myvatn, Iceland) and in *caldera* basins, whereas *crater lakes* are usually small. Lakes at active volcanoes are often heavily acidified by acidic brines rinsing into the lake water (14).

The main types of glacially formed lakes are (1) small *kar lakes* at the slopes of mountains at different altitudes, (2) *piedmont lakes* where glaciers from valleys reached the foreland at the foot of the mountains, and (3) extended *lake districts from low altitude glaciations* as on the Canadian Shield and the circum-Baltic area. Postglacial lakes of temperate climatic zones are only 8 to 12 thousand years old.

In the lowland area of large rivers, the flow of the running rivers often changes, leaving standing waters, oxbows or side waters, as *fluvial lakes*, which were parts of the rivers in the past or are permanently in open connection with the river system.

Lakes are more numerous as size decreases. Meybeck (8,10) gives the estimated worldwide number of lakes, ordered by size classes and by the origin of lake basins. A list of the deepest and largest lakes, by area and by water volume, is given by Herdendorf (15,16), including many uncertainties on the basic data of even the 50 most important inland waters of the world.

WATER BUDGET AND SALINITY OF LAKES

The oceans contain 83.5% of the world's water, the inland waters only 0.015%. Lakes contain a total water volume of 205,000 km^3; about 50% of this total volume is freshwater, on the one side, and saline water on the other side. The deepest and oldest lake, Baikal, has a volume of about 20% of the total freshwater volume of lakes and is the worldwide largest singular freshwater resource. The annual fluxes through the pools of the atmosphere, rivers, and groundwater are 496, 38, and 12 thousand km^3; exchange times are 10 days, 16 days, and 700 years, respectively. The volume of freshwater lakes is 100 thousand km^3; exchange times are 1 month to 500 years [data after (17,18)].

Lakes are standing waters that are usually connected with and included in the flow system of river catchments. The lakes within the catchment systems can be ordered by their degree of connection to the overall water flows (19). Lakes with intensive through-flow have high rates of flushing and water exchange and short retention times. The lake volume compared with the volume of all inflows per year gives the virtual *filling time*. The relation of the outflow and the lake volume gives the net exchange rate of the lake water. Including groundwater exchange, precipitation on the lake surface, and evaporation, the relation of all inputs to all losses of water gives the gross exchange rate; its reciprocal value is the *retention time* or average age of the water.

Depending on the given regional water balance, lake basins are permanently flushed, have an outflow, are in a steady state of the flow of water and of dissolved salts, and, thereby, contain freshwater. In areas with a negative water balance, the river catchments are *endorheic* systems, and terminal lake basins occur without outflows; here, the water finally evaporates, and the inflowing salts accumulate, leaving *saline lakes*. Saline lakes are typical of (semi)arid areas and contain nearly half of the world's lake water volume (20). Saline lakes (with salinities >3%) (21,22) are found in all climatic zones, warm, temperate, and cold regions, where negative water balances are given by large-scale climatic zones or by regional orographic conditions (rain-lee east of the Rocky Mountains in North America, east of the Andes in South America, or in the Iranian basin). Such endorheic river catchments, in which the water flow ends in terminal lakes, are the Jordan River system with the Dead Sea, the system of Lake Titicaca with Lake Poopó as the terminal saline lake, and the system of Lake Tahoe and Pyramid Lake in North America. In Central Australia, Lake Eyre is a large, endorheic saline basin. The highest possible salt concentrations are found in the Dead Sea (~300 g/L) and in Deep Lake (Antarctica) which never freezes; the water reaches −14.5 °C during the winter (22).

STANDARD COMPOSITION OF FRESHWATERS

Freshwaters, soft waters as well as hard waters, are chemically dominated by the carbonate system, $CO_3{}^{2-}$ and $HCO_3{}^{-}$ as anions, and Ca^{2+} and Mg^{2+} as cations; together they are the main constituents and the buffering system of neutral freshwaters. This is caused by rainwater that is weakly acidic from CO_2 and, thereby, dissolves the carbonatic minerals of soils and rock (23,24). In areas poor in carbonates, the water contains low concentrations of dissolved salts, and in other areas of dominating limestone, the water is rich in dissolved carbonates. The qualitatively similar composition of freshwaters is described as a worldwide "standard water composition" (25,26).

The gases in air, 78.09% N_2, 20.95% O_2, and 0.03% CO_2, are in physical equilibrium between air and water. At low temperatures, higher concentrations of gases dissolve in the water than at high temperature. The maximum content of dissolved oxygen and CO_2 in water is 14.5 (8.9) mg O_2/L and 1.005 (0.51) mg CO_2/L at 0 °C (20 °C).

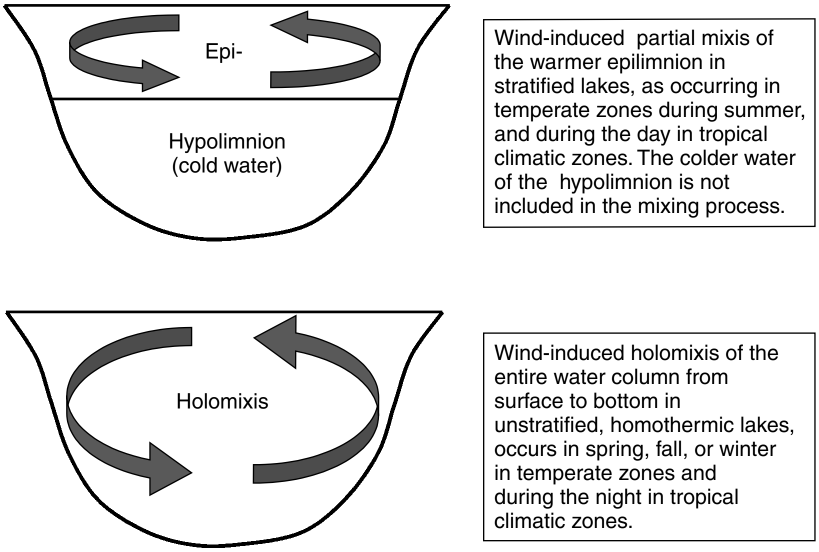
STRATIFICATION AND MIXING

Lakes are usually stratified into an upper layer, the epilimnion, which is well mixed by the wind, and a deep waterbody, the hypolimnion, which is not included in the mixing process. Stratification occurs seasonally in the temperate climatic zones, or in a diurnal–nocturnal rhythm in the tropical zones (Fig. 1). Ice covers block energy inputs by wind into the water column during the winter. The regime of stratification and mixis of the water column, as given by the climate, defines the types of lakes as (1) *monomictic*, (2) *dimictic*, or (3) *polymictic*, according to the number of periods of total mixing (*holomixis*) per year. Tropical lakes at low altitude are polymictic; they mix during the night and stratify during the day. Dimictic lakes have a stable stratification with a warm epilimnion during the summer and an ice cover during the winter; they show holomixis during the two seasonal periods of homothermy. One holomixis occurs in spring after ice melting when the surface water has the same temperature as the hypolimnion, usually 4 °C, and a second during late autumn before freezing. Monomictic lakes mix only once per year. The warm-monomictic lakes of oceanic-temperate regions never freeze and show holomixis during the winter. Cold-monomictic lakes are found in polar climatic regions; they are covered by ice during large parts of the year and melt only in summer when the water column reaches 4 °C and mixes from the surface to the ground.

The stability of stratification of a warm epilimnion and a cold hypolimnion determines whether wind forces mix only the uppermost layers, or the entire water column from the surface to the bottom. Stratification stability depends on the density gradient between the epilimnetic and the hypolimnetic partial waterbodies. Indicative numbers are the *Wedderburn Number* or the *Lake Number*, which, at given threshold values, predict optional holomixis with the next wind-forcing (27).

Climatic Zones and Lake Temperatures

Lakes are integrators of the regional climate and weather development (28). The surface temperatures follow the actual air temperature with a time delay, and lakes of the same region show time courses of similar surface temperatures. The deep water of lakes in polar and



Wind-induced partial mixis of the warmer epilimnion in stratified lakes, as occurring in temperate zones during summer, and during the day in tropical climatic zones. The colder water of the hypolimnion is not included in the mixing process.

Wind-induced holomixis of the entire water column from surface to bottom in unstratified, homothermic lakes, occurs in spring, fall, or winter in temperate zones and during the night in tropical climatic zones.

Figure 1. Seasonal or diurnal succession of stratification into warm epilimnion and cold hypolimnion and unstratified water column when the water is homothermic with complete overturn of the water from surface to ground (holomixis).

temperate continental climatic zones is at 4 °C, the temperature of water at its maximum density. The deep water of warm-monomictic lakes of temperate oceanic climatic zones in the Southern Hemisphere, in New Zealand and South America and also in western and southern Europe, has a temperature above 4 °C. The hypolimnetic temperatures remain from the last holomixis at the end of winter, and changes reflect long-term climatic conditions (29).

Waves and Oscillations

Driven by wind, waves emerge on the surfaces of lakes; their heights can be approximated by $h = 0.105\ (\text{fetch})^{0.5}$ (wave height and fetch given in cm; the *fetch* is the maximum length of the wind blowing across an open lake surface) (9). Less peculiar are oscillations along the lake axis, which have amplitudes of few centimeters at the lake surface (*seiches*). Their frequencies depend on the length of the lake axis, between minutes in small lakes and one day in large lakes. At the boundary layer between the epi- and hypolimnion, however, internal oscillations can reach wave amplitudes of 10 m or more. The periods of these internal oscillations are slower and reach 1 month in the largest lakes, such as Baikal or Tanganyika (1,27).

ECOSYSTEMS OF LAKES

The ecosystems of lakes belong to the best described and understood ecosystems because the composition of the community is limited in number of species and the populations are limited by the lake size. The seasonal development of the populations, their change in species composition, and the growth and decrease of the populations are well investigated and analyzed in terms of numbers of individuals as well as in terms of energetics and species composition (30).

Lakes have characteristic compartments as partial habitats of their ecosystems. The ecosystem of the pelagic zone of lakes is dominated by planktonic microorganisms, larger zooplankton, and fish. The phytoplankton is autotrophic and limited to the euphotic layers near the surface where light intensities are sufficient for photosynthesis and oxygen production. The limit between the *euphotic* and the *aphotic zone* is usually at depths where the light intensity decreases to <1% of that at the lake surface.

The *pelagic zone* is the body of free water of the lake, the *littoral zone* is the euphotic part at the lakeshore, and the *profundal* is the aphotic dark layer of the *benthic zone* below the littoral. The benthic community outside the littoral zone, the profundal, consists of the organisms living in and on the sediments, microorganisms, macrozoobenthos, and benthic fish species. Below the light limit for photosynthesis, the species of the benthic community, macro- and microorganisms, are heterotrophic and consumers of oxygen. All particles in the water eventually sink to the lake bottom, form annual layers of growing sediments (varves), and leave an archive of residuals. Therefore, the history and the development of the lake can be reconstructed from the microlayers of a sediment core, with respect to eutrophication and nutrient levels and impacts of climatic changes.

The littoral zone is the euphotic part of the benthic zone. The living community consists of autotrophic macrophytes and algae and of heterotrophic animals and microorganisms. The belt of macrophytes appears as an interface between land and water; wetland plants are on the land side of the belt, followed by plants rooting in the water and emerging in the air, swimming plants, and lastly submerged plants that cover the light bottom of the deeper littoral zone. The partial ecosystem of the littoral zone connects the land and water, and simultaneously, as a biologically reactive zone, retains and changes the flow of nutrients and other allochthonous inputs of matter into the lake's pelagic zone.

Trophic State and Productivity

Trophy is a measure of the level of nutrients and of the biological productivity resulting from nutrients supplies.

The organismic productivity of aquatic ecosystems, measurable as the formation of biomass, is limited by the availability of the rarest nutrient element (C,N,P,S,Fe,...). In temperate zones, phosphorus is usually the least available element because there is no gaseous transport form through the air and P is tightly sorbed on soil particles and retained on the land. The production of organic substance is limited by the availability of phosphorus, so the trophy (productivity) of lakes can be related to the P-content of the water at the start of the growing season (31,32). The process of growth needs a proportion of 106C:16N:1P as the atomic ratio of biomass (33,34). The primary production of phytoplankton and macrophytes—depending on P—reaches annual rates of 10 to 50 g C/m^2 of organic carbon in nutrient-poor lakes and more than 500 g C/m^2 in very nutrient-rich systems.

The biomass produced sediments to the lake bottom, where this dead organic substance is decayed by oxygen-consuming bacteria. Depending on the trophic state, the oxygen conditions in the hypolimnic water body reach different end points in late summer and fall. In oligotrophic lakes, the nutrients and productivity are low, as well as the following decomposition and oxygen losses in deep water. In eutrophic lakes, however, the nutrient supply and the resulting productivity are high. After decomposition in deep water layers, the oxygen content in the hypolimnion may reach critically low limits in late summer. The consequences of high nutrient supplies are mitigated in deep lakes with high hypolimnic volumes but are more severe in shallower lakes with small hypolimnic volumes and small oxygen reserves therein (Fig. 2).

Food Chains, Filtrators, and Size Spectra in plankton

Within the pelagic zone of lakes, the species of the plankton community can be structured by the food chain from the primary producers, the green algae, to herbivores, zooplankton species that feed on these algae, and carnivores that feed on herbivorous zooplankton. The efficiency of energy transfer from the lower to the higher trophic levels is about 10% from plants to animals and up to 30% from animal prey to their predators. Because there are losses of unused particles and dissolved organic matter (DOM) on all levels, recycling by bacteria as decomposers of DOM is important. Based on the bacteria as food, leading via bacteria-feeding protozoans to larger predators, the “lost” DOM is recycled again into the “normal” food chain by the “microbial loop.” This secondary food chain is important for the overall efficiency of the ecosystem as a processor of energy and its ability to recycle nutrient elements.

In oligotrophic systems, the organisms, prey and predators, are present in low concentrations, and a predator has to find and to grasp each single prey individually. The prey in such food chains is usually smaller than its predator by a factor of 10 to 20 by body length. Therefore, in oligotrophic planktonic systems, the food chain from green algae, via zooplankton to fish needs four to five subsequent trophic levels. The overall transfer efficiency with its losses at any transfer is small. In the more productive systems of meso- to eutrophic lakes, however, the concentrations of organisms from algae and bacteria to zooplankton and fish are high, and additional, new types of filtering predators appear. Filtrators use a filtering system, comb-like sieves in cladocerans (*Daphnia*), fine gill structures in filter-feeding fish (Coregonids), to collect large numbers of very small prey particles. The linear size relation between prey and filter-feeding predators is 100 × to 1000×, and, thereby, the length of the food chain becomes short, three levels from algae to fish. In temperate lakes, we find *Daphnia* as the keystone filtrator on the level of herbivores all over the world. The filtering, zooplankton-feeding fish of the genus

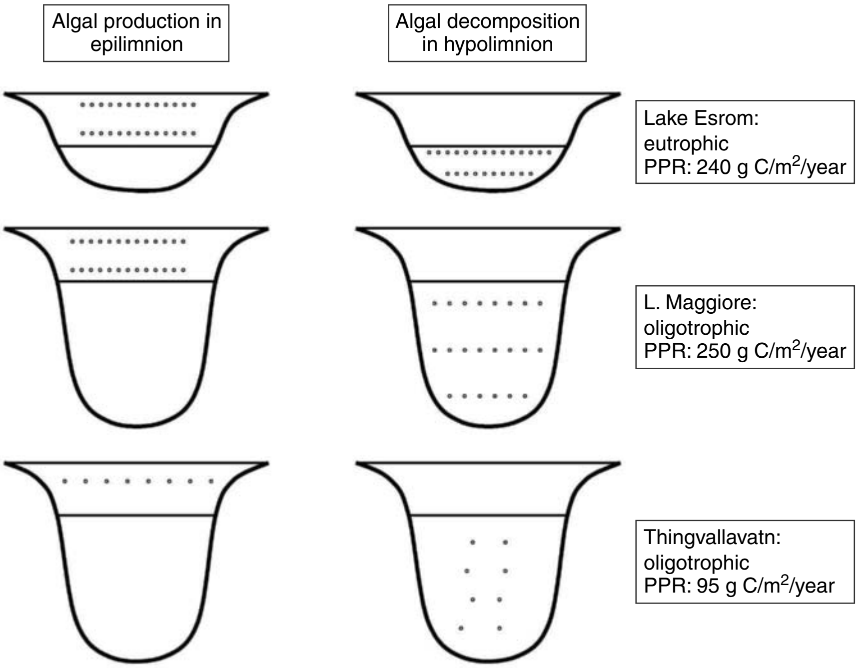


Figure 2. The relationship between the supply and demand of oxygen in deep water is determined by the intensity of the respective decomposition rate and the volume of the hypolimnetic waterbody of a given lake. The oxygen demand with algal decomposition consumes a large percentage of the supply in the small hypolimnic waterbody of L. Esrom, it is medium in L. Maggiore with its big hypolimnion, and it is unimportant in Thingvallavatn because the mass of algae is small and the big volume of the hypolimnion has a big oxygen reserve. L. Esrom is eutrophic, L. Maggiore has the same annual primary production (PPR) of algae, but is oligo-/mesotrophic because of its morphology. Thingvallavatn is a typical oligotrophic lake because of low primary production and its depth (redrawn from Reference 35).

Coregonus are found only in the Northern Hemisphere. In the ancient Lake Tanganyika, an evolution of a “new” filtrator occurred, *Limnotrissa*, where a zooplankton-feeding sardine, led to very high fish production. In other ancient tropical lakes, herbivorous *Tilapia* species appeared that filter-feed on algae.

The food web of any ecosystem might be described on the level of species composition and populations, according to its taxonomic structure. The system, however, might be alternatively viewed with an ataxonomic approach and explained functionally as a system of trophic levels linked by energy transfers: the “trophic-dynamic system” (34,36).

Another way to describe the planktonic food web and to explain some of its functions and properties is to view its size structure and the continuity of sizes as a spectrum. Investigations of the entire planktonic system revealed the plankton as a spectrum of size classes, in which the biomass of all size classes is equal. Many small organisms are present with the same sum of biomass, as are the fewer organisms of larger sizes. The regular pattern of body sizes over all organisms of plankton (37,38) corresponds to growth and physiological rates in a reciprocal way, fast overturn in the pools of small organisms and slow overturn in the big ones.

REGIONAL LAKE LIMNOLOGY

Glacial Lakes

The glaciated areas of the Canadian Shield, the Scandinavian mountains, and the adjacent sedimentary platforms of the circum-Baltic countries have been eroded by glaciation that left ten thousands of large and small lake basins. The large basins of the Hudson Bay and the Baltic Sea are corresponding central basins. The Baltic Sea was intermittently an inland lake and then became a brackish shelf sea. The surrounding areas from Finland to northern Germany have extended lake districts that cover large parts of the land. The “limnic ratio” is a measure of the percentage of the recent lake area of the deglaciated land area (8): world total deglaciated area: 6.8%; Scandinavian Shield: 12.2%; Finland: 9.4%; Norway: 13.9%; Sweden: 8.55%; South Baltic Platform: 2.2%; Canadian Shield:10.3%; and Patagonia: 3.0%. The lakes of this origin are the largest in Europe, Lakes Ladoga and Onega in western Russia and the large southern Swedish lakes, and in North America, the Laurentian Great Lakes and the large lakes of Canada (Table 1).

Formerly glaciated mountain districts are found on all continents (Table 1). The fjord lakes and foothill lakes in the deglaciated mountain areas are found in the Northern and the Southern Hemispheres of the temperate climatic regions in Scandinavia, the loghs/lochs of Ireland and Scotland, the English Lake District, the Alps, New Zealand, the Patagonian mountain areas of Chile and Argentina, and the Central and Northern Asian mountains. *Fjord lakes* are the deepest glacial lakes. Their mountain valley erosion basins have peculiarly steep borders and flat bottoms with depths of 500 m or more. Where the glacial erosions from valleys extend into the

foothill areas of the foreland, the characteristic *piedmont lakes* cover large areas, but they are shallow compared with fjord lakes or fjord-like parts of the same lake (e.g., L. Garda, L. Argentino, L. Buenos Aires, show both, deep fjord-like parts and large, shallow foothill areas).

Lakes in the (sub-)polar regions are covered by ice permanently or during the largest part of the year. Lake Vanda (Antarctica) has a permanent, clear, ice cover. The deepest water layers are stabilized by saline inputs and trap the down-welling light energy, leading to a temperature of 25 °C above the bottom (63 m) (22). Some large lakes in the Antarctic were found by satellite radar imaging under several thousand meters of glacial ice cover. The largest of these lakes, L. Vostok, is the size of Lake Ontario (39).

TROPICAL AND ANCIENT LAKES

The lakes of the (sub-)tropical climatic zone are described in textbooks by Beadle (42) and Serruya (43). The most important difference from temperate lakes is the diurnal variability of temperatures that are as large as the seasonal variability between summer and winter in temperate lakes. The restricted time of nocturnal holomixis presumably limits the maximum depth of mixis in deep tropical lakes. Therefore, the very deep lakes Tanganyika and Malawi are meromictic, and, consequently, have anoxic, deep waterbodies. The deep African Rift Valley Lakes are ancient lakes and, therefore, have peculiarities beyond their tropical sites (12).

The largest and deepest lakes of the world are also the oldest lakes: Baikal, Tanganyika, Malawi, and Issik-Kul. The most important ancient lakes are listed in Table 2. The old lakes originate from the Tertiary and have a long development with changing water levels that could be reconstructed by paleolimnological investigations. The best investigated ancient lake is L. Biwa, whose history is based on sediment cores that are 200 and 1000 m long, covering 0.5 to 1 million years (44). The oldest and deepest of the ancient lakes gave time to their biota for evolutionary processes which led to adaptive radiations of—mostly endemic—species, found 10 to 100× more numerously than in young lakes. There are >400 species of Cichlid fish species in Tanganyika and Malawi and >200 species of Gammarid crustacean species in Baikal. The ecosystem structure is severely changed by new keystone species in the food web and new top carnivores: in Lake Baikal the pelagic Gammarid *Macrohectopus* and Cottoidei fish and the freshwater seal *Phoca sibirica*. In Lake Tanganyika, the species *Limnotrissa* directs the food chain to high production of fish, whereas in the other large African lakes the insect larva *Chaoborus* plays the role of the main zooplankton feeder. This species leaves the lake when it becomes an adult insect, so the branch of the food chain is then lost for the lake ecosystem.

MAN-MADE LAKES: RESERVOIRS AND PIT LAKES

Man-made lakes are built in great numbers, ten thousands of reservoirs and pit lakes in the voids of surface mining. They show limnological peculiarities that come primarily from the management regime for reservoirs and from geogenic impacts on water chemistry for pit lakes in coal and ore mining districts. The state of reservoir building and the problems are presented by the World Commission on Dams (http://www.dams.org). Reviews and other comprehensive scientific publications on mining lakes are in an initial phase (50).

REGIONAL PROGRAMS FOR PROTECTING LAKES AND COLLECTING DATA

The protection of lakes and other surface waters is different regionally. The Environmental Protection Agency (EPA) has set standards in North America, and the

THE THEORY OF ALTERNATIVE STABLE STATES IN SHALLOW LAKE ECOSYSTEMS

ADRIAN E. WILLIAMS
APEM Ltd.
Manchester, United Kingdom

OVERVIEW

The idea of alternative stable states was first proposed in the late 1960s (1), and within ecological communities, it was described mathematically in the 1970s (2,3). The contemporary view of shallow lakes is that two alternative stable states can exist over a range of nutrient concentrations: a clear water state dominated by submerged macrophytes and a turbid phytoplankton-dominated state (4–8). Unique states may be found at either end of the nutrient continuum, but over a wide range of nutrient concentrations (<50 to several thousand $\mu g\ l^{-1}$ TP), either of these two states can exist, stabilized by a number of buffer mechanisms (5,6,9–11).

A “ball and cup” diagram is a simple way to visualize this idea (Fig. 1). The position of the ecological system (the ball) can change between the two states and settles at the bottom of the cup (stable equilibrium). The slope of the cup determines both the speed and the direction of the system change to a stable state. At either low or high

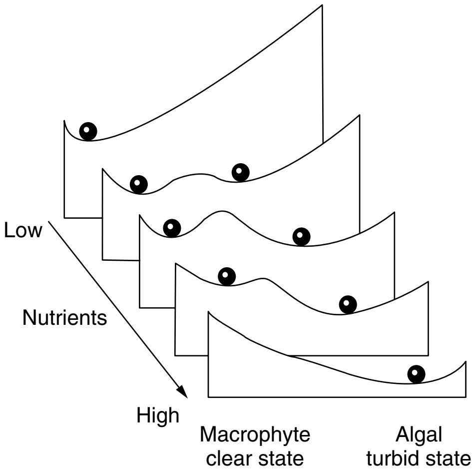

Figure 1. “Ball and cup” schematic of the potential for two stable states (clear water macrophyte-dominated versus turbid algal-dominated) to exist within a shallow lake under a wide range of nutrient conditions.

nutrient levels, one of the two stable states exists—the ball can only be in one location because of the slope of the horizon. However, between these points the system can rest in either cup (state). The ease with which one stable state can be switched to the other is indicated by the position of the two balls with respect to one another and the slopes that separate them. Therefore, if the starting position is a pristine, low-nutrient (oligotrophic), macrophyte-dominated, clear water lake, the nutrient levels can increase substantially before the only possible scenario is a turbid algal-dominated lake. However, to reverse the situation takes more than just reducing the nutrients as the ball can remain in the turbid state even at relatively low nutrient levels. To switch the state prematurely requires that a force be applied to the ball to push it over the edge of the algal cup and into the macrophyte state.

Therefore, each stable state has a number of buffer systems that help maintain that state, and through top-down and bottom-up processes, fish, plankton, invertebrates, macrophytes, and nutrients are all entwined in reciprocal feedback mechanisms that not only determine the state that is present (12,13) but can also be manipulated to force a shift.

Macrophyte buffer mechanisms that help maintain and stabilize a clear water state in shallow lake systems are numerous (4,14–16). Macrophytes act as habitats and refugia for macroinvertebrates and cladocerans that reduce the epiphyton and phytoplankton communities by grazing (6,17). Davis (18) suggested that the plant bed environment, often deoxygenated, favors grazers by discouraging their predators. Macrophytes may also release allelopathic chemicals (19); partake in the "luxury uptake" of nutrients, removing available nutrients for phytoplankton (20–22); and reduce available nitrate by anaerobic decomposition processes such as denitrification (23). Moreover, certain species of macrophytes have been shown to oxidize the sediment and reduce the release of phosphorus. With less available phosphorus in the water column, phytoplankton populations are reduced (24,25). In addition, stands of macrophytes reduce water movement within them. In consequence, suspended sediment resettles and turbidity falls, aiding the growth of macrophytes (26). Moss (10) suggests that even if light penetration is falling, submerged macrophytes may switch from low growing forms to taller species and that plants heavily encrusted with epiphyton may be able to shed their leaves and produce new growth. These processes competitively disadvantage phytoplankton and can buffer the macrophyte-dominated state.

Once established, on the other hand, phytoplankton can buffer the switch back to a macrophyte state by growing much earlier in the season than macrophytes in temperate regions. In doing so, they can curtail the development of turions, rhizomes, or seeds by shading in spring or reduce the formation of propagules by shading and competition for CO_2 in late summer (10). Submerged plants require carbon for growth, but algae have shorter CO_2 and HCO_3 diffusion pathways owing to their small size, thus removing the carbon available to the bulkier macrophytes (27). Some researchers have suggested that certain blue-green algae may even release chemicals toxic to macrophytes (28). In addition, phytoplankton-dominated open water has few refugia for grazing Cladocera; thus, any Cladocera venturing forth are typically removed by zooplanktivorous fish, which may be compounded by the fact that, with reduced macrophytes, few large macroinvertebrates would be available to large fish, favoring smaller sized fish feeding largely on zooplankton (6). Finally, in poorly flushed systems, phytoplankton species can consist of large filamentous or colonial blue-green algal species that are inedible to zooplankton, which along with the above mechanisms, all help to maintain phytoplankton-dominated water states over a wide range of nutrient concentrations.

By understanding the mechanisms that buffer and thus maintain the alternate stable states, it is possible to attempt to force a shift or switch from one state to another by manipulating top-down and bottom-up processes. Such attempts are often made during lake restoration projects when a desire exists to shift an algal-dominated turbid lake into a clear water macrophyte-dominated state. However, the long-term success of lake restoration projects, although they use knowledge of top-down and bottom-up processes, is not guaranteed and unexpected results are common (29–31). The uncertainty that surrounds these outcomes often stems from a lack of understanding about the buffer systems that stabilize the alternate states within the specific lake under restoration and an oversimplification of the top-down and bottom-up processes involved (13).

NOAA LAKE LEVEL FORECAST FOR LAKE MICHIGAN RIGHT ON TARGET

NOAA Great Lakes
Environmental Research Lab

July 17, 2003—How high or low the water level is in the five Great Lakes has long been of interest to those who use the lakes for commercial and recreational boating and fishing, energy, and as a source of drinking water. The levels have been measured and forecast monthly for many years, and NOAA scientists hit the bull's-eye with their July forecast of the water level of Lake Michigan.

"We were within inches of the actual measurement," said Cynthia Sellinger, deputy director of the NOAA Great Lakes Environmental Research Laboratory in Ann Arbor, Mich.

GLERL uses meteorological forecasts from the NOAA National Weather Service to forecast the lake levels six months out. Back in January, GLERL's Lake Michigan forecast was 176.61 meters—about 579 feet; in July the actual level was 176.65 meters—approximately 2 inches higher than the forecast. Sellinger meets monthly with her

---

colleagues from Environment Canada and the U.S. Army Corps of Engineers to forecast the levels.

Since 1997, Lake Michigan has dropped 4.1 feet, the largest drop in that short of time span since records have been kept. Lakes Michigan and Huron are often considered one body of water as they are connected by the Straits of Mackinac, located between the upper and lower peninsulas of the state of Michigan.

The other lakes are more difficult to forecast, because the water flow of Superior and Ontario are regulated by power companies and Erie gets 80 percent of its water from Michigan and Huron, Sellinger explained.

The Great Lakes—Superior, Michigan, Huron, Ontario, and Erie—are the major bodies of water within the Great Lakes Basin. The basin is located along the international boundary between Canada and includes portions of eight states and the provinces of Ontario and Quebec. Combined, these lakes make up the largest surface fresh water body in the world—they contain 90 percent of the U.S.'s fresh water and 20 percent of the world's fresh water.

The Great Lakes carry thousands of recreational and commercial ships annually. Lake levels are important to shippers, who must load the lake carriers with fewer goods when the levels are low and to recreational boaters, who often have to find dock space in deeper water. The Lakes provide drinking water to the 40 million residents as well as water to power and cool electric generating plants.

Lake levels have been dropping for the past six years and lake evaporation has increased significantly.

"The only good thing that comes out of lower lake levels is more beach for beach-goers," according to Sellinger. However, that also exposes and destroys some vital breeding habitat for lake wildlife.

Lake levels have been forecast before GLERL was formed in 1974. Part of the laboratory's mandate is to provide the lake level forecasts, a task that was given to GLERL when the research arm of the U.S. Army Corps of Engineers was transferred to the laboratory.

NOAA is dedicated to enhancing economic security and national safety through the prediction and research of weather and climate-related events and providing environmental stewardship of the nation's coastal and marine resources. NOAA is part of the U.S. Department of Commerce.

SUBMERGED AQUATIC PLANTS AFFECT WATER QUALITY IN LAKES

Karl E. Havens
South Florida Water Mgmt. District
West Palm Beach, Florida

BACKGROUND INFORMATION

A principal cause of water quality impairment in lakes and reservoirs is enrichment by excessive levels of nutrients, resulting in undesirable conditions that include noxious and/or toxic algae blooms (1), and taste and odor problems (2). The nutrient content of lake water is determined by a myriad of factors, including external loading rate, water residence time and depth, geochemical interactions in the water body, and biological processes. Biological processes are particularly important in shallow lakes. Fish and benthic animals recycle nutrients from bottom sediments, buoyant algae carry nutrients upward in the water column, settling rates of algae determine loss rates for water column nutrients, and plants facilitate various nutrient-scavenging processes (3,4). Submerged plants, in particular, can have major influences on water quality in terms of clarity, biomass of noxious algae, taste and odor, organics, and suspended solids—factors of major relevance to society's use of the water.

This chapter addresses four questions:

1. What types of submerged plants occur in lakes, and how does type of plant relate to water quality benefits?
2. What factors control the biomass and spatial extent of submerged plants?
3. What are the processes whereby plants affect lake water quality, in particular, the concentrations of nutrients, turbidity, and the occurrence of noxious algae?
4. How can lakes be managed to promote the development of submerged plants that will help to improve water quality?

For a detailed overview of the ecological role of submerged plants in shallow lakes, the reader may consult Jeppesen et al. (5) or Scheffer (3). For identification of different types of plants in lakes and for general information about their biology and distribution, there are a number of web-based resources provided by major universities; for example: http://aquat1.ifas.ufl.edu (University of Florida, Center for Aquatic and Invasive Plants).

TYPES OF SUBMERGED AQUATIC VEGETATION RELATIVE TO WATER QUALITY BENEFITS

Lakes can support rooted vascular plants (true plants that have tissues for gas and materials transport); plant-like macroalgae, such as *Chara* (shrimp grass) that do not have vascular tissues or roots; and filamentous algae that can form dense mats on the lake bottom, sometimes covering rocks and even other plants. Filamentous algae are least desirable from a water quality standpoint, because at high biomass, they can kill other plants by shading and they form floating noxious mats at the lakeshore when they decompose (3). *Chara* generally is a pioneer species that rapidly invades lake habitats after a disturbance (6,7), and because it does not have roots, all of its accumulated nutrient content may be recycled back into the water column if unfavorable conditions (e.g., reduced light, high wind, or cold water) cause the plants to be lost. Certain vascular plants, such as *Ceratophyllum* (coontail), also do not have roots and would have this same problem. In regard to *Chara*, note that clear water and low nutrient levels are most often associated with dense beds of this plant in temperate (8,9) and subtropical (7) lakes and that processes other than direct incorporation of nutrients into biomass may be most important for water quality improvement by *Chara* beds. Rooted vascular plants—common examples in North America are *Vallisneria* (eelgrass) and *Potamogeton* (pondweed)—are more permanent than *Chara*, and because they can transfer nutrients to their underground roots prior to seasonal “die-off,” they have potential to provide a better long-term nutrient sink.

FACTORS CONTROLLING THE BIOMASS AND EXTENT OF SUBMERGED VEGETATION

Scientists and lake managers have given considerable attention to the factors that control the biomass and spatial extent of submerged plants in lakes. Obviously, water depth plays a key role because ultimately it determines the amount of light that reaches the lake bottom where plants germinate from seeds (or oospores, in the case of algae) and begin to grow. However, light availability at any given depth is heavily influenced by the turbidity of the water, which is determined by the amount of suspended solids, algal cells, and dissolved organic matter. Hence, a number of authors have identified significant relationships between the maximal depth for submerged plant occurrence in lakes and simple indicators of turbidity, such as Secchi disk transparency (10–13). The relationships vary from lake to lake. For example, in Lake Okeechobee, Florida, the published models predict that submerged plants can occur at depths between 0.7 and 1.8 m, whereas plants actually occur at depths as great as 2.0 m. This may reflect the occurrence of plants that are adapted to low light levels in this turbid shallow lake (14). In general, *Chara* can occur at greater depths than vascular plants, for any given level of turbidity (15).

Experimental studies have confirmed the causal effect of underwater light availability on submerged plant growth (14,16). However, when evaluating field data, it can be difficult to tell whether plants are responding to variations in underwater irradiance or whether they are the cause of high irradiance in certain areas of a lake because they have various functions that reduce turbidity. It is a classic “chicken versus egg” paradox. Some shallow lakes display zones of clear water immediately adjacent to turbid water of the same depth (8), the only difference is that the clear areas have dense beds of submerged aquatic vegetation (SAV). In such instances, one might conclude that the plants have caused the clear water. In Lake Okeechobee, Florida, clear water expanded over an ever-increasing area during summer 2000, coincident with the expansion of large beds of *Chara*. Areas adjacent to the plant beds had more turbid water, but they also had slightly greater depths (6). It was not possible to establish a cause–effect relationship. Scheffer (3) provides a good overview of the issue of correlation versus causation as it pertains to SAV and turbidity in lakes, for those interested in more information on this subject.

In addition to depth and turbidity, sediment type may influence the distribution and biomass of submerged plants. Soft sediments that are readily suspended by wind, waves, and fish may not support plants, especially types like *Chara* that do not have roots. In Lake Okeechobee, which has areas of sand, peat, and mud sediments, *Chara* does not occur at locations that have soft organic mud, even when depth and light conditions appear to be favorable (7). A simple empirical model, based on water depth and sediment type, was able to predict at 75% accuracy the spatial distribution of *Chara* over a 170 km^2 landscape in that lake. The sediment type found also was the major factor controlling where plants could occur in Lake Kinneret, Israel (17), whereas water depth was the factor controlling the timing of plant occurrence.

Other factors that can influence the distribution and biomass of submerged plants include the degree of exposure to wind and waves (13,18), the slope of the lake bottom (19), and as mentioned before, overgrowth by filamentous algae (20).

PROCESSES WHEREBY SUBMERGED VEGETATION AFFECTS WATER QUALITY

When one compares lakes with and without dense submerged plants or follows the conditions in a lake over time as plants increase, striking changes in water quality are apparent. Water can change from murky green (algae blooms) to crystal clear (Fig. 1), and at the same time, nutrient levels in the water can dramatically decline. Even a relatively low biomass of submerged plants can attenuate peak concentrations of suspended algae (phytoplankton) in a lake’s water column (21; Fig. 2). The benefits of clear water and plants for the fish, wildlife, and humans who use the resource are obvious.

Submerged plants mediate changes in water quality by a variety of mechanisms. The focus here is on processes that control nutrient and light availability, rather than food web interactions. However, it should be recognized that a potentially important function of submerged plants is to provide refuge for large zooplankton (22). During the daytime, large zooplankton can escape fish predation by

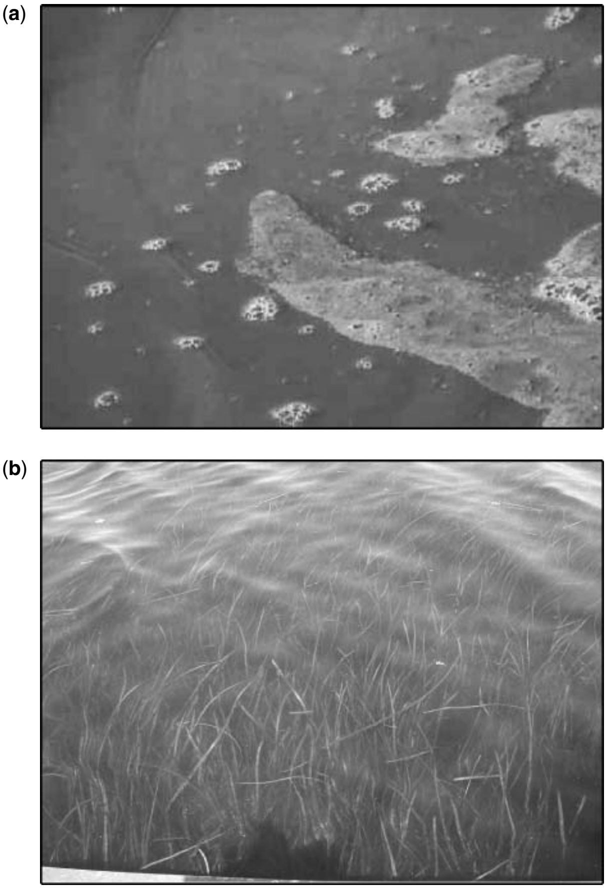

Figure 1. Photographs of typical conditions in turbid, phytoplankton-dominated lakes that have high levels of nutrients in the water column and blooms of algae (**a**), versus clear, plant-dominated lakes that have low nutrient levels in the water and no algal blooms. These photographs were taken by the author at Lake Okeechobee, Florida.

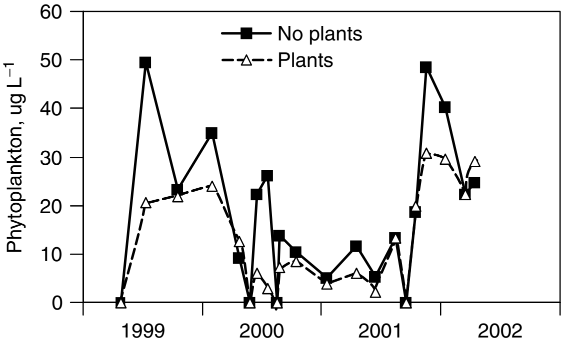

Figure 2. Data from the shoreline region of Lake Okeechobee, Florida, showing the concentrations of phytoplankton chlorophyll (μgL^{-1}) at sampling stations with plants versus stations without plants. The presence of plants dampens the peaks in phytoplankton, as a result of various processes described in the text. Modified from a figure in Havens (20).

migrating into the plant zone, and at night, when they are not susceptible to those visual predators, they can migrate out into the open water to graze on phytoplankton. The result is theoretically a reduction in algal biomass and reduced risk of nuisance algal blooms, although uncertainty remains about the magnitude of this effect. One of the complicating issues is that plants may also provide refuge for the small fish that eat zooplankton (22).

In a conceptual framework (Fig. 3), one mechanism whereby submerged plants can benefit water quality is the uptake (**U**) of dissolved nutrients that otherwise could fuel algal blooms and the array of adverse impacts shown in the diagram. Benthic algal mats can also take up nutrients from the water, further reducing availability for the bloom-forming phytoplankton. Much of the nutrient uptake by plants actually is associated with attached algae (periphyton) that grow on plant surfaces (23,24). Vascular plants and benthic algae also take up nutrients from lake sediments; it has been documented that benthic algal mats can substantially reduce the diffusive flux (**D**) of nutrients from sediments to the overlying water in both shallow freshwater and estuarine systems (25–27). All of the plants and algae mentioned here can at times excrete (**E**) dissolved nutrients back into the sediment or water column. Conditions that favor net growth of plants and/or benthic algal mats favor a net uptake of nutrients, which translates into better water quality.

Nutrients present in the water column or sediments in a dissolved form can also be transformed (**T**) into particulates that ultimately settle (**S**) to the lake bottom at a rate that depends on water column mixing (or lack thereof), the density of the water, and the characteristics of the particles. Plants can stimulate both the transformation of dissolved nutrients to particulates in the water and the rate of settling. In regard to transformation (**T**), when plants carry out intense photosynthesis, the pH of the surrounding water can be substantially elevated. At high pH (e.g., >10), much of the dissolved inorganic carbon (C) occurs as carbonate ions $(CO_3)^{-2}$ (28), which can be precipitated to the sediments, or onto the surface of plants, as calcium carbonate ($CaCO_3$). More important, from a water quality standpoint, is that this process can be accompanied by coprecipitation of phosphorus (29), as insoluble hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. Phosphorus is a nutrient that often is limiting to phytoplankton in freshwater lakes (30). Therefore, coprecipitation could help reduce phytoplankton growth and suppress formation of blooms. However, it must be noted that at high pH, the release of dissolved phosphorus from lake sediments (**D**) is sometimes enhanced, even under oxidized conditions (31). Depending on circumstances, this could counteract the effects on particle transformation.

Plants play an important role in settling of particles (**S**) by slowing the rate of water movement (32), and acting as sediment "traps" by intercepting particles using their leaves and stems; the particles subsequently sink to the lake bottom (33). The uptake of nutrients by periphyton, which ultimately provide particulate material (dead cells) to the sediments is another loss process mediated by plants. Once the particles settle within a plant bed, they are less likely to be re-suspended (**R**) because dense beds of submerged plants significantly reduce the amount of wind and wave energy that reaches the sediment surface (34).

Finally, it has been suggested that submerged plants might inhibit the growth of suspended algae by releasing

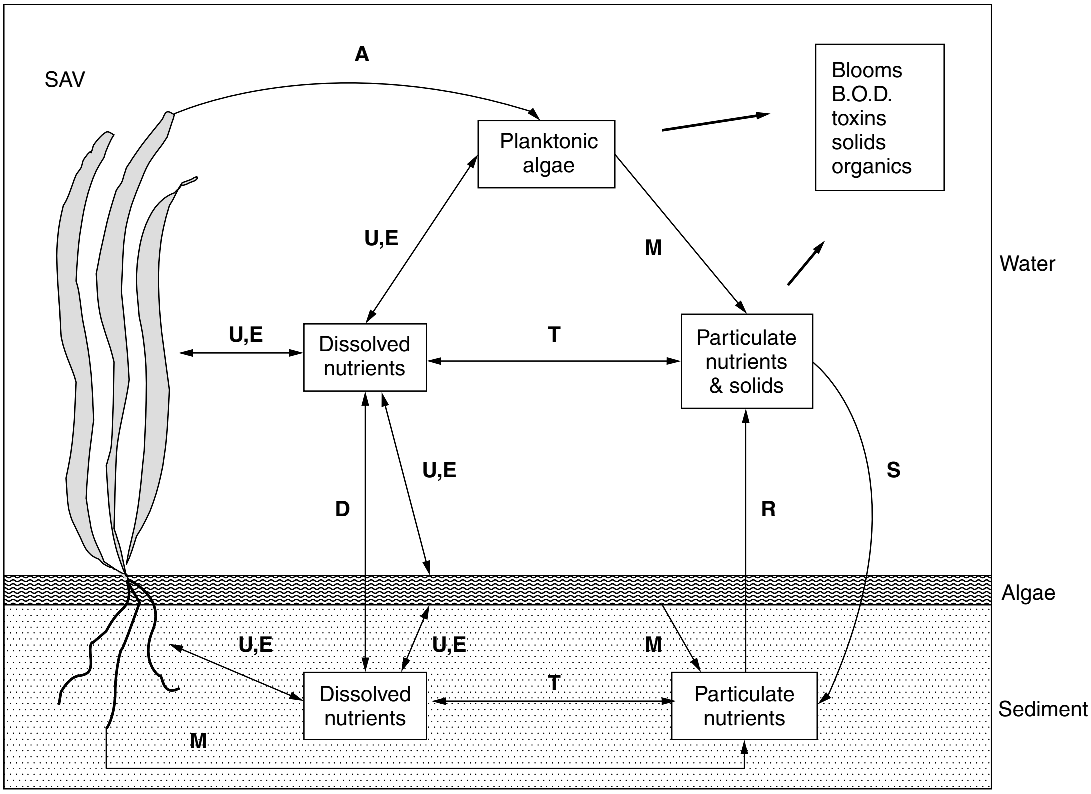

Figure 3. A simple conceptual model, illustrating how submerged aquatic plants and benthic algal mats influence the dynamics of phosphorus in a typical eutrophic lake. The arrows correspond to various processes: **A** = release of allelopathic chemicals; **U** = uptake of dissolved nutrients; **E** = excretion of dissolved nutrients; **T** = transformation of nutrients from dissolved to particulate form, or vice versa; **D** = diffusion of dissolved nutrients from sediments to water, or vice versa; **M** = mortality; **S** = settling of particles; and **R** = resuspension of particles by wind, waves, or bioturbation. B.O.D. = Biological Oxygen Demand. The two large arrows point to impacts of algal blooms and solids on the water resource. This figure is modified from a similar model presented in Havens et al. (23).

allelopathic chemicals (**A**) into the water column (35). This effect has been documented in controlled tank studies with a high biomass of plants and restricted water volume, but uncertainty remains regarding its importance in lake ecosystems.

MANAGING LAKES TO PROMOTE SUBMERGED VEGETATION

The total biomass of primary producers in a lake is controlled by nutrient input to the ecosystem (36), whereas partitioning of that biomass into phytoplankton and plants is determined by a complex set of factors. Understanding how particular environmental conditions influence submerged plants is critical to facilitating plant survival and growth, and in turn, maintaining good water quality (see below). Lakes dominated by soft organic sediments or heavily influenced by wind-driven waves are not well suited for submerged plants. However, even under these conditions, options may exist, such as dredging to remove soft mud or construction of wave barriers to provide protected areas for plants to grow (37). In lakes that have favorable sediments and low to moderate wave energy along the shoreline, the key factor controlling plants is likely to be light availability, which as noted before, varies with the depth and turbidity of the water. One of the factors controlling turbidity is the nutrient content of the water, which determines the abundance of phytoplankton cells that absorb light. Scheffer (38) noted that there is a complex relationship between nutrients and turbidity in lakes that varies with the presence or absence of plants. This relationship (Fig. 4) is highly relevant when considering how to establish plants in a nutrient-rich, turbid lake.

As a lake becomes enriched with nutrients, the turbidity of the water increases. In lakes with plants, the turbidity at any given nutrient level is lower than that in lakes without plants due to the mechanisms described before (Fig.3). Once a “critical turbidity” is reached, where light does not allow net growth to occur, plants are lost, and turbidity quickly increases (upward arrow), as the nutrients formerly sequestered by plants go into the biomass of phytoplankton in the water. To restore plants to a lake that has reached this state, nutrients must be reduced to a lower level than where the switch previously occurred (downward arrow). Both the clear-water, plant-dominated state and the turbid-water, phytoplankton-dominated state are highly stable—it takes a large

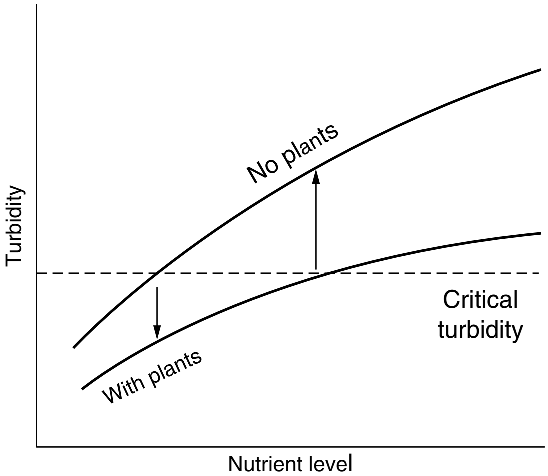

Figure 4. Relationship between turbidity and nutrient level in lake water, in lakes with versus without plants. Lakes with plants have a lower turbidity for any given nutrient level than lakes without plants. When nutrient levels increase in lakes with plants, the plants can be lost once a critical turbidity is reached, at which point the net growth of plants is zero. When this occurs, turbidity can rapidly increase (upward arrow). To restore the plants in such a lake (downward arrow), the nutrient level must be substantially reduced. This figure is modified from a diagram in Scheffer (3).

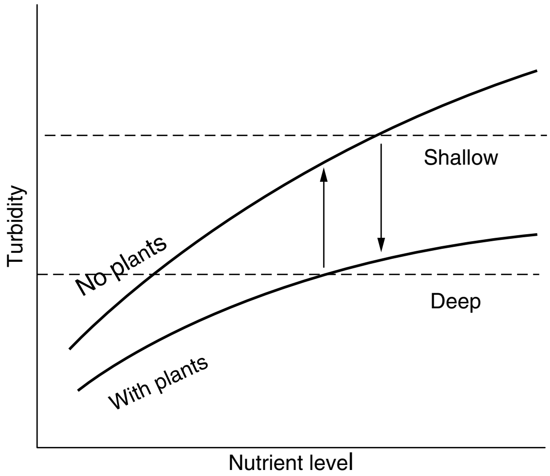

Figure 5. Effects of water depth on the occurrence of plants in turbid lakes. By substantially lowering the water level of a lake, the critical turbidity is increased (upper dashed line), and this can allow plants to recover (downward arrow), even though the nutrient level remains high. If the water level increases substantially (lower dashed line), the plants may be lost, even at a lower level of nutrients than that where they were recovered (upward arrow). Unless there is capability for strong control of water levels and no other adverse impacts of keeping the lake low (e.g., impacts on water supply), the ultimate solution to keeping plants and clear water in a lake is to reduce external nutrient inputs. This figure is based on information in Scheffer (3).

input of nutrients to switch a plant-dominated lake to a phytoplankton lake and an even larger reduction of nutrients to switch the lake back (3,38). This stability of states reflects the biological feedback loops that occur in the system. Plants cause clear water, which favors more plants, which cause even clearer water…etc. Phytoplankton cause turbid water, which reduces plants, which favors more phytoplankton, which further increases turbidity and so on.

Note that at extremes along the nutrient axis (extremely low or high nutrient levels), plants can exist in only one state—clear or turbid, respectively. However, for lakes that have moderate to high levels of nutrients and the possibility of alternative stable states (38), one method for switching a lake from phytoplankton to plant dominance is to reduce inputs of limiting nutrients, such as phosphorus and nitrogen (3,39). Ultimately, this is the path to lake restoration. However, an interim management strategy that can sometimes be used in tandem with nutrient reduction is to lower the lake's water level. Critical turbidity is a function of depth, so that in a deep lake, relatively low turbidity might be sufficient to prevent plant growth. However, in shallow water, enough light may reach the lake bottom to allow plants to germinate and grow. By lowering the water level, it is possible to raise the critical turbidity (Fig. 5), so that plants can become reestablished at a higher level of nutrients than that when the lake had deeper water. At this point, the lake has essentially been reset onto the lower curve.

A switch from turbid to clear water happened in the shoreline region of Lake Okeechobee, Florida, in summer 2000, after an intentional lowering of the water level was followed by a major drought (40). The water level in the lake dropped by more than 2 m, and the spatial extent of submerged plants increased from less than 10 to over 170 km^2 (16). Water in shoreline areas, which was highly turbid from algae blooms in the late 1990s, became crystal clear in 2000–2002. Recently, it has somewhat deteriorated, as higher water levels led to reduced biomass of plants. Ultimately, reduced nutrient input is the solution to the water quality problem in this and other nutrient-enriched lakes (39), because as long as alternative states exist, uncontrollable events, such as marked increases in water level or wind storms, could potentially shift a plant-dominated lake back to a turbid lake with phytoplankton blooms.

SUMMARY

Water quality in shallow lakes and reservoirs can be strongly influenced by biological processes, including those associated with fish, invertebrates, algae, and plants. The most striking influences often are those associated with submerged aquatic plants, which include rooted vascular plants, loosely attached macroalgae, such as *Chara*, and filamentous benthic algal mats. Where conditions favor high biomass and spatial extent of these plants, water turbidity generally is low, biomass of phytoplankton is low, and quality of water for drinking and other uses is good. The plants maintain these conditions by removing nutrients from the water; supporting attached algae that also sequester nutrients; stabilizing bottom sediments; and a variety of other physical, chemical, and biological processes. Actions to favor development of submerged plants in shallow, nutrient-enriched lakes can help to maintain good water quality, although the long-term solution still is to reduce external nutrient inputs.

LAKES—DISCHARGES TO

Laurel Phoenix
Green Bay, Wisconsin

Lakes have suffered from a long history of receiving pollutants from various sources. These pollutants degrade water quality, with implications for aquatic and terrestrial ecosystems as well as for a variety of issues for human populations dependent on that water and those ecosystems. The degree to which these pollutants degrade the lake depends on the amount and types of pollutants as well as the physical characteristics of the lake. For an introductory overview of how discharges to lakes are harmful, the pollutant sources and how pollutants are transported into the lake are described. The physical characteristics that determine the assimilative capacity of a lake are then covered. Finally, the effects that different pollutants have on lakes and their dependent ecosystems are explained as well as the ramifications for aquatic species, birds, wildlife, and humans.

POLLUTANT SOURCES AND TRANSPORT

Polluted discharges into lakes can come from watercraft, terrestrial sources, and atmospheric deposition. Watercraft are categorized into ships, boats, and recreational equipment. Terrestrial pollutant sources can be categorized into point and nonpoint sources. Point sources of pollution emanate from a single location, like a factory's pipe dumping effluent into a stream or lake. Nonpoint sources of pollution, often called "polluted runoff," can come from all over a landscape and from many locations at once, such as fertilizer runoff from suburban lawns or oil washing off city streets. Atmospheric deposition has characteristics of both point and nonpoint source pollution and so is treated separately here. Atmospheric deposition of pollutants originating from smokestacks travels through the air and then falls into the water.

Watercraft

Ships discharge a variety of pollutants into lakes. The ballast water that ships discharge into the water contains oils and invasive species. The entry of the zebra mussel into the Great Lakes is a good example of how an aquatic ecosystem can be significantly changed by the introduction of just one new species. Now, regulations require ships to dump their ballast water in the open ocean before entering the Great Lakes. Used oil from ship engines has also been dumped into lakes for years. Sewage from ships has also been dumped untreated into lakes, although cruise ships have recently been pressured to install onboard sewage treatment systems so that only treated effluent is dumped. Atmospheric deposition from smokestacks is becoming a more serious problem with increased global shipping. Ships burn low-grade diesel fuel and these carcinogenic compounds then enter lakes.

Boats used for recreation also pollute lakes. Boat owners may dump their sewage straight into the lake rather than pumping it out dockside at sewage receptacle facilities. Gas spills often happen at docks when gas pumping is not done with care, and some gas and oil are emitted into the water from outboard motors.

Smaller recreational equipment like jet skis pollute water with oil and gasoline at a far higher rate than outboard motors. Jet skis also damage littoral habitat, kill aquatic animals, or frighten aquatic species and disturb mating or nesting behaviors. Chromosomal damage in fish has been linked to the fossil fuel discharges from jet skis.

Terrestrial Point Sources

The most common point sources polluting lakes are sewage systems and industrial effluent pipes. Sewage can enter lakes either through intentional discharge of raw or treated sewage, or through occasional discharges from combined sewer overflows (CSOs). Depending on the city and on the country, one can find cities discharging raw sewage into lakes rather than spending the money to treat it properly. Sewage treatment plants in other cities may have primary, secondary, or tertiary sewage treatment, resulting in various types and concentrations of pollutant discharge into lakes or their tributaries. Combined sewer overflows are found in cities where stormwater and sewage flow down the same pipes, rather than flowing through separate stormwater and sanitary sewers. In rain events, the additional stormwater entering sewage pipes may be more than a sewage treatment plant's designed capacity. When this happens, sewer pipe outlets are designed to open and discharge raw sewage into a local stream or lake to prevent too much sewage from reaching the treatment plant; passing through the plant without sufficient treatment; and/or backing up into the city. Consequently, the raw or partially treated sewage from some cities contributes a daily material loading to a lake, whereas combined sewer overflows discharge sporadically as a result of heavy rain or rapid snowmelt. Some of the constituents of sewage are human waste, bacteria, viruses, chemicals, detergents, heavy metals, and pharmaceutical and personal care products (PPCPs) (1) such as antibiotics, steroids, birth control pills, shampoo, hair dye, and perfume.

Industrial pollutants enter a tributary or lake by a pipe, either intentionally through a permitting program or by accidental release. In the United States, any industrial facility, including sewage treatment plants, must have a National Pollutant Discharge Elimination System (NPDES) permit to discharge anything into a water body. The type, quantity, and concentration of pollutants from various industrial processes are written into the permit, thus limiting the effluent discharge to the permit limits. Pollutants may be chemical, biological (e.g., bacteria, viruses, or organic matter that deoxygenates the water), thermal, radioactive, metals, and so on. Because there is a permitting system, and since the name implies a reduction or elimination of pollutant discharges, it is widely assumed that permits issued are still within the assimilative capacity of the water body, and that the appropriate government agencies monitor and enforce permits to ensure that the water is not becoming degraded. Unfortunately, this is not the case, and rivers and lakes are receiving rising material loads.

Terrestrial Nonpoint Sources

Nonpoint source pollutants move into a lake from its entire drainage area. Nonpoint sources are grouped into urban runoff, mining, agriculture, silviculture, groundwater, and human transport. Urban runoff includes fertilizers, pesticides, and pet waste from lawns; oil, rubber, deicing chemicals, and metals from roads; and sediment from construction.

Mining contributes acid mine drainage to tributaries or lakes or can put cyanide into the water when it is used to leach gold out of gold ore. Strip mining transports sediment into streams. Agriculture contributes a significant portion of the overall nonpoint source pollutant load to lakes. These pollutants include sediment from erosion, pesticides mobilized from the soil by rain, and overapplication of commercial fertilizer or manure.

Silviculture primarily contributes pesticides and sediment to lakes. Pesticides used on tree farms or areas sprayed for infestations (e.g., gypsy moth) are transported through rain and snowmelt into water bodies. Sediment from road building for timber trucks or from clear-cutting or harvesting on steep slopes is also discharged into streams and lakes.

There are two primary types of pollutants moving through groundwater. Leaking septics contribute organic sewage material, *Escherichia coli*, viruses, and toxic household cleaners. Acid rain filters into soils, and the resulting chemical reaction then mobilizes mercury, manganese, aluminum, and zinc into the groundwater and then into lakes through subsurface flow. Humans can transport invasive species unintentionally or with purpose. For example, zebra mussels can “hitchhike” on a pleasure boat being hauled from one water body to another, or canals have been built that connect previously distinct ecosystems and allow migration of species into a new lake. Intentional transfer of invasive species happens when people get rid of pet fish by flushing them down the toilet or dumping them directly into streams or lakes, and this fish will now be an exotic species for that lake. Other exotic species can be placed in a lake with the intent of using them to control other aquatic animals or plants, but several of these experiments (e.g., carp) have backfired; new unexpected problems arise from the exotic introduction.

Atmospheric Deposition

Although some scientists may regard atmospheric deposition as a type of nonpoint source pollution, it is categorized here as distinct from terrestrial point or nonpoint source pollution because it comes from discrete sources (smokestacks), but from numerous locations. The type of airborne pollutant discharged from smokestacks depends on the type of industrial facility, the type of energy they use, and their chemical processes. For example, electrical generation plants burning coal, or other industries that use coal for their energy source, can emit lead, mercury, zinc, arsenic, uranium, sulfur dioxide, and nitrogen oxides. All of these can enter the water surface either through wet (rain or snow) or dry deposition. The heavy metals, radioactive uranium, and acid rain constituents have different effects on lakes. Downwind lakes close to these smokestacks will receive a heavier loading of heavy metals, whereas the SO_2 and NO_x that contribute to acid rain can travel much farther and degrade more distant lakes. Other industries emitting other kinds of chemicals or metals into the air will affect lakes according to how those metals or chemicals interact with lake chemistry or lake biota.

Atmospheric deposition of mercury is bioconverted by bacteria into methylmercury, a fat-soluble neurotoxin. It then moves up through and beyond the aquatic food chain. Regions receiving deposition of both mercury vapor and acid rain will result in an even higher conversion of elemental mercury in methylmercury, moving first into the water and then into the fish, wiping out entire fish species. Acid rain also mobilizes aluminum, manganese, and zinc from soils into the lake.

PHYSICAL CHARACTERISTICS OF LAKES

What is the assimilative capacity for a lake for certain types or amounts of pollutants? A lake’s ability to absorb pollutants without degrading its biological and chemical processes is a function of its physical characteristics. Some limnological characteristics are described here. (For more information into lake processes and response to pollutants, see Reference 2.) What is the lake’s volume and depth? The greater the lake volume, the more it can dilute pollutants down to less harmful concentrations. Vertical temperature differences found in deep lakes can stratify water into layers. This stratification, and whether or not the lake “turns over” (a mixing of the layers by turbulence in the water) in spring and fall, controls the amount of oxygen, nutrients, and other chemical cycling occurring in the upper or lower waters of the lake.

Therefore, stratification influences which types of pollutants may stay or have an effect only in the upper strata, only in the lower strata, or whether pollutants have access and impact throughout the entire water column and the sediment below. Because stratification controls temperature, it controls the rates of biochemical reactions, and these rates may also provide a buffering effect against some pollutants. Similarly, because stratification controls oxygen levels, pollutant loadings of organic materials (e.g., paper pulp, sewage effluent, manure) will have more negative impact during the times of year that oxygen levels are lowest. Consequently, the same daily amounts of material loadings to a lake can have different effects on the lake depending on the season.

The flushing rate of a lake describes how long it takes for new water inputs to the lake to entirely replace existing lake water with new water. How often the lake theoretically refills with new water affects how fast some of the pollutants entering a lake may be flushed out before they can harm lake processes very much. The higher the flushing rate, the more diluted some pollutants can be because some pollutants will not be able to stay in the lake for long.

The typology of a lake, whether it is naturally more oligotrophic or eutrophic, affects its ability to absorb some pollutants without changing lake characteristics significantly. Over hundreds or thousands of years, a lake naturally receives more nutrient inputs and naturally undergoes eutrophication, or nutrient enrichment, and slowly changes from oligotrophic to eutrophic. When rapid nutrient inputs are due to human action, this is called cultural eutrophication. A more oligotrophic lake is typically deep and has very clear green or blue water, high oxygen, few nutrients or calcium, and limited phytoplankton or other plant species. At the other end of the spectrum is a eutrophic lake, which is shallow and has opaque green or brownish green water, very low oxygen in summer, high nutrients and calcium, and frequent algal blooms in reaction to the high nutrient concentration. So, for example, a naturally oligotrophic lake would become more eutrophic in response to high sewage effluent or farm manure inputs, and a more eutrophic lake would have less assimilative capacity for high loadings of sewage effluent, since the lake is already heavily loaded with nutrients.

POLLUTANT FATE AND CONSEQUENCES

The various sources and transportation mechanisms of pollutants entering lakes of varying characteristics affect lakes in different ways and to different degrees. This section gives a brief sampling of some of the negative effects discharges to lakes can have on the water, sediment, and biota. (For a more comprehensive explanation of the various effects of different pollutant discharges into lakes, see Reference 3.)

Water

Lake water can be degraded in numerous ways. For example, heavy nutrient loading from sewage, manure, and runoff from agricultural soils high in phosphorus reduce the amount of oxygen in the water. Moreover, various chemical compounds and metals entering the lake change the natural rates of chemical cycling in the lake by changing the ion concentrations in the lake. Acid rain forces calcium out of solution as manganese, zinc, and aluminum are brought in.

Sediments

Pollutant deposition into lake sediments can seriously alter existing water chemistry. Chemical pollutants deposited into the lake sediment alter the chemical balance and exchange of chemicals between the sediment and water. Sediment becomes a long-term storage site for pollutants. If sediment gets stirred up later on because of turnover, floodflows from tributaries, or dredging, even more pollutants are released into the water and the food chain and once again chemical exchanges between the lake bottom and the water are altered. For example, lead in sediments deposited up through the 1970s from vehicle exhaust is still found in lake sediments today. Altering water chemistry of a lake affects all biota in the lake.

Plants

Plants are vulnerable in several ways to pollutant discharge. If the discharge into the lake is sediment from agricultural, silvicultural, or construction activities, this new sediment layer can smother existing plants. Chemical pollutants can kill off some aquatic plants. Thermal pollution from some industrial plants or their cooling towers can kill plants by altering water temperature. Invasive species introduced by ballast water or by "hitchhiking" on pleasure boats hauled from one lake to another can wipe out plants by increased depredation. Acid rain reduces phytoplankton as well as zooplankton populations, undermining the aquatic food chain.

Fish

Fish are also very vulnerable to discharges into lakes. Some fish can lose their food source if aquatic plants are harmed or eliminated by pollutants. Thermal pollution from industrial cooling water affects fish metabolism and reproduction. It also stresses fish by increasing oxygen demand in the water and makes fish more vulnerable to disease. Reproduction can also be harmed by contact or ingestion of some chemicals. There might be fewer eggs, damaged eggs, or no eggs. Recently, estrogen in animal manure, human hormones, caffeine, and wood-pulp plant effluents are among some of the suspected causes of male fish producing eggs in their sex organs (4). Chemicals like chlorine are added in sewage treatment or flushed through cooling tower pipes to kill bacterial slimes and then are discharged into the lake and kill fish. Biomagnification in the food chain of substances like mercury, polychlorinated biphenyls (PCBs), or dioxins can pass from the sediments through phytoplankton and zooplankton into smaller and then bigger fish. High acid rain amounts not only wipe out entire fish species, but also cause lakes and streams to become fishless.

Fish can even serve as a transport mechanism for these chemicals from one region to another. For example, salmon have been found to contaminate lakes when they go upstream for spawning and then die in streams and lakes and release the PCBs or dioxins into the lake water and sediments. Beluga whales in the St. Lawrence River downstream of the Great Lakes have suffered impaired fertility and death from the DDT, PCBs, lead, mercury, and insecticides they have been exposed to from discharges into the river as well as the Great Lakes. Once they have been dissected, their bodies must be disposed of according to hazardous waste regulations. Invasive species can harm fish. A northern snakehead, perhaps a former aquarium pet dumped by its owners, was recently caught in Chicago's Burnham Harbor on Lake Michigan (5). Snakeheads are considered "voracious eaters" and can consume many of the smaller fish in a lake. Invasive species may also start competing with existing fish by preying on the same food sources. Another exotic, the zebra mussel, affects fish by clearing the water and thus making fish more visible to prey.

Shellfish

Like fish, shellfish can also experience reduced reproduction from chemicals and hormones. For example, spawning behavior is altered by exposure to some antidepressants. Shellfish may face increased competition for food from invasive species. Shellfish also absorb and concentrate pollutants in their flesh, making them dangerous to eat.

Wildlife

Wildlife such as bear or cormorants can be harmed by biomagnification of PCBs, mercury, and so on when they eat the polluted fish.

Humans

Human populations are also harmed in numerous ways. Drinking water is degraded when a lake has industrial and agricultural chemicals, PPCPs, heavy metals, and so on in its source water. We know from painful experience how mercury causes Minimata disease or how cadmium, a byproduct of metal refinery, causes a disease that softens the bones. Algal blooms from cultural eutrophication give drinking water a bad taste and smell.

Shoreline use and value can also be diminished. Some lake pollution will force beaches to close, reducing recreational resources for locals and possibly keeping tourists away and out of the water because of *E. coli*, the smell and slime of algal blooms, and the toxins some blue-green algae produce. Heavy nutrient inputs into a lake can cause eutrophication that results in water that looks like pea soup and has a horrific smell. These can also cause a reduction in recreational use, when boats get caught up in algal mats or weedy macrophytes and tourists avoid an area, and lower the value of lakeshore properties. If fish or bear are unsafe to eat, then recreational opportunities are diminished. Tourists wanting to hunt and fish may go elsewhere, and those that continue to eat unsafe fish can harm their own health or have babies with birth defects.

PRESENT AND FUTURE CHOICES

Pollutant sources, transport, and fate have serious consequences for lakes. Cities will either have more degraded drinking water, with potential health consequences, or they will have to spend enormous amounts of money to purify the water enough to make it safe for human consumption. The effects of pollutants on aquatic life can not only affect food chains within the lake but can also harm birds, wildlife, and humans that depend on the aquatic species for food. The externalities of industrial production, sewage or stormwater treatment, and other land uses are then spread to new populations as well as rebounding on polluter populations themselves. Their quality of life degrades along with their drinking water, recreational options, and fish and wildlife populations.

LASERS SCAN LEVEES FROM THE AIR

John Hall
New Orleans District
U.S. Army Corps of Engineers

New Orleans District is taking to the air to learn more about the ground.

For good reason—for large jobs flying surveys are faster and cheaper than ground surveys. And the eye-in-the-sky is particularly handy in New Orleans District's 30,000 square miles of coastal Louisiana, where "ground" is a relative term.

The district is using laser technology called lidar, for LIght Detection And Ranging. It is analogous to radar, which stand for RAdio Detection And Ranging, except that lidar uses light beams instead of radio waves. A scanning laser rangefinder emits a beam of coherent light from a helicopter flying 45 miles per hour at an altitude of 220 feet. (The laser beam is invisible to the naked eye, and not intense enough to cause harm.) The beam bounces back and the lidar system's instruments gather vast amounts of data which can be sliced, diced, and served up in many forms. The process is almost effortless, compared to the labors of ground surveys in wetlands and bayous.

New Orleans District's first use of lidar was on the Lake Pontchartrain and Vicinity Hurricane Protection Project. Total cost was $124,000, with most of the dollars going to the contractor, John E. Chance and Associated, Inc., which specializes in corridor mapping (electric lines, highways, and levees).

A laser scanning rangefinder make a hefty instrument package for a helicopter (Photo courtesy of New Orleans District)

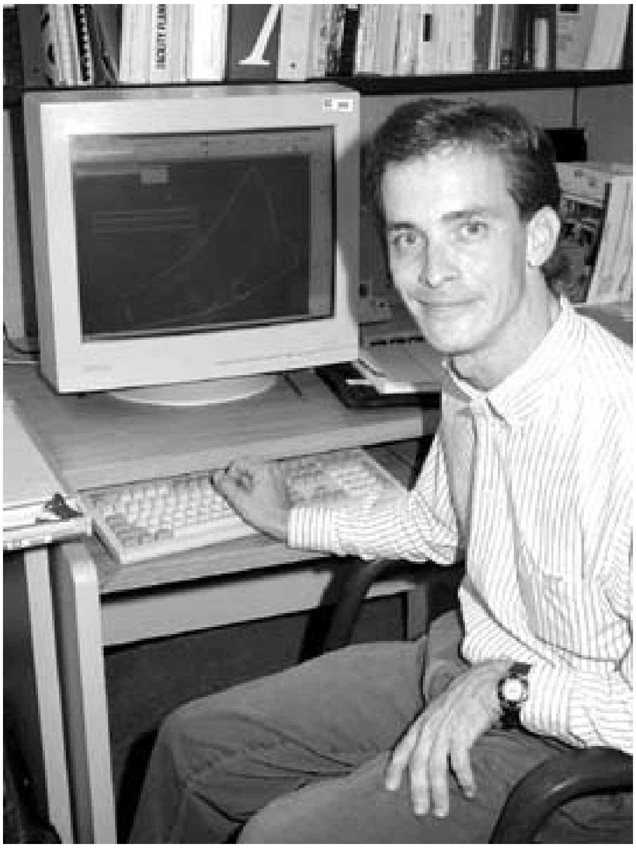
"We can rapidly determine levee heights without doing a ground survey," said Al Naomi, senior project manager of the hurricane project. "You can get a lot of data rapidly."

Indeed. The system produces 8,000 to 20,000 data points per second. But what does all this data really mean?

"It provides all three dimensions, the X, Y, and Z coordinates," said Terral Broussard, a district retiree who works for the contractor. This is trigonometry in action—three coordinates used to locate a point in space. The X and Y axis are length and width; the Z axis is the elevation.

Lidar surveys have been completed for all 125 miles of the Lake Pontchartrain and Vicinity project (www.mvn.usace.army.mil, click on hurricane box). These levees and floodwalls are in St. Bernard, Orleans, Jefferson, and St. Charles parishes. But lidar isn't limited to looking at levees. In New Orleans District, it is being considered for the Comite River Diversion Project, a flood control project to be built near Baton Rouge.

For land surveys, the laser is not the only sensor. Chance's helicopter also carries a video camera, and location is provided by the satellite-based Global Positioning System. The video provides high-resolution color images. On the computer screen, these pictures may be viewed as an overlay precisely placed amid the lidar data. Or, you can just turn the video loose and watch the levee roll by as if you were on the helicopter.



Mike Brennan, civil engineer, projects lidar information on his computer. (Photo courtesy of New Orleans District)

To illustrate, Mark Huber of Survey Section pulled up on his computer a lidar aerial view of the Causeway toll plaza in Metairie, La. Bright colors marked the elevations. In mid-screen, he overlaid a video picture with the tollbooths, parked cars, roadways, and even the bike path that circles underneath, all clearly visible.

"Lidar may not be quite as accurate as ground surveys," Naomi said. "But it's faster, cheaper and requires no landowner interface."

"Other (Corps) districts have used lidar for land mapping," Huber said. "We're the first to pull the final product from the raw data, creating levee cross sections and centerline profiles."

How extensively New Orleans District will use lidar is unclear. While lidar cannot retrieve data from water surfaces, vegetation does reflect its signals. That makes it a candidate for wetland surveys where ground surveying is inherently difficult.

Lidar apparently has a lot of use as a quick look, and for studies. The question is whether it will prove accurate enough for project design. But, according to Huber, no errors exceed six inches compared with ground surveys.

LEVEES FOR FLOOD PROTECTION

Stefano Pagliara
Simone Pozzolini
Università di Pisa
Pisa, Italy

Levees were among the first river training structures built to protect human settlements and activities from floods. A levee is an embankment whose primary purpose is to furnish protection from high water due to river floods.

Levees are similar to small earth dams, but there are important differences:

- Levees are subject to high water levels only for a limited period of time (of the order of hours or rarely days), so that a levee embankment is generally not subject to saturation conditions.
- Levee alignment is dictated primarily by flood protection requirements; this often results in construction on poor foundations.
- Borrow is generally obtained from areas adjacent to the levee site, which produce fill material that is often far from ideal.

Embankments that are subject to water loading for prolonged time periods or permanently should be designed using earth dam criteria.

DESIGN OF LEVEES

Levee design involves numerous factors, dealing with both hydraulic and geotechnical considerations (Fig. 1). Design factors may vary, and no general procedure can be established. However, it is possible to present a general stepwise design procedure (1) based on successful experience that can be used as a starting point in levee design. Such a procedure may be summarized by the following steps:

1. Conduct a geologic study based on a thorough review of available data; initiate preliminary subsurface explorations.
2. Analyze preliminary exploration data and establish preliminary soil profiles, borrow locations, and embankment sections.
3. Initiate final exploration to provide
   - additional information on soil profiles
   - undisturbed strengths of foundation materials
   - more detailed information on borrow areas and other required excavations.
4. Using the information obtained in step 3,
   - determine both embankment and foundation soil parameters, and refine preliminary sections where needed.
   - compute rough quantities of suitable material, and refine borrow area locations.
5. Divide the entire levee into reaches of similar foundation conditions, embankment height, and fill material, and assign a typical trial section to each reach.
6. Analyze each trial section for
   - foundation and embankment seepage;
   - slope stability;
   - settlement;
   - trafficability of the levee surface;
   - maintenance requirements.
7. Design special treatment to preclude any problems determined from step 6.
8. Based on the results of step 7, establish final sections for each reach, and define construction methods.
9. Design embankment slope protection.

Field Investigation and Laboratory Testing

Levee construction requires both field and laboratory investigation.

Field Investigation. The extent of field investigation depends on several factors (1). Conditions requiring extensive field investigation include poor experience in the area with respect to levee performance, significant levee height, bad foundation conditions, long high water duration, low quality of levee materials, high risk conditions in case of levee failure, and the presence of a concrete structure in the levee alignment.

Field investigation and testing are generally performed in three successive steps:

1. preliminary office geologic study;
2. field geologic survey;
3. field testing (preliminary phase and final phase).

Each step is described in Table 1.

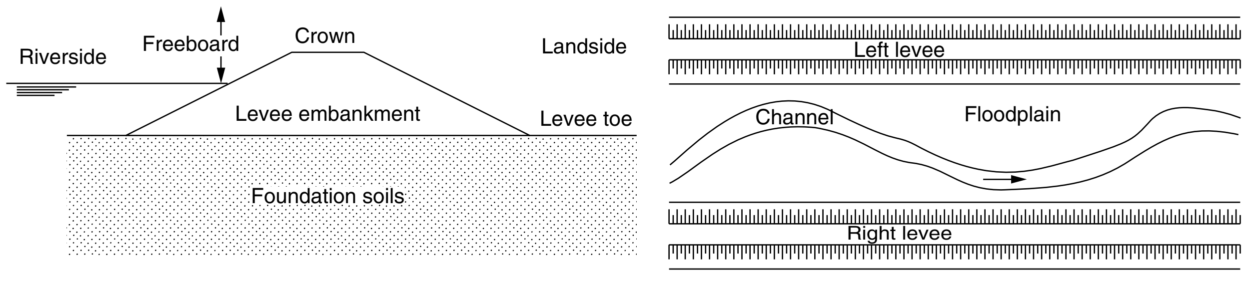


Figure 1. Sketch of a levee (cross section and plan view).

Table 1. Office Study and Field Investigation

Office study	Collection and study of — topographic, soil, and geologic maps — aerial photographs — existing information on soil and ground characteristics
Field survey	Observations and geologic analysis of the area, including such features as — riverbank slopes, rock outcrops, earth and rock cuts or fills — surface materials — poorly drained areas — evidence of instability of foundations and slopes — emerging seepage. — Physiographic features
Field testing	Preliminary phase — Widely spaced disturbed sample borings and test pits — Geophysical surveys or cone penetrometer test, used to interpolate between widely spaced borings — Borehole geophysical tests — Preliminary estimates of foundation strength Final phase — Additional disturbed sample borings — Undisturbed sample borings in critical reaches — Field vane shear tests, useful if undisturbed samples are unavailable. — Field pumping tests, providing information on large scale permeability of *in situ* deposits — Water table observations by piezometers in foundations and borrow areas

Laboratory Testing. Laboratory testing programs for levees vary from minimal to extensive, depending on the importance of the project and on the site conditions. Soil tests to be performed will vary according to the soil classification (Table 2).

Embankment Design

A levee cross section is generally trapezoidal berms may be added to ensure stability or seepage control. Berms are always used for high levee design.

Embankment design requires detailed analysis for levees of significant height, bad foundation conditions, or unsuitable embankment materials.

Embankment Geometry

Slope. Mechanical stability is largely dependent on the side slopes of the levee. The slope steepness is generally selected by considering the types of compaction, fill material characteristics, and foundation strength. For high levees, a soil mechanics stability analysis is required. For lower levees laid on proven foundations, recommended riverside slopes are about 1V:3H÷1V:3.5H; landside slopes are about 1V:2H÷1V:2.5H (V = Vertical; H = Horizontal).

Freeboard. Freeboard (the difference between the levee crown elevation and the high water stage) is used to account for uncertainties in levee performance. Many levees have been designed that have a 1-meter freeboard. Nowadays, the freeboard concept is less used in levee design. Risk-based analysis directly accounts for hydraulic uncertainties, and the geotechnical uncertainties are considered in the deterministic analysis of foundations and embankment behavior.

Crown Width. The width of the levee crown depends primarily on roadway requirement; it is in general in the range of 2.5–5 meters. To provide access for normal maintenance operations and flood fighting operations, minimum widths of 3.0–3.5 m are commonly used.

Stability Analysis. The principal mechanisms of levee failure are

Table 2. Laboratory Testing

Soil tests of fine-grained cohesive materials

- — Visual classification and water content determination
- — Atterberg limits
- — Permeability
- — Consolidation
- — Compaction
- — Shear strength

Soil tests of pervious materials

- — Visual classification
- — *In situ* density and relative density determination
- — Granulometry
- — Permeability
- — Consolidation
- — Shear strength

- — overtopping
- — piping
- — embankment or foundation slides
- — surface erosion.

Common methods used to analyze levee embankment stability are (2)

- — methods assuming definite boundary stress values;
- — methods based on the various soil characteristics that determine the failure state;
- — methods considering the degree of safety for force and momentum equilibrium;
- — methods comparing deformation work with the potential energy of the structure.

Primary attention should be devoted to the problems of defining the shear strengths, unit weights, geometry, and limits of possible sliding surfaces.

The more severe loading conditions for a levee are (1)

- — End of construction. Levee embankment and foundation stability must be analyzed using drained conditions for free draining soils and undrained conditions for low permeability soils.
- — Sudden drawdown. Excess pore water pressure can develop if a prolonged flood stage saturates the upstream embankment portion and then falls faster than the soil can drain. This can negatively affect riverside slope stability.
- — Steady seepage from full flood stage. Flood water levels can sometimes fully saturate levee embankments. This is an uncommon condition for ordinary levees but may be critical for landside slope stability.
- — Earthquake. Earthquake loadings are not normally considered in analyzing the stability of levees because of the low probability of coincidence with floods. Depending on the seismic characteristics of the study area, determination of liquefaction susceptibility may instead be required.

Shear strength selection under various loading conditions must consider soil type (free draining or low permeability) and pore water pressure conditions. Minimum factors of safety for the various stability analyses should be selected according to local regulations and to sound engineering judgement, considering failure consequences.

Measures to Increase Stability

Methods of Improving Embankment Stability. Levee stability can be enhanced by changes in embankment section, such as

Flattening Embankment Slopes. Flattening embankment slopes will usually increase the stability of an embankment against a shallow foundation type failure.

Stability Berms. Berms concentrate additional weight where it is most needed and force a substantial increase in the failure path. Berms can be an effective means of stabilization for shallow foundation and embankment type failures and also for more deeply seated foundation failures.

Methods of Improving Foundation Stability. Levees located on foundation soils of inadequate shear strength require some type of foundation treatment or the use of alternative design features in the levee section, such as a wider levee crest and flatter slopes. Foundation deposits that are prone to cause problems include very soft clays, sensitive clays, loose sands, natural organic deposits, and debris deposited by humans.

Means of dealing with inadequate foundation soils include

Excavation and Replacement. This procedure, though extremely effective, is economically feasible only where deposits of unsuitable material are not excessively deep.

Stage Construction. A levee is built in successive intervals of time where the strength of the foundation material is inadequate to support embankment weight, if built continuously at a pace faster than the foundation material can drain. Rest periods during levee construction permit dissipation of pore water pressures.

Stage construction is appropriate when pore water pressure dissipation is reasonably rapid. The rate of consolidation can be increased by using vertical drains. The disadvantages of this method are the delays in construction operations and uncertainty as to its scheduling and efficiency.

Densification of Loose Sands. Sands is generally not densified due to economic constrictions; possible exceptions are the presence of important structures in a levee system.

Levee Settlement. Evaluation of postconstruction settlement is important when settlement can result in loss of freeboard of the levee or damage to structures in the embankment. Detailed settlement analyses by theoretical analysis should be made when significant consolidation is expected, as under high embankment loads, embankments of highly compressible soil or built on compressible foundations, and near structures in levee systems founded on compressible soils.

Where foundation and embankment soils are pervious or semipervious, most of the settlement will occur during construction. For impervious soils, it is usually conservatively assumed that all the calculated settlement of a levee built in a normal sequence of construction operations will occur after construction.

Sometimes a levee is overbuilt by a given percentage of its height (varying from 0–10%) to take into account anticipated settlement of the foundation and within the levee fill itself, but overbuilding increases the severity of stability problems and may be impracticable for some foundations.

Seepage Control

Seepage flows develop when river waters flow through the embankment body or through foundation soils. Seepage is a very slow process, and the establishment of a seepage line generally requires a long time (2). As levees are exposed to high water levels for relatively short periods, the danger from seepage is more limited than that for earth dams.

Foundation Underseepage. Without control, underseepage flows in pervious foundations beneath levees may result in excessive pore water pressure, rupturing phenomena, and piping beneath the levee embankment. The principal seepage control measures are described in the following paragraphs (1). The effectiveness of seepage control measures can be evaluated by determination of flow-net, empirical methods, or mathematical solutions of seepage flow equations (Fig. 2).

Cutoffs. A cutoff beneath a levee stratum is one of the most positive means for blocking seepage through pervious soils. Cutoffs may consist of excavated trenches backfilled with compacted earth or slurry trenches usually located near the riverside toe. Steel sheet piling is generally not entirely watertight due to interlock leakage, but its use can significantly reduce the possibility of foundation piping. A cutoff must penetrate approximately 95% or more of the thickness of pervious strata to be effective, so constructing it is not economically feasible in the presence of thick pervious strata.

Riverside Blankets. Levees are frequently situated in alluvial areas on foundations that have natural surface covers of fine-grained impervious to semipervious soils overlying pervious sand and gravel. If these surface strata (or blankets) are continuous and extend riverward for a considerable distance, they can effectively reduce seepage flow and pore pressures landside of the levee.

The effectiveness of the blanket depends on its thickness, length, distance to the levee riverside toe, and permeability. Protection of the riverside blanket against erosion is an important feature.

Landside Seepage Berms. Landside berms provide additional weight useful for counteracting uplift seepage forces. Berms also cause an increase in the hydraulic length of seepage flows, providing a reduction in pressure forces at the landside toe.

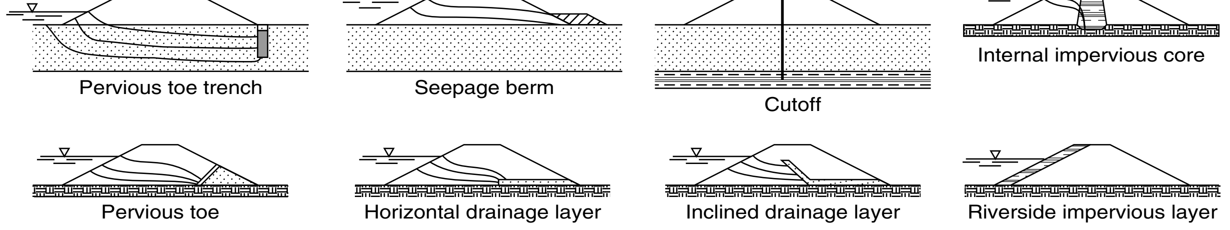
Seepage berms can improve the performance of existing impervious or semipervious top stratam but may also be placed directly on pervious deposits. Moreover, seepage berms increase the levee's landside slope stability.

Pervious Toe Trench. Partially penetrating toe trenches can improve seepage conditions close to the levee toe in a levee situated on deposits of pervious material overlain by little or no impervious material.

Pervious toe trenches are useful for controlling shallow underseepage. To collect deeper seepage flows, relief well systems may be used in conjunction with pervious toe trenches. Trench dimensions will vary according to the volume of expected underseepage, desired reduction in uplift pressure, and construction practicality. The trench backfill must be designed as a filter material. To improve drainage efficiency, trenches are often provided with perforated pipes to collect seepage.

Pressure Relief Wells. Pressure relief wells are used to reduce uplift seepage forces by providing controlled outlets for seepage that would otherwise emerge uncontrolled landward of the levee. They are installed where pervious strata underlying a levee are too deep to be penetrated by cutoff or toe drains and when the construction of landside seepage berms is not feasible due to space limitations.

The design of pressure relief well systems involves the determination of well spacing, size, and penetration in the underlying strata. Factors to be considered include



Pervious toe trench
Seepage berm
Cutoff
Internal impervious core
Pervious toe
Horizontal drainage layer
Inclined drainage layer
Riverside impervious layer

Figure 2. Seepage control devices.

depth, stratification and permeability of foundation soils, distance to the effective source of seepage, characteristics of the landside top stratum, and the degree of pressure relief desired.

Seepage Through Embankments. Embankment seepage emerging on the landside slope results in high seepage forces that decrease slope stability. Moreover seepage can soften fine-grained fill in the vicinity of the landside toe or lead to fine materials piping. Generally flood water stages do not act against a levee long enough to make seepage flows exit on the landside slope, but the combination of the effects of flood stages with a period of heavy precipitation may lead to consistent seepage flows. Various means to manage seepage trough embankments are described hereafter.

Pervious Toe Drain. Pervious toe drains provide a ready exit for seepage through an embankment and can lower the phreatic surface sufficiently so that no seepage will emerge on the landside slope. They can also be combined with partially penetrating toe trenches as a method for controlling shallow underseepage.

Horizontal Drainage Layers. Horizontal drainage layers essentially serve the same purpose as pervious toes but can extend further under the embankment requiring a relatively small amount of additional material. They can also protect the base of the embankment against high uplift pressures where shallow foundation underseepage is occurring. Sometimes horizontal drainage layers also carry away seepage from shallow foundation drainage trenches.

Inclined Drainage Layers. An inclined drainage layer is very effective for controlling internal seepage and is used extensively in earth dams, but it is rarely used in levee construction because of its cost. It might find use for short levee reaches in urban areas. An inclined drainage layer completely intercepts embankment seepage regardless of the degree of stratification in the embankment or the material type riverward or landward of the drain. Inclined drains must be tied into horizontal drainage layers to provide an exit for the collected seepage.

The design of pervious toe drains and horizontal and inclined drainage layers must ensure that such drains have adequate thickness and permeability to transmit seepage without appreciable head loss and, at the same time, prevent migration of finer soil particles. Moreover, the design of drainage layers must satisfy the criteria for filter design.

Landside Berms. Landside berms can also be very useful in embankment seepage control. For a brief description of their characteristics, refer to the previous paragraphs.

Embankment Zoning. To counteract seepage flows, a central impervious core or covering a riverside slope with an impervious layer can be useful. The latter is generally more economical than a central impervious core and, in most cases, is entirely adequate. As a matter of fact, levee embankments are often constructed as homogeneous sections as zoning is usually used in earth dams or in major levees.

PROTECTION OF RIVERSIDE SLOPES

The protection needed on a riverside slope to withstand the erosional forces of waves and stream currents depends on a number of factors such as floodwater stage duration, bank slope, erosion susceptibility of the embankment materials, presence of abrupt transitions, short-radius bends, or structures riverside of the levee that increase flow turbulence.

Several types of slope protection have been used. In general, high-class slope protection, such as riprap, articulated mat, soil cement, or paving should be provided on riverside slopes beneath bridges and adjacent to structures passing through levee embankments.

LEVEE CONSTRUCTION

Almost any soil is suitable for constructing levees, except very wet, fine-grained soils or highly organic soils. Levees of homogeneous cross section are generally made of silt, silty sand, or sandy clay. Fine-grained soils act as sealing materials due to their low permeability, but coarse components increase levee stability. The choice of material is often governed by the extent of local soils and by the technological experience of the contractor.

Levee embankments can be built with various degree of compaction. The central portion of the embankment may be compacted or semicompacted, but riverside and landside berms (for seepage or stability purposes) may be constructed of uncompacted or compacted fill. When foundations have adequate strength and where space is limited in urban areas both with respect to the quantity of borrow and levee geometry, compacted levee fill construction by earth dam procedures is frequently selected. This involves using select material, water content control, and compaction procedures. Where foundations are weak and compressible, high-quality fill construction is not justified because these foundations can support only levees with flat slopes. In such cases, uncompacted or semicompacted fill is appropriate. Uncompacted fill is generally used where the only available borrow is very wet and frequently has high organic content and where rainfall is very high during the construction season.

Except in seismically active areas or other areas requiring a high degree of compaction, compaction by vibration other than that afforded by tracked bulldozers is not generally necessary.

LEVEE REHABILITATION

As many levee systems are very old, the rehabilitation of existing levees is gaining greater prominence. Many techniques have been studied to rehabilitate existing levees. Recently, new working techniques that use geosynthetic materials extensively, have been introduced. Table 3 shows conventional and innovative levee rehabilitation techniques (3).

Table 3. Levee Rehabilitation Techniques

Problem	Conventional Rehabilitative Method	Innovative Rehabilitative Method
Overtopping protection	Rebuild	Cellular confinement system
	Vegetation	Reinforced grass
	Concrete slabs	Soil cement
Current and wave attack	Vegetation	Reinforced grass
	Revetment	Concrete block system
	Gabions	Soil cement
Rainfall surface erosion	Vegetation	Turf reinforcement mat
	Chemical stabilization	
Embankment seepage	Toe drain	Biopolymer chimney drain
	Conventional chimney drain	Biopolymer toe trench
Foundation seepage	Conventional toe trench	Jet grouted cutoff
	Conventional cutoff	
	Riverside blanket	
	Landside seepage berm	
	Pressure relief well	
Slope instability	Drainage	Reinforced soil slope
	Slope flattening and benching	Soil nailing
	Conventional restraint structure	Pin pile
	Chemical treatment	Stone-filled trench
		Geosynthetic drainage system
		Anchored geosynthetic system

LIMNOLOGY

Walter Geller
Annette Geller
UFZ Center for Environmental Research
Magdeburg, Germany

Limnology is the science of inland waters, also called epicontinental waters (1), including fresh and saline, standing (lenitic) and running (lotic) surface waters, estuaries, wetlands (2,3), and hyporheic (subterranean) waters (4) as ecosystems. Limnology integrates hydrological, physical, and chemical factors as framework constraints for ecological structures and processes. The first comprehensive publication coining the term "Limnology" was written by F. A. Forel (5) on Lake Geneva (Lac Léman) with chapters on geography, hydrography, geology, climatology, hydrology, hydraulics, thermics, optics, acoustics, chemistry, biology, history, navigation, and fisheries (see Ref. 6).

Limnology was traditionally focused on lake systems, as seen by the classic textbook of Hutchinson, *A Treatise on Limnology*, in Refs. 7–12. Other textbooks on limnology that present lake systems in detail, running waters, however, are treated only in a few chapters (13–16). In 1922, the International Association of Theoretical and Applied Limnology (SIL) was founded, and limnology became the science of aquatic ecosystems. The volumes of the book series *Die Binnengewässer* (edited by A. Thienemann since 1925) present the basics of limnological knowledge. The first concepts to compare lakes (17–20) were directed to lake types, referring to size and morphology, climate, the behavior to stratify and mix seasonally or diurnally (21), and different nutrient contents resulting in different productivity and oxygen regimes (temperate, tropical and polar lakes, mono-, dimictic, and polymictic lakes, oligotrophic and eutrophic lakes, clear-water and dystrophic brown-water lakes). Regional limnology was included by Hutchinson (7) and (22) with comprehensive surveys over the lakes of the world, their mode of origin, size, and number.

Studies of hydrobiologists first focused on an inventory of plants and animals, and then on the microorganisms in standing and running waters. A more general concept of productivity and energy flow in food chains was developed to describe the input and fate of matter and energy in ecosystems (23). Lakes all over the world were investigated according to Lindeman's "Trophic-Dynamic Concept" on a large-scale comparison of the functioning of lake ecosystems (24), being a part of the International Biological Programme (IBP). The nonbiological fields of limnology were treated by physicists (25–27) and chemists (28,29) in basic reviews and the textbooks *Aquatic Chemistry* and *Physics and Chemistry of Lakes*.

Institutions for limnological research, all focusing on lake limnology, were founded during the early decades of the twentieth century in Austria, England, France, Germany (including a first station on tropical limnology in Manaos, Brazil), Italy, the Netherlands, Sweden, Switzerland, Russia at Lake Baikal, the United States, and Canada. The only early stations for river ecology were at the Amazon and Volga rivers.

The limnology of creeks and rivers as part of aquatic ecology developed later than lake limnology (30,31). As running waters are more difficult to characterize, the development of concepts considered to suitably cover the relevant processes still proceeds. Typologies of rivers can be based on abiotic features as hydrological characteristics, water flow and its variability, the amount of dissolved and suspended matter, salt content and turbidity, and the course of temperature along the river and through time (32). *The Rivers Handbook* of Calow and Petts (33) has chapters on hydrology, physical and chemical characteristics, the biota, the ecosystem, and perturbations and biological impacts, and it addresses monitoring programs; modeling of hydrological development, of water quality, of sediment transport, and of biological responses; and the evolution of habitats.

First, in the early twentieth century fisheries, biologists divided European rivers along their stretch into distinct zones according to slopes, flow velocities, and the communities of fish (zones of salmonids, of cyprinids) (34). Benthos biologists amended this approach by including benthic invertebrates (rhitron, potamon) (35). In 1980, Vannote et al. (36) established the "River Continuum Concept" using the continuous shift along river stretches (1) of the relation between autotrophy and heterotrophy, and (2) of the relation between autochthonous nutrients, that are produced in the river, and allochthonous, terrestrial-borne nutrients. Rare or seasonal events as floods temporarily include the floodplains into the riverine system. The pulsed changes of dry and high-water conditions are essential for these systems adapted to regular floods, which affect the floodplains and offer new ecological niches (e.g., fruit-eating fish species in flooded Amazon forests) (37). The hereby derived "Flood Pulse Concept" sees the river as part of a larger ecosystem including the floodplains as system components being temporarily dry land or shallow flooded side-parts of the stream. The ecological continuity from water to land is approached by the "Concept of Ecotones" (38). The scale of integrated characteristics and management of the landscape results from enclosing the whole catchment area of the river system, based on the aquatic ecosystems, both rivers and lakes as partial systems. To characterize the structure and the hydrological processes within landscapes with respect to water flows, the integrated approach of the concept of "Ecohydrology" (39) was developed. The scale of catchment areas is the basis for the European Union (EU) "Water-Framework-Directive" that was established to keep or to reach a good/maximum chemical state and a good/maximum ecological state in all running waters and lakes of the EU-member states (40,41). Furthermore, special commissions have been established to deal with trans-boundary problems of water protection of rivers and lakes (Table 1).

Human use of land and waters changed the quality of inland waters with increasing population densities and by increasing loads of waste and nutrients impacting lakes and rivers. The limnology of creeks and rivers was predominantly developed within applied sciences, aiming at fisheries, water pollution by wastewater, the limits of self-purification of running waters, and solution of problems caused by pollution. Rivers have received urban wastewater for a long time. The pollution effects were first scientifically described at the beginning of the twentieth century. Kolkwitz and Marsson (42,43) characterized rivers from the source of pollution along stretches of self-purification by the benthic community's changes of species composition, being the base of the "Saprobic System." The saprobic system is still used as a biological tool to discriminate polysaprobic, mesosaprobic, and oligosaprobic conditions (44).

Wastewater pollution is a more severe threat for lakes than for rivers, because the organic loads, being nutrients for the aquatic organisms, remain in the lakes for years according to their water renewal time. The cumulative enrichment of nutrients, especially of phosphorus and nitrogen, with its biological consequences in lake waters (e.g., algal blooms) and the increasing of oxygen deficiencies in deep water layers, called "eutrophication," was observed in most lakes in densely settled areas of Europe and in North America. The increase of total phosphorus in lakes depends on the population density in the lake's catchment area. The limits for acceptable P-loadings of morphologically different lakes have been treated in comparative studies of the OECD in Europe and in Canada (45–48).

Systematic measures to reduce the inputs of P and N into surface waters have been taken for several decades (e.g., purification of wastewater in treatment plants, banning of detergents containing phosphate, abstraction of wastewater from lakes by ring-pipes). The results in many lakes clearly show that these efforts have been successful. The present state of nutrient loads of rivers and lakes in Europe and the development during the past is documented in reports, which can be downloaded from the European Environmental Agency (http://www.eea.eu.int/). Eutrophication of European lakes, in terms of phosphorus concentrations, generally is decreasing. The actual phosphorus concentrations are highest in the Eastern European countries and lowest in the Nordic countries. The state of surface waters in North America is documented in reports accessible from the U.S. Environmental Protection Agency (http://www.epa.gov).

Geological regions poor in carbonates are sensitive to acid rain as it changes the chemical composition of seeping runoff and ground- and surface-waters (49). Rain-acidified inland waters are carbonate-free, enriched in sulfate and aluminum, and acidic within a range between 4.5 and 5.5 pH units. Reports on long-term development and large-scale geographic distribution in EU-countries (50) showed that in Norway 6000 lakes (51) and in Sweden 17,000 lakes (52) were acidified. In southern Norway, 9630 fish populations were lost (53). Measures against acid rain and acidification of soils, lakes, and rivers started by reducing the emissions of acidic smoke (54) and direct treatment

Table 1. Commissions Established to Manage Inland Waters, River Basins, and Lake Catchments Including Trans-boundary Problems Within Their Catchment Areas. The Table Exemplarily Shows National and International Commissions and the Respective Lakes and Rivers

River, Lake, Basin	Commission	Web Page
Danube	International Commission for the Protection of the Danube River (ICPDR)	http://www.icpdr.org/pls/danubis/DANUBIS.navigator
Rhine	International Commission for the Protection of the Rhine River (IKSR)	http://www.iksr.org/
Elbe	International Commission for the Protection of the River Elbe (IKSE, SMOL)	http://www.ikse-mkol.de/html/ikse/ikse/deutsch/indexd.htm
Oder	International Commission for the Protection of the River Oder (signed by Germany, Czech Republic and Poland on 11 April 1996)	
Dnieper	International DNIPRO Fund (IDF)—National Program of Environmental Sanitation of River Dnipro Basin and Drinking Water Quality Improvement	http://greenfield.fortunecity.com/hunters/228/toppage1.htm
Bodensee, Lake Constance	International Commission for the Protection of the Lake Constance	http://www.igkb.de
Lake Geneva	Commission Internationale pour la Protection des Eaux du Lac Léman contre la pollution (CIPEL)	http://www.cipel.org
Great Lakes Basin	The International Joint Commission prevents and resolves disputes between the United States of America and Canada under the 1909 Boundary Waters Treaty. It assists the two countries in the protection of the trans-boundary environment, including the implementation of the Great Lakes Water Quality Agreement.	http://www.ijc.org http://www.epa.gov/glnpo
Lake Tahoe	Lahontan Regional Water Quality Control Board	http://www.epa.gov
Lake Washington	The Cedar River Basin Plan combines a traditional King County Basin Plan with a Non-point Source Pollution Action Plan. The Plan was prepared under the policy direction of the Watershed Management Committee composed of key tribal, state and local government agencies and non-govern-mental organizations, and a Citizens Advisory Committee of area residents.	http://dnr.metrokc.gov/wlr/watersheds/cedar-lkwa.htm/
Mississippi River Basin	The Mississippi River Initiative began 1997 and has developed into a coordinated federal effort to keep illegal pollution, ranging from raw sewage to industrial waste, out of the river and to restore the river and surrounding communities. The Initiative employs cooperative efforts of the Dept. of Justice, EPA, Customs Service, Coast Guard, Fish and Wildlife Service, FBI, and institutions of 26 U.S. states of the Mississippi River Basin.	http://www.epa.gov
Aral Sea basin	Inter-State Commission for Water Coordination (ICWC): Water ministers of the five states in the basin, Kazakhstan, Kyrgyzstan, Turkmenistan, Tajikistan and Uzbekistan; the ICWC was established 1992 with joint responsibility for water management with the two river basin agencies (Amu-Darya and Syr-Darya).	

Note: See IWAC (www.iwac-riza.org) for complete list of trans-boundary co-operations in Europe.

of acidic waters. In Sweden, 200,000 tons of lime were spread every year over 20 years, and 6000 lakes were treated. About half of the acidified area was restored until the early 1990s (55–57).

Manmade lakes worldwide amount to tens of thousands of reservoirs and pit lakes from surface mining on coal, gravel, and ores. Reservoirs show limnological peculiarities (58,59) that primarily result from the management regime. The state of reservoir building and its problems are presented by the World Dam Commission (http://www.wdc.org). The water chemistry of pit lakes from coal or ore mining is determined by geogenic impacts, mostly acidification and contamination by heavy metals. Reviews and other comprehensive scientific publications on mining lakes are in an initial state (60).

Some traditional institutions for limnology investigated "their" lakes over a long period. Eutrophication and acidification of surface waters by acid rain were recognized because of these long-term observations. The effects of countermeasures, stepwise reoligotrophication, and neutralization were also monitored hereby. Only long datasets by traditional long-term investigations (e.g., "Long Term Ecological Research") render possible the analyses of the responses of lakes and rivers (61). Presently, these datasets are reevaluated to track the effects of long-term changes of climate on the physical, chemical, and ecological behavior of lake systems and rivers (62,63). In addition, paleolimnologists get information for previous changes of climate and of nutrient inputs altering in the course of historical and geological times, by investigating the fossil rests of organisms and other suitable proximate-indicators in laminated lake sediments (64–66). In most lakes of temperate regions, the sediments show data reaching back to the end of the last glaciation, and to some million years in the oldest, tertiary lakes like Lake Biwa, Japan (67).

ADSORPTION OF METAL IONS ON BED SEDIMENTS

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

The adsorption characteristics of cadmium on bed sediments of the River Ganga (India) have been studied to determine the tolerance of the river system for the heavy metal load. The effect of various controlling parameters, initial concentration, solution pH, sediment dose, contact time and particle size, have been evaluated. The optimum contact time needed to reach equilibrium was approximately 60 minutes and was independent of the initial concentration of cadmium ions. The adsorption curves are smooth and continuous leading to saturation, suggesting a possible monolayer coverage of cadmium ions on the surface of the adsorbent. The extent of adsorption increases with pH. Furthermore, the adsorption of cadmium increases as adsorbent doses increase and as adsorbent particle size decreases. The two geochemical phases, iron and manganese oxides, probably support the adsorption of cadmium ions. The adsorption data have been analyzed by using the Langmuir and Freundlich adsorption models to determine the mechanistic parameters of the adsorption process. Isotherms have been used to obtain thermodynamic parameters, free energy change (ΔG^o), enthalpy change (ΔH^o) and entropy change (ΔS^o). The negative values of free energy change (ΔG^o) indicate the spontaneous nature of the adsorption of cadmium on bed sediments, and the positive values of enthalpy change (ΔH^o) suggest the endothermic nature of the adsorption process. The uptake of cadmium is controlled by bulk as well as intraparticle diffusion mechanisms.

INTRODUCTION

Heavy metals added to a river system by natural and man-made sources during their transport are partitioned among different compartments of aquatic ecosystems, such as water, sediment, and biota (1). The added heavy metals then undergo many different chemical changes, whereby a high degree of variation in metal concentrations occurs (1,2). Metals that do not remain soluble in water are adsorbed and accumulate on bottom sediments that act as a sink (3). The distribution of heavy metals in the bottom sediments is affected by the mineralogical and chemical composition of the suspended material, anthropogenic influences, and *in situ* processes such as deposition, sorption, and enrichment in organisms (4). Thus, in the natural conditions of the river water, suspended and riverbed sediments play an important role in buffering higher metal concentrations in water, particularly by adsorption and/or precipitation. Therefore, the study of sediments and their sorptive properties can provide valuable information relating to the tolerance of the system to the added heavy metal load and may determine the fate and transport of pollutants in the aquatic environment.

The tremendous increase in the use of heavy metals during the past few decades has resulted in an increased concentration of metals in waterbodies and has great environmental significance due to their toxicity and nonbiodegradable nature (5). Cadmium, one of the most toxic metals, finds its way to watercourses through wastewater discharges from metal plating and cadmium–nickel battery industries, phosphate fertilizers, mining, pigments, stabilizers, and alloys (6). The toxic effects of cadmium include high blood pressure, kidney damage, and destruction of testicular tissue and red blood cells (7). Even low concentrations of cadmium cause hypertensive diseases. The International Agency for Research on Cancer classified cadmium as one of the chemicals that is carcinogenic to humans (8). Therefore, understanding the environmental conditions and mechanisms that regulate the mobilization and distribution of cadmium in the environment is essential.

Gardiner (9) studied the effect of various parameters on the adsorption of cadmium on river mud and other natural solids. Koelmans and Lijklema (10) studied the adsorption of cadmium onto sediment and suspended solids in Lake Volkerak in The Netherlands and reported that cadmium is bound almost completely to geochemical iron, manganese, and organic phases. Wiley and Nelson (11) examined the influence of various factors on the adsorption of cadmium onto the sediments of Sturgeon Lake in Oregon and reported that pH is the most critical parameter affecting cadmium adsorption. Christensen (12) and Palheiros et al. (13) also reported almost similar findings. Bajracharya et al. (14) studied the effect of zinc and ammonium ions on the adsorption of cadmium on sand and soil and reported that both ions suppress adsorption capacity significantly. Fu and Allen (15) studied the adsorption of cadmium by oxic sediments using a multisite-binding model. The model has been used satisfactorily to predict the extent of adsorption across the pH range 4.5–7.0.

Despite the apparent wealth of information on adsorption processes, little is known about quantitatively describing adsorption by coarser sediment. The important components of the suspended load for geochemical transport are silt, clay, hydrous iron and manganese oxides, and organic matter. Generally, adsorption studies for sediment less than 50 μm in size predominate (13,16); those for sediment more than 75 μm in size are lacking because sorption decreases as particle size increase. Although clay and silt adsorb metal ions much better than coarser fractions of sediment, one should take into account that most river sediments contain 90–95% sand and only 0–10% clay and silt. Therefore, in river systems that have a high sand percentage and low clay and silt content, the overall contribution of the sand to adsorption of metal ions could be comparable to or even higher than that of the clay and silt fraction. Our earlier efforts to establish this hypothesis have been quite successful (17–19).

Recently, we studied the adsorption characteristics of zinc on bed sediments of the River Ganga (20). In this article, we report the adsorption of cadmium on bed sediments of the River Ganga to assess the tolerance of the river system to the added cadmium load. The importance of geochemical phases has been investigated. Adsorption data have been analyzed by using adsorption models to determine the mechanistic parameters of the adsorption process, and isotherms have been used to obtain thermodynamic parameters.

THE RIVER SYSTEM

The River Ganga is a perennial river formed by the confluence of two smaller rivers at Deoprayag. Bhagirathi is one of them originating at Gaumukh in the Gangotri Glacier, 3129 m above mean sea level; the other is Alaknanda that originates in Sapta Tal Glacier. After covering a distance of about 220 km in the Himalayas, it enters the plains at Hardwar, and after meandering across a distance of about 2290 km in the plains of Uttar Pradesh, Bihar, and West Bengal, it joins the Bay of Bengal through a large number of branches flowing in India and Bangladesh (Fig.1).

Physiographically, the area is generally flat, except for the Siwalik Hills in the north and northeast of the catchment. The area is devoid of any relief features of provinces except from deep gorges cut by drains and rivers flowing through the area. The drainage pattern is dominated by the River Ganga, which is the only major river flowing through the area. The meltwater of the glaciers in the upper Himalayas maintains a perennial supply of water in the River Ganga.

The region is characterized by a moderate type of subtropical monsoonal climate. It has a cool, dry, winter season from October to March, a hot, dry, summer season from April to June, and a warm rainy season from July to September. The average annual rainfall across the Ganga Basin varies from 780 mm in the upper part to 1040 mm in the middle course and 1820 mm in the lower delta of Bangladesh (21). It has been observed that the rainfall is heaviest in the northern region of Hardwar district, close to the foothills of the Himalayas, and becomes less southward. The major land use is agriculture, and there is no effective forest cover.

Geologically, the area is a part of the west Indogangetic plain, which is composed mainly of Pleistocene and subrecent alluvium brought down by the river action from the Himalayan region. At Hardwar, the sequence of sandstone and shales along with gravel beds and clays are grouped within the upper and middle Siwaliks. The soils of this region do not form a compact block. They differ from valley to valley and slope to slope according to different ecological conditions. The bed of the river is rocky down to Hardwar. The soils of the area are predominantly loam to silty loam and are normally free from carbonates. The pollution status of the River Ganga has been described earlier (22,23).

EXPERIMENTAL METHODOLOGY

Freshly deposited sediments from shallow water near the bank of the River Ganga at Hardwar in the state of Uttaranchal were collected in polyethylene bags and brought to the laboratory. Samples were taken from the upper 5 cm of the sediments where flow rates were low and sedimentation was assumed (24,25).

The size distribution of the sediment samples was analyzed by using nylon sieves to obtain various fractions. The textural features of the sediments were observed, and a preliminary classification made according to grain size and distinctive geochemical features. The important geochemical phases for the adsorption process are organic matter, manganese oxides, iron oxides, and clays. The contents of manganese oxide and iron oxide were measured as total manganese and total iron, respectively, and were extracted from the sediment samples using acid

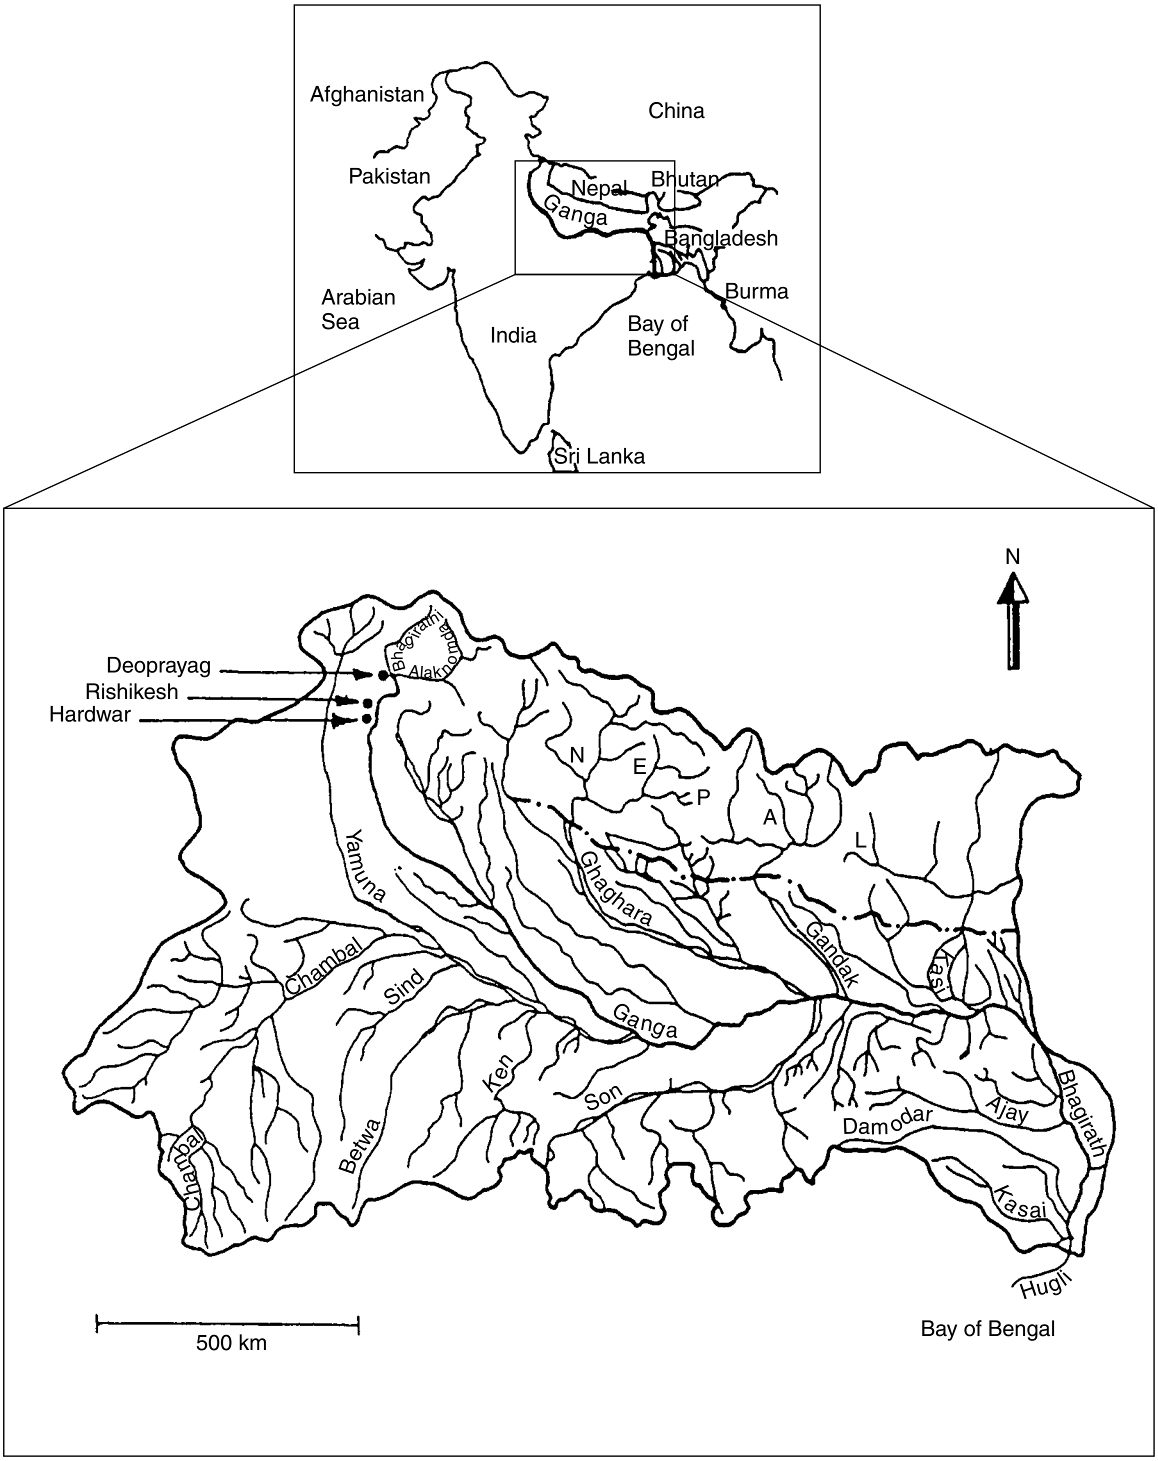

Figure 1. The Ganga Basin showing the locations of the sediment sampling sites.

digestion ($HF + HClO_3 + HNO_3$) in an open system. Organic matter was determined by oxidation with hydrogen peroxide.

All chemicals used in the study were obtained from Merck, India, and were of analytical grade. Aqueous solutions of cadmium were prepared from cadmium nitrate. Deionized water was used throughout the study. All glassware and other containers were thoroughly cleaned by soaking in detergent followed by soaking in 10% nitric acid for 48 h and finally rinsed with deionized water several times prior to use.

Adsorption experiments were conducted in a series of Erlenmeyer flasks of 100 mL capacity covered with Teflon sheet to prevent introduction of any foreign particles. Fifty mL of cadmium ion solution (200–2000 μg/L) was transferred in the flasks together with desired adsorbent doses (W_s in g/L), and placed in a water bath shaker maintained at 30 °C. A pH of 6.5 ± 0.1 was maintained throughout the experiment by using dilute HNO_3 and NaOH solutions. Aliquots were retrieved periodically and filtered through 0.45 μm cellulose nitrate membrane filters. The filters were soaked in 1% v/v HNO_3 for 1 h and thoroughly rinsed with deionized water prior to use.

The concentration of cadmium ions was determined by flame atomic absorption spectrometry, using a Perkin-Elmer Atomic Absorption Spectrometer (Model 3110) with air–acetylene flame. The detection limit for the cadmium ion was 0.0005 mg/L. Operational conditions were adjusted to yield optimal determinations. Quantification of metals was based on calibration curves of standard solutions of cadmium ion. These calibration curves were determined several times during the period of analysis.

RESULTS AND DISCUSSION

The content of important geochemical phases (iron and manganese) in different fractions of the sediment along with weight percentages are given in Table 1. The sediment has a coarse texture and is composed of more than 90% sediment of size >75 μm and <10% silt and clay. The organic content of the sediment was of the order of 0–1%. The background cadmium level in the various fractions of the sediments was negligible in the unpolluted zone, compared to the amount of adsorbate added for the adsorption tests. This confirms the absence of any cadmium particulate attached to the sediment particles.

It is evident from the data that the amount of manganese and iron in the various fractions of the sediment decreases as particle size increases. This indicates the possibility that the two geochemical phases act as active support material for the adsorption of cadmium ions. However, the relative contribution of the individual components could not be obtained from the present studies because the type and composition of a sediment's mineral and organic fractions vary simultaneously in natural systems, and the effect of individual constituents cannot be isolated. The content of iron in the sediment fractions is relatively higher and indicates the possible presence of iron minerals other than hydroxides. However, this result should be confirmed by further investigations. It is further evident from Table 1 that the sediment fraction of 150–210 μm particle size constitutes 68.6% of the total sediment load. Therefore, it was considered appropriate to study the adsorption of cadmium ions on this fraction (150–210 μm) and to compare it to the clay and silt fraction (<75 μm particle size) to demonstrate the importance of the coarser fraction in controlling metal pollution.

Table 1. Characteristics of Sediments

Sediment Fraction, μm	Weight, %	Total Mn, mg/g	Total Fe, mg/g
<75	9.8	1.570	68.2
75–150	13.5	1.420	62.0
150–210	68.6	1.199	58.0
210–250	6.6	0.844	55.1
250–300	0.7	0.830	52.1
300–425	0.6	0.823	52.0
425–600	0.2	0.824	52.0

OPERATING VARIABLES

Equilibrium Time (*t*)

To determine the equilibrium time for the adsorption process, adsorption experiments were performed for the uptake of cadmium ions for different contact times and for a fixed adsorbent dose of 0.5 g/L and an initial cadmium concentration of 1000 μg/L for the two particle sizes of adsorbent (0–75 and 150–210 μm) at pH 6.5 (Fig. 2). The solution pH for the experiments was close to that encountered in the river water. These plots indicate that the concentration of cadmium ions in solution becomes asymptotic to the time axis such that there is no appreciable change in the remaining concentration after 60 minutes in both fractions. This time is presumed to represent the time at which an equilibrium concentration is attained. All additional experiments were conducted for 60 minutes.

According to Weber and Morris (26), the uptake for most adsorption processes varies almost proportionately as $t^{1/2}$ rather than as contact time. Therefore, plots of

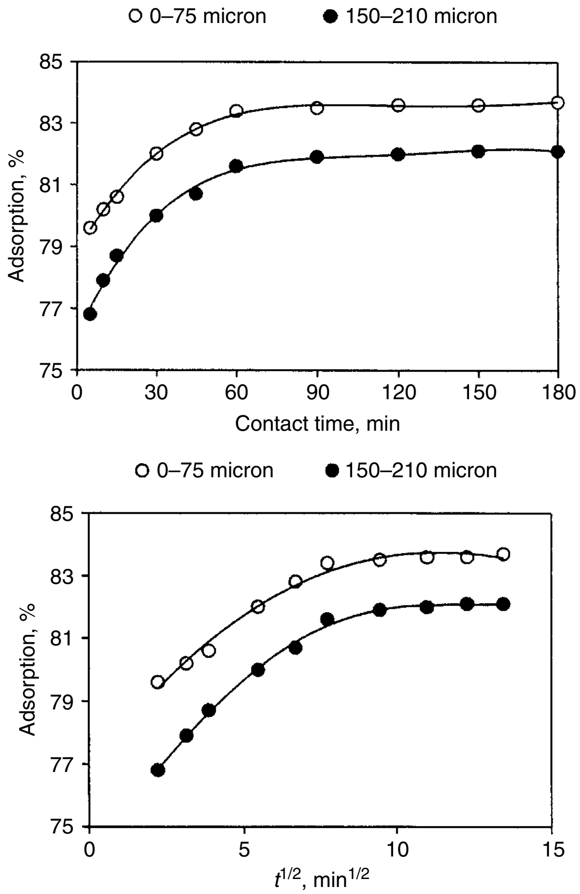

Figure 2. Effect of contact time (t and $t^{1/2}$) on percent adsorption of cadmium ions.

cadmium adsorbed, C_t versus $t^{1/2}$, are also presented for the two particle sizes of adsorbent in Fig. 2. It is clearly evident that adsorption of cadmium ions follow three phases: (1) an early extremely fast uptake (Phase I), (2) a transition phase (Phase II), and (3) an almost flat plateau section (Phase III). Phase I is attributed to the instantaneous use of the most readily available adsorbing sites on the adsorbent surface (bulk diffusion). Phase II, exhibiting additional removal, is attributed to the diffusion of the adsorbate from the surface film into the macropores of the adsorbent (pore diffusion or intraparticle diffusion), stimulating further migration of adsorbate from the liquid phase onto the adsorbent surface. Phase III, a plateau section, represents the equilibrium state.

Adsorption Isotherm

The adsorption isotherms for cadmium adsorption on the bed sediments, shown in Fig. 3, have a fixed adsorbent dose of 0.5 g/L at a pH of 6.5 ± 0.1. The adsorption data indicate linear distribution in the range 0 to 1000 μg/L. It is evident that for the same equilibration time, the amount of cadmium adsorbed is greater for greater initial concentrations of cadmium ions. In addition, the percentage adsorbed is greater for lower initial concentrations of cadmium and decreases as the initial concentration increases (Fig. 3). This is obvious because more efficient use of the adsorptive capacities of the adsorbent is expected from a greater driving force.

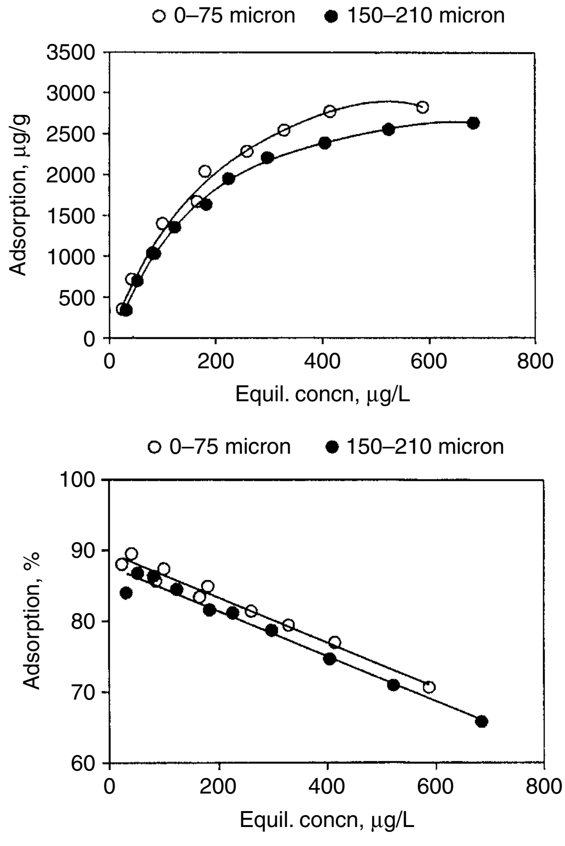

Figure 3. Adsorption of cadmium ions at different concentrations.

Comparing the two plots, it is clearly evident that the affinity of cadmium is greater for the <75-μm fraction, clay and silt, compared to the coarser fraction. It is also evident from Table 1 that the <75 μm fraction contains more iron and manganese than the 150–210 μm fraction, indicating the possibility of an association of these substrate (iron and manganese) with clay and silt particles. These findings illustrate the possible role of clay and silt as sites for cadmium adsorption. However, due to the paucity of data, correlation statistics could not be attempted to confirm this statement. The clay and silt constitute <10% of the total sediment load; comparing the weight percentages of the <75 μm to the 150–210 μm and their corresponding adsorption capacities for cadmium ions, it is clear that the coarser sediment contributes more than the clay and silt fraction in controlling cadmium pollution.

Effect of pH

The adsorption of cadmium on the riverbed sediments was studied across the pH range 2–7 for a fixed initial concentration of cadmium ($C_i = 1000$ μg/L) and an adsorbent dose of 0.5 g/L at particle sizes of 0–75 and 150–210 μm (Fig. 4). The pH of the solution was adjusted by using dilute hydrochloric acid and sodium hydroxide solutions. The pH was measured before and after the solution had been in contact with the sediment; the difference between the two values was generally less than 0.1 pH unit. A general increase in adsorption as the pH of solution increased was observed up to pH 6.0 for both fractions of the sediment. From the results, it is evident that the pH for maximum uptake of cadmium ion is 6.0. Further, it is apparent that the adsorption of cadmium rises from 6.5% at pH 2.0 to 83.3% at pH 6.0 for the clay and silt fraction (0–75 μm) and from 3.9% at pH 2.0 to 81.5% at pH 6.0 for the coarser sediment fraction (150–210 μm). A similar trend for pH was reported by Palheiros et al. (13) for the adsorption of cadmium on riverbed sediment.

Adsorbent Dose (W_s)

The effect of adsorbent dose on the adsorption properties of the bed sediments of the River Ganga was studied at

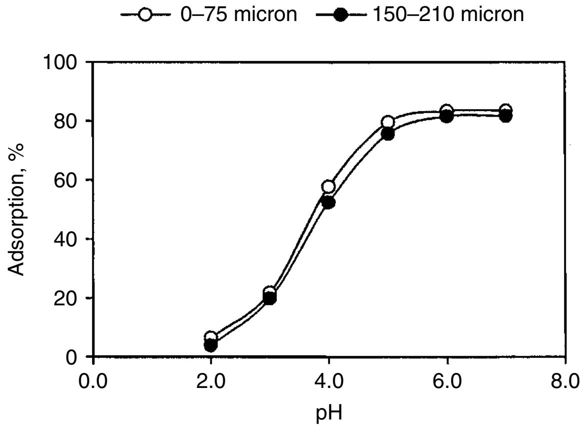

Figure 4. Effect of pH on adsorption of cadmium ions.

pH 6.5 using different adsorbent doses varying from 0.5 to 2.5 g/L and at a fixed initial cadmium concentration of 1000 μg/L (Fig. 5). The experiments were conducted in a water bath shaker to disperse the sediment particles in the aqueous medium. It was observed that for a fixed initial concentration of cadmium ($C_0 = 1000$ μg/L), the adsorption of cadmium per unit weight of adsorbent decreases as adsorbent load increases. On the other hand, the percent adsorption increases from 83.4 to 93.7% for the 0–75 μm fraction as the adsorbent load increases from 0.5 to 2.5 g/L. The adsorption of cadmium was higher for the 0–75 μm fraction compared to the 150–210 μm fraction. Because of the higher surface area as well as higher content of iron and manganese in the 0–75 μm fraction; these are the main driving forces for the adsorption of cadmium ions.

Particle Size (d_p)

The effect of adsorbent particle size on cadmium adsorption is shown in Fig. 5 for a fixed initial concentration of cadmium ($C_i = 1000$ μg/L), an adsorbent dose of 0.5 g/L, and at pH 6.5. These plots reveal that for a fixed adsorbent dose, smaller particles adsorb more cadmium. Further, it is observed that the percentage of cadmium adsorbed decreases from 83.4% on the 0–75 μm fraction to 77.4% on the 425–600 μm fraction. This result occurs because adsorption is a surface phenomenon; the smaller particle sizes offered a comparatively larger surface area and hence higher adsorption occurred at equilibrium. The higher content of iron and manganese in the 0–75 μm sediment fraction also accounts for greater adsorption of cadmium in this fraction compared to larger size fractions of the sediment.

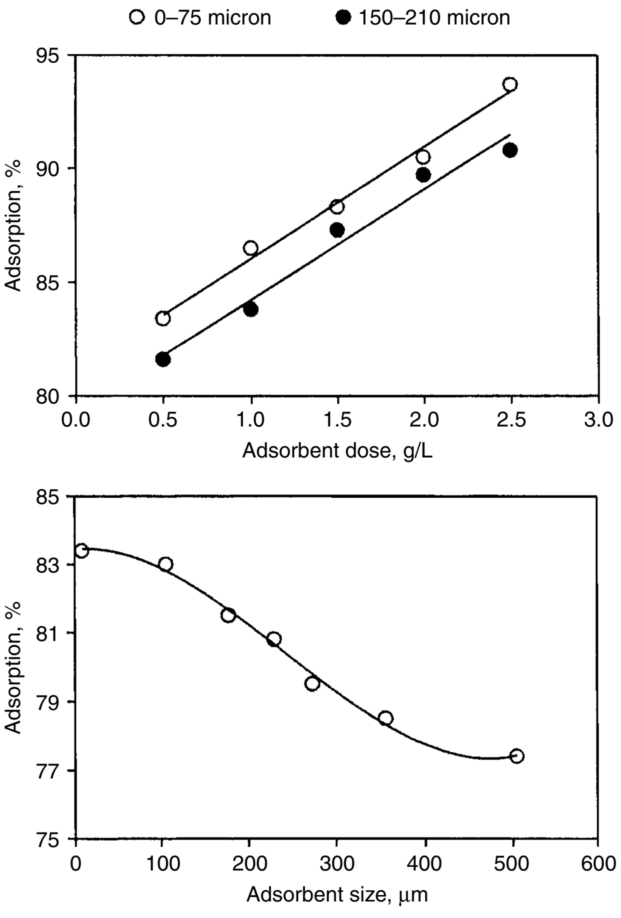

Figure 5. Effect of adsorbent dose and size on adsorption of cadmium ions.

ADSORPTION MODELS

Adsorption data for a wide range of adsorbate concentrations are most conveniently described by adsorption models, such as the Langmuir or Freundlich isotherm, which relate adsorption density q_e (metal uptake per unit weight of adsorbent) to equilibrium adsorbate concentration in the bulk fluid phase, C_e. The adsorption data for cadmium on the bed sediments of the River Ganga was analyzed using Langmuir and Freundlich models to evaluate the mechanistic parameters of the adsorption process.

Langmuir Model

Langmuir's isotherm model is valid for monolayer adsorption onto a surface containing a finite number of identical sites. The Langmuir treatment is based on the assumption that maximum adsorption corresponds to a saturated monolayer of solute molecules on the adsorbent surface, that the energy of adsorption is constant, and that there is no transmigration of adsorbate in the plane of the surface.

The linear form of Langmuir isotherm equation is represented by the following equation:

$$\frac{1}{q_e} = \frac{1}{Q^o} + \frac{1}{bQ^oC_e} \tag{1}$$

where q_e is the amount adsorbed at equilibrium time (μg/g), C_e is the equilibrium concentration of the adsorbate ions (μg/L), and Q^o and b are Langmuir constants related to maximum adsorptive capacity (monolayer capacity) and energy of adsorption, respectively. When $1/q_e$ is plotted against $1/C_e$, a straight line of slope $1/bQ^o$ and intercept $1/Q^o$ is obtained (Fig. 6), which shows that the adsorption of cadmium ions follows the Langmuir isotherm model. The Langmuir parameters, Q^o and b, are calculated from the slope and intercept of the graphs and are given in Table 2. These values may be used for comparison and correlation of the sorptive properties of the sediments.

Freundlich Model

The Freundlich equation, widely used for many years, is applicable to isothermal adsorption. This is a special case of heterogeneous surface energies in which the energy term, b, in the Langmuir equation varies as a function of surface coverage, q_e, strictly due to variations in the heat of adsorption (27). The Freundlich equation has the general form,

$$q_e = K_F C^{1/n} \tag{2}$$

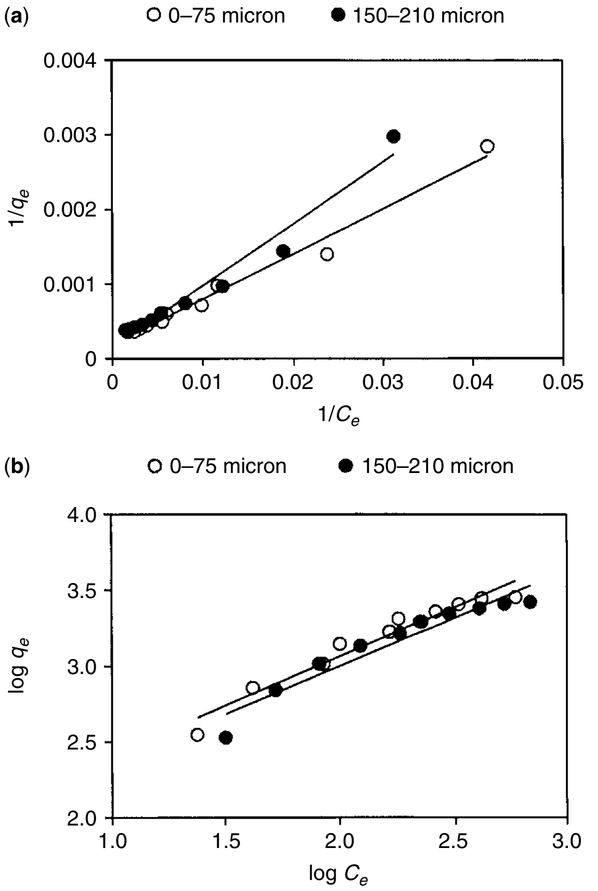

Figure 6. Graphical representation of adsorption isotherms: (**a**) Langmuir isotherm and (**b**) Freundlich isotherm.

The Freundlich equation is basically empirical but is often useful to describe data. Data are usually fitted to the logarithmic form of the equation,

$$\log q_e = \log K_F + \frac{1}{n}\log C_e \tag{3}$$

where q_e is the amount adsorbed (μg/g), C_e is the equilibrium concentration of the adsorbate ions (μg/L), and K_F and n are Freundlich constants related to adsorptive capacity and adsorptive intensity, respectively. When log q_e is plotted against log C_e, a straight line of slope $1/n$ and intercept log K_F is obtained (Fig. 6). This plot reflects satisfaction of the Freundlich isotherm model for the adsorption of cadmium ions on Ganga River sediment. The intercept of the line, log K_F, roughly indicates the adsorptive capacity, and the slope, $1/n$, indicates adsorptive intensity (28). The Freundlich parameters for the adsorption of two metal ions are given in Table 3.

Table 2. Langmuir Parameters for the Adsorption of Cadmium

Sediment Fraction, μm	Adsorption Maxima, Q^o, mg/g	Binding Energy Constant, b, mg/L
0–75	5.0	3.306
150–210	10.0	1.206

Table 3. Freundlich Parameters for the Adsorption of Cadmium

Sediment Fraction, μm	Adsorptive Capacity, K_F mg/g	Adsorptive Intensity, $1/n$
0–75	0.0045	1.765
150–210	0.0043	1.726

The Freundlich type adsorption isotherm is an indication of the surface heterogeneity of the adsorbent, and the Langmuir type isotherm corresponds to the surface homogeneity of the adsorbent. This leads to the conclusion that the surface of the bed sediments of the River Ganga is made up of small heterogeneous adsorptive patches that are similar to each other in respect to adsorptive phenomena (29).

THERMODYNAMICS

The effect of temperature on the adsorption of cadmium on bed sediments of the River Ganga is shown in Fig. 7 for a fixed adsorbent dose of 0.5 g/L and an initial cadmium concentration of 1000 μg/L at pH 6.5 for the two sediment fractions (0–75 μm and 150–210 μm). The temperature range used in the study was from 20 to 40 °C. It is evident from the plots that the adsorption of cadmium increases as temperature increases for both fractions, which may be mainly due to an increase in the number of active sites caused by the breaking of some bonds.

Thermodynamic parameters such as free energy change (ΔG^o), enthalpy change (ΔH^o), and entropy change (ΔS^o) were determined by using the following equations (30–32).

$$\Delta G^o = -RT\ln K_c \tag{4}$$

$$\Delta G^o = \Delta H^o - T\Delta S^o \tag{5}$$

where

ΔG^o = change in free energy, kJ/mol;
ΔH^o = change in enthalpy, kJ/mol;
ΔS^o = change in entropy, J/mol/K;
T = absolute temperature, K;
R = gas constant = 8.314×10^{-3};
K_c = equilibrium constant, defined as

$$K_c = \frac{C_{Ae}}{C_e} \tag{6}$$

where C_{Ae} and C_e are the equilibrium concentrations (μg/L) of the metal ions on the adsorbent and in the solution, respectively.

Equations 4 and 5 can be combined and rewritten as

$$\log K_c = \frac{\Delta S^o}{2.303R} - \frac{\Delta H^o}{2.303RT} \tag{7}$$

When log K_c is plotted against $1/T$, a straight line of slope $\frac{\Delta H^o}{2.303R}$ and intercept $\frac{\Delta S^o}{2.303R}$ is obtained (Fig. 8).

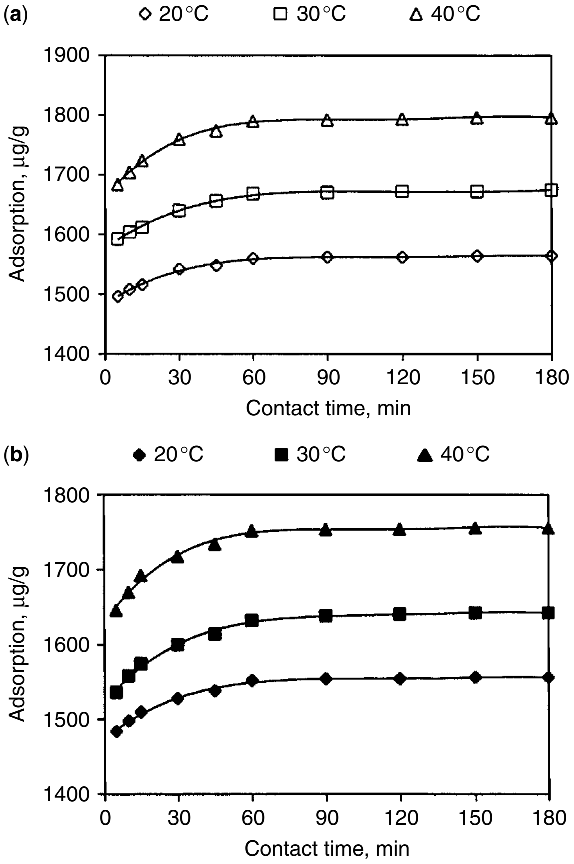

Figure 7. Effect of contact time and temperature on adsorption of cadmium ions: (**a**) sediment fraction = 0–75 µm; (**b**) sediment fraction = 150–210 µm.

The values of ΔH^o and ΔS^o were obtained from the slope and intercept of the van't Hoff plots of $\log K_c$ vs $1/T$ (Fig. 8). The thermodynamic parameters for the adsorption process are given in Table 4.

Positive values of ΔH^o suggest the endothermic nature of the adsorption. Negative values of ΔG^o indicate the spontaneous nature of the adsorption process. However, the negative value of ΔG^o decreased as temperature increased, indicating that the spontaneous nature of adsorption is inversely proportional to the temperature. The positive values of ΔS^o show increased randomness at the solid/solution interface during the adsorption process. The adsorbed water molecules, which are displaced by the adsorbate species, gain more translational energy than is lost by the adsorbate ions, thus allowing the prevalence of randomness in the system. The enhancement of adsorptive capacity at higher temperatures may be attributed to the enlargement of pore size and/or activation of the adsorbent surface (33).

Adsorption Dynamics

The rate constant of adsorption is determined by using the Lagergren first-order rate expression, (34–36):

$$\log(q_e - q) = \log q_e - \frac{k_{\mathrm{ad}}}{2.303} \times t \tag{8}$$

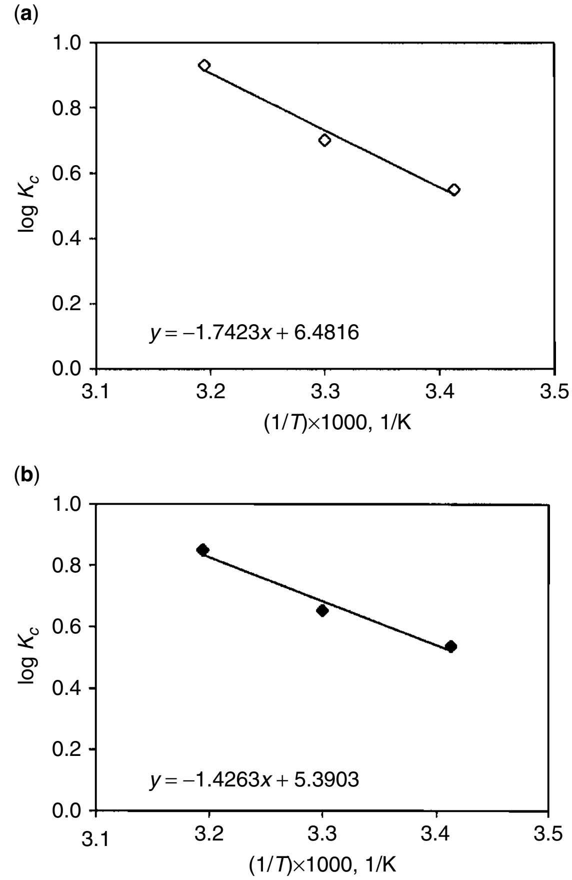

Figure 8. Van't Hoff plot for adsorption of cadmium ions: (**a**) sediment fraction = 0–75 µm; (**b**) Sediment fraction = 150–210 µm.

Table 4. Thermodynamic Parameters for the Adsorption of Cadmium

Sediment Fraction, µm	Temperature, °C	K_c	ΔG^o, kJ/mol	ΔH^o, kJ/mol	ΔS^o, J/mol/K
0–75	20	3.545	−3.083	33.36	124.1
—	30	5.024	−4.066	—	—
—	40	8.524	−5.576	—	—
150–210	20	3.444	−3.012	27.31	103.2
—	30	4.494	−3.786	—	—
—	40	7.064	−5.087	—	—

where q and q_e are the amounts of metal adsorbed (µg/g) at time t(min) and at equilibrium, respectively, and k_{ad} is the Lagergren rate constant for adsorption (1/ min). The straight line plots of $\log(q_e - q)$ versus t for different concentrations (Fig. 9) and temperatures (Fig. 10) indicate the applicability of this equation. Values of k_{ad} were calculated from the slope of the linear plots and are presented in Tables 5 and 6 for different concentrations and temperatures, respectively. The values of Lagergren rate constants (k_{ad}) were almost the same at both concentrations, whereas the value increases as temperature increases.

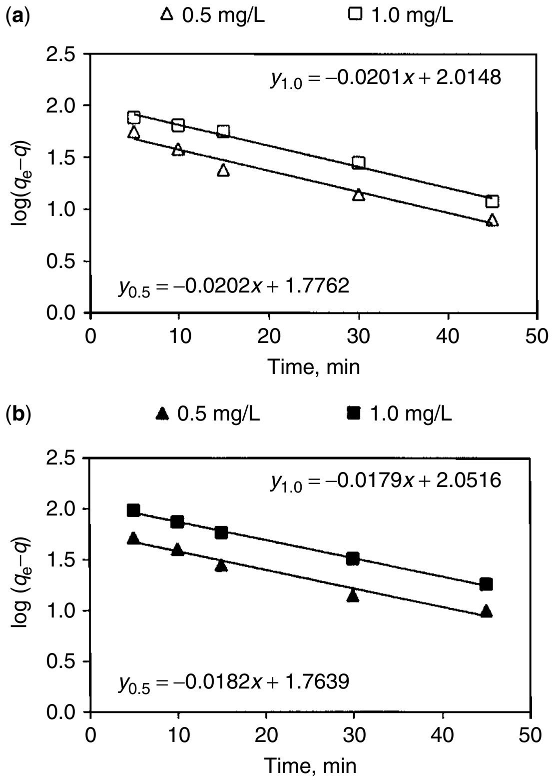

Figure 9. Lagergren plots at different initial concentrations: (**a**) sediment fraction = 0–75 μm; (**b**) sediment fraction = 150–210 μm.

Intraparticle Diffusion

The rate constant for intraparticle diffusion (k_{id}) is given by Weber and Morris (37):

$$q = k_{\mathrm{id}} t^{1/2} \tag{9}$$

where q is the amount adsorbed (μg/g) at time t (min). Plots of q versus $t^{1/2}$ are shown in Figs. 11 and 12 for different initial concentrations and temperatures, respectively. All plots have the same general features, an initial curved portion followed by a linear portion and a plateau. The initial curved portion is attributed to bulk diffusion, the linear portion to intraparticle diffusion, and the plateau to the equilibrium. This indicates that transport of cadmium ions from the solution through the particle solution interface, into the pores of the particle as well as the adsorption on the available surface of sediment, are both responsible for the uptake of cadmium ions. The deviation of the curves from the origin also indicates that intraparticle transport is not the only rate limiting step. The values of the rate constants (k_{id}) were obtained from the slope of the linear portion of the curves for each concentration of metal ions (Table 5) and temperature (Table 6). The values of intraparticle rate constants (k_{id}) increase as concentration and temperature increase.

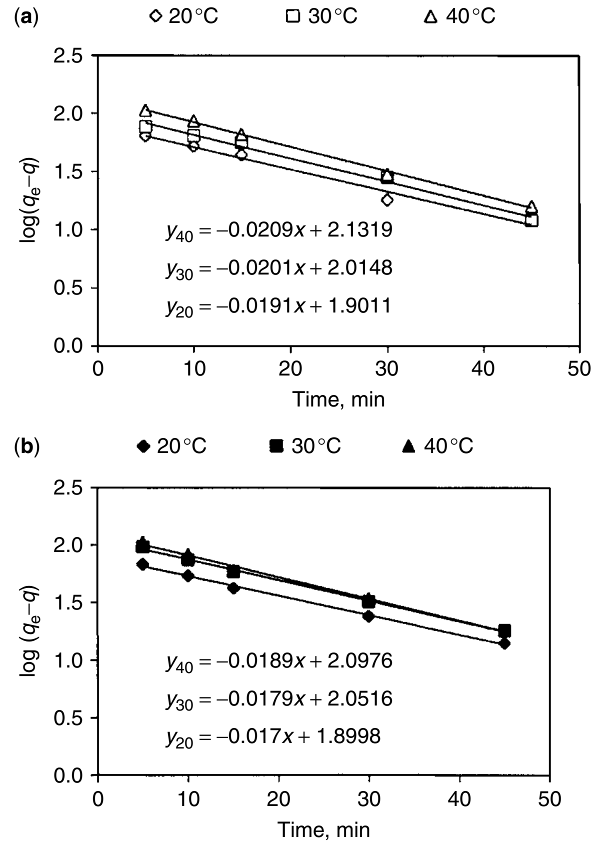

Figure 10. Lagergren plots at different temperatures: (**a**) sediment fraction = 0–75 μm; (**b**) sediment fraction = 150–210 μm.

Table 5. Rate Constants at Different Concentrations

Sediment Fraction, μm	Concentration, μg/L	Lagergren Rate Constant k_{ad} (1/ min)	Intraparticle Rate Constant k_{id}, μg/g/min
0–75	500	4.65×10^{-2}	3.84
—	1000	4.63×10^{-2}	9.88
150–210	500	4.19×10^{-2}	5.85
—	1000	4.12×10^{-2}	8.86

Table 6. Rate Constants at Different Temperatures

Sediment Fraction, μm	Temperature °C	Lagergren Rate Constant k_{ad} (1/ min)	Intraparticle Rate Constant k_{id}, μg/g/min
0–75	20	4.40×10^{-2}	8.11
–	30	4.63×10^{-2}	11.80
–	40	4.81×10^{-2}	14.29
150–210	20	3.92×10^{-2}	7.50
–	30	4.12×10^{-2}	10.00
–	40	4.35×10^{-2}	12.35

CONCLUSION

The study has demonstrated that river sediments provide good buffering capacity for metal loads. Although cadmium ions have more affinity for the clay and silt fraction of the sediment, the overall contribution of the coarser fraction to adsorption is greater compared to the clay and silt fraction. The pH of the solution is the most important parameter in the control of cadmium pollution.

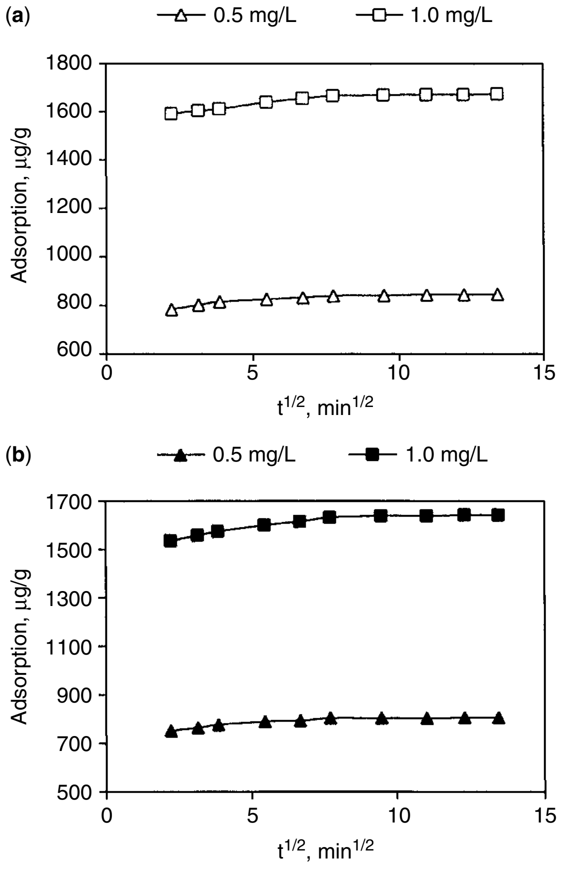

Figure 11. Intraparticle diffusion plots at different initial concentrations: (**a**) sediment fraction = 0–75 μm; (**b**) sediment fraction = 150–210 μm.

Iron and manganese oxides support the adsorption of cadmium. The adsorption data follow both the Langmuir and Freundlich isotherm models. The kinetic data suggest that the adsorption of cadmium is an endothermic process, which is spontaneous at low temperature. The uptake of cadmium is controlled by both bulk as well as intraparticle diffusion mechanisms. It is stated that in natural river systems, salinity and pH greatly affect the speciation of the metal ions and thus greatly interfere with their fixation on clay minerals. Adsorption/desorption equilibria and complexation with fulvic and humic acids also play an important role in speciation. Further studies are being planned to understand better the processes that affect the sorption of cadmium in natural systems.

MICROBIOLOGY OF LOTIC AGGREGATES AND BIOFILMS

Eric A. Strauss
Upper Midwest Environmental
Sciences Center
La Crosse, Wisconsin

INTRODUCTION

The microbial community is a vital component of lotic (flowing water) ecosystems and is important for nutrient cycling, organic matter decomposition, downstream transport of materials, and transfer of energy to higher trophic levels. Some of this microbial community is transported downstream as unattached cells; however, much of it is associated with suspended organic particles (i.e., aggregates) or attached to available substrate in biofilms. Research on microbial activity within organic aggregates has mostly been limited to marine and lake systems. As a result, more is known about the microbial communities and microbial processes in marine and lake aggregates compared with aggregates in lotic ecosystems. Conversely, biofilms have been studied in great detail in many systems, including lotic ecosystems. Many excellent and detailed reviews are available on the topics of aggregates and biofilms (1–11). Included here is a general overview of the microbiology and ecology of these topics and how they are relevant to lotic ecosystems.

LOTIC AGGREGATES

Origins and Terminology

Microorganisms readily colonize substrates in lotic ecosystems to form diverse and active communities. Suspended organic matter is often rich in nutrients and easily metabolized carbon, providing an especially good substrate for microbial colonization and growth and for the subsequent formation of lotic aggregates. Lotic aggregates can be defined as the interactive association between a microbial community and suspended organic matter in a flowing water system. The organic matter that is a central component of lotic aggregates may have a variety of origins including allochthonous and autochthonous particles and byproducts of animal and microbial activity. Allochthonous organic matter (e.g., wood, leaves, and terrestrial debris) readily enters lotic systems through various pathways. Larger particles tend to quickly settle onto the channel bed or get trapped in channel structures, whereas the smallest particles often become entrained in the flowing water. Over time, physical and biological processes fragment the large particles into smaller detrital particles, which can then become resuspended into the water column. Organic matter particles of autochthonous origin (e.g., biofilm slough and aquatic vegetation) also may become fragmented and entrained in the current in the same manner as those particles of allochthonous origin. Organic byproducts of animal activity such as fecal pellets and discarded invertebrate exoskeletons are common in highly productive systems and can be nutrient-rich substrates for microbial colonization (12). Aggregates also may form in conjunction with dissolved organic matter (13) or colloidal organic polymers that are small (1.5 nm to 0.45 μm), high-molecular-weight byproducts of organic matter decomposition that remain suspended in the water (14).

Aggregates have the potential to enlarge as they travel downstream by combining with other aggregates (aggregation) and to gather additional materials primarily through impaction (Fig. 1) (15). However, the physical forces exerted by flowing and turbulent water usually fragment larger aggregates (disaggregation), maintaining the aggregates at a smaller size compared with those found in nonflowing systems (16). Although relatively small, the size of lotic aggregates are still highly variable and can be further classified into microaggregates (<5 to 500 μm) and macroaggregates (>500 μm) (7). Larger aggregates are also sometimes called "river snow" in keeping with terminology used to describe similar aggregates present in marine (marine snow) and lake (lake snow) ecosystems (17,18). In the field of stream ecology, lotic aggregates may also be called seston, which can be defined as particles entrained in flowing water. A list of common terms and abbreviations used to describe suspended matter in lotic systems is provided in Table 1.

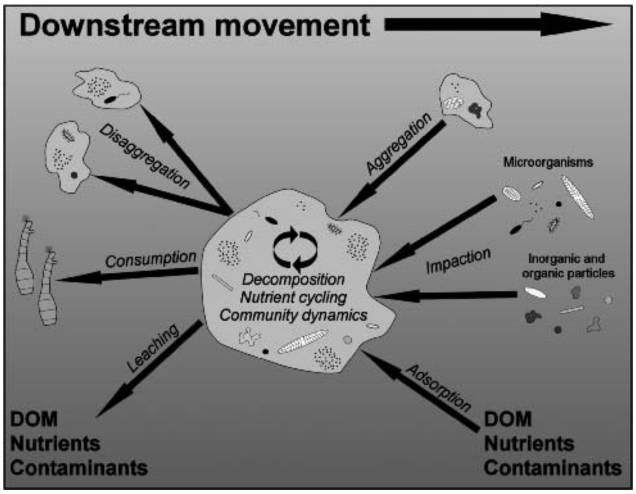

Figure 1. Conceptual diagram illustrating processes affecting lotic aggregate size and composition. DOM = dissolved organic matter.

Table 1. Common Terms, Abbreviations (in parentheses), and Sizes Used to Classify Suspended Matter in Flowing Water Systems

Term	Size
Dissolved organic matter (DOM)	<0.45 μm
Particulate organic matter (POM)	>0.45 μm
Course particulate organic matter (CPOM)	>1 mm
Fine particulate organic matter (FPOM)	0.45 μm to 1 mm
Aggregate	>0.45 μm
Macroaggregate	>500 μm
Microaggregate	<500 μm
Colloid	1.5 nm to 0.45 μm
Floc	>0.45 μm
Seston	>0.45 μm

The size ranges listed here are generally accepted definitions, but they can vary somewhat depending on application.

Microbial Community

Bacteria and other microorganisms secrete a viscous, slimy mixture of exopolymers (i.e., chains of polysaccharides) called glycocalyx. In general, the properties of exopolymers can contribute many beneficial functions to organisms including assisting in locomotion and adhesion to surfaces, and protection from abrasion, dehydration, and nutrient loss. More specifically, in lotic aggregates, the exopolymers bind the contents of aggregates together and assist in the capture of additional nutrients, organic matter, and other microorganisms. Much of the exopolymers associated with lotic aggregates are likely produced by microorganisms within the aggregate, but they also may accumulate via impaction with suspended exopolymers.

Microbial communities thriving within the fragile matrix of exopolymers and particles consist of a diverse heterogeneous assemblage of bacteria, algae, fungi, protozoa, and sometimes zooplankton. Compared with marine and lake ecosystems, relatively few studies have examined the microbial community structure of aggregates in lotic systems. However, many studies on marine aggregates have demonstrated that the concentration of algae, zooplankton, protozoa, and bacteria within aggregates is much greater, often 2–3 orders of magnitude, than in the surrounding water (7). Larger aggregates often support larger microbial communities, but smaller particles may be relatively more densely populated per unit surface area (19). Detailed microscopic analyses have shown that bacteria are not uniformly distributed within or on the surface of aggregates but form microcolonies (7). These microbial communities have temporally dynamic compositions that change quickly in response to conditions both inside and outside of the aggregate and can also exhibit seasonal patterns (17,20).

Inorganic (nitrogen, phosphorus, and silica) and organic (carbohydrates, amino acids, and dissolved organic carbon) nutrients are often 1–2 orders of magnitude more enriched in aggregates compared with surrounding water (7). In addition, many heavy metal and organic contaminants also readily adsorb to the aggregate matrix. As a result of these enriched conditions, downstream movement of aggregates is an important mechanism of transport for nutrients, organic materials, and contaminants. Moreover, these nutrient-rich substrates result in high growth efficiencies of heterotrophic bacteria associated with the lotic aggregates, which suggests that these aggregates are hot spots for microbial processes and the transfer of organic matter into bacterial biomass (20). Enzymes produced by aggregate-bound bacteria solubilize organic matter 1–2 orders of magnitude faster than the bacterial cells can assimilate the dissolved matter (21). This decomposition results in aggregate mass loss and leaching of dissolved organic matter back into the flowing water. Finally, consumption of lotic aggregates by many species of detritus- and filter-feeding organisms is a vital link of energy transfer between microbial and higher trophic levels (Fig. 1).

BIOFILMS

Biofilm Structure

Microbial biofilms are the thin slime layers that are observed on surfaces and substrates (e.g., rocks, sediment, vegetation, leaves, wood) in aquatic systems. Biofilms (sometimes called microbial mats) are similar to aggregates and possess many of the same general structural and functional attributes. For example, biofilms (like aggregates) contain microbial communities that are vital to lotic ecosystem function and are responsible for many key production, decomposition, and nutrient cycling processes (22). Highly developed biofilms are generally a few millimeters thick and can develop on virtually any available surfaces in natural lotic systems, provided the system has sufficient nutrients. Biofilm development is especially rapid on surfaces that contain or leach nutrients (e.g., particulate organic matter, POM) (2). Available surfaces are still colonized in nutrient-poor or oligotrophic systems, but biofilms are generally less developed. Under oligotrophic conditions, biofilm bacteria are often able to obtain limited nutrients by concentrating organics on the exopolymer matrix, using waste products of nearby microorganisms, and by pooling their biochemical resources (i.e., enzymes) to break down organic particles (11).

Historically, biofilms were thought to be a relatively homogeneous distribution of bacteria in an exopolymer matrix and nutrient and material delivery throughout the biofilm would be dominated by diffusion (2). However, recent advances in the analytical tools used to study biofilms have allowed scientists to more accurately characterize the structure or architecture of biofilms. For example, the application of confocal scanning laser microscopy has allowed nondestructive inspection of intact biofilm samples. This technique has revealed the physical structure of established biofilms to consist of a diverse microbial assemblage arranged in microcolonies and interspersed within a heterogeneous exopolymer matrix containing protrusions and a network of pores and channels (2,4). Microsensors, another relatively recent research tool, have been used to examine chemical properties in spatially explicit areas within biofilms and have found distinct differences in dissolved oxygen concentrations between the pores and channels in the matrix and the matrix itself. These differences suggest that such structures may facilitate water movement and nutrient delivery within the biofilm. Microsensors have also been used to quantify vertical chemical gradients in biofilms that have important implications for microbial community structure and biogeochemical processing (Fig. 2). Chemical gradients will be discussed further in the next section.

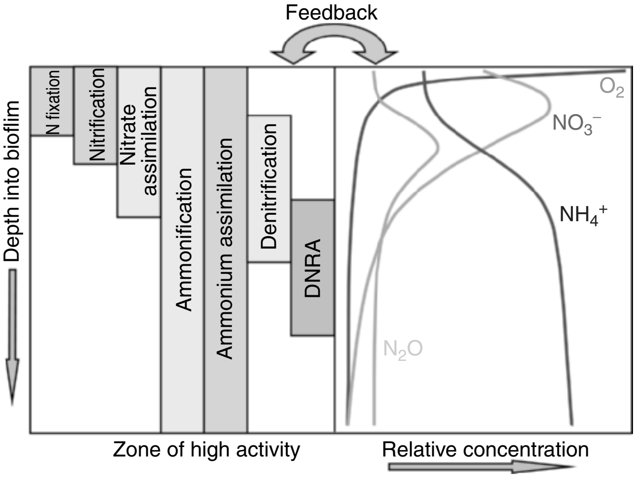

Figure 2. General patterns of nitrogen cycling (left) and relative concentrations of nitrogen constituents (right) in a lotic biofilm [redrawn and modified from Paerl and Pinckney (3)]. Feedback between the chemical and biological components facilitates the formation and equilibrium of the gradient (i.e., the chemical environment within the biofilm affects microbial processes and vice versa). DNRA = dissimilatory nitrate reduction to ammonium.

The physical stress caused by the turbulent flow of water in lotic systems can have significant effects on biofilm structure and organization. Many studies have observed that biofilms subjected to fast flowing water tend to be thinner, smoother, denser, more stable, and have lower surface sinuosity than biofilms in slower or nonflowing water (23,24). Cells occupying the surface of lotic biofilms have been observed to be arranged in formations that can withstand the higher shear stress; examples of these formations include hexagon-shaped structures and ripples positioned parallel to flow direction (24). Freely oscillating streamer-like structures are also sometimes observed adhered to the surface of lotic biofilms (8). Streamers are predominately single species colonies that elongate over time in the absence of disturbance.

Microbial Processes

The rates and types of microbial processes at work in any particular biofilm are largely regulated by the physical and chemical characteristics of the lotic environment. Several types of algae and cyanobacteria flourish in biofilms if sufficient nutrients are available and the overlying water is shallow and clear enough to allow adequate light penetration to the substrate. Oxygen (O_2) generated by these primary producers can reach very high levels and is a key factor supporting aerobic biofilm processes. In fact, under high-light conditions, the surficial area of well-lit biofilms can produce O_2 concentrations 2–3 times greater than atmospheric concentrations (25). Much, if not all, of the oxygen is respired as it is transported and diffused deeper into the biofilm creating a vertical gradient of oxygen concentrations throughout the biofilm (Fig. 2). Chemical gradients are common in biofilms and control which microbial processes are able to occur at certain depths. The opposite is also true; microbial processes control the availability of certain ions. The feedback relationship between these two factors quickly forms a relatively stable gradient equilibrium that is particularly important for the transformations and cycling of certain nutrients, primarily nitrogen, carbon, and sulfur.

The nitrogen cycle is a complex group of microbial processes that transform, oxidize, or reduce nitrogen ions among the various oxidation states. These processes occur under different environmental conditions, all of which can be located in distinct locations along the chemical gradients found in biofilms (Fig. 2). Nitrogen fixation, which is the conversion of atmospheric dinitrogen gas (N_2) to biologically available ammonium (NH_4^+), is predominately done by cyanobacteria; thus, it occurs in the upper, high-light areas of the biofilm. Nitrification, which is the oxidation of NH_4^+ to nitrate (NO_3^-), also occurs in the upper areas because it is an aerobic process. Bacteria that have the enzymes to reduce NO_3^- for assimilation likely occur throughout the biofilm profile, but they can only use NO_3^- where it is present. Organic matter is ubiquitous throughout the biofilm; therefore, ammonification (the release of NH_4^+ from organic matter) and the resulting NH_4^+ are also widespread. Ammonium assimilation into microbial biomass is not oxygen-dependent and can take place wherever NH_4^+ is present. Denitrification, which is the anaerobic reduction of NO_3^- to nitrite (NO_2^-), nitrous oxide (N_2O), and N_2, occurs deeper in the biofilm where oxygen is low and NO_3^- is high. Dissimilatory NO_3^- reduction to NH_4^+ is strictly an anaerobic process that occurs in the lowest areas of the biofilm where NO_3^- is still available.

It is generally accepted that bacterial activity and production of biofilm biomass is resource limited in lotic systems. Thus, nutrient availability and the quantity and quality of the dissolved organic carbon in the water have strong positive effects on bacterial activity in the biofilm (26,27). Total bacterial activity also often correlates well with primary production in biofilms because of the influx of oxygen and high-quality organic carbon provided by algae (27,28). Finally, vertical hydrodynamics of stream channels (i.e., upwelling and downwelling) can be an important means of nutrient and dissolved organic matter (DOM) delivery through the biofilm, which can subsequently increase microbial activity (29).

Under certain chemical or physical conditions, specialized biofilms that are dominated by unique groups of microorganisms may develop. For example, orange-colored iron-oxidizing biofilms are prevalent in areas where groundwater with high concentrations of reduced iron (Fe^{2+}) is discharged into oxygenated waters (30). Another example is the colorful biofilms of thermophilic bacteria and cyanobacteria that are commonly associated with water flowing from hot springs (Fig. 3). The colors of these biofilms depend primarily on the chlorophyll content in the cells, but also on the ratio of chlorophyll to carotenoids (yellow to red pigments) (31).

MICROORGANISMS IN THEIR NATURAL ENVIRONMENT

Matthias Koschorreck
Center of Environmental
Research (UFZ)
Magdeburg, Germany

GENERAL REMARKS

In their natural aquatic environment, microbes face conditions that principally differ from the picture of a mixture of different microbes swimming around in a kind of liquid culture. The study of microorganisms in laboratory cultures often gives limited information about the role and behavior of microorganisms in their natural habitat. Our understanding of microbes in their natural aquatic habitat was considerably increased by the development of *in situ* methods in the last decades. The introduction of microsensors allowed characterizing the microbial habitat on the size scale of microorganisms. The recent advances in microscopic techniques (confocal laser scanning microscopy, atomic force microscopy) offer the possibility of real 3-D examination of microbial aggregates or biofilms. Molecular techniques such as *in situ* hybridization to study the phylogeny and physiology of microorganisms in their natural environment are rapidly, improving.

A characteristic of the natural habitat is its heterogeneity. Hot spots of high activity may be surrounded by a "desert." Natural habitats are characterized by **gradients**. The co-occurrence of various, sometimes opposing, gradients creates a high diversity of ecological niches.

Depending on transport velocities and reaction rates, these gradients can occur on a meter scale (in open water) down to a micrometer (in sediments) or even submicrometer scale (in microbial aggregates) (Fig. 1). The natural environment is not static but subject to fast **temporal fluctuations**. Temporal fluctuations occur on different timescales from seasonal effects down to very short-term changes within seconds or minutes. A phototrophic microbial mat, for example, can shift from oxygen oversaturation to anoxia within minutes when it is darkened (1). Microorganisms have developed different strategies to cope with changing conditions. The largest part of the bacteria in aquatic systems is in a metabolically inactive dormant state, waiting for favorable conditions. Motility, often in combination with chemotaxis, is an important strategy for following changing gradients. Microorganisms can also alter their phenotypic properties in response to changing conditions. On the scale of microorganisms, surface effects are important and **diffusion** becomes the dominant transport process. Solid surfaces are covered by a diffusive boundary layer (DBL) (2) (Fig. 1).

The term microbes means bacteria, algae, fungi, and protozoa. This article focuses on the ecology of bacteria in aquatic environments. A general overview of aquatic microbiology can be found in Ford (3), Hurst et al. (4), or Sorokin (5).

HABITATS

Aquatic systems offer different habitats for microbes to live in: free water, sediment, and hyporheic interstitial (6). Of special importance are interfaces such as the surface of water, sediment, rocks (epilithon), and aquatic plants (epiphyton). Microbes that live in **free water** (pelagic organisms) can be dispersed as single cells or concentrated in aggregates (Fig. 2). Organic aggregates, which are larger than 500 μm, are called lake, river, or marine "snow" (7). They are hot spots of microbial life in aquatic systems and are enriched in nutrients compared to the surrounding water. The formation of aggregates allows direct syntrophic interactions such as the exchange of metabolic intermediates.

Natural waters typically contain between 0.5 and 5×10^6 bacteria per mL (5). Microbial numbers, diversity, and activities are usually higher in the **sediment** and at surfaces than in free water. Sediments typically contain about 10^9 bacteria per mL. The fraction of metabolically active cells is also higher in sediment compared to free water. In a Swedish lake, only 4% of the pelagic bacteria, 37% of epiphytic bacteria, and 46% of sediment bacteria were metabolically active (8). This can have several causes such as higher nutrient availability, higher habitat diversity, or protection against predation. Microbial numbers and activities usually decrease exponentially as sediment depth increases. The absence of turbulent mixing allows the patchiness and spatial (mostly vertical) gradients to form in the sediment. The situation is especially complex in the rhizosphere of aquatic plants.

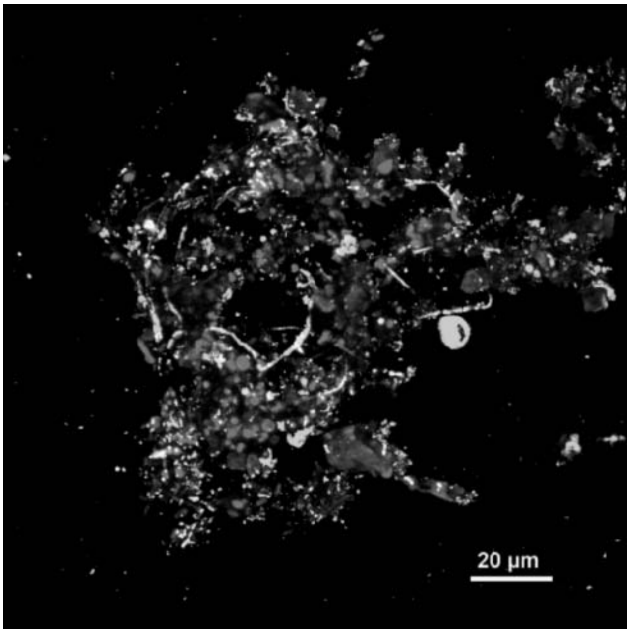

Figure 2. Confocal laser scanning micrograph of a lotic aggregate from the River Saale, Germany. Maximum intensity projection of 31 sections at 1 μm distance from four channels. Color allocation: reflection = white, autofluorescence of algae = blue, nucleic acid staining of bacteria = green, lectin stained glycoconjugates = red (courtesy of Thomas R. Neu) This figure is available in full color online.

Surfaces are often covered by biofilms (9,10) or microbial mats (11–13). Living attached to a surface allows microbes to stay in favorable places under conditions of moving water. A biofilm is a "surface accumulation, which is not necessarily uniform in time or space, that comprises cells immobilized at a substratum and frequently embedded in an organic polymer matrix of microbial origin" (10). The solid surface on which a biofilm develops is called the "substratum." Living conditions in biofilms may differ substantially from conditions in free water. Biofilms are enriched in nutrients, are a place of intensive biotic interactions, and may offer protection against unfavorable conditions. Biofilms are not stable but undergo different successional stages. Biofilm growth starts due to adsorption of cells to a substratum. As the biofilm growth thickers, its composition changes, transport processes influence metabolic activities in the biofilm, and it becomes more and more affected by shear stress which finally leads to detachment and washout of parts of the biofilm.

The liquid–gas interface is characterized by high concentrations of oxygen and hydrophobic substances and high light intensities. It is colonized by a special microflora called neuston (14).

Microbes play an important role in **artificial aquatic systems** such as wastewater treatment plants, biotechnological reactors, and drinking water supplies. Living conditions in such systems can differ substantially from natural habitats and are often characterized by high nutrient content and homogeneity (in reactors) or very low nutrient content (in drinking water). The general habitat characteristics and the adaptations of microorganisms, however, are similar in natural and artificial aquatic systems.

ABIOTIC FACTORS

Water

Per definition, aquatic bacteria live in habitats where water is available. Many natural waterbodies, however, temporarily dry out due to water level fluctuations. Organisms in such habitats develop strategies to survive periods of dessication. They may form spores or other resting stages.

Even if microbes are swimming in liquid water, it might not be available to them because of low water activity. Water activity expresses the ratio of water in the vapor phase to the amount in vapor saturated air (ranging from 0 to 1.0). Low water activity can be caused by high salt concentration. Most bacteria need a water activity higher than 0.98 which is the activity of sea water at 25 °C (14). Especially resistant halobacteria can live at water activities as low as 0.6. They are found in salt lakes or salt saturated evaporation ponds.

Substrates

Microbes need different types of substrates. These include electron donors, electron acceptors, macronutrients (carbon, nitrogen, and sulfur), micronutrients (e.g., different metals and trace elements). Many organisms also depend on organic substrates. The availability of electron acceptors (O_2, $NO_3{}^{2-}$, Fe^{III}, $SO_4{}^{2-}$, CO_2) is a major determinant of which physiological groups of microorganisms are predominant. Surface waters are mostly oxic, and aerobic microbes dominate. In sediments and under certain circumstances also in free water (groundwater, hypolimnion), conditions are anoxic, and anaerobic organisms dominate microbial populations (Fig. 1). Anoxic bacteria are also frequently found in oxic environments (15). These can be facultative anaerobes such as denitrifiers and also oxygen resistant anaerobes or strict anaerobes that live in anoxic microsites (e.g., inside microbial aggregates). The oxic–anoxic interface is a place of high microbial activity and special adaptations (16). At the oxic–anoxic interface, redox cycling of mobile electron carriers such as Fe^{II}/Fe^{III} or $H_2S/SO_4{}^{2-}$ can occur on a small spatial scale.

Heterotrophic microbes depend on organic substrates as a carbon source; autotrophs such as photosynthetic organisms or nitrifying bacteria can use CO_2 that is available in most aquatic systems which are buffered by a carbon buffer system. Exceptions are acidic waters where inorganic carbon is available only as physically dissolved CO_2 and potentially limits autotrophic growth.

Concentrations of nutrients are usually low in natural environments. Consequently, cells in natural water are usually much smaller than cells grown in culture media, and generation times are longer. Microbes have developed several strategies to survive starvation. Most obvious is the formation of metabolically inactive resting stages like spores or the increased affinity of nutrient uptake systems. All nutrients have to cross the diffusive boundary layer before they can be taken up by an organism. The diffusion flux to a cell depends on its surface to volume ratio, so smaller organisms are more efficient in diffusive substrate uptake (17). Microbial growth in natural environments is often very slow (18).

Temperature

Temperature is the second most important parameter besides nutrient availability that controls microbial growth in natural aquatic systems. Aquatic microbes can live in liquid water at all temperatures between freezing and boiling. The world record for hyperthermophilic bacteria is currently 113 °C, and many extreme thermophiles cannot growth at "normal" temperatures (19). Such extreme temperatures occur at submarine hydrothermal vents where water remains liquid at temperatures above 100 °C due to the hydrostatic pressure. Most natural aquatic habitats, however, are characterized by low temperatures. In deep lakes and in the oceans, great parts are colder than 5 °C, and microbial processes are slow. The temperature in the natural environment is usually below the optimum growth temperature of bacteria. Even polar or alpine ice is colonized by microorganisms, and the boundary between surface ice and water is a place of microbial life (20).

Light

Microbes are affected by light in different ways, both directly or indirectly. Light is the energy source of photosynthesis which can take place under aerobic and anaerobic conditions. Anoxic photosynthesis typically takes place at the chemocline where anoxic conditions meet maximum light intensities. High abundances of purple sulfur bacteria can be concentrated in only a few centimeter thick layer of water (21). It is especially important for phototrophic organisms to maintain their vertical position in the water column. To counteract sedimentation, microbes may use active movement or regulate buoyancy by intracellular gas vesicles (22). In moving water, pelagic organisms are continuously transported from regions of high light near the surface to darker conditions further down and back (23).

At the water surface or on mud surfaces, solar radiation can be inhibiting for microbial life. One strategy to prevent photodamage is migration of motile organisms into the sediment during periods of high illumination (24). Microorganisms have pigments to protect them from photodamage. UV radiation can alter nutrient conditions by mobilizing dissolved organic matter (25) or by reducing iron (26).

pH

Natural aquatic systems cover the whole pH range from 0 to 14, and all of them are inhabited by microbes (27). Acidophilic bacteria (28) live in extremely acidic waters. Basophiles and alkaliphiles live in hypersaline waters. The activity of microorganisms can modify the pH of their habitat. The oxidation of iron or sulfur compounds can lower the pH to extreme values below pH 2. Photosynthetic activity can create local pH values higher than pH 10 in phototrophic biofilms (29).

Shear Stress

Water movement affects microbes mechanically in aquatic habitats and is an important regulator of biofilm growth. High current velocities cause detachment and washout of attached microorganisms (9). On the other hand, drift is an import mechanism for colonizing new habitats.

BIOTIC INTERACTIONS

Food Web

Microbes play an important role in the food web in aquatic environments. Bacteria, flagellates, and microzooplankton consume dissolved organic matter (DOM) which is released by phytoplankton. By this **microbial loop** (30), energy and nutrients are returned to the main food chain. In unproductive aquatic systems, bacterial production can exceed phytoplankton production and make these systems net sources of CO_2 (31).

Bacteria **compete** with eukaryotic algae and phagotrophs for resources. Usually, bacteria play a larger role in low productivity (oligotrophic) ecosystems compared to highly productive (eutrophic) systems. Oligotrophic systems that have low nutrient concentrations and higher proportions of soluble organic C favor heterotrophic bacteria to phytoplankton and phagotrophic heterotrophs (32). The microbial mineralization of organic matter is a complex network of different reactions carried out by different organisms.

Syntrophy

In anoxic environments, the degradation of organic matter resulting in the accumulation of uncompletely oxidized intermediates such as acetate or hydrogen gas is energetically unfavorable. Methanogens and sulfate reducers can, for example, consume hydrogen gas and lower its partial pressure so that the hydrogen producing process becomes thermodynamically favorable. This “interspecies hydrogen transfer” allows the degradation of compounds which are refractory to degradation by the pure culture of a single species (33). A prerequisite of such syntrophic interaction is that the organisms are close spatially.

Grazing

Bacterial numbers in pelagic systems and in surface sediment are often controlled by grazing. Microorganisms have developed different strategies against grazing. They can change cell size, change cell shape to longer forms, or form multicellular aggregates (34). Some bacteria are not digested by higher organisms but live as endosymbionts inside bigger aquatic organisms.

Bioturbation

The activity of macroorganisms can greatly modify the sediment environment (35). Organisms and particles can be moved by bioturbation, and porewater chemistry might be changed. Bioturbation can increase both homogeneity or patchiness of the sediment and introduce short-term changes of conditions.

Bacteriophages

Viruses are the most abundant biological entities in aquatic systems. Typical abundances of these 20 to 200 nm particles are 10^{10} per liter in surface water. They probably infect all organisms and influence biogeochemical and ecological processes as well as gene transfer among microorganisms (36).

CONCLUDING REMARK

Due to the development of new methods for studying microbes in their natural environment, we now have a first impression of the complexity of the natural habitat. Many issues such as biotic interactions in aggregates and biofilms, the reaction of microbes to quickly changing environmental conditions, and their distribution in very heterogeneous environments remain important topics for further research. The study of the distribution, role, and function of microbes in their natural aquatic environment is one of the most exciting areas in aquatic ecology.

CALIBRATION OF HYDRAULIC NETWORK MODELS

SRINIVASA LINGIREDDY
LINDELL E. ORMSBEE
DON J. WOOD
University of Kentucky
Lexington, Kentucky

INTRODUCTION

Availability of reliable network modeling software coupled with affordable computing hardware technology has led to rapid growth in the use of hydraulic network models for design, planning, and operational studies of water distribution systems. Friendly graphical user interfaces (GUIs) and integrated computer-aided design (CAD) and geographic information systems (GIS) modeling environments helped drastically reduce model development time and the associated costs. The validity of these models, however, depends largely on the accuracy of input data and the assumptions made in developing the model. Although carefully developed models tend to have greater control on much of the data associated with the model, certain model parameters exist that are either not readily available or difficult to obtain. Such parameters typically include pipe roughness factors and nodal demands and their spatial and temporal distribution. As a result of the difficulty of obtaining economic and reliable measurements of both of these parameters, final model values are normally determined through the process of model calibration. Model calibration involves adjustment of these and other uncertain network model parameters until the model results closely approximate actual observed conditions as measured from field data. In general, a network model calibration effort should encompass seven basic steps:

1. Identification of intended use of the model
2. Identification of calibration model parameters and their initial estimates
3. Model studies to determine calibration data sources
4. Data collection
5. Macrocalibration
6. Sensitivity analysis
7. Microcalibration

These steps have been successfully tested by the authors on several model calibration studies. Each of these steps is discussed in the following sections.

IDENTIFICATION OF INTENDED USE OF THE MODEL

Before calibrating a hydraulic network model, it is important to first identify its intended use (e.g., pipe sizing for master planning, operational studies, design projects, rehabilitation studies, water quality studies) and the associated type of hydraulic analysis (steady-state versus extended-period). Usually, the type of analysis is directly related to the intended use. For example, water quality and operational studies require an extended-period analysis, whereas some planning or design studies may be performed using a steady-state analysis. In the latter, the model predicts system pressures and flows at an instant in time under a specific set of operating conditions and demands (e.g., average or maximum daily demands). In extended-period analysis, the model predicts system pressures and flows over an extended period (typically 24 hours).

Both the intended use of the model and the associated type of analysis provide some guidance about the type and quality of collected field data and the desired level of agreement between observed and predicted flows and pressures (1). Models for steady-state applications can be calibrated using multiple static flow and pressure observations collected at different times of day under varying operating conditions (e.g., fire hydrant flow test data). On the other hand, models for extended-period applications require field data collected over an extended period (e.g., one to seven days).

In general, a higher level of model calibration is required for water quality analysis or an operational study than for a general planning study. For example, determining ground elevations using a topographic map may be adequate for the latter, whereas the former may require an actual field survey. Such considerations obviously influence the methods used to collect the necessary model data and the subsequent calibration steps.

IDENTIFICATION OF CALIBRATION MODEL PARAMETERS AND THEIR INITIAL ESTIMATES

The second step in calibrating a hydraulic network model is to determine initial estimates of the primary model parameters. Although most models will have some degree of uncertainty associated with several model parameters, the two model parameters that normally have the greatest degree of uncertainty are the pipe roughness coefficients and the demands to be assigned to each junction node.

Pipe Roughness Values

Initial estimates of pipe roughness values may be obtained using average literature values or directly from field measurements. Various researchers and pipe manufacturers have developed tables that provide estimates of pipe roughness as a function of various pipe characteristics, such as pipe material, pipe diameter, and pipe age. Table 1 shows typical Hazen–William roughness factors (2). Although such tables may be useful for new pipes, their specific applicability to older pipes decreases significantly as the pipes age. In addition, the variation in roughness with pipe age depends on other factors, such as water chemistry, and will vary from location to location. As a result, initial estimates of pipe roughness for all pipes other than relatively new pipes should normally come directly from field testing. Even when new pipes are being used, it is helpful to verify the roughness values in the field because the roughness coefficient used in the model may actually represent a composite of several secondary factors such as fitting losses and system skeletonization.

Adjusting Pipe Roughness vs. Pipe Diameter

The approach of adjusting pipe roughness values assumes that the pressure drop is entirely because of frictional and other minor losses within the pipeline. If the intended use for the calibrated model does not include water quality simulations, this approach of adjusting pipe roughness value will have little or no impact on model results. On the other hand, this approach might seriously affect results from water quality simulations, which is particularly true when a substantial portion of the distribution system comprises fairly old pipelines. Loss of carrying capacity in such pipes is not only because of increased roughness but also because of the reduced flow area resulting from tuberculation, scaling, sedimentation, and biofilm growth. Flow area reductions as high as 50% are not uncommon in certain distribution systems. Although adjusting pipe roughness to reflect the reduction in carrying capacity will not affect hydraulic gradeline and pressure calculations, significant deviations in simulated water quality parameters are possible as the erroneous velocities are used in water quality calculations. Therefore, for more accurate water quality predictions, it might be prudent to adjust the pipe diameters by limiting roughness coefficients to certain predetermined values. For example,

Table 1. Typical Hazen–William Pipe Roughness Factors

Pipe Material	Pipe Age	Pipe Size (Inches)	C Factor
Cast Iron	New	All Sizes	130
	5 years old	12 and Over	120
		8	119
		4	118
	10 years old	24 and Over	113
		12	111
		4	107
	20 years old	24 and Over	100
		12	96
		4	89
	30 years old	30 and Over	90
		16	87
		4	75
	40 years old	30 and Over	83
		16	80
		4	64
	50 years old	40 and Over	77
		24	74
		4	55
Welded Steel	Values of C the same as for cast-iron pipes, 5 years older		
Riveted Steel	Values of C the same as for cast-iron pipes, 10 years older		
Wood Stave	Average value, regardless of age		120
Concrete or Concrete Lined	Large sizes, good workmanship, steel forms		140
	Large sizes, good workmanship, wooden forms		120
	Centrifugally spun		135
Vitrified	In good condition		110
Plastic or Drawn Tubing			150

1 inch = 25.4 mm.

if the computed Hazen–William roughness coefficient for a pipeline is 40, one could limit the coefficient to about 90 and compute the pipe diameter that would produce the measured pressure drop.

Spatial and Temporal Distribution of Nodal Demands

The second major parameter determined in calibration analysis is the average (steady-state analysis) or temporally varying (extended-period analysis) demand to be assigned to each junction node. Initial average estimates of nodal demands can be obtained by identifying a region of influence associated with each junction node, identifying the types of demand units in the service area, and multiplying the number of each type by an associated demand factor. Alternatively, the estimate can be obtained by first identifying the area associated with each type of land use in the service area and then multiplying the area of each type by an associated demand factor. In either case, the sum of these products is an estimate of the demand at the junction node. Although in theory the first approach should be more accurate, the latter approach is more expedient. Estimates of unit demand factors are available from water resource handbooks and textbooks (3).

MODEL STUDIES TO DETERMINE CALIBRATION DATA SOURCES

After model parameters have been estimated, the accuracy of the model parameters can be assessed, which is done by executing the computer model using the estimated parameter values and observed boundary conditions and then comparing the model results with the results from actual field observations. Collecting accurate and appropriate field data is crucial for proper calibration of a hydraulic network model. One should use at least 10 to 20 pressure readings measured at locations evenly spread over the water distribution system for steady-state calibration. These pressure readings should ideally be collected when the network is under “stressed” conditions, i.e., during a peak-hour demand condition, during filling cycle of a ground-level pumped storage tank, or during hydrant flow tests. Under these conditions, the increased flowrates make the pressure readings more sensitive to small changes in pipe roughness values. The hydrant flows that produce more than 15 psi drop from static pressures are ideal for calibration studies. In most distribution systems, the peak-hour demands may not provide 15 psi drop at sufficient number of locations. Ground-level pumped storage tanks are not common in most distribution systems. Therefore, hydrant flow tests provide a logical alternative for pressure reading in most systems. However, not every hydrant flow will result in an adequate pressure drop. Hydrants located at or near large pressure mains, supply sources, and elevated storage tanks tend to provide less than the desired pressure drop. On the other hand, certain hydrants might yield very little flow while showing large pressure drops (e.g., 80 psi of pressure drop while yielding only 200 gpm) because of localized losses such as constricted flow areas. Although a network model that is yet to be calibrated may not be meaningful for planning and operational studies, it can provide some insight into the locations for hydrant flow tests that provide reasonable flows and adequate pressure drops. The following procedure is recommended to locate hydrants for calibration field studies.

- Perform hydrant flow analysis on all hydrants in the distribution system. Hydrant flow analysis appears to be a standard feature in most commercial modeling packages and provides information on flowrate that a hydrant can deliver while maintaining a minimum pressure of 20 psi throughout the distribution system. One could use the nearest junction nodes in place of hydrants if the model does not contain the hydrant information.
- Compute the flowrate per unit pressure drop (difference between static and residual pressure) for each hydrant.
- Rank order the hydrants from lowest to highest of flowrate per unit pressure drop.
- Select about 15 to 25 hydrants from the top of the list that are evenly scattered throughout the distribution system. Care must be taken to avoid hydrants with unusually low flowrates to pressure drop ratios. A closer look at these hydrants and related flows might reveal problems with the network model. The authors have also found that unusually high flowrate to pressure drop ratios could be because of network anomalies that can be corrected by a close observation of network model parameters.

DATA COLLECTION

The next step is to acquire calibration data from field studies. This section describes the general procedures for collecting and recording field data.

Fire Flow Tests

Fire flow tests are useful for collecting both discharge and pressure data for use in calibrating hydraulic network models. Such tests are normally conducted using both a normal pressure gauge (for measuring both static and dynamic heads) and a Pitot gauge (for use in calculating discharge). In performing a fire flow test, at least two separate hydrants are first selected for use in the data collection effort. One hydrant is identified as the pressure or residual hydrant, whereas the remaining hydrant is identified as the flow hydrant. The general steps for performing a fire flow test are illustrated by McEnroe et al. (4).

In order to obtain sufficient data for an adequate model calibration, it is important that data from several fire flow tests be collected. Before conducting each test, it is also important that the associated system boundary condition data be collected, which includes information on tank levels, pump status, etc. It is a common practice for the local fire departments to conduct hydrant flow tests and record the time of day and corresponding flows and pressures. However, in most cases, such records do not include the boundary conditions associated with each hydrant flow test, as the main purpose for their tests is to rate the fire hydrant and not necessarily for hydraulic calibration. Therefore, care must be taken to avoid hydrant flow data that does not include the associated boundary conditions data. Table 2 may be used as a template when collecting calibration data using hydrant flow tests.

Telemetry Data

In addition to static test data, data collected over an extended period of time (typically 24 hours) can be very useful for use in calibrating network models. The most common type of data will include flowrate data, tank water level data, and pressure data. Depending on the level of instrumentation and telemetry associated with the system, much of the data may be already collected as part of the normal operations. For example, most systems collect and record tank levels and average pump station discharges on an hourly basis. These data are especially useful in verifying the distribution of demands among the various junction nodes. If such data are available, the data should first be checked for accuracy before use in the calibration effort. If such data are not readily available, the modeler may have to install temporary pressure gauges or flowmeters in order to obtain the data. In the absence of flowmeters in lines to tanks, inflow or discharge flowrates can be inferred from incremental readings of the tank level.

In systems with ground-level pumped storage tanks (Fig. 1), the tanks are filled during off-peak demand periods using the high system pressures. Pressures in the distribution system drop dramatically during tank-filling operation, thereby providing an opportunity to use the associated data for model calibration. Tank telemetry data, along with a few static pressure readings within the distribution system where a significant drop occurs, could be used for calibrating the network model in lieu of hydrant flow test data.

EVALUATE MODEL RESULTS

Using fire flow data, the model is used to simulate the discharge from one or more fire hydrants by assigning the observed hydrant flows as nodal demands within the model. The flows and pressures predicted by the model are then compared with the corresponding observed values in an attempt to assess model accuracy. In using telemetry data, the model is used to simulate the variation of tank water levels and system pressures by simulating

the operating conditions for the day over which the field data was collected. The predicted tank water levels are then compared with the observed values in an attempt to assess model accuracy.

Model accuracy may be evaluated using various criteria. The most common criteria are absolute pressure difference (normally measured in psi) or relative pressure difference (measured as the ratio of the absolute pressure difference to the average pressure difference across the system). In most cases, a relative pressure difference criteria is normally preferred. For extended period simulations, comparisons are normally made between the predicted and observed tank water levels. To a certain extent, the desired level of model calibration will be related to the intended use of the model. For example, a higher level of model calibration will normally be required for water quality analysis or an operational study as opposed to use of the model in a general planning study. For most applications, a maximum state variable (i.e., pressure grade, water level, flowrate) deviation of less than 5–10% is generally regarded as satisfactory (1).

Deviations between results of the model application and the field observations may be caused by several factors, including: (a) erroneous model parameters (i.e., pipe roughness values and nodal demand distribution), (b) erroneous network data (i.e., pipe diameters, lengths, etc.), (c) incorrect network geometry (i.e., pipes connected to the wrong nodes, etc.), (d) incorrect pressure zone boundary definitions, (e) errors in boundary conditions (i.e., incorrect PRV value settings, tank water levels, pump curves, etc.), (f) errors in historical operating records (i.e., pumps starting and stopping at incorrect times), (g) measurement equipment errors (i.e., pressure gauges not properly calibrated, etc.), and (h) measurement error (i.e., reading the wrong values from measurement instruments). The last two sources of errors can hopefully be eliminated or at least minimized by developing and implementing a careful data collection effort. Elimination of the remaining errors will frequently require the iterative application of the last three steps of the model calibration process—macrocalibration, sensitivity, and microcalibration. Each of these steps is described in the following sections.

MACROCALIBRATION

In the event that one or more of the measured variable values are different from the modeled values by an amount that is deemed to be excessive (i.e., greater than 30%), it is likely that the cause for the difference may extend beyond errors in the estimates for either the pipe roughness values or the nodal demands. Possible causes for such differences are many, but may include

- valves that are open in the system but modeled as closed or partly closed
- valves that are closed or partly closed in the system but not modeled correctly
- inaccurate pump curves or pumps defined by useful power rather than head/flow data
- incorrect pump (on/off) status data or pump operating speeds for variable speed pumps
- inaccurate tank telemetry data
- inaccurate flow or pressure gauges
- incorrect pipe sizes and lengths (typographical errors)
- inaccurate pressure regulating valve settings
- incorrect network geometry
- inaccurate junction or hydrant elevations
- hydrants located on wrong pipes near multiple pipe junctions (Fig. 2)
- incorrect pressure zone boundaries
- missing or incorrect demand data—especially pertaining to large users (e.g., hospitals, schools, etc.)

The best way to adequately address such errors is to systematically review the data associated with the model in order to ensure its accuracy (5). In most cases, some data will be less reliable than other data. This observation provides a logical place to start in an attempt to identify the problem. Model sensitivity analysis provides another means of identifying the source of discrepancy. For example, if it is suspected that a valve is closed, this assumption can be modeled by simply closing the line in the model and evaluate the resulting pressures. Potential errors in pump curves can sometimes be minimized by simulating the pumps with negative inflows set equal to observed pumps discharges (6).

Plotting pressure contours pertaining to the simulation that produced undue low pressure (compared with the measured value) might provide an insight into certain problem areas. For example, a significant flow constriction (wrong pipe diameter or partially closed valve) in the model would produce rapid pressure drops that could be easily traced using the pressure contour plots. Probing into headloss/1000 values in the vicinity of the hydrant under question might help trace the problem pipes. In general, it would be relatively easier to trace the problems if the simulated pressure reading is significantly lower than the measured value. Only after the model results

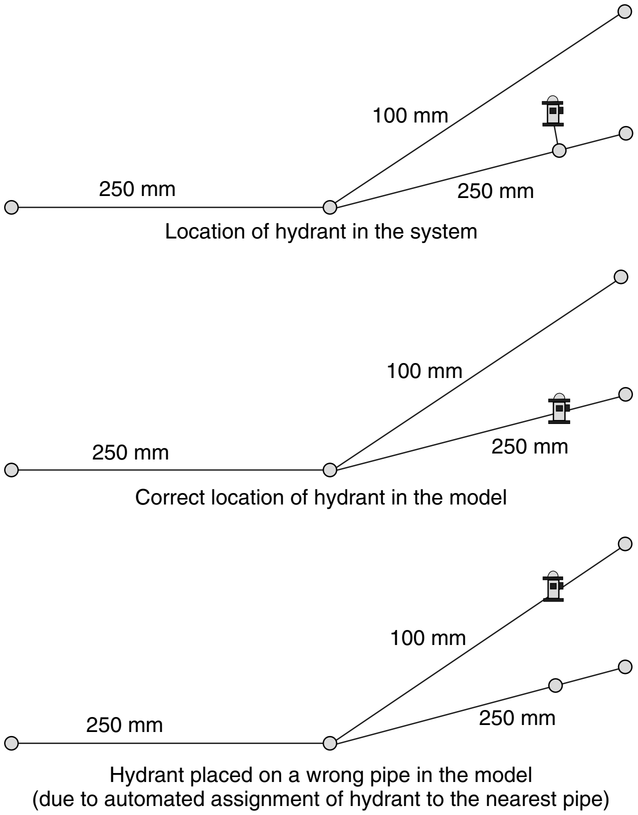

Figure 2. Example depicting misplaced hydrant.

and the observed conditions are within some reasonable degree of correlation (usually less than 20% error) should the final step of micro-level calibration be attempted.

SENSITIVITY ANALYSIS

Before attempting a micro-level calibration, it is helpful to perform a sensitivity analysis of the model in order to help identify the most likely source of model error. This analysis can be accomplished by varying the different model parameters by different amounts and then calculating the associated effect. For example, many current network models have as an analysis option the capability to make multiple simulations in which global adjustment factors can be applied to pipe roughness values or nodal demand values. By examining such results, the user can begin to identify which parameters have the most significant impact on the model results and thereby identify potential parameters for subsequent fine tuning through micro-level calibration.

MICROCALIBRATION

After the model results and the field observations are in reasonable agreement, a micro-level model calibration should be performed. As discussed previously, the two parameters adjusted during this final calibration phase will normally include pipe roughness and nodal demands. In many cases, it may be useful to break the microcalibration into two separate steps: (a) steady-state calibration, and (b) extended-period calibration. In performing a steady-state calibration, the model parameters are adjusted to match pressures and flowrates associated with static observations. The normal source for such data is from fire flow tests. In an extended-period calibration, the model parameters are adjusted to match time-varying pressures and flows as well as tank water level trajectories. In most cases, the steady-state calibration will be more sensitive to changes in pipe roughness, whereas the extended-period calibration will be more sensitive to changes in the distribution of demands. As a result, one potential calibration strategy would be to first fine tune the pipe roughness parameter values using the results from fire flow tests and then try to fine tune the distribution of demands using the flow/pressure/water level telemetry data.

Historically, most attempts at microcalibration have typically employed an empirical or trial and error approach. Such an approach can prove to be extremely time-consuming and frustrating when dealing with most typical water systems. The level of frustration will, of course, depend somewhat on the expertise of the modeler, the size of the system, and the quantity and quality of the field data. Several commercial software packages offer an optimized calibration feature that would ease some of the frustration associated with model calibration. Genetic algorithm (GA)-based techniques for model calibration appear to be popular with the commercial software packages. The optimized calibration techniques obtain an optimal set of decision variables (e.g., pipe roughness values and nodal demands) that minimize the average deviation between measured and calculated pressures and flows while satisfying all system and bound constraints (7). Although one would expect this to be a one-time process, several factors force repeated use of this approach until a more satisfactory set of decision variables are obtained. One of the reasons for repeated use of optimized calibration runs is the way the pipelines are grouped. GA-based approaches solve for optimal group roughness values instead of roughness values for individual pipelines. Alternatively, they can solve for an optimal multiplication factor for the preassigned roughness values for all the pipes in a group. Pipes of similar roughness characteristics (estimated based on material, age, and diameters of the pipes) are treated as one group. However, this is a highly subjective process and therefore offers opportunities for regrouping and reapplying the optimized calibration technique. Similarly, the explicit bound constraints on the pipe group roughness values offer opportunities for relaxing/tightening of the bounds and reapplying the optimized calibration technique. The iterative procedure for model calibration using optimized calibration approach is summarized in the following.

- Setup the model to include calibration data (observed pressures and flow readings).
- Group the pipes based on similar roughness characteristics.
- Estimate the roughness values for each group of pipes.
- Set up an upper and lower bound for each group of pipes based on estimated group roughness values. As

an initial guess, these bounds should be within 20% to 30% of the estimated values.

- Perform optimized calibration.
- Compare measured and calibrated pressure readings.
- If not satisfactory, or if any of the calibrated group roughness values reach the bounds, relax the bounds by a small percentage and rerun optimized calibration.
- Repeat the trials until satisfactory results are obtained.
- If the bounds had to be relaxed beyond a reasonable value for a group of pipes, it would imply a problem with network data and not necessarily the roughness values. Go back to macrocalibration probing the network in and around the area of concern, and repeat macrocalibration, sensitivity analysis, and microcalibration steps.

Although this procedure outlines the iterative method for obtaining optimal set of group roughness values, it can be easily modified when calibrating the model for other parameters such as nodal demands and their spatial and temporal distribution (7)

SUMMARY AND CONCLUSION

Network model calibration should always be performed before any network analysis planning and design study. A seven-step methodology for network model calibration has been proposed. Historically, one of the most difficult steps in the process has been the final adjustment of pipe roughness values and nodal demands through the process of micro-level calibration. With the advent of recent computer technology, it is now possible to achieve good model calibration with a reasonable level of success. As a result, little justification remains for failing to develop good calibrated network models before conducting network analysis. It is expected that future developments and applications of both GIS and SCADA technology will lead to even more efficient tools.

NUMERICAL MODELING OF CURRENTS

Rudi Rajar
University of Ljubljana
Ljubljana, Slovenia

INTRODUCTION

Description of Currents

Currents—water movement—appear in all surface waters: rivers, lakes, coastal seas, and oceans. This flow of water is almost always turbulent, which means with many irregular eddies of different size. Currents are sometimes near to steady movement (not changing with time), but mostly the movement is unsteady, significantly changing with time.

In rivers the currents are more aligned nearly in one dimension (1D), although in larger rivers they can be quite complex and three-dimensional (3D). In shallower rivers or coastal seas the modeling of currents is sometimes two-dimensional (2D), but in reality *all* currents are three-dimensional (3D); that is, the water velocities are in all three directions, although often they are an order of magnitude greater in the two horizontal directions than in the vertical direction.

In surface waters the current circulation has different orders of magnitude.

Global currents are large-scale currents, typical for every world ocean. They are often quasisteady in long-term average, and with their enormous transport of heat from the equator to the poles, and vice versa, they significantly affect climate and weather on the continents. The main driving forces are the temperature gradients between the poles and the equator and the wind. Due to the earth's rotation, the main pattern of global currents is typically from the poles toward the equator on the west side of continents (cold currents), and from the equator to the poles on the east side of continents (warm currents). Some of these global currents are the cold Peru (or Humboldt) current along the west coast of South America (toward the equator), the warm Kuroshio current from the equator along the east coast of Asia, and the warm Gulf Stream along the east coast of North America. The last is deflected by the topography of the coastline toward northern Europe, causing a relatively mild climate along the Scandinavian coastline.

Local currents (mesoscale and microscale currents) are currents in smaller regions, as in coastal (or shelf) seas, which are defined as shallower than about 200 m, to distinguish them from the oceans. Of course, local currents at a smaller scale appear also in lakes and rivers.

Importance of Current Circulation

Numerical modeling of currents usually includes modeling of additional parameters that are important in water ecology. When solving practical problems, the following parameters must be determined: (1) water current (circulation), (2) transport of sediments with currents, (3) transport of any contaminants, and (4) biochemical processes of contaminants.

Water current circulation is always the basis for calculation of the transport of any contaminant. But in many cases, knowledge of the current velocities is used directly, for example, in designing river or marine coastal protection, where the computation of current patterns helps determine bank and riverbed erosion and the optimum form of the protection structures. Transport of sediment is also important from two points of view. In river reservoirs, lakes, or coastal bays, sedimentation is often a big problem. Over the years, river reservoirs upstream of dams are filled with sediments and thus lose their useful storage volume. Even more important is the fact that most contaminants are bound to suspended sediments and often over 90% of the contaminant transport is the result of sediment transport with less than 10% in dissolved form. Determining the transport by currents of any contaminants in surface waters is very important. These can be nutrients, affecting the growth of algae and possibly causing eutrophication, or any toxic chemical. Coastal seas often receive large amounts of contaminants from rivers. Many coastal settlements discharge their wastewater (sometimes untreated) into coastal seas. Determination of currents and contaminant transport—most often by numerical modeling—is essential to determine consequences of pollution and to plan the optimum location of wastewater outlets. A special problem is oil spill, where numerical modeling of the spreading oil slick can help in clean up or can help to find the culprit of the pollution. Heat can also be considered as a kind of contaminant. Coastal thermal or nuclear power plants dispose of their waste heat into the sea. As the water temperature should not increase over a certain limit (usually 3 °C over the "natural" temperature), these power plants should be located at sites where strong currents transport away and mix the waste heat. Because contaminants are not only transported and spread (dispersed) over the water body but are also prone to different transformations due to biochemical processes, another quite difficult task of numerical models is to simulate these processes.

The importance of global currents is crucial. As already stated, global currents significantly affect climate and weather on the continents. The El Niño phenomenon is well known to cause catastrophic changes of weather over large parts of continents. Global currents are also important carriers of nutrients and contaminants of all types, and they influence the fish migration. Many oceanographic studies are carried out to determine details of global currents, their changes (e.g., prediction of the effect of future global warming), and their important influence on the environment.

Methods of Determination of Currents

To determine currents in surface waters, there are three methods: numerical modeling, physical modeling, and field measurements. Numerical modeling is the most appropriate methodology. However, most often it should be combined with field measurements and sometimes with physical modeling.

Physical models were widely used before the era of fast computers. Studied regions were built at a reduced scale in large hydraulic laboratories, and water was pumped to the models. Current velocities and other important parameters were then measured and used to model nature, using physical laws of similitude. However, there are several difficulties in applying this methodology: physical models are expensive and time consuming to build and operate; it is practically impossible to simulate very large regions; and it is almost impossible to reliably simulate biochemical processes.

Field measurements are becoming very important. As numerical models almost always demand calibration and verification of the simulated results, reliable data for comparison can only be obtained by field measurements. This technology is developing very fast. Remote sensing (e.g., satellite images) can provide the pattern of sea surface temperature, or chlorophyll concentration over very large regions. As these patterns depend on transport by currents, this methodology can be used for verification and calibration of numerical models. *In situ* measurements (directly by ships, buoys) are also necessary in combination with the remote sensing technique.

In fact, reliable simulation of currents and contaminant transport can only be attained by the combined application of numerical models and field measurements.

NUMERICAL MODELS

What Is a Numerical Model?

A simplified definition of numerical model is the following: a computer code that can describe or "simulate" a certain physical phenomenon, in this case current circulation and contaminant transport in surface water bodies. The simulation is never perfect, as the real physical phenomenon is too complex, and too many parameters and processes are involved. However, most often, the simulations are accurate enough to essentially help at solving different scientific and engineering problems.

Every numerical model basically consists of three parts: (1) basic equations, describing the physical phenomena; (2) all the necessary input data (e.g., description of topography, data on physical properties of water and contaminants); (3) "forcing factors"—the data about forces that cause water and sediment movement and sources of contamination. The modelers call these "boundary conditions," because these data determine the behavior of the model and essentially influence the results.

A numerical model can be compared to a physical model: in both cases the form (topography) of the water body must be given (for numerical model in digital form), as well as the physical properties of the water and boundary conditions. The final results are the same in both cases. The result of a numerical model can even be presented as an animation, showing, for example, water circulation—similar to a movie taken on a physical model.

Dimensions of Numerical Models of Currents

One-dimensional models simulate the flow in one dimension only—for example flow along a river. Topography is given with cross sections; the distance between them depends on how big the river is and on the required accuracy. For unsteady flow, the result is time-dependent depth and velocity in each cross section. Contaminant concentration can also be calculated in every cross-section and at every time step.

Two-dimensional models are usually used in shallow coastal seas or lakes. The computational region (in the horizontal plane) is divided into control volumes of rectangular or other polygonal form (possibly also curvilinear) and bottom and bank topography is given as input data. There is only one control volume from surface to the bottom. The result of simulation is depth and two components of horizontal velocity and possibly contaminant concentration in every control volume and at every time step.

Three-dimensional models are similar to 2D models: the difference is that the computational region is additionally divided into layers along the depth. In this way, the whole computational domain is divided into "bricks" in all three dimensions. Besides the parameters mentioned with 2D models, the vertical velocity component is also computed.

Three-dimensional models are the most sophisticated and basically the most accurate. However, the real accuracy and reliability of the models depend on the accuracy of the input data and on the calibration, verification, and validation of the models.

Forcing Factors

The water movement or, current is caused and influenced by four "forcing factors."

Wind has an important effect on the water surface. With its shear stress it causes the surface layer of water to move basically in the direction of the blowing wind. Due to the law of continuity, this movement also causes movement of other water layers. If the phenomenon is taking place in a closed basin, layers near the bottom must move in the opposite direction to the wind. In general, the movement is complex and depends on the bottom and bank topography. In larger seas and oceans, the earth's rotation essentially influences the current pattern (1). A good numerical model must take into account all these influences.

Tide influences the current pattern. When simulating currents inside a semienclosed bay or coastal sea, the boundary condition for the model is represented by the time variation of tidal level at the open boundaries.

Inflow of rivers also affects the currents, with its inflow of mass and momentum.

Density gradients—variations of density with space and/or time—also cause water circulation. The density changes are most often caused by gradients of temperature and salinity; therefore, this type of forcing is also called "thermohaline forcing."

The relative importance of the four forcing factors can vary with different cases. Wind and river inflow are usually the most important forcing factors in lakes and smaller coastal seas, while tide is the most important factor in small and middle-sized coastal areas. Density gradients and winds are very important for ocean circulation. A good numerical model should include all four forcing factors, although in many cases some less important ones can be neglected entirely.

Numerical Methods

The water movement or current is described by a system of differential equations, basically a scalar continuity equation (mass conservation) and a vector momentum equation, which has as many scalar components as the dimension of the model. Because these equations are nonlinear, the solution is very complex. Basically two groups of numerical methods are used for their solution: finite difference methods and finite element methods. With the first group of methods, the computational domain is divided into control volumes of polygonal forms (possibly with curvilinear sides), while with finite element methods, the domain is divided into different unequal geometric bodies. The finite difference methods are a bit simpler at transforming the differential equations into finite difference forms, while the finite element method can better adjust the control volumes to irregularly shaped boundaries. In the simulation of currents, the finite difference models are more often used.

The number of control volumes into which the computational domain is divided depends on the accuracy of the input data and on the required accuracy of the results. Typically, the domain is divided into 100–150 cells in each horizontal direction, and into 15–30 layers along the depth. Computing time is long and fast computers are needed for the computation of currents.

Verification, Calibration, and Validation of Models

For each simulated case, the applied model has to be checked for reliability.

Verification of a model is the first test, which shows whether the phenomenon is correctly simulated. Then the model should be ***calibrated***. Most often there are a few parameters in the model simulations for which the proper values are not accurately known, so a series of simulations are carried out with variable values of these parameters. The simulation results are compared with results of measurements (or possibly results of another model). In this way the proper values of the parameters are determined. (Example parameters are diffusion coefficients for turbulence or dispersion of contaminants.) When the simulated results are in acceptable agreement with measurements, the model is "verified" and "calibrated." It is then used to simulate other similar cases, for which the model parameters were not calibrated. If the results are in agreement with measurements, the model is "validated."

CASE STUDIES

A: Transport of Radioactive Contaminants in Japan Sea

The Japan Sea is a large, almost enclosed sea between the Japanese islands, Sakhalin Island, the Siberian coast, and Korea. Its length is about 1800 km, its width 900 km (see Fig. 1), and the maximum depth is about 3900 m. The relatively weak exchange of water with the Pacific Ocean is achieved through four straits (Fig. 1), the widest being Tsushima Strait between Korea and the Japanese islands.

A large amount of radioactive (RA) waste has been deposited in the Japan Sea, off Vladivostok, at a depth

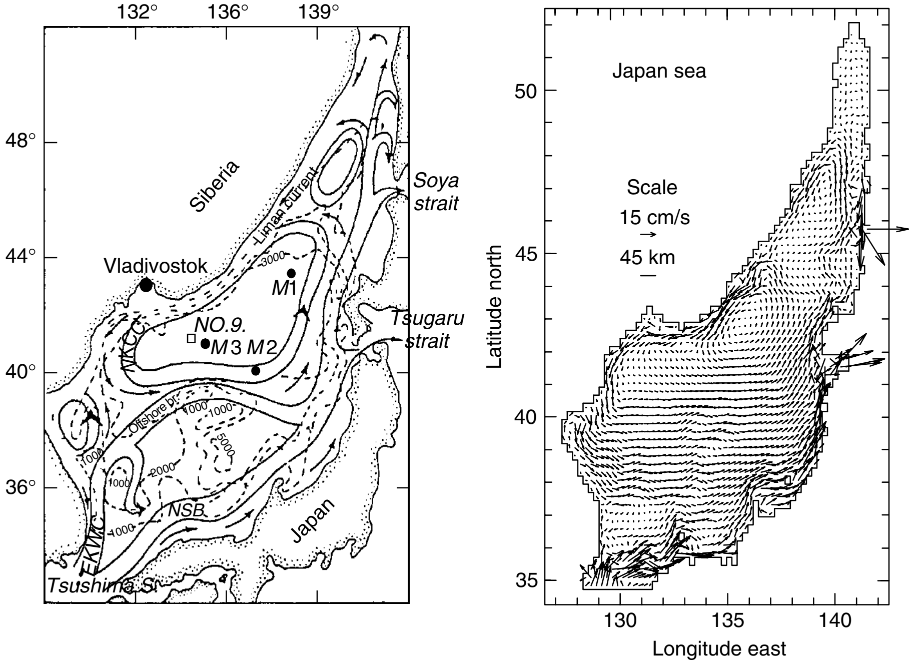

Figure 1. Measured surface currents in the Japan Sea (left) and surface currents simulated by the PCFLOW3D model (right). (From Ref. 3.).

of about 3500 m. Concern existed in Japan that leaking containers with RA waste could cause contamination of fish and other marine organisms in the Japan Sea. A research model should answer the questions: (1) In what concentrations and after what time would the RA contaminants reach the surface layers? (2) Where might they be transported by currents and dispersion? In the simulations, the possible leaking of the radionuclides was supposed to be at location No. 9 (Fig.1).

The first task was to determine the current circulation (4). A 3D numerical model PCFLOW3D was used (2,3). The 3D circulation was driven by three forcing factors: thermohaline forcing, wind, and the inflow/outflow surface currents. The computations were carried out taking into account the measured seasonally averaged temperature and salinity distribution and seasonal winds. A uniform wind field was accounted for (9.5 m/s in winter, 0 m/s in summer). The inflow current through the Tsushima Strait (a branch of the global Kuroshio current) was taken into account.

After some calibration, the results of the model were compared with the observed pattern of the surface currents (Fig.1). It can be seen that agreement is good; the simulated spirals have the same direction and strength as the measured ones. Some measurements also confirmed proper simulation of bottom currents.

On the basis of the computed winter and summer hydrodynamic circulation, transport and dispersion of radioactive contaminants were further simulated. The calculated amount of radioactive contaminants released in 90 d was 1 TBq (10^{12} becquerels), from dumping location No. 9 (Fig. 1).

The final results of the simulations have shown that the RA contaminants would reach the surface mainly in the northern part of the Japan Sea. The first contaminants would reach the surface layers (above 180 m depth, where fishing is possible) after 3 years; the amount would increase in time and would attain a maximum after about 30 years. But the maximum concentrations would be on the order 1E-2 Bq/m^3, which is far below the natural background values and hence would not represent any danger for the environment.

B: Simulation of Mercury Cycling in the Mediterranean Sea

Mercury is a highly toxic metal, especially in its organic form, monomethylmercury. An international project carried out in 2002–2004 had the goal to determine the natural and anthropogenic sources of mercury in the Mediterranean region and to determine the distribution of the most important mercury forms by the use of a three-dimensional numerical model (5).

Again, the current circulation had to be determined first. It was calculated for four annual seasons. Forcing factors were the following: (1) thermohaline forcing, that is, density gradients due to temperature and salinity distribution (obtained by measurements) in the whole computational domain and also along the depth; (2) wind, and (3) inflow from rivers and exchange of water through the Gibraltar and Bosporus. Verification and calibration of the model were carried out on the basis of numerous measurements. Figure 2 shows a comparison of simulated and measured currents for the summer season.

Transport and dispersion of mercury were then simulated, sources arriving from rivers, through straits from adjacent seas, and from some known point sources of contamination. Verification and calibration of the transport–dispersion part of the model were carried out on the basis of numerous measurements of relevant parameters. Three cruises by a large research ship *Urania* over the whole Mediterranean Sea provided measurements. Figure 3 shows the distribution of mercury, simulated over one year of inflow from the sources of contamination.

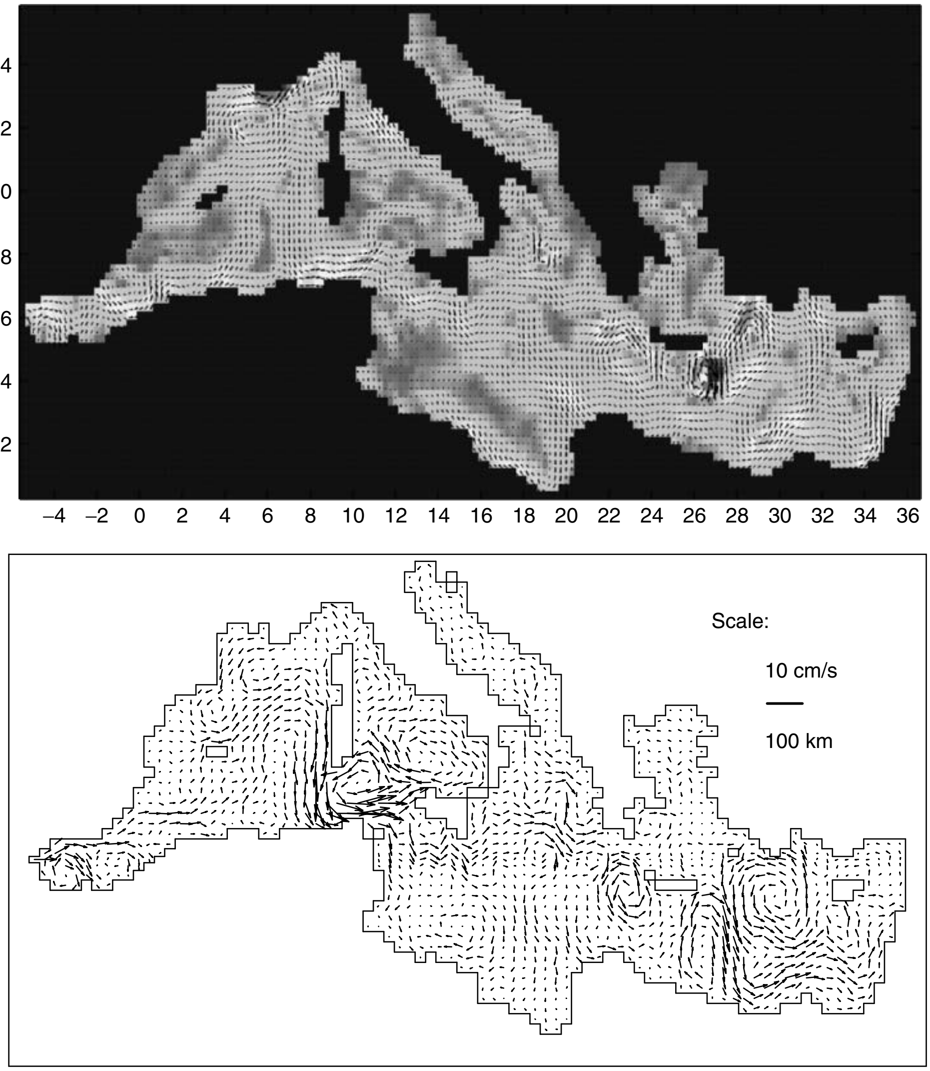

Figure 2. (Top) Measured average currents in the Mediterranean in the summer season. (Bottom). Simulated currents for the same season.

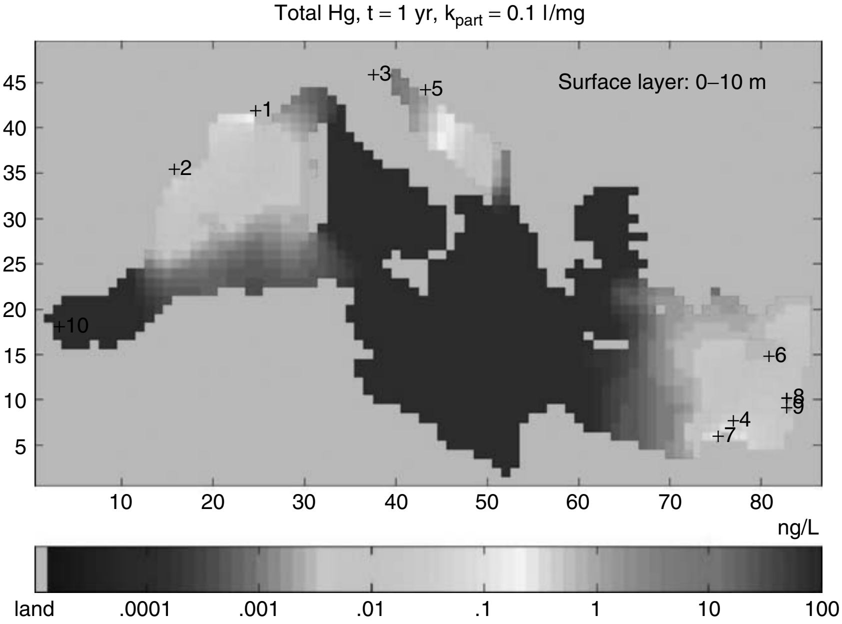

Figure 3. Concentration of total mercury in the surface layer of the Mediterranean Sea, after 1 year of simulation by PCFLOW3D model. Sources of contamination are from rivers and point sources, marked by numbers.

One of the goals of the project was also to couple the water model with the atmospheric model (which also simulates circulation and mercury transport) into a general integrated model. As there is permanent exchange of mercury between the water surface and the atmosphere, the integrated model gives a more realistic result about global mercury cycling and contamination in the region. The general model was finally used as a tool to predict possible measures to diminish concentration of toxic mercury in the Mediterranean region.

UNCERTAINTY ANALYSIS IN WATERSHED MODELING

Thorsten Wagener
The Pennsylvania State University
University Park, Pennsylvania

INTRODUCTION

All watershed modeling studies unavoidably contain uncertain elements. This uncertainty is propagated into the model predictions and impacts subsequent decision-making. If not taken into account properly, this can lead to model predictions that are assumed to be more reliable than they actually are. The usefulness of these predictions in any decision-making context therefore becomes questionable.

A watershed model is the numerical representation of our perception of the hydrologic system at hand. It consists of a model structure (i.e., underlying equations), model parameters (i.e., system invariants), and model states. The model is driven by measurements of variables entering the watershed (e.g., precipitation and energy) and compared to observations of the system response (e.g., streamflow or groundwater heads).

SOURCES OF UNCERTAINTY

Sources of uncertainty in this context are manifold and basically include every element that is needed for the modeling of a watershed as described above. The main uncertainties are listed and described here. The first uncertainty present when modeling watershed systems originates from the modelers' limited understanding of the real world (i.e., uncertainty in the perceptual model used).

Perceptual Model (PM) Uncertainty. A PM (1) is a conceptual representation of the watershed that is subsequently translated into mathematical (numerical) form in the model. The PM is therefore based on our understanding of the real-world watershed system. This understanding might be low, particularly with respect to subsurface system characteristics and water flowpaths, and therefore our PM might be uncertain.

The next group of uncertainties is related to the mathematical/numerical model and its components. These components and the related uncertainties are:

Model Structure (Equation) Uncertainty. The ambiguity present in the PM usually means that a variety of model structures seem to be feasible representations of the watershed at hand prior to any modeling being undertaken. Unfortunately, analysis of the performance of the selected model structures in reproducing observed watershed behavior is often insufficient to distinguish between them and some ambiguity about an appropriate structural system representation remains.

Model Parameter Uncertainty. Models of watershed hydrology necessarily aggregate the natural heterogeneity of watershed characteristics and processes into individual model components. These components are characterized by model parameters that describe, for example, storage size, water residence time, or flowpath. The scale at which these parameters can be measured is commonly different from the scale at which they are applied within the model. At least some of the model parameters therefore have to be estimated through a process of parameter adjustment (manually or automatically), where the parameters are varied until observed and modeled system behavior agree as much as possible. Most watershed models contain a large number of nonlinearly interacting parameters, which makes this a very difficult task, and some uncertainty commonly remains with respect to the question of whether a unique best parameter set has been found.

Model State Uncertainty. With respect to state uncertainty one has to distinguish between initial state uncertainty and state uncertainty after a certain time series of data has been processed by the model. The first uncertainty can usually be taken care of by including a warm-up period that is excluded from the performance analysis. Alternatively, the initial state can be optimized, similarly to the parameter adjustment process described above. State uncertainty during model simulation stems from biases in the model predictions. It can be reduced using data assimilation techniques, that is, approaches that recursively assimilate measurements of the model output variable from previous time steps to adjust the model states to reduce predictive uncertainty.

Variable Uncertainty. This is another, less often considered uncertainty, originating from the problem of simulated and observed variables not being exactly the same quantity (2). For example, predictions and measurements of soil moisture might be at different scales and therefore a perfect match should not be expected or is not even something the modeler should strive for (3).

Input (Forcing) and System Response Data Uncertainty. There are also uncertainties that are related to the measurements of forcing and response variables. These stem, for example, from an inability to capture the spatial distribution of rainfall or from problems in capturing the true streamflow discharge. These uncertainties can only be reduced outside the modeling process, for example, through better measurement techniques.

Generally, no satisfactory means of considering all these uncertainties simultaneously in a watershed modeling exercise have yet been developed (3). Additionally, the modeler is faced with the problem that, in many cases, the distance between the (erroneous) observation and the uncertain prediction of streamflow is the only measure of deviation (error) at each time step, providing very little information for model evaluation.

APPROACHES TO UNCERTAINTY ANALYSIS

A wide variety of techniques for uncertainty analysis in watershed hydrology are available and often applied (3,4). These methods differ, for example, in underlying philosophy and assumptions and in sampling strategies applied. Little guidance is available to help modelers decide what approach might be the most suitable one for their situation (1). While the differences are large, there is some overlap between all the approaches. In principle, all techniques for uncertainty analysis can be reduced to three basic steps. The main potential approaches that are applied for uncertainty analysis in watershed hydrology are described based on this three-step approach.

1. *Define What Constitutes a Behavioral Model*. The definition of what constitutes a behavioral model can roughly be divided into two types of definitions, those that follow a strict statistical approach, and those using set-theoretic measures not consistent with traditional statistics. The former are based on assumptions about the structure of the model residuals, that is, the differences between observed and simulated system response. Typical assumptions are that the error is Gaussian and has a constant variance in time (3). The second type is less bound by a formal statistical framework, but this is commonly defended with the statement that the structure of the uncertainty is unknown in most modeling studies and that restricting assumptions are therefore not justifiable. Examples of the second type include the generalized likelihood uncertainty estimation (GLUE) (2) framework and fuzzy measures.
2. *Find All Models that Comply With This Definition in the Feasible Parameter Space*. The search for all models that are consistent with the definition consists of two parts. First is the search for all parameter sets within a certain model structure that provide behavioral predictions. This search is commonly performed using various types of random sampling (e.g., uniform random sampling or types of stratified sampling) or using population evolution based techniques. The use of Monte Carlo Markov chains can be very efficient in this context if the assumptions that have to be made about the shape of the response surface are justified.

   The second part of the search is related to the problem that potentially different model structures can provide behavioral predictions for a certain case. This is an even more difficult task since the model space is not just infinite, but also unbounded. No systematic approach exists to explore this search space. Approaches suggested include the use of ensembles of model structure (e.g., in a Bayesian framework) (5) or the inclusion of a more complex error model that takes the imperfection of the selected model structure into account (6).
3. *Propagate the Predictions of All Identified Models into the Output Space While Considering Other Uncertainties (e.g., in the Forcing Data)*. Three basic approaches are applied for the propagation stage, first-order, statistical, and set-theoretic. The first approach only propagates the mean and the variance of the predicted variable, based on means and variances of inputs and parameters. An overview of the most popular first-order approaches is provided by Melching (7). Statistical approaches sample from the posterior parameter distributions derived in step 2 and usually make assumptions about the distributions of input uncertainties to derive ensembles of predictions. Ensembles of inputs and/or parameter sets, not necessarily sampled from strict statistical distributions, are also propagated in the set-theoretic approach.

CONCLUSION

Uncertainty is an unavoidable element in any watershed modeling exercise. It has to be considered if the model simulations should be used in a decision-making context. Main uncertainties include those stemming from a lack of understanding of the hydrologic system, the problem of identifying appropriate model structure and parameters, and uncertainties in the measured data. While many approaches exist that can be used for uncertainty analysis, little guidance is available to choose the best approach for a certain study. A three-step structure is common to all approaches and potential implementations are discussed above. Future developments in this area will focus on a more realistic representation of the uncertainties present, techniques that allow for the explicit and simultaneous consideration of all uncertainties, and better sampling strategies.

WATERSHED MODELING

Thorsten Wagener
The Pennsylvania State University
University Park, Pennsylvania

INTRODUCTION

Models of watershed hydrology are important tools in hydrological investigations for operational and research purposes. Areas of application are the extension of streamflow time-series in space (1–3) and time (4,5), evaluation of a watershed response to climate (6,9) and/or land-use variability and change (8,9), calculation of design floods (10,11), as load models linked to water quality investigations (12), real-time flood forecasting (13–15), and the provision of boundary conditions for atmospheric circulation models (16,17). This multitude of, often very specific, tasks and circumstances has contributed to the development of a vast number of watershed models starting in the early 1960s (see Todini (18), for a historical review). These models are usually a mixture of linear and nonlinear functions, combined to represent those processes occurring in the specific watershed and important for the study objectives at hand. Watershed models are also used in water quality studies, but the focus here is simulation of the quantitative response and general features of these models.

WATERSHED PROCESSES

The hydrologic cycle is a closed system in the sense that no water is lost. Only part of the processes that constitute the hydrologic cycle are relevant for watershed modeling. A watershed is therefore an open system with respect to inputs (mainly precipitation and energy) and outputs (mainly streamflow, but also surface and subsurface losses). A schematic description of the main processes in a typical watershed system is shown in Fig. 1. Models of watershed hydrology represent these processes using different mathematical approaches and different levels of spatial detail. It is important to consider that the part of the watershed system reproduced in the model usually depends on the prevailing processes and also on the modeling purpose and available data (3). For example,

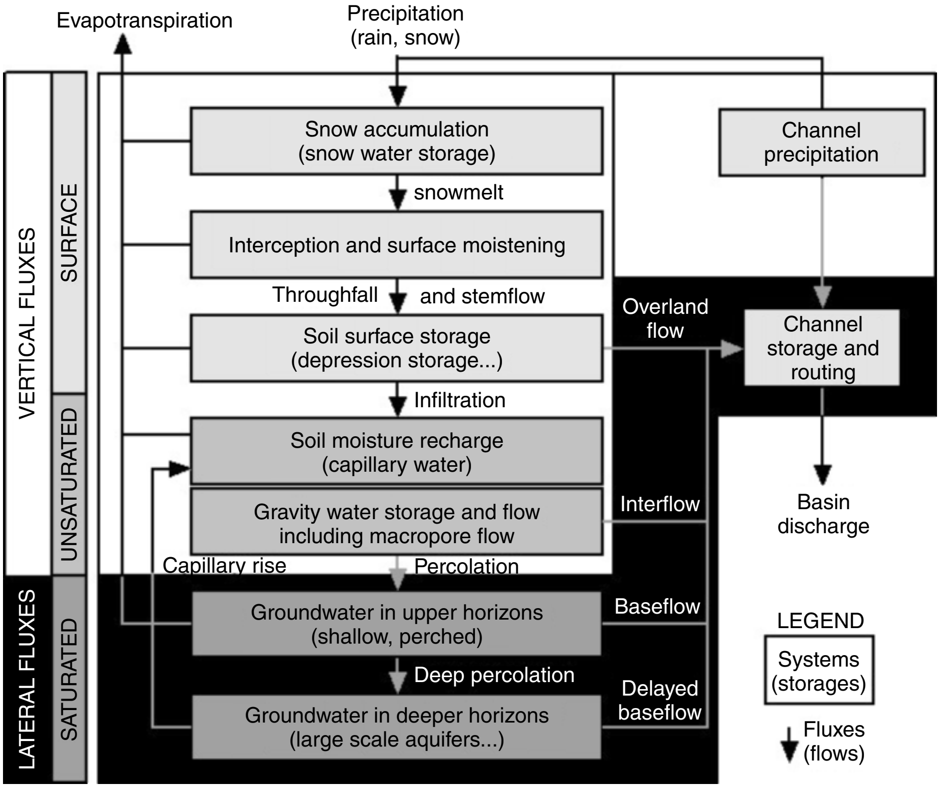

Figure 1. Schematic of watershed processes (after Reference 19).

routing processes are usually not required if the modeling purpose is simulation of the watershed outflow at a monthly time-step.

WATERSHED MODEL CLASSIFICATION

It is common to classify watershed models into three distinct types (20; Fig. 2): (1) *empirical* (also called data-based, metric, or black-box), (2) *conceptual* (also called parametric, explicit soil moisture accounting, or gray-box) and (3) *physically based* (also called mechanistic or white-box) model structures. There are, however, models that have characteristics of more than one group.

Empirical models use available time series of input and output variables (precipitation, streamflow, temperature, etc.) to derive both the model structure and the corresponding parameter values. They are therefore purely based on the information retrieved from the data and generally do not include prior knowledge about catchment behavior and flow processes, hence, the name black box. Popular examples of empirical models are artificial neural networks (ANN; 21,22) and transfer functions (TF; 23). Empirical models are usually spatially lumped; they treat the catchment as a single unit. Variants on purely empirical TF models are *data-based mechanistic models*. They constrain the degrees of freedom to those structures that are physically interpretable, thereby using the hydrologist's understanding of the natural system (24–26).

Conceptual models (3,27) are built from storage elements that represent parts of the watershed where water is temporarily stored, such as soil, aquifers, or streams. These elements are filled through fluxes such as rainfall, infiltration, or percolation, and empty through evapotranspiration, runoff, drainage, etc. Based on a conceptualization of the real-world watershed, the modeler, specifies the structure of these models a priori, for example, the number of and connections between storage elements. These models are also usually spatially lumped. This means that large parts of the (heterogeneous) watershed are integrated in a single (homogeneous) element. The consequence of this process is that the model parameters lose some of their physical meaning and cannot be measured on the required scale. Rather, the modeler has to use observations of the watershed response to find appropriate values for the model parameters (see next section). Some models are based on a semidistributed approach, in which different models represent individual subwatersheds. This approach is finding increased attention in the literature (28). Conceptual models form the large majority of models used in operational hydrology. Their dependence on measurements of the watershed response (mainly streamflow) limits their use in ungauged watersheds. However, research is ongoing to resolve this problem (3,29).

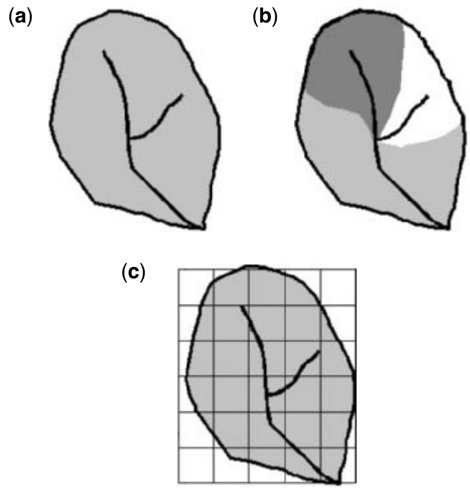

Figure 2. Classification of watershed models according to spatial discretization used: (**a**) lumped, (**b**) semidistributed, and (**c**) distributed.

Physical models (30,31) are based on conservation of mass, momentum, and energy. The spatial discretization applied is usually based on grids, but sometimes also on some type of hydrologic response unit or triangular irregular networks (32). Physical models are therefore particularly attractive for studies that require a high level of spatial detail, such as studies on soil erosion or diffuse-source pollution (33). The initial idea underlying these models was that the degree of physical realism on which these models are based would be sufficient to relate their parameters, such as soil moisture characteristics and unsaturated zone hydraulic conductivity functions for subsurface flow or friction coefficients for surface flow, to physical characteristics of the catchment (18), thus eliminating the need for observed system response to condition the parameters of the model. However, the currently available physical models do not fulfill this ideal. They suffer from extreme data demand, scale-related problems (e.g., the measurement scales are different from the process and model (parameter) scales), and overparameterization (34). A number of key parameters—applied to a large number of elements—still has to be estimated from measurements to capture the uniqueness of a specific watershed (35). The expectation that these models could be applied to ungauged catchments has therefore not been fulfilled (36). Beven (34) argues that this type of model is applied in a way similar to lumped conceptual models, though on a different scale.

A general characteristic of all current models is that they do not provide reliable predictions in ungauged basins (3). The general behavior of a watershed is reasonably constrained by the model structure (i.e., the constituent equations), but some adjustment of model parameters is required to capture the unique characteristics of the system under investigation. A large number of popular models of watershed hydrology can be found in Singh (37) and Singh and Frevert (38,39).

WATERSHED MODELING PROCEDURES

Many authors have suggested procedures for using watershed models. Examples are given in Beven (32) and in Anderson and Burt (40). They vary slightly in the steps included and definitions used. A procedure using commonly found elements is shown in Fig. 3 (after

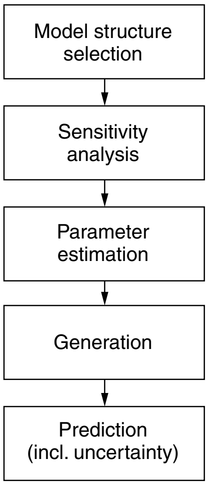

Figure 3. Typical elements of a watershed modeling procedure.

Reference 3). The elements considered are model structure selection, sensitivity analysis, parameter estimation, generalization, and prediction (including uncertainty estimation).

The first step for the modeler is to *select* (or develop) *a model structure*, a combination of mathematical equations, that describes the watershed system as a function of the system characteristics (e.g., saturation or infiltration excess dominated runoff production), the modeling objective (e.g., do the effects of routing have to be considered if only the monthly response is wanted?), and the available data (e.g., a simple evapotranspiration function has to be used if measurements of variables such as humidity or wind speed are not available). Personal preferences and experience in using a particular model structure might also play an important role in the selection process. Woolhiser and Brakensiek (41, p. 15) conclude that "*objective methods of choosing the best model* (structure) *have not yet been developed, so this choice remains part of the art of hydrological modelling*." However, future modeling tools might include knowledge-based approaches to support the decision-making process of the hydrologist for selecting an appropriate model structure.

Sensitivity analysis tests the sensitivity of the model output to changes in the model parameters (or even to uncertainty in the model input or in other model elements). This can be done before parameter estimation to find parameters that are particularly important for model performance—the estimation process can then be focused on these, or it can be done after the calibration as part of the uncertainty analysis—to identify parameters that are particularly uncertain. The simplest approach is a perturbation technique where one parameter is varied over its feasible range while the remaining parameters are kept at reasonable values, although more sophisticated approaches exist (32).

As stated before, the current generation of watershed models generally requires some sort of *parameter estimation* to enable the model to match observed and calculated system behavior, for example, to give reliable predictions. This process is sometimes referred to as calibration. Within this step, the performance of selected parameter sets in reproducing the observed system behavior is evaluated (Fig. 4). either by visual inspection or by calculating some function F that summarizes how well simulated and observed system behavior match:

$$F = f(e) \tag{1}$$

where f is some aggregation function applied to e, the vector of residuals calculated as

$$e_t = z_t - y_t \tag{2}$$

where z is the observed system response, for example, a time series of streamflow; y is the calculated system response; and t is the time step. The modeler attempts to make the function F as small (or large depending on the chosen formulation) as possible, either by manually adjusting the parameters or through some automatic procedure. See Duan et al. (42) for a state-of-the-art review of current techniques.

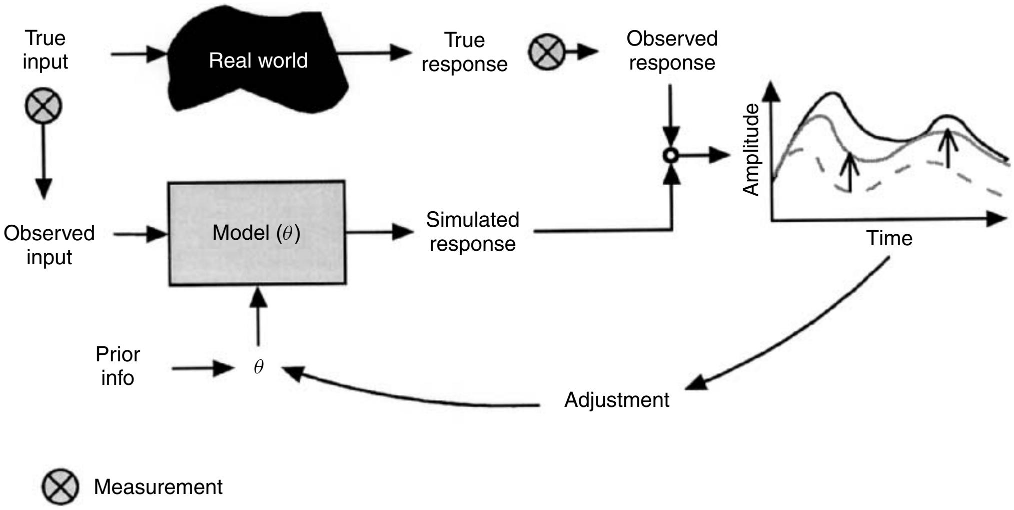

Figure 4. Calibration of a watershed model. The symbol θ represents a parameter vector, y is the system output (usually streamflow), and t denotes time.

The problem with this step of conditioning the parameters on observations is that it can result in parameter values that depend on the specific time series used (e.g., a particular climate period). Some modelers include a *generalization* stage to avoid this. During this stage, the model (including the parameter set found most representative of the system at hand) is applied to another time series of measured system response, not used during parameter estimation, but usually of the same variable. A model is assumed generally applicable if its performance does not degrade significantly during this process (43).

The model can then be used for *prediction*. However, there is a wide variety of factors that introduce *uncertainty* into the modeling process. These are for example, the inability of the modeler to find a "best" parameter set, uncertainties in measuring input and output data, and problems in finding an appropriate model structure to represent the system under investigation. These uncertainties have to be considered and incorporated in the model predictions. It is therefore sensible to state these uncertainties explicitly and include confidence limits that denote the ranges in which the predictions of the model are most likely to fall (44,45).

MODELING OF WATER QUALITY IN SEWERS

Ole Mark
Asian Institute of Technology
Hørsholm, Denmark

Modeling of water quality in sewers emerged during the late 1990s. The water quality and amount of water in sewers are dominant factors for designing wastewater treatment plants and for analyzing water quality impacts from sewer overflows. In addition, sewage under anaerobic conditions may cause corrosion of pipes, malodors, and pose health risks for sewage workers. Hence, it is of utmost importance to analyze and understand the transport and transformation of wastewater in sewers. Ideally, modeling of sewer systems and wastewater treatment plants should be based on the same general principles and done in integrated models to pursue an integrated understanding and management of sewers, wastewater treatment plants, and receiving waters. However, it must be stressed that the transformation of wastewater in sewers is not identical to the processes in activated sludge and biofilm systems—so even though several similarities exist between sewers and wastewater treatment plants, modeling of water quality in sewers is a discipline of it own. This article focuses on how to model water quality in sewers.

THE SEWER AS A PHYSICAL, BIOLOGICAL AND CHEMICAL REACTOR[1]

To model water quality in sewers, it is necessary to know the various types of sewers and their water quality characteristics. For a detailed description of the processes in sewer, refer to specialized literature (1). Around the world, all sewers can basically be divided into three categories:

1. storm sewers
2. wastewater sewers
3. combined sewers.

Storm Sewers. Storm sewers dominantly transport rain water, mainly runoff, during rain from city areas. Typically, storm water runoff has low concentrations of pollution and the concentration time for the storm sewer system is usually rather short—of the order of minutes to a few hours. If the concentration time is short and the concentrations are low, then aerobic conditions will dominate, and there will be only a low level of transformation and biological activity in the storm water.

Sanitary Sewers. Sanitary sewers transport wastewater from residences, commercial areas, and industries. Depending on the local layout of the sewer system, the wastewater may be transported by gravity or in pumped lines (in areas with insufficient ground slope available). The concentration time for sanitary sewers may be up to 1–2 days. Wastewater typically has high concentrations of pollution and biodegradable material, so wastewater sewers are potentially a place of high biological activity.

Combined Sewers. Combined sewers transport just wastewater in dry weather and both wastewater and

---

[1] The terminology "The sewer as a physical, chemical and biological reactor" has been largely promoted through the work of the Sewer Systems & Processes Working Group under IWA and in particular promoted by Prof. Thorkild-Hvitved-Jacobsen, Aalborg University, Denmark, and Prof. Richard Ashley, University of Bradford, UK.

runoff from city areas during rain. The concentration time in a combined sewer system, may be rather, short or it may rise to the order of 1–2 days. During dry weather flow, combined sewers operate like sanitary sewers, but during rain, rainwater that has a lower concentration of pollutants is added, and the transport time of the water to the wastewater treatment plant is significantly reduced. When a combined sewer system is overloaded, the excess water is discharged into receiving waters (a river, lake, or a coastal area), and this combined sewer overflow (CSO) may seriously deteriorate the water quality in the receiving waters.

The impact on recipients from overflows from sewer systems can be divided into three typical problems:

1. toxic impact due to un-ionized ammonia discharged mainly from CSOs
2. oxygen depletion
3. hygienic problems caused by fecal coliform.

Hence, the selection of an appropriate modeling approach for water quality in sewers depends both on the type of sewer system and the nature of the problem. Un-ionized ammonia in a combined sewer system may be accurately modeled by applying an advective dispersion model, considering that ammonia is conservative. However, it is a must to include biological and chemical processes to model hydrogen sulfide in a pumped wastewater pipe whose retention time is more than 3–4 hours. The following sections focus on modeling various types of water quality problems in sewers.

DETERMINISTIC MODELING OF WATER QUALITY

The strength of deterministic models for water quality in sewers is increased understanding of the individual processes and their interaction. Deterministic modeling of water quality in sewers and urban drainage can be divided into two groups:

1. quasi-conservative pollution
2. nonconservative pollution.

Modeling water quality in sewers is a challenging task, which assumes that the model is built and verified step by step. Note that a small error in the hydrodynamic model is carried 100% into the water quality model. A volume error of 10% more water in the hydrodynamic model will directly imply that the concentration of pollution in the water quality model will be too small. At present, modeling of pollutant transport may be calculated by using an advective–dispersion model such as MOUSE TRAP (3). Models transporting the pollution by pure advection (no dispersion) are InfoWorks (4) and the SWMM models (EPA SWMM, MIKE SWMM, and XP SWMM) (5). As software for modeling sewers develops rapidly, it is suggested that the reader always seek the latest information from the software suppliers of the models.

Modeling of Quasi-Conservative Pollution

The term *Quasi-Conservative Pollution* covers pollution that is not significantly transformed while it is in the sewer system. Ammonia and phosphorous are water quality parameters, which certainly are not 100% conservative, but which in most cases can be modeled with sufficient accuracy assuming that they are conservative (6,7).

Dissolved conservative pollution can typically be modeled by assigning a measured concentration to the wastewater and to the rain. The resulting concentration in the sewers is then effectively a dilution of the wastewater based on the land use and local industrial load to the sewer system. At this point, it is important that the model applied for pollution modeling represents the transport of pollution inside each pipe. The model must have computational grid points within each pipe otherwise there will be too much dispersion in long pipes, resulting in lowered peaks of concentration.

Modeling of Nonconservative Pollution

The term *Nonconservative Pollution* covers situations where biological and chemical processes play a significant role during the time the water passes through the sewer/drainage system. In this case, modeling the pollution by an advective–dispersion model will be insufficient and will give misleading results. Some examples of *Nonconservative Pollution* are BOD, COD, and hydrogen sulfide. If the sewer system has a very short concentration time, even BOD and COD may be modeled by ignoring the water quality processes, but a contribution from erosion of sediment deposits in the sewers must still be included.

The advective–dispersion model basically has only one calibration parameter, the dispersion coefficient, because advection of the pollution depends fully on the hydrodynamics. To determine the dispersion coefficient, a tracer measurement can be done with salt, rhodamine, uranine, or a similar substance, or the model can be calibrated based on measurements during rainfall of a quasi-conservative pollutant such as ammonia. A tracer study is highly recommended because it verifies that the model accurately describes the transport of a conservative substance under known flow conditions. In addition to finding the dispersion coefficient, the tracer measurement program serves three purposes:

- verification of the assumptions about infiltration to the sewer system
- the possibility of fine-tuning the Manning numbers along the sewers in the tracer measurement
- validation of the capability of the modeling system to describe the physical transport of the dissolved pollutants.

In conclusion, a tracer study serves well as a verification process of a hydrodynamic model. If the model fails to reproduce the tracer results, then there is no reason to continue the study to model anything related to water quality. The final set of input data to the advection-dispersion model consists of

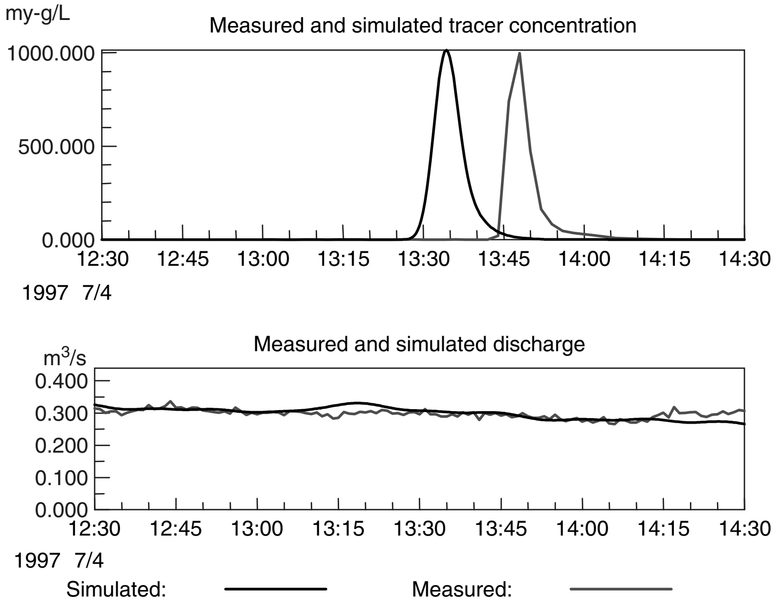

Figure 1. Example of tracer study results, showing that the hydrodynamic model needs to be recalibrated.

1. diurnal variation of dry weather flow
2. diurnal variation of concentration
3. infiltration
4. rainfall runoff
5. major industrial loads in terms of flow and concentration.

The discrepancies between a tracer study and advective dispersion, shown in Fig. 1, are for the city of Helsingborg, Sweden (7).

During the measurements, the tracer dose was added as a half-minute long pulse. From the figure, it can be seen that there was a very good match between the measured and simulated flow, but the timing of the measured and the simulated peaks was out of phase for the tracers. It was found that this occurred because the Manning numbers were never calibrated properly and only a flow gauge and not a water level gauge was available at this location in the sewers. Simulation results by applying an advective dispersion model for modeling various water quality parameters can be seen in Fig. 2 for the Helsingborg sewer system in Sweden.

Sediment Attached Pollution

Pollution may be attached to sediments, especially BOD, COD and phosphorous (2,8). When suspended sediment or sediment deposits exist in sewers, it is of utmost importance to include a model that can also simulate sediment transport processes in the sewers—including erosion and deposition of sediments. Principles for modeling sediment transport in sewers can be found in Mark et al. (9) and IWA (2).

Modeling Nonconservative Pollution by Application of a Water Quality Model

Nonconservative pollution in sewers must be modeled by describing the water quality processes along with the advective dispersion mode, preferably based on a hydrodynamic model. At this time, only the MOUSE TRAP model has such capabilities (3). The SWMM models (EPA SWMM, MIKE SWMM and XP SWMM) and InfoWorks (4) have only an advection model.

The transformation of pollution may either be modeled by applying a model based on decay rates or by using a model based on the physical, biological, and chemical processes, such as the WATS model (1). The WATS model has thus been successfully applied to wastewater modeling in the Estoril sewer system in Portugal (10). Good case studies demonstrating the applicability of water quality process models during rain are still lacking at this time.

To calibrate a water quality process model, it is of utmost importance to have a minimum of two stations measuring hydraulic and water quality parameters in the important sewers in the catchment because the water quality parameters will determine a process rate, which can be found only by comparing the measurements from two or more measurement stations. Some typical water quality processes under aerobic conditions can be seen in Fig. 3.

MODELING HYDROGEN SULFIDE

Understanding and modeling hydrogen sulfide is important because it introduces problems such as corrosion of pipes and other metal constructions in sewers. It is toxic, it poses a serious health risk to the sewer maintenance staff, and it releases noxious odors to the city environment. Further, it may inhibit sewage treatment processes (11). A high sulfide content may be toxic to fish in streams affected by sewer overflow (12). Hydrogen sulfide develops under anaerobic conditions in sewers, and it interacts with anaerobic water quality processes (1,13). Hydrogen sulfide has traditionally been modeled by using empirical equations such as: Thistlethwayte (14), Boon and Lister (15), Pommery & Parkhurst (16), and Nielsen

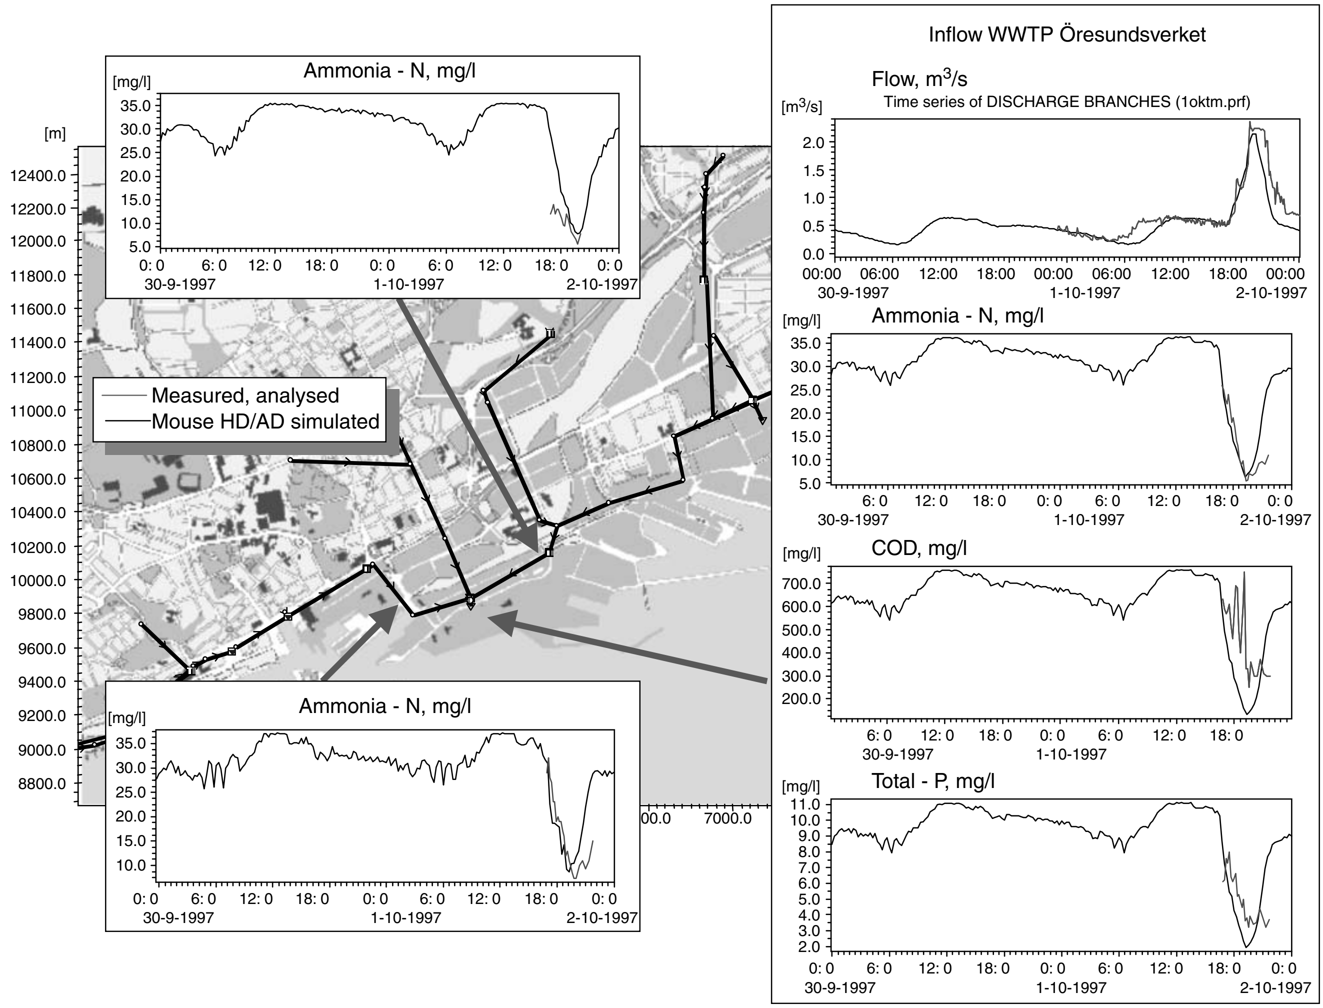

Figure 2. Wet weather sampling. Examples of measured flow and wastewater analyses compared to preliminary MOUSE hydrodynamic and advective dispersion simulation results.

and Hvitved-Jacobsen (17). Note that the four empirical models in these references were developed by using data from pressure mains, so they are not generally applicable to all sewer systems. At present, the only hydrogen sulfide model in commercial software is the MOUSE TRAP model (18). This model includes an advective dispersion model and four empirical equations for sulfide buildup. In addition, oxygen demand and extra Michaelis–Menten expressions are included in the model, so it approaches a more deterministic description of sulfide production.

A more recent and generally applicable model for hydrogen sulfide in sewers is the WATS model (1). The WATS model applies an integrated aerobic and anaerobic concept to the transformation of organic matter and sulfur in wastewater (1).

MODELING FECAL COLIFORM IN SEWERS

Experience modeling fecal coliforms has shown that coliform cannot be considered conservative or without natural decay in the receiving waters (20), for example, in the sea, where the main controlling parameters for bacterial decay are salinity, temperature, and light intensity. At present, limited knowledge is available concerning the transport of coliform in sewers; it is modeling fecal coliform in sewers by using a first-order decay rate is suggested (21); it is conservative when the concentration time in the sewer system is short—up to a few hours (22).

A PROCEDURE FOR MODELING WATER QUALITY IN SEWERS

In most cases, sediment affects pollution significantly, and when the concentration time of the sewer system is long (as a rule of thumb, 3–4 hours), the interaction of BOD/COD and oxygen must be taken into account in the model to produce reliable results. When the oxygen level plays a significant role, for instance, in modeling hydrogen sulfide, a water quality process model is a must. A consistent procedure for water quality modeling is outlined here. Each step in the modeling procedure must be completed and verified before continuing to the next step. If the model results at a step are unsatisfactory, then it is not feasible to continue because the outcome of each step depends on

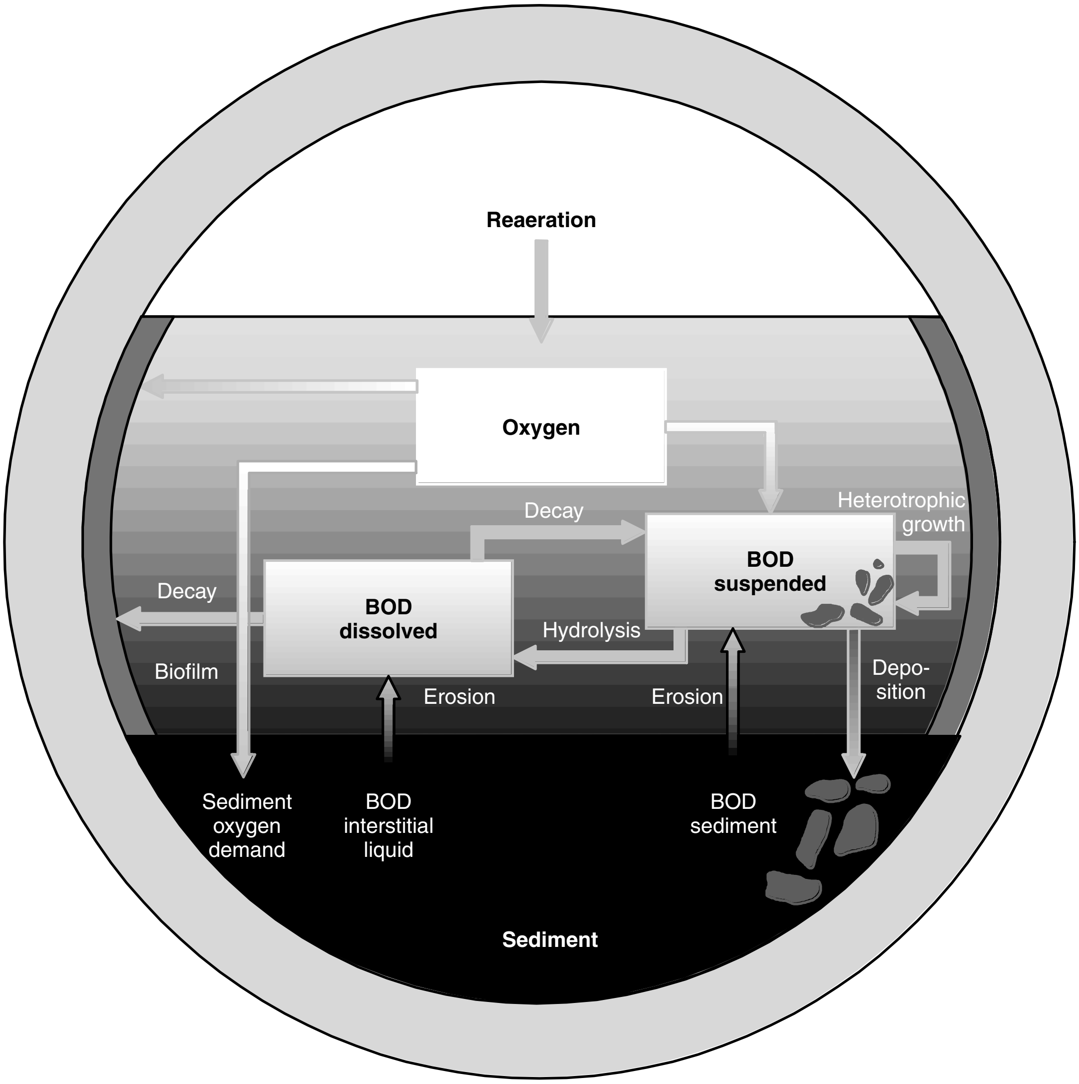

Figure 3. Example of water quality processes in wastewater under aerobic conditions.

the success of the previous steps. The modeling procedure is as follows:

1. Make a tracer verification of the hydrodynamic model, and apply a pure advection and/or advective–dispersion model.
2. Model a real quasi-conservative pollutant, for example, ammonia for both dry weather flow and rainstorms.
3. Analyze the ratio of dissolved and particulate COD and BOD, and check if a “first flush” exists.
4. If the water quality parameters in the study are attached to sediment, then model the sediment transport of the suspended solids.
5. To determine the water quality process rates, obtain measurements of flow and pollution for relevant periods at upstream and a downstream locations in the sewer system.
6. Model dissolved COD and BOD using the process rates from step 5.
7. Model total COD and BOD as the outcome of the modeling of the dissolved COD/BOD and the sediment transport of particulate COD and BOD.

LONG-TERM SIMULATION OF POLLUTION

High computational speed has made it feasible to carry out hydrodynamic and water quality simulations applying deterministic models. These models allow computing annual loads of pollutants to a WWTP or annual loads discharged from CSOs. In addition, extreme events can be modeled, such as those giving rise to high CSO discharges of water and pollutants that can cause fish kills. Through long term simulation, extreme events can be assigned return periods, providing information concerning how often various events occur. In Fig.4, the result from a 3-month simulation is seen. Long-term simulations generally require data spanning three to five times the (return) period of interest.

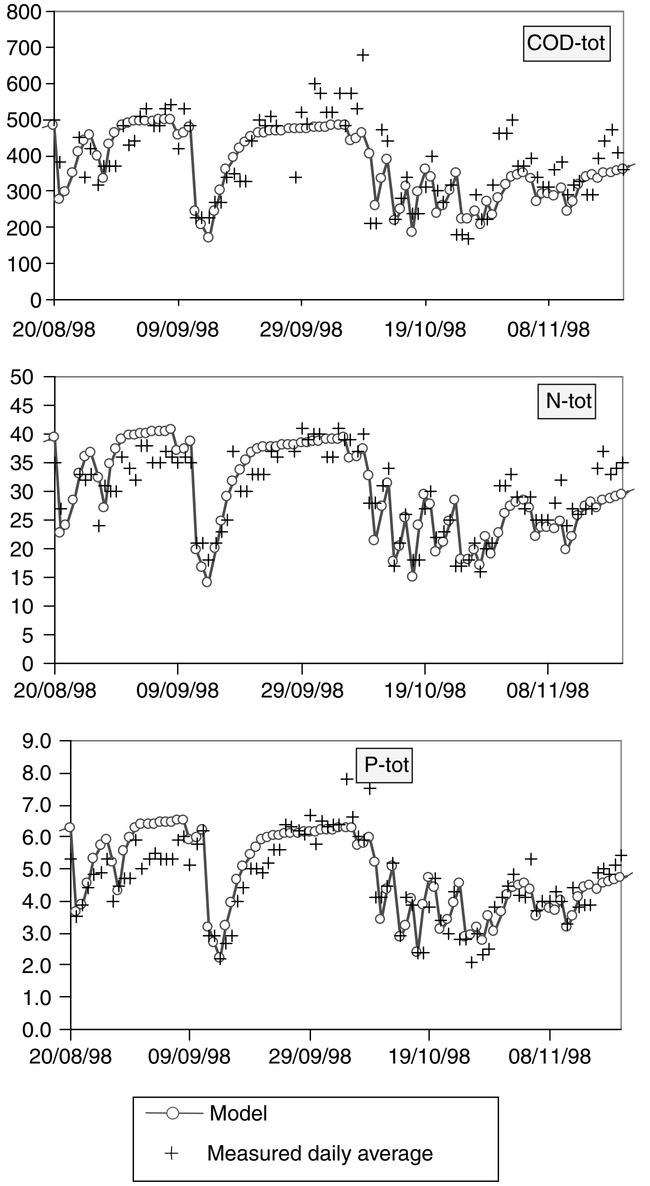

Figure 4. Simulated ammonium concentration in the inflow to the Øresundsverket, WWTP, Helsingborg, compared with analyzed 24 hourly values (each workday).

FUTURE PERSPECTIVES AND CHALLENGES IN RELATION TO MODELING OF WATER QUALITY IN SEWERS

At present, it is feasible to model water quality and pollution in sewers. However, for successful modeling, it is of great importance to understand the hydrodynamics, the transport of pollution, and the potential associated biological and chemical processes. Further, a model describing the dominant processes is essential. And, finally, a systematic procedure must be applied whereby the performance of the water quality model is verified step by step.

Holistic analysis of the sewer system, the wastewater treatment plant, and receiving waters is still an emerging area that has potential for integrated analyses of overall performance. The sewer system and the water quality processes in the sewers play a key role in this analysis, and, as more information becomes available concerning modeling of water quality in sewers, more solutions, and hopefully, better and sustainable solutions may be developed for handling the water in sewer systems.

MODELING OF URBAN DRAINAGE AND STORMWATER

Ole Mark
Asian Institute of Technology
Hørsholm, Denmark

Sutat Weesakul
DHI Water & Environment
Bangkok, Thailand

INTRODUCTION

The construction and operation of urban drainage and stormwater systems have historically been driven by the objectives of maintaining public hygiene and preventing flooding. All over the world, cities have grown rapidly during the last century, and city authorities have built and continuously expanded storm and wastewater drainage facilities. Many old cities have developed according to their varying historical needs and visions. Hence, the layout and design of the infrastructure have gradually developed into rather complex systems, which require tools to handle such situations.

An understanding of the physical system and its interaction with the environment is a prerequisite for effective planning and management of urban drainage and stormwater systems. In this respect, computer models provide the opportunity for well-structured analyses of the current performance of a system and the effect of potential changes in the system; they offer a sound scientific framework for coordinated management and planning. Apart from assessing different scenarios, the models also help to improve process understanding. Urban drainage models are used to understand the often rather complex interaction between rainfall and overflow/flooding. Once the existing conditions have been analyzed and understood, alleviating schemes can be evaluated, and the optimal scheme implemented.

Today's advances in computer technology allow many cities all over the world to report overflows from their sewers yearly using a combination of measurements and modeling, and in many places, they manage local and minor flooding problems using computer-based solutions. This involves developing computer models of the drainage/sewer system, for instance, by using software such as InfoWorks (1), MIKE URBAN (2), MOUSE (3), PCSWMM (4), and SWMM (4). All are hydrodynamic modeling packages that solve the one-dimensional equations of St. Venant.

TYPES OF MODELS USED FOR URBAN DRAINAGE AND STORMWATER SYSTEMS

Any model is a simplified mathematical representation of a physical system. This representation may be based on a ***deterministic*** approach (i.e., a fixed relationship between physical disturbance and its effect, such as model results) or it could be ***stochastic***, involving terms of probability in the model inputs and the interpretation of model results. Models for urban drainage and stormwater are predominantly deterministic models, and the text below refers only to this class.

Furthermore, deterministic models applied to urban drainage can be roughly classified as ***physical models*** and ***conceptual models***. Placing a model in one of these classes relies on the level of mathematical sophistication of the treatment of underlying physical processes in the model. Practically, models are classified according to the importance of empirical parameters for the models' ability to describe these processes accurately. The reliance on empirical parameters classifies the model as conceptual and emphasizes the need for validation against field measurements. In this context, various hydrologic models would belong to the class of conceptual models; a hydrodynamic network model is an example of a physical deterministic model.

BRIEF HISTORY OF URBAN DRAINAGE MODELING

Modeling of urban sewer and drainage systems dates back to the late 1960s when the U.S. EPA funded the development of the first version of the EPA Stormwater Management Model (SWMM). The first version 1.0 of SWMM was released in 1971. Around this time, Wallingford (UK) and DHI Water and Environment (DK) developed their first one-dimensional flow models, but it was not until 1982–86, with the release of the commercial software packages, MicroWASSP (1982), MOUSE (3), and PCSWMM (4), that they were no longer 'labeled' as 'in-house software.' These modeling packages came very soon after the first PCs hit the market. Since the release of personal computers (PC), modeling software for urban drainage has closely followed and fully used the full powers of the PC. As PCs have become more powerful, the modeling software has increased in complexity, and the size of the urban drainage model has gone from a maximum of around 250–500 pipes in the mid-1980s to modeling the drainage systems of mega cities, (e.g., models with thousands of pipes). Computer modeling of urban drainage has not added much new within the basic theory of urban hydrology and hydraulics, but it brought fast and user-friendly computations of the St. Venant equations to the broad engineering community. During the 1990s, modeling of urban drainage broke new ground by developing both theoretical and modeling approaches for sediment transport and water quality in sewers, processes which today are still not fully understood. Lately, major modeling packages have been fully embedded in Geographical Information Systems (GIS) to ease model building based on the registrations in the databases of the local authorities and to present model output in conjunction with the cities' infrastructural data.

CALIBRATION AND VERIFICATION OF MODELS: FIELD MEASUREMENTS

Urban drainage models are expected to reproduce the behavior of the modeled system with a high level of accuracy. This is usually ensured through parameter calibrations and the verification of model results against the measured performance of the real system. Calibration involves adjusting the model's key parameters, to minimize the differences between the model results and the field measurements (e.g., water levels). A continuous period or a set of intermittent events used for calibration should include a full range of expected operational conditions in the system. Verification provides proof that the model generates results within the acceptable error range. Reliable verification should be carried out for a simulation period or intermittent event(s), which are different and independent of those used for the model calibration.

All models must, if possible, be calibrated before application. Conceptual models require more attention in this respect compared to fully deterministic, physical models because the assumptions of the conceptual models must also be proven valid. Thus, in urban drainage modeling, the focus of model calibration is usually on hydrologic models (conceptual), whereas the deterministic hydrodynamic models of the drainage network typically require only minor adjustments for accurate performance. However, independently of the applied model type, good modeling practice requires thorough model verification before application.

Reliable field measurements in sewers and drains and the results of laboratory analysis (in the case of water quality modeling) are essential for successful model verification (i.e., for the model application as a whole). The harsh environment in sewers and urban drains (poisonous gases and pathogenic microorganisms in confined conduits, aggressive fluids, floating debris), as well as particular hydraulic conditions (alternating free-surface and pressurized flow, rapid flow surges, etc.) requires special monitoring equipment and highly trained specialists for good results. Routinely measured variables include water level, flow velocity, conductivity, temperature, pH, etc. The chemical and biological properties of the water, as well as sediment characteristics, are obtained by manual or automated sampling, followed by laboratory analyses.

APPLICATIONS OF MODELS TO URBAN DRAINAGE AND STORMWATER SYSTEMS

Urban drainage and stormwater models are usually set up and applied for specific analyses, and a model of the same part of a city may be differently schematized and calibrated for different objectives, based on the application type. The next sections briefly describe common applications of urban drainage and stormwater modeling:

- modeling of water quality
- modeling of urban flooding
- modeling the interaction between urban drainage systems, receiving waters, and wastewater treatment plants.

MODELING OF WATER QUALITY

Modeling of wastewater is important for predicting the inflow of both water quantity and quality to wastewater treatment plants and for precise descriptions of overflow from sewer systems (overflow of a mix of wastewater and rainwater from combined sewer systems)—combined sewer overflows (CSO) and overflow from sanitary sewer systems (SSO). Traditionally, overflows are modeled by using a rainfall runoff model as input to a hydrodynamic pipe flow model in conjunction with a diurnal description of the wastewater produced by the people living in the city.

In the past, the performance of a sewer system was characterized by most Environmental Protection Agencies (EPAs) by the number of overflow events per year. If a sewer system had less than, e.g., five overflows/year, it was considered satisfactory performance. This was a performance criterion which was feasible to check and implement, but it could not account for the actual volumes spilled. It was realized that five overflows/year could be spilling one thimble of water five times, or it could be huge volumes of water spilled five times. When modeling was introduced, it was possible to compute volumes from all overflows in a drainage system. In the past, they all had to be measured to get a picture of the complete overflow from the system. Relatively cheap and reliable application of models for calculating overflow volumes and pollution emissions for the entire system changed the EPA focus from a frequency/year to a consideration of the yearly overflow volumes, whenever that was more appropriate. For instance, for lakes, the accumulated overflow of nitrogen and phosphorus from the drainage system is most important, whereas the number of spills is less important. For smaller streams, the loads from extreme events causing high ammonia or low oxygen concentrations may be the dominant processes. The approach to sewer rehabilitation/optimization was changed from a reduction of the number of spills/year to a reduction of the yearly overflow volumes together with consideration of the load to receiving waters. In other words, "The focus went downstream."

The load to streams and rivers would typically be computed based on a conceptual hydraulic model such as the SAMBA model (5). This kind of model is simplified so that it includes only computation of a time–area runoff hydrograph together with the most significant elements in the pipe/drainage system, weirs, pumps, locations with divergent flow, and outlets. Due to the simplifications, the calculations are very fast and suitable for scanning a large number of alternative layouts of drainage systems. In the early days of computer modeling, this kind of modeling was the only way to calculate annual loads and extreme statistics of discharges of water and pollutants based on historical time series of rain events. The model focused on the requirements from the EPA.

The introduction of water quality modeling of urban drainage such as MOSQITO (6) and MOUSE TRAP (7) in the middle of the 1990s, extended the possibility of hydrodynamic modeling of "clean" water to include modeling of the transport of pollution and sediments in the sewer and drainage systems. This further enhanced the description of the modeling of wastewater and the pollution loads to the receiving water because this kind of water quality modeling provides an accurate description of the dilution process when rainwater mixes with sewage, together with an estimate of the water quality processes in the system. The outcome was more accurate computations of concentrations of conservative pollutants in the CSO and, for example, ammonia can be modeled accurately in most cases. For more information concerning modeling water quality, refer to the section in the Encyclopedia of Water, **Modeling of Water Quality in Sewers**.

During the 1990s, long-term simulations of drainage network hydraulics and water quality gradually became standard practice, facilitating simulation of long historical time series of rain and their impact in terms of overflow or load on the wastewater treatment plant. This combination of the simulation of wet weather conditions by using the dynamic pipe flow model and a simple hydrologic model to simulate the dry weather conditions makes it possible to simulate many years (>20 years, but feasible length of simulation period depends on model size, computer speed, and rainfall data duration) continuously within a reasonable computational time on a PC. The results can be presented based on the statistical occurrence of impacts, for example, in terms of overflow volume. Understanding the behavior of the system and its interaction with the environment, gained from long-term simulation, is superior to simulation of selected single rains because the uncertainty from selecting a few representative rains is removed. Furthermore, based on a long-term simulation, the statistics are made on the computed output (the impact of the rain) in terms of CSO, SSO, or flooding. In the past, the statistics were made during the selection of the rains because as they would be input for the simulation.

MODELING OF URBAN FLOODING

The problems arising from urban flooding range from minor ones, such as water getting into the basements of a few houses, to major incidents where large parts of cities are inundated for several days (Fig. 1). Most modern cities in developed countries typically have smaller scale problems, due to locally insufficient sewer capacity. Other cities, for instance, in Asia-Pacific, can have more severe problems because there is insufficient drainage and much heavier local rainfall. The situation is further aggravated because cities in developing countries grow rapidly these days, but do not have the funds necessary to extend and rehabilitate their existing drainage systems. For more information concerning urban flooding, refer to the section in the Encyclopedia of Water, **Urban Flooding**.

Figure 1.

Modeling urban flooding differs significantly from modeling pipe flow, which has a confined geometry can be measured accurately and easily. The flow is basically one-dimensional and accurately described by the St. Venant equations. When the water leaves the drainage/stormwater system, it flows onto a three-dimensional ground surface where the flow routes and paths are not well defined. The surface must be described by a digital elevation model containing roads and houses in the flooded areas. Modeling surface flooding takes on additional data in an environment where the local geometry is difficult to describe accurately and the flow pattern may be one- or two-dimensional. Recently, a model was developed that combined a one-dimensional pipe flow model and a two-dimensional surface flood model (8). This approach allows exchanging surcharge water and flow in the pipe network The results can be used to identify hazardous flood zones, where high velocity occurs (9). Another two-dimensional model using a shallow water equation has been developed to study the flow characteristic of street flooding when water escapes from manholes (10). Modeling urban flooding is an emerging area where applications have started to appear during the last decade. For further information, refer to Mark et al. (11).

Examples of cities that experience urban flooding problems on a larger scale are Bangkok, Thailand; Dhaka, Bangladesh; Ho Chi Min City, Vietnam; Mumbai, India; and Phnom Penh, Cambodia. In the year 2000, nearly 17,000 telephone lines in Mumbai went out of service after flooding occurred, and the electricity supply was switched off for a long time in most areas for safety reasons. The floods reached 1.5 m deep in the locations that were most severely inundated. Fifteen lives were lost in the Mumbai flooding (Times of India, July 25, 2000). In Dhaka, even a little rain can inundate parts of the city for several days. The situation was highlighted in September 1996, when the residents of Dhaka experienced ankle to knee-deep water in the streets. Heavy traffic jams occurred because of the stagnant water on the streets, and daily activities in parts of the city were almost paralyzed. In 1983, Bangkok was flood inundated for six months, which caused direct damage worth approximately 6,600 million baht ($149 million) (12).

MODELING THE INTERACTIONS AMONG URBAN DRAINAGE SYSTEMS, RECEIVING WATERS, AND WASTEWATER TREATMENT PLANTS

"Integrated modeling" in urban drainage is a term describing "*Modeling of the interaction between urban drainage systems, the receiving waters, and wastewater treatment plants*." The term, "receiving waters" is used here for groundwater, streams, rivers, lakes, the sea, etc. Most urban areas have these three components. Few who are involved in managing these systems would disagree with the statement: "It is logical and beneficial to plan, design and operate these components in an integrated manner" (13).

Integrated modeling is a complex exercise due to the sheer size of the model problem and also due to the different modeling approaches for each subsystem that has developed during modeling history. The hydrodynamics in flow and water levels can be directly transferred between subsystems, but presently water quality modeling is handled completely differently in channels/rivers and at the wastewater treatment plant. This causes problems in the interface and data transfer between subsystems, which again impacts accurate modeling of WQ processes.

The logic behind integrated management is old, and a number of separate tools exist. The advent of computer models has been the biggest single factor in the development of integrated analyses. Because of technology limitations in the past, historical reality has been removed from integration, and independent pragmatic criteria for each component have been the norm (13). These are some examples.

- Sewers are typically designed to contain storms of a specific return frequency without surcharging, rather than protecting against flooding.
- Combined sewer overflows are engineered to pass forward flow dictated by downstream sewer or WWTP capacity rather than the ability of the receiving water to accept the overflows.
- Treatment plants themselves are often designed to cope with an arbitrary multiple of dry weather flow, rather than treating all flow from the sewer system.

In most parts of the world, there have been fragmented planning and management of the sewer system, the wastewater treatment plant, and receiving waters. Furthermore, there is a general lack of methodology and technology available for integrated planning and management. Finally, there is simply a lack of a regulatory framework for "integrated thinking." An exception to this "rule" is the UPM procedure (14) in the United Kingdom, which is highly recommended reading. Today's challenge is to move the legislation from individual consideration of each subsystem's performance to integrated management of the urban wastewater system.

The quality of an integrated model for an urban drainage system depends strongly on the quality of the WQ sewer model, which today is the weakest link in integrated modeling. Despite these uncertainties, integrated modeling is still very beneficial, and the future will surely be dominated by integrated modeling.

REAL-TIME MODELING

At present, hydrologists working in urban areas are facing many new challenges imposed by the ever-changing hydrologic environment in cities. In such conditions, emphasis is focused on managing the urban systems as efficiently as possible within the existing infrastructure by applying currently available information and technology, where real-time modeling plays an increasingly important role. It occurs in two types of applications:

- modeling real-time control and active real-time control of urban drainage systems
- modeling as a real-time decision support tool.

MODELING REAL-TIME CONTROL AND ACTIVE REAL-TIME CONTROL OF URBAN DRAINAGE SYSTEMS

In the early 1990s real-time control of sewers (RTC) was recognized as a big leap forward to achieving superior operation of many sewer systems. Since then, RTC has certainly been proven an eminent solution for some sewer systems to reduce the risk of flooding and the amount of CSO at the same time. But RTC has not been implemented to the extent it was foreseen in the early 1990s, and it seems as if RTC never became "the big thing" that was envisaged. Some of the reasons behind the slow implementation of RTC in the real world are due to the risks of applying RTC, and the safety precautions which have to be taken to ensure smooth and secure operation of the RTC system in case of a power failure or other abnormal incidents.

The aim of RTC modeling of an urban drainage/stormwater system is to develop the strategies applied in real life for pumps, weirs, and gates and to evaluate the impact and risk from malfunctions, in a system controlled by RTC. For example, what is the flood risk if a weir or a gate is stuck during a rain?

Today RTC is applicable for

- reducing the flooding risk by using the storage capacity within the sewer system,
- reducing pollution spills from sewer overflows by retaining more stormwater and sewage within the

sewer system as a result of attenuated flows and storage,

- reducing capital costs by minimizing the storage and flow carrying capacity requirements within the system,
- reducing operating costs by optimizing pumping costs and providing the information necessary to implement effective maintenance procedures, and
- enhancing wastewater treatment plant performance by balancing inflow loads and allowing the plant to operate closer to its design capacity, thereby reducing the variability of the final effluent.

When the feasibility of RTC is evaluated for a sewer system, it is important to be aware of the changes in flow pattern introduced by RTC. If RTC is applied during dry weather flow, for example, to level out the flow to a wastewater treatment plant, it must be investigated if the new flow conditions introduced by using RTC cause sediment deposits to develop in new and undesired places. If this is the case, then sediment deposits may increase the risk of flooding, or the entire saving gained by applying RTC may be spent on increased cleaning and maintenance. Neither would be a good outcome.

MODELING AS A REAL-TIME DECISION SUPPORT TOOL

Applying a model in conjunction with real-time data (e.g., rain data) provides means for improving the information about the current status of the urban drainage system. In general, rain gauges provide information only at specific locations. The application of a model provides the possibility of filling information gaps between the rain gauges and computing the future impact of the rain. Models can be automatically executed in real time, for example, when the rainfall at specified locations exceeds preset threshold values. Based on the forecast by a hydrologic model or an urban drainage model, the level of information about the hydrologic system can be extended into the future. Real-time hydrologic information makes it possible to detect potential hazards shortly before or just after they happen, for example, heavy rainfall recorded in certain parts of the catchment that causes flooding, or overflows, and actions can be taken to mitigate the problems in the drainage system. Another example is that local traffic control can redirect traffic to roads not flooded or provide decision support to the operators of pumps and weirs in the system (15).

The application of real-time hydrologic information is not the full solution to overflow and flooding problems, but it may mitigate flood problems and in this way reduce the economic losses and the stress on people and the environment. Finally, the information generated by a real-time hydrologic information system can be applied by using the historical data for design and maintenance analyses to achieve better functionality of the urban hydrologic system before the next heavy rain arrives. In this fashion, the system can also be used to train operators.

FUTURE PERSPECTIVES AND CHALLENGES IN MODELING URBAN DRAINAGE

Calibration Support for Urban Drainage and Stormwater Systems

Today, urban drainage and stormwater models are calibrated to reproduce measurements of flow, water levels, and velocity through a manual calibration procedure. The reliability of the modeling is highly dependent on the adequacy of the calibration procedure. Traditionally, the model is calibrated manually using a trial-and-error parameter adjustment procedure. At present, however, automatic calibration support is being widely discussed (16) as a replacement for the manual calibration procedure, which is subjective and can be time-consuming. Automatic methods for model calibration take advantage of the speed and power of computers, and are objective and relatively easy to implement. Automatic calibration supports are still emerging. So they need to be checked, and the calibration must be thoroughly evaluated by an experienced engineer because the automatic calibration procedure may stop at a local minimum of the objective function, or it may not converge sufficiently toward the chosen objective due to deficiencies in the measured data.

WATER QUALITY MODELING

Modeling water quality in sewers is still an emerging area because water quality and sediment transport processes are difficult to describe precisely and the theory is still developing. At present, a number of practical operational problems in sewers push the research toward sustainable urban drainage systems and practical solutions to handle significant problems such as hydrogen sulfide production. Hydrogen sulfide causes a noxious smell in the public environment; it corrodes pipes and pumps in sewer networks; and poses a health risk to people working inside sewers, for example, during maintenance. When a sewer pipe collapses due to corrosion from hydrogen sulfide, it imposes huge costs on society to restore the pipe. Therefore, there is a need to understand and manage the phenomenon of hydrogen sulfide formation, and the emerging development of modeling tools for this problem makes it possible to assess causes and alleviating measures.

MODELING THE INTERACTION BETWEEN URBAN DRAINAGE SYSTEMS, RECEIVING WATERS, AND WASTEWATER TREATMENT PLANTS

The future challenge within integrated modeling is to develop a consistent modeling formulation for water quality in sewers, the wastewater treatment plant, and receiving waters, which can be carried across the three subsystems. Furthermore, water quality processes in sewers are at present still an emerging area of research, and need more research. Finally, legislation must be revised nearly all over the world to deal with permits to systems which are optimized from a holistic point of view. Today, around the world, most legislation focuses

Next Page

only on one single sub-system, independently of the rest. This will open optimization of the total urban drainage system rather than optimizing each subsystem individually.

MODELING UNGAUGED WATERSHEDS

THORSTEN WAGENER
The Pennsylvania State University
University Park, Pennsylvania

INTRODUCTION

Models of watershed hydrology are irreplaceable tools in today's research and practice. Their areas of application are wide reaching, from water management and flood forecasting, to their use as load models for water quality studies. A vast number of these models have been developed since the 1960s and they differ in temporal and spatial discretization, processes described, and in the constituent equations used. However, there are also similarities that have consequences for the way these models are commonly applied. All models of watershed hydrology aggregate the real hydrologic system on a particular element scale in space and time. The spatial scale might vary from grid cells of tens of meters to models that treat the whole catchment as a single unit, and the temporal scale might vary, for example, from 15-minute intervals to monthly time steps. It is common to assume homogeneity of processes or watershed characteristics on scales smaller than the one applied, that is, parameters are assumed to be effective on a certain scale (Fig. 1), although the heterogeneity of the real world on smaller scales is sometimes described by distribution functions (2). The characteristics of each model element, for example, storage or infiltration capacity, are described by parameters within the model. A common problem is that the scale on which these characteristics can be measured are usually different, mostly smaller, than the scale of the model element. The effect of this difference between model and measurement scale is that one has to revert to alternative methods to estimate model parameters. The usual approach is to observe the responses of the real hydrologic system, for example, streamflow, and compare them to predictions of the model. The modeler then adjusts the model parameters, in a process usually referred to as calibration, until model predictions and observations are as close as possible. Calibration can be performed using manual or automatic techniques and the available literature on this subject is immense. Between 3 to 10 years of observations are required for calibration, depending on the model complexity and the informational content of the data (3). Shorter periods can suffice when the data sufficiently trigger the response modes of the model (4).

Alternatives to model calibration have to be found when no or insufficient time series of the variable under investigation are available for this process. This is a common problem, even in countries that have extensive measuring networks such as the United Kingdom that has more than 1400 gauging stations (5). It is also possible that sufficiently long streamflow time series are available but that the modeling objective is the prediction of a different variable, for example, groundwater levels. Then, a calibration with respect to the variable under study

Previous Page

only on one single sub-system, independently of the rest. This will open optimization of the total urban drainage system rather than optimizing each subsystem individually.

MODELING UNGAUGED WATERSHEDS

Thorsten Wagener
The Pennsylvania State University
University Park, Pennsylvania

INTRODUCTION

Models of watershed hydrology are irreplaceable tools in today's research and practice. Their areas of application are wide reaching, from water management and flood forecasting, to their use as load models for water quality studies. A vast number of these models have been developed since the 1960s and they differ in temporal and spatial discretization, processes described, and in the constituent equations used. However, there are also similarities that have consequences for the way these models are commonly applied. All models of watershed hydrology aggregate the real hydrologic system on a particular element scale in space and time. The spatial scale might vary from grid cells of tens of meters to models that treat the whole catchment as a single unit, and the temporal scale might vary, for example, from 15-minute intervals to monthly time steps. It is common to assume homogeneity of processes or watershed characteristics on scales smaller than the one applied, that is, parameters are assumed to be effective on a certain scale (Fig. 1), although the heterogeneity of the real world on smaller scales is sometimes described by distribution functions (2). The characteristics of each model element, for example, storage or infiltration capacity, are described by parameters within the model. A common problem is that the scale on which these characteristics can be measured are usually different, mostly smaller, than the scale of the model element. The effect of this difference between model and measurement scale is that one has to revert to alternative methods to estimate model parameters. The usual approach is to observe the responses of the real hydrologic system, for example, streamflow, and compare them to predictions of the model. The modeler then adjusts the model parameters, in a process usually referred to as calibration, until model predictions and observations are as close as possible. Calibration can be performed using manual or automatic techniques and the available literature on this subject is immense. Between 3 to 10 years of observations are required for calibration, depending on the model complexity and the informational content of the data (3). Shorter periods can suffice when the data sufficiently trigger the response modes of the model (4).

Alternatives to model calibration have to be found when no or insufficient time series of the variable under investigation are available for this process. This is a common problem, even in countries that have extensive measuring networks such as the United Kingdom that has more than 1400 gauging stations (5). It is also possible that sufficiently long streamflow time series are available but that the modeling objective is the prediction of a different variable, for example, groundwater levels. Then, a calibration with respect to the variable under study

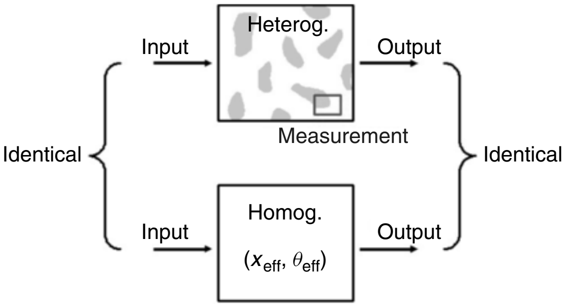

Figure 1. Definition of effective parameters and differences in scale between measurements and hydrologic modeling. (Modified from Reference 1).

would not be possible. With respect to the modeling of ungauged watersheds, there is also a difference whether the required predictions are limited to particular events or whether continuous simulation is required. Some reasonable estimates for event-based models can be derived, but this is not the case for continuous models where the predictions are highly uncertain (6). These two cases are therefore treated separately here.

MODELING THE EVENT-BASED WATERSHED RESPONSE

Empirical models are usually used for modeling individual events. In these models, the response characteristics of watersheds (e.g., mean annual flood or the percentage runoff) are related to watershed descriptors (e.g., area, drainage density, or dominant soil types) using regression equations (7;8, p. 301).

Another empirical approach that is very popular for event-based modeling in ungauged watersheds in many parts of the world is the curve number (CN) method. This approach was originally developed by the Soil Conservation Service for watersheds in the United States (9;10, pp. 147 et ff.). The basis of this technique is the assumption that the ratio of direct runoff to total precipitation is equal to the ratio of retained water to the potential maximum retention. The value of the potential maximum retention S can be calculated using values for CN:

$$S = \frac{1000}{\text{CN}} - 10 \tag{1}$$

where S is calculated in inches. Actual values for CN (0–100) given in tables or graphs are a function of soil type, land use, and antecedent moisture conditions (10, pp. 148–149), which makes this approach so attractive for modeling ungauged watersheds. These graphs and tables were originally derived from measured rainfall-runoff data on a small watershed or hillslope scale (8, p. 184).

These parametrically simple event-based models have been applied with some success (7,11). However, there is a trend to move from event-based models to those that provide continuous simulation because the initial conditions for event-based models are a major source of uncertainty. A recent workshop report on challenges in hydrologic predictability noted "in watershed rainfall-runoff transformation ... initial and boundary conditions are the critical issues" (12, p. 17). This problem has led to a more holistic approach to flood management in some countries. In the United Kingdom, for example, there is a move to replace event-based modeling with continuous approaches (13,14).

MODELING THE CONTINUOUS WATERSHED RESPONSE

Several approaches to estimating parameters in ungauged watersheds are available for continuous simulation models. The two most common approaches are (1) the derivation of regression relationships between model parameters and watershed characteristics (5,6,15–17) and (2) estimation of parameter values from measurable watershed (mainly soil) properties (18–23).

In the first approach, a chosen model structure is calibrated to a large number of watersheds for which sufficiently long and informative observations are available. An attempt is then made to derive regression equations that predict its value using a combination of several watershed characteristics. A separate equation is commonly derived for each model parameter. The parameter values in the ungauged watershed can then be estimated using the derived equations and a prediction can be made. Figure 2 shows a typical procedure for extrapolating parameters from gauged watersheds using regression analysis (6). The steps are as follows (Fig. 2): (1) Select catchments and their characteristics. (2) Select and calibrate the local model structure. (3) Select and calibrate the regional model structure. (4) Predict flow at the ungauged site. Currently, this is probably the most often applied technique; however, Wagener et al. (6) found considerable uncertainty in typical predictions using this approach.

Sometimes, it might be possible to derive at least some of the model parameters directly from measurable watershed characteristics. The scale difference between model parameters and measurements might be relatively small for some parameters if the model uses a very fine spatial distribution, or simple equations can be used to derive these parameters from a combination of watershed characteristics. Koren et al. (22), for example, show how storage capacities can be estimated from soil properties such as field capacity and wilting point. These properties are usually derived from point samples analyzed on the laboratory scale. This makes using these values for lumped parameter estimation questionable because *there is generally no theory that allows the estimation of the effective values within different parts of a heterogeneous flow domain from a limited number of small scale or laboratory measurements* (8). On the other hand, this approach does not assume that all the model parameters are independent as in the earlier mentioned regression technique. The idea of Koren et al. (22) is therefore rather to derive good initial estimates for a subsequent calibration procedure in gauged watersheds, that is, to reduce the calibration effort, and also for ungauged watershed and distributed modeling approaches. Very few examples can be found in the literature where models, using only measured parameters, have been applied without further calibration. It is unlikely that reliable

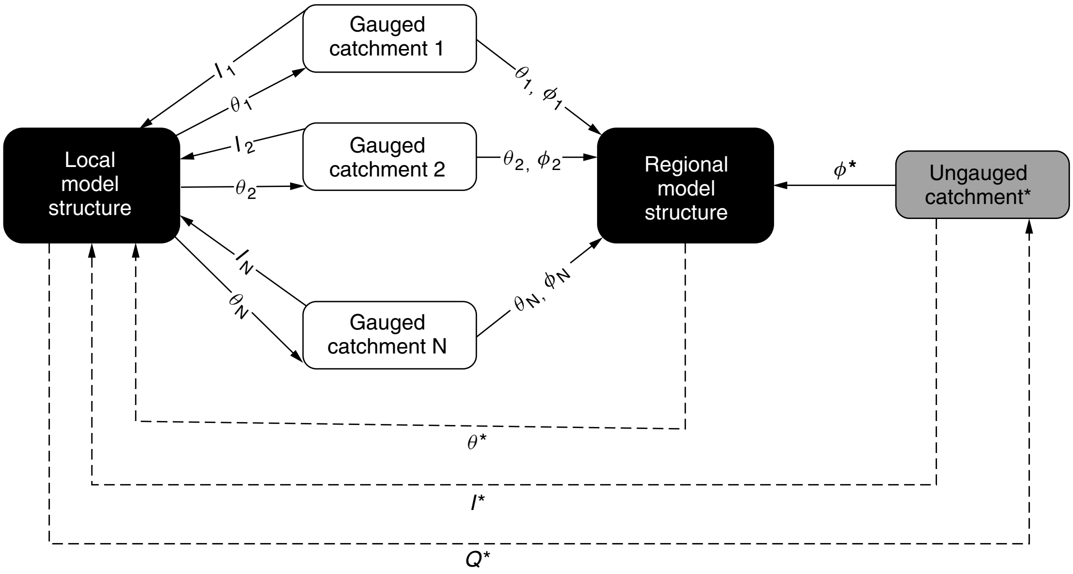

Figure 2. Schematic description of the statistical regionalization approach. (Modified from Reference 6).

predictions can be obtained by this approach from the current generation of model structures.

CONCLUSION

The ungauged problem is currently an area of extensive research and it can be expected that considerable progress will be made during the coming years (6,24,25). The complexity of the problem requires a holistic approach that can be provided only by a wide variety of hydrologists working on different topics. However, the potential value of the scientific outcome is very high. Current predictions in ungauged watersheds have to be considered as very uncertain though and must be used carefully in decision-making.

CORPS TURNED NIAGARA FALLS OFF, ON AGAIN

Frank Balon
Buffalo District,
U.S. Army Corps of Engineers

Niagara Falls, one of the Seven Natural Wonders of the World, attracts millions of tourists each year. But 30 years ago tourists flocked to see an unprecedented sight the mighty Falls reduced to a mere trickle by the engineering skill of Buffalo District.

Niagara Falls is 19 miles downstream from Lake Erie. Goat Island divides the Niagara River into two channels, separating Niagara Falls into American Falls on the American side and Horseshoe Falls on the Canadian side.

Public concern arose in the mid-1960s regarding the talus (rock fragments) accumulation at the base of the American Falls, which many felt detracted from its natural beauty. Three major rockfalls occurred in 1931, 1954 and 1959, depositing about 130,000 cubic yards of rock at the Falls' base.

In 1965, Congress authorized the U.S. Army Corps of Engineers to study the measures needed to preserve and enhance the beauty of the American Falls. The results of the Corps' study were submitted to the International Joint Commission (IJC) which, at the request of the American and Canadian governments, began an independent inquiry in 1967. The Commission established the American Falls Study Board, which included representatives from the Corps, Environment Canada, and eminent landscape architects to consider possible alternatives for preserving American Falls' future.

The IJC recommended to both countries that American Falls be temporarily dewatered to facilitate a timely and thorough study. The governments agreed, and on June 12, 1969, a rock cofferdam stopped the flow over American Falls. The Falls remained dry until November 25, 1969, when a backhoe removed the cofferdam.

The stark contrast between Niagara Falls with water and without actually increased tourist volume to the area

Once stripped of its cascading white waters, the 1,100-foot-wide, 200-foot-high precipice revealed sights never before seen. One rock outcrop closely resembled a human profile. Another giant block of rock at the fall's base was larger than most houses in the city of Niagara Falls.

Special measures were taken to prevent damage to aquatic life in the American Falls channel. Terrestrial vegetation in the channel's small islands were protected and irrigated. Sprinklers kept Rochester shale wet on the face of the American Falls. In addition, railings at viewing areas were relocated and mass rock was stabilized to protect workers and the viewing public from injury.

While American Falls was dewatered, the board conducted a detailed geologic exploration. Forty-six core holes, totaling 4,882 feet, were bored. Dye and water testing on the completed holes identified weak points in the rock mass. Face mapping included topographic, stratigraphic and structural studies. Additional testing included terrestrial photogrammetry of the Falls' face, mapping rock fractures and joints, and measuring both

---

Workers were lowered by cranes, in safety cages, to inspect the face of the falls

water pressure in rock joints and horizontal movement in the adjacent rock mass.

"It was thrilling to walk on the American Falls riverbed shortly after dewatering and to view closely the huge exposed boulders," said Andrew Piacente, a civil engineering technician in the Water Control Branch. Piacente served as the district engineer's field representative to the American Falls Working Committee and the American Falls Board of Control during the project.

Talus studies involved examining the cobbles and boulders to determine their size, rock type and condition. The talus blocks were photographed and mapped. Talus depth ranged from 25 to 50 feet.

The board considered three alternative methods for removing all or part of the talus, and estimated the time and costs associated with each. The rock removal methods involved using either a cableway system between the U.S. and Canada, large cranes on and below the Falls' crest, or a large rock crusher together with a portable conveyor. The board determined a cableway with land disposal to be the most practical method.

Data gathered from the geologic exploration was used to build a realistic model of the American Falls 1/50th its actual size. The model, built by Ontario Hydro, included removable talus blocks, which allowed accurate simulation of various talus arrangements. The turbulence, mist, illumination, and volume of water were all closely duplicated.

Far from ruining the Falls' tourist appeal, the dewatering significantly increased tourist volume. People traveled thousands of miles to see the Corps unparalleled engineering feat.

"I've seen the Falls five or six times before, in winter and in summer," said a tourist quoted in the June 13, 1969 issue of the *Buffalo Courier Express*. "But this is the best time to see it. It's so unique."

Public opinion was considered very important. Public displays describing the Falls and the Board's undertakings were exhibited in both countries. The dewatering program received intensive national and international media coverage. Public opinion was strongly in favor of maintaining the Falls' natural appearance, leaving the accumulated talus fully intact.

In the end, the board agreed. After exhaustive deliberation, the IJC recommended that the U.S. and Canadian governments leaving the talus totally intact, considering the cost of removal, the irreversible nature of the project, and the resulting accelerated erosion. In addition, the IJC concluded that artificial means should not be employed to prevent further erosion of the Falls' crest.

The timeless beauty of majestic Niagara Falls continues to inspire and serve as a symbol of international cooperation between the U.S. and Canada. A 1975 IJC report to both governments stated that "consideration of the preservation and enhancement of the beauty of the American Falls cannot be limited to their physical aspects. The appeal and fascination of the Falls mean different things to different people. Their beauty is in the eye, the mind, and the heart of the beholder."

OPEN CHANNEL DESIGN

Xing Fang
Lamar University
Beaumont, Texas

An open channel flow is a flow having a free surface, which is subject to atmospheric pressure. This type of flow is typically found in rivers, creeks, irrigation canals, drainage conduits or ditches, culverts, spillways, and sanitary sewers. When water flows partially in a closed conduit (e.g., sewer pipe), this flow should be treated as an open channel flow. Open channel design is to design a channel to carry a certain amount of flow from one location to another under any provided channel geometry and topographic conditions. Design discharge that a channel needs to convey/carry is predetermined by a hydrological analysis. The analysis could be a simple application of the rational method ($Q = CIA$, where Q is the peak discharge, C is the watershed runoff coefficient, I is the average design rainfall intensity, and A is the upstream watershed area) or a complex watershed hydrological modeling, which may include rainfall design hyetograph, rainfall loss estimation, transformation of rainfall excess into runoff, and hydrograph routing at rivers detention/retention ponds, and reservoirs.

Parameters to define channel geometry include channel shape, cross-sectional area (A), wetted perimeter (P), hydraulic radius (R), top width (T), and hydraulic depth (D). Table 1 gives proprieties for common geometric channel shapes. Side slope of a channel (z, z_1, z_2 in Table 1)

Table 1. Geometric Properties of Different Channel Cross Sections

Channel Definition	Area (A)	Wetted Perimeter (P)	Hydraulic Radius (R)	Top Width (T)	Hydraulic Depth (D)
Rectangle	By	$b + 2y$	$\frac{by}{b+2y}$	b	y
Trapezoid with equal side slopes	$(b + zy)y$	$b + 2y\sqrt{1+z^2}$	$\frac{(b+zy)y}{b+2y\sqrt{1+z^2}}$	$b + 2zy$	$\frac{(b+zy)y}{b+2zy}$
Triangle with equal side slopes	zy^2	$2y\sqrt{1+z^2}$	$\frac{zy}{2\sqrt{1+z^2}}$	$2zy$	$0.5y$
Trapezoid with unequal side slopes	$by + 0.5y^2(z_1 + z_2)$	$b + y(\sqrt{1+z_1^2} + \sqrt{1+z_2^2})$	$\frac{by + 0.5y^2(z_1+z_2)}{b + y(\sqrt{1+z_1^2} + \sqrt{1+z_2^2})}$	$b + y(z_1 + z_2)$	$\frac{by + 0.5y^2(z_1+z_2)}{b + y(z_1+z_2)}$
Triangle with unequal side slopes	$0.5y^2(z_1 + z_2)$	$y(\sqrt{1+z_1^2} + \sqrt{1+z_2^2})$	$\frac{0.5y^2(z_1+z_2)}{y(\sqrt{1+z_1^2} + \sqrt{1+z_2^2})}$	$2(z_1 + z_2)$	$0.5y$
Circle	$(\theta - \sin\theta)d_0^2/8$	$0.5\theta d_0$	$\left(1 - \frac{\sin\theta}{\theta}\right)d_0/4$	$d_0 \sin(0.5\theta)$ or $2\sqrt{y(d_0 - y)}$	$\left(\frac{\theta - \sin\theta}{\sin\theta/2}\right)d_0/8$
Parabola	$2/3\ Ty$	$T + \frac{8y^2}{3T}$	$\frac{2T^2y}{3T^2 + 8y^2}$	$\frac{3A}{2y}$	$2/3y$
Round cornered rectangle $Y > r$	$\left(\frac{\pi}{2} - 2\right)r^2 + (b + 2r)y$	$(\pi - 2)r + b + 2y$	$\frac{\left(\frac{\pi}{2} - 2\right)r^2 + (b+2r)y}{(\pi - 2)r + b + 2y}$	$b + 2r$	$\frac{(\theta/2 - 2)r^2}{b + 2r} + y$
Round-bottomed triangle	$\frac{T^2}{4z} - \frac{r^2}{z}(1 - z\cot^{-1}z)$	$\frac{T}{z}\sqrt{1+z^2} - \frac{2r}{z}(1 - z\cot^{-1}z)$	$\frac{A}{P}$	$2[z(y - r) + r\sqrt{1+z^2}]$	$\frac{A}{P}$

Symbol definition: y is depth; b is bottom width; z, z_1, and z_2 are side slopes of horizontal versus vertical; d_o is diameter; and r is radius for rounded corners of rectangle and triangle. Angle $\theta = 2\cos^{-1}[(d_o - 2y)/d_o]$, which ranges from 0 to 360 degrees.

is given as the horizontal increase with a unit vertical increase. Except for rectangular channels, hydraulic depth is not equal to the water depth y (Table 1) because the depth of water is variable in each cross section along flow lines. Hydraulic depth or mean depth (A/B) is therefore used and computed by dividing the cross-sectional area (A) by the width of the free surface (i.e., top width B). Wetted perimeter (P) is the total length of the channel boundary at a section wetted by the flowing liquid, and hydraulic radius (R) is determined by dividing channel cross-sectional area (A) by wetted perimeter (P). For very wide natural rivers (top width B is much larger than water depth D), hydraulic radius is approximately equal to mean depth D.

The flow in an open channel is uniform if the depth of flow does not vary along the length of the channel. The volumetric flow rate (discharge in ft^3/sec or m^3/sec) in a uniform open channel flow can be determined from the Continuity (conservation of mass) Equation 1 and Manning's Equation 2:

$$Q = VA \tag{1}$$

$$V = \frac{m}{n}R^{2/3}{S_0}^{1/2} \tag{2}$$

where V is the mean velocity of flow at a cross section, $m = 1.0$ (m$^{1/3}$/s) in SI units or $m = 1.49$ (ft$^{1/3}$/s) in English (British Gravitational) units, n is the Manning's roughness coefficient (dimensionless), R is the hydraulic radius, S_0 is the channel bed slope, and A is the cross-sectional area. Typical values of n for various channel conditions are given in Table 2. For channels with different roughness

Table 2. Typical Manning's n Coefficients (1)

Type of channel	Minimum	Normal	Maximum
Riveted and spiral steel	0.013	0.016	0.017
Coated cast iron	0.010	0.013	0.014
Uncoated cast iron	0.011	0.014	0.016
Galvanized wrought iron	0.013	0.016	0.017
Black wrought iron	0.012	0.014	0.015
Corrugated metal	0.021	0.024	0.030
Glass	0.009	0.010	0.013
Cement mortar	0.011	0.013	0.015
Finished concrete	0.010	0.012	0.014
Concrete culvert, straight	0.010	0.011	0.013
Concrete culvert with bends, connections	0.011	0.013	0.014
Concrete sewer with manholes, inlets, etc.	0.013	0.015	0.017
Wood stave	0.010	0.012	0.014
Clay drainage tile	0.011	0.013	0.017
Brick work	0.012	0.015	0.017
Earthen channel, straight, clean	0.017	0.020	0.025
Channel, straight with short grass, few weeds	0.022	0.027	0.033
Natural creeks and small streams (clean, straight, full stage, no rifts or deep pools)	0.025	0.030	0.033
Major streams (top width at flood stage greater than 100 ft)	0.025	—	0.060
Flood plains (pasture with high grass)	0.030	0.035	0.050

coefficients (n_i, $i = 1, \ldots, N$) over the cross section (e.g., main channel and floodplain), a composite roughness (n_e) can be calculated by Equation 3 (2,3):

$$n_e = \left(\frac{\sum_{i=1}^{N} P_i n_i^{3/2}}{\sum_{i=1}^{N} P_i} \right)^{2/3} \qquad (3)$$

For a composite channel (not simple geometry in Table 1), one should apply Manning's equation to compute discharges for each subchannel and summarize them to obtain the discharge in the whole channel.

For open channel design, channels should be classified as nonerodible channels and erodible channels. Most nonerodible channels are constructed and lined by using concrete, rip-rap, interlocking blocks, geotextiles, and vegetation, which can withstand erosion satisfactorily under all operational velocities. Unlined channels formed in natural materials (e.g., sand, gravel, sandy loam, firm soil, stiff clay) are generally erodible, especially under high velocity as encountered, e.g., during floods. To prevent the overtopping of channel lines by surface waves and surges, a *freeboard* is recommended; it is defined as the vertical distance from the top of the channel to the water surface at the design discharge. An average freeboard from 1.4 ft to 3.6 ft for discharges from 10 to 3000 ft^3/sec, respectively, is recommended by the U.S. Bureau of Reclamation (4). Number of economical factors, for example, cost for land requisition controlled by channel top width, cost for lining channel controlled by wetted perimeter and materials, and cost of excavation controlled by channel area, can affect final selection of channel geometry.

In open channel design, the dimensions of a channel are computed for uniform flow; and Manning's equation (Equation 2) is applied after channel cross section (e.g., rectangle or trapezoid) and design discharge are specified. For lined channel design, one typically designs the channel with the best hydraulic section (Table 3), where the channel section has the least wetted perimeter for a given cross-sectional area and the channel is most hydraulic efficient. The best hydraulic section may not give the most economical channel because it could result as a very wide channel with a higher cost for land requisition. The semicircle has the least perimeter among all sections with the same area, but it may not be the most practical to construct with conventional materials. If one wants to design a concrete trapezoidal channel capable of carrying 500 cfs with a channel slope of 0.0002 ft/ft. If one uses the best hydraulic section for trapezoidal channel given in Table 3 and applies Manning's equation Equation (2) as given below, water depth (y) is determined as 8.8 ft and channel width is 10.1 ft:

$$500\,cfs = \frac{1.49}{0.015}\left(\sqrt{3}y^2\right)\left(\frac{y}{2}\right)^{2/3}(0.0002)^{1/2} \qquad (4)$$

If a channel is placed in erodible material, the permissible velocity method can assure channel stability. For a trapezoidal unlined channel design, approximate permissible side slopes for various materials are given in Table 4 and maximum permissible velocities and roughness coefficients n are given in Table 5. One may use the best hydraulic section concept as the first estimate of the geometry for an erodible channel by using permissible side slope. If the velocity of the best hydraulic section at the design discharge is greater than the maximum permissible velocity, one needs to redo the design by using the maximum permissible velocity as the design velocity.

Table 4. Channel Side Slopes for Various Kinds of Materials (1)

Materials	Side Slopes (Horizontal:Vertical)
Rock	Nearly vertical
Muck and peat soils	1/4:1
Stiff clay or earth with concrete lining	1/2:1 to 1:1
Earth with stone lining	1:1
Firm Clay	1 1/2:1
Loose Sandy soil	2:1
Sandy Loam	3:1

Table 5. Maximum Permissible Velocities and Manning's *n* Values for Common Channel Materials (1,5)

Materials	V (ft/s)	Manning's n
Fine sand	1.50	0.020
Sandy loam	1.75	0.020
Silt loam	2.00	0.020
Firm loam	2.50	0.020
Stiff clay	3.75	0.025
Fine gravel	2.50	0.020
Coarse gravel	4.00	0.025

Table 3. Best Hydraulic Sections (1)

Cross Section	Area A	Wetted Perimeter P	Hydraulic Radius R	Top Width T	Mean Hydraulic Depth, D
Trapezoid (half of hexagon)	$\sqrt{3}y^2$	$2\sqrt{3}y$	$1/2\,y$	$4/3\,\sqrt{3}y$	$3/4\,y$
Rectangle (half of a square)	$2y^2$	$4y$	$1/2\,y$	$2y$	y
Triangle (half of a square)	y^2	$2\sqrt{2}y$	$1/4\,\sqrt{2}y$	$2y$	$1/2\,y$
Semicircle	$0.5\pi y^2$	πy	$1/2\,y$	$2y$	$0.25\pi y$
Parabola $T = 2\sqrt{2}y$	$4/3\sqrt{2}y^2$	$8/3\sqrt{2}y$	$1/2\,y$	$2\sqrt{2}y$	$2/3\,y$

Note: y = Maximum water depth in cross section.

If one wants to design an earth trapezoidal channel using sandy loam and capable of carrying 500 cfs with channel slope of 0.0002 ft/ft, first design the channel for a best hydraulic cross section, which means that the hydraulic radius is half of the water depth (y). For a sandy loam channel, the recommended side slope $m = 3$ and application of Manning's equation results in a water depth of 8.2 ft and a flow velocity of 2.55 ft/s, which is great the maximum permissible velocity ($V_{\max}$) for sandy loam (Table 5). One has to use the maximum permissible velocity method to redesign the channel cross section:

$$V = 1.75 = \frac{1.49}{n} R_H^{\frac{2}{3}} S^{\frac{1}{2}} = \frac{1.49}{0.02} R_H^{\frac{2}{3}} (0.0002)^{\frac{1}{2}}$$

$$\therefore \quad R_H = 2.14 \text{ ft}$$

$$\therefore \quad A = by + 3y^2 = Q/V = 500/1.75 = 285.7 \qquad (5)$$

$$\therefore \quad P = b + 2y\sqrt{m^2 + 1} = b + 2y\sqrt{10} = A/R_H = 285.7/2.14 = 133.5 \qquad (6)$$

Using a trial-and-error method to solve Equations 5 and 6, one can get $y = 2.27$ ft and $b = 119.0$ ft. The final channel cross section with a 1-ft freeboard gives:

$$P_{tot} = 119.0 + 2(3.27)\sqrt{10} = 139.7 \text{ ft } (42.58 \text{ m})$$

$$T = 119.0 + 2 \times 3 \times 3.27 = 138.6 \text{ ft } (42.25 \text{ m})$$

$$A_{tot} = 119.0(3.27) + 3(3.27)^2 = 421.2 \text{ ft}^2 \ (39.0 \text{ m}^2)$$

ORGANIC COMPOUNDS AND TRACE ELEMENTS IN FRESHWATER STREAMBED SEDIMENT AND FISH FROM THE PUGET SOUND BASIN

Dorene E. MacCoy
Robert W. Black
National Water Quality
Assessment Program
U.S. Geological Survey

As part of the National Water-Quality Assessment (NAWQA) Program, the USGS is investigating contaminants in streambed sediment and aquatic organisms and their relation to land use. One such study is being done in the Puget Sound Basin, which is located in northwestern Washington State and includes streams and rivers that drain to the Puget Sound, the Strait of Georgia, and the Strait of Juan de Fuca, but does not include marine waters. The basin encompasses 13,700 square miles; forest, urban, and agriculture are the principal land uses.

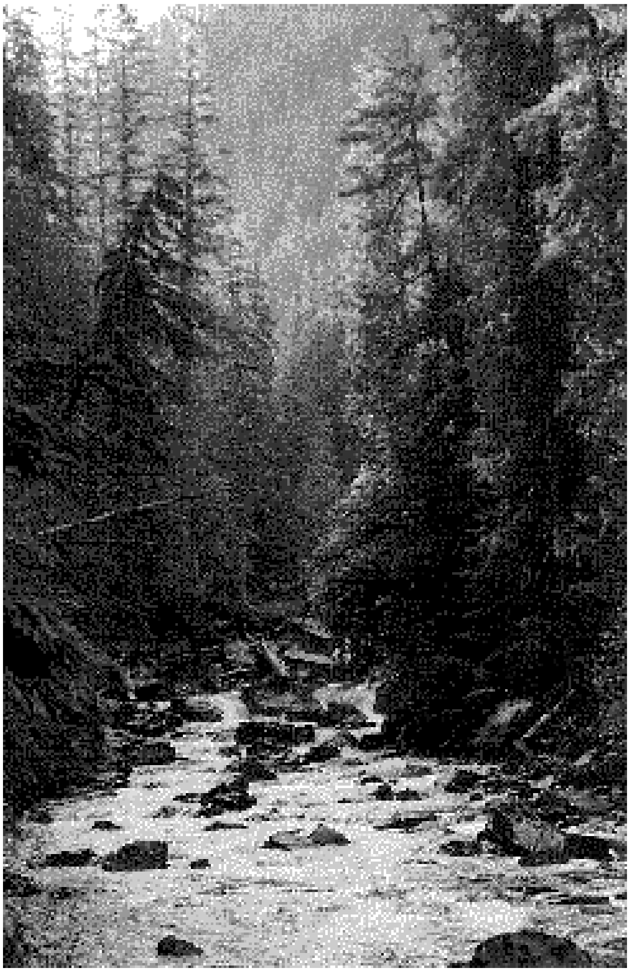
Urban stream

Agricultural stream

SUMMARY OF FINDINGS

Organochlorine Compounds—Highest concentrations of organochlorine compounds in streambed sediment were at an urban site on Thornton Creek near Seattle, where total chlordane, DDT, DDD, and DDE were found to exceed Canadian sediment quality guidelines. Concentrations are compared to Canadian guidelines because there are no sediment quality guidelines in the State of Washington.

Highest concentrations of organochlorine compounds in sculpin (a bottom-feeding fish) were found at the Thornton Creek site. Polychlorinated biphenyls (PCBs) and total DDT (DDT + DDD + DDE) exceeded New York State criteria for protection of fish-eating wildlife at Thornton Creek, and total PCB's exceeded these criteria at the West Branch Kelsey Creek at Bellevue, another urban site.



Forest stream

Concentrations are compared to New York State criteria because there are no criteria for protection of fish-eating wildlife in the State of Washington.

Effects—Elevated levels of organochlorine compounds such as DDT and PCBs are toxic to all animals and can bioconcentrate in tissue, cause tumors, and cause hormonal and behavioral problems. They can also suppress the immune and respiratory systems and cause abnormal development in aquatic species. The primary effect on aquatic communities is to reduce numbers of sensitive species, allowing species that are more resistant to contaminants to become dominant (Harte and others, 1991).

PAHs—Polycyclic aromatic hydrocarbon concentrations in streambed sediment exceeded Canadian guidelines in most urban streams and were highest at the West Branch Kelsey Creek at Bellevue.

Effects—Many PAHs, such as benzo(a)anthracene, benzo(a)pyrene, and chrysene, are carcinogenic, causing tumors in fish and other animals, and are acutely toxic to some organisms. Noncarcinogenic PAHs, such as fluoranthene, phenathrene, and pyrene, are also toxic to some organisms. The effects on aquatic organisms of the PAHs found in sediment at Kelsey Creek are unknown, but concentrations of benzo(a)pyrene as high as those observed in this study can cause precancerous tumors in fish (Eisler, 1987).

Trace elements—Concentrations of arsenic, cadmium, lead, mercury, and zinc frequently exceeded forest and reference conditions in streambed sediment and sculpin in urban streams.

Effects—Elevated levels of arsenic, cadmium, lead, mercury, and zinc may not be of concern in a naturally metal-rich region such as Puget Sound because the aquatic system has adapted to this type of environment, but excessive amounts of these elements can affect the nervous, respiratory, circulatory, and reproductive systems of aquatic organisms, as well as affect their development and feeding habits (Rand and Petrocelli, 1985).

DATA COLLECTION AND ANALYSIS

Streambed sediment and whole sculpin tissue were analyzed to assess the occurrence and distribution of contaminants and to better understand the fate of contaminants in the environment (Table 1). We collected samples in September 1995 from 18 sites, which were characterized on the basis of the predominant land use in the stream's basin—4 agricultural sites, 9 urban sites, 2 forest sites, and 3 reference sites, which are mostly forested and receive minimal impact from humans. At each site we collected the top 2–3 centimeters of streambed sediment in depositional areas; predatory bottom-feeding fish (sculpin) were collected from 17 of these sites. (See Crawford and Luoma, 1994, and Shelton and Capel, 1994, for a more complete description of the methods used.)

Fine-grained sediment and tissue accumulate trace elements and organic compounds associated with anthropogenic (human-related) activities. Sculpin are bottom-feeding fish that are not usually consumed by humans but are eaten by other fish and fish-eating wildlife. Organic compounds analyzed for were organochlorine pesticides, total PCBs, and other organic compounds (of the other organic compounds, only PAH values that exceeded Canadian guidelines are reported because they may have the most potential to harm aquatic and related organisms).

EVALUATION OF DATA

We compared our data to guidelines and criteria for organic compounds to show possible adverse effects to aquatic

Table 1. Contaminants Analyzed for in Streambed Sediment and Whole Sculpin Tissue from the Puget Sound Basin

Contaminant	Sediment[1]	Tissue
Organochlorine compounds	31 pesticides; total PCBs	26 pesticides; total PCBs
Other organic compounds	64	not analyzed[2]
Trace elements	44	22

[1] Finer than 2.0 millimeters for organic compounds, finer than 63.0 micrometers for trace elements.

[2] Tissue analysis too costly for this study.

organisms and fish-eating wildlife, and to local forest and reference conditions for selected trace elements to show possible effects of land use (Fig. 1).

Organic compounds—We compared levels of organochlorine compounds and PAHs detected in sediment to draft interim freshwater sediment quality guidelines developed by the Canadian Council of Ministers of the Environment (CCME). These guidelines were developed from toxicity and species abundance data for benthic organisms from studies throughout North America and represent total concentrations in sieved and unsieved sediment samples (CCME, 1995). The guidelines used are the threshold effects level (TEL), below which adverse effects to aquatic organisms are expected to occur **rarely**, and the probable effects level (PEL), above which adverse effects are predicted to occur **frequently**. Concentrations that exceed these guidelines may or may not have adverse effects on aquatic organisms; the comparisons should be used to indicate **potential** sediment quality problems that may warrant further study.

We compared concentrations of organochlorine compounds in sculpin to New York State Department of Environmental Conservation (NYSDEC) criteria (Newell and others, 1987). These criteria were determined from laboratory experiments using fish-eating wildlife and are considered one of the best sets of criteria for evaluating the effects of contaminated fish tissue on wildlife.

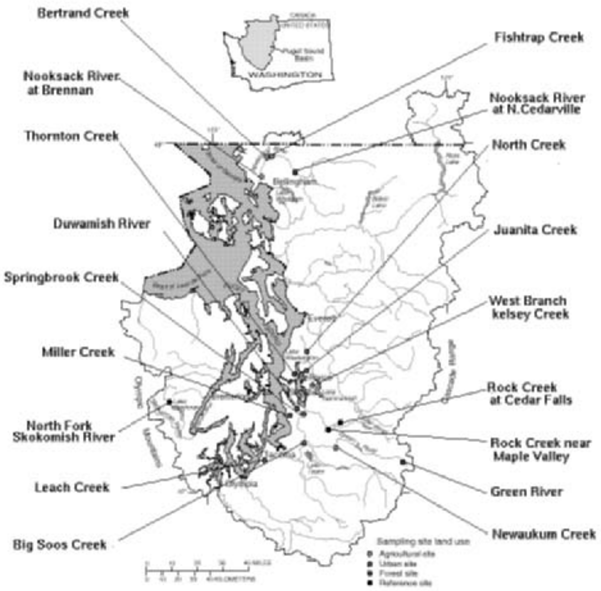


Figure 1. Puget sound basin.

Trace elements—We compared concentrations of selected trace elements in streambed sediment and sculpin

Figure 1 table. Organic compounds that exceed Canadian probable effects levels (PEL) and New York State Department of Environmental Conservation (NYSDEC)criteria, and trace elements that exceed median of forest and reference conditions at sampling sites in the Puget Sound Basin

Site	Sediment	Tissue
Bertrand Creek near Lynden	arsenic, cadmium, chromium, nickel, zinc	zinc
Nooksack River at Brennan	chromium, nickel, zinc	arsenic, chromium, lead, mercury, nickel, zinc
Thornton Creek near Seattle	arsenic, cadmium, chromium, lead, mercury, nickel, zinc, DDT	arsenic, lead, mercury, PCBs
Duwamish River at golf course at Tukwila	arsenic, cadmium, lead, zinc	arsenic, mercury
Springbrook Creek at Tukwila	arsenic, cadmium, chromium, lead, mercury, nickel, zinc	no tissue sampled
Miller Creek near Des Moines	arsenic, cadmium, chromium, lead, mercury, nickel, zinc	arsenic, lead, mercury
North Fork Skokomish River at Staircase Rapids	arsenic, chromium, nickel, zinc	arsenic
Leach Creek near Steilacoom	arsenic, cadmium, chromium, lead, nickel, zinc	arsenic, zinc
Big Soos Creek above hatchery near Auburn	arsenic, cadmium, chromium, lead, nickel	—
Fishtrap Creek at Flynn Road	arsenic, cadmium, chromium, lead, nickel, zinc	arsenic, mercury
Nooksack River at North Cedarville	nickel	—
North Creek below Penny Creek near Bothell	arsenic, cadmium, chromium, lead mercury, nickel, zinc	arsenic, mercury
Juanita Creek at La Juanita	arsenic, cadmium, chromium, lead, nickel, zinc	arsenic, cadmium, lead, mercury
West Branch Kelsey Creek at Bellevue	arsenic, cadmium, chromium, lead, mercury, nickel, zinc, PAHs	arsenic, cadmium, lead, mercury, zinc, PCBs
Rock Creek at Cedar Falls near Landsburg	arsenic, cadmium	chromium, nickel, zinc
Rock Creek near Maple Valley	cadmium, lead, zinc	mercury
Green River above Twim Camp	mercury	arsenic, nickel, zinc
Newaukum Creek near Black Diamond	cadmium, lead, zinc	—

tissue to median concentrations from the forest and reference sites. Land-use impacts may cause concentrations from the agricultural and urban sites to exceed these medians.

ORGANIC COMPOUNDS DETECTED IN STREAMBED SEDIMENT

Organochlorine pesticides were detected at 3 of the 18 sites sampled for streambed sediment: an agricultural site on Fishtrap Creek in the northern part of the basin, an urban site on Thornton Creek near Seattle, and a reference site on Rock Creek near Maple Valley. The highest concentrations were found at the urban site on Thornton Creek (Fig. 2).

PAHs were most frequently detected in streambed sediment samples from urban streams. The highest concentrations were found in the sample taken fromWest Branch Kelsey Creek at Bellevue (Table 2). (See also Tables 3–7.)

Definitions of organic compounds found in the Puget Sound Basin

DDT (dichlorodiphenyltrichloroethane) is an organochlorine insecticide banned from use in the U.S. in 1972. Total DDT refers to the sum of DDT and its breakdown products DDE and DDD.

Chlordane is an organochlorine insecticide banned from use in the 1980's. Total chlordane refers to the sum of *cis*-chlordane, *trans*-chlordane, *cis*-nonachlor and *trans*-nonachlor.

HCB (hexachlorobenzene) is a fungicide used as a seed and soil treatment, restricted from use in the 1980's.

Dieldrin is an organochlorine insecticide with restricted use in the U.S. since the1970's.

Heptachlor epoxide is a breakdown product of the organochlorine insecticide heptachlor. It was used in the U.S. until the1970's.

PCBs (polychlorinated biphenyls) are by-products of a variety of industrial products. Manufacture was stopped in the 1970's. There are over 209 breakdown products of PCBs, and total PCB refers to the sum of all forms detected.

PAHs (polycyclic aromatic hydrocarbons) are natural by-products of forest fires. Other sources include the steel and petroleum industry, the manufacture of coal tar and asphalt, power generation, burning trash, and vehicle emissions. Tons are emitted to the atmosphere and introduced to aquatic environments through oil spills and sewage discharge.

ORGANOCHLORINE COMPOUNDS DETECTED IN TISSUE

Total PCBs and/or at least 1 of 26 organochlorine pesticides were detected in tissue at 2 agricultural and 6 urban sites. The highest concentrations and greatest ranges of organochlorine compounds were detected at the Thornton Creek site (Fig. 3).

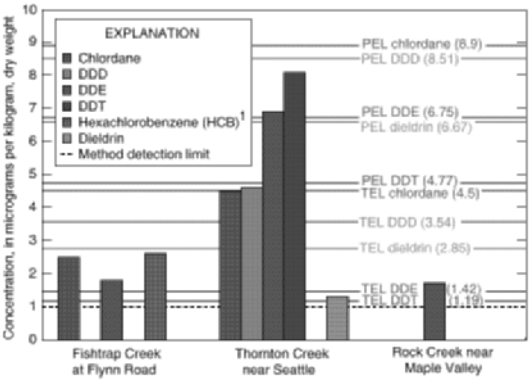

Figure 2. Concentrations of organochlorine pesticides in streambed sediment from selected sites in the Puget Sound Basin compared to Canadian criteria.(TEL, threshold effects level; PEL, probable effects level). [1]No published Canadian data for HCB.

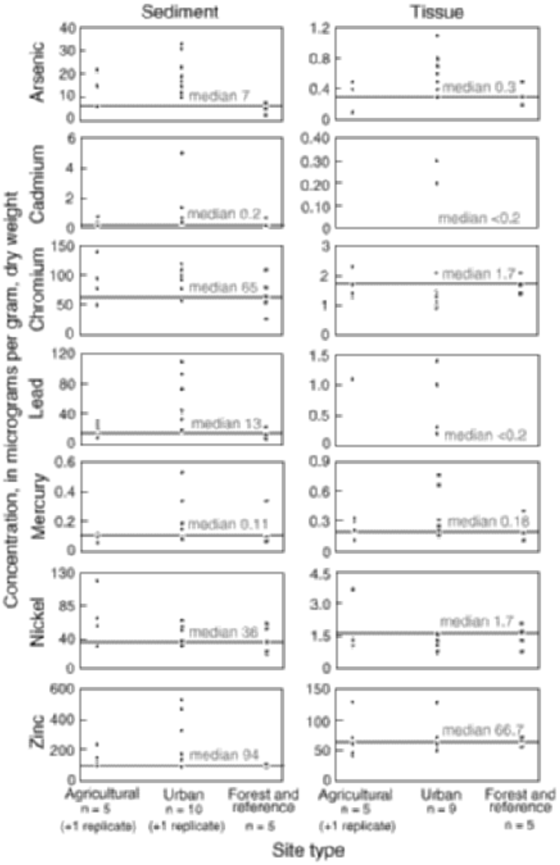

Figure 4. Concentrations of selected trace elements detected in streambed sediment and whole sculpin tissue collected in the Puget Sound Basin compared to the median of forest and reference site data. (n, number of samples; +1 replicate, one replicate sample data included; <, less than).

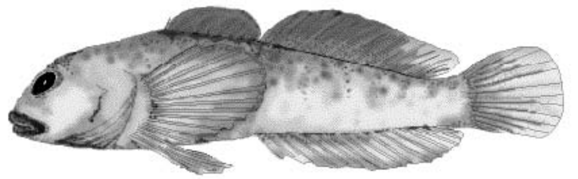

TRACE ELEMENTS DETECTED IN STREAMBED SEDIMENT AND WHOLE SCULPIN TISSUE

Concentrations of arsenic, cadmium, chromium, lead, mercury, nickel, and zinc were elevated in streambed sediment and sculpin from agricultural and urban sites compared to concentrations from the forest and reference sites. Arsenic and the heavy metals cadmium, lead, mercury, and zinc had the highest concentrations and the greatest range of concentrations at urban sites compared to those from the agricultural and the combined forest and reference sites, indicating possible enrichment of these elements in the urban areas (Fig. 4). The concentrations detected do not necessarily have negative impacts on the environment, but do suggest that land use may have led to increased levels of these elements.

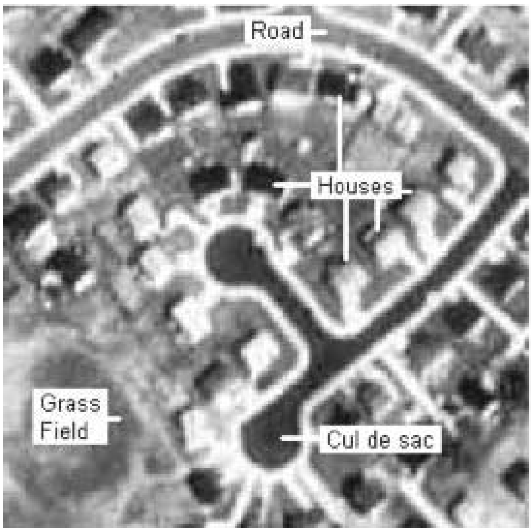
IMPERVIOUS COVER—PAVING PARADISE

Sandra Bird
U.S. Environmental
Protection Agency

THE IMPORTANCE OF IMPERVIOUS COVER

Nonpoint source pollution is pollution from diffuse sources such as urban/suburban areas and farmlands; this is now recognized as the primary threat to water quality in the United States. As urban and suburban development increases, the amount of land covered with impervious surfaces—areas where infiltration of water into the underlying soil is prevented—also increases. Roadways and rooftops account for the majority of this impervious area. Research in recent years has consistently shown a strong relationship between the percentage of impervious cover in a watershed and the health of the receiving stream. Scientists generally agree that stream degradation consistently occurs at even relatively low levels of imperviousness (10 to 20%). Increased impervious surfaces alter stream hydrology resulting in lower flows during droughts and higher peak flows during floods. Roadways and other impervious areas channel pollutants directly into streams without their being processed during transport through the soil. With advance planning and identification of at-risk watersheds, total impervious cover can be reduced during development within a watershed, and steps can be taken to mitigate the impacts of added impervious cover.



Examples of impervious cover

GIS AND SPATIAL DATA

A Geographic Information System (GIS) is a computer system capable of assembling, storing, manipulating, and displaying geographically referenced information (i.e., data identified according to set locations). The way maps and other data have been stored or filed as layers of information in a GIS makes it possible to perform complex analyses.

With the aid of GIS software, a human analyst can efficiently and accurately identify and categorize ground features visible in computer-generated versions of aerial photographs that represent true map distances available throughout the nation. High-resolution satellite imagery is rapidly expanding use of remote sensing techniques for impervious cover estimation. Classified land cover data are now available throughout the country. Detailed road networks and block level census data are other GIS data sources available to aid in estimating impervious cover.

RESEARCH OBJECTIVE

Impervious cover is proposed as an indicator of aquatic conditions for sub-watersheds throughout the country. Researchers are focusing on methods that would be useful in doing region-wide environmental assessments. The usefulness of impervious cover as an indicator is a function of the ease and accuracy for estimating it. Testing is underway to determine with what degree of accuracy impervious cover can be estimated for sub-watershed areas from data available throughout a region.

RESEARCH SUMMARY

An impervious cover test data set for 56 sub-watersheds in Frederick County, MD was developed and used to evaluate different estimation techniques suitable for application to a regional-scale characterization. Using a combination of data sources, researchers were able to estimate the percentage of impervious cover in a watershed to within +/− 1%.

Additional impervious cover data sets are being developed from aerial photographs for approximately 209 watersheds in the Atlanta, GA area for two time periods. These data sets will be used to confirm estimation methods and to determine the accuracy of methods to project future changes in impervious surface area. The estimation technique that was developed in this research project can be used by local and national agencies to target watersheds for monitoring and mitigation efforts.

PHYTOREMEDIATION BY CONSTRUCTED WETLANDS

Rupali Datta
Dibyendu Sarkar
Alpana Khairom
Chacharee Therapong
University of Texas at San Antonio
San Antonio, Texas

A constructed wetland is a wastewater treatment facility that duplicates the processes in natural wetlands. Constructed wetlands are complex, integrated systems in which water, plants, animals, microorganisms, and the environment interact to improve water quality. Phytoremediation, defined as cleansing of the environment using vegetation, is the primary water treatment process in constructed wetlands. The advantages of phytoremediation using constructed wetlands are that it is environmentally friendly, a sustainable technology, and cost-effective; the primary disadvantages are potentially incomplete removal of pollutants and pest attraction. Successful implementation of phytoremediation technology in constructed wetlands is a function of a number of interrelated biophysicochemical factors, including the types and fate of toxicants, characteristics of soil and sediment, plant species and plant uptake, hydrology and water flow, and microbial population. Hence, phytoremediation by constructed wetlands generally reflects an integrated multidisciplinary effort that combines plant biology, microbiology, surface chemistry, hydrology, and environmental engineering. The initial construction of wetlands, taking into account all these factors to design the most appropriate and effective method for removing target pollutants is labor-intensive and expensive, but low maintenance and operating costs make constructed wetlands a much more economically viable alternative to conventional physical and chemical treatments. Above all, the use of plants in environmental cleanup may guarantee a greener and cleaner planet for us and for future generations.

INTRODUCTION

The rising demands of modern day society for economic development and improved standards of living are leading to increased use of raw materials (1). The use of chemicals has played a key role in the development of agriculture, industry, housing, transport, textiles, and health. Their use has contributed significantly to the rise in the standard of living among populations around the world, but a major side effect has been the continuous release of both natural and man-made substances, including gases, heavy metals, volatile organic compounds, soluble organic compounds, suspended solids, and nitrogen and phosphorus compounds into the air, water, and terrestrial environments. Recent research is increasingly focused on the ecological and human health effects of contaminants, and guidelines or standards on soil, drinking water, irrigation water, crop tissues, foodstuff, biosolids, and fertilizers are now becoming available (2). In addition to the human impact, some contamination problems result from geologic activity. For example, reports on reduced iron in Denmark, fluoride in Bavaria and Moldova, and arsenic in Bangladesh and India illustrate the fact that natural geochemical conditions may cause locally elevated concentrations of metals (1).

Environmental remediation technologies use physical, chemical, or biological processes that attempt to eliminate, reduce, isolate, or stabilize a contaminant or a multitude of contaminants (3). Depending on the technology used, the process may take place either at the location of the contamination (*in situ*), or the contaminated soil or water may be removed for *ex situ* treatment. The cost of environmental remediation using conventional techniques can be very high, a fact that has turned out to be the driving force in the development of new remediation technologies. Phytoremediation, defined as the cleansing of the environment using vegetation, has emerged as an effective, inexpensive, and environmentally friendly alternative for remediating contaminated soil and ground water (4). Commercial use of phytoremediation is currently rather limited; most of the technologies being developed are primarily at the experimental stage. The most developed and widely used phytoremediation technique is the use of constructed wetlands for treating wastewater from municipal sewage treatment facilities and industrial processing operations (5).

Wetlands prevent floods, store water for times of drought, and most importantly, clean silt and pollutants from runoff by trapping sediment and contaminants. By doing so, they prevent chemical and sedimentary pollution of rivers, lakes, and coastal waters; hence, environmentalists refer to wetlands as nature's kidneys (6). The physicochemical properties of wetlands provide many positive attributes for remediating contaminants (7). The rhizosphere of wetland vegetation provides an enriched culture zone for microbes involved in degradation (8). Furthermore, sediments or soils in wetlands display reducing conditions, which promotes certain remediation reactions (9). Chemical pollutants are also taken up by wetland plants, where they are accumulated and biotransformed to less toxic and/or immobile states (10) or are volatilized into the atmosphere (11). Plants also supply fixed carbon to sediments, which is an energy source for bacterial transformation of chemical contaminants (12). Constructed wetland ecosystems are typically characterized by carefully selected and induced biophysicochemical properties favorable for chemical, bio- and phytoremediation of contaminants, such as enhanced surface retention, complimentary redox conditions, hyperaccumulating vegetation, and degrading microbial population, and hence, provide conditions that help transform harmful pollutants to less harmful products or essential nutrients that can be used by the biota (13).

Although natural wetlands and terrestrial phytoremediation are traditionally used for removing wastes, phytoremediation using constructed wetlands is becoming more popular due to their efficiency in treating pollutants and cost-effectiveness. This article provides an overview of the types of constructed wetlands, their advantages and disadvantages, the pollution removal mechanisms (with particular emphasis on phytoremediation attributes), and their effectiveness in removing organic pollutants, nutrients, pathogens, and heavy metals.

TYPES OF CONSTRUCTED WETLANDS

A constructed wetland is a designed, man-made complex of saturated substrates, emergent and submerged vegetation, animal life, and water that simulates natural wetlands for human use and benefits (14). Constructed wetlands offer an economical and largely self-maintaining alternative to conventional treatment of water contaminated by a variety of pollutants such as organic chemicals, toxic metals, and nutrients (14).

Wetland systems are typically described in terms of the position of the water surface (15). Accordingly, there are two basic types of constructed wetlands:

- subsurface flow systems
- free-water surface flow systems

Subsurface Flow Systems

A subsurface flow (SF) wetland is specifically designed for treating certain types of wastewater and is typically constructed as a bed or channel containing appropriate media (Fig. 1). Coarse rock, gravel, sand, and other soils have been used, but a gravel medium is most common in the United States and Europe (15). The medium is typically planted with the same types of vegetation present in marshes, and the water surface is designed to remain below the top surface of the medium. The sizes of these systems range from small on-site units designed to treat septic tank effluents from individual homes, schools, apartment complexes, and parks that treat a few hundred gallons of wastewater per day to 1.5×10^7 liters per day systems that treat municipal wastewater (15). There are approximately 100 SF systems in the United States that treat municipal wastewater, the majority of these treat less than 3.8×10^3 m^3/day (15). The most commonly used vegetation in SF wetlands includes cattail (*Typha* sp.), bulrush (*Scirpus* sp.), reed (*Phragmites* sp.), and sedge (*Carex* sp.). The submerged plant roots provide a substrate for microbial processes. Because most emergent macrophytes can transmit oxygen from leaves to roots, there are aerobic areas on the root surfaces. The remainder of the submerged environment in SF wetlands tends to remain devoid of oxygen (17). These systems are very useful in removing biochemical oxygen demand (BOD), total suspended solids (TSS), metals, and organic pollutants.

Free-Water Surface Flow Systems

Free-water systems (FWS) are designed to simulate natural wetlands, such as bogs, swamps, and marshes where water flows over the soil surface at a shallow depth (Fig.1). In FWS wetlands, water flows over a vegetated soil surface from an inlet point to an outlet point. The sizes of FWS wetlands systems range from small on-site units designed to treat septic tank effluents to large units that occupy more than 40,000 acres (15). Similar to SF systems, the most commonly used emergent vegetation includes cattail, bulrush, and reeds (17). The plant canopy formed by the emergent vegetation shades the water

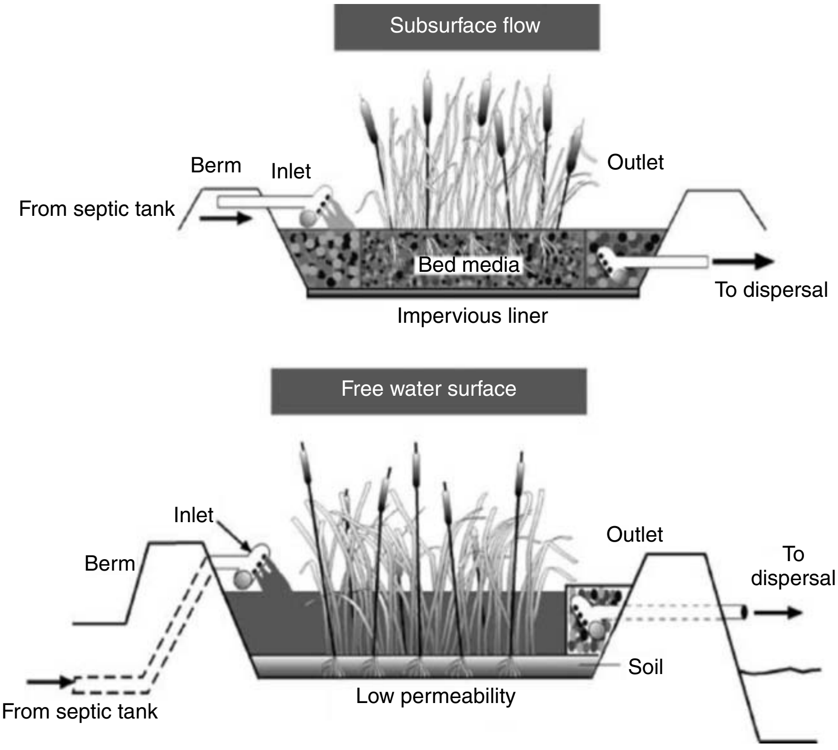


Figure 1. Subsurface flow and free-water systems (16).

surface, prevents the persistence and growth of algae, and reduces wind-induced turbulence in the water flowing through the system (15). Submerged portions of the living plants, the litter accumulated from the previous growth, and the standing dead plants provide a substrate for the microorganisms responsible for biological treatment in the system. Oxygen is available at the water surface and on living surfaces, allowing for aerobic activities. However, the bulk of the activities in the wetland is anaerobic (15). The low velocity and laminar flow of the influent in FWS systems result in very effective removal of TSS that contain BOD components, fixed forms of total nitrogen (TN) and total phosphorus (TP), trace levels of metals, and complex organics. The particulates are either oxidized or reduced and release soluble forms of BOD, TN, and TP, which are either adsorbed by soil/sediment or removed by microbial or plant populations in the wetland (15).

The use of FWS constructed wetlands has increased significantly since the late 1980s. SF wetlands are not now typically selected for larger flow municipal systems. The higher cost of the rock or gravel media makes a large SF wetland uneconomical compared to a FWS wetland despite the smaller area required for a SF wetland (15). Cost comparisons have shown that at flow rates above 60,000 gallons per day, it is usually cheaper to construct a FWS wetland system. However, there are exceptions where public access, mosquito, or wildlife issues justify selecting a SF wetland. Currently, FWS systems are widely distributed in 32 states in the United States (15).

ADVANTAGES AND DISADVANTAGES OF CONSTRUCTED WETLANDS

Constructed wetlands provide various advantages. This widens their appeal among professionals, from engineers and those involved in the workings of wastewater treatment facilities to the environmentalists and people concerned with recreation. Unlike some water issues in which the advantages to one group are disadvantages to another, the effective operation of constructed wetlands can provide broad benefits to a wide range of interests (18). Some of the more obvious benefits are listed here:

- Constructed wetlands are less expensive to build than other treatment options. There is no need for high cost, electromechanical equipment or for high consumption of electrical energy. If properly constructed and maintained, the wetlands provide efficient treatment of wastewaters (6).
- Operating and maintenance expenses (energy and supplies) are low. They require only periodic (rather than continuous) on-site labor (6).
- They are tolerant of fluctuating hydraulic and contaminant loading rates (19).
- They facilitate water recycling and reuse (15).
- Constructed wetlands have great tolerance for varying amounts of wastewater loading. The loading rates can be altered by varying livestock production levels, changing climatic conditions, and changing management (6).
- They can be aesthetically pleasing and may also provide additional benefits such as wildlife habitat, public recreation, environmental education, and groundwater recharge (6).

However, there are certain obvious disadvantages and negative side effects from the operation, maintenance, and effectiveness of constructed wetlands:

- Constructed wetlands require a continuous supply of water and also require water level management to sustain vegetation (6).
- They require more land area than the conventional treatment plants, if advanced treatment is desired (14).
- Surface wetlands attract mosquitoes and may cause other pest problems (14).
- Treatment efficiency may vary based on the effects of season and weather (6).
- High levels of ammonia can destroy vegetation in wetlands (6).
- The long-term effectiveness of constructed wetlands is not well documented. Wetland aging may contribute to a decrease in contaminant removal rates over time.

POLLUTANT REMOVAL MECHANISMS

Pollutant removal processes occur by interaction with wetland vegetation, the water column, and the wetland substrate. The processes may be physical, chemical, or biological (20).

Physical pollutant removal processes in wetland systems occur due to the presence of plant biomass and substrate media. Plants physically retard the pathways of sedimentation; the soil or gravel substrate acts as a filter bed, thereby aiding physical removal of suspended solids by straining (20).

Chemical reactions between inorganic pollutants can lead to their precipitation from the water column as insoluble compounds. Exposure to atmospheric gases and sunlight can lead to the breakdown of certain organic pollutants and destruction of pathogens. Antibiotic chemicals can also play a role in removing pathogens from wastewater (20).

Biological processes play a major role in removing pollutants in constructed wetland systems. Six major biological reactions have been identified as aiding the pollutant removal performance of wetlands, photosynthesis, respiration, fermentation, nitrification, denitrification, and biological phosphorus removal (7). A more detailed discussion of biological mechanisms, particularly in regard to bio- and phytoremediation, is presented in a later section.

As in any other biological wastewater treatment system, wetland process rates depend on various environmental factors, such as temperature, pH, oxygen availability, and hydraulic and pollutant loads (21,22). Under some environmental conditions, process rates may slow down or cease altogether, or even reverse, releasing pollutants. In general, the effectiveness of pollutant removal processes that rely on biological activities may be reduced due to a decrease in metabolic activities caused by low temperature; many metabolic activities are less effective if the pH is either too high or too low (20). Hydraulic overloading occurs when the flow exceeds the design capacity, thus reducing the actual hydraulic retention time. Pollutant overload occurs when the influent pollutant loads exceed the process removal rates; for example, nutrient overloads can cause excess algal bloom leading to eutrophication, and decomposition of excessive organic matter can consume dissolved oxygen resulting in anaerobic conditions (20–22). Nutrient and organic matter overloading may even reverse many pollutant removal processes (20).

PHYTOREMEDIATION ATTRIBUTES OF CONSTRUCTED WETLANDS

Phytoremediation using wetlands is a potentially economical remediation alternative that plays an important role in sustaining and restoring the environment. It has been an important aspect of constructed wetlands, which have been used successfully to detoxify large volumes of wastewater that contain dilute concentrations of contaminants. Pollutants in wastewater are generally removed by plants in a symbiotic association with beneficial soil bacteria (23). For many years, scientists and engineers have observed improvement in the quality of water flowing through natural wetlands. This knowledge is of invaluable importance in designing the most effective constructed wetland systems. However, assessing the phytoremediation potential of constructed wetlands is still a rather complex issue due to variable conditions of hydrology, soil/sediment types, plant species diversity, and seasonal effects on plant growth and water chemistry (24). Williams (7) provides an analytical assessment of the phytoremediation attributes of constructed wetlands, as discussed following.

The physicochemical properties of wetlands provide many positive attributes for remediating contaminants (7). The expansive rhizosphere of wetland herbaceous shrub and tree species provides an enriched culture zone for microbes involved in degrading pollutants (8,25,26). Most wetland soil/sediment zones have strongly reducing conditions (9). Remediation reactions that require reducing conditions are enhanced under the low redox potential of wetland systems (27).

However, anaerobic reducing conditions also decrease the depth to which plant roots penetrate, restricting plant uptake and rhizosphere actions to shallower aquifer levels (7). Zones of wetlands interfacing with flowing water systems can provide conditions for aerobic oxidation-dependent degradation reactions. Redox conditions within rhizospheres can also be altered by oxygen delivery by plant roots (28).

The oxidation states of wetlands are also strongly related to hydrology. The rise and fall of the water table can greatly alter redox zones (7). Soil porosity, percolation rates, and horizontal hydrologic conductivity rates control the rate of oxygen delivery to subsurface layers. Slower vertical and horizontal flow rates with high microbial activity quickly produce reducing conditions. Conversely, more rapid subsurface flows increase oxygen delivery, thereby slowing the decline in redox (7). Plant roots can transport oxygen to the surrounding rhizosphere (28–30) along with plant tissue air spaces connected to belowground biomass (31). Complex interactions among the microbial community, plant species composition, soil/sediment characteristics, and hydrology create a complex set of remediation reactions in wetland ecosystems (7).

Phytoremediation reactions are influenced by seasonal variability of physical and chemical characteristics in response to terrestrial and climatic events (7,32). Plant photosynthesis and standing crop biomass exhibit dramatic seasonal changes in nearly all tidal freshwater vegetation communities (9). Long-term ecological succession can shift plant species composition in the wetlands thereby altering phytoremediation characteristics because phytoremediation by one wetland community may not be the same as that which the new successional plant community develops (7). Hence, successful long-term phytoremediation must carefully consider the management implications of secondary successions to avoid ecological shifts away from optimal plant community structure (33).

Given all the factors that can influence the effectiveness of a wetland system and keeping in mind that specific requirements vary depending on the functional role of wetland plants in the treatment systems, broad generalizations can still be made about the characteristics of plant species that are most suitable for constructed wetland wastewater treatment systems (34):

- ecological acceptability, that is, no significant weed or disease risks or danger to the ecological or genetic integrity of surrounding natural ecosystems;
- tolerance to local climatic conditions, pests, and diseases;
- tolerance of pollutants and hypertrophic waterlogged conditions;
- ready propagation and rapid establishment, spread, and growth;
- high pollutant removal capacity, either through direct assimilation or storage, or indirectly by enhancing microbial transformations.

Cattails (*Typha* sp.), bulrushes (*Scirpus* sp.), reeds (*Phragmites* sp.), and sedges (*Carex* sp.) generally meet these requirements and hence, are the typical macrophytes (rooted plants that anchor to the substrate) of choice in the majority of constructed wetland systems, including both subsurface flow and freshwater surface flow types (20).

EFFECTIVENESS OF PHYTOREMEDIATION IN WETLANDS

Constructed wetlands can remove a range of pollutants, including biodegradable organic substances, metals, and nutrients. Natural wetlands have lower efficiency in removing pollutants than constructed wetlands (10). The growth and adaptation of plants to anoxic conditions in wetland sediments drives many of the biological and chemical processes to transform the pollutants to a variety of forms that differ in mobility and toxicity (12). For example, the activity of plant roots alters the surrounding conditions in the sediment, enhancing the rate of transformation and fixation of metals (35).

The following section, derived primarily from Williams (7) and Sundaravadivel and Vigneswaran (20), presents a review of the performance of both constructed and natural wetlands in regard to phytoremediation of the aforementioned three major classes of chemical pollutants.

Removal of Organics

Organic contaminants, such as trichloroethylene (TCE) and pesticides, have been remediated effectively by a variety of phytoremediation actions of terrestrial and wetlands species (7). Cunningham et al. (36) identified the following phytoremediation actions for successfully removing organic contaminants: accumulation into biomass, phytovolatilization, cellular degradation, and rhizosphere degradation. Hybrid poplars have had increasing success in phytoremediating TCE (37) and other volatile organic compounds (VOCs). Several VOCs, including TCE, were removed from surficial groundwater and subsequently degraded by poplar (*Populus deltoids* x *trichlocarpa*) test plots near toxic disposal sites in Maryland (38). Nietch et al. (39) experimented with bald cypress (*Taxodium distichum*) to remediate TCE and found that the TCE flux through bald cypress into surrounding air space decreased from day to night and from August to December. Much of this flux was controlled by evapotranspirational seasonality.

Nzengung et al. (40) summarized phytoremediation research on halogenated organic chemicals (HOC) by *Elodea candensis, Myriophyllum aquaticum, Salix nigra*, and *Populus deltoides* and identified four major phytoremediation processes: (1) rapid sequestration by partitioning to lipophilic plant cuticles; (2) phytoreduction to less halogenated metabolites; (3) phytooxidation to haloethanols, haloacetic acids, and unidentified metabolites; and (4) assimilation into plant tissues as nonphytotoxic products. Additional types of VOC, semivolatile, and nonvolatile compounds were evaluated for their phytoremediation potential by hybrid poplar (41). Burken and Schnoor (41), developed the transpiration stream concentration factor (TSCF) and the root concentration factor (RCF) for 12 such compounds, including aniline, phenol, nitrobenzene, benzene, atrazine, and toluene. Newman et al. (42) reported phytoremediation via reductive dechlorination by *Populous trichocarpa* and emphasized the ecological concern of selecting a phytoremediating species that grows well in the local habitat, while not ecologically destabilizing existing communities. In another study, Ensley (43) reported that duckweed (*Lemna gibba*) reductively dechlorinates chlorinated phenols.

Removal of Metals

Wetland sediments are generally considered a sink for metals and, in the anoxic zone, may contain very high concentrations of metals in a reduced state (44). As such, the bioavailability of metals in wetlands is low compared to that in terrestrial systems with oxidized soils. Water-soluble and exchangeable metals are most bioavailable, metals precipitated as inorganic compounds or metals complexed by humic substances or metals adsorbed onto hydrous oxides are potentially bioavailable, and metals precipitated as insoluble sulfides and metals bound to the crystal lattice of minerals are essentially unavailable (45). Because of reducing conditions, the depth of wetlands to which plants can penetrate is limited, and this restricts the uptake of contaminants and rhizosphere actions to shallower levels (7).

Understanding the role of phytoremediation in metal removal from wetlands has progressed over the years from basic uptake studies to quantification of chemical speciation and bioavailability and the role of genetic engineering in metal hyperaccumulation (46–50). In New Zealand, submerged, rooted aquatic species, such as *Ceratophyllum demersum*, were hyperaccumulators of arsenic (CF or concentration factor of 20,000) compared to cattail, *Typha orientalis* (CF of 100), a popular wetland plant species (46). Water hyacinths (*Eichhornia crassipes*), well known for their use in wastewater treatment, have also been found effective in accumulating heavy metals and in the uptake of pesticide residues, PCB, DDE, DDD, and DDT (47,51). Apparently, water hyacinths carried out phytoremediation by root sorption, concentration, and/or metabolic degradation (47). Duckweed (*Lemna minor*) and water velvet (*Azolla pinnata*) both effectively removed iron and copper at low concentrations; however, water velvet does not grow from May to October, and such production seasonality translates to a limited phytoremediation interval (52).
