COMBINED SEWER OVERFLOW TREATMENT

C.A. Prochaska
A.I. Zouboulis
Aristotle University of Thessaloniki
Thessaloniki, Greece

INTRODUCTION

Combined sewer overflows (denoted hereafter as CSOs) occur when flows exceed the hydraulic capacity of either the wastewater treatment plant (denoted as WWTP) or the collection system that transports the combined flow of storm water and sanitary sewage to the WWTP. The principal components of a combined sewer system include (1) the contributing drainage area (catchment) and wastewater sources, (2) the combined sewer pipe network and interceptor(s), (3) the regulator and diversion structures, and (4) the CSO outlets (Fig. 1).

When an overflow occurs, the excess flows tend to be discharged into the neighboring receiving body of surface water. CSOs typically discharge a variable mixture of raw sewage, industrial/commercial wastewater, polluted runoff, and scoured materials that build up in the collection system during dry weather. These discharges contain a variety of pollutants that may adversely impact the receiving waterbody, including pathogenic microorganisms, viruses, cysts, and chemical and floatable materials. Health risks associated with bacteria-laden water may result from dermal contact with the discharge, from ingestion of contaminated water, as well as from consumption of fish or shellfish.

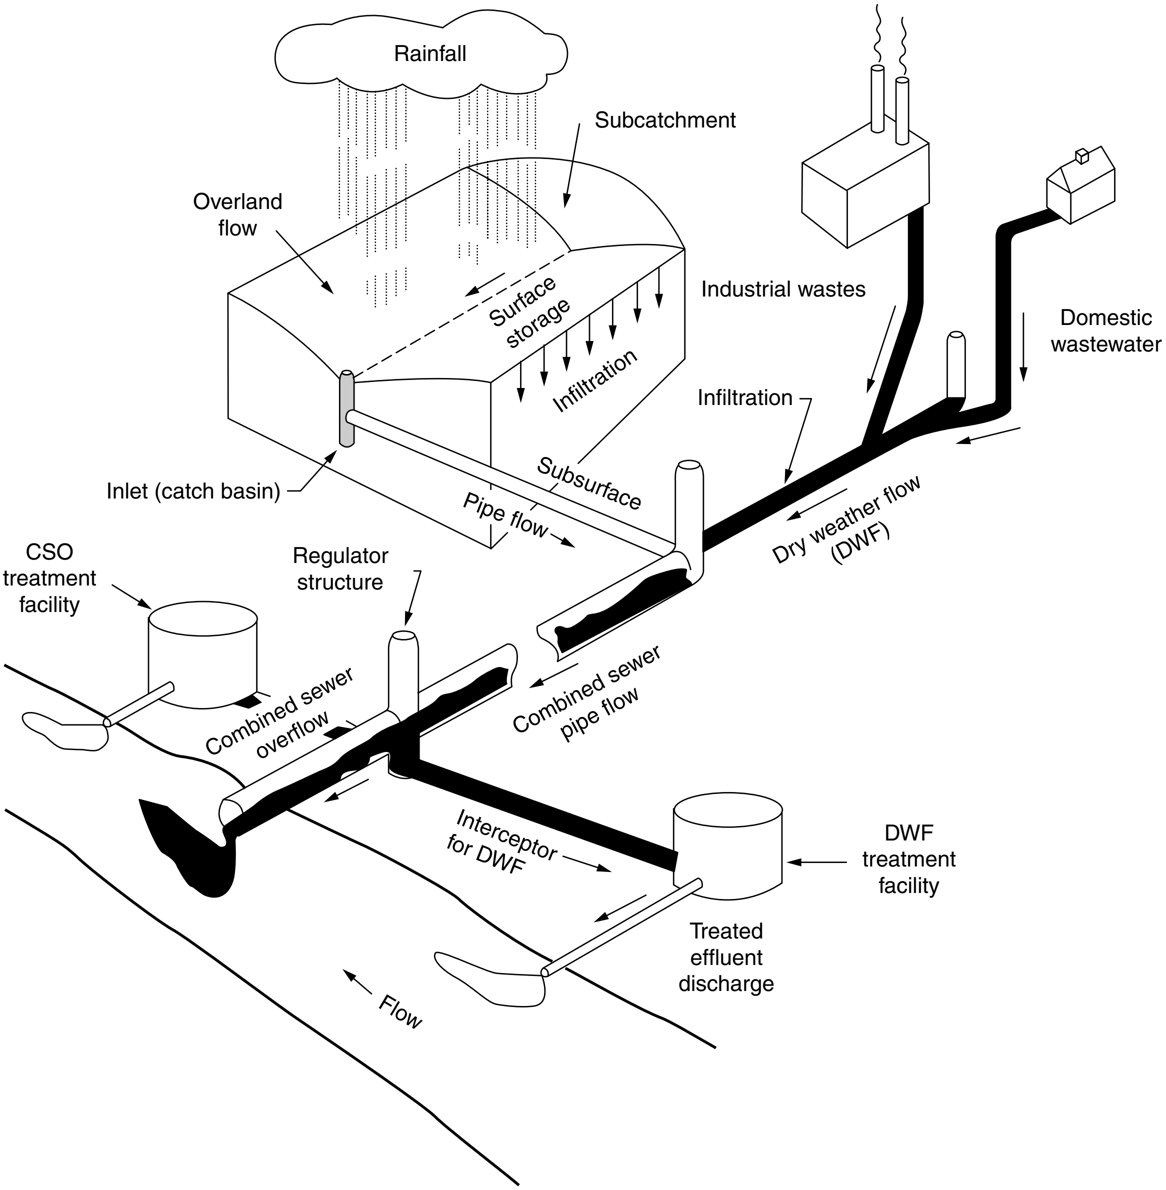

Figure 1. Schematic diagram of a combined sewer system (2).

The methods used to treat CSOs can be classified as physical, chemical, and biological and methods that include a combination of some or all the above, such as treatment by constructed reed beds (1).

PHYSICAL TREATMENT

Physical treatment alternatives include sewer separation, retention basins, swirl/vortex technologies, screening, netting systems for floatable control, dissolved air flotation, and filtration. Most of these physical unit operations have been in use for many years and are considered reliable. Physical treatment operations are usually flexible enough to be readily automated and can operate over a wide range of flows. They can also stand idle for long periods of time without affecting treatment efficiency (1).

Sewer Separation

Separation is conversion of a combined sewer system into separate storm water and sanitary sewage collection systems. This alternative, historically considered the ultimate answer to CSO pollution control, has been reconsidered in recent years because of increased cost and major disruptions to traffic and other daily community activities from separated collection systems. Several potential benefits of sewer separation might warrant its consideration in specific cases:

1. Eliminating CSOs and preventing untreated sanitary sewage from entering the receiving waters during wet weather. Sanitary sewage is a more objectionable source of certain pollutants, such as TSS, sanitary floatables, and bacteria.
2. Reduced volume of flow to be treated at the publicly owned treatment works (POTWs), thus reducing operating and maintenance (O & M) costs by eliminating surface runoff inflows during wet weather.
3. Reduced infiltration and excess flow to a POTW for new sanitary sewer construction, replacing old combined sewers.
4. Reducing upstream flooding, as well as overflows, when the existing combined sewers are undersized and back up frequently during storms.
5. Being more effective and economical than treatment facilities for remote segments of a combined sewer system, serving relatively small areas.

Retention Basins

CSO retention basins (RBs) capture and store some of the excess combined sewer flow that would otherwise be bypassed to receiving waters. Stored flows are subsequently returned to the sewer system during dry weather, when the in-line flows are reduced and more capacity is available at the treatment facility. RBs can be designed to control both flow rate and water quality.

Figure 2 shows an example of a multistage CSO RB that has some treatment capabilities. This facility handles peak flows by routing them through a mechanical bar screen and then pumping them into the first compartment. The main function of the first compartment is to allow primary settling and grit removal. If the flows continue to rise, the

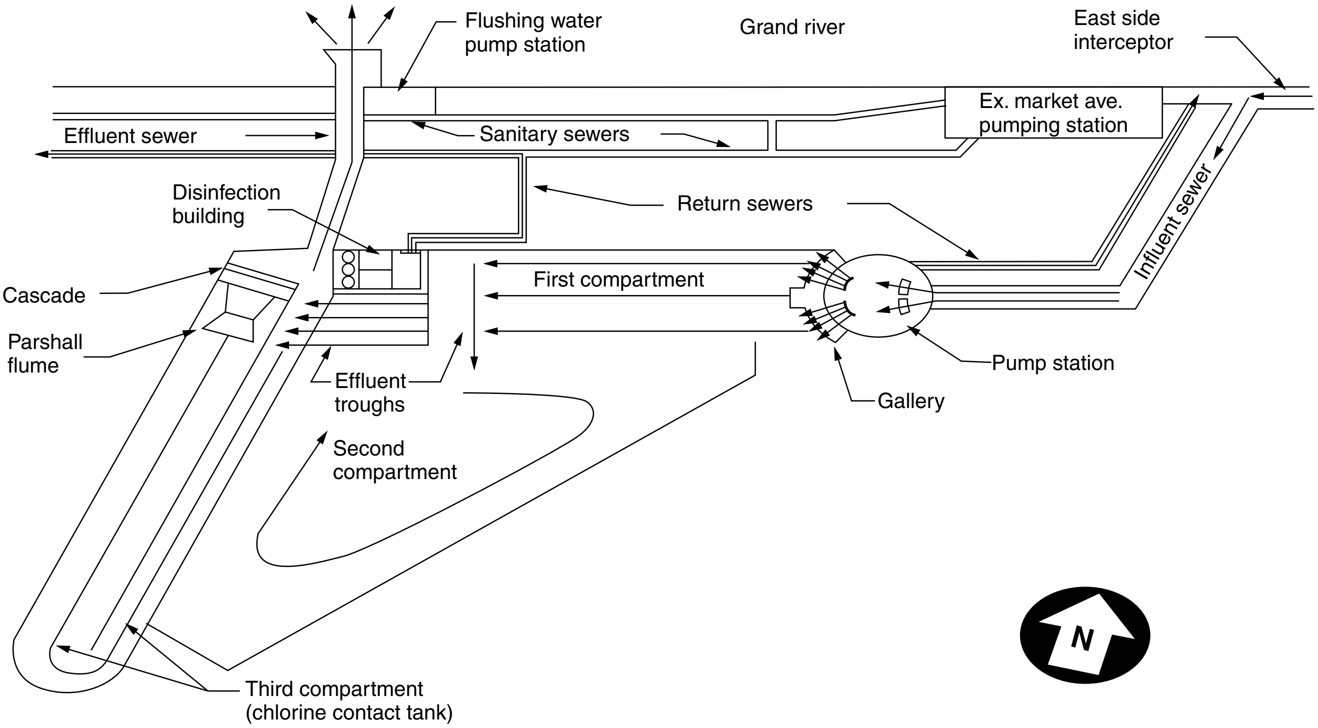

Figure 2. Multistage CSOs RBs (3).

first compartment fills and then spills over into the second compartment. This compartment is designed specifically to store most of the overflow from the first compartment. The second compartment is also equipped with a floor wash system that flushes all settled sediments into a collection trough. If the flows continue to rise, the water spills over into a series of troughs, where sodium hypochlorite is applied for disinfection. The flow is then routed to a contact tank (third compartment), which eventually returns the water to the nearby surface waters (2).

These are the primary concerns in the operation of RBs:

1. Managing flows to and from the retention basin.
2. Preventing the combined sewage from becoming septic or handling the wastewater appropriately after it has become septic.
3. Removing accumulated solids and floatables.
4. Disinfecting basin overflows to receiving waters.

Swirl/Vortex Technologies

Solids separation devices, such as swirl concentrators and vortex separators, have been used in Europe and (to a lesser extent) in the United States. These devices are relatively small, compact solids separation units with no moving parts. A typical vortex-type CSO solids separation unit is illustrated in Fig. 3. During wet weather, the outflow from the unit is throttled, causing the unit to fill and to self-include a swirling vortex-like flow regime. Secondary flow currents rapidly separate settleable grit, as well as floatable matter. The concentrated foul matter is intercepted for treatment, whereas the cleaner, treated flow can be discharged to receiving surface waters. These devices are usually intended to operate under very high hydraulic flow regimes.

Screening

Generally, there are two types of bar screens, coarse and fine. Both are used at CSOs control facilities; with each type provides a different level of solids removal efficiency. Although there is no industrial standard for classifying screens based on aperture size, coarse bar screens generally have a 0.04 to 0.08 m clear spacing between bars, whereas fine screens generally have rounded or slotted openings of 0.3 to 1.3 cm clear space.

Coarse Screens. Coarse screens are constructed of parallel vertical bars and are often referred to as *bar racks* or *bar screens*. In CSO control and treatment facilities, coarse screens are usually the first unit of equipment in the system. These screens are usually set at 0 to 30° from the vertical and are cleaned by an electrically or hydraulically driven rake mechanism that removes the collected material from the screen continuously or

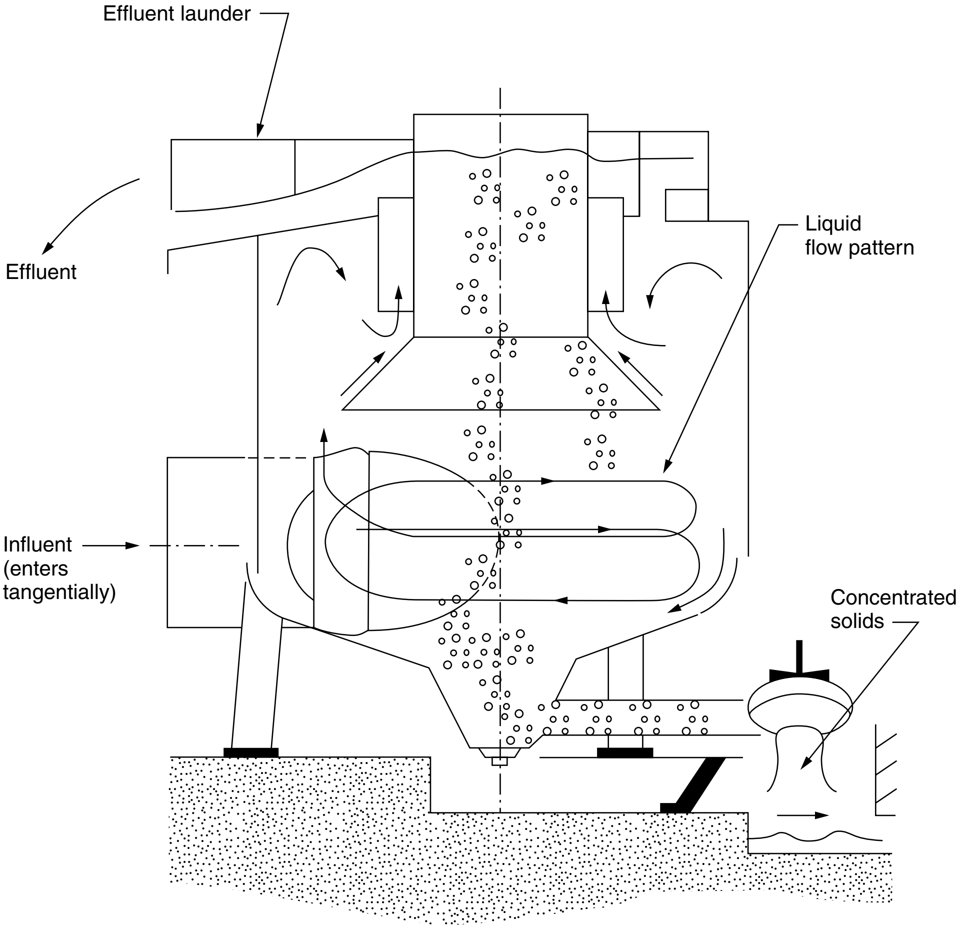

Figure 3. Cross section through a typical vortex-type solids separation device (1).

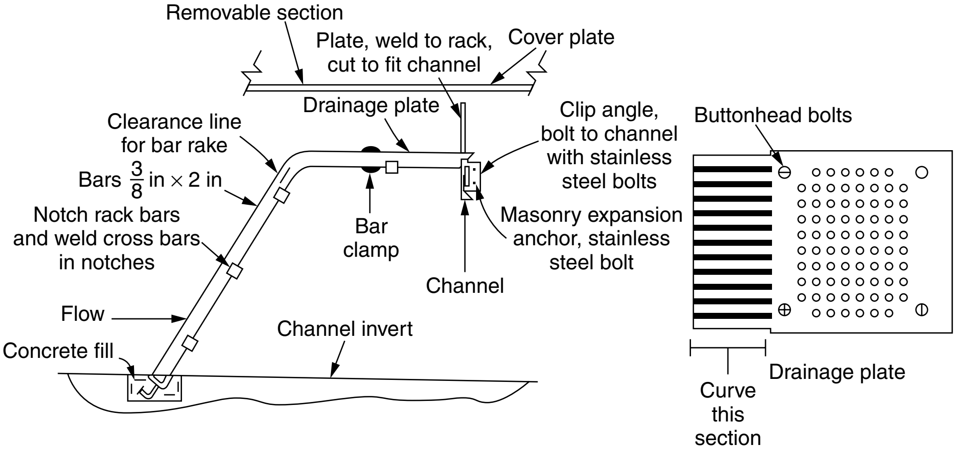

Figure 4. Diagram of trash rack used for treating CSOs (2).

periodically. The most common type of bar screen used at CSO control facilities is a trash rack. Trash racks typically have 0.04 to 0.08 m clear spacing between bars. Figure 4 is a diagram of a typical trash rack.

Fine Screens. Fine screens at CSO facilities typically follow coarse bar screening equipment and provide the next level of physical treatment in removing the smaller solid particles from the waste stream. Both fixed (static) and rotary screens have been used in CSO treatment facilities.

Fixed fine screens are typically provided with horizontal or rounded slotted openings of 0.02 to 1.27 cm. The screens are usually constructed of stainless steel in a concave configuration, at a slope of approximately 30° from the vertical. Flow is discharged across the top of the screen. The flow then passes through the slotted openings, and solids are retained on the screen surface. Solids are discharged from the screen surface by gravity and by washing onto a conveyor belt or other collecting system.

Rotary fine screens include externally and internally fed screens. Externally fed screens allow the wastewater to flow over the top of the drum mechanism and through the screens surfaces, while collecting solids onto the screen surface. As the screen rotates, a system of cleaning brushes or sprayed water removes debris from the drum. Internally fed systems discharge wastewater in the center of the drum, allowing the water to pass through the screen into a discharge channel, while solids are removed from the screen surface by cleaning brushes or a water spray.

In response to the need for solids and floatables control during storms, proprietary screen products, such as the ROMAG^{TM} screen, have been designed for wet weather applications (Fig. 5). The ROMAG^{TM} screen partitions the flow, sending screened flow to the CSO discharge point, while keeping solids and floatables in the flow directed toward the sanitary sewer. This screen works as follows: excess flow enters the screening chamber, flows over a spill weir, and proceeds through the screen into a channel, which discharges flow to a neighboring receiving waterbody. Floatables trapped by the screen move laterally along the face of the screen via combs/separators to the transverse end section of the pipe, where they can be directed to the sanitary sewer line for ultimate removal at the wastewater treatment plant. Screen blinding is prevented by a hydraulically driven rake assembly.

Netting Systems for Floatables Control

Floatables control technologies are designed to reduce or eliminate the visible solid waste that is often present in CSO discharges. The Netting Trash-Trap^{TM} system is a modular floatables collection system, located at the CSO outfall. It uses the passive energy of the effluent stream to drive the floatable materials into disposable mesh bags. These bags are suspended horizontally in the CSO flow stream within a support structure. The construction methodology and method of installation at the outfall are determined site-by-site. Ever since, several other end-of-pipe, but also in-line configurations have been developed and implemented.

The standard nets used in the system are designed to hold up to 0.7 m^3 of floatables and a weight of 227 kg each. For the floating units, the effluent stream and the collected floatables are directed into the bags by two floating booms and curtains, which run from the front corners of the pontoon to either side of the outfall, where they attach to a vertical piling that has a roller

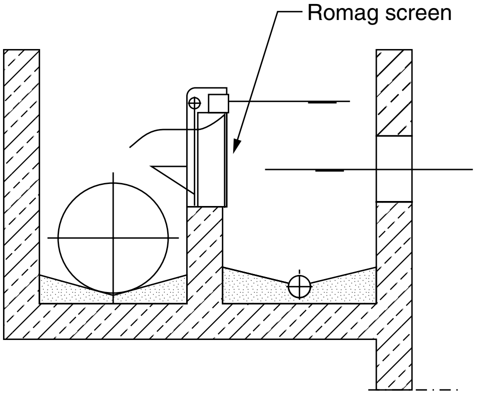

Figure 5. ROMAG^{TM} "combing" mechanical screen (vertical) for CSO floatables control (4).

mechanism or a shoreline support. This design allows the boom to float and accommodate changes in the water level. The extended curtains are weighted to conform to the water bottom. The maximum high water level, expected at the site, determines the depth of the curtain. Certain modifications of the outfall design may include adding structural support, attaching structural struts and strut anchor support, and adding foundations.

Dissolved Air Flotation

Dissolved air flotation (DAF) removes solids by introducing fine air bubbles into the CSO stream. The air bubbles can attach to solid particles suspended in the liquid, causing the solids to float toward the surface, from where they can be skimmed off. This technology has been tested in several CSO applications. A major advantage of DAF is its relatively high overflow rate and short detention time, which results in reduced facility size, compared to conventional sedimentation. Oil and grease are also more readily removed by DAF. Operating costs for DAF are high, due to larger energy demand, and skilled operators are usually required for efficient operation.

Filtration

Dual media high rate filtration has been piloted for treating of CSO flows. A two-layer bed, consisting of coarse anthracite particles on top of less coarse sand, was used. After backwash, the less dense anthracite remains on top of the sand. Filtration rates of 16 gal/ft^2/min or more were used, resulting in substantially smaller space requirements, compared with sedimentation. Demonstration test systems included pretreatment by fine-mesh screens. The addition of chemical coagulant agents improved the performance considerably. Filtration is more appropriately applied after pretreatment by fine screening. Operation may be automated but tends to be rather O & M intensive. Intermittently operated sand filters can also be used for CSO treatment and show considerable promise for larger scale operations (3).

CHEMICAL TREATMENT (MAINLY DISINFECTION)

Chlorine

Chlorine has long been the disinfectant of choice for most disinfection systems. It offers reliable reduction of pathogenic microorganisms at reasonable operating costs. Disinfection by chlorine is the most common method used to kill pathogenic microorganisms at WWTPs, but this methodology may not be feasible at all CSOs for several reasons:

1. CSOs occur intermittently, and their flow rate is highly variable, thus making it difficult to regulate the addition of disinfectant.
2. CSOs have high concentrations of suspended solids.
3. CSOs can vary widely in temperature and bacterial composition.
4. Disinfectant residuals, following the use of chlorine, may be prohibited from entering receiving waters.
5. CSO outfalls are often located in remote areas and thus, may require automated controls for the disinfection systems.

In addition to these problems, increased health and safety concerns for using chlorine to disinfect CSOs have prompted the development of alternative disinfectant agents/methods, which often present fewer problems and health hazards. Alternative methods to chlorine addition have been developed and evaluated for the continuously disinfecting wastewater discharges to small streams or sensitive waterbodies and are now also being considered for treating CSOs and other episodic discharges. These include the use of chlorine dioxide, the application of ozonation or of ultraviolet radiation, the addition of peracetic acid, and electron beam irradiation (e-beam) (5).

Ozone

Ozone is a strong oxidizer and is applied to wastewater as a gas mixture with air. Its use in CSO treatment facilities for wastewater disinfection is relatively new; few facilities are currently using ozone for disinfection. This can be attributed to the higher initial capital costs of ozone generating equipment. Ozone is equal or superior to chlorine in “killing” power for pathogenic microorganisms, but it does not cause the formation of harmful by-products (halogentated organics), as does chlorination (5).

Ultraviolet Radiation

UV radiation is electromagnetic radiation used for disinfection. UV disinfection incorporates the spectrum of light between 40 and 400 nm. Germicidal properties range between 200 and 300 nm; 260 nm is the most lethal. The primary method for using UV disinfection is to expose wastewater to a UV lamp. UV radiation is not a chemical disinfection method; it avoids the addition of chemical reagents, and it disinfects without altering the physical or chemical properties of water. However, UV efficiency is affected by the presence of suspended solids in the CSOs, which scatter and absorb light and lower the method’s efficiency. Thus, UV disinfection is not very effective for CSOs that containing high TSS (5).

Peracetic Acid

Peracetic acid (CH_3COOOH, denoted PAA), also known as ethaneperoxoic acid, peroxyacetic acid, or acetyl hydroxide, is a very strong oxidant. Based on limited demonstration data for disinfecting secondary treatment plant effluents, peracetic acid appears to be an effective disinfectant and should be further evaluated for treating CSOs. The equilibrium mixture of hydrogen peroxide and acetic acid that produces PAA is too unstable and explosive to transport; therefore, PAA must be produced on site. The decomposition of PAA results in the formation of acetic acid, hydrogen peroxide, and oxygen (5).

Electron Beam Irradiation

Electron beam irradiation (e-beam) uses a stream of high energy electrons that is directed into a thin film of water or sludge. The electrons break water molecules apart and produce a large number of highly reactive chemical species (mainly radicals), including oxidizing hydroxyl radicals, reducing aqueous electrons, and hydrogen atoms. These are the main disadvantages of this method:

1. Increased safety considerations due to the use of high-voltage technology and the generation of X-ray radiation.
2. There is no full-scale application experience for CSOs.
3. High capital costs.
4. High O & M costs.
5. Thin process flow stream.
6. Sufficient pretreatment straining of influent is also required to remove most of suspended solids for efficient application of this system (5).

BIOLOGICAL TREATMENT AND COMBINED SYSTEMS

The use of biological treatment, combined with certain of the aforementioned physical–chemical treatment processes, for treating CSO presents certain serious limitations:

1. The biomass used to assimilate the nutrients in the CSOs must also be kept alive during dry weather, which can be rather difficult, except at an existing treatment plant.
2. Biological processes are subject to upset under to erratic loading conditions.
3. The land requirements for this type of treatment plant can be excessive near an urban area.
4. Operation and maintenance can be costly, and the facilities require highly skilled operators.

Some biological treatment technologies are used in CSO control as elementary parts of a WWTP. Pump-back or bleed-back flows from CSO storage facilities commonly receive secondary (biological) treatment in the treatment plant, once wet weather flows have subsided. In a WWTP, which has maximized the wet weather flows that are accepted, the hydraulic flows are sometimes split; only a portion of the primary treated flows is subjected to secondary treatment to avoid process upset. The split flows are blended again before the exit and disinfected appropriately for final discharge (1).

Constructed Wetlands

Constructed wetlands are artificial wastewater treatment systems, consisting of shallow (usually 1 m deep) beds, that have been planted with aquatic plants, and which rely upon natural microbial, biological, physical, and chemical processes to treat CSOs. They typically have impervious clay or synthetic liners and engineered structures to control the flow direction, liquid detention time, and water level. Depending on the specific type of system, they may contain inert porous media, such as rock, gravel, or sand. Constructed wetlands have been classified in the literature into two types.

Free water surface (FWS) wetlands (also known as surface flow wetlands) closely resemble natural wetlands in appearance; they contain aquatic plants, and water flows through the leaves and stems of the plants. Vegetated submerged bed (VSB) systems (also known as subsurface flow wetlands) do not resemble natural wetlands because they have no standing water. Wastewater (i.e., CSOs) stays beneath the surface of the medium, flows in contact with the roots and rhizomes of the plants, and is not visible or available to wildlife. Finally, the term vertical flow wetland is used to describe a typical vertical-flow sand or gravel filter, which has been planted with aquatic plants. Successful operation of this type of system depends mainly on its operation as a filter (i.e., frequently applying dosing and draining cycles) (7).

Figure 6 shows a typical cross section of a horizontal subsurface flow wetland (also known as a reed bed). These systems are used to treat the excess combined sewer flow that would otherwise be bypassed to receiving waters, with good treatment efficiency that meets the tight permitting conditions. During exceptionally dry weather, secondary or tertiary treated effluent can be diverted to this system to conserve the plantings and the microorganism's population in the system (6).

BIOLOGICAL PHOSPHORUS REMOVAL IN THE ACTIVATED SLUDGE PROCESS

Michael H. Gerardi
Linden, Pennsylvania

Phosphorus often is the limiting nutrient that promotes the excessive growth of aquatic plants, especially algae, and excess quantities of phosphorus often are present in the effluent of activated sludge processes in quantities greater than those required for the growth of aquatic plants. Excess phosphorus promotes not only the undesired growth of aquatic plants but also the undesired impacts of the death of the aquatic plants upon the receiving water. Therefore, state and federal regulatory agencies limit the quantity of phosphorus in the effluent. The requirement limiting the quantity of phosphorus in the effluent of activated sludge processes is becoming more and more stringent for municipal wastewater treatment plants. For example, discharge limits for total phosphorus of 2 mg/L or lower have been applied broadly to many plants in the lower Susquehanna River Basin.

Several environmental concerns related to the excessive growth of aquatic plants include clogging of receiving waters and the production of color, odor, taste, and turbidity problems when the receiving waters are used for potable water supplies. The die-off of large numbers of aquatic plants results in oxygen depletion when the plants decompose. Those portions of the aquatic plants that do not decompose accumulate in the receiving waters and contribute to eutrophication or rapid aging of the receiving waters. Additionally, some algae release toxic compounds.

Municipal wastewater contains 10–20 mg/L of total phosphorus. The total phosphorus consists of inorganic and organic phosphorus. Inorganic phosphorus consists of phosphorus-containing compounds that do not contain carbon and hydrogen. Organic phosphorus-containing compounds do contain carbon and hydrogen. Significant and common inorganic phosphorus-containing compounds are orthophosphate (PO_4-P) and polyphosphates. Orthophosphate makes up approximately 50–70% of the total phosphorus in influent and approximately 90% of the phosphorus in the effluent of municipal wastewater treatment plants.

Orthophosphate is the preferred phosphorus nutrient for aquatic plants. The forms of orthophosphate found in the influent and effluent of wastewater treatment plants are pH dependent. At pH values <7 the $H_2PO_4{}^-$ form is dominant, whereas the $HPO_4{}^{2-}$ form is dominant at pH values >7. The forms of orthophosphate in the influent and effluent are produced through dissociation (Eq. 1).

$$H_2PO_4{}^- \rightleftharpoons HPO_4{}^{2-} + H^+ \tag{1}$$

Significant and common organic phosphorus-containing compounds include phytin, nucleic acids, and phospholipids. Phytin is an organic acid found in vegetables such as corn and soybean. Phytin is difficult to digest and is found in domestic wastewater. Nucleic acids are large complex molecules that contain genetic material. Phospholipids also are large and complex molecules that are used in the production of structural materials. Phytin, nucleic acids, and phospholipids degrade slowly in the activated sludge process. Their degradation results in the release of orthophosphate. It is the orthophosphate that is used as the phosphorus nutrient by bacteria and incorporated into cellular material or MLSS (mixed liquor suspended solids) in the activated sludge process.

The degradation of organic compounds in activated sludge processes and the incorporation of phosphorus into new cellular material are achieved by a large and diverse population of bacteria. However, there are some bacteria that are capable of removing and storing phosphorus in quantities larger then their cellular needs. Bacteria that are capable of removing phosphorus in excess quantities are known as "phosphorus-accumulating organisms" (PAO) or "poly-P bacteria" (Table 1). Of all poly-P bacteria, *Acinobacter* is the most commonly known and studied. Phosphorus is removed from the wastewater in the orthophosphate form and stored by the poly-P bacteria as polyphosphate granules. Removal of phosphorus by poly-P bacteria often is termed "luxury uptake of phosphorus."

There are several operational measures that can be used in activated sludge processes to remove phosphorus

Table 1. Genera of Wastewater Bacteria that Contain Poly-P Species

Acinobacter	*Escherichia*
Aerobacter	*Klebsiella*
Aeromonas	*Moraxella*
Arthrobacter	*Mycobacterium*
Beggiatoa	*Pasteurella*
Enterobacter	*Pseudomonas*

Table 2. Biological and Chemical Measures Available for Phosphorus Removal

Operational Measure	Description
Chemical precipitation	Use of alum, ferric chloride, ferrous sulfate, or lime at a high pH; results in increased operational costs for chemical addition and disposal of chemical sludge
Assimilation	Phosphorus incorporated into cellular material (MLSS) as 1–3% dry weight and wasted from the activated sludge process
Biological phosphorus removal	Phosphorus incorporated into cellular material (MLSS), especially poly-P bacteria, as 6–7% dry weight and wasted from the activated sludge process
Biological/chemical techniques	Precipitation of phosphorus released by poly-P bacteria under anaerobic condition and chemically precipitated with alum, ferric chloride, ferrous sulfate, or lime

from the effluent. These measures include biological and chemical techniques (Table 2). Phosphorus as orthophosphate can be removed from wastewater through its chemical precipitation as a metal salt at a high pH. Chemical compounds commonly used to precipitate orthophosphate include alum, ferric chloride, ferrous sulfate, and lime. Orthophosphate also can be removed through its incorporation as cellular material. By increasing the MLSS, more orthophosphate is incorporated into bacterial cells. However, the amount of phosphorus in the bacterial cells is only 1–3% by dry weight. Orthophosphate also can be removed by combined biological and chemical techniques and through biological phosphorus removal.

Of the biological and chemical measures available for phosphorus removal, biological phosphorus removal offers several advantages when compared to other measures. For example, biological phosphorus removal is relatively inexpensive due to the reduction in chemical costs and sludge disposal costs associated with chemical addition to precipitate orthophosphate. Biological phosphorus removal is also capable of removing phosphorus to low effluent concentrations.

Biological phosphorus removal or luxury uptake of phosphorus occurs when orthophosphate uptake by poly-P bacteria exceeds cellular requirements. If luxury uptake of phosphorus does not occur in an activated sludge process, the phosphorus content of the activated sludge is approximately 1–3% on a dry weight basis. If luxury uptake of phosphorus does occur, the phosphorus content of activated sludge is approximately 6–7%.

Bacteria that are capable of luxury uptake of phosphorus enter activated sludge processes in fecal waste and through inflow and infiltration as soil and water bacteria. These bacteria are unique and remove phosphorus in excess of cellular needs in the presence of rapidly degradable organic compounds when transferred from an anaerobic (fermentative) tank to an aerobic tank.

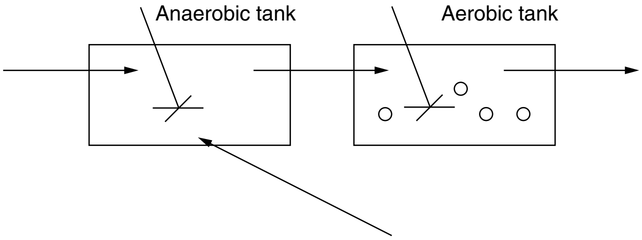

Figure 1. Microbial activity in the anaerobic tank. In the anaerobic tank, soluble cBOD is fermented in the absence of free molecular oxygen and nitrate ions. The fermentation process produces a variety of fatty acids. The acids are rapidly absorbed by the poly-P bacteria and stored as an insoluble starch (PHB). In order to absorb the fatty acids and store them as starch, energy in the form of orthophosphate is released by the poly-P bacteria to the bulk solution.

Table 3. Soluble Fatty Acids Produced in the Anaerobic Tank

Fatty Acid	Formula
Formic acid	HCOOH
Acetic acid	CH_3COOH
Propionic acid	CH_3CH_2COOH
Butyric acid	$CH_3CH_2CH_2COOH$
Valeric acid	$CH_3CH_2CH_2CH_2COOH$
Caproic acid	$CH_3CH_2CH_2CH_2CH_2COOH$

In the anaerobic tank (Fig. 1) that has a retention time of 1–2 h, fatty acids are produced in large quantities through fermentation (Table 3). Fermentation is the microbial degradation of organic compounds without the use of free molecular oxygen (O_2) or nitrate ions ($NO_3{}^-$). Poly-P bacteria quickly absorb the fatty acids produced through fermentation. Although the fatty acids are absorbed, the acids are not degraded. Instead, the soluble fatty acids are stored in the form of insoluble starch granules (poly-β-hydroxybutyrate or PHB).

The conversion of fatty acids to insoluble starch granules and the storage of the granules requires the expenditure of energy by the poly-P bacteria. The expenditure of energy results in a release of orthophosphate from the poly-P bacteria into the fermentative tank. With the production of PHB in the poly-P bacteria, the fermentative tank contains two "pools" of phosphorus—influent phosphorus and poly-P bacteria released orthophosphate.

In the aerobic tank (Fig. 2) that has a retention time of 1–2 h, PHB granules are solubilized and degraded with the use of free molecular oxygen. The degradation of PHB granules results in the release of a large quantity of energy that is captured and stored by the poly-P bacteria. The energy is stored in the bacteria in the form of insoluble phosphate granules or voluntin. Phosphorus is removed from the activated sludge process when MLSS (bacteria) is wasted.

There are several processes available for the biological removal of phosphorus. Often biological phosphorus removal is combined with nitrification and denitrification. Nitrification is the oxidation of ammonium ions ($NH_4{}^+$) to nitrate ions ($NO_3{}^-$), while denitrification is the reduction

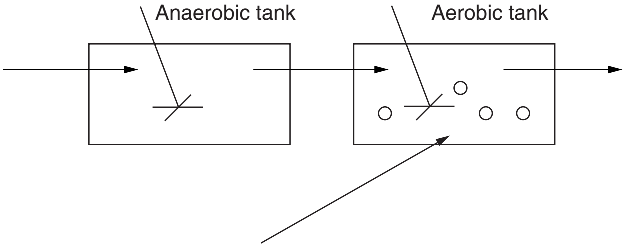

Figure 2. Microbial activity in the aerobic tank. In the aerobic tank, PHB is solubilized and degraded in the presence of free molecular oxygen. The degradation of PHB results in the production of carbon dioxide, water, and new bacterial cells. Phosphorus released in the anaerobic tank as well as phosphorus present in the waste stream are absorbed by poly-P bacteria and stored in phosphorus granules.

of nitrate ions to molecular nitrogen (N_2) and nitrous oxide (N_2O). Nitrification and denitrification are responsible for the biological removal of nitrogen from wastewater. When nitrification and denitrification are combined with biological phosphorus removal, these three biological processes are known as biological nutrient removal (BNR). There are five significant processes used for biological phosphorus removal or BNR. Several of these processes are proprietary. These processes are the A/O, Phostrip, A2O, Bardenpho, and UCT.

Biological nutrient removal processes are either mainstream or sidestream (Table 4). A mainstream process contains an anaerobic tank within the major wastewater flow from influent to effluent. A sidestream process contains an anaerobic tank outside the major wastewater flow.

Of the nutrient removal processes, two are designed to remove phosphorus only. These processes are the A/O and the Phostrip. The A/O (anaerobic/oxic) process is a mainstream process (Fig. 3). The A/O process is patented by Air Products and Chemicals, Incorporated and is similar to a conventional activated sludge process.

The Phostrip process is a sidestream process and includes biological and chemical phosphorus removal (Fig. 4). A stripper tank is included in the Phostrip process. This tank has an anaerobic condition where phosphorus is released by poly-P bacteria from the return activated sludge (RAS). The released phosphorus is removed from the stripped tank by elutriation water. Lime is added to the elutriation water as it leaves the stripper tank. The addition of lime results in the precipitation of phosphorus as calcium phosphate.

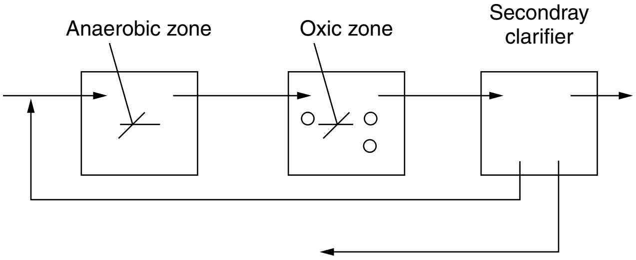

Figure 3. The A/O process.

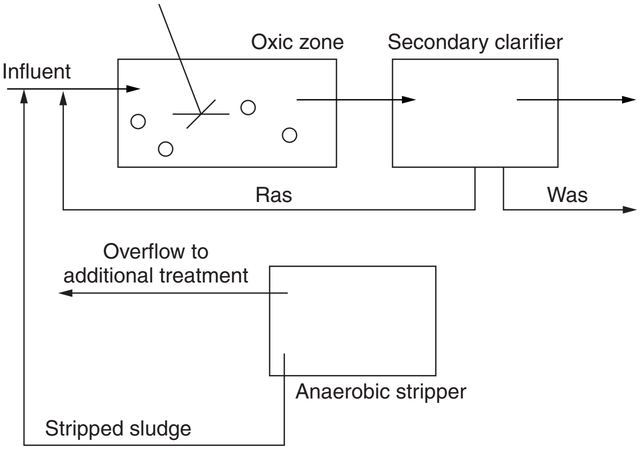

Figure 4. The Phostrip process.

The A2/O process consists of an anaerobic zone, an anoxic zone, and an oxic zone. As wastewater and bacteria move through these three zones, phosphorus is removed biologically and nitrogen is removed through nitrification and denitrification. Fermentation occurs in the anaerobic zone and phosphorus is released to the bulk solution by poly-P bacteria. In the anoxic zone nitrate ions are used (denitrified) by facultative anaerobic bacteria (denitrifying bacteria) to degrade soluble carbonaceous BOD. In the oxic zone ammonium ions (NH_4^+) in the wastewater and ammonium ions released from nitrogen-containing compounds are oxidized (nitrified) to nitrate ions (NO_3^-).

The Bardenpho process is licensed and marketed in the United States by Eimco Process Equipment Company. The Bardenpho process includes five zones (anaerobic zone, anoxic zone, oxic zone, anoxic zone, and oxic zone). The University of Capetown or UCT process also contains anaerobic, anoxic, and oxic zones. However, the UCT

Table 4. Nutrient Removal Processes

Process Name	Nutrient Removed		Process		Chemical Precipitation
	Nitrogen	Phosphorus	Mainstream	Sidestream	
A/O		X	X		
Phostrip		X		X	X
A2/O	X	X	X		
Bardenpho	X	X	X		
UCT	X	X	X		

process is designed to reduce the quantity of nitrate ions returned to the anaerobic zone in order to optimize the phosphorus removal.

As phosphorus and nitrogen discharge limits become more stringent for activated sludge processes in the United States, these nutrient removal systems will become more popular. The choice of the biological nutrient removal system is based on cost, wastewater composition, and nutrient removal requirements.

PHOTOCATALYTIC MEMBRANE REACTORS IN WATER PURIFICATION

INTRODUCTION

General

Potable water, industrial water, and wastewater are often polluted by toxic organic species. Some classical methods (1,2) to cleanup waters, before sending them to rivers or to municipal drinking water supplies, transfer pollutants from one phase to another, hence creating further waste streams. New methods, such as those involving heterogeneous photocatalytic reactions, allow in many cases a complete degradation of organic pollutants to small and non-noxious species, without using chemicals, thus avoiding sludge production and its disposal.

Membrane separation processes, thanks to the selective property of membranes, have already proved to be competitive with other separation processes (3–7). Photocatalytic membrane reactors (PMRs) have some advantages compared to conventional photoreactors. Indeed, confining the photocatalyst to the reaction environment as a result of the presence of the membrane enables operation with high amounts of catalyst, control of the residence time of the molecules in the reactor, and realization of a continuous process with simultaneous product(s) separation from the reaction environment. Some PMR configurations using membranes ranging from microfiltration (MF) to reverse osmosis (RO) have been investigated (8–13).

The influence of various operating parameters on the photodegradation rate of pollutants present in aqueous effluents by means of discontinuous and continuous photocatalytic processes in the presence of NF membranes has been reported (14). Moreover, the possible use of solar radiation (15–18) in PMRs is of particular interest as the energy cost is one of the main drawbacks for industrial applications. Although many papers on photocatalysis have been published, the cases where membrane and photocatalyst are coupled are very few.

Historical Background

The use of photocatalysis in waste treatment is usually based on the electronic excitation of a polycrystalline semiconductor caused by light absorption that drastically alters its ability to lose or gain electrons, promoting decomposition of pollutants to harmless by-products. Photocatalytic processes in liquid phase have been applied to the degradation of several organic compounds (19–24). Only a few compounds such as chlorofluorocarbons, trifluoroacetic acid, and 2,4,6-trihydroxy-1,3,5-triazabenzene (cyanuric acid) cannot be completely degraded by photocatalytic methods (24). The formation of transient by-products, more toxic than the starting substrates, could be observed in some cases. The research on types of reactors that can be used in photocatalysis is very active, and slurry photocatalytic reactors suitable for the requirement of continuous operation are described in the literature (25,26). Nevertheless, as the chemical industry is characterized by an almost exclusive use of continuous processes, a photocatalytic powder for potential application purposes should possess a suitable size and mechanical characteristics in addition to good catalytic properties. To date, only rare examples of pilot plant photoreactors have been reported, as the difficulty of making a clear assessment of the costs of the photocatalytic processes (which are typically efficient only in dilute systems) have prevented a wider development of them from an application perspective. Some authors have immobilized the semiconductor on Pyrex glass sheets (27,28), on aerogels (29), or on particles having high surface area (e.g., alumina or silica gel) (30,31). In all these methods, a drawback is the mass transfer resistance of the reacting species, which could control the reaction rate. Despite the potential advantages of using hybrid membrane photoreactors, the research on coupling photocatalysis and membranes is not yet sufficiently developed. Some papers reported in the literature concern the use of cellulose microporous membranes (32); porphyrin containing membranes (33); porphyrins immobilized as photosensitizers on sulfocationic membranes (34); filtration coupled to catalysis (35,36); and TiO_2 immobilized inside the membrane (37), physically deposited on the membrane surface (38), or confined in suspension by means of the membrane (8,9,10,39).

FUNDAMENTALS OF HETEROGENEOUS PHOTOCATALYSIS

A simple definition of heterogeneous photocatalysis implies only the acceleration of a photoreaction by the action of a solid catalyst, which may interact with the species to be degraded and/or with the intermediates, depending on the reaction mechanism. The catalytic nature of the process should be demonstrated by checking that the turnover number (TON) is greater than 1. TON can be defined as the ratio of the number of photoinduced transformations for a given period of time to the number of photocatalytic sites. The total surface area of the solid photocatalyst can be considered when the number of sites is unknown, but figures of TON obtained in this way are lower limits. The most widely used semiconductor

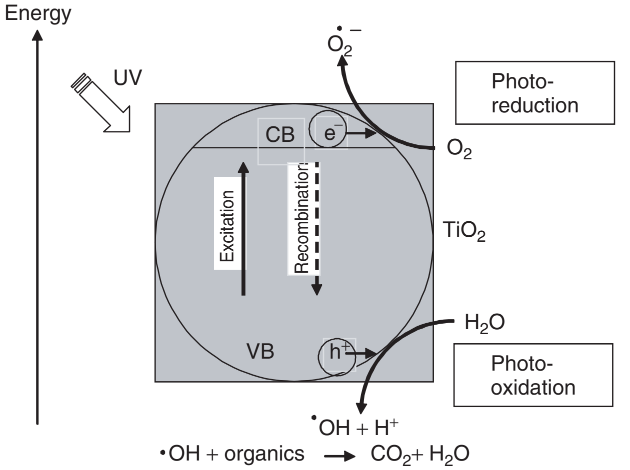

Figure 1. Basic photocatalytic mechanism occurring when a semiconductor particle (e.g., TiO_2) is irradiated.

photocatalyst is polycrystalline TiO_2, in the allotropic phases of both anatase and rutile (the anatase phase appears generally more photoactive), although the use of many other solids (ZnO, WO_3, CdS, MoS_2, CdSe, Fe_2O_3, etc.) has also been reported (40–42). When a semiconductor is illuminated with light of suitable energy (i.e., greater than its bandgap), electrons are promoted from the valence band (vb) to the conduction band (cb), acquiring the reducing power of the cb energy; positive holes are created in the vb, acquiring the oxidation power of the vb energy. This photoproduced pair can give rise to recombination with emission of thermal energy and/or luminescence or to redox (reduction–oxidation) reactions involving electron acceptor or donor species adsorbed on the surface of the catalyst particles (Fig. 1). Consequently, the recombination rate of the photoproduced electron–hole pairs should be as low as possible in order to favor their availability on the surface of the catalyst particle.

A photocatalyst should possess some essential characteristics: (1) light absorption should occur in the near UV and possibly in the visible wavelength ranges; (2) the stability should be such that its re-utilization is possible; and (3) some thermodynamic and kinetic constraints should be fulfilled (43). The photoreactivity depends not only on the intrinsic electronic characteristics of the photocatalysts, but also on their structural, textural, and surface physicochemical features. Among them we can cite the vb and cb energies, the bandgap value, the lifetime of photogenerated electron–hole pairs, the crystallinity, the allotropic phase, the particle sizes, the presence of defects and dopants, the specific surface area, the porosity, the surface hydroxylation, and the surface acidity and basicity. The relative weight of their importance for the studied reaction determines the final level of the photoreactivity. For this reason, it is often difficult to explain and to discuss exhaustively the observed photoreactivity trends by considering only a few properties of the photocatalysts. The steps shown in Table 1 occur when polycrystalline TiO_2 is used in aqueous medium in the presence of O_2 and a generic substrate.

The oxidant radicals along with the holes can give rise to oxidant attacks on a wide variety of substrates. The presence of O_2 is essential in order to trap photoproduced electrons, improving the charge separation and consequently the availability of the holes.

The application of heterogeneous photocatalysis to the purification of aqueous effluents containing dissolved organic and/or inorganic species (e.g., CN^-) has been widely studied. Nevertheless, it is worth noting that analytical studies to check if noxious intermediates are produced under irradiation are essential when the scale-up of photoreactors is proposed for application purposes.

FUNDAMENTALS OF MEMBRANE PROCESSES

Membrane processes are separation methods at the molecular level that have received more interest in recent years for their possibility of being used in many industrial applications. The main goals of such processes are concentration of a solute by removing the solvent, purification of a solution by removing nondesirable components, and fractionation of liquid or gaseous mixtures. Membrane separation processes offer interesting opportunities in pollution control, in the production of drinking water (44), and in the treatment of industrial wastewater (45). A membrane can be defined as a selective barrier between two phases (46,47); it can be thin or thick, natural or synthetic, neutral or charged, the structure can be homogeneous or heterogeneous; and the mass transport can be active or passive. In the last case the driving force can be due to a difference of pressure, concentration, or temperature. The driving force has the capacity to transport a component more rapidly

Table 1. Some Essential Steps When Polycrystalline TiO_2 Is Used in Photodegradation Processes of Noxious Organic and Inorganic Substrates

Role of TiO_2	*Role of* O_2
$TiO_2 + h\nu \rightarrow TiO_2\ (e^-_{(cb)} + h^+_{(vb)})$	$O_2 + e^-_{(cb)} \rightarrow {}^{\bullet}O_2{}^-$
$OH^- + h^+_{(vb)} \rightarrow {}^{\bullet}OH$	${}^{\bullet}O_2{}^- + H^+ \rightarrow {}^{\bullet}HO_2$
	$2{}^{\bullet}HO_2 \rightarrow O_2 + H_2O_2$
	$H_2O_2 + {}^{\bullet}O_2{}^- \rightarrow OH^- + {}^{\bullet}OH + O_2$

Substrate Degradation

Substrate $+ {}^{\bullet}HO_2 \rightarrow$ products

Substrate $+ {}^{\bullet}OH \rightarrow$ products

Substrate $+ h^+_{(vb)} \rightarrow$ products than others owing to different physical and/or chemical properties between the membrane and the components. The membrane is assembled in a module whose geometry is generally plane or cylindrical and in which the feed is separated into two streams called retentate (the treated feed) and permeate.

Each membrane process is characterized by the employement of a particular type of membrane. Some processes are microfiltration, ultrafiltration, nanofiltration, and reverse osmosis (48) in decreasing order of particles size and increasing pressures (0.1–0.2 to 50–100 bar) used as driving forces. Other membrane processes concern the separation of ionic species by applying an electrical potential (electrodialysis), the separation of mixtures of volatile liquids (pervaporation), and the separation of water from nonvolatile solutes (membrane distillation) by means of a temperature difference (49).

SOME CASE STUDIES OF PHOTOCATALYTIC MEMBRANE REACTORS USED TO PHOTODEGRADE POLLUTANTS

Preliminary Remarks

The pioneering studies for coupling photocatalysis and membrane separations focused on the optimization of the system configuration (14). A continuous operation system (feed feeding and permeate withdrawing) was reported by Molinari et al. (39) involving the use of TiO_2 particles in suspension (Fig. 2). This configuration seems appropriate for industrial applications, so experimental results deriving from this system will be mostly reported in the following. Membrane rejection of the target species with and without photodegradation was measured to obtain information on the performance of the system. Degussa P25 TiO_2 (specific surface area ≅ 50 m^2/g; crystallographic phase, ~80% anatase and 20% rutile) was used as the photocatalyst. Some of the molecules chosen as model pollutants were 4-nitrophenol (4-NP) and two dyes—patent blue ($C_{27}H_{31}N_2NaO_6S_2$) and congo red ($C_{32}H_{22}N_6Na_2O_6S_2$). The extent of the degradation of the contaminant was determined by UV-visible measurements and total carbon (TC), total organic carbon (TOC), and total inorganic carbon (TIC) determinations.

4-Nitrophenol Degradation in Batch and Continuous Membrane Photoreactors

When NF-PES-010 or N30F nanofiltration membranes were tested (the first one was the most permeable), the permeate fluxes through the membranes in the presence of suspended catalyst were a little lower than those found in the absence of catalyst. Deposition of the catalyst on the membrane was mimimized by using a cell geometry that guaranteed turbulence and presence of vortexes in the bulk of the solution above the membrane.

Photodegradation of 4-NP in batch (recycle) and continuous system configurations showed, for both types of membranes, bell-shaped curves of permeate concentration as a function of time. The concentration of 4-NP in the permeate was attributed to three factors: rejection, photocatalytic degradation, and adsorption. The increase of the initial concentration of permeate in the bell-shaped curves was lowered by the photocatalytic degradation that was responsible for the decrease of the concentration both in the retentate and in the permeate. Although 4-NP concentration in the retentate for the continuous configuration decreased less quickly than for the discontinuous one, the continuous system seems more promising for industrial application (39). In this system the optimum choice of the ratio between the irradiated volume and the total volume, V_i/V_t, was important. When the total suspension volume was increased from 400 to 700 mL, for instance, V_i/V_t increased owing to a constant recycle volume and, consequently, 4-NP abatement was higher due to an increased percentage of irradiated with respect to recycled suspension. The UV radiation mode was also important. The immersed lamp was found to be three times more efficient than the external lamp. Indeed, 99% w/w 4-nitrophenol degradation was achieved after about 1 h in the first case, whereas about 3 h were needed in the second case (39).

Photodegradation of Other Pollutants

NF-PES-010 and NTR-7410 nanofiltration membranes were tested in degradation runs after determination of their permeability and rejection for a variety of pollutants (50). It was found that membranes hold both catalyst and pollutants, but the NTR-7410 membrane tested at 8 bar gave a higher water permeate flux (105 $L/h \cdot m^2$) than the NF-PES-010 one (30 $L/h \cdot m^2$). The NTR-7410 membrane was also able to retain small molecules carrying negative charges (like the membrane) as a result of Donnan exclusion and, at 6 bar, yielded fluxes ranging between 20 and 40 $L/h \cdot m^2$. The results of rejection tests and photodegradation studies of humic acids, patent blue dye, and 4-NP in a system utilizing this membrane are described in the following.

The NTR-7410 membrane, not surprisingly, provided 100% retention of humic acids as they are made up of oligomers with molecular sizes greater than the membrane cutoff (600–800 g/mol). For patent blue (molar weight = 567 g/mol and initial concentration 10 mg/L), membrane rejection was about 78.6%. With respect to 4-NP, 0% rejection occurred at pH 6.75, while at pH 11 a rejection of about 77% and a negligible adsorption were observed. The pH dependence of rejection of 4-NP is to be expected by taking into account its acid–base properties and the resultant electrostatic interaction between 4-NP and the membrane (51,52):

$$C_6H_4NO_2OH + H_2O \rightleftharpoons C_6H_4NO_2O^- + H_3O^+$$

$$R\text{—}SO_3{}^-H^+ + H_2O \rightleftharpoons RSO_3^- + H_3O^+$$

Humic acids are found in many natural waters (53) and often induce fouling problems when membranes are used. The interaction between humic acid and the particulate TiO_2 photocatalyst has been explored by Lee et al. (54) who found that (1) humic solution or TiO_2 suspension alone produced essentially a constant membrane flux of 160–170 $L/h \cdot m^2$ and (2) the mixture gave initial flux of 145 $L/h \cdot m^2$ that decreased to 101 $L/h \cdot m^2$ (a decrease of approximately 30%) in the first 30 min of operation. When the photoreactor was illuminated, a constant flux was measured during 6 h, consistent with destruction of humic acid. These authors proposed that the photocatalyzed conversion of humic acid into smaller and/or less absorptive species was occurring and concluded that "photocatalytic reactions appear to be attractive for the control of fouling materials such as natural organic matter."

Continuous Membrane Photoreactor at High Pollutant Concentrations

The detrimental effect caused by a high pollutant concentration could be minimized by taking advantage of the ability of the membrane to retain both the catalyst and the pollutant. In order to investigate this, the photocatalytic system was tested in a continuous process with an initial concentration of pollutant in the photoreactor equal to zero, that is, in the presence of distilled water. A concentrated solution was continuously fed with a flow rate equal to that of the removed permeate. This solution was immediately diluted in the reactor, so photodegradation was effective at low pollutant concentration, although it was continuously fed at high concentration. Control of the residence time of the pollutant in the reactor was possible with the result that very low concentrations in the permeate could be obtained.

This approach was tested by performing humic acid photodegradation studies (50) with an initial concentration in the photoreactor equal to zero and feeding a 200-mg/L solution. It was possible to maintain steady-state pollutant concentrations lower than 5 mg/L and 2 mg/L in the retentate and in the permeate, respectively. It was observed that the humic acid rejection was not 100% and this was mainly due to the lower size of the humic acid oligomers produced during the photodegradation process.

The continuous process was also tested for high concentration (500 mg/L) feeds of patent blue dye and 4-NP. The photodegradation rate of patent blue was found to be lower than that obtained for other pollutants, possibly because of adsorption of the acid dye on the amphoteric catalytic surface, preventing UV light absorption. Indeed, at the end of the run, the catalyst was a dark blue color.

Degradation of Dyes in the Continuous Membrane Photoreactor

In order to achieve a better control of the residence time of pollutants, such as the dyes during the photodegradation process, a hybrid photoreactor was used in which the nanofiltration membrane was able to confine selectively dyes (congo red and patent blue) and catalyst in the reaction ambient while the permeate was withdrawn (55). The experimental results of runs carried out with patent blue in the membrane photoreactor with suspended catalyst showed that the photodegradation reaction followed pseudo-first-order kinetics (observed rate constant equal to $3.76 \times 10^{-3}\ min^{-1}$). A similar run carried out in the absence of membrane showed an observed rate constant of $1.02 \times 10^{-2}\ min^{-1}$. The lower reaction rates for both dyes obtained by using the membrane with respect to that obtained in its absence were due to the smaller volume of irradiated suspension (320 against 500 mL) because a part (180 mL) circulated in the pipes of the plant and in the membrane cell.

The possibility of successfully treating highly concentrated solutions of both dyes was examined, allowing the setup shown in Fig. 2 to work as a continuous system. In particular, the transient condition in the membrane photoreactor was studied by separating the effects of accumulation, adsorption, and photodegradation. Results of three runs with congo red for which the initial concentration of pollutant inside the photoreactor was zero are reported in Fig. 3.

The first run, carried out in the absence of UV light and photocatalyst, indicated that the initial rate of dye accumulation in the photoreactor was 0.151 mg/min. The second run, carried out in the absence of UV light but in the presence of TiO_2, indicated that no increase of dye concentration occurred in the photoreactor during the first 45 min of continuous working of the plant because the congo red feed was adsorbed onto the catalyst surface. After the active sites of the catalyst were saturated, the concentration of the dye in the retentate increased linearly with an accumulation rate of 0.136 mg/min, very close to that determined for the first run. In the third run the continuous degradation of congo red in the presence of UV light and catalyst was performed and concentrations in the retentate and in the permeate versus irradiation time are reported. It can be noticed that, due to the concurrent

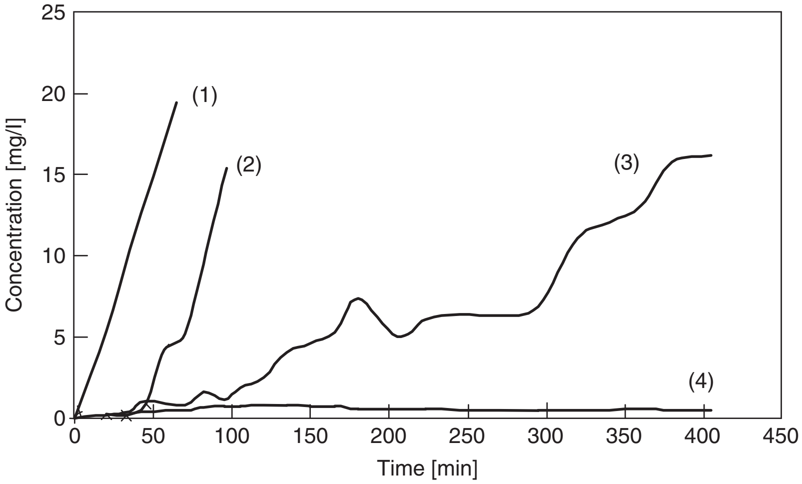

Figure 3. Concentration of congo red in the retentate and in the permeate versus time for three different continuous runs. (1) Absence of UV light and TiO_2; (2) absence of UV light and presence of TiO_2; (3) presence of UV light and TiO_2 for retentate; and (4) presence of UV light and TiO_2 for permeate. $V = 500$ mL; $T = 303$ K; $C_0 = 0$ mg/L; $C(O_2) = 22$ ppm; TiO_2 amount = 1 g/L; $C_{\text{feed}} = 500$ mg/L; initial permeate flux, $J_{p_{\text{in}}} = 74.2$ L/(m$^2 \cdot$ h); final permeate flux, $J_{p_{\text{fin}}} = 29.8$ L/(m$^2 \cdot$ h); lamp, 125-W medium pressure Hg immersed lamp; initial pH = 6.42; membrane, NTR-7410; $\Delta P = 3.5$ bar.

effect of dilution, adsorption, and photodegradation, the accumulation rate in the retentate was lower than that observed during the other two runs. The concentration of congo red in the permeate was virtually zero because the membrane maintained the substrate in the reacting ambient. The permeate flux (J_p) throughout all the runs decreased from the initial value of 74.2 L/m$^2 \cdot$ h to the value of 29.8 L/m$^2 \cdot$ h and, consequently, the dye feeding rate also decreased. It is worth noting that the average photodegradation rate (0.274 mg/min) calculated for the overall run was lower than the average feeding rate (0.416 mg/min), calculated for the first 180 min, while it was 0.049 mg/min higher for longer time (average feeding rate 0.225 mg/min).

Degradation of patent blue was also tested in the continuous system under the same experimental conditions used for congo red and the results are reported in Fig. 4. During the transient state (250–300 min in this specific case) the dye accumulated in the photoreactor because the photodegradation rate (0.570 mg/min) was lower than the feeding rate (0.863 mg/min). Subsequently, steady-state conditions were achieved, owing to the lower permeate flowrate, and no difference was observed between photodegradation and feeding rates. The rejection of NTR-7410 membrane at steady-state conditions with respect to patent blue was 44.6%.

Use of the membrane was beneficial because in addition to its role as a barrier for the catalyst, the product [i.e., cleaned up water (the permeate)] contained a very low concentration of dye with respect to the feed. It was approximately 1% in the case of congo red and approximately 11% in the case of patent blue with respect to 500 mg/L of the feed. It is worth noting that the concentration of the product corresponded to that of the retentate (approximately 3% for congo red and approximately 22% for patent blue) if the membrane was not used.

CONCLUSIONS

The continuous membrane photoreactor that combines both the advantages of classical photoreactors (catalyst in suspension) and membrane processes (separation at molecular level) appears very promising. Photocatalytic degradation can be carried out in reasonable times due to the high irradiated surface area of the suspended particles in the batch.

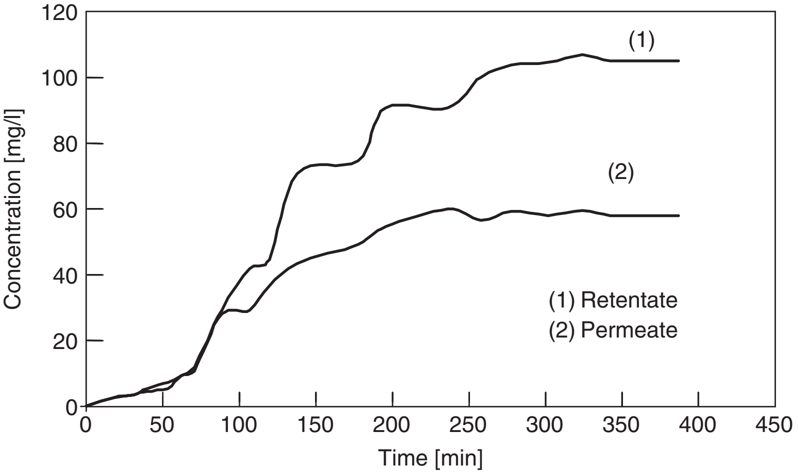

Figure 4. Concentration of patent blue in the retentate and in the permeate versus time for a continuous photodegradation run carried out in the setup showed in Fig. 2. $V = 500$ mL; $T = 303$ K; $C_0 = 0$ mg/L; $C(O_2) = 22$ ppm; TiO_2 amount = 1 g/L; $C_{\text{feed}} = 500$ mg/L; regime permeate flux, $J_{p_{\text{regime}}} = 78.4$ L/(m$^2 \cdot$ h); lamp, 125-W medium pressure Hg immersed lamp; initial pH = 5.61; membrane, NTR-7410; $\Delta P = 7.0$ bar.

Properly selected membranes should have both the capability to retain the catalyst and to partially reject organic species, enabling control of the residence time in the reacting system.

In studies of 4-nitrophenol degradation, three factors—rejection, photocatalytic degradation, and adsorption—were found to contribute to maintain the steady-state 4-NP concentration in the permeate at very low values. The adsorption phenomenon is particularly important when oscillating concentrations of pollutant are fed to the membrane photoreactor, resulting in a negligible variation of concentration in the permeate.

Photoreactors with an immersed lamp are generally more efficient than systems with external lamp. In addition, the pH of the polluted water, the molecular weight of the pollutant, and the type of pollutant and membrane are variables influencing pollutant rejection as a result of charge repulsion (Donnan exclusion) effects.

In order to select a suitable membrane, rejection should be determined during operation of the photoreactor. The pressure in the membrane cell, the pH of the polluted water, the molecular size of the pollutants, and the photogenerated by-products and intermediate species can influence the permeate flux of the membrane and consequently its choice.

High initial concentrations of the pollutants (e.g., 4-NP, patent blue, congo red) lower the photodegradation rate; however, this problem can be solved by diluting the feed in the reactor and by controlling the residence time of the pollutant by means of the membrane.

The experimental results available in the literature indicate that the choice of a suitable membrane is essential for applying the photocatalytic membrane processes to the treatment of real effluents. Furthermore, use of photocatalysis combined with RO processes for drinking water production can eliminate the membrane fouling problem and the need for plant sanitizing.

The hybrid continuous photoreactor where a nanofiltration membrane is used can give advantages over other approaches: simplification of clean-up or purification of various types of waters (for industrial, municipal/domestic, and agricultural uses), no sludge production, and saving in chemicals usage. It is expected that these hybrid processes will be considered particularly when plant upgrade is planned and, especially, if sunlight energy can be used for irradiation.

EPA'S NATIONAL PRETREATMENT PROGRAM, 1973–2003: THIRTY YEARS OF PROTECTING THE ENVIRONMENT

Office of Water—United States
Environmental
Protection Agency

EPA's National Pretreatment Program has led the way to dramatically reduce or eliminate discharges of pollutants to sanitary sewer systems and to the nation's water bodies. The Program controls a complex array of industrial wastestreams in order to prevent interference or pass—through of municipal treatment system processes. Without these controls, a number of harmful pollutants could make their way into the nations' waters. Federal, state, and local partnerships are central to the successful implementation of the Program. Renewed commitment and support to the Pretreatment Program will conserve the environmental gains of the last 30 years, strengthen strategic partnerships, and prepare communities to meet the pollution challenges of the 21st Century.

THE PRETREATMENT PROGRAM

Pollutants in industrial wastewater may compromise municipal treatment plants' processes or contaminate the nation's waters. To protect municipal treatment plants and the environment, the Pretreatment Program requires industrial dischargers to use treatment techniques and management practices to reduce or eliminate the discharge of harmful pollutants to sanitary sewers. The Pretreatment Program is a core part of the Clean Water Act's National Pollutant Discharge Elimination System (NPDES), and it has helped communities:

- Maintain and restore watershed quality, at a much lower cost than upgrading treatment;
- Encourage pollution prevention;
- Increase beneficial uses of sewage sludge;
- Prevent formation of poisonous gases in the sanitary sewer system;
- Meet wastewater discharge standards; and
- Institute emergency—prevention measures.

Goleta, California's pretreatment program makes it possible for marine life—fish, sea stars, and coral—to thrive at the city's Sanitary District outfall

The Pretreatment Program's strategic partnerships go beyond ensuring the success of Publicly Owned Treatment Works (POTWs). The partnerships—involving approximately 1,500 communities and 27,000 industrial facilities nationwide—promote:

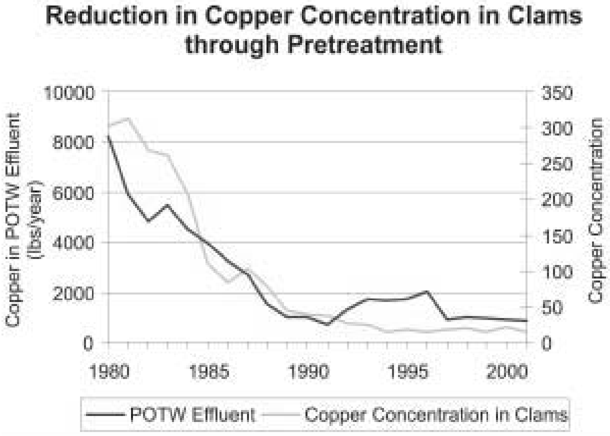
- Protection of drinking water supplies, by reducing contaminants released into source waters by POTWs;
- Prevention of overflows that include raw sewage from sewers, through controls on oil and grease;
- Extension of the life of the nation's wastewater infrastructure, which has an estimated funding gap of over $6 billion per year, through controls on corrosion;
- Worker safety, by protecting workers from harmful fumes through limits on the discharge of dangerous gases and gas—forming substances; and
- Homeland security, by ensuring proper disposal of wastes from decontamination showers.

PARTNERSHIPS THAT WORK

Through the Pretreatment Program, POTWs have worked intensively in a federal, state, and local partnership that is a model of intergovernmental cooperation.

National data affirm the Pretreatment Program's success

- Industries release fewer toxic contaminants to POTWs. Data from EPA's Toxics Release Inventory show that industries have reduced the amount of pollutants they discharge to sewage treatment plants during the past 10 years.



Through its pretreatment program, Palo Alto, California has reduced pollutants discharged to San Francisco Bay. As the quantity of copper in the POTW's effluent has improved, copper levels in clams near the city's outfall have decreased

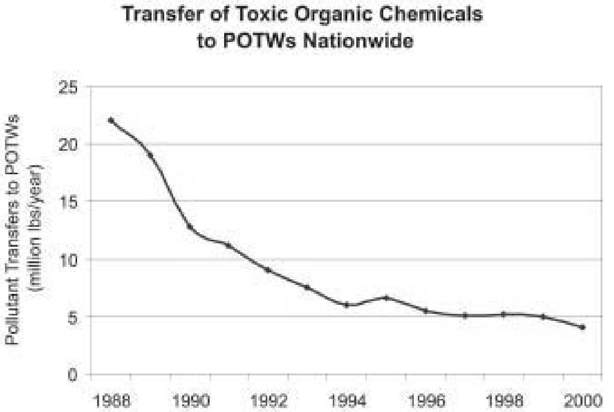
---

- POTWs now generate sewage sludge that poses fewer threats to public health and the environment. An Association of Metropolitan Sewerage agencies (AMSA) survey of biosolids concluded that the Pretreatment Program was directly responsible for reductions in metals found in sewage sludge. Surveyed POTWs experienced a modest 13 percent decline in metals not regulated by the Pretreatment Program. However, concentrations of metals regulated under the Pretreatment Program decreased considerably, dropping 59 percent from 1986 to 1997.
- Because of the successful implementation of industrial discharge limitations, more POTWs are able to apply sewage sludge to land. For example, six Midwestern states saw a significant increase in the percentage of POTWs whose sludges qualified for the term 'biosolids.' More than 90 percent met metals limitations that allow POTWs to land apply their biosolids. As a result of this national progress, many POTWs, like the Unified Sewerage Agency of Washington County, Hillsboro, Oregon, have been able to use 100 percent of the biosolids they produce. Hillsboro applies 11,000 dry metric tons annually to amend soils and improve crop production.

SUPPORTING KEY ENVIRONMENTAL AND PUBLIC HEALTH PROGRAMS

Drinking Water Protection. EPA's Pretreatment Program has been helping communities protect their sources of drinking water for the last 30 years by:

- Protecting POTWs' treatment processes from upsets, which could compromise the treatment facility's ability to treat harmful substances, such as pathogens. Elevated pathogen levels could have substantial impacts on public health if the pathogens exit POTWs and enter surface waters. Downstream drinking water treatment facilities may be challenged by significantly higher—than—normal pathogen levels.

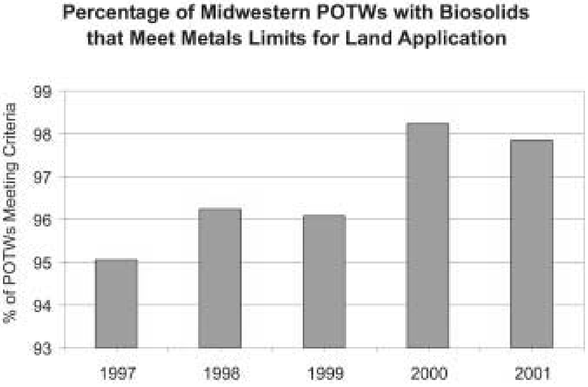


The Toxics Release Inventory is a publicly available EPA database that contains information on toxic chemical releases and other waste management activities reported annually by covered industry groups and the federal government

- Controlling industrial releases of carcinogenic contaminants that might otherwise be discharged to municipal sewage treatment plants. Without controls on industrial dischargers, carcinogens might pass through the sewage treatment plant and enter reservoirs tapped for drinking water supplies. Therefore, the Pretreatment Program eliminates the need to install additional, expensive water treatment equipment to protect the long—term health of consumers.

CSO, SSO, and storm water management—Combined and Sanitary Sewer Overflows (CSOs and SSOs) contain raw sewage, and may also carry industrial waste and debris. EPA's wet—weather programs recognize the importance of the Pretreatment Program in helping communities:

- Mitigate overflows. For example, many cities halt discharges of waste flows from industrial facilities to the combined sewer system during wet weather



Data obtained from EPA's Permit Compliance System, representing information reported to EPA by POTWs in Illinois, Michigan, Minnesota, Ohio, and Wisconsin

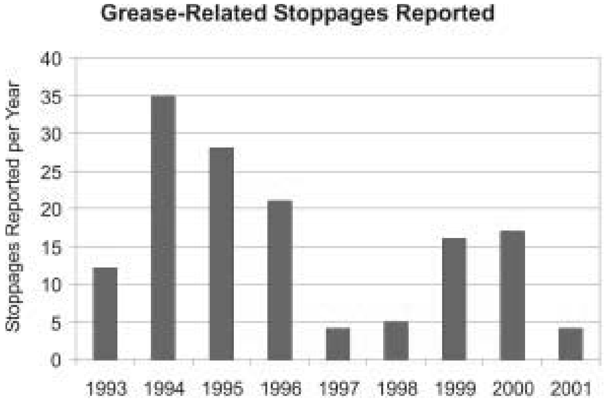
Overflowing sewer due to a sewer blockage events. In addition, industries may retain storm water from their properties and release it to the sewer system after the storm has ended and sewer system capacity is adequate.

- Control grease buildup in sewers—a major cause of SSOs. As part of their pretreatment programs, many communities require food service establishments to recycle all fats, oils, and greases or to use oil and grease removal equipment. Annapolis, Maryland's pretreatment program practically eliminated SSOs associated with the restaurant community.
- Inventory and control non—domestic sources of pollutants, the types of pollutants discharged, and the volume of industrial flow. These inventory efforts not only protect wastewater treatment plants, but also help identify industrial contributions to municipal separate storm sewer systems.

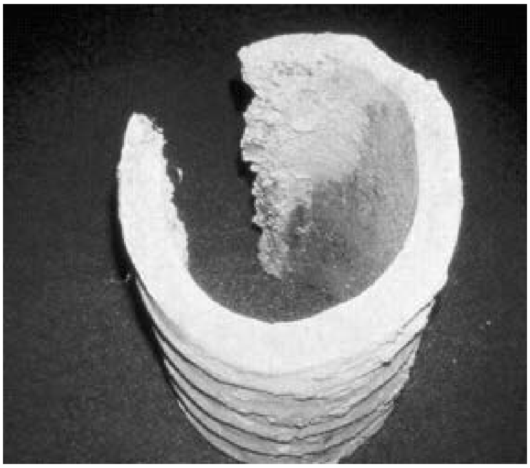
Infrastructure Protection—Pretreatment programs help to protect underground infrastructure from costly damage and the need for premature replacement. The gap between the average annual funding needed and the funding available for wastewater treatment and collection systems is estimated to be $6.1 billion per year from 2000 to 2019. EPA's Pretreatment Program helps to extend the life of infrastructure and postpones costly replacement. For example, limits on pH prevent corrosion of collection systems and treatment plants from acidic discharges. Discharge limits on sulfides and sulfate—bearing wastewaters also protect infrastructure from corrosion caused by bacteria.

Worker and Public Safety—Ensuring safety is an important goal of EPA's Pretreatment Program. The Program accomplishes this goal by:

- Protecting the physical integrity of the sewer system. Volatile organic compounds discharged to sewers may accumulate in the head space of sewer lines, increasing the potential for explosions that may cause significant damage. Discharge limitations and management practices required by the Pretreatment Program reduce the likelihood of such catastrophes.



San Antonio, Texas achieved significant reductions in grease—related stoppages through its pretreatment program



Example of a sewer pipe damaged by hydrogen sulfide corrosion

- Preventing the buildup of poisonous gases. Discharges of toxic organics can generate poisonous gases, through various kinds of mixing and chemical reactions. Appropriate pretreatment discharge limits prevent this gas build up.

Homeland Security Initiatives—As they increase their preparedness for possible terrorist attacks, communities across the country will rely on their local pretreatment programs. The Pretreatment Program helps communities build contingency plans for the control and disposal of decontaminated wastes, such as wastes from decontamination showers. Recently, pretreatment authorities in Boca Raton, Florida managed the disposal of anthrax wastes as part of clean-up activities in that city.

FUTURE CHALLENGES

The Pretreatment Program must evolve to face tough new challenges in protecting public health and the environment. Future challenges include:

- *Addressing emerging industries and pollutants*. Every year, new industries and new pollutants of concern challenge POTWs. For example:

A safety issue: Discharges of hexane from an industry into Louisville, Kentucky's sewer system collapsed sewer lines and destroyed streets throughout the city in 1981

  - The Pretreatment Program must keep pace with the constant shifts in industrial processes and the development of new industries and chemicals. For example, in the 1980s and 1990s, the rapid growth of the semi—conductor industry required new pretreatment program strategies. Mounting evidence now suggests that persistent, bioaccumulative, and toxic (PBT) chemicals, surfactants, and hormone—disrupting substances can pass through wastewater treatment plants and endanger human health. Through their pretreatment programs, communities continue to address changes in industrial operations.
  - New effluent guidelines for transportation equipment cleaning and centralized waste treatment facilities address highly complex industries with a history of disrupting POTW treatment. Communities will rely on the Pretreatment Program as the vehicle to implement these guidelines and control these highly variable and highly toxic wastestreams.
- *Water conservation and reuse*. Industries and municipalities have a growing understanding of the economic benefits of using water more efficiently. Effluent waters from POTWs are increasingly used for irrigation and for cooling in power generation and industrial processes. The high quality waters needed for these uses emphasizes how important pretreatment is to the growing area of water reuse and conservation.
- *Improving watershed quality through Total Maximum Daily Loads (TMDLs)*. TMDLs are established to ensure that rivers and streams meet their intended uses, such as recreational areas and drinking water supplies. State and local pretreatment personnel are increasingly called upon to provide expertise in developing appropriate TMDLs and community—based strategies. These individuals are aware of the contributions from industrial pollutants within the local watershed and sewer—shed, and can share their knowledge of how to implement pollutant limits while pursuing complex watershed—based solutions.

Communities will rely on the leadership of the Pretreatment Program to meet these and other unanticipated challenges. While the Program has had many successes in the last 30 years, a firm commitment to the federal, state, and local partnerships established under the Program is critical to protecting public health and the environment in the future.

PROBLEMS ENCOUNTERED DURING PIPE REPAIR AND RENEWAL

Sanjiv Gokhale
Vanderbilt University
Nashville, Tennessee

INSTALLATION PROBLEMS

Installation Problems—Sliplining

The major problem encountered during sliplining of an existing sewer is improper preparation of the interior of the sewer prior to the inserting the sliplining pipe.

1. Obstructions such as roots, large joint offsets, extended laterals, rocks, or other debris that would prevent the passage of or the damage to the liner pipe sections must be removed or repaired prior to the installation of the new liner pipe.
2. Prior to the insertion of the new liner pipe, a test mandrel or pipe section should be pulled through the existing line to ensure that the liner may be inserted without damage or restrictions.
   (a) The mandrel should be of a length equal to the longest pipe that will be inserted.
   (b) The mandrel test may indicate that short lengths of pipe should be used if the angular deflection negates using longer pipe.

The accurate location and installation of the laterals presents a difficult problem for the Contractor.

1. Existing lateral and sewer connection locations must be carefully determined.
2. The installation of the laterals to provide a leak-tight system is critical.

The diameter of the slipliner pipe is smaller than the host or existing sewer, so inverts and connections to existing manholes must be watched closely.

Grouting the annular space between the existing sewer and the slipliner pipe must be done with great care.

1. Flotation during grouting is a potential problem. The liner pipe should be flooded to a depth of 2 to 3 feet prior to beginning the placement of the grout.
2. The grout should be placed to ensure that the lift heights, grout density, and the sewage flow depth are coordinated to control the line pipe deformation within allowable limits. Point loads causing excessive dents or bulges should be avoided. The maximum pipe diameter deflection for sliplined pipe is 5%. Close monitoring of grout pressure is essential during grouting to prevent buckling of the liner pipe.

Installation Problems—Cured-in-Place Pipe (CIPP)

A difficult problem with CIPP is the location of laterals. The Contractor relies on the “dimples” in the new liner and accurate measurements.

A difficult problem is wrinkles or folds in the flow line in the finished product.

1. This problem could result from improper sizing of the liner bag size.
2. Wrinkles also occur due to head loss in the filling operations.

Inadequate curing of the liner, resulting from the wrong temperature or time duration, may result in soft spots. The Contractor inserts a section of material called dry liner at the soft spot in the liner, which corrects this problem when cured.

Care should be taken to determine if laterals that are to be abandoned are indeed dead. A good rule of thumb to follow is that if you cannot see a plug or cap from inside the main line, then the lateral must be reinstated.

Although not a Contractor problem, a homeowner who has a bad trap on the house sewer may experience a highly offensive odor from the chemical reaction at cure-out. It is offensive but not harmful. This problem can be reduced if the Contractor instructs the homeowners to fill the traps of floor drains with water.

Installation Problems—Gunite

Care should be taken to remove the “rebound.” Some Contractors may try to trowel the rebound and leave it at the bottom of the pipe.

One of the keys for a successful gunite operation is the skill of the nozzleman. Most specifications list qualifications for the nozzleman. Apprentices should be allowed to work only with proper supervision.

Make certain that all leaks in the substrate are stopped. Running water will prevent the material from achieving the proper bond to the substrate.

RADIOACTIVE WASTE

James Crocker
Richland, Washington

Radioactive waste is a concern with regard to water quality when the waste is released into the environment or has the potential to be released into the environment. Air and water containing radioactive contamination may be released directly into the environment if the activity of the contamination is within defined levels. The World Health Organization (WHO) has established release guidelines as explained below. In the United States, the Nuclear Regulatory Commission (NRC) regulates radioactive discharges from commercial nuclear facilities. The NRC regulations are found in Codified Federal Regulations (CFR) 10 CFR 20.106. Limits for radioactive air and water are given in 10 CFR 20, Appendix II, Table 2 for releases to the environment, and in 10 CFR 20, Appendix II, Table 3 for releases of radioactive water into sewers. The United States Department of Energy (DOE) has also established requirements for release of radioactive water and air from DOE facilities. These requirements are provided in DOE Order 4500. The United States Environmental Protection Agency (EPA) provides standards for releases into water sources that may potentially be used as drinking water (see Drinking Water Limits). Of the relatively few instances of radionuclides exceeding levels of concern, most are from natural sources (1,2).

RADIOACTIVITY AND RADIATION

If the energy released during radioactive decay is high enough to strip electrons from other atoms, or split the nuclei of other atoms, the radiation is called ionizing. It is this ionizing radiation that poses the health risk associated with radionuclides. Four types of ionizing radiation exist: alpha, beta, gamma, and neutron. Alpha, beta, and neutron radiation are particles that are released when the isotope decays. An alpha particle is the nucleus of a helium-4 atom, thus consisting of two neutrons and two protons, and no electrons, therefore having a +2 charge. Alpha radiation is easily stopped by only moderate shielding, for example, two or three pieces of paper, or human skin. Neutrons have no charge and therefore do not interact as easily with other atoms when released as radiation. Beta particles are energetic electrons and have a −1 charge. Gamma rays are not particles, but rather electromagnetic radiation, similar to x-rays. Gamma rays and beta particles have both the ability to penetrate farther than alpha particles and interact more than neutrons, and they are therefore typically the more hazardous form of ionizing radiation. However, if alpha particles are ingested, they may present a significant health hazard as an internal contamination. The time for the atoms of a radioactive compound to decay to one half of their starting concentration is called the half-life of the isotope. Two sources of radionuclides exist in drinking water, naturally occurring and anthropogenic.

NATURALLY OCCURRING SOURCES

Naturally occurring radioactive isotopes originate in Earth’s crust and the upper atmosphere. Cosmic rays and other extraterrestrial ionizing radiation form the radioactive isotope tritium in Earth’s upper atmosphere. This isotope is incorporated into natural rainfall and therefore eventually reaches Earth’s surface. Radioactive isotopes, including uranium-238, radium-226, radium-228, and strontium-90, were formed in Earth's crust during the birth of the Solar System about 5 billion years ago. Radon is a daughter product formed when uranium decays. Groundwater may therefore contain levels of radionuclides that are somewhat elevated.

Of the two kinds of naturally occurring isotopes, stable and unstable, only unstable isotopes pose a health concern (3). Therefore, the natural isotopes of primary interest with regard to water quality are uranium-238, radium-226, radium-228, uranium-238, radon, and tritium.

Anthropogenic (Manmade) Sources

The primary sources of manmade radioactive contamination in water are tritiated cooling water effluent from nuclear reactors, tritiated water from nuclear fuel-reprocessing facilities, medical sources, and nuclear fallout from nuclear weapons testing. Effluent from nuclear facilities must meet strict regulatory requirements. In comparison with the large number of safe operating hours accumulated by nuclear facilities over the years, instances of accidental release of radioactive contamination into the environment are rare.

DRINKING WATER LIMITS

The World Health Organization (3) provided guidelines for upper limits of radioactive contamination in drinking water consumed by large populations over a lifetime as:

Gross beta contaimination	1000 pCi/L
Radium-226	10 pCi/L
Strontium-90	30 pCi/L

In the United States, if water is discharged into a water source that may be used for drinking water, such discharge is regulated by the EPA (4). The EPA has updated its standards for radionuclides in drinking water, and it has set a new standard for uranium, as required by the 1986 amendments to the Safe Drinking Water Act. The standards are as follows:

Combined radium-226/228	5 pCi/L
Beta emitters	4 mrems
Gross alpha	15 pCi/L
Uranium	30 μg/L

TREATMENT TECHNOLOGIES

Unlike other chemical contaminants, radionuclides cannot be altered by chemical reactions to form nonradioactive products through normal chemical means. The isotopes that emit radiation will continue to do so no matter what chemical compounds they form. Only through the passage of time will the radioactive compounds decay naturally into their associated daughter products, eventually becoming radioactively stable isotopes. Although the radionuclides will continue to emit radiation, the chemical compounds emitting this radiation can be removed by conventional water treatment methods. Cox (5) stated that 70–90% of the radioactive materials appearing in surface waters are removed in conventional water treatment facilities. According to DeZuane (1), more than 99% of radioactive contaminants that percolate into soils via rainwater are removed naturally. If further removal is required beyond these levels, several standard water treatment methods may effectively remove the contamination (2).

Radionuclides of primary interest that may require removal from water sources are uranium-238, radium-226, radium-228, radon, and strontium-90. Uranium may be removed by lime softening, ion exchange (anion and/or cation), reverse osmosis, electro-dialysis, activated alumina, or a combination of coagulation with sedimentation and filtering. Radium-226 and radium 228 may be removed by lime softening, cationic ion exchange, reverse osmosis, or electro-dialysis. Strontium-90 may be removed by lime softening, cationic ion exchange, reverse osmosis, ultrafiltration (UF), or electro-dialysis. A combination of air stripping and granulated activated carbon is an effective technique for removing radon from water (2).

MEMBRANE FILTRATION PROCESSES

In membrane filtration, particles in the range of 0.0001 μm to 1.0 μm are removed from water. This process involves removal of dissolved constituents, as opposed to other filtration processes that remove colloids and larger particles. In UF, the particles are separated from the water by a sieving mechanism. In reverse osmosis (RO), small particles are rejected by the water layer adsorbed on the surface of the memberane (6). An electrodialysis system passes an electric current through the solution, which causes the cations to move to the anode and the anions to move to the cathode. This movement results in alternating cells of concentrated and dilute salts, which are flushed out from the units and in this way removed from the waste water. Ref. 6, pp. 1104–1137, for additional information.

AIR STRIPPING

Air stripping is an effective method for removing radon from radon-contaminated water (Fig. 1a). In air-stripping equipment, the contaminants in the water phase are transferred into the air phase. The contact area between the clean air phase and the water phase controls the removal rate and therefore the process efficiency. Higher contact areas provide increased removal efficiencies. Water is usually introduced in the top of a cylindrical tower and air is blown in from the bottom, although other arrangements are used. Air stripping may be carried out in several types of equipment, including packed towers, sparged or agitated vessels, or tray towers. In packed towers, high-surface area packing maximizes interphase surface area. Sparged vessels, also called bubble columns, introduce the air into the water to form small bubbles that rise upward through the water. Tray towers contain multiple vertically stacked trays that are made to allow the air to move upward through the water via small openings. The water flows across the trays and down through baffled weirs to the bottom of the tower, which produces foaming and the gas–liquid contact required to produce the mass transfer (6,7).

Several gas stripping systems are being used in the United States to remove radon from drinking water. A good summary is provided in Table 1 (8).

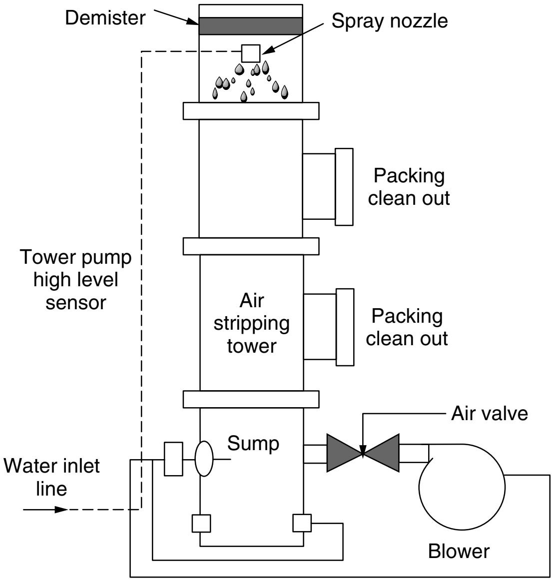


Figure 1. Air stripping town.

CHEMICAL PRECIPITATION

Heavy metals such as uranium and strontium may be removed from contaminated water by converting their soluble salts to insoluble salts that will precipitate. Typically, the pH of the waste stream is first adjusted, and an appropriate chemical is added to convert the soluble metal salts into carbonates, sulfides, or hydroxides of the metal (see LIME SOFTENING). A flocculating agent is then added to promote discrete particle agglomeration, usually performed in a vessel with slow mixing. The flocculated particles are then removed from the stream by either filtration or settling (9). The chemical precipitants and flocculants required depend on the chemistry of the specific waste water system being considered for treatment (6).

LIME SOFTENING

Lime softening is used in a variety of ways to precipitate Group II A ionic species from water (for example, ions of magnesium, calcium, strontium, and radium) and may be used to remove uranium contamination. Lime (calcium hydroxide) is added in either lump, powder, or slurry form to carry out the following simple reactions:

1. $\mathrm{H2CO3} + \mathrm{Ca(OH)2} \rightleftharpoons \mathrm{CaCO3(s)} + \mathrm{2H2O}$
2. $\mathrm{Ca(HCO3)2} + \mathrm{Ca(OH)2} \rightleftharpoons \mathrm{2CaCO3(s)} + \mathrm{2H2O}$

Reaction 1 shows the reaction of the lime with the carbonic acid component typically in water. This reaction does not precipitate any of the desired ionic contaminants, but it must be considered because it creates a lime demand. Reaction 2 shows the removal of two calcium ions. Radioactive ionic contaminants may be removed in a similar manner. Ferrous sulfate is often used in conjunction with lime softening. Many additional chemical reactions may also occur during lime softening. For more information on these reactions, and dosing calculations, refer to Ref. 10, p. 270, and Ref. 6, p. 495 (10–12).

ION EXCHANGE

Ion exchangers operate on the principle of exchanging ions from an insoluble resin with the ions that are present in water. Ion exchange is a common method for removing heavy metals from waste water streams. Resins that typically remove metals include zeolites, anionic and cationic resins, and chelating resins. Chelating and ionic resins that are selective for uranium, strontium, and radium have been developed (6,9).

ACTIVATED CARBON TREATMENT

Activated carbon has been used in conjunction with other waste removal systems such as air stripping to remove radon (8). The radon is adsorbed onto the activated carbon, and it may be regenerated by heating the carbon to sufficient temperatures. See AIR STRIPPING.

RECLAIMED WATER

Absar Ahmad Kazmi
Nishihara Environment
Technology, Inc.
Tokyo, Japan

INTRODUCTION

Reclaimed water is water from a wastewater treatment plant (WWTP) that has been treated and can be used for nonpotable uses such as landscape irrigation, cooling towers, industrial processes, toilet flushing, and fire protection. The inclusion of planned water reclamation, recycling, and reuse in water resource systems reflects the increasing scarcity of water resources to meet societal demands, technological advancements, increased public acceptance, and improved understanding of public health risks.

Per capita water use in the United States has quadrupled since the beginning of the twentieth century. Americans typically consume between 60 and 200 gallons (230 to 760 liters) per capita each day. The use of reclaimed water for nonpotable purposes can greatly reduce the demand on potable water sources—this use is encouraged by diverse organizations such as FEMP, EPA, and the American Water Works Association (AWWA). Municipal wastewater reuse amounts to about 4.8 billion gallons (18 million m^3) per day (about 1% of all freshwater withdrawals). Industrial wastewater is far greater—about 865 billion gallons (3.2 billion m^3) per day.

Reclaimed water contains valuable nitrogen, phosphorus, and other nutrients, which promote plant growth. At the same time, the water meets stringent disinfection standards. Experience has shown that contact with reclaimed water does not promote waterborne disease transmission. In fact, reclaimed water quality standards are more stringent than those for surface streams, rivers, and irrigation channels. Reclaimed water is delivered through pipelines that are completely separate from the potable water system.

In some areas of the United States, reclaimed water may be referred to as irrigation quality ("IQ") water, but potential uses can extend well beyond irrigation. Using higher levels of treatment, such as reverse osmosis, reclaimed water as a potable source is technically and economically feasible. New technological breakthroughs in membrane filtration and combined biological and filtration treatment offer unprecedented opportunities for water recycling, especially in isolated locations and regions where the water supply is severely limited.

BENEFITS OF USING RECLAIMED WATER

- It saves millions of gallons of drinking water each day.
- Its use for nonpotable (nondrinking) purposes is less expensive for the vast majority of of customers.
- It delays the need for developing costly new water sources and building very expensive treatment plants.
- There is no odor or staining from its use.
- It allows a city to comply with permits relating to its water supply and wastewater treatment.
- It minimizes negative effects around underground water sources, preserving the quality of life for plants and wildlife.
- It reduces fertilizing costs because reclaimed water is rich in nitrogen and phosphorus.

POTENTIAL USES OF RECLAIMED WATER

Urban public water supplies are treated to satisfy requirements for potable use. However, potable use

Table 1. Summary of EPA Suggested Guidelines for Water Reuse[a]

Levels of Treatment	Types of Reuse	Reclaimed Water Quality	Reclaimed Water Monitoring	Setback Distances
1. Disinfected tertiary[b]	Urban reuse[c]	pH = 6–9	pH = weekly	15 m (50 ft) to potable water supply wells[d]
	Food crop irrigation	$BOD_5 \leq 10$ mg/L Turb. ≤ 2 NTU	BOD = weekly Turb. = cont.	
	Recreational impoundments	*E. coli* = none Res. $Cl_2 \geq 1$ mg/L	*E. coli* = daily Res. Cl_2 = cont.	
2. Disinfected secondary	Restricted-access-area irrigation	pH = 6–9	pH = weekly	30 m (100 ft) to areas accessible to the public (if spray irrigation)
		BOD_5 = 30 mg/L	BOD = weekly	
	Food crop irrigation (commercially processed)	TSS = 30 mg/L	TSS = cont.	
		E. coli = 200/100 mL	*E. coli* = daily	
			Res. Cl_2 = cont.	90 m (300 ft) to potable water supply well
	Nonfood crop irrigation Landscape impoundments (restricted access) Construction Wetlands habitat	Res. $Cl_2 \geq 1$ mg/L

[b] Filtration of secondary effluent.

[c] Uses include landscape irrigation, vehicle washing, toilet flushing, fire protection, and commercial air conditioners.

[d] Setback increases to 150 m (500 ft) if impoundment is not sealed.

(drinking, cooking, bathing, laundry, and dishwashing) represents only a fraction of the total daily residential use of treated potable water. The remainder may not require water of potable quality. In many cases, water used for nonpotable purposes, such as irrigation, may be drawn from the same ground or surface source as municipal supplies, creating an indirect demand on potable supplies. There are opportunities for substituting reclaimed water for potable water or potable supplies for uses where potable water quality is not required. Specific water use where reuse opportunities exist include

- urban
- industrial
- agricultural
- recreational
- habitat restoration/enhancement, and
- groundwater recharge

FEDERAL GUIDELINES FOR RECLAIMED WATER REUSE

The U.S. Environmental Protection Agency (1) has suggested reclaimed water quality guidelines for the following reuse categories:

- urban reuse
- restricted-access-area irrigation
- agricultural reuse—food crops
- agricultural reuse—nonfood crops
- recreational impoundments
- construction uses
- industrial reuse
- groundwater recharge
- indirect potable reuse

Levels of treatment, minimum reclaimed water quality, reclaimed water monitoring, and setback distances are suggested for each reuse category (1). The guidelines are summarized in Table 1 for the two principal levels of treatment—disinfected tertiary (filtered secondary effluent) and disinfected secondary effluents.

CONSTITUENTS OF RECLAIMED WATER

The constituents of municipal wastewater subject to treatment may be classified as conventional, nonconventional, and emerging. Typical constituents included under each category are described in Table 2. The term conventional is used to define those constituents measured in mg/L that are the basis for designing most conventional wastewater treatment plants. Nonconventional applies to those constituents that may have to be removed or reduced using advanced wastewater treatment processes before the tank can be used beneficially. The term emerging is applied to those classes of compounds measured in the micro- or nanogram/L range that may pose long-term health concerns and environmental problems as more is known about the compounds. In some cases, these compounds cannot be removed effectively, even by advanced treatment processes.

WATER RECLAMATION TECHNOLOGIES

As noted in the previous section, the constituents of wastewater subject to treatment may be classified as conventional, nonconventional, and emerging. Conventional

Table 2. Classification of Typical Constituents in Wastewater

Classification	Constituent
Conventional	Total suspended solids
	Colloidal solids
	Biochemical oxygen demand
	Chemical oxygen demand
	Total organic carbon
	Ammonia
	Nitrate
	Nitrite
	Total nitrogen
	Phosphorus
	Bacteria
	Protozoan cysts and oocysts[a]
	Viruses[b]
Nonconventional	Refractory organics
	Volatile organic compounds
	Surfactants
	Metals
	Total dissolved solids
Emerging	Prescription and nonprescription drugs[c]
	Home care products
	Veterinary and human antibiotics
	Industrial and household products
	Sex and steroidal hormones
	Other endocrine disrupters

[b] Plaque-forming units/100 mL.
[c] Pharmaceutically active substances.

constituents are removed by conventional treatment technologies. Advanced treatment technologies are used most commonly for removing nonconventional constituents. The removal of emerging constituents occurs in both conventional and advanced treatment processes, but the levels to which individual constituents are removed are not well defined. Typical performance data for selected treatment combinations are presented in Table 3.

PLANNING FOR WASTEWATER RECLAMATION AND REUSE

In effective planning for wastewater reclamation and reuse, the objectives and basis for conducting the planning should be defined clearly. The optimum water reclamation and reuse project is best achieved by integrating both wastewater treatment and water supply needs into one plan. This integrated approach is somewhat different from planning for conventional wastewater treatment facilities where planning is done only for conveyance, treatment, and disposal of municipal wastewater. Effective water reclamation and reuse facilities should include the following elements: (1) assessment of wastewater treatment and disposal needs, (2) assessment of water supply and demand, (3) assessment of water supply benefits based on water reuse potential, (4) analysis of reclaimed water market, (5) engineering and economic analyses of alternatives, (6) implementation plan

Table 3. Treatment Levels Achievable from Various Combinations of Unit Operations and Processes Used for Water Reclamation

	Typical Effluent Quality, mg/L, Except Turbidity, NTU						
	TSS	BOD$_5$	COD	Total N	NH$_3$-N	PO$_4$-P	Turbidity
Activated sludge + granular medium filtration	4–6	<5–10	30–70	15–35	15–25	4–10	0.3–5

[a] Removal process occurs in the main flowstream as opposed to sidestream process.

with financial analysis, and (7) a public information program.

TECHNICAL CONSIDERATIONS

For a successful reclaimed water project, one or more of the following ingredients are required: (1) high cost water or a need to extend the drinking water supply, (2) local public policy encouraging or mandating water conservation, (3) availability of high quality effluent from a WWTP, and (4) recognition of environmental or other nontangible benefits of water reuse.

Technologies vary with end uses. In general, tertiary or advanced secondary treatment is required; either usually includes a combination of coagulation, flocculation, sedimentation, and filtration. Viruses are inactivated by granular carbon adsorption plus chlorination or by reverse osmosis, ozonation, or UV exposure. Dual water systems are beginning to appear in some parts of the country where the water supply is limited, such as Southern California. Office buildings may have two water lines coming in—one for "freshwater" and the other for reclaimed water. The former is for all potable uses, the latter for nonpotable uses.

Piping and valves used in reclaimed water systems should be color-coded with purple tags or tape. This minimizes piping identification problems and cross-connection problems when installing systems. Liberal use of warning signs at all meters, valves, and fixtures is also recommended. Note that potable water mains are usually color-coded blue, and sanitary sewers are green. Reclaimed water should be maintained at 10 psi (70 kPa) lower pressure than potable water mains to prevent backflow and siphonage in the event of accidental cross-connection. Although it is feasible to use backflow prevention devices for safety, it is imperative never to connect reclaimed and water piping directly. One additional precaution is to run reclaimed water mains at least 12 in. (30 cm) lower (in elevation) than potable water mains and to separate them from potable or sewer mains by a minimum of 10 ft (3 m) horizontally. Reclamation can be complex when the water supplier and the wastewater utility are not the same. In addition, issues of water ownership are withdrawn from one use to accommodate another.

WASTEWATER TREATMENT AND RECYCLING TECHNOLOGIES

Imram Ali
C.K. Jain
National Institute of Hydrology
Roorkee, India

Due to the continuous population growth, uneven distribution of water resources, periodic droughts, and water pollution, it is very important to develop water treatment and recycling technologies for economic, effective, and fast water treatment and reclamation. Different types of water treatment and recycling techniques and their basic principles, applications, costs, maintenance, and suitability are discussed. In addition, a systematic approach to water treatment and recycling, involving understanding, evaluating, and selecting parameters, is presented. A comparison of the technologies is discussed from the view points of performance, sludge production, life cycle, operation, and maintenance. Brief guidance for selecting appropriate technologies for specific applications is also evaluated.

INTRODUCTION

Water is a very important constituent of the ecosystem on the earth and an essential component of life. The quality of our water resources is deteriorating day by day due to the continuous addition of undesirable constituents to them. The main sources of water contamination are industrial, domestic, and agricultural activities and other environmental and global changes. The groundwater and surface water at many places in the world are not suitable for drinking because of the presence of toxic pollutants. If this continues, the world will be in great trouble in a few decades. Therefore, the importance of water quality preservation and improvement is essential. Continuous population growth, uneven distribution of water resources, and periodic droughts have forced scientists to search for new and effective water treatment and recycling technologies (1). There is a great need for developing suitable, inexpensive, and rapid wastewater treatment and reuse or conservation methods.

In this article, different types of wastewater treatment and recycling techniques and a systematic approach to water treatment and recycling methods are discussed. Technologies are compared in terms of their performance, sludge production, life cycle, operation, and maintenance costs. The main purpose of this article is to provide guidance for selecting appropriate technologies or combinations for specific applications.

WASTEWATER TREATMENT AND RECYCLING TECHNOLOGIES

Water treatment technologies are used for three purposes: water source reduction, wastewater treatment, and recycling. At present, unit operations and processes are combined to provide what are called primary, secondary, and tertiary treatment. Primary treatment includes a very preliminary physical purification process (filtration by bar screen, grit chamber, etc.). Secondary treatment deals with chemical and biological processes for treating wastewater. In the tertiary treatment process, wastewater (treated by primary and secondary processes) is converted into good quality water which can be used for different purposes such as drinking, industrial, and medicinal. In the tertiary process, up to 90 to 99% of the pollutants are removed, and water is safe for the specific use. In a complete water treatment plant, all three processes are combined to produce good and safe quality water.

Despite various advanced technologies for water treatment and reclamation, economic, effective, and rapid water treatment and reclamation on a commercial level is still a challenging problem. Prior to water treatment and reclamation, one should be aware of the qualitative and quantitative nature of water pollutants. Managing the removed pollutants (sludge) should also be kept in mind. A systematic approach to water treatment and recycling technologies involves understanding the technology which includes construction and operating cost, maintenance, and management of removed pollutants. A comparison of these wastewater treatment and reclamation technologies is presented in Table 1. A detailed literature survey of water treatment and recycling technologies has been carried out through analytical, chemical, water abstracts, and other journals, and a brief discussion of them is presented here. Water treatment and recycling technologies classified on the basis of their working principles are given below:

1. physical technologies
2. chemical technologies
3. electrical technologies
4. thermal technologies
5. biological technologies

Physical Technologies

Treatment and recycling technologies involving physical forces are known as physical technologies. These include screening, filtration and centrifugal separation, micro- and ultrafiltration, reverse osmosis, crystallization, sedimentation and gravity separation, flotation, and adsorption.

Screening, Filtration, and Centrifugal Separation. Pieces of cloth, paper, wood, cork, hair, fiber, kitchen refuse, and fecal solids in wastewater are removed by screening. The main idea of screening is to remove solid wastes from wastewater. Generally, screening is used as the very first step in a wastewater treatment plant. Screens of various sizes are used for this purpose, the size of the screen selected is based on the size of the solids in the wastewater.

Table 1. A Comparison of Wastewater Treatment and Recycling Technologies

Wastewater Technologies	Applicability[a]	Suitability[b]	Cost (US$ per Million Liters of Treated Water)

[b] R: reclamation; T: treatment; and Sr: source reduction.
[c] Rarely Used.

Filtration is a very simple physical process in which insoluble contaminants are removed by passing the water through a setup of pores of different sizes, depending on the presence of solid contaminants. It is used to remove suspended solids, greases, oils, and bacteria. Various types of filters such as membranes and cartridges, made of sand, gravel and other granular materials are used. The filtration technique is applicable below 100 mg/L suspended solids and 25 mg/L oil and grease. These constituents can be reduced up to 99%. Filtration is used for both water treatment and recycling. Water produced by filtration is used in adsorption, ion exchange, or membrane separation processes. Potable water is also produced by filtration. The cost of filtration varies from 20 to 450 US$ per million liters of treated water (1,2).

In centrifugal separation, suspended noncolloidal solids (up to 1 μ) are separated from water by centrifugal forces. Wastewater is placed in centrifugal devices and rotated at different speeds, and the solids (sludges) are separated and discharged. The extent of separation of suspended solids depends on their densities and the speed of the centrifuge. The applications include source reduction and separation of oils and greases. The different types of centrifuges available and in use are solid-bowl, basket type, directflow, and countercurrent flow. The cost of wastewater treatment ranges from 20 to 450 US$ per million liters of treated water (1,2).

Micro- and Ultrafiltration. Particles and other microbes from 0.04 to 1 μ are removed by microfiltration provided that the total suspended solids do not exceed 100 mg/L. The filters used are in the form of cartridges. Commercially available cartridges are made of cotton, wool, rayon, cellulose, fiberglass, polypropylene, acrylics, nylon, asbestos, and fluorinated hydrocarbon polymers. These are arranged in as tubular, disc, plates, spiral, and hollow fiber forms. The life of cartridges varies from 5 to 8 years depending upon the concentration of dissolved solids. Preremoval of suspended solids is an important factor in the life of cartridges. The operating pressure in this process ranges from 1 to 3 bar. Applications include removal of solids and microbes. Water purified by this technique is used for the food and drink industries, soft drinks, pharmaceuticals, photofilm processing, swimming pools, and drinking (2,3). It has also been used as a wastewater source reduction technique.

Ultrafiltration is a low-pressure membrane separation process that removes high molecular weight materials, colloids, pyroxenes, microorganisms, and suspended solids from wastewater. Ultrafiltration membranes are manufactured from a wide variety of polymers, and minerals in the range of 0.005 to 0.10 μ. The membranes are made of polysulphonates, polyacrylonitriles, polyamides, PVDF, and zirconium oxides. To achieve the required filtration, membranes are arranged in tubular, disc, plates, spiral, and hollow fiber forms. The life of membranes varies from 5 to 8 years and may be increased as discussed above (2). The cost of treated water varies from 10 to 400 US$ per million liters.

Reverse Osmosis. Reverse osmosis (RO), also known as hyperfiltration, is a classical method of purification that came into existence since the advancement of semipermeable membranes. It has received great attention nowadays as the best water recycling technique. The separation and concentration of a dissolved species is achieved due to the hydraulic gradient across the semipermeable membrane. Pressure greater than osmotic pressure is applied for the process. The most commonly used membranes are made of cellulose, nylon, polyether, polyethyl urea, polyphenyl oxides, phenylenes, and polyamide. To achieve the required filtration, membranes are arranged in tubular, disc, plate, spiral, and hollow fiber forms. The partition coefficients of solutes between water and the membrane play an important role in removing water pollutants. The free energy of interaction between water and membrane sites is also responsible for the RO process. The pH, pressure, size, and molecular weight of the solute and time of operation are considerable factors in RO.

RO has been used as a separation and concentration technique at macro- and microlevels for removing large, nonpolar, ionic, and toxic substances. Up to 85–99% total dissolved solids (TDS), organic dissolved matter (ODM), and bacteria can be removed by this method. It has been used for treating wastewater from sanitary wastes, municipal leachates, petrochemicals, electroplating, textiles, coal, gasification, pulp and paper, steel, and electronic industries (3,4). It rejects 100% of bacteria, viruses, and other microbes, and, therefore, it is used to prepare ultrapure water for pharmaceuticals, medicines, and electronics. In addition, it has been used for source reduction. RO is today's most economical process for potable water production from saline water.

The life of RO membranes is 2–5 years, depending on the nature of the wastewater treated. The flux and the quality of the permeate may decrease over a long period of time due to membrane fouling from humic acids, bacterial slimes, or scales that may accumulate on the RO membranes. Phenols also clog the membranes. To increase the efficiency and life of RO systems, pretreatment is necessary to minimize the concentration of colloidal and dispersed solids. Physicochemical coagulation with lime has been used to minimize colloids, turbidity, dispersed oil phases, metal ions, and suspended matters. Sodium hydroxide solution (pH 9–11) has been used to clean RO membranes in case of silica and sulfate fouling (5,6). Silica can also be removed from membranes by ion retarding resins that have high affinity for strong acids, together with conversion of the weak acid [$Si(OH)_4$] into much stronger acid (H_2SiF_6). Bacterial inhibitor solutions are circulated (to check the bacterial growth) into the RO tubules or discs before stopping the process for a long period (5). Phenolics may be removed from RO membranes by circulating hydrogen peroxide solution. The cost of the process varies from 10 to 450 US$ per million liters of treated water.

Crystallization. In this process, soluble constituents are removed by raising their concentrations to the point where they start to crystallize. This is done either by evaporation, by lowering the temperature of the water, or by adding other solvents. It is useful for treating wastewater that has high concentrations of TDS, including soluble organics and inorganics. During the process, other constituents such as bicarbonate, ammonia, and sulfite may break down and may be converted into various gases and, therefore, crystallization sometimes may be used for pH control. The treated water from this process is of high quality. Crystallization is generally used for wastewater released from cooling towers, coal and gas fired boilers, paper, and dyeing plants. It is also used for source reduction. The commonly used devices for crystallization include forced circulation, draft tube baffle, surface cooled crystallizers, and fluidized suspension. The cost of the technique ranges from 50 to 150 US$ per million liters of treated water (3,7).

Sedimentation and Gravity Separation. In this process, suspended solids, grit, and silt are removed by allowing water to remain undisturbed/semidisturbed for different time periods. The suspended solids settle by gravity (1,2). The time period depends on the size and density of the solids. Various types of tanks are designed for this purpose. Some chemicals such as alum are used to adjust pH and augment the process. Gravity separation can reduce oil concentrations and suspended solids up to 99% and 60%, respectively. Generally, sedimentation is carried out prior to a conventional treatment process. It is a very useful method for treating effluents from the paper and refinery industries. Water treated in this process is used for industrial water supply, water for ion exchange, and membrane processing. The technique is also used for source reduction. The cost of treated water varies from 2 to 10 US$ per million liters.

Flotation. This technique removes suspended solids, oils, greases, and biological solids by adhering them, to air or gas bubbles (1,2,8). The solids thus adhered to gas or air bubbles form agglomerates, which in turn accumulate at the water surface and are removed. Some chemicals such as alum and activated silica help in the flotation process. Compressed air is allowed to pass through water, which helps in the flotation process. Some workers have also used electroflotation as an effective process for water treatment and recycling. Up to 75% and 99% of suspended solids and oil/grease are removed, respectively, by this process. Flotation requires water tanks of different sizes. Flotation is a common and essential component of a conventional water treatment plant. It is a very effective technique for treating wastewater from the paper and refinery industries. The cost of the operation varies from 5 to 25 US$ per million liters of treated water.

Adsorption. Adsorption (1,2,9) is a surface phenomenon defined as the increase in concentration of a particular component at the surface or interface between two phases. Adsorption efficiency depends on a number of parameters such as pH, temperature, concentration of pollutants, contact time, particle size of the adsorbent, and nature of adsorbents and pollutants. Suspended particles, oils, and greases reduce the efficiency of the process and, therefore, pre-filtration is required. It is considered a universal water treatment and reclamation process because it can be applied to remove soluble and insoluble organics, inorganics, and biological solids. Different types of adsorbents are used in the adsorption process. The most commonly used adsorbents are activated carbon, fly ash, metal oxides, zeolites, moss, biomass, and geothites. At the industrial level, pollutants are removed from wastewater by using columns and contactors filled with the required adsorbents. The extent of removal varies from 90 to 99%. Adsorption is used for source reduction, wastewater treatment, and reclamation for potable, industrial, and other purposes. The basic problems of adsorption are regeneration of columns and column life. The cost of the technique ranges from 50 to 150 US$ per million liters of treated water.

Chemical Technologies

Water treatment methods involving the use of chemicals are chemical technologies. Precipitation, coagulation, oxidation, ion exchange, and solvent extraction are the main chemical methods for wastewater treatment and reclamation.

Precipitation. Dissolved contaminants may be converted into solid precipitates by adding chemicals (2,10) that react with the soluble pollutants and form precipitates. The most commonly used chemicals for this purpose are different types of alum, sodium bicarbonate, ferric chloride, ferric sulfate, ferrous sulfate, and lime. pH and temperature are the controlling factors in the precipitation process. Precipitation is carried out in sedimentation tanks; 40 to 60% removal of pollutants by precipitation has been reported. The presence of oil and grease may cause a problem in precipitation. The applications of precipitation include wastewater treatment (from nickel and chromium plating) and water recycling. Specific applications include water softening and removal of heavy metals and phosphate from wastewater. The major problem in precipitation is managing the large volume of sludge produced. The cost varies from 15 to 500 US$ per million liters of treated water.

Coagulation. The suspended nonsettleable solids in wastewater are allowed to settle by the addition of certain chemicals in a process called coagulation (1,11). The commercially available chemicals are alum, starch, iron compounds, activated silica, and aluminum salts. In addition, synthetic cationic, anionic, and nonionic polymers are very effective coagulants but are usually more costly. pH, temperature, and contact time are the most important controlling factors in the coagulation process. In a biological treatment plant, microbes and other organics floated on the surface are removed by the addition of certain coagulants. It is the main component of a wastewater treatment plant and its application includes wastewater treatment, recycling, and removal of heavy metal ions and fluoride. The cost of the treated water varies from 20 to 500 US$ per million liters.

Oxidation. In chemical oxidation, organic compounds are converted into water and carbon dioxide or some other products such as alcohols, aldehydes, ketones and carboxylic acids which are biodegradable (1,12). Chemical oxidation is carried out by potassium permanganate, chlorine, ozone, peroxides, air, and chlorine dioxides. The rate of chemical oxidation depends on the nature of the oxidants and pollutants. pH, and temperature also play a crucial role in the rate of chemical oxidation. Ammonia, cyanide, sulfides, phenols, hydrocarbons, and some pathogens may be removed by chemical oxidation. Chemical oxidation is used for wastewater treatment and recycling for industry and irrigation. It is also a useful and effective method for source reduction. The cost of the technique ranges from 100 to 2000 US$ per million liters of treated water.

Ion Exchange. Ion exchange is a process in which ions in wastewater are exchanged with solid materials called ion exchangers (1,13). It is a reversible process and requires low energy. The ion exchangers are of two types, cation and anion exchangers, that can exchange cations and anions, respectively. Ion exchangers are resins of natural or synthetic origins that have active sites on their surfaces and, generally, are in the form of beads. The most commonly used ion exchangers are sodium silicates, zeolites, polystyrene sulfonic acid, acrylic and methacrylic resins. Ion exchange is used to remove low concentrations of inorganics and organics (up 250 mg/L). The concentration of organics and inorganics can be reduced up to 95%. Applications include the production of potable water, water for industries, pharmacy, research, and softening for boiler feed, fossil fuels, nuclear power stations, paper, and, electronic industries. It has also been used for source reduction. Pretreatment of water is required in the presence of oil, grease, and high concentrations of organics and inorganics. One million liters of wastewater are treated for 50 to 200 US$.

Solvent Extraction. Organic solvents that are immiscible with water and can dissolve water pollutants are added to wastewater to remove pollutants. The technique is called solvent extraction (14). A maximum concentration of TDS of 2000 mg/L can be reduced up to 90% by solvent extraction. The most commonly used solvents are benzene, hexane, acetone, and other hydrocarbons. The technique is effective to remove only the dissolved organics, oils, and greases in wastewater. However, certain metal ions and actinide chemicals may be removed by the method. It is also used for water treatment and recycling in chemical process plants, phenol, gasoline, and acid industries. It has also been used for water source reduction. The presence of suspended solids may cause a problem in solvent extraction and, hence, requires pretreatment. The cost varies from 250 to 2500 US$ per million liters of treated water.

Electrical Technologies

Water pollutants are removed under the influence of electric current in electrical water treatment and recycling technologies. Electrical water treatment technologies are summarized below.

Electrodialysis. In this technique, water soluble ions are allowed to pass through ion selective semipermeable membranes under the influence of an electric current (1–3,15). The ion selective membranes are made of ion exchange material. They may be cation and anion exchangers, which permit outflow of cations and anions, respectively. The process, operated either in a continuous or batch mode, has two electrodes on which an emf. is applied. To obtain the desired degree of demineralization, membranes are arranged either in parallel or series. The dissolved solids removal depends on pH, temperature, the amount of current applied, the nature of the pollutants, selectivities of the membranes, the wastewater flow rate, fouling and scaling by wastewater, and the number and configuration of stages. Applications include production of potable water from brackish water. This technique has also been used for water source reduction. A maximum concentration of 200 mg/L of TDS can be reduced by 90% by electrodialysis. Membrane fouling occurs as in reverse osmosis. Cleanup and other precautions should be taken as discussed in the reverse osmosis section. The cost of treated water varies from 10 to 400 US$ per million liters of water.

Electrolysis. The technique in which the soluble inorganics and organics are either deposited or decomposed on the surface of electrodes by an electrochemical redox reaction is called electrolysis (16). Metal ions are deposited on the electrode surface, and organics are decomposed into carbon dioxide and water or some other products. It has been used to remove turbidity and color from wastewater. This method is effective for the removal of TDS below 200 mg/L and, therefore, requires pretreatment of wastewater. The technique comprises a water tank or tanks in series with two or a series of electrodes of the required metal. The electrodes are specific with respect to the dissolved metal ions in wastewater. The most important controlling factors for this process are pH, temperature, amount of current applied, and contact time. Electrolysis as a technique for wastewater treatment is not yet developed completely and is still at the research and development stage. It has been rarely used commercially for wastewater treatment. However, its applications include treating some industrial effluents especially enriched with metal ions and some organics. It may be used as a water source reduction technique. The advantages of this technique comprise the further use of deposited metal ions without any waste management problem.

Thermal Technologies

Techniques involving the use of heat energy for water treatment and recycling are thermal technologies. The most commonly used techniques for wastewater treatment and recycling are evaporation and distillation.

Evaporation. Evaporation is a natural process and is generally used to reduce waste liquid volume. In modern development, it has been used as a water treatment method (2,3,17). The water surface molecules escape from the surface under natural conditions, and these escaped molecules are collected as pure liquid water. Mechanical evaporators have been used for water recycling. Sometimes, vacuum evaporation has been used for wastewater recycling, and these are operated by steam or electric power. Evaporation is effective for removing inorganic and organic (except volatile organics) contaminants, and it works even at very high concentrations (about 10%) of pollutants. Foaming, scaling, and fouling along with suspended solids and carbonates are the major problems in evaporation because they create maintenance problems. Evaporation applications include treating wastewater from the fertilizer, petroleum, pharmaceutical, and food processing industries. It is also used for water supply to ion exchangers and membrane processes. Water from evaporation has been used for cooling in towers and boilers. It can be used as a technique for water source reduction. The cost of water production varies from 10 to 200 US$ per million liters.

Distillation. In distillation, water is purified by heating it up to 100 °C at which liquid water vaporizes and leaves the pollutants behind (1,18). The vapors generated are cooled to liquid water. The wastewater should be free of volatile impurities. Water produced by this technique is about 99% free from impurities. Various types of boilers with multistage and double distillation are used in this process. The size of the boilers depends on the quantity of water required. Applications of distillation in water treatment and reclamation include water supplies in laboratories, pharmacy, and medicinal preparations. Distillation is effective for preparing potable water from sea and brackish water. The cost of water production varies from 10 to 2000 US$ per million liters.

Biological Technologies

Biological treatment has a reputable place in various water treatment and recycling methods (1–3,19,20). Soluble and insoluble organic pollutants are oxidized by microbes in this process. Water is circulated in a reactor that maintains a high concentration of microbes, and the microbes convert organic matter into water, carbon dioxide, and ammonia. Sometimes, the organic matter is converted into other products such as alcohol, glucose, and nitrate. Wastewater should be free of toxic organics and inorganic pollutants. The maximum concentrations of TDS, heavy metals, cyanides, phenols, and oil should not exceed 16,000, 2.0, 60.0, 140, and 50 mg/L, respectively. Biological treatment includes aerobic and anaerobic digestion of wastewater. The cost of Biological treatment varies from 10 to 200 US$ per million liters of treated water.

Aerobic Process. When air or oxygen in dissolved form is available freely to wastewater, then the biodegradable organic matter undergoes aerobic decomposition, caused by aerobic and facultative bacteria. The extent of the process depends on oxygen availability, retention time, temperature, and the biological activity of the bacteria. The rate of biological oxidation of organic pollutants may be increased by adding chemicals required for bacterial growth. The technique is effective for removing dissolved and suspended volatile and nonvolatile organics. The concentration of biodegradable organics can be reduced up to 90%. Applications include treating industrial wastewater to reduce BOD, COD, nitrogen, and phosphorous. The disadvantage of this method is the production of a large quantity of biosolids, which require further costly management.

Anaerobic Process. If free or dissolved oxygen is not available to wastewater, then anaerobic decomposition called putrefaction occurs. Anaerobic and facultative bacteria convert complex organic matter into simpler organic compounds of nitrogen, carbon, and sulfur. The important gases evolved in this process are nitrogen, ammonia, hydrogen sulfide, and methane. The applications of the anaerobic process to organic pollutant digestion are as discussed in the aerobic process.

CONCLUSION

There is a scarcity of safe and good quality water at present, and it will become more problematic in the near future. Wastewater treatment technologies differ from each other in terms of their principles, scope of application, speed, and economy. All techniques of primary and secondary treatment processes have their own importance and are essential. Therefore, no comparison can be done, whereas wastewater recycling technologies (tertiary treatment) can be compared. The feasibility of any water recycling technique at a commercial level depends on the costs of construction, maintenance, and operation. Sludge management is also an important factor in the selection of technology. Adsorption is considered the best and a universal technique, and it can be used to remove a wide variety of pollutants. It is also a rapid process with a very low cost of construction, maintenance, and operation using low cost adsorbents. Reverse osmosis is also used widely because the water quality is good but the costs of construction and maintenance are comparatively high, and it is rarely used in developing countries. Beside these two, other techniques such as micro- and ultrafiltration, ion exchange, electrodialysis, solvent extraction, and distillation are used for specific purposes, but their use is restricted at potable and industrial levels. Electrolysis as a water recycling technique is in its development stage, and hopefully it will be the best technique on a commercial scale in terms of its cost, maintenance, and speed. The advantages of this technique are a wide range of applications.

WASTEWATER TREATMENT PROCESSES AND WATER REUSE

Kevin S. McLeary

Environmental Protection
Harrisburg, Pennsylvania

TREATMENT PROCESSES

The selection of wastewater treatment processes depends on the influent characteristics, the quality of effluent required, and the cost. Treatment can be divided into these stages: preliminary, primary, secondary, and advanced treatment.

Preliminary Treatment Processes

The objective of preliminary treatment is to prepare wastewater for further treatment by removing large objects and grit from the wastewater. These materials may otherwise impede the efficiency or increase the maintenance of downstream processes. Typical preliminary treatment may include screening, grit removal, comminution, and flow equalization.

Screening. Screening removes large objects and trash that could interfere with, clog, or damage downstream equipment, such as pumps, valves, actuators, mechanical aerators, and biological filters. Bar screens typically consist of inclined steel bars spaced at equal intervals in a channel through which the wastewater flows. Large solids are removed from the wastewater by the bars, which must be cleaned either manually or mechanically. Due to their putrescible nature, screenings are usually landfilled. When designing bar screens, bar size, bar spacing, angle of inclination, and wastewater approach velocity must be considered (1).

Manually cleaned screens usually have bar spacings ranging from 1 to 2 inches, and the bars are inclined from 30° to 45° to the horizontal (1). The screens are cleaned by raking the screenings onto a sieve plate to allow for drainage.

Mechanically cleaned screens typically have bar spacings ranging from 0.5 to 1.5 inches and are inclined from 0° to 30° from the vertical (1). The screen automatically starts the cleaning process after a preprogrammed operating time but also has a high-level override.

Grit Removal. Grit consists of sand, gravel, and other non- or minimally putrescible material that may wear mechanical equipment or accumulate in process tanks. Grit has a high settling velocity and settles quickly (1). Grit chambers are frequently aerated, which keeps the light organic materials in suspension and allows the heavy grit particles to settle to the bottom of the tank to be collected (1).

Comminution. Comminutors shred materials without removing them from the wastewater. Comminutors have a bypass channel and a screening device that may be used if the comminutor must be taken out of service (1). The basic parts of a comminutor include a screen and cutting teeth on a revolving drum. The drum has slots cut into it. The teeth shred the material as it is trapped against the screen. The shredded solids then pass through the drum slots and out of the bottom opening through an inverted siphon (2). Shredded materials cause problems in downstream process units, so comminutors are not frequently installed in new wastewater treatment plants (1).

Equalization. Equalization is used in plants that have significant variations in hydraulic or organic loading. It provides relatively uniform loading throughout the day. Uniform loading increases the efficiency and reliability of downstream process units. In addition, the downstream treatment units no longer have to treat highly variable influent, so the sizes of the units may be decreased (1).

Equalization tanks may be designed either as in-line or side-line units. The sizing should be based on an influent flow hydrograph during wet weather. To prevent detained wastewater from becoming septic, a dissolved oxygen concentration of 1 mg/L must be maintained in the tank (3). Equalization tanks should be mixed to prevent solids from settling.

Primary Treatment Processes

Sedimentation. Primary sedimentation is the oldest and most widely used operation in treating wastewater (1). It removes solids to produce an effluent that is suitable for downstream biological treatment.

Solids removal is governed by retention time and surface settling rate. The surface settling rate is the volumetric flow rate over the surface area of the clarifier. Particles whose settling velocity is greater than the surface settling rate are removed from the wastewater stream. However, if the detention time is too long, the wastewater turns septic.

Clarifier design is based on the average design flow and the peak hourly flow. Flows are generally limited to 1000 gallons per day/ft^2 for design flow and 1500 gpd/ft^2 at peak hourly flow (3). The calculated settling area is based on both flows, and the larger clarifier is selected.

Secondary Treatment Processes

Activated Sludge Processes. Activated sludge is a biological process that uses microorganisms to treat wastewater in an aerobic environment. Wastewater is introduced into the reactor tank where it is mixed with microorganisms that are returned from the clarifier. This mixture of raw wastewater and return activated sludge is called mixed liquor. The microorganisms are then allowed to flocculate and settle under quiescent conditions in a clarifier; treated wastewater flows over weirs for further treatment or discharge. There are several variations on the conventional activated sludge process, including plug flow, step feed, tapered aeration, complete mix, contact stabilization, sequencing batch reactor, and extended aeration.

Plug Flow. A plug flow reactor is configured so that the wastewater flows through a long, narrow channel during treatment. It approximates flow through a pipe. In an ideal plug flow reactor, there is no longitudinal mixing of wastewater.

Step Feed. Step feed is a variation of the plug flow reactor. In this variation, the wastewater influent is introduced into the reactor at several points, rather than adding the entire influent stream at the beginning of the reactor. It provides equalization of the load over the reactor volume.

Tapered Aeration. Tapered aeration is another variation on the plug flow reactor. The reactor influent is introduced at the front end of the reactor, but the aeration pattern is different. Approximately 50% of the aeration capacity is in the first third of the reactor, where the oxygen demand is the highest, and less is supplied further down the reactor, where the demand is less.

Complete Mix. A complete mix reactor is the opposite of a plug flow reactor. All of the wastewater is completely mixed throughout the reactor. To facilitate mixing, complete mix reactors are shorter and wider than plug flow reactors. Due to the rapid mixing of the contents, complete mix reactors can tolerate shock loads better than plug flow reactors.

Contact Stabilization. Contact stabilization is a process where treatment takes place in two tanks. The wastewater is introduced into the contact tank with microorganisms. The organics are not degraded in the contact tank but are absorbed into the microbial cells. After clarification, the settled sludge is returned to a reaeration tank, where the microorganisms then degrade the organics that were absorbed during the contact process.

Sequencing Batch Reactor. A sequencing batch reactor is a variation of the complete mix reactor. Both wastewater stabilization and settling take place in the same tank in sequenced phases. Wastewater is introduced into the tank (fill phase), where it is mixed and aerated. Following a "react phase," both mixing and aeration are turned off, and the wastewater is allowed to settle quiescently (settle phase). The treated wastewater is then decanted from the top of the reactor (decant phase), and the sequence begins again.

Extended Aeration. The extended aeration process is a suspended growth system that operates in the endogenous respiration phase of microbial growth. This process requires low organic loading rates, long aeration times, and high mixed liquor concentrations. This process is commonly used in prefabricated package treatment plants for small communities.

Aeration Requirements. The dissolved oxygen concentration in the aeration tanks should be greater than 2 mg/L at all times. To supply sufficient air for treatment, all of the treatment processes except extended aeration should be designed to provide 1.1 lb of oxygen per pound of biochemical oxygen demand (BOD) oxidized. Because of the additional aeration needs of endogenous respiration, extended aeration systems require 1.5 lb of oxygen per pound of BOD oxidized. This does not include the air required for nitrification (3).

Fixed Film Processes. Fixed film processes are biological treatment processes using microorganisms attached to a support medium. As the wastewater flows over the medium, the microorganisms absorb the organics. The biofilm builds up, as wastewater is treated, and eventually sloughs off. Like activated sludge, the sloughed microorganisms are then allowed to settle under quiescent conditions in a clarifier.

In a trickling filter, the wastewater flows through a rotating arm, which distributes it over the top of the medium. To maintain proper liquid flow for efficient operation of the filter, a portion of treated wastewater must be recirculated back to the filter.

In a rotating biological contactor, microorganisms are attached to a plastic disk, which is rotated through the wastewater. When the microorganisms are submerged, they absorb organics. During the time the microorganisms are exposed to the air, they receive the oxygen that they require for treatment. Unlike trickling filters, however, no recirculation is required.

Stabilization Ponds. Stabilization ponds are typically large, lined basins, which may be aerobic, anaerobic, or facultative. Ponds are designed around a detention time measured in days, rather than hours, and are relatively shallow compared with other biological treatment processes. These design criteria mean that a large land area is required for ponds, and they are usually used only in small communities. Their advantages include low construction and operating costs.

Advanced Treatment Processes

Nitrification. Ammonia nitrogen is converted to nitrate in a two-step process. Ammonia is first converted to nitrites, and the nitrites are then converted to nitrates. This conversion is oxygen intensive. For each milligram of ammonia converted to nitrate, 4.6 mg of oxygen is required. In addition, each milligram of ammonia converted consumes 7.14 mg of alkalinity (4).

Nitrification may occur in the same tank as carbon oxidation in a single sludge process, or it may take place in a separate nitrification tank. Because nitrifying organisms have a slower growth rate than the organisms for carbon oxidation, the process requires longer detention time and longer mean cell retention time.

Biological Phosphorus Removal. Phosphorus removal can be enhanced in a biological system by first creating an anaerobic zone followed by an aerobic zone. In biological phosphorus removal, from 2.5 to 4 times more phosphorus can be removed than in a secondary treatment process (4).

To generate energy for cell growth in the anaerobic stage, phosphorus is released from the internal polyphosphates of the cell, resulting in an increase in the liquid phosphorus concentration (3). In the aerobic zone, there is a rapid uptake of the soluble phosphorus for the resynthesis of intracellular polyphosphates. More phosphorus is absorbed by the cells than was released in the anaerobic zone.

There are three major biological phosphorus removal methodologies: the Anaerobic/Oxic (A/O) process, the PhoStrip process, and the sequencing batch reactor. The A/O process is proprietary, and phosphorus removal depends on the influent ratio of BOD to P. The PhoStrip process is also proprietary. Phosphorus removal does not depend on the BOD:P ratio, but chemicals must be used to precipitate the phosphorus (4). The SBR can be designed to provide anaerobic conditions during the treatment cycle, which release phosphorus. When the reactor is then aerated, the phosphorus is absorbed from the wastewater and is incorporated into the biomass.

Denitrification. Denitrification is the removal of nitrogen from wastewater. In an anoxic environment, several species of bacteria can use nitrates, rather than oxygen, as their energy source. Denitrification converts the nitrates into nitrogen gas and additional biomass (4). The process requires a carbon source for completion. In wastewater treatment, it is common to use the wastewater itself for the carbon supply. The raw wastewater flows into an anoxic zone with return sludge and a large mixed liquor recycle. The recycle ratio is determined by the ammonia concentration and the required effluent nitrate concentration. The anoxic zone then denitrifies by using the nitrates created in the mixed liquor. Following the anoxic zone, the wastewater flows to an aerobic zone to strip nitrogen gas. The process may be repeated for additional nitrogen removal. Denitrification is normally done in a plug flow type system, an oxidation ditch, or a sequencing batch reactor (4).

Biological Dual-Nutrient Removal. Biological dual-nutrient removal is the reduction of both nitrogen and phosphorus in wastewater by biological methods. Biological dual-nutrient removal is achieved through several proprietary treatment processes, including the A^2O process, the Bardenpho process, the University of Capetown (UCT) process, and the Virginia Initiative (VIP) process (4). These processes use the aerobic process for carbon oxidation, the anoxic process for denitrification, and the anaerobic process for biological phosphorus removal, although arrangement of the processes varies. The UCT process and the VIP process are further complicated by the use of internal recycle streams.

Air Stripping. Air stripping is a method of removing volatile compounds from a solution. Air is introduced at the bottom of a packed tower. Wastewater flows down the tower from the top and contacts the air countercurrently. The driving force in air stripping is the concentration difference between the air and the wastewater. The tower medium may become fouled, resulting in high operating and maintenance costs.

Coagulation/Sedimentation. Coagulation/sedimentation uses chemicals to enhance the sedimentation of solids, precipitate pollutants, or remove phosphorus. The chemicals most commonly used in the coagulation/sedimentation process are lime, alum, iron salts, and polymers (2). Coagulation involves destabilizing colloidal particles through any of several processes, including double layer compression, charge neutralization, enmeshment, or interparticle bridging (5). The particles then aggregate and settle out.

Alum is typically used in the chemical removal of phosphorus, although iron salts may also be used. Phosphorus removal occurs by the formation of an insoluble precipitate of aluminum or iron phosphate. Alum and iron also react with hydroxyl radicals in the water, forming hydroxides in addition to phosphates.

Filtration. Filtration is the removal of wastewater solids by passing the wastewater through granular media. Some of the media that have been used include sand, anthracite coal, diatomaceous earth, perlite, and granular activated carbon. Sand filters are the most commonly used filters in wastewater treatment, although filters can also consist of multiple types of media, such as coal over sand or coal over silica sand over garnet sand (5).

Particles may be removed by interstitial straining. However, smaller particles must be transported to the surfaces of the media, where an attachment mechanism retains the particles. Transport mechanisms may include gravitation, diffusion, and interception. These processes depend on the physical characteristics of the media. The attachment mechanism may include electrostatic attraction, chemical bridging, or adsorption. These processes are functions of the coagulant and the chemical characteristics of the wastewater and media (5).

Filters are classified as slow filters, rapid filters, or pressure filters. Slow filters require a buildup of solids on the top surface of the filter through which the wastewater must pass, which requires a low application rate. This buildup strains particles from the wastewater. Rapid filters and pressure filters use the entire depth of the media and may be operated at higher loadings than slow filters.

Activated Carbon Adsorption. Adsorption is a process where molecules of a compound adhere to a solid surface. The most commonly used adsorbent in wastewater treatment is activated carbon. Activated carbon comes in two forms, powdered and granular. Powdered activated carbon (PAC) is added to the mixed liquor in the aeration tanks and is removed from the wastewater by settling. Granular activated carbon (GAC) is used in a packed bed (2).

The adsorptive capacity of the carbon is a function of the material and method used to create the activated carbon as well as the chemical properties of the compound to be adsorbed. In general, organics are completely removed until the adsorptive capacity is exhausted. At this point, the effluent concentrations increase (2). Spent activated carbon may be regenerated by heating.

Membrane Systems. Membrane processes use a semipermeable barrier that allows the water to flow through but retains the contaminants. There are several types of membrane systems in wastewater treatment, including reverse osmosis, nanofiltration, microfiltration, and ultrafiltration. All of these processes use pressure to force water through the membrane.

Ultrafiltration may be used to remove molecules that have a molecular weight of 500 or greater and have a low osmotic pressure at moderate concentrations. This includes bacteria, viruses, proteins, and clays (5). Reverse osmosis is used to separate small molecules whose osmotic pressure is high. Microfiltration and nanofiltration are membrane systems that lie between ultrafiltration and reverse osmosis.

Membrane processes are subject to fouling of membranes. These processes should be pilot tested to determine which process and membrane work best for any given application.

Disinfection Processes

Chlorination/Dechlorination. Chlorine has been used as a disinfectant for many reasons, including inactivation of a wide range of pathogens, maintenance of a residual, and cost. As chlorine dissolves in water, it forms hypochlorous acid, which dissociates into hypochlorite ions and hydrogen ions and decrease the pH. Lower pH values cause less dissociation, which is preferable, because hypochlorous acid is a much more effective disinfectant than hypochlorite. Sodium and calcium hypochlorites also form hypochlorous acid when dissolved, but they also liberate hydroxyl ions, and thus increase the pH of the wastewater. Chlorine is toxic, so dechlorination may be required, which is usually done by using sulfur dioxide to reduce the chlorine to chlorides. Sodium metabisulfite or sodium bisulfite may be used instead of sulfur dioxide in small facilities. The reactions are nearly instantaneous, and detention times are less than 2 minutes.

Ozonation. Ozone is a powerful oxidant that can disinfect wastewater using less contact time and lower dosages than other chemical methods. It has high germicidal efficiency against a wide range of organisms, and it does not leave a residual (6). Because of its instability, ozone must be generated on-site. Ozone is applied to wastewater in closed contactors. The off-gas from the contactors contains high concentrations of ozone, which must be destroyed before it is discharged to the atmosphere.

Ultraviolet Light Disinfection. Ultraviolet light is a form of electromagnetic radiation at wavelengths of 100–400 nm. Electromagnetic radiation at wavelengths from 240–280 nm inactivates microorganisms by damaging their nucleic acid (6). Ultraviolet lamps operate in much the same way as fluorescent lamps. The UV radiation is generated by passing a current through mercury vapor. The mercury lamps may be low-pressure or medium-pressure lamps. Low-pressure lamps emit most of their energy at a wavelength of 253.7 nm, which is in the optimal range. Medium-pressure lamps generate a lesser portion of their energy in the optimal range, but the intensity of the radiation is much greater than that of the low-pressure lamps, and fewer lamps are required (6).

REUSE

Types of Reuse Applications

Urban Reuse. Reclaimed wastewater may be used in an urban setting to irrigate public parks, recreation areas, and residential landscaping (7). Some water codes even consider the use of potable water for landscape irrigation as “a waste or an unreasonable use of such water” when reclaimed water is available (2). Other urban uses include fire protection, dust control for construction activities, and concrete production. The water for urban reuse activities is obtained from a dual distribution system (one for potable water and one for reclaimed water) (7). Reclaimed wastewater may also be used inside buildings for toilet flushing (2).

Industrial Reuse. Reclaimed water can be used in industrial activities, for cooling water (once-through or recycled), industrial process water (tanning, textiles, pulp and paper manufacturing), and boiler feed water. Recycled cooling water must be of higher quality than once-through cooling water because evaporation concentrates pollutants. Industrial process water quality depends on the quality of the product. Higher quality products require higher quality process water. High-pressure boilers require nearly pure water, whereas lower pressure boilers may be able to operate with less pure water (7). Potential problems in the industrial reuse of wastewater include mineral scaling and biological growth (4).

Agricultural Irrigation. Reclaimed water includes nutrients, such as nitrogen and phosphorus, which are used by plants. Reclaimed water also includes valuable trace elements that are vital to plant growth at low concentrations. Salinity is the most important factor in agricultural irrigation (7). As soil salinity increases, plants expend more energy to adjust the salt concentration within their cells, and less energy is available for plant growth. Soil salinity increases as a function of evapotranspiration (4). The ability of plants to tolerate salinity varies widely, from sensitive plants such as citrus fruits and berries to tolerant crops, such as barley and cotton. Salt is especially detrimental to plants at the germinating and seedling stages. Salinity may be decreased by leaching or the overapplication of wastewater to carry away excess accumulated salt (7).

Habitat Restoration/Enhancement and Recreational Reuse. These uses typically include wetlands, recreational impoundments, stream augmentation, and snowmaking. Wetlands serve valuable functions, such as flood attenuation, wildlife and waterfowl habitat, aquifer recharge, and water quality enhancement. Recreational impoundments can serve noncontact uses, such as water hazards on golf courses; human contact activities, such as fishing, boating, and swimming; and the manufacture of snow for skiing. The quality of reclaimed water for contact activities must be higher than that for noncontact uses (7).

Groundwater Recharge. Groundwater can be recharged by surface irrigation or subsurface injection. Subsurface injection may require a higher degree of treatment because water does not receive the benefit of additional treatment by surface soils. Groundwater recharge applications are often used to establish barriers to saltwater intrusion in coastal areas, to provide additional treatment for later reuse, to augment aquifer levels, to provide water storage, and to prevent or control the subsidence of soils (7). Other types of reuse, such as agricultural or landscape irrigation may also provide additional benefits by recharging groundwater (4).

Table 1. Suggested Treatment

Type of Use	Recommended Degree of Treatment
Urban	
Landscape irrigation, fire protection	Secondary, filtration, disinfection
Restricted access irrigation	Secondary, disinfection
Construction	Secondary, disinfection
Industrial Reuse	
Industrial cooling, once-through	Secondary
Industrial cooling, recirculated	Secondary, disinfection
Agricultural Irrigation	
Food products, not commercially processed	Secondary, filtration, disinfection
Food products, commercially processed	Secondary, disinfection
Nonfood products	Secondary, disinfection
Habitat Restoration/Recreational	
Recreational impoundments	Secondary, filtration, disinfection
Landscape impoundments	Secondary, disinfection
Environmental (wetlands, stream augmentation)	Secondary, disinfection
Groundwater Recharge	
Surface irrigation	Primary
Subsurface injection	Secondary
Augmentation of Potable Supplies	
Indirect reuse, aquifer spreading	Secondary, disinfection
Indirect reuse, aquifer injection	Secondary, filtration, disinfection, advanced
Indirect reuse, surface augmentation	Secondary, filtration, disinfection, advanced

Augmentation of Potable Supplies. Potable supplies may be augmented by either direct or indirect methods. Direct potable reuse is objectionable and is used only in one installation in the world, in Windhoek, Namibia, and there it is used only intermittently. Indirect reuse may involve the discharge of treated effluent into a body of water upstream of a water intake. The effluent may then be further treated by natural processes and by dilution. Indirect use may also involve applying effluent to groundwater by surface irrigation or subsurface injection, where the wastewater is further treated by the soil and aquifer before being withdrawn for potable uses (7).

Treated Effluent Characteristics. The quality of the effluent required depends on the use of the wastewater. For stream discharges or applications that are not being used for drinking water or in public contact areas, secondary treatment may be all that is required. However, for more sensitive uses, such as water that will eventually be used for potable water supplies, for high-quality industrial applications, or for uses where there will be significant human contact, advanced treatment may be required.

Note that there are no national treatment standards for reuse applications. Different jurisdictions may have different treatment requirements, depending on use. EPA has recommended degrees of treatment for various applications, as shown in Table 1 (7).

WASTEWATER RECLAMATION AND REUSE RESEARCH

Jorg E. Drewes
Colorado School of Mines
Golden, Colorado

Water reclamation is the treatment of wastewater to make it reusable. Water reuse is the beneficial use of the treated water and can serve either nonpotable or potable applications (1). Nonpotable water reuse includes all water applications other than augmenting drinking water supplies. Nonpotable reuse is occurring as agricultural and landscape irrigation, recreation, wildlife habitat maintenance (stream-flow augmentation), in-building applications (such as toilet flushing), industrial cooling, and groundwater recharge. Potable water reuse refers to the use of highly treated reclaimed water to augment drinking water sources. Direct potable reuse, where reclaimed water after advanced treatment is piped directly into the potable water system, is limited to rare cases. For indirect potable reuse, reclaimed water can either be discharged into a surface water or infiltrated into the subsurface to augment, in part, a drinking water supply source. Infiltration into the subsurface can be accomplished by either direct injection into the aquifer or by surface spreading which provides additional soil–aquifer treatment (SAT) when water percolates through the subsurface. The majority of research activities in wastewater reclamation and reuse reflects the main concerns about potable and nonpotable water reuse, such as (1) protection of public health, (2) reliable treatment of wastewater to meet strict water quality requirements for the intended reuse, and (3) gaining public acceptance (1,2).

WATER REUSE RESEARCH TO PROTECT PUBLIC HEALTH

The majority of research activities in water reuse has been conducted on health effects which can be classified as direct effects, indirect effects, and issues related to the aesthetic quality of reclaimed water (3,4). Figure 1 illustrates health effects related to water reuse.

Direct and indirect health effects that might occur from consumption of pathogens (including enteric viruses, parasites, and enteric bacteria) and organic and inorganic chemicals in reclaimed water could be manifested via short-term exposure and acute effects or through chronic exposure and latent effects. These chronic effects of organic and inorganic constituents or their metabolites are of particular concern to the extent that they relate to incidences of cancer. There is also increasing concern about endocrine-disrupting compounds (EDC) and pollutants originating from pharmaceuticals and active ingredients in personal care products (PPCPs), which are present in municipal wastewater and continually introduced as complex mixtures to the aquatic environment (5,6). EDCs are exogenous agents that interfere with the production, release, transport, metabolism, binding, action, or elimination of the natural hormones in the body responsible for maintaining homeostasis and regulating developmental processes. Among compounds that have endocrine activity are both synthetic chemicals produced industrially (such as surface active agents, pesticides, plasticizers, food additives, birth control pills, herbal supplements, and cosmetics) and naturally occurring compounds (such as sex steroids, plant-produced estrogens, and heavy metals) (7). The occurrence of PPCPs in domestic effluents is reported in studies since the late 1980s (8,9). The major concern for the presence of pharmaceuticals in

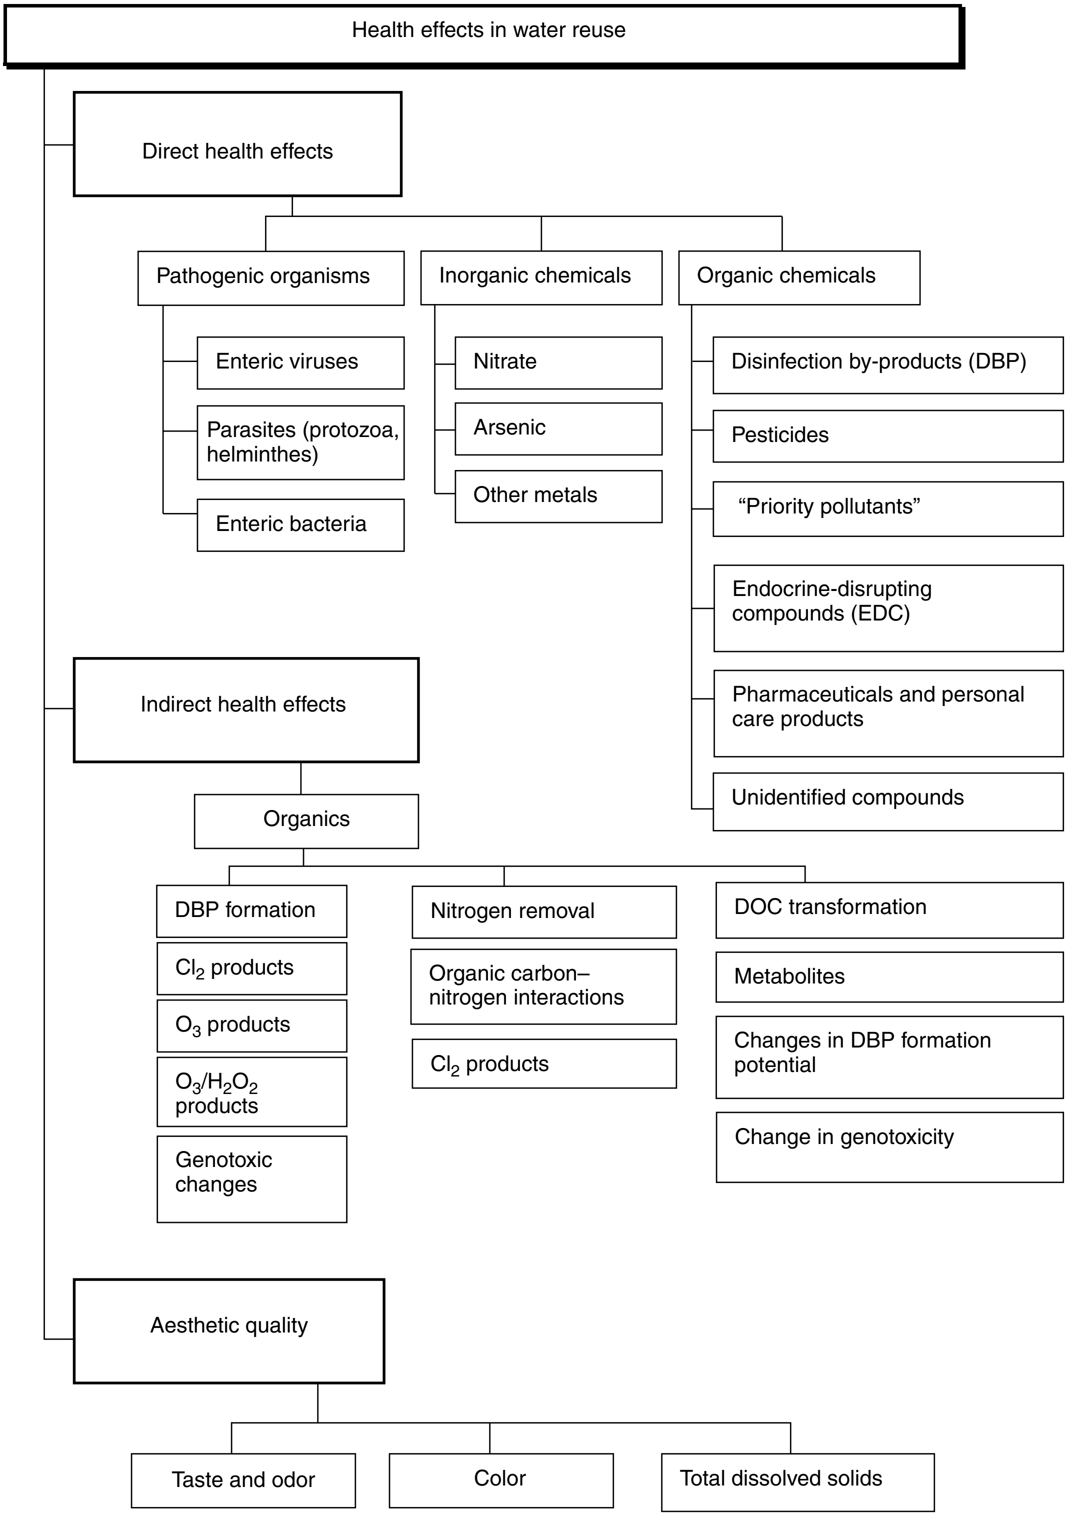

Figure 1. Research activities related to health effects in water reuse.

reclaimed water ultimately used for human consumption is not necessarily acute effects on human health, but rather the manifestation of imperceptible effects that can accumulate over time ultimately to cause truly profound changes (5). Effects might occur over long periods of time in certain populations, so changes would not be distinguishable from natural events or ecological succession. A continuous research effort is directed to unknown and unidentified organic contaminants. The toxicological risk, or safety, of these mixtures may never be known precisely. This presents an ever-present element of uncertainty for all reclaimed water projects involving potable reuse and justifies continuous monitoring and research. The aesthetic quality of reclaimed water is determined by taste and odor, color, and total dissolved solid (TDS) concentration.

Nonpotable Reuse

The main research issues in nonpotable reuse are the fate and transport of pathogens, nitrogen, and TDS during water reclamation and reuse. Today, these issues do not present a significant barrier to implementing nonpotable reuse projects, and direct nonpotable reuse today is the dominant planned reuse venue for supplementing public water supplies worldwide. Table 1 summarizes key research studies on pilot and full scale in nonpotable reuse and lists their main research objectives, locations, and references. This selection of important research studies is not complete nor does it indicate any type of ranking regarding their scientific and technical merits, but it directs the reader to important research in the field.

Enteric microorganisms are the contaminants of greatest concern in reusing reclaimed wastewater. Pathogen removal has been addressed in several research studies that focus on the efficiency of different pretreatment technologies for virus inactivation during subsequent disinfection, the survival of enteric microorganisms on food crops that have been irrigated with reclaimed water, as well as disease outbreaks from consuming contaminated foods, and the fate and transport of microorganisms in reclaimed water during artificial groundwater recharge. Recent research advances also resulted in better methods of detecting pathogens. Findings of these research studies suggest that tertiary treatment (such as coagulation/flocculation, lime clarification, dual-media filtration) and disinfection are necessary for many reuse applications to ensure pathogen reduction. Current research activities on pathogen removal address treatment plant reliability, removal of new and emerging enteric pathogens of concern, and the ability of new technologies to effect pathogen reduction (20).

For water reuse, the nonmetals ammonia, nitrite, and nitrate are of particular health significance because nitrate concentrations significantly higher than 10 mg N/L can cause methemoglobinemia in infants. Research is directed to aboveground treatment technologies and the efficiency of soil–aquifer treatment systems in removing nitrogen from reclaimed water. In the sustainable operation of local water reuse systems, the total solids concentration represents a significant challenge to the water reuse research community to develop strategies for minimizing salt buildup in local water cycles and cost-efficient treatment and disposal techniques.

Potable Reuse

Potable reuse involves a broad spectrum of potential health concerns. The major concerns are that adverse health effects could result from introducing pathogens, toxic organic chemicals, or inorganic constituents into groundwater that is consumed by the public (21). Treatment efficiency and reliability in removing pathogens are very important in potable reuse where even short-term exposure to pathogens could result in significant risk to the exposed population (22). Enteric viruses were not found in reclaimed water at field sites employing tertiary treatment but were observed in reclaimed water that had secondary treatment followed by chlorination (16). Table 2 summarizes key research studies at pilot- and full-scale potable water reuse facilities.

An assessment of health risks from potable reuse cannot be considered definitive because of limited chemical and toxicological data and inherent limitations in available toxicological and epidemiological methods. The mix of contaminants in the watershed of a reclamation facility might vary from site to site, so health effects studies

Table 1. Key Research Studies on Pilot and Full Scale in Nonpotable Water Reuse

Research Objective	Type of Water Reuse	Location	Research Study	Reference
Behavior of nitrogen and organic contaminants	Groundwater recharge	Phoenix, Arizona	Flushing Meadows project	10, 11

are applicable only to a specific location (4). In findings from research studies conducted at full-scale indirect potable reuse facilities, there is no indication that health risks from using reclaimed water are greater than those from using existing water supplies or that concentrations of regulated chemicals and microorganisms in product water exceeded established drinking water standards set by the U.S. EPA (23,27–29,31). The limited data and extrapolation methodologies used in toxicological assessment may present limitations and uncertainties in overall risk characterization. Similarly, epidemiological studies may suffer from the fact that many cancers have latency periods of 15 years or more. In addition, these types of studies require large populations to uncover the generally low risks from low concentrations of potential carcinogens.

The scope of inorganic chemical health issues in potable water has not changed significantly in several decades. In general, the health hazards from inorganics are well established. However, the threshold for risk protection has changed because of new information for some inorganics such as lead and arsenic. The fact that most forms of nitrogen can be readily converted to nitrate ions either in the treatment process or in soils makes managing nitrogen a significant issue in potable reuse projects.

WATER REUSE RESEARCH IN WASTEWATER TREATMENT TECHNOLOGIES

Research in water reuse has contributed to significant progress in developing sound technical approaches to produce a high quality and reliable water source from reclaimed wastewater (2,33). The evolution of water reclamation technology is illustrated in Fig. 2 for water treatment processes that lead to indirect potable reuse.

Findings of research studies and the advent of new water treatment technologies have resulted in an evolution of water reclamation technologies since the first water reclamation facilities for indirect potable reuse were established in the early 1960s (Fig. 2a). Primary treatment and secondary treatment are still the basic treatment in current water reclamation facilities for removing particulate matter and degradable organic material, respectively. In the early 1970s, treatment trains were developed to improve the removal of pathogens and trace organics by adding lime clarification, granular activated carbon, and reverse osmosis (Fig. 2b,d). Since the late 1990s, the use of microporous membranes in ultrafiltration (UF) and microfiltration (MF) as a pretreatment in reverse osmosis has become the industry standard for indirect potable reuse applications (Fig. 2c,e). Disinfection, conducted over decades using chlorine, is critically reviewed by many utilities and more and more substituted by disinfection using ultraviolet light. With the proper dosage and installation, UV radiation is a proven and effective bactericide and viricide for wastewater and does not contribute to the formation of known toxic by-products (Fig. 2e). This dynamic in incorporating new unit operations in water reclamation is proceeding with the advent of membrane-coupled bioreactors that can substitute for conventional primary and secondary treatment, including tertiary filtration. Membrane bioreactors (MBR) consist of a biological reactor where suspended biomass and solids are separated by microfiltration membranes whose nominal pore sizes range from 0.1 to 0.4 μm. MBRs can operate at much higher mixed liquor suspended solids (MLSS) concentrations (15,000 to 25,000 mg/L) than conventional activated sludge processes. These (**a**) Montebello Forebay surface spreading grounds, County Sanitation Districts of Los Angeles County, California; continuous, started in 1962

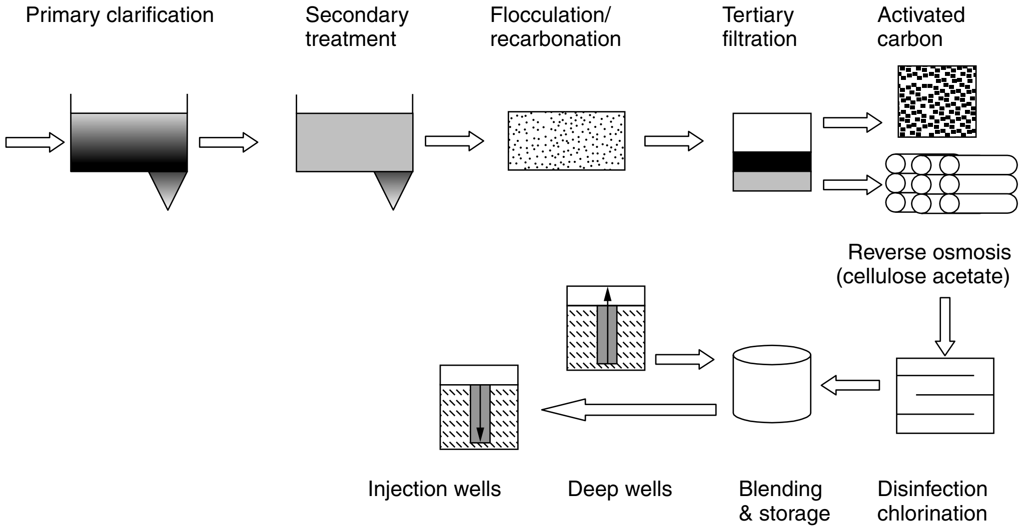
advantages are enhanced by a small footprint and high effluent quality with respect to turbidity, total suspended solids (TSS), biochemical oxygen demand (BOD), and pathogens (2).

WATER REUSE RESEARCH RELATED TO PUBLIC PERCEPTION

The ultimate success of any water reuse program is determined by its level of public acceptance. Several indirect potable reuse projects have failed to emphasize public support and resulted in project termination, although the technical and scientific evaluation was well done. Gaining public acceptance has and will initiate research programs related to human health and public involvement and education (34).

RESEARCH NEEDS IN THE FUTURE

Water quality requirements for nonpotable reuse are quite tractable, and treatment requirements are not likely to change significantly in the future, but drinking water quality standards are likely to become more rigorous. The number of contaminants to be monitored is increasing, and, for many contaminants, the maximum contaminant levels and action levels are decreasing. Thus, it is appropriate to anticipate more restrictive treatment requirements and water quality limits and (**d**) Water Factory 21, Orange County Water District; 1977



(**e**) Water Factory 21, Orange County Water District; 2002

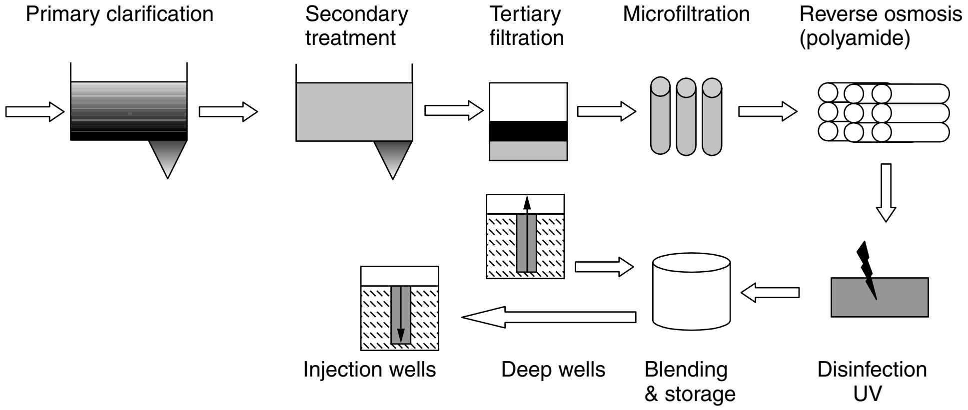


Figure 2. (*continued*).

to design facilities accordingly. Continued and future research will contribute to further progress in designing and operating water reclamation and reuse facilities. Some key topics will include assessment of health risks from trace pollutants in reclaimed water; improvement of monitoring techniques to evaluate microbiological quality; optimization of treatment trains and integration of membrane processes in producing reclaimed water; brine disposal strategies for membrane treatment processes; evaluation of the fate of microbiological, chemical, and organic contaminants; and development of surrogate parameters in combination with *in vitro* and *in vivo* assays to detect unidentified organic compounds in reclaimed water (1,4).

WASTEWATER RECLAMATION AND REUSE

RASHEED AHMAD
Khafra Engineering Consultants
Lilburn, Georgia

Because of growing population and increasing urbanization, many communities throughout the world are approaching or reaching the limits of their available water supplies. Wastewater reclamation and reuse has become an attractive option for conserving and extending available water supplies. Wastewater reclamation and reuse may also present communities an opportunity for pollution abatement when it replaces effluent discharge to sensitive surface waters.

The terminology currently used in wastewater reuse engineering is derived from sanitary and environmental engineering practice. The water potentially available for reuse includes municipal and industrial wastewater, agricultural return flows, and storm water. Of these, return flows from agriculture irrigation and storm water are usually collected and reused without further treatment. *Wastewater reclamation* involves treating or processing wastewater to make it reusable, and *wastewater reuse* or *water reuse* is the beneficial use of the treated water. Reclamation and reuse of water frequently require water conveyance facilities for delivering the reclaimed water and may require intermittent storage of the reclaimed water prior to reuse. In contrast to reuse, *wastewater recycling* or *water recycling* normally involves only one use or user, and the effluent from the user is captured and redirected back into that use scheme. In this context, the term *wastewater recycling* is applied predominantly to industrial applications such as in the steam—electric, manufacturing, and mineral industries.

The use of reclaimed wastewater where there is a direct link from the treatment system to the reuse application is termed *direct reuse*. Direct reuse provides water for agricultural and landscape irrigation, industrial applications, urban applications, and dual water systems. *Indirect reuse* includes mixing, dilution, and dispersion of reclaimed wastewater by discharge into an impoundment, receiving water, or groundwater aquifer prior to reuse, such as in groundwater recharge.

Indirect wastewater reuse, through effluent disposal to streams and groundwater basins, has been an accepted practice throughout the world for centuries. Communities that are situated at the end of major waterways have a long history of producing potable water from river water sources that have circulated through multiple cycles of withdrawal, treatment, and discharge. Similarly, riverbeds or percolation ponds may recharge underlying groundwater aquifers with treated wastewater, which in turn, is withdrawn by downgradient communities for domestic water supplies. These kinds of uses are considered unplanned indirect reuse. However, indirect reuse can also be planned, for example, the artificial groundwater recharge program in Los Angeles County, California, where reclaimed water has provided a source of water since the 1960s.

It is also important to differentiate between *potable* and *nonpotable* reuse applications. *Potable water reuse* refers to the use of highly treated reclaimed water to augment drinking water supplies. Although direct potable reuse is limited to extreme cases, it consists of incorporating reclaimed water into a potable water supply system without relinquishing control over the resource. *Nonpotable water reuse* includes all water applications other than drinking water supplies. Currently, on an international scale, direct nonpotable water reuse comprises the dominant mode of wastewater reuse for supplementing public water supplies for uses such as landscape and agricultural irrigation.

The potential health risks of wastewater reclamation and reuse are related to the extent of direct exposure to the reclaimed water and the adequacy, effectiveness, and reliability of the treatment system. The goal of each water reuse project is to protect public health without unnecessarily discouraging wastewater reclamation and reuse. Regulatory approaches stipulate water quality standards in conjunction with requirements for treatment, sampling, and monitoring. In 1992, the U.S. Environmental Protection Agency (USEPA) issued “Guidelines for Water Reuse” (1); however, specific criteria for wastewater reclamation in the United States are developed by individual states, often in conjunction with regulations on land treatment and disposal of wastewater. The World Health Organization (2) has published guidelines for reuse in agricultural irrigation. These guidelines stipulate stringent microbial water quality requirements. In recent years, many state agencies in the United States have developed their own reclamation and reuse standards. Besides microbial water quality criteria, these standards include standards for total suspended solids (TSS), biochemical oxygen demand (BOD), pH, and, in some cases, residual chlorine.

Wastewater reclamation and reuse are becoming more common and are gaining acceptance among communities and regulatory agencies. They have proven effective and successful in creating a new and reliable water supply, while not compromising public health. Nonpotable reuse is a widely accepted practice that will continue to grow. The primary drawback is cost, as these systems often require traditional water treatment facilities and a separate distribution system. The current advances in wastewater technology, especially in membrane processes, are expected to reduce the cost of wastewater reclamation and reuse in the future.

WASTEWATER RECLAMATION AND REUSE TREATMENT TECHNOLOGY

Rasheed Ahmad
Khafra Engineering Consultants
Lilburn, Georgia

The effective treatment of wastewater to meet water quality objectives for water reuse applications and to protect public health is a critical element of water reuse systems. Municipal wastewater treatment consists of a combination of physical, chemical, and biological processes and operations to remove solids, organic matter, pathogens, metals, and sometimes nutrients from wastewater. General terms used to describe different degrees of treatment, in order of increasing treatment level, are preliminary, primary, secondary, tertiary, and advanced treatment. A disinfection step for control of pathogenic organisms is often the final treatment step prior to distribution or storage of reclaimed wastewater. Wastewater reclamation, recycling, and reuse treatment systems are derived from applying technologies used for conventional wastewater treatment and drinking water treatment. The goal in designing a wastewater reclamation and reuse system is to develop an integrated cost-effective treatment scheme that can reliably meet water quality objectives.

The degree of treatment required in individual water treatment and wastewater reclamation facilities varies according to the specific reuse application and water quality requirements. The simplest treatment systems involve solid/liquid separation processes and disinfection, whereas more complex systems involve combinations of physical, chemical, and biological processes employing multiple-barrier treatment approaches for contaminant removal.

Primary treatment is the removal of particulate matter, typically by settling, with or without coagulants. In conventional wastewater treatment facilities, primary treatment includes screening and comminution for removal of large solids, grit, and sedimentation. Conventional primary treatment is effective in removing particulate matter 50 microns or larger. This process, in general, removes nearly 50% of the suspended solids and 25–50% of the biochemical oxygen demand (BOD_5) from the untreated wastewater. The removal efficiency of primary treatment processes can be increased by adding coagulants before gravity sedimentation. For most wastewater reuse applications, primary treatment alone is not adequate to meet water quality objectives.

Secondary treatment systems consist of biological treatment processes coupled with solid/liquid separation. They are intended to remove the soluble and colloidal organic matter that remains after primary treatment. Biological treatment consists of applying a controlled natural process, in which microorganisms remove soluble and colloidal organic material from the waste and are, in turn, removed themselves. To carry out this natural process in a reasonable time, the biological treatment systems are designed to maintain a large active mass of bacteria within the system. The basic principles remain the same in all biological processes, but the techniques used in their application vary widely. A useful classification divides these systems into *attached (film) growth or suspended growth processes*. Attached growth processes use a solid medium on which bacterial solids are accumulated to maintain a high population. Attached growth processes include trickling filters, rotating biological filters, fluidized beds, intermittent sand filters, and a variety of similar systems.

Suspended growth processes maintain an adequate biological mass in suspension within the reactor by employing either natural or mechanical mixing. In most processes, the required volume is reduced by returning bacteria from a secondary clarifier to maintain a high solids concentration.

Suspended growth processes include activated sludge and its various modifications, oxidation ponds, and sludge digestion systems. The effluent from conventional secondary treatment processes contains levels of suspended solids and BOD_5 ranging from about 10 to 30 mg/L. Depending on process operation, from 10% to 50% of the organic nitrogen is removed during conventional secondary treatment, and phosphorus is converted to phosphate. The sludge produced during secondary processes is treated by aerobic or anaerobic digestion, composting, or other solids processing technologies. For many wastewater reclamation and reuse systems, secondary treatment can adequately remove organic matter from wastewater. Frequently, secondary treatment is supplemented by filtration for additional removal of particles and by disinfection for microbial inactivation.

Tertiary treatment is the additional removal of colloidal and suspended solids by chemical coagulation and granular medium filtration. The advanced treatment is directed toward reduction in ammonia, organic nitrogen, total nitrogen, phosphorus, refractory organics, and dissolved solids. Tertiary and advanced treatment processes are normally applied downstream of biological treatment. Advanced treatment processes, in addition to chemical coagulation and granular medium filtration, refer to ion exchange, air stripping, chemical oxidation, adsorption, membrane treatment, and disinfection. Coagulation processes involve the addition of chemicals to wastewater to promote aggregation of particles for enhanced solid/liquid separation by sedimentation and filtration. Common coagulants used are alum (aluminum sulfate), ferric sulfate, and ferric chloride. Various types of polyelectrolytes or polymers are used in conjunction with chemical coagulants to improve process effectiveness. Chemical coagulation processes have a role in removing phosphorus, ammonia, and particulate matter.

Granular medium filtration uses a column consisting of a filter medium such as sand or anthracite. Wastewater is passed through the granular medium and particles are removed by impaction, interception, and physical straining. The filter is cleaned (this process is known as backwashing) after it reaches head-loss or turbidity breakthrough. Filters are generally used as a polishing unit and also, in some cases, as a pretreatment step for disinfection, activated carbon adsorption, ion exchange, or reverse osmosis. Filters are very effective in reducing pathogen concentrations.

Ion exchange is a chemical phenomenon in which materials in solution are removed by interchange with other ions immobilized within a solid matrix through which the flow passes. This process is used for removing nitrogen, metals, and dissolved solids.

Membrane processes include microfiltration, ultrafiltration, nanofiltration, and reverse osmosis. A membrane is a thin layer of natural or synthetic material capable of separating substances when a driving force is applied across the membrane. Reverse osmosis is used primarily to remove dissolved salts.

Nanofiltration is used to soften waters and remove color. Ultrafiltration and microfiltration are used to remove turbidity, pathogens, and other particulate matter. Membranes are normally classified by solute exclusion size, which is sometimes referred to as *pore size*. Membrane filtration works by passing water at high pressure through a thin membrane in the form of hollow fiber or spirally wound composite sheets. The contaminants are retained on the high-pressure side and frequently must be cleaned by reversing the flow and flushing the waste. Periodic chemical cleaning may be required to remove a persistent contaminant. Membrane assemblies are contained in pressure vessels or cartridges. Low-pressure membranes, in the form of either ultrafiltration (UF) or microfiltration (MF), have become more economical in both capital and operating costs and have received increased application in wastewater reuse and reclamation. Fouling of the membrane is a major problem challenging widespread application of this technology.

In recent years, the use of membrane bioreactors is proving to be an alternative to conventional biological processes. Membrane bioreactor technology combines a biological treatment process with a membrane system to provide organic and suspended solids removal. Installation within a biological reactor system typically replaces sedimentation and filtration as a means of separating mixed liquor suspended solids (MLSS) from treated effluent. Flow passes through the membranes, and solids remain in the biological treatment process. The benefit of immersed membrane technology is the amount of membrane surface area that is in contact with the process fluid. This large surface area allows operating membranes at much lower pressures.

Disinfection is an essential treatment component for almost all wastewater reclamation and reuse applications. The most common type of disinfection system in wastewater reclamation is chlorine disinfection. Ultraviolet (UV) disinfection has earned a reputation as a viable alternative to chemical disinfection processes in wastewater reclamation and reuse applications. The other technologies mentioned such as air stripping, chemical oxidation, and carbon adsorption are used in specific situations.

Water reuse for some applications, such as irrigation, is seasonal. Storage represents an important step between wastewater treatment and water reuse. Storage acts to equalize flow variations and to balance the production of reclaimed water with the use of water. Another benefit of storage is the additional residence time and treatment afforded.

Wastewater reclamation and reuse treatment technologies are drawn from currently practiced water and wastewater treatment technologies. However, some of the technologies such as membrane and ultraviolet disinfection, which are not widely used in conventional wastewater treatment plants, are gaining more viability in wastewater reuse and reclamation applications. This may be attributed to lower cost of operation and better process understanding and control of membrane and ultraviolet technologies. It may also stem from stricter regulatory standards and emphasis on multiple-barrier treatment techniques. The selection of treatment technologies for wastewater reclamation and reuse application depends on the type of reuse. For *urban reuse*, wastewater may require filtration and disinfection in addition to secondary treatment, whereas for *agricultural reuse*, secondary treatment with disinfection can meet reclaimed water quality standards. However, *indirect potable reuse* generally has to meet the strictest water quality standards. Hence, advanced wastewater treatment may be required to meet *indirect potable reuse* standards.

Technology, Inc.
Tokyo, Japan

When human feces and urine are diluted with flushing water or other gray water (such as from washing, bathing, and cleansing activities), it becomes sewage, domestic wastewater, or sanitary wastewater. In other words, from the standpoint of sources of generation, sewage or domestic wastewater may be defined as a combination of the liquid- or water-carried wastes from residences, institutions, and commercial and industrial establishments, together with such groundwater, surface water, and stormwater as may be present. Sewage can be classified into two types.

- *Domestic sewage or domestic wastewater*: human excrement, waterborne human excretion, or water-carried wastes from liquid or nonliquid culinary purposes, washing, cleansing, laundering, food processing, or ice production;
- *Municipal sewage or municipal wastewater*: municipal liquid waste originating primarily from residences, but may include contributions from

1. holding tanks in recreational vehicles, boats, and houseboats;
2. commercial, institutional, and industrial sources; and
3. inflow and infiltration.

SEWAGE COMPOSITION AND CONTAMINANTS

Body wastes, food waste, paper, rags, and biological cells form the bulk of suspended solids in sewage. Even inert materials such as soil particles become fouled by adsorbing organics to their surfaces. Although suspended solids are biodegradable by hydrolysis, biodegradable material in sewage is usually considered soluble organics. Soluble organics in sewage are composed chiefly of proteins (40–60%), carbohydrate (25–50%), and lipids (approximately 10%). Proteins are chiefly amino acids; carbohydrates are compounds such as sugars, starches, and cellulose. Lipids include fats, oil, and grease. All of these materials contain carbon that can be converted to carbon dioxide biologically, thus exerting oxygen demand. Proteins also contain nitrogen, and thus a nitrogenous oxygen demand is also exerted. The biochemical oxygen demand (BOD) test is therefore used to quantify biodegradable organics. All forms of waterborne pathogens may be found in sewage wastewater. These include bacteria, viruses, protozoa, and helminthes. These organisms are discharged by persons who are infected with disease. A list of contaminants commonly found in sewage, along with their sources and environmental consequences, is given in Table 1.

The quantity and composition of sewage vary widely from location to location depending on, for example, food diet, socioeconomic factors, weather, and water availability. Quantitatively, constituents of sewage may vary significantly, depending on the other kinds of wastewater and the amount of dilution from the infiltration/inflow into the collection system. The results of analyzing a typical municipal wastewater or sewage from a municipal collection system are given in Table 2. The composition of wastewater from a given collection system may change slightly on a seasonal basis, reflecting different water uses. Additionally, daily fluctuations in quality are also observable and correlate well with flow conditions. Generally, smaller systems with more homogenous uses produce greater fluctuations in wastewater composition.

Table 2. Typical Analysis Of Municipal Wastewater

Constituent, mg/L	Concentration Strong	Medium	Weak
Solids, total	1200	720	350
Dissolved, total	850	500	250
Fixed	525	300	145
Volatile	325	200	105
Suspended, total	350	220	100
Fixed	75	55	20
Volatile	275	165	80
Settleable solids, mL/L	20	10	5
Biochemical oxygen demand, 5-day, 20 °C (BOD$_5$)	400	220	110
Total organic carbon (TOC)	290	160	80
Chemical oxygen demand (COD)	1000	500	250
Nitrogen, total as N	85	40	20
Organic	35	15	8
Free ammonia	50	25	12
Nitrites	0	0	0
Nitrates	0	0	0
Phosphorus, total as P	15	8	4
Organic	5	3	1
Inorganic	10	5	3
Chlorides	100	50	30
Alkalinity, as CaCO3	200	100	50
Grease	150	100	50

SEWAGE TREATMENT

If untreated sewage is allowed to accumulate, decomposition of the organic material it contains can lead to the production of large quantities of malodorous gases. In addition, untreated sewage usually contains numerous pathogenic or disease-causing microorganisms that dwell in the human intestinal tract. Sewage also contains nutrients, which can stimulate the growth of aquatic

Table 1. Important Wastewater Contaminants

Contaminant	Source	Environmental Significance
Suspended solids	Domestic use, industrial wastes, erosion by infiltration/inflow	Cause sludge deposits and anaerobic conditions in aquatic environment
Biodegradable organics	Domestic waste	Cause biological degradation, which may use up oxygen in receiving water and result in undesirable conditions
Pathogens	Domestic waste	Transmit communicable diseases
Nutrients	Domestic and industrial waste	May cause eutrophication
Refractory organics	Industrial waste	May cause taste and odor problems, may be caustic or carcinogenic
Heavy metals	Industrial waste, mining etc.,	Are toxic; may interfere with effluent reuse
Dissolved inorganic solids	Increase above level in water supply by domestic and/or industrial use	May interfere with effluent reuse

plants, and it may contain toxic compounds. For these reasons, the immediate and nuisance-free removal of sewage from its sources of generation, followed by treatment and disposal, is not only desirable but also necessary in an industrialized society. In the United States, it is now mandated by numerous federal and state laws. Sewage treatment is generally classified into on-site or off-site treatment systems according to nonsewered or sewered facilities.

ON-SITE SEWAGE TREATMENT SYSTEMS

They generally refer to individual septic tanks followed by soakpits. A septic tank is used to receive the wastewater discharged from individual residences and other nonsewered facilities. A septic tank followed by a soil absorption system constitutes what is known as conventional on-site sewage management system. Sludge has settled to the bottom of the septic tank over a period of years, and the liquid and surface scum layer is called septage. Septage and sludge generally require some level of treatment prior to final disposal or reuse. In many cases, septage is discharged to a municipal wastewater treatment plant and treated as a wastewater source. In separate treatment situations, the options of treatment include conventional wastewater treatment processes, conventional sludge treatment processes, land treatment, or a combination of aquatic treatment and constructed wetlands. Sludge can be treated in digesters or sludge lagoons as a liquid, or it can be dewatered and treated by land composting or land application.

OFF-SITE SEWAGE TREATMENT SYSTEMS

Off-site sewage treatment refers to the sewerage system that conveys wastewater to a chosen off-site disposal system. It is composed of a combination of unit operations and processes to reduce certain constituents of wastewater to an acceptable level. Many different combinations are possible. Municipal wastewater treatment systems are often divided into primary, secondary, and tertiary subsystems. The purpose of primary treatment is to remove solid materials from the incoming wastewater. Secondary treatment usually consists of biological conversion of dissolved and colloidal organics into biomass that can be subsequently removed by sedimentation. Contact between microorganisms and organics is optimized by suspending the biomass in wastewater or passing the wastewater over a film of biomass attached to solid surfaces. Secondary systems produce excess biomass that is biodegradable through endogenous catabolism by other microorganisms. Secondary sludges are usually combined with primary sludge for further treatment by anaerobic biological processes.

DOMESTIC SEWAGE

Kevin S. McLeary
Pennsylvania Dept. of
Environmental Protection
Harrisburg, Pennsylvania

CHARACTERISTICS OF DOMESTIC SEWAGE

Physical Characteristics

Fresh sewage typically has a light brown color. As it ages, oxygen is depleted, and anaerobic microorganisms begin to use other electron acceptors, including sulfates, nitrates, iron, and manganese. As sulfates are reduced, hydrogen sulfide is produced, which can combine with metals in the sewage. The color gradually changes from light brown to gray and eventually to black as a result of the metal sulfides.

The odor of fresh sewage is usually not objectionable, but as it ages, anaerobic microorganisms produce odors that are much more offensive than the odor of fresh sewage.

Odor. Some of the disagreeable compounds formed by the anaerobic decomposition of sewage include hydrogen sulfide, indole, skatole, cadaverine, and mercaptans (1).

Solids. Total solids are made up of soluble solids and suspended solids and are determined by evaporating a known volume of sewage at a temperature of 103–105 °C and weighing the residue. Total suspended solids (TSS) are determined by filtering a sample, followed by drying and weighing (in mg) the residue, and dividing by the volume of the sample (in L). Dissolved solids are the difference between the total and suspended solids. The suspended solids are further separated into settleable and nonsettleable solids. The settleable solids are those that will settle to the bottom of a cone-shaped container in a 60-minute period. The solids (total, suspended, or dissolved) can further be divided into volatile and fixed fractions. Samples are dried and then heated to 550 °C. The volatile materials are burned off, and the fixed solids are weighed. The volatile solids are presumed to be organic material, and the nonvolatile solids are presumed to be inorganic.

Temperature. The temperature of sewage is generally warmer than that of the water supply because of heat added by homes, businesses, and industrial activities. Sewage temperatures vary with the seasons and geography. In cooler climates, temperatures may vary from 7–18 °C (45–65 °F), and in warmer climates, the temperatures may vary from 13–24 °C (55–75 °F) (1).

Chemical Characteristics

Organic. The chief constituents of the organic compounds found in sewage are proteins (40–60%), carbohydrates (25–50%), and fats and oils (10%). Other compounds that may be present in small quantities include surfactants, pesticides, organic priority pollutants, and volatile organic compounds (2).

The organic strength of sewage is measured by a test called biochemical oxygen demand (BOD). The test does not directly measure the concentration of the organics, but rather measures the amount of oxygen that is used as the organic compounds are degraded by microorganisms.

Inorganic. The major inorganic constituents of sewage include alkalinity, sulfates, and metals as well as compounds of nitrogen and phosphorus. Alkalinity is a measure of buffering capacity against changes in pH and is a result of the presence of anions such as hydroxides, carbonates, and bicarbonates. Sulfur is an important element in the formation of proteins and is released when they are degraded. Metals occur naturally at low concentrations in water. Table 1 shows metal concentrations that may be found in sewage.

Small quantities of metals are vital to the biological treatment process as trace nutrients. However, at higher concentrations, metals are toxic to the treatment process.

Nitrogen. Inorganic nitrogen is in the form of ammonia, nitrites, and nitrates. Ammonia exists as both dissolved ammonia gas (NH_3) and the ammonium ion (NH_4^+). Nitrite comprises only a small portion of the inorganic nitrogen and is formed by the oxidation of ammonia. Nitrate is the most oxidized form of inorganic nitrogen in sewage treatment. Nitrate concentrations are a concern in water reuse applications because of methemoglobinemia. The drinking water standard for nitrate has been established at 10 mg/L as nitrogen.

Phosphorus. Inorganic phosphorus may be present as several orthophosphate ions (PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, and H_3PO_4). Phosphorus is an important nutrient for storing energy in cells. It is important for microorganisms, and phosphorus is frequently the limiting nutrient for phytoplanktonic (e.g., algae) growth in the aquatic environment. As the limiting nutrient, the growth of algae can be related to the phosphorus concentration. Excessive growth of algae can cause eutrophication of lakes and other slow moving bodies of water.

Gases. As sewage flows through the collection and conveyance system, atmospheric gases such as nitrogen, oxygen, and carbon dioxide may dissolve in the water. In addition to atmospheric gases, the organic compounds in the sewage begin to decompose, and the decomposition products, such as ammonia, hydrogen sulfide, and methane, also dissolve in the sewage (2).

Table 1. Metals Concentrations in Sewage Treatment Plant Influent[a]

	Concentration, mg/L	
Metal	Range	Average
Arsenic	0.0001–5	0.187
Chromium	0.0006–9	0.255
Copper	0.004–20	0.637
Lead	0.001–5	0.138
Mercury	0.0001–0	0.034
Nickel	0.002–7	0.294
Silver	0.0002–5	0.173
Zinc	0.024–2,027	39.4

[a] Reference 3.

Biological Characteristics

Untreated sewage is an ideal medium for microbiological organisms. It provides inorganic and inorganic nutrients that are needed for cell growth (3). Almost every type of microorganism can be found in sewage. The most abundant types include bacteria, viruses, protozoa, and helminths.

Bacteria. Bacteria are the principal microorganisms requiring the treatment of sewage. Bacteria convert carbonaceous materials into various gases and additional cell mass (2). One of the most common pathogens found in sewage is *Salmonella*. *Shigella*, the leading cause of recreational waterborne outbreaks in lakes and rivers, is also found. Some of the other bacteria that have been identified in sewage include *Vibrio, Mycobacterium, Clostridium, Leptospira, Yersinia, Escherichia coli*, and *Campylobacter* (4).

Viruses. Viruses are parasitic particles that consist of a strand of DNA or RNA. They invade living cells and redirect the cell to reproduce the virus, which accumulates within the cell. When the host cell dies, the viruses are released (2). Viruses of concern in sewage include enteroviruses, rotaviruses, reoviruses, parvoviruses, adenoviruses, and hepatitis A virus.

Protozoa. Protozoa are organisms that feed on bacteria and other microorganisms and are vital to the operation of biological treatment systems. Important protozoa in sewage treatment include amoebas, flagellates, and ciliates. There are also pathogenic protozoa in sewage. *Giardia lambia* and *Cryptosporidium* are included in this category (2).

Helminths. Sewage may contain a number of worms (helminths) that are of great concern. There are two major phyla of helminth that may be present, platyhelminthes and aschelminthes. Platyhelminthes are flatworms, including flukes and tapeworms. Nematodes are the major aschelminthes (roundworms) of concern in sewage. Of special concern are *Trichinella, Necator, Ascaris*, and *Filaria* (2).

Pathogenic Organisms. Pathogens are organisms that are highly infectious. Pathogens usually found in sewage are discharged by humans who are infected with or are carriers of a disease. These pathogens typically cause typhoid fever, diarrhea, cholera, and other diseases of the gastrointestinal tract.

Indicator Organisms. There is a large number and variety of pathogenic organisms in sewage. The time, cost, and difficulty of analyzing for all of these organisms would be excessive. To provide a level of confidence in pathogen concentrations, a substitute organism should be found for analysis. The ideal organism would be present when pathogenic organisms are present, be absent when pathogenic organisms are absent, be easy and inexpensive to analyze, and not be a pathogen itself. An organism that meets these criteria is called an indicator organism (5). The most widely used indicator organism in sewage treatment is fecal coliform bacteria.

TREATMENT TECHNOLOGY

Sewage must receive a minimum of a secondary treatment. A secondary treatment is defined as a 30-day average concentration of biochemical oxygen demand and total suspended solids not to exceed 30 mg/L, where the 7-day average does not exceed 45 mg/L. The definition also includes an 85% removal requirement for BOD and TSS. Sewage effluent that may contact humans or be indirectly used for water supply may require additional treatment. Selection of treatment technology is dependent in large part on the influent characteristics, the quality of the effluent required, and cost.

Treatment is normally classified as either physical/chemical or biological and can be broken down into several stages: preliminary treatment, primary treatment, secondary treatment, and tertiary treatment.

Preliminary Treatment Processes

Preliminary treatment is a physical process intended to remove large objects and grit from sewage (5). The removal of these materials is necessary because they could reduce the efficiency or increase the maintenance of downstream processes (6). Preliminary treatment may include the following processes: screening, grit removal, comminution, and flow equalization.

Screening. Screening removes large objects that could clog or damage downstream equipment. Screens typically consist of inclined steel bars spaced at equal intervals in a sewage channel. Common practice is to use a mechanically cleaned bar screen that has an emergency bypass channel containing a manually cleaned screen (7). Design parameters for bar screens include bar size, bar spacing, angle of inclination, channel width, and sewage approach velocity (6).

Grit Removal. Grit consists of sand, gravel, and other high specific gravity material that may abrade and wear mechanical equipment or may accumulate in treatment tanks. A common method for grit removal involves using aerated grit chambers, in which diffused air is introduced to the sewage along the bottom of one side of a rectangular chamber. This creates a rolling motion that keeps the lighter organic materials in suspension but allows the heavier grit particles to settle to the bottom of the tank, where they are removed (6).

Comminution. Comminutors are devices that shred materials without removing them from the sewage. They are typically designed with a bypass channel containing a screening device that may be used if the comminutor is removed from service. The basic parts of a comminutor include a screen and cutting teeth on a revolving drum that has slots cut into it. The cutting teeth shred the material as it is trapped against the screen. The shredded solids then pass through the drum slots and out of the bottom (7). These shredded materials can cause problems, such as clogging, in downstream process units. As a result, comminutors have fallen out of favor in the design of sewage treatment plants (6).

Equalization. Equalization is used in plants to dampen variations in hydraulic or organic loadings. Sewage flows into the unit at a variable rate but is removed at a relatively constant rate. Equalization is used to provide relatively uniform loading throughout the day and to increase the performance of downstream process units (6). Equalization tanks may be designed either as in-line or side-line units.

Equalization tanks must be aerated to prevent the contents from becoming septic and should be mixed to prevent solids from settling. Aeration equipment should be capable of maintaining a dissolved oxygen concentration of 1 mg/L (8). Mixing may be provided by diffused air systems, mechanical mixers, or both.

Primary Treatment Processes

Sedimentation. Primary sedimentation is the oldest and most widely used process in treating sewage (6). It is a physical process whose goal is to achieve solids separation.

Solids removal by sedimentation is a function of retention time and surface settling rate. The surface settling rate is defined as the volumetric flow rate over the surface area of the clarifier in units of velocity. Particles whose settling velocity is greater than the surface settling rate are removed from the sewage stream. However, if the detention time is too long, the sewage turns septic, and gas bubbles formed in the sewage reduce the efficiency of the process. A typical minimum side water depth for primary clarifiers is 10 feet. To allow for adequate settling, a minimum distance of 10 feet should separate the inlet and the outlet (8). Clarifier design is typically based on two flows, the average design flow and the peak hourly flow. The calculated size of the clarifier is based on both flows, and the larger clarifier is selected.

Secondary Treatment Processes

Activated Sludge Processes. Activating sludge is a biological treatment process using a suspension of microorganisms to treat sewage in an aerobic environment. The microorganisms are allowed to flocculate and settle under quiescent conditions, and treated sewage then flows over weirs for further treatment or discharge. Solids from the bottom of the clarifier are recycled to the reactor to provide an adequate concentration of microorganisms for treatment. The contents of the reactor, called mixed liquor, must be aerated and mixed by using either mechanical aerators or diffused air.

There are several variations of the conventional activated sludge process. These include plug flow reactors, including step feed, tapered aeration, extended aeration, and complete mix reactors, including sequencing batch reactors.

A plug flow reactor has a configuration in which the sewage flows through a long, narrow channel for treatment. It approximates flow through a pipe. In an ideal plug flow reactor, there is no longitudinal mixing of the sewage. A step feed reactor is a variation of the plug flow reactor in which the sewage is introduced into the reactor at several places. This allows more equal distribution of the organic load. Tapered aeration is another variation of the plug flow reactor. In tapered aeration, the majority of the aeration capacity is provided at the head of the reactor, where the organic load is the highest, and less aeration is provided where the organic load is lower. Extended aeration is a treatment process requiring long detention times (typically greater than 24 hours) and low organic loadings. Extended aeration is commonly available in package-type treatment plants and is economical for small treatment plants.

A complete mix reactor is the opposite of a plug flow reactor. All of the sewage is completely mixed in a short, wide reactor. Due to rapid and complete mixing of the reactor contents, complete mix reactors can tolerate shock loads better than plug flow reactors. A sequencing batch reactor (SBR) is a variation of the complete mix reactor; stabilization, settling, and equalization take place in the same tank, eliminating the need for a clarifier.

Aeration Requirements. The dissolved oxygen concentration in aeration tanks should be greater than 2 mg/L at all times. Treatment processes (except extended aeration) should be designed to provide 1.1 lb of oxygen per pound of BOD treated. Extended aeration systems generally require 1.5 lb of oxygen per pound of BOD treated. These aeration requirements do not include the aeration capacity needed for nitrification. If nitrification is required, an additional 4.6 lb of oxygen per pound of ammonia nitrogen is required (8).

Fixed Film Processes

Trickling Filters. Trickling filters are a fixed film process where the microorganisms are attached to a stone or plastic medium. The sewage flows through a rotating arm, which distributes it over the medium. As the sewage flows over the medium, the microorganisms absorb organics from the sewage. When the sewage is not being applied to that specific section of the medium, air flows through the filter, providing the oxygen that the microorganisms need for respiration.

Sewage is recirculated back to the filter to maintain a proper application rate for efficient operation of the filter, to equalize the organic loading to the filter, and to prevent the microorganisms from drying out.

Rotating Biological Contactors. Rotating biological contactors (RBCs) are another version of the fixed film process. The microorganisms are attached to a plastic disk, which is partially submerged and rotated through the sewage. When the microorganisms are submerged, they absorb organics. During the time the microorganisms are exposed to the air, they receive the oxygen that is required for treatment. Treatment efficiency is a function of the surface area of the disks, more surface area provides greater treatment. Unlike trickling filters, no recirculation is required for rotating biological contactors.

Stabilization Ponds. Stabilization ponds are large, lined basins, that may be aerobic, facultative, or anaerobic. Ponds use detention time measured in days, rather than hours, and are typically relatively shallow compared with other biological treatment processes. Thus, a large land area is required for ponds, and they are usually used only in small communities. Their advantages include low construction and operating costs.

Aerobic ponds may be aerated mechanically or naturally. Natural aeration is by atmospheric diffusion and production of oxygen by algae. Facultative ponds have several stratified layers—an upper, aerated section; a lower, anaerobic section; and an intermediate section consisting of both aerobic and anaerobic processes. Anaerobic ponds may be up to 30 feet deep and are used for treating high strength (typically industrial) waste. Deep ponds maximize anaerobic conditions.

Tertiary Treatment Processes

Nitrification. Ammonia nitrogen is converted to nitrate in a two-step process, in which ammonia is first converted to nitrites and the nitrites are then converted to nitrates. The rate-limiting step is the conversion of ammonia to nitrite. Nitrification can co-occur with carbon oxidation, or it may take place in a separate nitrification tank. The reaction rate is slower and, therefore, requires a longer detention time than carbon oxidation. Nitrifying organisms have a slower growth rate than the organisms for carbon oxidation, and the process requires a longer mean cell residence time (sludge age).

Biological Phosphorus Removal. Biological phosphorus removal can be enhanced in a two-step process. The first step takes place anaerobically. The microorganisms release phosphorus to generate energy for the uptake of organics. The second step is aerobic. In this step, the microorganisms absorb large amounts of phosphorus to replace the phosphorus that was lost in the anaerobic step, as well as to store additional energy for the next "feast or famine" feeding cycle.

There are three major biological phosphorus removal methodologies—the Anaerobic/Oxic (A/O) process, the PhoStrip process, and the sequencing batch reactor (2). Both the A/O process and the PhoStrip process are proprietary. Phosphorus removal in the A/O process is dependent on the BOD:P ratio; the PhoStrip process is independent of this ratio. The PhoStrip process does require additional chemicals for phosphorus removal, however. The sequencing batch reactor may be cycled to achieve biological phosphorus removal but usually is used for smaller flows and with more limited design data.

Denitrification. Denitrification is the removal of the inorganic nitrogen from sewage. Several species of bacteria can use nitrates, rather than oxygen, as their energy source. These bacteria convert the nitrates into nitrogen gas (2).

In the denitrification process, raw sewage flows into an anoxic zone with return sludge and return mixed liquor from an aerobic zone. The anoxic zone denitrifies by using the nitrates in the mixed liquor. Following the anoxic zone, the sewage flows to an aerobic zone where nitrates are created. The nitrates are then recycled to the anoxic zone for removal. Denitrification is normally done in a plug flow type system or in an oxidation ditch, although a sequencing batch reactor may be programmed for denitrification (2).

Biological Dual Nutrient Removal. Biological dual nutrient removal is the reduction of both nitrogen and phosphorus from sewage by microorganisms. Several proprietary treatment processes, including the A^2/O process, the Bardenpho process, the University of Capetown (UCT) process, and the Virginia Initiative Plant (VIP) process, have been developed for dual nutrient removal (2).

These processes are a combination of the denitrification process and the biological phosphorus removal process. The proprietary systems may use from three to five stages to achieve the desired nutrient removal, but all have the use of an anaerobic zone in common, followed by an anoxic zone, followed by an aerobic zone. Some of the processes may use two anoxic zones and/or two anaerobic zones with different recycle streams to achieve greater nutrient removal, but the treatment principles are the same.

Coagulation/Sedimentation. Coagulation/sedimentation requires chemical addition to enhance the sedimentation of solids, precipitate pollutants, or remove phosphorus. The chemicals most commonly used are lime, aluminum salts, ferric salts, and polymers (7).

Chemical phosphorus removal occurs by the addition of chemicals to the sewage, which create an insoluble phosphate precipitate. Alum is frequently used in the chemical precipitation of phosphorus, although iron salts may also be used. Alum also reacts with hydroxyl radicals in the water, forming aluminum hydroxide, in addition to aluminum phosphate. Iron (III) reacts in the same manner.

Filtration. Filtration is the removal of solids by passing the sewage through a bed of granular media. Although the most commonly used filters are composed of sand, filters may also consist of multiple types of media, such as coal over sand or coal over silica sand over garnet sand (9). Filters may be classified as slow filters, rapid filters, or pressure filters. Slow filters require a buildup of a biological mat on the upper surface of the filter, which provides greater treatment, but requires a low application rate, and therefore requires a larger area. Rapid filters and pressure filters depend on the entire depth of the media for filtration and may be operated at higher loading rates than slow filters, although backwashing of the media is required.

Activated Carbon Adsorption. Adsorption is a process by which a compound adheres to a solid surface. In sewage treatment, activated carbon is the most commonly used adsorbent. Activated carbon comes in two forms, powdered and granular. Powdered activated carbon (PAC) is applied in slurry form at the head of the aeration tanks and is removed in the final clarifiers. Granular activated carbon (GAC) is used in a filter bed (7). Carbon adsorption is used only where highly treated effluent is required.

Membrane Systems. Membrane processes involve the use of a semipermeable barrier. The membrane allows the water to flow through and retains the contaminants. There are several types of membrane systems in sewage treatment, including reverse osmosis, nanofiltration, microfiltration, and ultrafiltration. All of these processes require pressure to force water through the membrane. Ultrafiltration requires the least pressure, whereas reverse osmosis requires the greatest pressure. Membrane processes are subject to fouling of the membranes. These processes should be pilot tested to determine which process and membrane will work best. Like carbon adsorption, membrane processes are used when only high-quality effluent is required.

Disinfection Processes

Chlorination/Dechlorination. Chlorine has been used as a disinfectant for sewage for several reasons, including inactivation of a wide range of pathogens, maintenance of a residual, and economy. There are several forms of chlorine that may be used: gaseous chlorine, sodium hypochlorite, and calcium hypochlorite. Chlorine is toxic to aquatic life, so the recent trend has been to dechlorinate the sewage before discharge to the receiving stream, which is usually done by using sulfur dioxide to reduce the chlorine to chlorides. Sodium metabisulfite or bisulfite may be used as a substitute for sulfur dioxide in small facilities. Reaction times are nearly instantaneous, and detention times are usually less than 2 minutes.

Ozonation. Ozone is a very powerful oxidant. It can inactivate sewage pathogens with less contact time and a lower dosage than other disinfection methods. It is effective against a wide range of organisms, and it does not leave a toxic residual (10). Ozone must be generated on-site because it is unstable. Ozone is generated by corona discharge, which consists of passing clean, dry air or oxygen through electrodes, which are separated by a dielectric and a gap.

Ultraviolet Light Disinfection. Ultraviolet radiation whose wavelengths are in the range of 240–280 nm inactivate microorganisms by causing damage to their DNA (10). Ultraviolet lamps operate in the same way as fluorescent lamps—the radiation is generated by passing an electrical current through ionized mercury vapor. The mercury lamps may operate at low or medium pressures. Low-pressure lamps emit the majority of their energy at 253.7 nm, which is in the optimal range for inactivation. Medium-pressure lamps generate a smaller portion of their energy in the 240–280 nm range, but the intensity of their light is much greater. Therefore, fewer medium-intensity lamps are required for the same amount of disinfection (10).

SOLIDIFICATION/STABILIZATION OF HAZARDOUS SOLID WASTES

Th. A. Ioannidis
A.I. Zouboulis
Aristotle University of Thessaloniki
Thessaloniki, Greece

INTRODUCTION

Solidification/stabilization is an established technology that has been used for almost 20 years to treat a variety of toxic or hazardous wastes. Historically, this technology belongs to the top five source control treatment technologies, used at Superfund remedial sites, as presented in Fig. 1 (1).

Stabilization is a process by which sufficient quantities of specific additives (reagents) are added to hazardous materials to reduce the toxic nature (properties) of a waste by converting the toxic constituents into an appropriate solidified form. As a result, (a) the rate of contaminant migration into the surrounding environmental media is minimized, and (b) the level of toxicity is substantially reduced, as determined by the application of the appropriate leaching tests, such as TCLP. The procedure of solidification/stabilization has shown considerable promise, and it is commonly used for the fixing different waste types. The wide use of stabilization for treating (mainly) inorganic-laden wastes derives primarily from

1. the lack of better alternatives; for example, toxic metals do not biodegrade and they do not change in atomic structure/properties, when incinerated.
2. the well-defined physicochemical mechanisms taking place, such as precipitation and adsorption (2).

SOLIDIFICATION/STABILIZATION TECHNOLOGY

Solidification and stabilization (denoted hereafter as S/S) waste treatment processes involve mixing specialized additives or reagents with hazardous waste materials to reduce, by physical or chemical means, the solubility or mobility of contaminants in the surrounding environmental matrix. Solidification and stabilization are closely related; both use several chemical, physical, and thermal processes or an appropriate combination of them, to detoxify hazardous wastes.

The term "solidification/stabilization" refers to a general category of processes, that are used to treat a wide variety of hazardous (or toxic) wastes, including mostly solids, but also liquids. Nevertheless, solidification and stabilization are considered distinct technologies.

Solidification refers to processes that encapsulate a waste to form a solid material and to restrict the migration of contaminant by decreasing the available surface area, which is exposed to leaching, when contacting liquids and also by coating the waste with low-permeability materials. Solidification can be accomplished by a chemical reaction between the hazardous waste and the binding (solidifying) reagents or by the application of mechanical processes (e.g., compaction). The solidification of fine solid waste particles (i.e., those whose diameters are below 100 μm) is referred to as *microencapsulation*, whereas

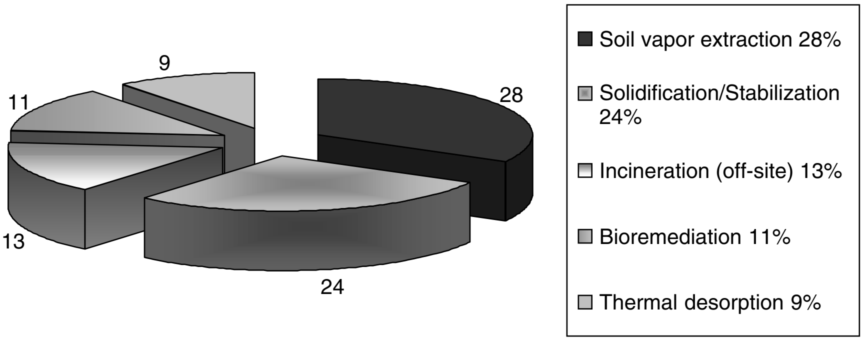

Figure 1. The top source control treatment technologies used at Superfund remedial sites.

the solidification of a large block or container of waste is referred to as *macroencapsulation*.

Stabilization refers to processes that involve chemical reactions, which reduce the leachability of the product (stabilized waste). Stabilization immobilizes the hazardous materials or reduces their solubility through appropriate chemical reactions. The physical nature of the waste may or may not be changed by this process.

Solidification refers to processes that encapsulate the waste in a monolithic solid, which has sufficient structural integrity. The encapsulation may be that of compacted fine waste particles, or of a large block, or container of wastes. Solidification does not necessarily involve a chemical interaction between the waste and the solidifying reagents, but the binding of waste in the product (monolith) may be mechanical. Migration of contaminants is restricted by the large decrease in surface area, which is exposed to eventual leaching, and by isolating the waste within an impervious capsule.

Stabilization refers to processes, which reduce the risk posed by a waste, through the conversion of contaminants into a less soluble, immobile, or less toxic form, whereas the physical nature of the waste may not be necessarily changed. Phosphates, sulfides, carbonates, and several other materials have been used as appropriate treatment reagents.

In many instances, stabilization takes place exclusive of solidification. A stabilized product should have low leaching characteristics. Many of the reagents used for the S/S method can also be used in other chemical treatment (oxidation) processes, such as in dechlorination of liquid wastes. S/S systems can be used to treat contaminated soil or wastes in place, or they can be employed to treat excavated wastes externally, preparing them for subsequent disposal (3).

Solidification involves the formation of a solidified matrix that physically binds the contaminated material. Stabilization, also referred to as *fixation*, usually uses a chemical reaction to convert the hazardous constituents of the waste to a less mobile form. The general approach for S/S treatment processes involves mixing or injecting treatment agents into the contaminated soils. Inorganic binders, such as cement, fly ash, or blast furnace slag, as well as organic binders, such as bitumen, have been used to form a crystalline, glassy, or polymeric framework around the waste.

The dominant mechanism by which metals are immobilized in the absence of anions such as phosphates, carbonates, halides, or sulphates, is the precipitation of respective hydroxides within the solid matrix. S/S technologies are not useful for certain forms of metal contamination, such as species that exist as anions [e.g., Cr(VI) or arsenic], or for metals whose hydroxides are very soluble (e.g., mercury).

The S/S technology may not be applicable at polluted sites, containing wastes that include organic compounds, especially when volatile organic contaminants are present. The application of mixing and heating processes, associated with the hydration of binders, may release organic vapors. Pretreatment, such as air stripping or incineration, may be used to remove the volatile organics during preliminary treatment and to prepare the waste for the S/S of residues. The chemical composition of the contaminated matrix, the amount of water present, and the ambient temperature also affect the application of S/S technologies. Some factors can interfere with the effectiveness of the S/S process by inhibiting bonding of the waste to the binding material, retarding the setting of the mixtures, decreasing the stability of the matrix, or reducing the strength of the solidified products.

Cement-based binders and stabilizers are commonly used materials, when implementing S/S technologies (4). Portland cement, a mixture of Ca silicates, aluminates, alumino ferrites and sulfates, is an important cement-based material. Pozzolanic materials, which consist of small spherical particles, formed by coal combustion in lime and cement kilns, such as fly ash, are also commonly used for S/S. Pozzolans exhibit cement-like properties, especially when their silica content is relatively high. Portland cement and pozzolans can be used alone or together to obtain optimal stabilization properties for a particular waste or polluted site (5).

Organic binders may also be used to treat metals by polymer microencapsulation. This process uses organic materials, such as bitumen, polyethylene, paraffins, waxes, and other polyolefins, as thermoplastic or thermosetting resins. For polymer encapsulation, the organic materials are heated and mixed with the contaminated matrix at elevated temperatures (120–200 °C). The organic materials polymerize, agglomerate the waste, and as a result, the waste matrix is encapsulated (5). The organics are volatilized and collected, and the treated material is extruded for disposal or possible reuse (e.g., as paving material).

The contaminated material may require a certain extent of pretreatment to separate rocks and other debris and to dry the feed material. Polymer encapsulation requires more energy and more complex equipment than cement-based S/S operations. Bitumen (asphalt) is the cheapest and most common thermoplastic binder (5). S/S is achieved by mixing the contaminated material with appropriate quantities of binder/stabilizer and with water. The mixture sets and cures to form a solidified matrix, which contains the hazardous constituents. The cure time and handling characteristics of the mixture and the final properties of the hardened cement depend on the specific composition of the binder/stabilizer used (i.e., amount of cement, pozzolan, water, etc.).

Vitrification is the process of converting solid materials into a glass-like substance. This process is increasingly being considered for treating various toxic or hazardous wastes. The mobility of metal contaminants can be highly decreased by the application of high temperatures to the contaminated waste, which results in the formation of vitreous material, usually as oxide solids. During this process, the increased temperature may also cause the volatilization and/or destruction of organic contaminants or of volatile metal species (such as Hg), which must be carefully collected for further treatment or disposal. Most contaminated soils can be treated by vitrification, and a wide variety of inorganic and organic contaminants can be targeted. As a stabilization process, vitrification may immobilize inorganics by incorporating them into the glass structure or by encapsulating them within the product (glass). Vitrification may be performed *ex situ* or *in situ*, although the *in situ* processes are preferred, due to lower energy requirements and cost. The performance and characteristics of vitrification make it the focal point of treatment systems applied to high-level radioactive waste (HLW) around the world (6).

Ex situ S/S processes can be easily applied to excavated soils because the necessary mechanical methods are available to provide vigorous mixing, which is needed to combine the binder/stabilizer with the contaminated material. Pretreatment of a solid waste may be necessary to screen and crush large rocks and debris. Mixing can be performed via *in-drum, in-plant*, or whole area mixing processes. In-drum mixing may be preferred for treating small volumes of wastes or for toxic wastes. In-plant processes use rotary drum mixers for batch processes or pug mill mixers for continuous treatment. Larger volumes of wastes may be excavated and moved to a contained area for area mixing. This process involves layering contaminated material with the stabilizer/binder and subsequent mixing with a backhoe or similar equipment. Mobile, as well as fixed treatment plants are available for *ex situ* S/S treatment. Smaller pilot-scale plants can treat up to 100 tons of contaminated waste or soil/day; larger portable plants typically process 500 to over 1000 tons/day.

S/S techniques are also available to mix binder/stabilizer with the waste or contaminated soil *in situ*. *In situ* S/S technology is less labor- and energy-intensive than *ex situ* processes, which require excavation, transport, and disposal of the treated material. The *in situ* S/S method is also preferred, when volatile or semi-volatile organics are present in a waste because otherwise the excavation would expose these contaminants to the air. However, the presence of bedrock, large boulders, cohesive soils, oily sands, and clays may preclude the application of the *in situ* S/S method at certain sites. It is also more difficult to provide uniform and complete mixing, when applying *in situ* processes. The binder may be mixed with the contaminated matrix using in-place mixing, vertical auger mixing, or injection grouting. In-place mixing is similar to *ex situ* area mixing, except that the waste or soil is not excavated prior to treatment.

The *in situ* process is useful for treating surface or shallow contamination and involves spreading and mixing binders with the waste, using conventional excavation equipment, such as draglines, backhoes, or clamshell buckets. Vertical auger mixing uses a system of augers to inject and mix the binding reagents with the waste. Larger (2–4 m diameter) augers are used for shallow drilling (depths of 3–13 m) and can treat 400–800 m^3/day. Deeper applications of S/S methods (up to 50 m deep) can be achieved by using ganged augers (up to 1 m in diameter each), which can treat 100–300 m^3/d. Finally, injection grouting may be performed to inject the binder, containing suspended or dissolved reagents, into the treatment area under pressure. The binder permeates the surrounding soil and cures in place (7).

The main generic elements of typical S/S are presented in Fig. 2.

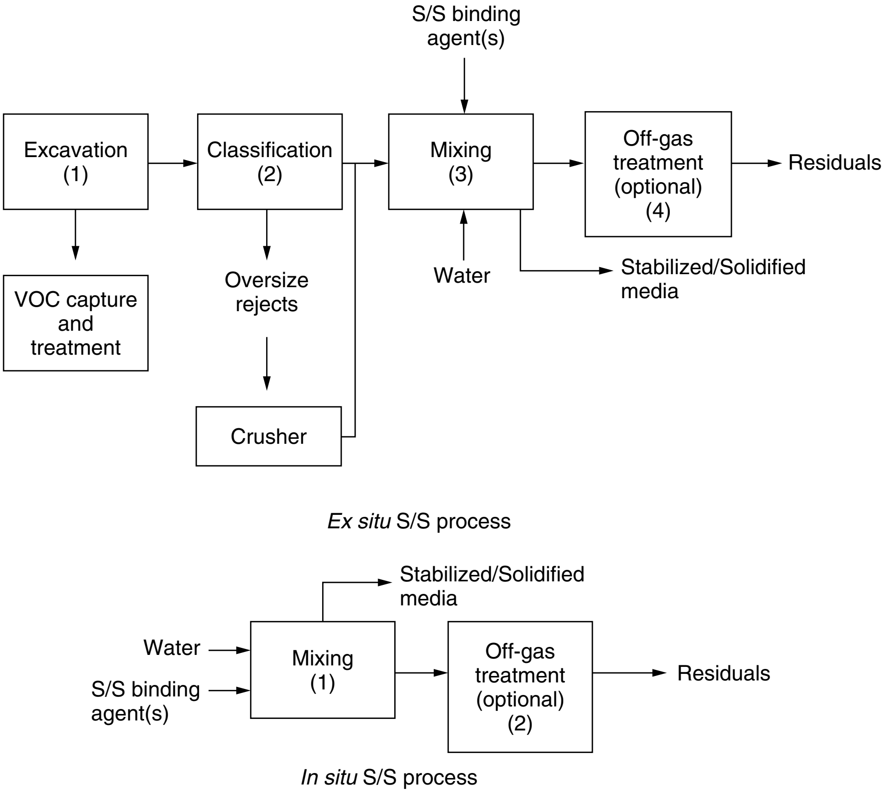

Figure 2. Generic elements of typical S/S processes.

KEY FEATURES OF S/S PROCESSES FOR BEST MANAGEMENT PRACTICES (BMPs)

The key features of S/S processes for BMPs are briefly presented in the following:

- This process requires the mixing of reagents, either on- or off-site.
- As a result of S/S application, contaminants are immobilized.
- Similarly to other immobilization technologies, S/S does not destroy inorganic wastes but may alter or change organic wastes.
- Stabilization can be combined with encapsulation or other immobilization technology.
- The application of S/S may increase the total volume of materials, which must be handled as waste for disposal.
- The wastes treated by the S/S method may be amenable to further reuse, following this treatment.
- Field application may involve the installation of any or all of the following:
  - a) auger type drilling and mixing equipment for *in situ* applications.
  - b) dust collection systems.
  - c) volatile emission control systems.
  - d) bulk storage tanks.

CROSS-MEDIA TRANSFER POTENTIAL OF POLLUTANTS AFTER S/S

There is a certain potential for the cross-media transfer of pollutants, after S/S:

1. There is always a risk of inaccurate site characterization, which has to be considered during the application of technology for treating soils. The solid material encountered at the remedial site may not be similar to the soils studied during laboratory treatability or pilot-scale tests. Additional contaminants may be encountered, whereas the percentage of the fine-grained fraction may be significantly different from that expected. These factors may lead to long-term storage or generation of a high volume of residuals that increases the potential for cross-media transfer of pollutants.
2. Also, during remediation, implementation, including staging and site preparation (e.g., clearing, grubbing), drilling, well installation and trenching operations, mobilization and demobilization of equipment, excavation, transport of materials across the site, and certain treatment activities, there is high potential for fugitive dust emissions due to the movement of equipment at the site. In addition, these activities can enhance the volatilization of VOCs (volatile organic compounds), SVOCs (semivolatile organic compounds), and of other potentially hazardous materials into the atmosphere.
3. During pretreatment operations, such as excavation, storage, sizing, crushing, dewatering, neutralization, blending, and feeding, there is the potential for dust and VOC emissions from the contaminated media (solid or liquid wastes).
4. The migration of contaminants to uncontaminated areas may occur during mobilization or demobilization.
5. VOC and SVOC emissions tend to increase during periods of hot and dry weather.
6. Leaching of contaminants to neighboring surface waters can occur from uncovered stockpiles and from excavated pits.
7. Improper handling and disposal of residues, such as sediment/sludge residuals or postwashing wastewaters, may allow contaminants to migrate into and pollute uncontaminated areas.
8. The posttreatment discharge of wastewater produced, when improperly managed, can also cause migration of contaminants.

Additional concerns for the application of S/S technology include

1. The leaching of contaminants or excess reagents to groundwaters from the treated wastes, which are disposed of on-site.
2. The long-term degradation of the stabilized mass, creating a potential for release of solidified hazardous constituents, reagents, VOCs, etc. from the treated waste.

WASTE CHARACTERISTICS THAT MAY INCREASE THE LIKELIHOOD OF CROSS-MEDIA CONTAMINATION FROM THE APPLICATION OF S/S TECHNOLOGIES

The effectiveness of S/S applications can be compromised and provoke cross-media contamination under certain conditions, which are identified in the following (8). However, some of these limitations might be overcome with various technology-specific modifications and variations.

1. The main physical mechanisms that can interfere the effective application of S/S process include
   - a. Incomplete mixing due to the presence of high moisture or organic chemical content, resulting in only partial wetting or coating of the waste particles with the stabilizing and binding agents and aggregation of untreated waste into lumps.
   - b. Disruption of the gel structure of the curing cement or pozzolanic mixture by hydrophilic organics in the waste soil to be treated.
   - c. Undermixing of dry or pasty wastes.
2. The main chemical mechanisms that can interfere with the S/S process include
   - a. chemical adsorption
   - b. precipitation
   - c. nucleation

Additional factors, which can interfere with the S/S/process include

a. the precise tailoring of waste composition to the S/S process used.
b. The treatment of waste containing oil and grease in moderate to high concentrations.

APPLICATION AND PERFORMANCE OF S/S

Types of Applications

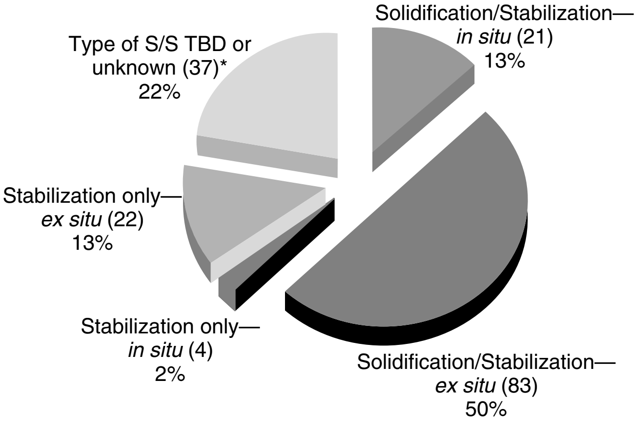
The majority of S/S projects at Superfund remedial sites are *ex situ* applications, where inorganic binders and additives were used to treat metal-containing waste. Organic binders were used for treating specialized wastes, such as radioactive wastes, as well as those containing specific hazardous organic compounds. The S/S method was used to treat wastes containing mainly organic contaminants in a small number (6%) of the total number of projects.

Performance

Most performance testing for S/S waste products has been conducted after curing was completed, whereas only limited data are available on long-term performance of S/S at Superfund remedial sites. The available performance data for the behavior of metals in these projects showed that S/S can meet established performance goals. Also, only limited data were available on the behavior of organics; however, the S/S process met the established performance goals for several projects.

SPECIFIC TYPES OF S/S APPLICATIONS

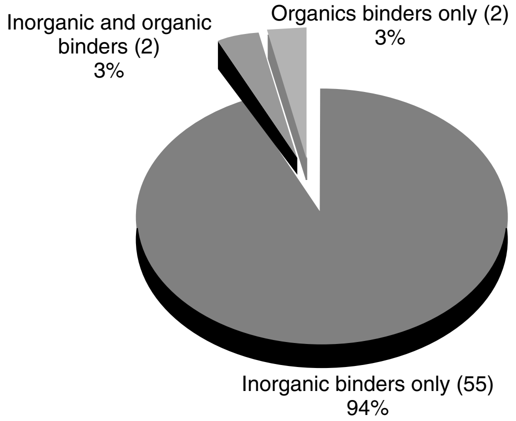
Figure 3 shows a breakdown of S/S projects by specific application type, which include *ex situ* S/S, *in situ* S/S, *ex situ* stabilization only, and *in situ* stabilization only. A specific type of S/S application was identified for 88% of the completed projects. S/S (*in situ* and *ex situ*) represents 63% of the S/S projects, compared to 15% for stabilization only (*in situ* and *ex situ*).



* Includes 3 *in situ* projects.

Note: The number of projects by type is shown in parentheses. TBD= (still) to be determined.

Figure 3. S/S projects by type. Total number of projects: 167.



Note: Inorganic binders consist of cement, fly ash, lime, soluble silicates, or sulfur. Organic binders consist of asphalt, organophilic clay, or activated carbon.

Figure 4. Binder materials used for S/S projects. Total number of projects: 59.

Figure 4 shows the types of binders used for S/S projects at Superfund remedial sites, including inorganic binders, organic binders, and appropriate combinations of organic and inorganic binders. Many of the binders used included one or more proprietary additives. Specific examples of inorganic binders included cement, fly ash, lime, soluble silicates, and sulfur-based binders; organic binders included asphalt, epoxide, polyesters, and polyethylene. More than 90% of the S/S completed projects used inorganic binders. In general, inorganic binders are less expensive and easier to use than organic binders, which are generally used to solidify radioactive wastes or other specific hazardous organic compounds.

COST DATA

Information about the cost of using S/S to treat wastes at Superfund remedial sites was available for 29 completed projects. The total costs for S/S projects ranged from \$75,000 to \$16 million, including the cost of excavation, treatment, and disposal (for *ex situ* applications). The cost per m^3 of treated waste ranged from \$10 to approximately \$1500/m^3. The average cost/m^3 for these projects was \$340, including two projects with relatively high costs (approximately \$1500/m^3). Excluding those two projects, the average cost was \$250/m^3 (1).

Additional information (3,4) indicates that the cost of *in situ* S/S can range from as little as \$25 to \$50/m^3 to as much as \$120 to \$250/m^3, depending on the volume to be treated, the structure of the soil (porosity), the treatment depth, the specific type of main contaminant to be stabilized/solidified, and the desired posttreatment objectives (leachability, permeability, or bearing ratio). The low end of the cost range would apply to solidifying, whereas the high end would apply to treating high concentrations of contaminants at great depths. Typical costs for application at a hazardous waste site, consisting of sands to silts, at a depth up to 9 m, has been estimated at around \$90 to \$120/m^3; around 20% would be the cost of reagent/additive.

WASTEWATER TREATMENT—SMALL SCALE

Guenter Langergraber
BOKU—University of Natural Resources and Applied Life Sciences
Vienna, Austria

Small wastewater treatment plants are defined as those to which fewer than 2’000 people are connected or those whose flow is less than 200 m^3/d. These are treatment plants for small communities, villages, institutions, hotels, and camping resorts.

There are a tremendous number of small wastewater treatment plants worldwide. Small treatment works are needed mainly in rural areas to treat municipal wastewater. However, technologies to treat wastewater from industry are also important. The separate treatment of wastewater from certain processes provides opportunities to reuse water and to reduce the overall consumption of freshwater.

In rural areas and also in large cities that are not yet provided with sewers, sanitation requirements can be met at a reasonable price and on a reasonable timescale by constructing small but highly compact and efficient plants to serve clusters of dwellings.

Small wastewater treatment plants are required to satisfy very different needs which can be integrated into infrastructures at very different stages of development and sophistication. Engineers are called upon to provide technologies that are reliable, easy to operate and control, and tolerant of variations in the influent. The task is difficult and needs an interdisciplinary approach that takes into account local conditions.

REQUIREMENTS FOR SMALL WASTEWATER TREATMENT PLANTS

Rural areas have some general characteristics:

- small communities, groups of houses, and also single houses sometimes where large distances are between them,
- low population density; and
- primarily agricultural use and only little industry.

These properties result in

- highly fluctuating wastewater flows, and
- high concentrations of wastewater constituents with high fluctuations.

Additionally only few trained personnel are available to operate wastewater treatment plants. As a result, some general requirements for small wastewater treatment plants in rural areas can be formulated:

- simplicity of technology,
- simple operation and maintenance,
- high robustness,
- large volume to buffer the high fluctuations of flow and concentrations,
- high stability, and
- low surplus sludge production.

TREATMENT METHODS

Wastewater treatment alternatives (for small communities) can be broadly subdivided into the following categories that represent the basic approaches to wastewater conveyance, treatment, and/or disposal (1):

- *Natural systems* use soil as a treatment and/or disposal medium, including land application, constructed wetlands, and subsurface infiltration. Some sludge and septage handling systems, such as sand drying beds, land spreading, and lagoons, are included.
- *Conventional treatment systems* use a combination of biological, physical, and chemical processes and employ tanks, pumps, blowers, rotating mechanisms, and/or mechanical components as part of the overall system. These include suspended growth, fixed growth, and combinations of the two. This category also includes some sludge and septage management alternatives, such as digestion, dewatering, and composting systems and appropriate disposal.
- *Alternative collecting systems* that use lightweight plastic pipe buried at shallow depths that have fewer pipe joints and less complex access structures than conventional gravity sewers. These include pressure, vacuum, and small-diameter gravity sewer systems.
- *Alternative treatment systems* use source control and separating systems. Wastewater can be separated

into blackwater—waste from toilets—and graywater—the part of the wastewater which is not mixed with excreta (from kitchens, bathrooms, and laundries). Blackwater can further be separated into urine (yellowwater) and feces (brownwater).

Depending on the local situation, different requirements arise for the treatment of organic matter, nutrients, and pathogens. In principle, all treatment methods that are used for large-scale wastewater treatment can be applied in small wastewater treatment plants. However, treatments that meet the special requirements of small systems should be favored.

Table 1 summarizes treatment alternatives to fulfill different effluent requirements. In many countries, systems for partial treatment combined with chemical precipitation are the only treatment and may serve as pre-treatment for additional future treatment steps. It is well understood that, in most cases, the relatively low removal rates in primary clarifiers and septic tanks do not comply with treatment goals and that septic tanks, especially, are perfectly suited for pre-treatment in infiltration systems and constructed wetlands. Although construction and operation of anaerobic pre-treatment is simple, only appropriate sludge control, it has been shown, guarantees settling of solids and partial hydrolysis by methanogenic fermentation. In all other treatment systems, biochemical oxidation is the most important process and determines, to a great extent, the size and costs of the treatment system.

Pathogen removal in nitrifying systems is generally higher than that in nonnitrifying systems. If very low microbial contamination is required, disinfection methods have to be applied.

Table 2 classifies treatment systems as low and high rate systems. In low rate systems, only lower hydraulic and contaminant loading rates can be applied, oxygen transfer is limited to natural diffusion and convection processes, the biomass concentration is lower, and therefore the specific volume and area requirements are higher. However, they are easier to operate and maintain and require, therefore, less skilled personnel.

The advantages of using natural systems are their “low-tech/no-tech” nature, which means that these systems

Table 1. Treatment Alternatives to Fulfill Different Effluent Requirements[a]

Treatment Requirement	Treatment Alternatives
Partial treatment (pre-treatment)	• Primary clarifier • Septic tank • Imhoff tank • Anaerobic pond • Surface-flow constructed wetlands
Physicochemical treatment	• Chemical precipitation combined with partial treatment one- or two-stage (+flocculation)
Complete organic matter removal	• Nonaerated and aerated pond • Rotating biological contactor • Trickling filter • Biofilter • Moving bed reactor • Subsurface horizontal-flow constructed wetlands • (Activated sludge)
including phosphorus removal	• Chemical precipitation in combination with most other technologies
including nitrification	• Extended aeration • Sequencing batch reactors (SBR) • Rotating biological contactor • Trickling filter • Biofilter • Moving bed reactor • Subsurface vertical-flow constructed wetlands • Sand infiltration
including denitrification	• Activated sludge • Sequencing batch reactors (SBR) • Rotating biological contactor • Trickling filter • Biofilter • Moving bed reactor • Subsurface-flow constructed wetlands
Pathogen removal	• Activated sludge, sequencing batch reactors (SBR) • Soil infiltration • Subsurface vertical-flow constructed wetlands • Disinfection (UV, chlorine, ozone)

are relatively easy to construct and operate; and their low costs (especially operating costs), which makes them attractive to communities with a limited budget. However, their simplicity and low cost may be deceptive in that the systems require frequent inspections and constant maintenance to ensure smooth operation (low maintenance does not mean no maintenance).

Mainly because of the land requirements for natural systems, many communities prefer technical systems, which tend to require less land and permit better control of the operation. However, these systems generally are high cost and require more skilled personnel to operate them. The disadvantages generally relate to the cost of construction and ease of operation. Mechanical systems can be costly to build and operate because they require specialized personnel. Generally, the complexity and cost of wastewater treatment technologies increase with the quality of the effluent produced.

Table 3 compares the specific reactor area and volume of systems used in small wastewater treatment plants. Additionally, the capability of the systems to nitrify is shown.

All systems described can be used for decentralized or 'on-plot' treatment and centralized or 'off-plot' treatment. For decentralized solutions, safe disposal of excreta takes place on or near a single household or a small settlement. Centralized solutions collect excreta from individual houses and carry them away from the plot to be treated off-site. The selection of the most appropriate sanitation system is influenced by ecological, technical, social, cultural, financial, and institutional factors.

COSTS

The costs of a wastewater treatment plant can be subdivided into investment and operating costs. To include the payback of the investment, the investment costs are transformed into yearly costs (using an economical interest rate; 3.5% is used in the examples given below). In the examples, the assumed lifetime of the treatment system (SBR and constructed wetland) is 20 years; for the sewer system, a lifetime of 40 years is assumed.

Table 4 compares specific investment, operating, and yearly costs of a technical treatment system (SBR) and a constructed wetland (subsurface vertical-flow, intermittently loaded). Additionally, two sizes of the treatment plant are compared, 100 and 500 PE (people equivalent). Both treatment systems have to fulfill the same effluent requirements (nitrification); the same sewer line configuration is used in both cases. The investment and operating costs for the sewer are estimated at about $1500\ \mathrm{EUR} \cdot \mathrm{PE}^{-1}$ and $5\ \mathrm{EUR} \cdot \mathrm{PE}^{-1} \cdot \mathrm{yr}^{-1}$, respectively. The investment costs for the two treatment systems are similar; specific costs increase as plant size decreases. However, the constructed wetland system shows lower operating and therefore lower yearly costs.

Seven different treatment scenarios for individual solutions for wastewater treatment of a single house (5 PE) are compared:

1. *Technical treatment system*: A conventional technical treatment system is used, and the effluent is discharged.

Table 3. Specific Reactor Area and Volume of Systems Used in Small Wastewater Treatment Plants[a]

System	Area/PE, m^2	Volume/PE, m^3	Contact Time	Nitrification
Nonaerated pond	10	10–15	>20 d	—
Soil infiltration	4–20	7–12	—	+
Surface-flow constructed wetland	5–10	5–15	>10 d	—
Aerated pond	3	4–7	>3–6 d	±
Subsurface horizontal-flow constructed wetland	4–8	3–5	1–4 d	—
Buried sand filter	4–6	4–6	1 h–7 d	+
Subsurface vertical-flow constructed wetland	2–5	1–3	1–3 d	+
Nitrifying trickling filter	0.17–0.3	0.45–0.6	6–10 min.	+
Extended aeration	0.12–0.25	0.35–0.6	1–3 d	+
Sequencing batch reactors (SBR)	0.1–0.2	0.3–0.5	1–3 d	+
Nitrifying rotating biological contactor	0.1–0.18	0.17–0.25	10–20 h	+
Nonnitrifying trickling filter	0.05–0.08	0.13–0.18	3–6 min	—
Nonnitrifying rotating biological contactor	0.04–0.07	0.07–0.13	8–15 h	—
Nitrifying biofilter	0.005–0.01	0.02–0.03	30–50 min.	+
Nonnitrifying biofilter	0.005–0.01	0.013–0.03	20–40 min.	—

Table 4. Comparison of Specific Investment, Operating, and Yearly Costs for a Technical Treatment System (SBR) and a Constructed Wetland[a]

System		SBR		Constructed Wetland	
Size of the Treatment Plant	PE	500	100	500	100
Investment costs	$EUR \cdot PE^{-1}$	430	770	420	690
Operating costs	$EUR \cdot PE^{-1} \cdot yr^{-1}$	22	44	15	36
Yearly costs	$EUR \cdot PE^{-1} \cdot yr^{-1}$	128	174	120	160

[a] Reference 4, modified.

2. *Constructed wetland*: A constructed wetland system is used instead of the technical solution. The effluent is discharged.
3. *Cesspit and disposal* of cesspit waste: All wastewater is collected in a cesspit, and the cesspit waste is disposed of periodically at a wastewater treatment plant.
4. *Cesspit and agricultural use* of cesspit waste: The same as No. 3, but the cesspit waste is used in agriculture.
5. *Cesspit for blackwater (disposal* of cesspit waste) and constructed wetland for *graywater treatment*: Blackwater and graywater are separated. Only blackwater is collected in the cesspit and disposed of periodically. Graywater is treated using a constructed wetland.
6. *Cesspit for blackwater* (*agricultural use* of cesspit waste) and constructed wetland for *graywater treatment*: The same as No. 6, but the cesspit waste is used in agriculture.
7. *Urine separation* (agricultural use of urine and feces) and constructed wetland for graywater treatment: Separation of urine and feces; both are used in agriculture. Graywater is treated using a constructed wetland.

Table 5 compares the investment, operating, and yearly costs for different treatment scenarios.

The constructed wetland system has yearly costs lower than to the conventional technical treatment system. When all wastewater is collected in a cesspit, the yearly costs of the scenario for agricultural use of the cesspit waste are only about 75% of the yearly costs when disposing of the waste at a wastewater treatment plant. However, all scenarios using source separation have the lowest operating and yearly costs. Separating toilet water from graywater leads to a tremendous reduction of the volume that has to be collected, and, therefore, the operating and also the yearly costs drop drastically. Urine separation has the lowest costs and, additionally, closes water and nutrient cycles on a local scale. Therefore, it is a promising system toward more ecologically sound sanitation.

SUMMARY

Wastewater treatment plants for small communities, groups of houses, and also single houses have to handle special wastewater characteristics such as highly fluctuating wastewater flows and high concentrations of wastewater constituents (and additionally with high fluctuations). Therefore, treatment systems for small-scale applications should have high process robustness and stability and a large buffer volume. Additionally, they should have simple technology, they should be easy to operate and maintain, and should have low surplus sludge production.

Table 5. Comparison of Investment, Operating, and Yearly Costs for the Treatment Alternatives for a Single Household with 5 PE[a]

Scenario		1	2	3	4	5	6	7
System[b]		Technical System	CW	CP	CP	CP (BW)	CP (BW)	US

[b] CW: constructed wetland; CP: cesspit; CP(BW): cesspit only for blackwater; WWTP: wastewater treatment plant; AU: agricultural use; US: urine separation.

Different requirements for treatment efficiency arise, depending on the local situation. Several treatment methods can be used to meet these requirements. The selection of the most appropriate sanitation system is influenced by ecological, technical, social, cultural, financial, and institutional factors.

For a small wastewater treatment plant, especially, low operating costs are essential. It was shown that for single households, solutions with source control separating at least blackwater and graywater yield significantly lower costs compared to solutions where the different types of wastewater are mixed and, therefore, a large volume has to be treated.

BACKGROUND

Microbial foaming and bulking are among the most frequent and widespread problems in activated sludge (AS) wastewater treatment plants (WWTPs). Bulking has plagued AS plants almost since their inception nearly a century ago, whereas microbial foaming was not documented until around 30 years ago. Both problems are associated with the excessive growth of various filamentous bacteria, although the mechanisms by which they form are not fully understood. Initial attempts to identify these bacteria shifted attention from engineering aspects to the microbiological activities fundamental to the activated sludge process. Subsequently, filament identification keys and abundance scales became routine tools for monitoring filamentous populations in activated sludge. More recently, molecular biological techniques have enabled more detailed and precise study of the diversity and ecology of bacterial communities associated with foaming and bulking.

CURRENT REGULATION OF WASTEWATER TREATMENT

Within the European union, treated effluents must comply with the standards set out in the EU Urban Wastewater Treatment Directive (1). The Directive states the minimal standards for the treatment and disposal of wastewater and waste sludge via WWTPs. These standards include the maximum biological oxygen demand (BOD; 20 mg/L) and level of suspended solids (SS; 30 mg/L), known as the 20:30 standard, allowed in treated effluents (2). In AS plants, the quality of the final effluent is governed by factors that affect both biological oxidation in the aeration basins and sludge separation in the final clarification tanks.

FOAMING AND BULKING ARE SLUDGE SEPARATION PROBLEMS

Central Role of Activated Sludge Floc

Activated sludge is comprised of three-dimensional aggregate structures, known as flocs, that contain microorganisms and abiotic matter. The structure of these flocs, including firmness, shape, and size determines the settling and compacting characteristics of the sludge solids. In ‘healthy’ flocs, filamentous bacterial growth creates a framework onto which other floc-forming bacteria can attach, and provides the strength required for the floc to remain intact in the turbulent environment of the aeration basin (3). However, excessive growth of various types of filaments can alter floc structure and interfere with the separation and recycling of sludge solids; this is observed in both microbial foaming and bulking.

Mechanism of Foam Formation

Microbial foam manifests on the surfaces of activated sludge aeration tanks as a dense, frothy, grey-brown, viscous scum, often described as having a ‘chocolate mousse’ appearance (Fig. 1). The majority of microbial foams are extremely stable and persistent and can accumulate to depths of more than a meter (4).

Foams consist of aggregates of air bubbles in liquid, flocs, and large numbers of filamentous bacteria, which selectively accumulate on the surface of mixed liquor

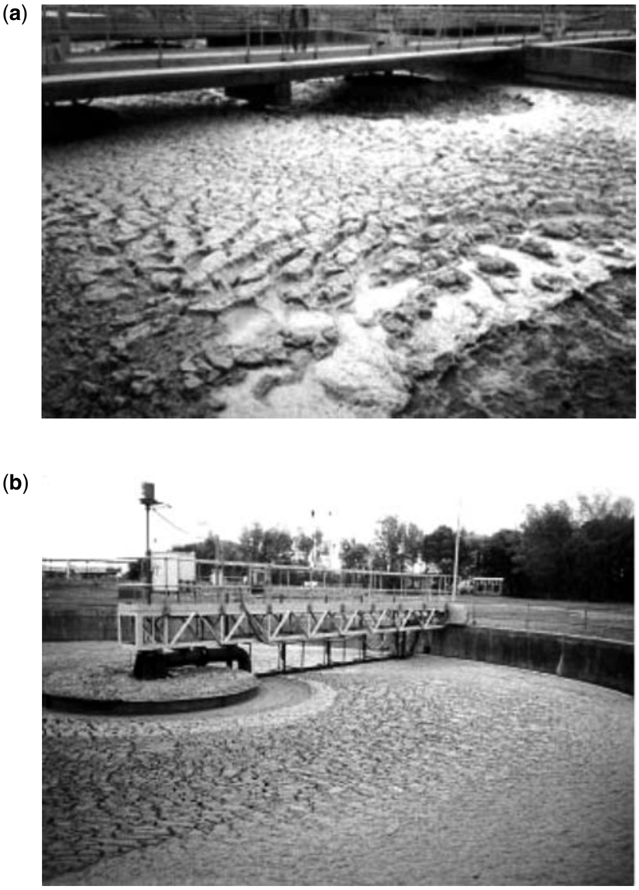

Figure 1. Microbial foam on the surface of (**a**) a mechanically agitated aeration basin and (**b**) a final clarifier, where it has partially dried out placing the tank out of operation.

by flotation. It is thought that excessive growth of hydrophobic bacteria in the mixed liquor renders flocs hydrophobic and hence amenable to attachment to air bubbles that are introduced to the mixed liquor by aeration. Large open flocs, it is thought, require only a few hydrophobic sites to adhere to air bubbles (5). The air bubble–floc aggregates have a lower density than water and rapidly rise to the surface of aeration basins where they accumulate. Hydrophobic solids stabilize the foam by bridging the bubble lamellae, preventing liquid drainage and subsequent breakdown.

Microbial Bulking

Bulking is caused by extensive and uncontrolled growth of various filamentous bacteria, both within and extending from the confines of flocs into the bulk liquor (Fig. 2). This results in a diffuse, open floc structure and interfloc bridging that can interfere with the settling and compaction of sludge solids in the final clarifiers. The supernatant is usually clear because bulking flocs filter out suspended particles (6). Although a blanket of scum may appear on the mixed liquor surface, bulking sludge is generally less easy to detect visually than foam. Several empirical methods have been devised and are widely used in the wastewater industry to monitor sludge characteristics and diagnose bulking. These include the diluted sludge volume index (DSVI; 7) total extended filament length (TEFL), and subjective filament abundance scales (4,8).

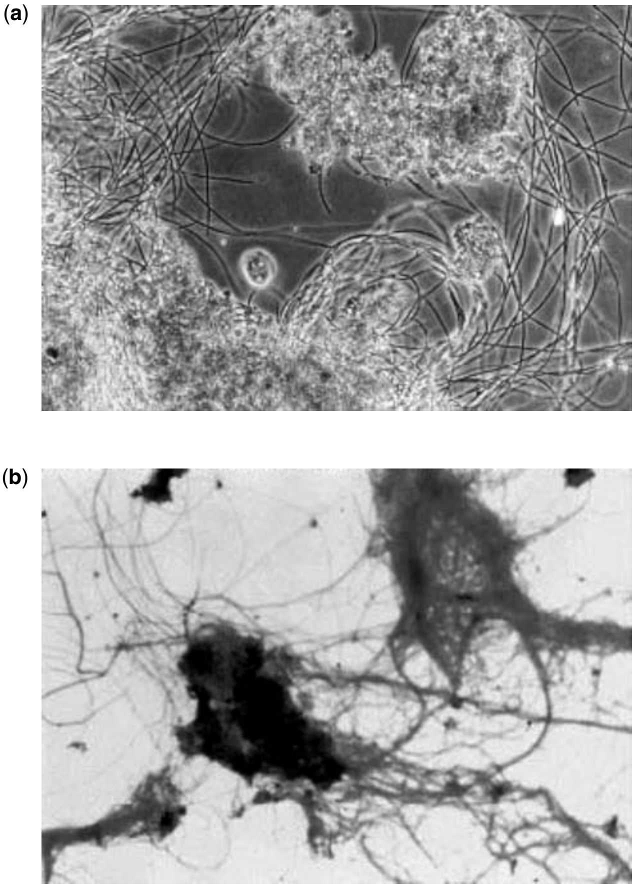

Figure 2. Microscopic examination of bulking activated sludge: (**a**) wet mount preparation viewed under phase contrast (×330 magnification) showing excessive growth of Eikelboom type 021N extending into the bulk phase and bridging adjacent flocs and (**b**) Gram-stained preparation viewed under bright-field (× 330) showing 021N filaments stained gram-negative forming large entangled knots (upper right) and surrounding the flocs (lower left).

Problems Caused by Foaming and Bulking

Foaming and bulking lead to a number of problems that may compromise operational efficiency and effluent quality and have inevitable financial and regulatory repercussions:

- Overflow of foam or blanket scum to the final clarifiers may lead to increased BOD and SS levels in the final effluent.
- Loss of solids means increased substrate-loading rates per unit of sludge in the aeration basins.
- Poor sludge settling and compaction caused by bulking affects the dewatering characteristics of waste activated sludge.

- Thick foams inhibit mixing and oxygen transfer at the surfaces of mechanically aerated basins, thereby restricting biological oxidation.
- Spillage of foam onto plant walkways can create hazardous working conditions, limit access to sections of the treatment unit, and create cleaning and odor problems.
- Release of poorly clarified effluent to receiving waters may disperse enterobacteria and viruses that are pathogenic to humans or animals.
- Pathogens may be carried in aerosols arising from windblown scum, which may be inhaled or ingested by plant workers or local inhabitants (9).

PREVENTION AND CONTROL OF FOAMING AND BULKING

There are no definitive procedures for preventing and controlling either foaming or bulking. Most proposed measures are derived from experiences within one plant or laboratory scale system or from questionnaire-based surveys and hence not universally applicable (4,10–12). Chemical treatment methods, such as chlorine or hydrogen peroxide dosing, are only temporary measures; these oxidants are nonselective; therefore, organisms that are beneficial to the AS process may also be adversely affected. Antifoaming agents, bioadditives containing enzymes, microorganisms and nutrients, coagulants and iron salts, used to treat foams, vary in success but are generally not cost-effective. Filaments implicated in foaming and bulking are considered slow growers and may be washed out of the AS system by reducing the sludge age or mean cell residence time (MCRT). This approach is usually not suitable in plants where nitrification is essential because the MCRT necessary for nitrifying bacteria exceeds that required to washout filaments. Selector technology is an engineering approach, whereby modified or additional bioreactor tanks impose environmental conditions that place undesirable filaments at a competitive disadvantage to other floc-formers (13,14). However, selector tanks are not effective against all foaming or bulking filament types as these can vary considerably in their metabolic activities.

BACTERIA INVOLVED IN FOAMING AND BULKING

Filament Identification Schemes

Eikelboom (15) published the first key recommended for identifying filaments in activated sludge. In this scheme, filaments were identified by taxonomic name or given a morpho-type number and assigned to groups based on morphology, staining properties, example, Gram's stain, and the occurrence of cell inclusions, example, sulfur granules, determined by microscopy. This artificial classification, used in conjunction with filament abundance scales, has enabled comparative studies of filament composition and floc structure in AS plants in different regions of the world, under different plant operating conditions, and during bulking and foaming episodes. Microscopic examination is relatively simple and inexpensive, and regular monitoring can provide an early indication of foaming and bulking (16,17). Several additional schemes are available for filament identification (4,8,18), including color posters (19) and computer software formats (20).

The Usual Suspects

Numerous foaming and bulking plants have been surveyed worldwide to establish the relative abundance of different filament types. The same filaments are often reported in different geographical regions, though their relative abundance may vary, and several filaments occur in both foaming and bulking sludges. Foaming was originally attributed to gram-positive branched filaments identified as members of the genus *Nocardia* (21). Subsequent studies have reported many other species related to *Nocardia* in foams, including nonfilamentous types; these organisms are phylogenetically related and are termed collectively mycolic acid-containing actinomycetes (22,23). The gram-positive, unbranched filament *Microthrix parvicella* (24) has also been reported in foaming AS plants in many parts of the world (Fig. 3).

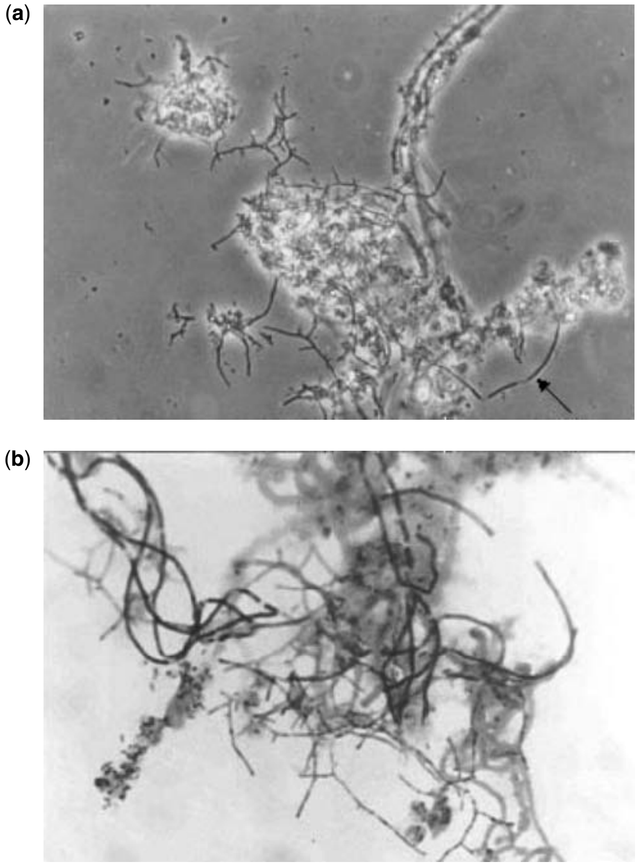

Figure 3. Microscopic examination of foaming activated sludge: (**a**) Wet mount preparation viewed under phase contrast (× 1000 magnification) and (**b**) Gram-stained preparation viewed under bright-field (× 1250). The dominant filaments are the spaghetti-like *Microthrix parvicella* with empty sections in trichome (arrow) and right-angled branched filaments with irregular staining patterns identified as mycolic acid-containing actinomycetes.

Other dominant filaments include *Halisocomenobacter hydrossis*, *Nostocoida limicola*, *Sphaerotilus* spp., and Eikelboom types 1863, 0092, 0041, and 0675 (13).

Filaments regularly associated with bulking in various parts of the world include *H. hydrossis*, *M. parvicella*, *Nocardia* spp., *N. limicola*, *Sphaerotilus natans, Thiothrix* spp., and types 021N, 1701, 0041, 0092, and 0675 (4,16). Geographical variations in filament populations may reflect differences in climate, wastewater composition, plant design, and operating conditions.

Isolation and Characterization of Filaments

Filament identification schemes provide a simplified view of the bacterial communities in activated sludge. Few bacteria can be accurately identified using only microscopy. Selective isolation studies, whereby dilutions of activated sludge or individual filaments extracted by micromanipulation are plated onto various nutrient media (23,24), enable the cultivation of bacteria in the laboratory for further characterization and identification. Studies that examine the genetic, phenotypic, and physiological traits of such organisms reveal that filaments with identical morphologies may be only distantly related in evolutionary terms and have quite different metabolic requirements (25,26). This, in turn, has profound implications for the development of engineering strategies to the control foaming and bulking organisms.

FACTORS AFFECTING THE GROWTH OF FOAMING AND BULKING ORGANISMS

Plant operating parameters, including mode of aeration, feed to mass ratio, and sludge retention time or MCRT, reportedly influence the proliferation of particular filament types (4). The composition of influent wastewater, substrate concentrations, and abiotic factors such as dissolved oxygen concentration, ambient temperature, mixed liquor pH, and redox potential are also important. The growth rates of bacteria and hence their ability to remain within the AS system also depend on their nutrient requirements and metabolic versatility. Mycolic acid-containing actinomycetes provide a good example because they can metabolize a diverse range of substrates. Many members of this group also produce biosurfactants (27,28), which aid foam stabilization and provide selective access to oils and fats prevalent in wastewater (29), which gives them a competitive advantage over many other bacteria.

MOLECULAR BIOLOGICAL TOOLS

Molecular biological techniques developed in the last decade are providing new insights into the complexity, dynamics, and ecophysiology of bacterial populations implicated in foaming and bulking. Fluorescent *in situ* hybridization (FISH) enables detecting and enumerating of particular phylogenetic groups of bacteria in activated sludge, irrespective of their morphology (30). Fluorescent-labeled nucleic acid probes can be designed to target cells of the whole bacterial community or at different phylogenetic levels down to individual species or even subspecies (31–33). Quantitative microautoradiography (QMAR) used together with FISH, allows *in situ* measurement of the uptake of specific radiolabeled substrates by individual bacterial cells that belong to particular phylogenetic groups (34). Information on the substrate utilization kinetics of different filamentous bacteria will help us to understand why they predominate in bulking or foaming AS plants and the operating conditions under which this occurs.

EXAMPLE: MONITORING FOAM-FORMING BACTERIA USING FISH

The micrograph image in Fig. 4a shows an example of FISH using two fluorescent-labeled probes. The technique involves fixation of an activated sludge sample to preserve the bacterial populations present, followed by permeabilization of the cells to allow the probes to enter and hybridize with target nucleic acid sequences. Treated samples are mounted on microscope slides and viewed by epifluorescence microscopy using a confocal laser scanning microscope (CLSM). Images of randomly selected fields of view can be captured, and the cells in a known volume

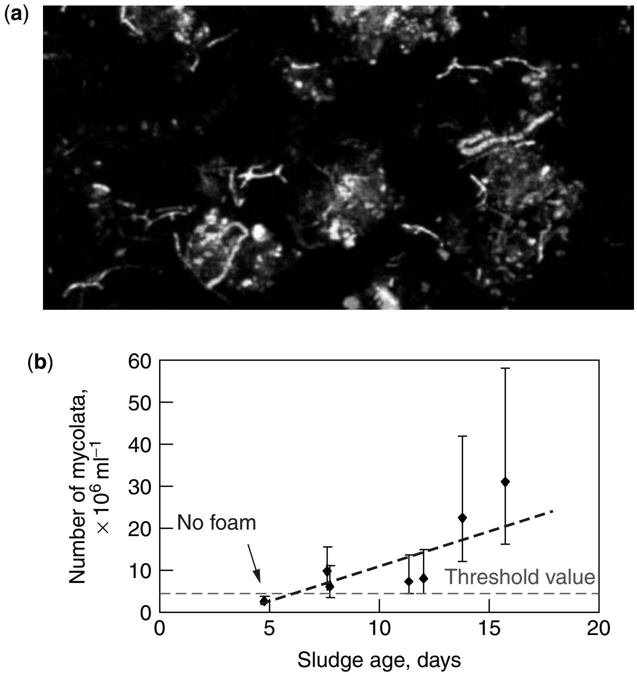

Figure 4. Fluorescent *in situ* hybridization: (**a**) Confocal laser scanning micrograph of activated sludge taken from a foaming WWTP. The sample is hybridized with two nucleic acid probes, a eubacterial-specific probe (Bact338) labeled with fluorescein isothiocyanate (FITC), which fluoresces green, and a mycolata-specific probe (Myc657) labeled with tetrarhodamine isothiocyanate (TRITC), which fluoresces red. Only bacterial cells that hybridize with both probes and appear yellow-orange in color are mycolata (mycolic acid-containing actinomycetes). (**b**) Plot showing the relationships between sludge age, numbers of mycolic acid-containing actinomycetes determined using quantitative FISH and foaming in an AS reactor. The error bars indicate 95% confidence intervals (courtesy of R. J. Davenport, unpublished data; 2003).

of activated sludge calculated using computer software. FISH has been used to monitor changes in the abundance of mycolic acid-containing actinomycetes in an AS plant operated at different sludge ages. The graph in Fig. 4b shows that a significant rise in the numbers of these organisms occurs with increasing sludge age and that there is a threshold in numbers that triggers foaming (32).

AQUEOUS BEHAVIOR OF ELEMENTS IN A FLUE GAS DESULFURIZATION SLUDGE DISPOSAL SITE

Frank J. Castaldi
Brown and Caldwell
Austin, Texas

FLUE GAS DESULFURIZATION PROCESS DESCRIPTION

Most conventional combustion processes emit sulfur oxides, nitrogen oxides, carbon oxides, particulate matter, and other potentially harmful pollutants into the air. Solid wastes from combustion processes or from associated control technologies present disposal and environmental health problems. Adverse water-related health and ecological effects might result when chemical compounds and metals are leached from solid residues.

Flue gas desulfurization (FGD) systems are end of process pollution abatement techniques used primarily for removing sulfur dioxide from coal-fired utility and industrial boiler combustion gases. The technology has also been successfully applied to Claus sulfur recovery unit tail gas and sulfuric acid plant tail gas streams. Sulfur dioxide (SO_2) and particulate emissions are controlled by a flue gas scrubber system. The scrubber is often designed as an integral part of the steam generation plant. It consists of a two-stage venturi-absorber scrubber module designed to treat boiler flue gas. The flue gas from the boiler enters the air quality control system through a common plenum. The gas stream is sent to the individual scrubber modules from this plenum.

The sulfur-laden flue gas first passes through an electrostatic precipitator or venturi scrubber for particulate removal and then into a multistage absorber where it contacts the absorption slurry. Scrubbed gas passes through a demister and is reheated prior to discharge to the atmosphere to provide buoyancy and prevent condensation. Sulfur dioxide removal is normally 85–90%. Up to 99% of the particulate matter is removed from the gas stream at this point (1). The particles are entrained in the liquid that drops into the bottom sump. The gases then pass through the SO_2 absorber section. The SO_2 is removed by adsorption as the gas stream is drawn through stainless steel sieve trays that are sprayed with the absorption slurry. This slurry with the absorbed SO_2 also drops into the bottom sump. The gas stream then passes through a demister section in which excess moisture and mist are removed. Then, the gases are reheated to increase the gas temperature for improved gas buoyancy and to reduce the probability of deposits on the induced air fans. Upon exiting the scrubber, the gases are sent to the stack.

Wet desulfurization processes produce large quantities of nonregenerable waste. Wet scrubbing processes may use calcium carbonate ($CaCO_3$), calcium oxide (CaO), alkaline fly ash, and sodium carbonate (Na_2CO_3) as scrubbing materials (2,3). Limestone-based FGD systems are nonregenerable processes where the reactive component in the absorbent slurry combines chemically with SO_2 to form a sludge that consists of fly ash, water, calcium sulfate, and calcium sulfite. The calcium sulfate and calcium sulfite sludges are waste by-products. Sodium-based scrubbing systems produce sludge that typically contains unspent scrubber material, sodium sulfite and sulfate, and entrained fly ash. Unlike calcium-based systems, the waters that characterize sodium-based FGD processes and their associated sludge have high concentrations of dissolved solids dominated by sodium and sulfate ions. Sodium-based FGD processes and their associated sludge pond systems may also generate hydrogen sulfide as a by-product, which could be emitted into the atmosphere.

LIMESTONE/LIME-BASED FGD SYSTEMS

In limestone-based FGD systems, ground limestone mixed with water is used for making up the scrubber slurry. The slurry water is recycled from settling ponds where solids accumulate. The SO_2 and sulfur trioxide (SO_3) are removed from the flue gas stream by reaction with the aqueous solution of limestone. The major component of limestone is $CaCO_3$. The products from the SO_2 reaction are carbonic acid (H_2CO_3) and calcium sulfite hemihydrate ($CaSO_3{\bullet}\frac{1}{2}H_2O$). The products from the SO_3 reaction are carbonic acid and calcium sulfate dihydrate ($CaSO_4{\bullet}2H_2O$). The reactions are presented here:

$$SO_2 + 1.5\ H_2O + CaCO_3 \longrightarrow H_2CO_3 + CaSO_3{\bullet}\tfrac{1}{2}\ H_2O$$

$$SO_3 + 3\ H_2O + CaCO_3 \longrightarrow H_2CO_3 + CaSO_4{\bullet}2\ H_2O$$

The pH of the slurry is maintained at 5.5 to 6.0. The optimum pH for the chemical reactions is 5.6 to 5.8. If the pH exceeds 5.8, the amount of limestone required increases, and soft scale begins to accumulate rapidly. If the pH drops below 5.6, a hard gypsum ($CaSO_4{\bullet}2H_2O$) scale builds up on scrubber surfaces. Adjusting the rate at which limestone is added to the slurry controls the pH of the slurry.

In a lime-based FGD process, lime and sulfur dioxide react to form calcium sulfite or sulfate as follows:

$$CaO_{(s)} + SO_2 + \tfrac{1}{2}H_2O \longrightarrow CaSO_3{\bullet}\tfrac{1}{2}\ H_2O$$

$$CaO_{(s)} + SO_2 + 2\ H_2O + \tfrac{1}{2}\ O_2 \longrightarrow CaSO_4{\bullet}2\ H_2O$$

In this process, first lime hydrates and dissolves in the aqueous phase. Next, sulfur dioxide dissolves in the aqueous phase where it participates in numerous ionic reactions. Finally, calcium sulfite and sulfate form precipitates that are removed from the aqueous phase.

Oxidation is important in this system. If the system oxidation is very low, all of the calcium sulfate produced will leave in the liquid phase. If the oxidation is below a critical value, generally considered to be approximately 20%, the sulfur will leave as a solid solution of calcium sulfite/sulfate. If the oxidation rate is high, the sulfate builds to supersaturation, and gypsum precipitates. If the extent of supersaturation is above 1.3 to 1.4, scaling can occur (4–6).

Under ideal conditions, a forced-oxidized limestone-based FGD system will produce wallboard grade gypsum. An important factor in the quality of the gypsum produced by such a FGD system is the amount of chlorine in the coal. The chlorine content of the fuel and the chloride concentration in the makeup water control the volume of liquid bleed needed to manage the chloride level in the FGD system. Because few chloride ions can leave the process in the washed gypsum product, almost all of the chloride that enters with the coal must be purged from the system as a blowdown. This blowdown is the FGD scrubber purge water, which will require treatment before it can be discharged to most receiving waters.

The solid wastes generated by combustion are removed from the system as slurries. The electric power industry generally uses ponds and landfills to dispose of sludge. When an oxidation step is included, the limestone-based FGD system yields a sludge that is mostly calcium sulfate (gypsum). Inhibited or nonforced oxidation systems produce sludges that are mostly calcium sulfite. The solids that settle to the bottom of the settling ponds are periodically dredged. The majority of the solid waste is disposed of in a company-owned landfill.

FGD SCRUBBER PURGE WATER CHARACTERISTICS

Table 1 presents the chemical characteristics of purge waters from forced and inhibited oxidation limestone-based FGD systems (7). These data indicate that purge water from FGD systems that are designed for forced oxidation are lower in reduced sulfur species than nonforced oxidation processes but may still contain high concentrations of thionates and sulfur–nitrogen compounds. Trithionate is the dominant thionate in nonforced oxidation systems, whereas dithionate is most prevalent in forced oxidation purge water. Thiosulfate is the dominant reduced sulfur species in nonforced oxidation FGD system purge water.

These wastewaters contain numerous alkali metals and alkaline earth metals, as indicated in Table 2; calcium,

Table 1. FGD Scrubber Purge Water Characterization[a]

Parameter	Nonforced Oxidation, mg/L	Forced Oxidation, mg/L
pH units	6.3	6.9
Total alkalinity as $CaCO_3$	130	450
Total dissolved solids	58,200	11,700
Chemical oxygen demand	1,340	1,260
Chloride	28,900	3,460
Fluoride	30	23
Ammonia as nitrogen	<5	<5
Total Kjeldahl nitrogen	9.5	7.8
Nitrate as nitrogen	<2	<2
Nitrite as nitrogen	<0.1	6.4
Sulfide	<5	<5
Sulfite	41	<6
Sulfate	815	4,730
Thiosulfate	1,010	<12
Total hydrolyzable sulfur (as sulfate)	2,570	3,600
Dithionate	54	162
Trithionate	427	<6
Tetrathionate	102	<6
Hydroxylamine disulfonate (HADS)	386	127
Selenium	0.536	0.204
Nickel	0.929	0.972
Iron	8.98	0.019
Calcium	6,770	1,190
Magnesium	4,420	1,450

[a] Reference 7.

magnesium, sodium, potassium, and barium are present at the highest concentrations (8). The high chloride content of the combusted coal is the principal reason for the elevated concentrations of calcium and magnesium in the inhibited (nonforced) oxidation limestone-based FGD system purge water. Aluminum, cadmium, chromium, cobalt, copper, lead, manganese, molybdenum, silver, nickel, and iron also are present at detectable concentrations, but only nickel exists at levels requiring treatment.

Table 2. FGD Scrubber Purge Water Metals Analysis[a]

Parameter	Nonforced Oxidation, mg/L	Forced Oxidation, mg/L
Aluminum	0.707	0.0733
Antimony	<0.00532	0.0022
Arsenic	<0.00345	<0.00345
Barium	1.02	0.245

Manganese	1.44	40
Molybdenum	0.1	0.0663
Potassium	174	18.4
Silver	0.00164	0.00268
Sodium	1580	123

[a] Reference 8.

These purge waters also contain selenium at concentrations that require treatment to achieve an acceptable discharge quality. It is known that selenium forms complexes with both thionates and thiosulfate. Typical selenium–thionate complexes include selenopentathionate [$Se(S_2O_3)_2{}^{2-}$] and selenotrithionate; selenothiosulfate ($SeS_2O_3{}^{2-}$) is a typical complex of selenium and thiosulfate (7). These complex ions of selenium can increase the concentration of dissolved selenium in FGD sludge disposal pond waters.

ASH POND AND FGD SLUDGE POND WATER QUALITY

The ash pond and the FGD sludge pond are the major wastewater treatment facilities at electric utilities. The pond waters from FGD sludge disposal sites are usually slightly alkaline and oxidized; pH values are between 7 and 9, and oxidation–reduction potential (ORP) values are from +490 to +290 mV, respectively. Below the oxidized surface layer, the sludge and porewaters are generally highly reducing; ORP values average approximately −300 mV. In this environment, rainfall can impact the dissolution of sulfate, sulfite, and sulfide solids which in turn controls the leachate concentrations of metals (e.g., barium, calcium, cadmium, copper, iron, nickel, lead, strontium, and zinc), metalloids (e.g., antimony, boron, arsenic), and nonmetals (e.g., fluorine and selenium). Field observations have indicated that anaerobic, heterotrophic sulfate-reducing and denitrifying microbes are present in significant populations in FGD sludge and impact the geochemistry of these materials (2,3). Consequently, the low ORP measurements typically observed in FGD sludge porewater are indicative of active dissimilative metabolism that results in microbial reduction of sulfate to hydrogen sulfide.

FGD sludge porewater chemical characteristics for both calcium-based and sodium-based SO_2 scrubber systems are presented in Table 3 (2,3). These data show the range of constituent concentrations that may be found in FGD sludge porewater for a variety of coals and sulfur removal processes. Table 4 presents a comparison of constituent chemistries for FGD sludge liquors and elutriates from a variety of calcium-based and sodium-based SO_2 scrubber systems for power plants that burn either western or eastern US coals (9,10). The large variation in the water chemistry of desulfurization sludges is indicative of the complex nature of FGD sludge–water systems as well as the potential environmental impact that may result from improper disposal of these materials. Elevated concentrations of arsenic, boron, chloride, fluoride, and selenium in FGD sludge liquors and elutriates present unique problems for environmental management and control.

A high potential for H_2S odors from FGD sludges is suggested by the porewater sulfur speciation data. The substantial quantity of reduced sulfur species observed in porewaters results partly from dissimilatory sulfate reduction by *Desulfovibrio sp*. and related microorganisms (2). It is surmised that the variation in the concentrations of reduced sulfur species may result from microbial use of thiosulfate and sulfite as well as sulfate and the degree of oxygen penetration into the underlying sludge porewaters.

Table 3. FGD Sludge Porewater Chemical Characteristics

Constituent	Calcium-Based SO_2 Scrubber Systems (3), mg/L	Sodium-Based SO_2 Scrubber Systems (2), mg/L

Fluoride	1.4–70	0.7–3.0
Sulfate	720–30,000[c]	2,100–18,500[b]

[a] References 9 and 10.
[b] The high-end concentration of sodium is for dual alkali FGD sludge and reflects a single measurement on an unwashed filter cake.
[c] The high-end concentrations of chloride and sulfate are for limestone scrubbing of FGD sludge and reflect a closed-loop process using cooling tower blowdown for process makeup water.
[d] Chloride forms weak complexes with many metals, including calcium, and these may be scavenged from solution by fly ash.

Ash pond water at a typical bituminous coal-fired power plant may contain a number of pollutants that can impact the local soil and groundwater. These include the metals aluminum, copper, mercury, lead, nickel, and thallium; the metalloids arsenic and antimony; and the nonmetal selenium. Generally, fly ash handling wastes are the largest source of pollutants to an ash pond (11,12). Other smaller sources include bottom ash handling, plant sump wastes, and cooling tower discharges. Coal pile runoff may also be an intermittent source of pollution along with fly ash sluice water, which is generally at a low pH.

Under typical conditions, ash ponds provide sufficient residence time to reduce suspended solids concentrations below discharge limits (13,14). The solid particles that remain are those that are near or below the density of water and those that are so small that they exhibit properties that create a repelling force and prevent agglomeration and settling in the residence time available to them. These particles are generally clays and fine silt soils from naturally occurring portions of the fly ash waste stream or from commingled stormwater runoff. Heavy metal contaminants such as aluminum and iron in the discharge of ash ponds are directly related to the concentration of suspended effluent solids.

Arsenic and selenium are predominately present in their dissolved state in ash pond water and are poorly removed by this treatment. The forms most commonly found in ash pond water are arsenate (Arsenic V) and selenite (Selenium IV). The speciation of these constituents affects wastewater management because each element has a different treatment requirement that results from differences in their aquatic toxicity. For example, arsenate is more toxic to aquatic life than arsenite (Arsenic III). Fortunately, arsenate is effectively removed by iron coprecipitation, which is also an effective treatment for removing selenite from ash pond water (15). However, neither arsenite nor selenate (Selenium VI) are effectively removed by ferric oxyhydroxides. The fact that soluble arsenic and selenium are not effectively removed by ash ponds suggests that coprecipitation does not occur under normal operating conditions. This indicates a lack of either a source of ferric or ferrous ions within these ponds.

The wet sluicing of fly ash to a pond will increase the apparent concentration of copper and selenium in the pond for certain coal types (8). Wet sluicing will also affect the water quality throughout the pond. The elevated selenium concentrations in ash pond water are due primarily to the increased loading of the soluble form of this constituent that results from the physical act of sluicing. Copper concentrations are also high because of the lower pH conditions that are a consequence of the wet sluicing operation. The relationship between the copper concentration and the pH is supported by solubility theory in that the apparent concentration of copper is an order of magnitude higher at pH 6 than at pH 7 in slightly acidic ash ponds. The percent sulfur in the coal and the calcium content in the dry fly ash influence the pH of the ash sluice water. The solubilities of other metals are not as impacted as is copper by pH changes in the range 5 to 7.

Similarly, the character of the ash influences the concentrations of all heavy metals in an ash pond. For example, acidic fly ash contains high levels of carbonates and sulfates that affect the solubility of certain metals (e.g., copper, nickel, zinc) in the pond water. The amount of iron hydroxide present in the water influences the removal of trace metals by precipitation. Although the range of pH changes vary in different ash pond systems, heavy metal concentrations generally increase with decreasing water pH (8).

Both arsenic and selenium have been removed from wastewater using ferric oxyhydroxide treatment at low pH (7,15). Arsenate is removed effectively by iron coprecipitation at pH values up to 9, and selenite can be treated up to pH 7. However, both constituents are removed more effectively at lower pH. Ferric oxyhydroxide treatment is also effective for removing chromium (III), cadmium, lead, nickel, zinc, and vanadium from FGD sludge pond water. However, it is less effective for removing chromate (chromium VI) and completely ineffective for removing selenate (selenium VI) and boron from FGD sludge pond water.

The metals concentrations in ash and FGD sludge ponds are different because the capture mechanisms of the electrostatic precipitator (ESP), which removes fly ash from the flue gas, and the FGD scrubber, which removes SO_2 from the flue gas, are different. The FGD system captures less ash but more of the volatile metals than the ESP system (13). This results in a higher concentration of dissolved metals in FGD sludge pond water. The two treatment systems are also different because of differences in pond pH. The pH in the FGD sludge pond is usually lower than the pH in an ash pond system because of the nature of the limestone absorption system used for acid gas control in FGD scrubbers (16).

Metals that volatilize and stay in the gaseous form are captured preferentially in the FGD scrubber. Mercury in flue gas exists either as oxidized or elemental mercury. Generally, oxidized mercury is easily captured by the FGD system (17). It is also common to detect nickel at higher concentrations in FGD sludge ponds than in ash ponds because of the effect of chloride on nickel solubility. The presence of chloride at concentrations greater than 10 mM/L in FGD process liquor results in higher nickel solubility by forming soluble nickel–chloride complexes (8). Higher nickel concentrations in FGD sludge ponds also result from the fact that this metal is added with the limestone slurry. The loading of nickel from limestone slurry accounts for approximately 75% of all nickel found in the water of FGD sludge ponds.

The water-phase concentrations of most metals (i.e., copper, mercury, nickel, and zinc) are higher in FGD sludge ponds than in ash ponds. Copper and zinc concentrations are highest at a pH below 6 but decrease as pH values increase. The concentrations of aluminum and arsenic may be higher in ash ponds than in FGD sludge ponds because the concentrations of these constituents tend to increase at the higher pH of the ash pond (8).

Selenium is generally found at higher concentrations in water from FGD sludge ponds than in typical ash ponds (7). Selenium lies just below sulfur in the periodic table, and its chemistry is similar in many respects. Selenium exhibits variable valence from −II to +VI; the most common forms are Se^{2-}, Se^{4+}, and Se^{6+}. Several compounds containing selenium in the various oxidation states are shown in Table 5 with their sulfur analogs. Selenite (selenium IV) is the predominate form of selenium found in waters from ash ponds, and selenate (selenium VI) is the predominate form of selenium found in the waters from FGD sludge ponds (8).

Selenide is the dissociated form of hydrogen selenide (H_2Se). Like its sulfur analog (H_2S), hydrogen selenide is volatile in its associated form, although its vapor pressure is slightly lower than that of hydrogen sulfide. However, hydrogen selenide has much less tendency to volatilize than hydrogen sulfide because its pK_a (3.9) is much lower than that of $H_2S (pK_a = 7.0)$. The principal forms of selenium in FGD sludge pond water are selenite and selenate, which are stable in water and act independently of each other. Generally, selenite is present at lower concentrations because it occurs mainly in acidic and moderately oxidizing waters whereas selenate is predominant in waters that are alkaline and oxidizing. The occurrence of selenium as an oxyanion in water gives it acid characteristics. Selenous acid (H_2SeO_3) is a weak acid ($pK_a = 2.8$) that dissociates in water to $HSeO_3^-$ and SeO_3^{2-}. The concentrations of SeO_3^{2-} and $HSeO_3^-$ are pH dependent; SeO_3^{2-} occurs predominantly at a neutral pH. The hydroxides of iron readily adsorb selenite, thus fixing it in soils as a ferric–selenite complex. However, selenic acid (H_2SeO_4) is a strong acid ($pK_a = -3.0$) that dissociates to give SeO_4^{2-}. Selenate salts are more soluble than the corresponding selenite salts and are not affected by iron hydroxides (7). Selenate behaves like the sulfate ion in natural waters. Consequently, selenium can readily enter the food chain as selenate through soils, into plants, and finally to animals. Elemental selenium exists in several crystalline and amorphous forms; the crystalline metallic form is the most stable and relatively insoluble in water.

The remaining selenium in FGD sludge pond water is probably present as selenotrithionate, a complex ion (7). It is surmised that the addition of the thiosulfate ion displaces sulfite from selenotrithionate to give

Table 5. Forms of Selenium and Sulfur in FGD Sludge Pond Water (7)

Valence	Selenium	Sulfur
−II	Selenide (Se^{2-})	Sulfide (S^{2-})
0	Elemental (Se^0)	Elemental (S^0)
+IV	Selenite (SeO_3^{2-})	Sulfite (SO_3^{2-})
+VI	Selenate (SeO_4^{2-})	Sulfate (SO_4^{2-})

Table 6. Results of TCLP Analysis of Sludges from Treatment of Oxidized FGD Scrubber Water[a]

Metal	Sludge Concentration,[b] mg/kg	TCLP Leachate Concentration,[c] mg/L	Allowable Leachate Regulatory Limit,[d] mg/L
Arsenic	0.0418	<0.0233	5.0

Cadmium	0.308	0.0146	1.0
Chromium	12.0	0.0047	5.0
Lead	13.8	<0.0107	5.0
Mercury	0.206	<0.0003	0.2
Nickel[e]	12.4	0.116	NA[f]
Selenium	17.3	0.341	1.0
Silver	0.0179	0.0049	5.0

[a] Reference 8.

[b] The solids resulted from selenium treatment applied to oxidized FGD scrubber water.

[c] After the leaching period, the solids were recombined with the original filtrate before the TCLP was performed. The total solution was then filtered and collected for analysis.

[d] Allowable TCLP regulatory limits in 40CFR261.24.

[e] Nickel is not a TCLP metal.

[f] NA = Not applicable.

selenopentathionate, as follows:

$$Se(SO_3)_2{}^{2-} + 2S_2O_3{}^{2-} \longrightarrow Se(S_2O_3)_2{}^{2-} + 2SO_3{}^{2-}$$

Solutions of selenopentathionate undergo slow decomposition in a FGD sludge pond to produce elemental selenium and the tetrathionate ion. This process probably accounts for the loss of selenium from nonforced-oxidized FGD sludge pond waters when these waters are retained in surface impoundments at ambient temperature for several weeks or more. Usually, the presence of selenopentathionate and selenotrithionate in FGD sludge pond water increases the concentration of dissolved selenium in pond waters. Therefore, it is surmised that inhibition of the removal of selenium from FGD sludge pond water is due to the formation of selenium–thionate complexes that are formed by the presence of thiosulfate in the pond (7).

The results of the Toxicity Characteristic Leaching Procedure (TCLP) performed on sludges from the treatment of oxidized FGD scrubber water are presented in Table 6 (8). The treatment involves contacting the FGD scrubber water with the ferrous ion and hydrated lime to remove the oxyanions of selenium and several divalent and trivalent metal cations such as chromium, lead, and nickel. These constituents appear at elevated concentrations in the resultant wastewater treatment sludge. Nevertheless, the results of the TCLP analysis on this sludge indicate that all constituents are within the allowable leachate regulatory limit.

SLUDGE TREATMENT AND DISPOSAL

Ludovico Spinosa
National Research Council
BARI, Italy

The management of sewage sludge is a major problem in wastewater treatment. Sludge amounts to about 2% by volume of processed sewage, but handling it accounts for up to 50% of total operating costs. Furthermore, during the last few years, there has been a worldwide movement toward a common strategy for any kind of waste; the priorities are reusing waste materials and taking advantage of their energy content.

Treatment of sludge is aimed at rendering it suitable for use or disposal at minimum cost. The low solids concentration (2–3%), and the presence of pathogens, heavy metals, organic pollutants and potentially putrescible organic matter are the main problems to be faced and solved. Other factors influencing sludge processing technology are the need to extract as much energy and material as possible from the sludge itself and the introduction of stricter regulations that require higher levels of treatment before disposal.

PRODUCTION AND CHARACTERIZATION

Three principal categories of sewage sludge can be identified: primary, derived from mechanical and preliminary treatments; secondary or waste activated, from biological treatments; and tertiary, from final physicochemical treatments.

Typical sludge quantities and concentrations are reported in Table 1. They range from 0.2 to 5.0 L/cap/d and 0.7% to 10.0%, respectively; 2 L/cap/d at 4% solids concentration is the typical production of primary plus activated sludge from municipal plants.

The selection of the best processing sequence preliminarily requires knowledge of the sludge characteristics. Total, suspended, and volatile solids content, density of dry solids (1.3–2.1 g/cm^3), pH, sludge volume index (SVI), specific resistance to filtration (values of the order of 10^{12} m/kg at 49 kPa generally indicate good filterability), capillary suction time (CST, optimal values around 10 s using a 10-mm reservoir), compressibility coefficient, floc strength, caloric value (ranging from 21 to 28×10^3 kJ/kg volatile solids), and nutrient content are the most common parameters.

Rheological properties are also of great importance because they influence almost all treatment and utilization/disposal operations. This is particularly true for land application and storage and transportation steps because the selection of the most suitable equipment and procedure is strongly dependent on physical consistency and flow characteristics.

TREATMENT

Treatment options are numerous, but (1) thickening and dewatering to reduce sludge volume and subsequent handling costs and (2) stabilization to reduce putrescibility due to organic matter are of prevailing interest. Disinfection also plays an important role.

Thickening

Thickening, normally carried out before stabilization reduces sludge volume by two to three times. Generally, solids concentration remains below 10%, the sludge behaves as a liquid, and is still pumpable by conventional equipment.

Gravity thickening in tanks is often the most cost-effective method. A thickener may be provided with vertical pickets to facilitate the release of water and gases. Loading rates range from 1.6 to 3.3 kg/m^2/h for mixed sludges, and hydraulic retention times are lower than 24 h to avoid odor problems. As an alternative, sludges can also be thickened by various mechanical systems, such as drainage belts, rotary-drum thickeners, and centrifuges, which sometimes require adding a polyelectrolyte for sludge conditioning. Sludges can be also thickened by dissolved air flotation units.

Dewatering

By dewatering, volume reduction greater than by thickening is obtained, and the sludge becomes paste-like. To improve performance, dewatering is generally preceded by conditioning (chemical or physical).

In chemical conditioning, the particle charge is neutralized, and flocculation is promoted by organic reagents (polymeric macromolecular compounds characterized by monomer type, molecular weight, ionic charge, and degree of hydrolysis) or inorganic reagents (such as iron and aluminum salts, lime, or a combination).

The conditioner type and dosage can be assessed by general laboratory tests, for example, a jar test, specific resistance to filtration and CST, and specific tests for each type of dewatering technology. Physical methods include thermal conditioning, freezing, and the use of inorganic admixtures. Thermal conditioning involves heating sludge at 180–220 °C for 30–90 minutes; sludge sterilization also occurs. Conditioning by freezing seems to be justified only if accomplished by natural means. The use of inorganic substances (e.g., ash, diatomaceous earth) can produce a mixture that has improved filtering characteristics and is usually less compressible than the sludge alone. Dewatering can be accomplished naturally (by drying beds) or mechanically (by filtration or centrifugation).

Drying Beds

When land is available, dewatering by nature can be attractive. On the beds, sludge is placed 15–30 cm deep,

Table 1. Typical Sludge Quantities and Characteristics

Type	Quantity, L/cap/d	Solids Concentration, %	Nitrogen, %-DM	Phosphorus, %-DM	Potassium, %-DM
Raw primary	0.9–2.2	2.0–8-0	1.5–7.0	0.3–2.8	<1.0
Raw activated	1.4–7.3	0.5–1.5	3.0–10.0	1.0–7.0	0.1–0.9
Raw pr. + act.	1.8–2.8	3.0–6.0	4.0–6.0	1.0–1.2	—
Dig. pr. + act.	0.5–1.0	2.0–12.0	1.0–6.8	0.2–5.7	<4.0
Tertiary	0.2–8.0	5.0–10.0	—	—	—

Note: DM = dry matter.

and the time required to reach a liftable state ranges from a few days to several months, depending on climate and sludge characteristics. The area required ranges from 0.05 to 1.40 m^2/cap. Lagoons are similar, but sludge is placed at depths 3 to 4 times greater than in a bed. Lagoons are generally used for long-term storage and, eventually, for cold digestion.

Mechanical Equipment

Mechanical dewatering can take place by filtration, with a filter press or belt press, or by centrifugation. Schemes of these machines are shown in Fig. 1. Filtration under pressure is carried out for 1.5–6.0 h at 0.5–1.4 MPa and is the only operation that allows a cake concentration >30%. Conventional plate filter press operation requires a great deal of labor to open and clean equipment, and yield is low. The automation of plate movement and cloth washing make labor reduction possible, and yield can be increased by using membrane type machines.

In belt pressing, dewatering takes place through an initial drainage step followed by compression under rollers, where sludge also undergoes shearing action due to the relative movement of the two belts. Specific flow rates of 2–3 m^3/h/m belt width are common for municipal sewage sludge, and cake concentrations of 25–30% can be expected. Special care must be taken in belt washing which requires a rinsing water flow rate of 50–200% of that of input sludge.

The type of centrifuge used mostly consists of a cylindrical–conical shell (bowl), that has an internal Archimedean screw (scroll/conveyor) that revolves at a speed slightly lower than that of the bowl. The solid–liquid separation takes place like sedimentation but at g values up to 3000. Pool depth, beach length, and bowl/conveyor differential speed are the most important variables that affect performance. The main advantages consist of indoor solid–liquid separation and limited equipment size, but cake concentrations higher than 25% are normally difficult to obtain. The main general features of filter presses, belt presses, and centrifuges are summarized in Table 2.

Innovations include the development of screw presses, continuous filter presses, high-pressure belt presses, and new generation centrifuges, such as the centripress.

Stabilization

Stabilization is employed mainly for odor control, although pathogen reduction is also achieved. Available options are biological stabilization (anaerobic digestion, aerobic stabilization, and composting), normally permanent in effect, and chemical stabilization (by lime addition), normally temporary. The addition of various oxidizing

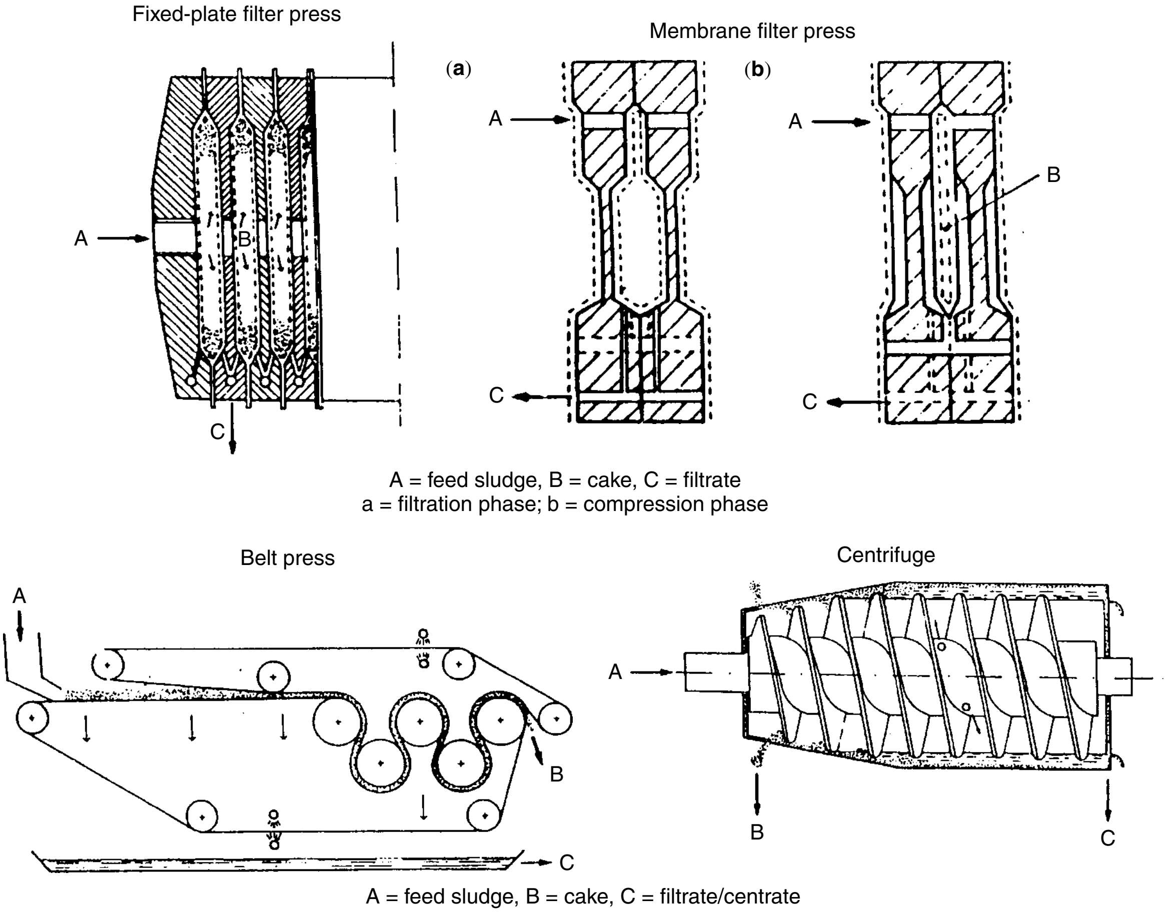

Figure 1. Schemes of dewatering machines.

Table 2. Dewatering Equipment Features

Type	Cake Concentration, %	Separation Efficiency, %	Area Requirement	Energy Demand
Filter press	>30	>95	high	low
Belt press	25–30	around 95	medium–high	medium
Centrifuge	<25	<95	low	medium–high

chemicals (ozone, hydrogen peroxide, etc.) is another possibility, but less used.

Anaerobic Digestion

Anaerobic digestion consists of biological degradation of organic substances in the absence of free oxygen. The organic matter is first liquified and converted by acid-forming bacteria to short-chain acids, then converted by strictly anaerobic methanogenic bacteria to methane, carbon dioxide, and other trace gases.

The simplest process is to store the sludge in open basins for several months, but now this has limited application, especially in cold climate, because of operational and safety problems. A heating process at 35 °C in mesophilic conditions is the norm. The advantages include methane production, no need for oxygen supply, lower net sludge production, and easier solubilization of complex organics. Among the disadvantages, operating control, maintenance problems, heat requirements, supernatant quality, and high capital costs must be mentioned.

Factors that affect the process are feeding modalities, mixing (external pumping, internal mechanical mixing, and internal gas mixing), temperature, pH, bicarbonate alkalinity, volatile acids, and toxics. Typical systems are (1) the low-rate (unheated, unmixed, and intermittently fed); (2) the one-stage high-rate (heated, mixed, and continuously fed); and (3) the two-stage high-rate, a combination of above systems (Fig. 2).

Biogas production of 0.75–1.10 m^3 per kg of volatile solids destroyed, consisting of 65–70% CH_4, 30–35% CO_2, and traces of H_2, H_2S, and volatile solids destruction as high as 60% can be expected.

The most important criterion for digester design is the volumetric loading rate. Reported values range from 0.4 to 8.0 kg volatile solids/m^3/d, depending on digester type. However, as a result of better understanding of digestion kinetics, the solids retention time parameter is now recognized as more important. Hydraulic retention times range from 7 to 30 days.

The development of low-cost spark ignition engines suitable for operation on biogas gives the possibility of

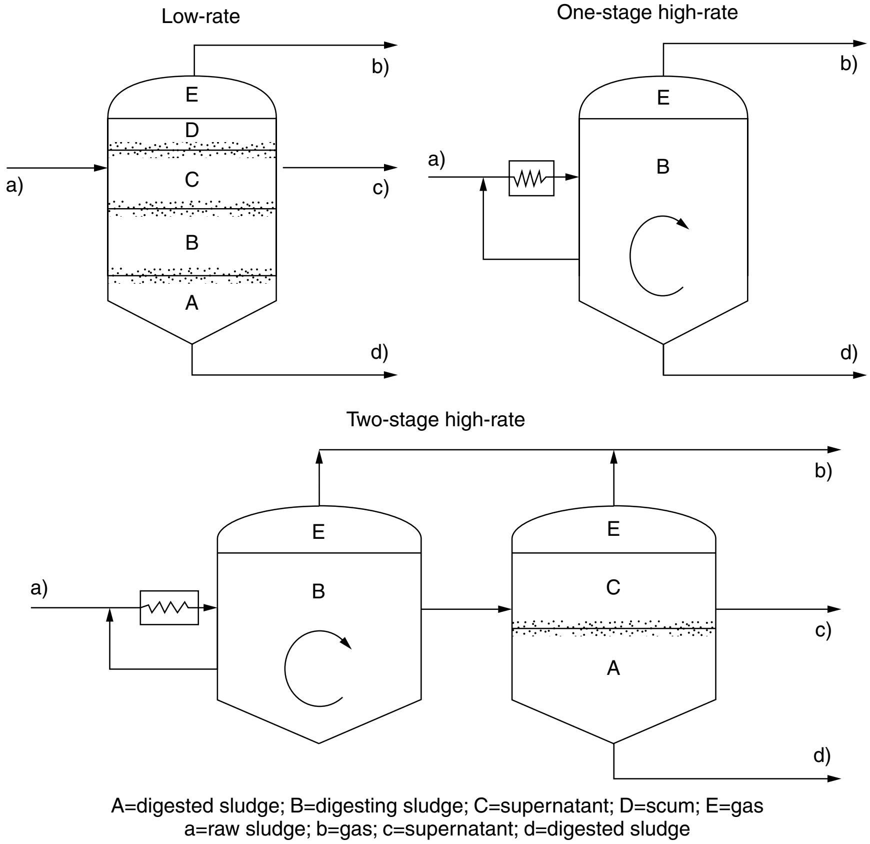

Figure 2. Anaerobic digestion systems.

generating power at small works, even rural, thus making the operation of digesters more attractive economically.

Aerobic Stabilization

Sludge can be stabilized by simply aerating it in open basins. Alternatives are cold stabilization at ambient temperature and autoheated stabilization in thermophilic conditions at high temperature. Cold stabilization involves relatively large energy use for aeration and mixing. Retention times of 10–20 days are normally necessary, but 50 days or more are not uncommon in cold climates. This process is justified at small plants, where the realistic maximum reduction of volatile solids is 40%. In an autoheated process, the heat produced by oxidation of organic matter is conserved to produce a temperature rise to 55 °C or more, thus involving stabilization in only 3–5 days and also sanitizing. The essential prerequisite of this process is effective heat insulation.

As an alternative, oxygenation can be provided by pure oxygen. The gas throughput and consequent heat losses can be minimized and the process operated in more favorable conditions. Another system is the dual-digestion process in which sludge is treated at 50–70 °C by thermophilic aerobic digestion followed by anaerobic digestion without the need for further heating.

Composting

Composting is an aerobic process in the solid phase that converts biodegradable organic substances to a stable, hygienic, and humus-like material under the combined activity of a mixed population of bacteria, fungi, actinomycetes, and protozoa. Composting is considered a treatment option to sludge agricultural refuse.

The main operating variables that affect performance are (1) moisture content (optimal 50–60%) to support microbial activity; (2) carbon to nitrogen ratio (optimal 25–30) to avoid slow processing at high ratios or ammonia volatilization at low ratios; (3) aeration to permit metabolism and respiration of microorganisms and oxidation of organic molecules and avoid development of malodors; (4) temperature (optimal 55–60 °C) to obtain pathogen reduction without inhibiting microorganism growth; and (5) pH, even if quite a wide range is acceptable (5.5–8.0).

Several techniques can be adopted; they differ mainly in aeration and mixing modalities, but all of them consist of basic steps including (1) addition of bulking agents to provide a sufficiently porous and soft mixture suitable for processing; (2) aeration and attainment of a temperature of about 60 °C to destroy pathogens and reduce moisture; (3) further storage (curing) to complete stabilization; and (4) refining treatments, generally including separation and recycling of bulking agents, screening, granulation, and packaging. The general categories of composting plants are open systems, confined ones, and closed or in-vessel systems (Fig. 3).

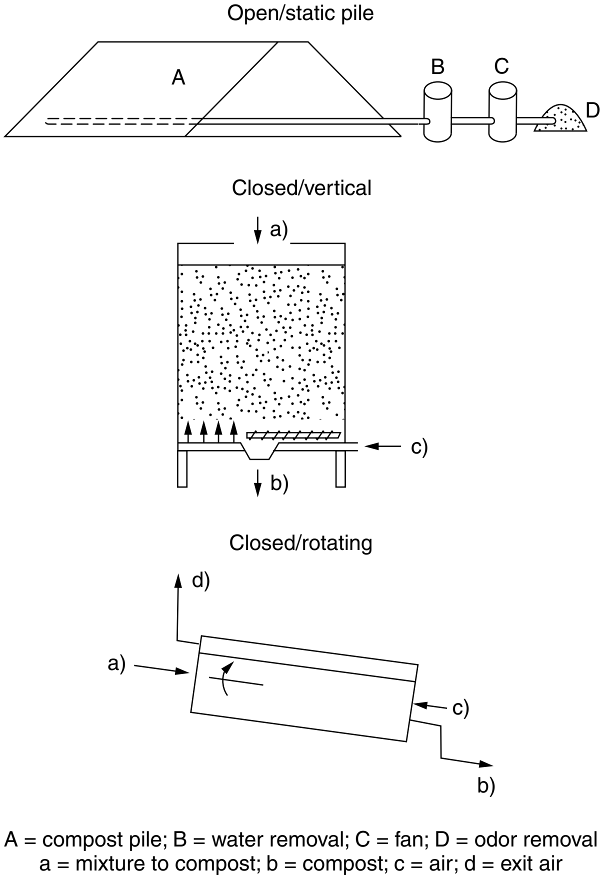

Figure 3. Schemes of composting systems.

In open systems, the material is arranged in windrows and aerated either by simply turning the mass (turned pile) or by forced ventilation (static pile). Stabilization occurs in 15–40 days, followed by a suitable period of maturation. A long, high-temperature period is to be avoided because most microorganisms do not survive temperatures above 60 °C for long time, even if this has a positive effect in reducing pathogens. Therefore, several processes include an initial phase of suction, which permits temperature to rise for a few days, followed by blowing with temperature control. Confined and in-vessel systems, both horizontal and vertical, comprise mechanical equipment that provides better control of turning, ventilation, and other operating variables. The advantages of closed systems over open ones include more effective odor control, indoor operation, insensitivity to climate, and low labor requirements.

Chemical

The process consists of adding lime to sludge to raise the pH above 12 and maintain it for 2 hours, at least. Capital costs are generally low, but the overall economics depend very much on the local price of lime. Calcium hydroxide (slaked lime) or calcium oxide (quick lime) can be used. Quicklime also has the ability to dewater sludge. Lime tends to eliminate odors and reduce pathogenic content, but lime-treated sludges are not chemically stable.

Disinfection

Disinfection reduces the number of pathogenic microorganisms in a raw sludge to a level where they are no longer a risk to human, animal, or plant health. Disinfection can be attained by several methods that act by different mechanisms. Only pasteurization and irradiation have disinfection as the main purpose; other processes disinfect as a secondary effect.

Pasteurization is a heat treatment process carried out at a temperature of 70 °C for 30 minutes. The process is often combined with a stabilization process; it is normally carried out before anaerobic mesophilic digestion.

Ionizing radiation for disinfection uses directly ionizing particles (electrons), produced by accelerators and indirectly ionizing electromagnetic radiation (X), obtained from radionuclides sources, such as ^{60}Co and ^{137}Cs. In general, the doses required for sludge disinfection are 500 krad for liquid sludge and 1000 krad for dewatered sludge.

In composting, the heat generated by biological oxidation is the most important lethal factor, but microbial competition also plays an important röle. A temperature of 55–60 °C for a few days seems to be the lower limit for disinfection.

When lime is added to a liquid sludge, the lethal factor for pathogens is the high pH; when calcium oxide is added to dewatered sludge, an additional factor is the temperature rise to 80 °C. In aerobic thermophilic digestion, biological oxidation results in a temperature rise through which disinfecting action may be obtained; temperatures of 60–70 °C can be reached when aerating with pure oxygen. This process should be carried out preferably as a batch process to prevent microorganisms in raw sludge from reaching the end product before they have been killed. Limited hygyenic effects can also be obtained through anaerobic and aerobic digestion. Sludge processed by thermal conditioning is sterilized and also easily dewaterable; in addition, the sterilizing effect is particularly persistent.

UTILIZATION/DISPOSAL

Land application, thermal processing, and landfilling are available and well-known practices for utilization/disposal of sludge.

Land application

Sludge can be used in agriculture by spreading it on land directly or after composting. Direct use leads to several advantages through recycling of nutrients (i.e., inorganic and organic nitrogen and phosphorus) and organic matter which positively affect soil structure by increasing porosity, stability of aggregates, water retention, and also pH and cation exchange capacity.

However, this practice raises several problems, mainly from the presence of toxic and phytotoxic pollutants, both inorganic and organic, and pathogens. Although numerous processes that can ensure disinfection have been developed, no such reliable methods exist to neutralize or eliminate heavy metals, so regulations set limits for the maximum concentrations of these metals in sludges and the soil, as well as for the maximum disposable quantities for a certain number of years.

Annual nutrient requirements depend on the crop. In most cases, sludge amounts that supply adequate nitrogen also supply phosphorus, but in excess of crop needs, at possible risk of polluting ground- and surface waters. It is also necessary to consider the actual amounts of nutrients available in the first year and those that will become available in subsequent years. Additional sources of potassium are generally required. Annual nitrogen, phosphorus, and potassium use by selected crops are listed in Table 3.

Land application is recommended for sludges from small and medium wastewater works that are close to disposal fields and serve comparatively non-industrialized areas. Direct application to land is, however, subject to great variability over time, depending on crop type and weather conditions, but sludge production is continuous. For these reasons, the agricultural use of compost is often preferred because this material can be more easily stored, transported, and used at times and on sites different from those of production. Composting also involves the production of a safer and more hygienic product.

Thermal processing

Thermal processing includes incineration, pyrolysis, and drying.

Incineration. Incineration involves complete oxidation of volatile matter and the production of an inert residue (ash). If enough water has been removed, the organic material, will sustain combustion; therefore, sludge incineration must be preceded by effective dewatering or drying. The types of sludge incinerators most commonly used are the multiple-hearth furnace (MHF) and the fluidized bed furnace (FBF). The rotary kiln furnace (RKF) is typically used for hazardous waste incineration, but it is also suitable for sewage sludge because of its great adaptability (Fig. 4).

An MHF consists of a vertical, cylindrical, refractory-lined reactor containing a number of horizontal hearths. Rabble arms, supported by a single central shaft, rake

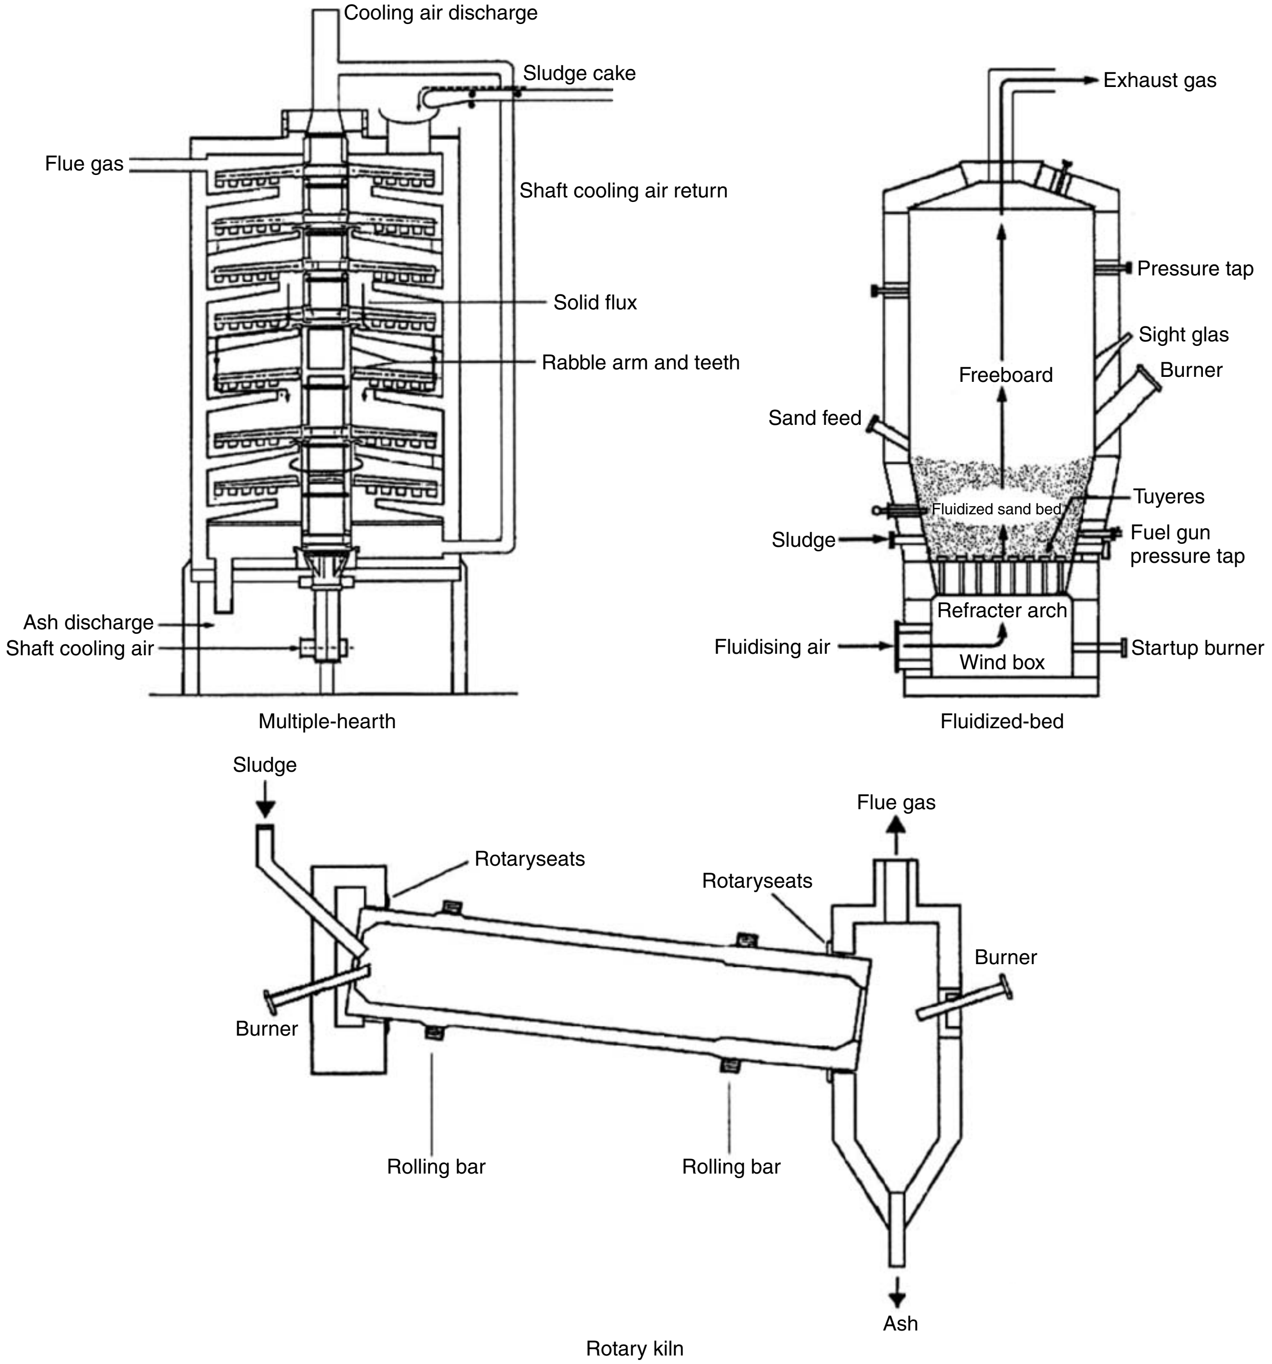

Figure 4. Typical cross sections of furnaces.

the sludge radially across the hearths from the top to the bottom, countercurrently with air and hot gases. Three zones can be distinguished in the furnace: the drying zone in the upper part (gas temperature up to 400 °C), the burning zone in the central–low part (gas and solid phase temperatures of 850–900 °C), and the ash cooling zone in the lowest part (temperatures of ash and air generally <200 °C). The typical design values of a MHF are 2–8 m diameter, 4–14 hearths, a hearth loading rate of 30–60 kg wet sludge/m^2/h, and 100–125% excess air.

The advantages are flexibility with respect to feed quality and loading rates and low fuel consumption due to effective heat recovery inside the equipment. The disadvantages include possible odor problems and emissions of volatile substances (due to the low temperature of the exhaust gas), high need for excess air (due to low turbulence), and high maintenance costs because of many moving parts. Moreover, high fuel consumption is needed, if afterburning of exhaust gases is required to destroy volatile compounds and products of incomplete combustion.

An FBF consists of a cylindrical, refractory-lined shell containing a sand bed that is fluidized, during operation, by air through a distributor plate below the bed. The temperature of the bed is controlled at about 750 °C. FBFs fall into two categories: bubbling and circulating; the latter allows a higher fluidization velocity and very intensive mixing. Particles are carried out of the vertical combustion chamber by the flue gas and are removed in a cyclone to be returned to the FBF through a loop seal. Typical design parameters of a bubbling FBF, which is much more common than the circulating type, are 3–8 m bed diameter, a solid loading rate of 150–300 $kg/m^2/h$, 40–60% excess air, two to three times of fixed bed height (bed expansion), and 1.5–10% of sand losses in 100 h.

The advantages of FBF are low excess air (due to the high turbulence), low NO_x production (due to effective control of combustion temperature), reliability (no moving parts), flexibility for shock load, adaptability to sludges of different moisture content (dewatered, partially dried, fully dried), heat storage capacity by sand bed, and possible abatement of acidic compounds within the bed using additives such as limestone and dolomite. The disadvantages include ash and sand carryover and possible formation of a block of vitrified sand when salts of low melting points are present. This problem can be attenuated by an adding chemicals to bind the alkaline salts.

An RKF consists of a refractory-lined cylindrical shell mounted at a slight incline from the horizontal plane (2–3%) that slowly rotates (0.25–1.50 rpm). Varying the rotational speed allows control of the solid residence time and ensures adequate mixing. The excess air requirement ranges from 100–200%. The advantages include possible melting of ash (but blockage must be avoided), no need for pre-treatments, and adaptation to many feed mechanism designs.

Good performance of thermal process plants also depends on providing proper auxiliary equipment and devices, which include receiving and storage systems, pre-treatment equipment, a feeding system, flue gas cleaning, heat recovery, ash handling, wastewater disposal, and process monitoring.

The main problem in incineration is the potential toxicity of gaseous emissions, but several devices are available for emission abatement at high efficiency. The particulate is generally small, and the legal standards can be easily met; a few metals, particularly Pb and Cd, are poorly retained, but the environmental hazard is slight primarily because the amounts in sludge are small. The problem of toxic substances, such as pesticides and PCBs, can be overcome by afterburning at high temperature (>1000 °C). On the other hand, flue gases represent a potential source of energy, usable to preheat the incoming furnace air, in sludge conditioning, or for external uses.

The volume reduction by incineration is more than 90% compared to the volume of dewatered sludge. The ash is free of pesticides, viruses, and pathogens, and the metals are in the less soluble oxide form.

Pyrolysis

Pyrolysis is a process in which organic material is decomposed at high temperature in an oxygen-deficient environment. This action causes irreversible chemical changes and produces gas, oil, and char (solid residue). The residence time, temperature, and pressure in the reactor are controlled to produce various combinations and compositions of these products.

True pyrolysis involves a total absence of air and applying all required heat externally to the reactor. Partial combustion, also known as starved-air combustion, involves adding a small amount of oxygen to the reactor: the oxygen sustains combustion of a portion of the reactor contents which, in turn, produces the heat required to pyrolyze the remainder of the contents. Pyrolysis has the potential advantage of reducing air pollution and producing useful by-products.

Drying

Drying is the simplest thermal process for producing a solid product. If metals and organic contaminants are low, dried sludge is an acceptable fertilizer. The main drawback is the cost to evaporate the water from the sludge cake; moreover, the end product must be sold to make the operation economical.

Landfilling

Landfilling is a convenient solution where enough space is locally available at reasonable fees. In any case, it is a necessary support to all other systems to dispose of materials that cannot be reused and for maintenance and/or emergency during shutdown periods.

Only well-dewatered sludges are suitable for landfilling. Solids concentrations of at least 20–25% are generally required, but values up to 30–35% are often necessary because the corresponding physical consistency could be too low to support the cover material. A good level of stability is also necessary to avoid possible emissions of bad odors. Co-disposal, with solid wastes or soil, is often practiced.

The basic landfill types are the (1) trench (narrow and wide), (2) area, (3) in-fill mound, (4) fill layer, and (5) dike containment modes. Sludge is spread in layers within a confined area and then daily covered with a thin, continuous layer of inert material.

The main problems are leachate and biogas control. Leachate may be controlled through natural conditions, imported soils or amendments used as liners and/or cover, membrane liners, and collection and treatment. Soil's natural permeability can be reduced by adding imported clays or synthetic materials such as high-density polyethylene (HDPE).

Biogas production typically starts a few months after deposition, reaches a maximum after 5–7 years, and continues for many years at a reducing rate. Gas control techniques can be classified as permeable and impermeable methods. Permeable methods usually entail installing a gravel-filled trench outside or wells inside the filled area to intercept and vent gas into the atmosphere or to an energy recovery system; a forced vacuum extraction system is often appropriate. Gas migration is also minimized by placing a low permeability barrier around the landfill.

PRODUCTION OF USABLE MATERIALS

Many other methods to recover usable materials from sludge are available. The recovery of nitrogen (separated by stripping or as struvite) and phosphorus (generally by chemical/physical processes) is becoming of great interest, together with that of the organic fraction as a raw material for activated carbon. Other significant alternatives include the production of (1) slag, char, and Portland cement from dewatered sludge cake and (2) slag, brick, tile, and artificial lightweight aggregate (ALWA) from incinerated ash. Use as animal feed can also be mentioned.

CODISPOSAL WITH MUNICIPAL SOLID WASTES

The combined management of sewage sludge and municipal solid wastes allows, in most cases, overcoming specific technical problems arising from handling them separately, and obtaining significant economic advantages and environmental benefits.

In composting, the different characteristics of solid wastes and sewage sludge can be integrated usefully to obtain a final product of better quality because the relatively higher solids content and carbon to nitrogen ratio of solid wastes can counterbalance the lower solids concentration and carbon to nitrogen ratio of sludge.

In co-incineration, sewage sludge drying can take place by using the excess heat recovered from solid waste combustion, but greater attention in designing and operating furnaces and exhaust gas abatement systems is required.

Co-landfilling provides faster waste stabilization, better leachate quality, and higher biogas production, but the operating procedures must be carefully planned.

WASTEWATER SLUDGE

Izrail S. Turoviskiy
Jacksonville, Florida

TYPES AND CHARACTERISTICS OF SLUDGE

Types of Sludge

The Environmental Protection Agency (EPA) has defined sewage sludge as any solid, semisolid, or liquid residue removed during the treatment of municipal wastewater or domestic sewage, including solids removed during primary, secondary, or advanced wastewater treatment, scum, septage, and sewage sludge products. Instead of using the term sludge, some specialists have used the terms residual, sediments, solids, slime-solid, or biosolids, depending on its condition or its usefulness and whether it meets the applicable criteria for that particular term.

Sludge is a suspension including solid and semisolid materials separated and generated from the liquid wastewater stream of a treatment plant during purification of municipal wastewater, industrial wastewater, or natural water in mechanical, biological, or physicochemical facilities.

Depending on the type of wastewater plants and facilities, the following sludge can be generated:

- —primary raw sludge: settleable solids separated from the wastewater stream during sedimentation in clarifiers (primary settling tanks);
- —activated sludge: a complex of microorganisms of the colloidal type with adsorbed and partially oxidized admixtures, precipitating in the secondary clarifiers in the biological treatment of wastewater;
- —sludge generated in industrial wastewater purification. This sludge has a different chemical composition, quantity, and moisture content, depending on the type of industry and wastewater treatment processes, some levels of radionuclides may be present;
- —sludge from the treatment of natural water (groundwater, surface water) that is generated during the production of potable water: the composition of this sludge depends on the composition of the natural water and the types of reagents used to purify the water.

The wastewater sludge (biosolids) products can also be classified by the type of treatment process as the following:

- —aerobically digested activated sludge or a mixture of it with primary sludge;
- —anaerobically mesophilic or thermophilic digested primary sludge or its mixture with thickened activated sludge;
- —dewatered sludge from mechanical dewatering devices;
- —dried sludge from sludge beds;
- —thermally treated or dried;
- —biothermally treated (compost).

The main and more useful process of municipal and industrial wastewater purification is the biological activated sludge process. The by-products of this process are two types of sludge, such as primary and waste activated sludge, containing up to 99% of contaminants removed from wastewater.

Primary Raw Sludge

Definition. Primary raw sludge is the sediment from clarifiers whereby wastewater and solids are separated to produce clarified effluent and sludge. The main raw sludge components are proteins, nitrogenous compounds, cellulose, sugar, carbohydrates, grease, fats, macronutrients (nitrogen, phosphorous, potassium), micronutrients, bacteria, and viruses. It has high moisture and poor dewatering ability. Fresh sludge is a gray or light brown colored suspension; its particles are of different sizes and composition, and it has a less intense sour odor than septic sludge. Because of the high content of organic material, it decays rapidly, the sludge condition becomes septic, its color changes to dark gray or black, and it generates an objectionable sour odor. Sludge is a hazardous

Use as animal feed can also be mentioned.

CODISPOSAL WITH MUNICIPAL SOLID WASTES

The combined management of sewage sludge and municipal solid wastes allows, in most cases, overcoming specific technical problems arising from handling them separately, and obtaining significant economic advantages and environmental benefits.

In composting, the different characteristics of solid wastes and sewage sludge can be integrated usefully to obtain a final product of better quality because the relatively higher solids content and carbon to nitrogen ratio of solid wastes can counterbalance the lower solids concentration and carbon to nitrogen ratio of sludge.

In co-incineration, sewage sludge drying can take place by using the excess heat recovered from solid waste combustion, but greater attention in designing and operating furnaces and exhaust gas abatement systems is required.

Co-landfilling provides faster waste stabilization, better leachate quality, and higher biogas production, but the operating procedures must be carefully planned.

WASTEWATER SLUDGE

Izrail S. Turoviskiy
Jacksonville, Florida

TYPES AND CHARACTERISTICS OF SLUDGE

Types of Sludge

The Environmental Protection Agency (EPA) has defined sewage sludge as any solid, semisolid, or liquid residue removed during the treatment of municipal wastewater or domestic sewage, including solids removed during primary, secondary, or advanced wastewater treatment, scum, septage, and sewage sludge products. Instead of using the term sludge, some specialists have used the terms residual, sediments, solids, slime-solid, or biosolids, depending on its condition or its usefulness and whether it meets the applicable criteria for that particular term.

Sludge is a suspension including solid and semisolid materials separated and generated from the liquid wastewater stream of a treatment plant during purification of municipal wastewater, industrial wastewater, or natural water in mechanical, biological, or physicochemical facilities.

Depending on the type of wastewater plants and facilities, the following sludge can be generated:

- —primary raw sludge: settleable solids separated from the wastewater stream during sedimentation in clarifiers (primary settling tanks);
- —activated sludge: a complex of microorganisms of the colloidal type with adsorbed and partially oxidized admixtures, precipitating in the secondary clarifiers in the biological treatment of wastewater;
- —sludge generated in industrial wastewater purification. This sludge has a different chemical composition, quantity, and moisture content, depending on the type of industry and wastewater treatment processes, some levels of radionuclides may be present;
- —sludge from the treatment of natural water (groundwater, surface water) that is generated during the production of potable water: the composition of this sludge depends on the composition of the natural water and the types of reagents used to purify the water.

The wastewater sludge (biosolids) products can also be classified by the type of treatment process as the following:

- —aerobically digested activated sludge or a mixture of it with primary sludge;
- —anaerobically mesophilic or thermophilic digested primary sludge or its mixture with thickened activated sludge;
- —dewatered sludge from mechanical dewatering devices;
- —dried sludge from sludge beds;
- —thermally treated or dried;
- —biothermally treated (compost).

The main and more useful process of municipal and industrial wastewater purification is the biological activated sludge process. The by-products of this process are two types of sludge, such as primary and waste activated sludge, containing up to 99% of contaminants removed from wastewater.

Primary Raw Sludge

Definition. Primary raw sludge is the sediment from clarifiers whereby wastewater and solids are separated to produce clarified effluent and sludge. The main raw sludge components are proteins, nitrogenous compounds, cellulose, sugar, carbohydrates, grease, fats, macronutrients (nitrogen, phosphorous, potassium), micronutrients, bacteria, and viruses. It has high moisture and poor dewatering ability. Fresh sludge is a gray or light brown colored suspension; its particles are of different sizes and composition, and it has a less intense sour odor than septic sludge. Because of the high content of organic material, it decays rapidly, the sludge condition becomes septic, its color changes to dark gray or black, and it generates an objectionable sour odor. Sludge is a hazardous waste which must be stored, disposed of, or reused, in accordance with hazardous waste regulations. Sludge regulations limit sludge disposal alternatives based on the treatment level provided, pathogen removal, and the heavy metals content. Treatment processes include conditioning, dewatering, stabilization (control of odor, pathogens, biodegradable toxins, and vectors), and disinfecting resulting in a valuable land application and soil conditioning product that has many useful properties.

Quantity and Moisture. The mean moisture content of the sludge discharged from primary clarifiers is 95% for gravity-flow removal and 93.8% for removal by plunger pumps. The quantity of raw primary sludge is approximately 0.4–0.5% of the volume of wastewater treated. The quantity of municipal wastewater primary sludge with 95% moisture can be estimated by assuming that 39.0 cu ft/1000 persons is produced daily.

Chemical Composition. The composition of sludge from primary settling tanks (clarifiers) depends on the nature of the wastewater being treated and particularly the type and quantity of industrial wastewater treated together with municipal wastewater. The dry solids of sludge consist of organic matter (60–75%) constituted of protein, fats, and carbohydrates. The ultimate composition of the dry solids of sludge includes carbon, hydrogen, sulfur, nitrogen, and oxygen. The typical composition of raw primary sludge is as follows (% of dry solids): grease and fats 6–30, protein 20–30, nitrogen 1.5–8.0, phosphorus 0.8–2.8, potassium 0.1–1.0, and cellulose 8–15. The mineral constituents include SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO, K_2O, Na_2O, and other minerals. Wastewater sludge may also contain heavy metals such as cadmium, chromium, cobalt, copper, lead, mercury, nickel, and zinc. Alkalinity and pH are the most important of the easily measured chemical parameters affecting sludge conditioning. Raw primary sludge has a pH range of 5.0–8.0, alkalinity (mg/L as $CaCO_3$) of 500–1500, and organic acid (mg/L as HAc) 200–2000.

Waste Activated Sludge

Definition. Activated sludge gets its name from the interaction between wastewater and microorganisms (bacteria, protozoa, and rotifers) in the presence of dissolved oxygen in a biological process of wastewater purification. Association of microorganisms that use organic material as food, remove suspended solids, and adsorb and mineralize wastewater contaminants are given the name activated sludge. The average sizes of activated sludge flocs are 1–4 mm; they have a light gray, yellow gray, or dark brown color. As the biological process of wastewater purification takes place, activated sludge increases. After the biological process of wastewater purification, activated sludge settles in secondary clarifiers. From the secondary clarifiers, the main part of the activated sludge is moved into aeration tanks to participate in the biological process; the other part receives treatment as waste activated sludge.

Activated sludge contains mostly bacterial cells that are viscous and difficult to dewater. The parameters of activated sludge sedimentation are sludge volume index (SVI), sludge density index (SDI = SVI/100), and sludge age determined by a settleometer test. An SVI less than 100 mL/g indicate an older, denser, fast settling sludge that has a thick, scummy, dark tan foam in aeration tanks. An SVI of more than 100 mL/g indicates a young, slow settling, light density sludge. An optimal SVI is 70–130 mL/g. An SDI of more than 1 g/cm^3 indicates old sludge; an SDI of less than 1 g/cm^3 indicates a young sludge. Sludge age refers to the number of days for which the suspended solid particles remain under aeration (5–15 days). The following microorganisms are Indicators of activated sludge age in order from young to old: amebas, flagellates, ciliates, and rotifers.

Quantity and Moisture. The moisture content of the activated sludge discharged from secondary clarifiers after aeration tanks is 99.2–99.7%. Gravity or belt gravity thickening of waste activated sludge is a very important process because of the high volume and moisture content in waste activated sludge. After gravity thickening, waste activated sludge has a moisture content of 97–98%, and volume is decreased 5–10 times. After belt gravity thickening, waste activated sludge has a moisture content of about 95%. In the process of belt gravity thickening, added polymers can reduce the moisture content. Thickened activated sludge is often treated together with primary sludge. For approximate computations, the quantity of the mixture of primary sludge and gravity thickened activated sludge at an average moisture content of 96.2% can be assumed as 0.6–1% of the volume of wastewater treated.

Chemical Composition. Activated sludge consists of microorganisms and adsorbed particles. The activated sludge dry solids consist of 70–75% organic matter. The dry solids contain carbon, hydrogen, nitrogen, sulfur, and oxygen. Activated sludge contains (% of dry solids) 6–7.5 fats, 2.4–7.5 nitrogen, 2.8–11.0 phosphorous, potassium up to 0.4%, and approximately 2.5–3 times less carbohydrates and two times more protein than primary raw sludge, the major minerals present in dry solids. Activated sludge can contain Cr, Cu, Ni, Pb, Cd, and other elements. The alkalinity of activated sludge is 580–1100 (mg/L as $CaCO_3$), organic acids 1100–1700 (mg/L as HAc), and pH 6.5–7.5.

Physical Properties

Granulometric Composition. Primary raw sludge contains 5–20% of particles larger than 7–10 mm, 9–33% 1–7 mm, and 50–88% below 1 mm in which about 45% have sizes less than 0.2 mm of the total weight of dry solids. In activated sludge, the quantity of particles less than 0.2 mm is 90%, below one mm 98%, particles of 1–3 mm 1.6%, and over 3 mm 0.4% of the weight of dry solids. The organic part of sludge decays rapidly, and an increase in the quantity of finely dispersed and colloidal particles and bound water results in a decrease in the water separation from the sludge and poor dewatering ability.

Density and Fluidity. The average density of activated sludge is 0.7–1.3 g/cm^3. The density of primary sludge is about 1 g/cm^3, and the density of the sludge dry solids is 1.2–1.4 g/cm^3. Primary raw sludge whose moisture is higher than 90% is a fluid; when moisture is 86–90%, it looks like sour cream; when moisture is 82–86%, it looks like a slush; and when moisture is less than 82%, it looks like a light thin soil. Waste activated sludge whose moisture is 88–91% looks like sour cream, and when moisture is 85–87% like thin soil. At a concentration of solids above 5% of primary sludge and above 3% of activated sludge, they are non-Newtonian which means that head losses are not proportional to velocity and viscosity. They are also thixotropic which means that they become less viscous when stirred.

Dewatering Characteristics. Dewatering is a process of natural or mechanical removal of water from sludge. The dewatering characteristics of sludge can be obtained by measuring the volume of filtrate collected from sludge and the time it takes to filter using varying doses of conditioning reagents. The most commonly used tests are the Specific Resistance Test, the Buchner Funnel Filtration Test, and the Capillary Suction Time Test (CST).

The water in sludge may be present as free water and water bound physicomechanically, physicochemically, or chemically. The more bound water present in sludge, the more energy or reagents must be used to condition sludge to remove bound water by dewatering. The separation of water from sludge depends on the size of the solid particles; the smaller the particles, the poorer the water separation from the sludge. Any process that reduces the size of the suspended solids particles has a negative effect on conditioning and dewatering. The chemical composition of sludge exerts a significant influence on its treatment. Compounds of iron, aluminum, chromium, and copper, as well as acids and alkalis, improve the processes of precipitation, thickening, and dewatering and reduce the consumption of chemical reagents for conditioning of sludge before dewatering. Oils, fats, and nitrogen compounds intensify anaerobic sludge digestion but interfere with thickening and conditioning processes.

Thermophysical Characteristics. The specific heat of a mixture of primary and thickened activated sludge is (3.5–4.7) × 10,000 Joule/(kg K). The heat of combustion of sludge dry solids equals 16.7–18.4 MJ/kg, the heat for incinerating fuel matter is 23.4–26.9 MJ/kg of sludge organic. The heat value is higher for raw sludge and lower for activated sludge. Sludge burns at a temperature of 430–500°C (800–1000°F); to eliminate odors, the temperature needs to be raised to 800–850°C (1500°F). For an increase in the moisture and ash of the sludge, there is a decrease in the heat of combustion and liberation of volatiles. In the process of thickened activated sludge aerobic digestion, 3.6 kcal are released/g volatile (organic) suspended solids oxidized (15 MJ/kg). The reduction of 1 kg of organic sludge during composting of dewatered sludge creates an average of 21 MJ/kg of heat. Raw primary sludge has a thermal content 6,800–10,000 Btu/lb.

Bacteriological Content

The activated sludge process is the most efficient biological process for removing coliforms, pathogenic bacteria, and virus particles from wastewater; they are transported to primary and activated sludge. The primary sedimentation of sewage allows reducing 30–70% of microorganisms and bacteria. After activated sludge treatment, the reduction of microorganisms and bacteria reaches 90–99%. The average level of indicator bacteria and pathogens, such as coliforms, *Streptococcus, Salmonella*, enteric viruses, and parasite ova/cysts reaches millions n/g dry weight of sludge. The diversity of microbial flora makes it difficult to enumerate the total population.

Biosolids

The Water Environment Federation (WEF) has adopted a policy of encouraging the use of the word biosolids in place of sludge to promote public acceptance of reused water projects. The term biosolids is used to connote the primary organic solid product of treatment that meets US EPA or other applicable criteria for beneficial use. The term biosolids has been used by WEF in the last few years instead of sludge. The type and level of wastewater and sludge treatment has an effect on the type, quantity, and quality of the biosolids generated. Biosolids are the solid organic matter produced as by-products of municipal wastewater treatment processes (also known as sewage sludge) that can be beneficially used, especially as a soil amendment, in accordance with standards and requirements. Sludge regulations limit biosolids disposal alternatives based on the treatment level provided.

CONCLUSION

Primary and waste activated sludge are two main types of sludge (biosolids) formed in wastewater purification. The quantity of a mixture of primary and thickened waste activated sludge whose average moisture is 96.2% reaches 1.0% of the treated wastewater. High moisture with bound water and small solid particles make sludge difficult to dewater. The dry solids of sludge consist of organic matter and minerals. The microbiological population of sludge includes millions of coliforms, pathogenic bacteria, and viruses. Sludge (biosolids) contains macronutrients, such as nitrogen, phosphorus, potassium, and micronutrients. After treatment (thickening, conditioning, stabilization, dewatering, disinfecting), biosolids meet regulatory requirements for pathogens, vector attraction reduction, and heavy metal content and become beneficial valuable products, which can be applied to land for soil conditioning, preventing soil erosion, and as fertilizer.

PROCESSING OF SLUDGE

Izrail S. Turoviskiy
Jacksonville, Florida

Wastewater sludge is a high moisture suspension in which water is bound by small solid particles. The main parts of the sludge solids are organic and contain different types of microorganisms, pathogenic bacteria, viruses, and parasites. On the other hand, sludge contains valuable organic macronutrients, such as nitrogen, phosphorus, potassium, and micronutrients, such as elements and metals. Wastewater sludge is hazardous waste which must be stored, disposed of, or be reused in accordance with standards and regulations based on the treatment level provided.

The main purpose of treatment is to prepare sludge for removal from wastewater treatment plants and to produce biosolids that can be used as a soil amendment and conditioner. To achieve this goal, treatment processes of sludge should include thickening and dewatering to decrease sludge volume and moisture and disinfection and stabilization to control odor, pathogens, and vectors.

SLUDGE TREATMENT

Thickening

Thickening is an economically effective process to increase sludge concentration and decrease sludge volume by removing some free water to the extent that the sludge remains in the fluid state. The objectives of thickening are to produce a relatively solids-free supernatant and to produce a sludge that can be pumped without difficulty. Sludge can be thickened by using gravity thickeners, gravity belt thickeners, rotary drums, separators, centrifuges, and flotators. Rotary drums and gravity belt thickeners are mechanical devices that remove free water from wastewater sludge using gravity. Centrifugation is a process in which centrifugal force (usually about 500 to 3000 times the force of gravity) is applied to a sludge slurry to accelerate the separation of the solid and liquid fractions. Flotation thickening is a solid–liquid separation caused by introducing fine air bubbles into the liquid phase. Adding polymers in waste activated sludge thickening allows removing more water.

Gravity thickening is a common method of solid–liquid separation to reduce the sludge volume handled in the dewatered/sludge disposal of a wastewater treatment facility. During the process of waste activated sludge gravity thickening, the concentration of dry solids increases, on average, from 0.2 to 2.0% and the volume of sludge is reduced 10 times. However, when the thickening process lasts 8–10 hours or more, organic putrefaction occurs, the microorganisms of the activated sludge perish without air, the amount of colloids increases, and part of the free water is transformed into a bound state of water with dry solids. Unthickened activated sludge usually has better dewatering abilities than thickened sludge. On the other hand, dewatering or digesting nonthickened activated sludge does not make sense due to the large volume and low initial concentration of dry solids. The kinetics of the process of activated sludge thickening determines the rational concentration of dry solids.

Conditioning

Conditioning is a chemical or physical process that improves the dewaterability of a sludge during its preparation for dewatering. Sludge conditioning consists of such methods as inorganic chemical conditioning, organic chemical conditioning, thermal conditioning, elutriating, and freeze–thawing. Chemical conditioning is a commonly used method. By this process, chemicals such as ferric chloride, lime, organic polymers, and others are added to sludge to coagulate or flocculate the fine particles and decrease bound water. It is a unique process vital to the successful operation of sludge thickening and dewatering systems. Thermal conditioning uses elevated temperatures and pressures to promote the separation of solids and liquid through the release of cell-bound water. By using thermal conditioning, sludge can often be mechanically dewatered without using chemicals. Freeze–thaw conditioning substantially decreases consumption of reagents required for conditioning sludge that was mechanically dewatered.

Dewatering

Dewatering is the process of natural or mechanical removal of water from sludge during which the sludge loses its fluidity, becomes damp solids, and can be transported in bulk. The dewatering processes currently in use include natural methods such as air drying on drying beds, lagoons, and mechanical methods such as belt press filtration, centrifugation, vacuum filtration, and pressure filtration. Moisture in sludge may be bound physicomechanically, physicochemically or bonded chemically and can also be present as "free water." Conditioning of sludge before dewatering allows increasing part of the free water, and more water can be removed by mechanical dewatering. Primary raw sludge has better dewatering ability than mixtures of primary raw sludge and thickened activated sludge and better than digested sludge. Dewatering often is followed by sludge aerobic or anaerobic digestion. During the dewatering process, the water is not completely removed from the sludge. The moisture remains within 70–80% limits. At that moisture level, sludge loses its fluidity and may be moved by conveyors. Sludge, generally, should be dewatered before it is thermally dried, composted, alkali stabilized, or incinerated.

Stabilization

Stabilization is one of the more frequently used methods of sludge treatment (especially if the sludge will be used as a fertilizer). All sludge requires some form of treatment, whether stabilization, thickening, or dewatering, possibly followed by drying, composting, and incineration, or a combination of one or more of these processes, before being discharged into the natural environment. Stabilization is a combination of processes of sludge treatment to meet U.S. EPA or other applicable criteria for beneficial use. The process of stabilization is necessary to eliminate the potential of putrefaction of sludge's organic part, to prevent offensive odor dissemination, and to reduce volatile and pathogen content. Two criteria typically used to measure biosolids stability include the volatile solids content and pathogen indicator organism reduction. The following methods of sludge stabilization are in use: aerobic digestion, anaerobic digestion, alkaline stabilization, composting, thermal drying, heat/wet air oxidation, acid (oxidation) disinfecting, and some others.

Aerobic Digestion. Aerobic digestion has been widely used in wastewater treatment plants (WWTP) for many years. Aerobic digestion is a process of oxidizing the organic part of the sludge by microorganisms in special tanks in the presence of oxygen (air aeration of sludge). Aerobic sludge digestion stabilizes raw sludge and produces biosolids for further treatment and disposal. The process of aerobic sludge digestion may be conducted using several technological schemas. The duration of the volatile part of solids oxidation depends on the food/microorganism ratio, temperature, intensity and quantity of the air aeration, and also on wastewater composition and technological demand. This process is more useful for digesting and stabilizing thickened activated sludge.

Anaerobic Digestion. Anaerobic digestion is a biological process that reduces volatile solids by using microorganisms in the absence of oxygen and reduces odor and pathogen content. Digesters are cylindrical reservoirs with conical bottoms; the upper section of the reservoir has a sealed cover with a device for collecting the gas. Two types of anaerobic digestion processes are in use: mesophilic and thermophilic. Mesophilic processes occur in the temperature range of 32–35 °C. The thermophilic process operates at higher temperature (50 to 55 °C) to reduce organic solids and pathogen content further. The quantity of gas obtained during digestion is approximately 1.0 m^3 for every 1.0 kg of disintegrated organic sludge. The following composition of the gas can be expected: methane—60 to 70%; carbon dioxide—16 to 34%; nitrogen, hydrogen, and oxygen—0.4 to 6%. The heat of combustion of this gas averages around 21 million Joule/m^3(MJ/m^3). Anaerobic digestion is a widely used stabilization process for primary or a mixture of primary and thickened waste activated sludge.

Alkaline Stabilization. Alkaline stabilization of sludge produces biosolids that are reduced in pathogen and vector attraction, and meet Class "A" requirements. Of the chemicals used for sludge stabilization, the most common is quicklime or hydrated lime, which is added to sludge before or after dewatering. The quantity of lime added is determined so that the pH of the sludge and lime mixture is raised to 12.0 or above for a period of 2 hours.

Composting. Various composting processes are used, such as windrow composting, aerated static piles, and in-vessel composting. This technology includes mixing dewatered sludge with an added bulking agent (sawdust, peat, wood chips, bark, etc.) and aerating the mixture. In sludge composting, a biothermal process takes place in which microorganisms reduce the sludge's organic in the presence of oxygen. This aerobic process is accompanied by a rise in temperature to about 55–65 °C and a decrease in moisture content. The quantity of organic sludge reduced during composting averages 25%. A reduction of 1.0 kg of sludge organic creates an average 21 MJ/kg of heat. Taking in to account heat losses and heating of compost material, it is necessary to spend approximately 4 MJ of heat to evaporate 1.0 kg of water. Thus, the reduction of 1.0 kg of organic sludge allows removing 5.0 kg of water from the sludge. Besides that, part of the moisture is removed from the sludge by natural evaporation. The total quantity of moisture removed from the sludge depends on climate factors, the season of the year, the dimensions of the piles, duration of composting, and intervals between shoveling over. Removal of moisture from the sludge produces compost at a moisture content of approximately 50–55%. During composting, the heat generated by the decomposition of the organic portion of the sludge stabilizes and renders the sludge harmless transforming it into usable soil conditioning biosolids.

Thermal Drying. Thermal drying is used to destroy pathogens, to eliminate odor, and to reduce most of the water content and the volume of sludge and transportation costs of the biosolids. Thermal drying of sludge is conducted in drying systems consisting of a drying device and the auxiliary equipment, which includes furnaces with a fuel supply system, feeders, cyclones, scrubbers, blowing equipment, conveyors and bins, monitoring and measurement instruments, and automatic control equipment. Depending on the consistency of the sludge, its end uses and quantity, spray dryers, drum dryers, opposed jet dryers, dryers with suspended and fluidized beds, pneumatic pipe dryers, and other different types of heat dryers can be used. Thermal drying can produce dry biosolids whose moisture content ranges from 10–40%, but it does require fuel for processing.

Incineration. Sludge is incinerated if it is impossible or economically infeasible to use, if storage is limited or unavailable, and also when it is required for sanitary and hygienic considerations. The most commonly used types of incinerators are multiple-hearth and fluidized-bed furnaces. Incineration dramatically reduces the volume of sludge and completely disinfects it. The preparation of sludge for incineration requires dewatering and/or thermal drying. When considering incineration, it is important to choose a method that yields safe exhaust gases and techniques to reduce the amount of energy required and/or provide some, if not all, of the required energy from another sludge process.

CONCLUSION

The purpose of sludge treatment is to reduce the moisture content and the volume of sludge; it renders the sludge harmless, prepares it for biosolids use, and moves biosolids from the WWTP. The most common types of sludge treatment are thickening, dewatering, and stabilization, which can be used one after the other consecutively and in various combinations. Stabilization refers to a number of processes, which reduce volatile solids, pathogen levels, vector attraction, and odor. Sludge must be stabilized before use and disposal. The variety of wastewater sludge treatment alternatives allows comparing and choosing cost-effective technology for each wastewater treatment plant.

MUNICIPAL STORM WATER MANAGEMENT

C.A. Prochaska
A.I. Zouboulis
Aristotle University of Thessaloniki
Thessaloniki, Greece

INTRODUCTION

Enlargement of urbanization and industrial activities around the countryside have significantly altered the natural landscape of watersheds. The hydrological changes resulting from urbanization are shown in Fig. 1 (1).

This, in turn, has adversely affected both the quantity and the quality of storm water runoff and has contributed to the chemical, physical, and biological impairment of receiving waters. Several studies have shown that heavy metals, synthetic organics, pesticides, fuels, waste oils, and pathogens commonly contaminate storm water that originates from urban and industrial areas. To help improve the quality of storm water discharges, the U.S. Congress amended the Clean Water Act in 1987, which directs the Environmental Protection Agency (EPA) to develop the National Pollutant Discharge Elimination System (hereafter termed NPDES). Under NPDES regulations, the municipalities must develop storm water management plans that include specific controls to reduce the discharge of pollutants to the maximum extent practicable. The management plans must also address the legal, administrative and financial aspects of the municipality's storm water control program.

The municipal storm water management programs all involve similar elements. These include mainly public information/participation, elimination of illegal

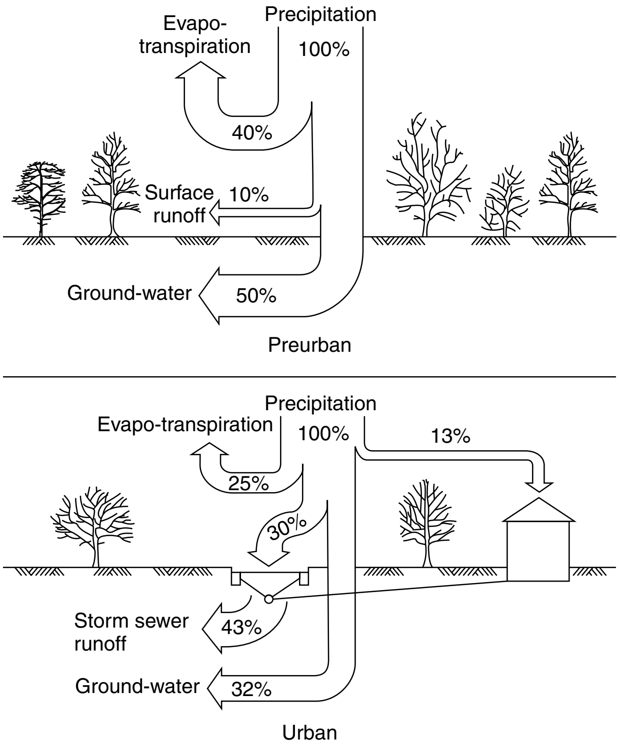

Figure 1. Comparison of water distribution before and after urbanization (1).

discharges, public agency activities, control of industrial/commercial storm water discharges, new development management, storm water treatment, program evaluation, and monitoring. The activities associated with each of these essential program components are presented briefly in the following (2):

PUBLIC INFORMATION/PARTICIPATION

This element is considered the most important early action and is the cornerstone of effective pollution prevention. Its objectives are to inform the public, commercial entries, and industries about the proper use and disposal of materials and waste and to correct the practices of storm water runoff pollution control. The public information activities include the development of general and focused information materials, as well as public service announcements. The participation activities include citizen monitoring programs, stenciling of storm drain inlets with “no dumping” signs and organized creek cleanups.

ELIMINATION OF ILLEGAL DISCHARGES

The elimination of illicit connections to the storm drain system and the prevention of illegal dumping are other essential early action elements. The objective is to ensure that only storm water or otherwise authorized discharges can enter the storm drains. The relevant activities include inspection of storm drain outfalls, surveillance of storm drain systems, and enforcement actions.

PUBLIC AGENCY ACTIVITIES

Many public agency activities may affect storm water pollution. Some activities prevent or remove storm water pollution; other activities are actually sources of pollution. The objective of this element is to ensure that routine municipal operations and maintenance activities are initiated or improved, to reduce the likelihood that pollutants are discharged to the storm drain system. The relevant activities include street sweeping; maintenance of storm drain inlets, lines, and channels and catch basins; corporation yard management; and the application of specific recycling programs. Coordination of road maintenance and flood control activities with storm water management program is also included.

CONTROL OF INDUSTRIAL/COMMERCIAL STORM WATER DISCHARGES

Industrial and commercial sources may contribute substantial pollutant loading to a municipal storm drain system. The objective of this element is to identify and effectively control the industrial and commercial sources of concern. The relevant activities include compilation of a list of industrial and commercial sources, identification of appropriate pollution prevention and control measures, and inspection of respective facilities. The focus is not only on facilities associated with industrial activity, as defined in the storm water regulations, but on any facility that conducts industrial activities, as well as commercial facilities, such as automotive operations and restaurants. This effort is expected to complement federal and state industrial storm water permitting efforts.

NEW DEVELOPMENT MANAGEMENT

New development (and redevelopment) areas offer the greatest potential for implementing the most effective pollution prevention and control measures. The objective of this element is to reduce the likelihood of pollutants entering the storm drain system from areas of new development or significant redevelopment during and after the construction period. The relevant activities include mainly the review of existing local permitting procedures and the modification of the procedures to identify and assign appropriate site design, erosion control, and permanent storm water control measures.

STORM WATER TREATMENT

The initial focus of storm water management programs is on pollution prevention and source control. The subsequent treatment of collected storm water is expected to be a rather costly alternative. There may be opportunities, however, for installation or retrofitting of structural control. The objectives of this element are to study the various treatment alternatives available, to test the feasibility of conducting the activities, and to determine the effectiveness of the treatment through pilot-scale projects. The main available treatment system alternatives are the following:

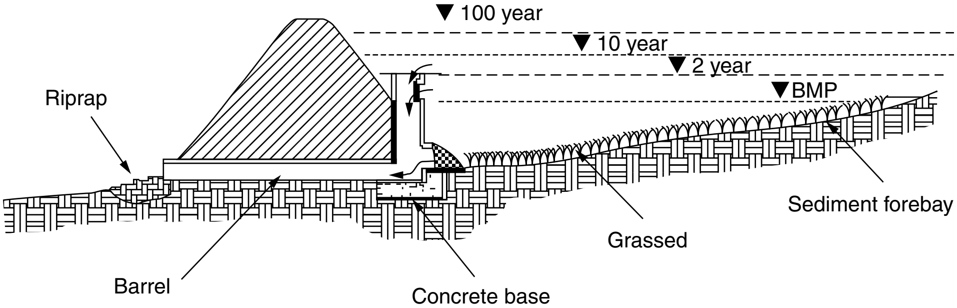

Figure 2. Detention basin (2).

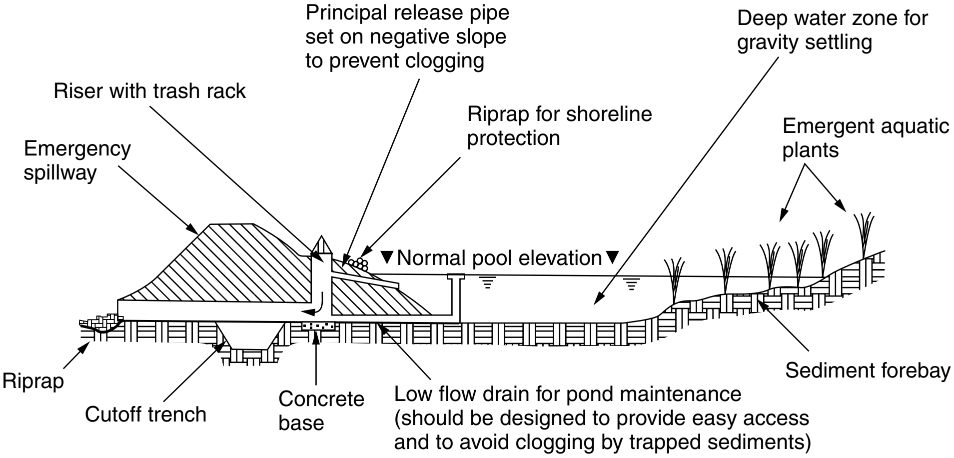

Figure 3. Retention pond (2).

1. *Infiltration systems*, which capture a volume of runoff and infiltrate it into the ground. Infiltration facilities may include infiltration basins, infiltration trenches, or porous pavement systems.
2. *Detention systems*, which capture a volume of runoff and temporarily retain that volume for subsequent release. Detention systems do not retain a significant permanent pool of water between runoff events; a common type is shown in Fig. 2.
3. *Retention systems*, which capture a volume of runoff and retain that volume until it is displaced in part or in total by the next runoff. Retention systems, therefore, maintain a significant permanent pool volume of water between runoff events. The details of a retention pond are shown in Fig. 3.
4. *Constructed wetland systems* are similar to retention and detention systems, except that a major portion of the water surface area (in pond systems) or bottom (in meadow-type systems) contains wetland vegetation. This group also includes wetland channels. A typical wetland system design is shown in Fig. 4 (3).
5. *Filtration systems* use some combination of granular filtration media, such as sand, soil, organic material, carbon or a membrane, to remove constituents found in runoff.
6. *Vegetated systems (biofilters or bioretention systems)*, such as swales and filter strips, are designed to convey and treat either shallow flow (swales) or sheet flow (filter strips) runoff. A diagram of a typical bioretention area is shown in Fig. 5.
7. The method of *minimizing directly connected impervious surfaces* describes a variety of practices that can be used to reduce the amount of surface area directly connected to the storm drainage system by minimizing or eliminating the traditional curb and gutter. This is considered to a nonstructural practice, but it has been included here because of the need to design and construct alternative conveyance and treatment options.
8. *Miscellaneous and vendor-supplied systems*, which include a variety of proprietary and miscellaneous systems that do not fit under any of the above categories. These may include catch basin inserts, hydrodynamic devices, and filtration devices.

PROGRAM EVALUATION

Storm water management programs are expected to change as they mature. Consequently, they should have built-in flexibility to allow for changes in priorities, needs, or levels of awareness. The objective of this element is to provide a comprehensive annual evaluation and report of the program's effectiveness. The measures of effectiveness include mainly quantitative monitoring to assess the effectiveness, the specific control measures, and the detailed accounting of program accomplishments and funds and staff hours expended. The annual report provides an overall evaluation of the program and sets forth plans and schedules for the coming year. The annual report is considered a program's self-audit and

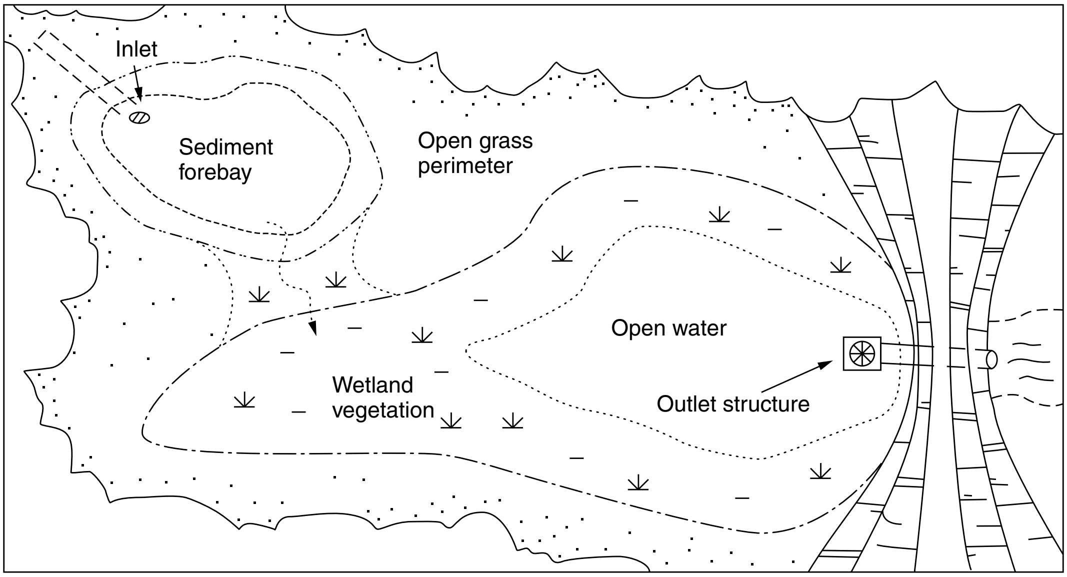

Figure 4. Constructed wetland system (3).

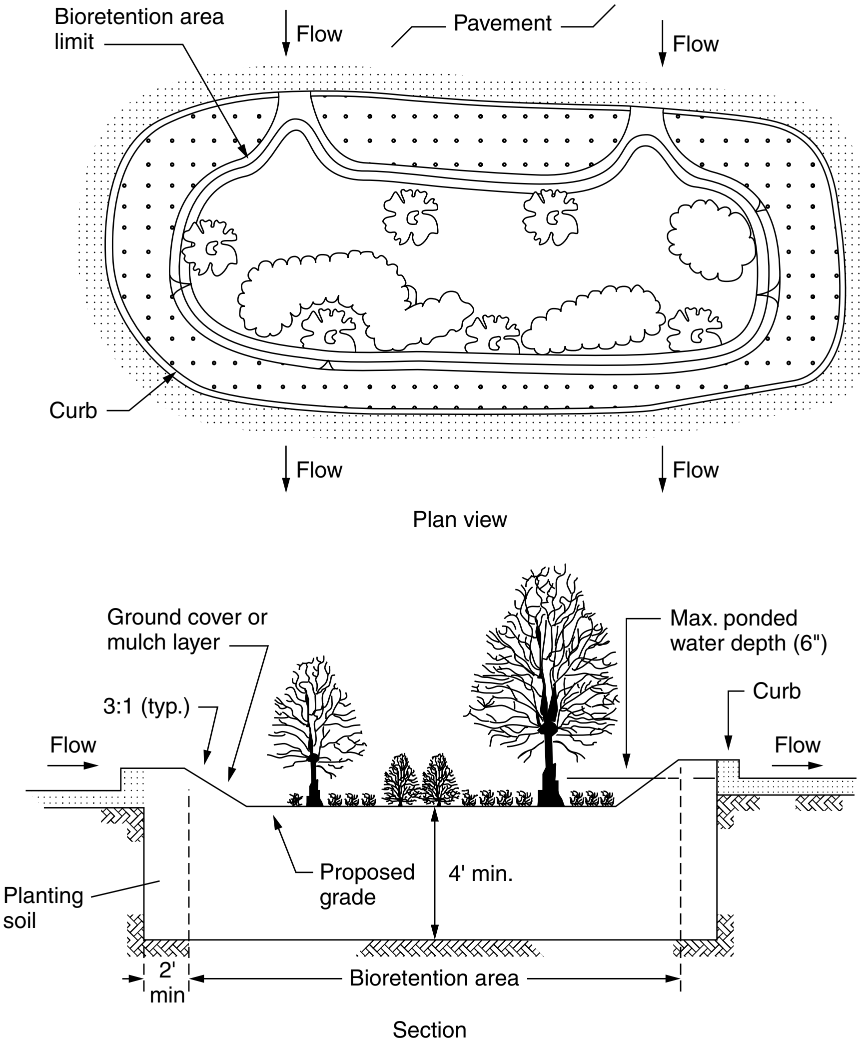

Figure 5. Bioretention system (3).

provides a mechanism to propose modifications to the storm water management plan in response to program accomplishments or failures. The annual report also serves as the key regulatory tool for providing accountability and public review in accordance with the respective NPDES permit.

MONITORING

Monitoring is an essential component of any pollution control program. The objectives are to obtain quantitative information to measure program progress and effectiveness, to identify the sources of pollutants, and to document the reduction of pollutant loads (if any). The success of the monitoring program can be measured by the ability to make more informed decisions on a program's direction and effectiveness. The monitoring activities include primarily the baseline monitoring of storm drain discharges and receiving waters and is focused on special studies to identify sources of pollutants and to evaluate the effectiveness of specific control measures. The types of monitoring may include water column measurements, sediment measurements, and nonsampling and analysis measurements, such as the number of outfalls inspected or the amount of material removed by regular maintenance actions. Toxicity identification and evaluations are also integral components of monitoring programs.

WHAT WASTEWATER UTILITIES CAN DO NOW TO GUARD AGAINST TERRORIST AND SECURITY THREATS

U.S. Environmental Protection
Agency—Office of
Wastewater Management

One consequence of the events of September 11th is a heightened concern among citizens in the United States over the security of their critical wastewater infrastructure. The nation's wastewater infrastructure consisting of approximately 16,000 publicly owned wastewater treatment plants, 100,000 major pumping stations, 600,000 miles of sanitary sewers and another 200,000 miles of storm sewers, is one of America's most valuable resources, with treatment and collection systems valued at more than $2 trillion. Taken together, the sanitary and storm sewers form an extensive network that runs near or beneath key buildings and roads, and is contiguous to many communication and transportation networks. Significant damage to the nation's wastewater facilities or collection systems would result in: lose of life, catastrophic environmental damage to rivers, lakes and wetlands, contamination of drinking water supplies, long term public health impacts, destruction of fish and shellfish production, disruption to commerce, the economy and our normal way of life. Although many wastewater utilities have already taken steps to increase security, the following recommendations provide many straightforward, commonsense actions to increasing security and reducing threats from terrorism. Many of these actions are recommended by the Association of Metropolitan Sewer Agencies, the Water Environment Federation, and other leading professional organizations. The recommendations include:

GUARDING AGAINST UNPLANNED PHYSICAL INTRUSION

- Lock all doors and set alarms at your office, pumping stations, treatment plants, and vaults, and make it a rule that doors are locked and alarms are set;
- Limit access to facilities and control access to pumping stations, chemical and fuel storage areas, giving close scrutiny to visitors and contractors;
- Post guards at treatment plants, and post "Employee Only" signs in restricted areas;
- Control access to storm sewers;
- Secure hatches, metering vaults, manholes and other access points to the sanitary collection system;
- Increase lighting in parking lots, treatment bays, and other areas with limited staffing;
- Control access to computer networks and control systems, and change the passwords frequently;
- Do not leave keys in equipment or vehicles at any time.

MAKING SECURITY A PRIORITY FOR EMPLOYEES

- Conduct background security checks on employees at hiring and periodically thereafter;
- Develop a security program with written plans and train employees frequently;
- Ensure all employees are aware of communications protocols with relevant law enforcement, public health, environmental protection, and emergency response organizations;
- Ensure that employees are fully aware of the importance of vigilance and the seriousness of breaches in security, and make note of unaccompanied strangers on the site and immediately notify designated security officers or local law enforcement agencies;
- Consider varying the timing of operational procedures if possible so if someone is watching the pattern changes.

- Upon the dismissal of an employee, change passcodes and make sure keys and access cards are returned;
- Provide Customer Service staff with training and checklists of how to handle a threat if it is called in.

COORDINATING ACTIONS FOR EFFECTIVE EMERGENCY RESPONSE

- Review existing emergency response plans, and ensure they are current and relevant;
- Make sure employees have necessary training in emergency operating procedures;
- Develop clear protocols and chains-of-command for reporting and responding to threats along with relevant emergency management, law enforcement, environmental, public health officials, consumers and the media. Practice the emergency protocols regularly;
- Ensure key utility personnel (both on and off duty) have access to crucial telephone numbers and contact information at all times. Keep the call list up to date;
- Develop close relationships with local law enforcement agencies, and make sure they know where critical assets are located. Request they add your facilities to their routine rounds;
- Work with local industries to ensure that their pretreatment facilities are secure;
- Report to county or State health officials any illness among the employees that might be associated with wastewater contamination;
- Report criminal threats, suspicious behavior, or attacks on wastewater utilities immediately to law enforcement officials and the relevant field office of the Federal Bureau of Investigation.

INVESTING IN SECURITY AND INFRASTRUCTURE IMPROVEMENTS

- Assess the vulnerability of collection system, major pumping stations, wastewater treatment plants, chemical and fuel storage areas, outfall pipes, and other key infrastructure elements;
- Assess the vulnerability of the storm water collection system. Determine where large pipes run near or beneath government buildings, banks, commercial districts, industrial facilities, or are contiguous with major communication and transportation networks;
- Move as quickly as possible with the most obvious and cost-effective physical improvements, such as perimeter fences, security lighting, tamper-proofing manhole covers and valve boxes, etc.;
- Improve computer system and remote operational security;
- Use local citizen watches;
- Seek financing for more expensive and comprehensive system improvements.

While wastewater utilities are the key to improving security of our wastewater treatment plants and collection systems, EPA, other Federal agencies, and both industry and managerial trade associations also provide help and support. EPA is working with AMSA and other groups to develop training courses and technical materials for wastewater utilities and State personnel on assessing vulnerabilities and improving security. EPA is working collaboratively with the Association of Metropolitan Water Agencies and other groups to develop an Information Sharing and Analysis Center to bolster coordinated notification and response to threats and vulnerabilities at both water and wastewater facilities. A number of technical projects are underway to help increase security of the nation's critical wastewater infrastructure.

WASTEWATER TREATMENT TECHNIQUES—ADVANCED

Miguel A. Valenzuela
Instituto Politecnico
Nacional—ESIQIE. MEXICO

ADVANCED OXIDATION PROCESSES (AOP)

All advanced oxidation processes are characterized by a common chemical feature: production of $OH^\bullet$ radicals.

Table 1 and Fig. 1 show a list of AOP and their applicability.

These radicals are suitable for achieving complete abatement and mineralization of pollutants. AOP usually operate at or close to ambient temperature and pressure. The potentialities offered by AOP can be exploited to integrate biological treatments by oxidative degradation of toxic substances, entering or leaving the biological stage (1–2). The usual two AOP are the Fenton process and photocatalysis:

Fenton Process

Production of $OH^\bullet$ radicals by Fenton's reagent occurs when addition of H_2O_2 is added to Fe^{2+} salts (3): It has been demonstrated that Fenton's reagent can destroy toxic

Table 1. Some Advanced Oxidation Technologies

Reactions
Fenton-Type reactions
$Fe^{2+} + H_2O_2 \rightarrow {}^{\bullet}OH + Fe^{3+} + OH^-$
Ozone—peroxide—UV systems
$O_3 + {}^{-}OH \rightarrow O_2{}^{-} \rightarrow {}^{\bullet}OH$
$3O_3 + UV(< 400\ nm) \rightarrow 2{}^{\bullet}OH$
$H_2O_2 + UV(< 400\ nm) \rightarrow 2{}^{\bullet}OH$
$H_2O_2 + O_3 \rightarrow 2{}^{\bullet}OH$
$H_2O_2 + O_3 + UV \rightarrow {}^{\bullet}OH$
Semiconductor oxides—UV systems
$TiO_2 + hv \rightarrow TiO_2(h^+ + e^-)$
$H^+ + OH^- \rightarrow {}^{\bullet}OH$
Radiolysis (high-energy beams)
$H_2O \rightarrow e^-{}_{aq} + H^{\bullet} + {}^{\bullet}OH + (H_2, H_2O_2, H_3O^+)$
Wet oxidation (WO) systems
$RH + O_2 \rightarrow R^{\bullet} + HO_2{}^{\bullet}$
$RH + HO_2{}^{\bullet} \rightarrow R^{\bullet} + H_2O_2$
$H_2O_2 + M \rightarrow 2\ OH^{\bullet}$
$RH + OH^{\bullet} \rightarrow R^{\bullet} + H_2O$
$R^{\bullet} + O_2 \rightarrow ROO^{\bullet}$
$ROO^{\bullet} + RH \rightarrow ROOH + R^{\bullet}$
Sonolysis (ultrasound)
$H_2O \rightarrow H^{\bullet} + {}^{\bullet}OH$

compounds such as phenols and herbicides in wastewaters. Irradiation by UV-vis light strongly accelerates the degradation rate of organic pollutants (4). The application of the Fenton process requires strict pH control; sludges can be formed which create disposal problems.

Photocatalysis

In this process, hydroxyl and other radicals are generated at the surface of an UV-absorbing powder (called a photocatalyst). The most widely used photocatalyst is the wide band-gap (3.2 eV) semiconductor TiO_2 in its anatase crystalline form (5–6). TiO_2 absorbs UV light at wavelengths below ~ 380 nm creating an excess of electrons in the conduction band ($e^-{}_{cb}$) and holes in the valence band ($h^+{}_{vb}$):

$$TiO_2 \longrightarrow (e^-{}_{cb} + h^+{}_{vb})$$

The carriers can diffuse to the surface where they react as follows:

$$h^+{}_{vb} + OH^- \longrightarrow OH^{\bullet}{}_{ads}$$

and

$$e^-{}_{cb} + O_2 \longrightarrow O_2{}^{\bullet -}{}_{ads}$$

where ads = adsorbed to the surface of TiO_2 particles.

Organic pollutants may adsorb on the surface of TiO_2 particles, and there they are attacked by the adsorbed $OH^{\bullet}$ radicals and holes. The $O_2{}^{\bullet -}$ radicals can further disproportionate as follows:

$$2O_2{}^{\bullet -}{}_{ads} + 2H^+ \longrightarrow H_2O_2 + O_2$$

Although the quantum yield of TiO_2 photocatalyzed reactions is rather low, the system does have the advantage that it can use UV photons in the near UV (blacklight UV fluorescent lamps or the UV portion of solar radiation) (Fig. 2). Compilations of substances which can be mineralized using photocatalysis are now available (7).

COMPLEXATION/FLOCCULATION

It has been shown that dissolved humic substances (DHS), bind (complex) organic solutes via hydrophobic interactions, forming humic–contaminant complexes in the aqueous phase. The use of DHS in flushing solutions to enhance desorption of hydrophobic contaminants from sediments was suggested by several researchers (8–10). It was further proposed to remove the humic–contaminant complexes by flocculation using alum or ferric salts, followed by press filtration and incineration or disposal of the resulting precipitate.

The treatment process follows two stages: (1) binding of Dissolved Humic Acid (DHA) by the dissolved contaminants to form complexes (complexation stage) and (2) precipitation of DHA and the associated contaminant by using a flocculant (alum or ferric chloride, flocculation stage). This process can be applied to remove various classes of hydrophobic organic pollutants such as PAHs, PCBs and chloro-organo pesticides from industrial wastewater. Additionally, this technology has the advantage that it may be coupled to the general water treatment process (Fig. 3) (11)

CONDUCTING POLYMERS

Conducting polymers have ion exchange properties induced by charging and discharging processes (12). For instance, polypyrrole (PPy) can function as an anion exchanger, whereas PPy modified with polystyrenesulfonate anions (PPy/PSS$^{\bullet}$) works as a cation exchanger (Fig. 4) (13,14). Such a modified polymer can be used as an electrochemically switchable ion exchanger for water softening (15). This ion exchanger can be regenerated without chemical additives or aqueous electrolysis.

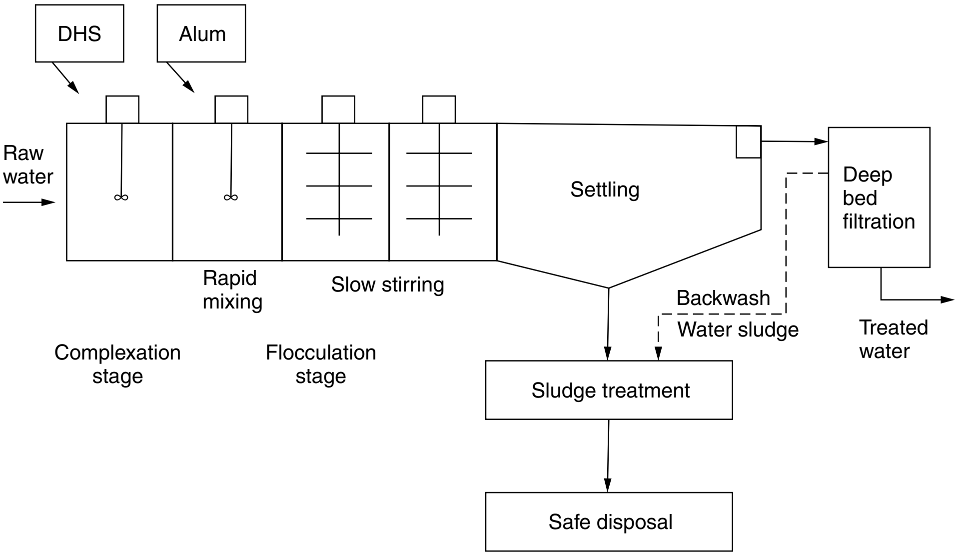

Figure 3. Flow diagram of the complexation—flocculation process coupled with a common water treatment operation. (*Source*: Reference 11).

IONIZING IRRADIATION

High energy irradiation (γ rays, X rays, and electron beams) interacts with water to generate a variety of free radicals, principally $OH^{\bullet}$, $H^{\bullet}$ and hydrated electrons. If H_2O_2 or O_3 is present in the water, the $H^{\bullet}$ and the hydrated electrons are converted efficiently to $OH^{\bullet}$ radicals. This process is based on electron accelerators. An attempt has been made to use combined electron beam and ozone for treating municipal wastewater in aerosol flow (Fig. 5) (16,17).

MEMBRANE/SONICATION/WET OXIDATION

Hybrid systems are becoming popular for treating waste streams that are otherwise difficult to handle. For instance, the powder-activated carbon–activated sludge system (PACT system by Zimpro Environmental, Inc.) is a classic example of such systems. OXYMEM is another hybrid process, where wet oxidation and nanofiltration were used together to treat bioresistant industrial wastewater containing polyethylene glycol. It has also been demonstrated that sonication followed by wet oxidation (SONIWO) is a useful hybrid process for treating refractory waste. Conventional bioprocesses may not be amenable to biodestruction of the effluent from reactive bath dye. "Membrane-sonication-wet oxidation" (MEMSONIWO) is a hybrid process applied to water conservation via recycling. The membrane unit allows concentrating the waste, and then the permeate (mostly water) can be recycled. The concentrate from the membrane unit can, then, be treated by sonication to

make it suitable for wet oxidation. After wet oxidation, the water can be discharged or recycled (18).

SORPTION BY ZEOLITES

It is well established that the sorption characteristics of zeolite-type materials are defined by pore size and charge properties (19). Most naturally occurring zeolites bear a relatively high framework charge arising from Al^{3+} substitution for Si^{4+} in the crystal lattice; this results in a structure of high cation-exchange capacity. Such zeolites have been used as ion exchangers to treat water and are incorporated into systems for treating radioactive waste (removal of $^{137}Cs^+$ and $^{90}Sr^{2+}$) and for removing NH_4^+ from wastewater. Zeolites that have high SiO_2/Al_2O_3 ratios have a low capacity to retain cations but are more hydrophobic and can, therefore, sorb uncharged molecules. In laboratory studies using batch sorption equilibria, high Si large-pore mordenite (MOR) and ZSM-5, it was found, have sorption properties for methyl tert-butyl ether (MTBE) and trichloroethylene (TCE) that are superior to those of activated carbon (Table 2) (20).

SUPERCRITICAL WATER OXIDATION

Supercritical water oxidation (SCWO) is considered a promising technology for treating several wastes (21–24). SCWO is a process where oxidation takes place in water above its critical point (647 K, 22.1 MPa). SCWO is an environmentally acceptable technology that produces a disposable clean liquid (pure water), clean solid (metal oxides, salts), and clean gas (CO_2, N_2). Recently, there has been increasing interest in using heterogeneous catalysts in SCWO (Fig. 6). Catalysts can increase the oxidation rates, reduce the residence times and temperatures

Table 2. Solution Concentrations and Percent Removal after Equilibration of 100 μg/L Solutions with 5 mg of Solid Phase[a]

	MTBE		$CHCl_3$		TCE

required for treatment, and possibly control the selectivity of the reaction pathways (25).

ULTRASONIC IRRADIATION

Sonochemical effects are due to the phenomenon of "cavitation," the nucleation and the behavior of bubbles in a liquid (26,27). In wastewater treatment, a bubble of cavitation may function as a microreactor which destroys volatile organic compounds inside (28–30). The cavity may also be thought as a $H^{\bullet}$, $OH^{\bullet}$, $OOH^{\bullet}$ radical source that react with pollutants in the bulk of the solution (Fig. 7). Several potential applications of ultrasonic irradiation have been reported recently.

TRENCHLESS REPAIR AND REHABILITATION TECHNIQUES

Sanjiv Gokhale
Vanderbilt University
Nashville, Tennessee

Trenchless technology (TT) consists of a wide range of methods, materials, and equipment for installing new or rehabilitating existing underground pipelines and utility systems with minimal excavation of the ground. According to the North America Society of Trenchless Technology (NASTT), trenchless construction is “a family of methods, materials, and equipment capable of being used for the installation of new or replacement or rehabilitation of existing underground infrastructure with minimal disruption to surface traffic, business, and other activities.”

Open-cut trench construction has proven expensive, especially in congested urban areas, because it requires disruption of surface activities. Some problems caused by the open-cut method include traffic disruption, economic impact on local businesses, damage to existing utilities, and concerns for worker safety. The development and use of trenchless techniques has expanded rapidly over the past 10 years. The reason for this exceptional growth is the desire to install or rehabilitate underground pipeline systems with minimum impact on society and the environment. The benefits of trenchless technology are quite apparent compared with the conventional open-cut process. However, it is necessary to evaluate the suitability and appropriateness of any rehabilitation system, trenchless or otherwise, on a project-by-project basis with due consideration of all project criteria, such as size and material of pipe, level of deterioration, hydraulic capacity, etc.

According to a 2003 survey (http://www.oildompublishing.com/UC/uchome.html) of trenchless construction methods used by municipalities, the percentage of all municipal projects using trenchless construction methods has grown by 180% (new installation) and 270% (rehabilitation), respectively, over the past 5 years.

BASICS OF PIPELINE RENOVATION USING TRENCHLESS TECHNIQUES

Trenchless pipeline renewal methods offer several advantages over conventional dig-up and repair/replace methods:

- minimize disturbance to existing site, underground utilities, and environment;
- are more suitable for difficult underground conditions, such as high water table and unstable soils;
- require less exposed work area, therefore involving lesser risk to the workers and public; and
- minimize the need for spoil removal and disposal.

The primary trenchless pipeline-system renewal methods can be divided into five categories (Table 1):

Table 1. Trenchless Pipeline Renewal Methods

Method	Diameter Range, in.	Maximum Installation Lengths, ft.	Liner Material[a]	Application
		Sliplining:		
Segmental	12–150	5000	PE, PP, PVC, GRP	Gravity & pressure
Continuous	4–60	1000	PE, PP, PVC, GRP	Gravity & pressure
Spiral wound	4–100	1000	PE, PP, PVC, PVDF	Gravity
		CIPP:		
Inverted in place	4–108	3000	Thermoset resin	Gravity & pressure
Winched in place	4–54	500	Thermoset resin	Gravity & pressure
		Close-Fit:		
Swaged	4–15	700	HDPE, PVC	Gravity & pressure
Folded	3–24	1000	HDPE, MDPE	Gravity & pressure
Expanded spiral	4–36	1000	HDPE, MDPE	Gravity & pressure
		Spray-on Lining:		
Cement mortar	4–36	NA	Cement mortar	Gravity & pressure
Shotcrete	>42	NA	Cement mortar	Gravity & pressure
Epoxy	4–24	NA	Epoxy	Gravity & pressure
		Point Source Repairs:		
Robotic	8–30	NA	Epoxy & cement mortar	Gravity
Grouting	NA	NA	Chemical grouting	Any

Point CIPP	4–24	50	Fiberglass/polyester resin	Gravity

[a] **Definitions of Acronyms**: PE: Polyethylene; PP: Polypropylene; PVC: Polyvinyl chloride; PVDF: Polyvinylidene chloride; GRP: Glassfiber reinforced polyester; HDPE: High density polyethylene; MDPE: Medium density polyethylene.

- sliplining
- cured-in-place pipe (CIPP)
- close-fit pipe
- spray lining
- point source repair

Sliplining

Sliplining is one of the earliest forms of trenchless pipeline rehabilitation. There are three main types of sliplining: continuous, segmental, and spiral wound. A new pipe of smaller diameter is inserted by pulling, pushing, or spiral winding it into the host pipe, and the annulus between the existing pipe and the new pipe is grouted. Small liners may be pulled in manually but most require a winch (Fig. 1). The winch applies a steady, progressive pull to place the liner inside the host pipe. The liner pipe is generally butt-fused to its design length. Numerous designs of pipe pushing machines, both manual and hydraulic, are available. In most instances, an insertion pit is required for the pushing machine. The pushing machine grips the liner pipe and pushes it forward into the host pipe. The gripping mechanism is then released and returned to the starting position, and the process is repeated. Segmental liners are generally used to reduce the size of the insertion pit. Pipe joints are generally of the mechanical type with either a snap-fit or a screw-on mechanism. For spirally wound liners, strips of PVC material are passed through a winding machine and a helically wound liner pipe is manufactured *in situ*. To increase the stiffness of the liner pipe, ribbed strips are used, with "T-beams" forming on the outer surface. The winding machine is normally located down a manhole or a small excavation. The tube travels down the host pipe as more strips are fed into the machine. The whole tube is rotating during the installation, so the limiting factor is usually the friction and weight of the liner that the winding machine is capable of turning. An alternate spirally wound technique overcomes this drawback by using a winding machine that travels through the host pipe, thereby removing the need to rotate the liner itself.

This method has the merit of simplicity and is relatively inexpensive. One of the chief drawbacks of sliplining is the resulting decreased cross-sectional area. In some instances, however, despite the reduced cross section, the hydraulic capacity of the pipeline may actually increase due to the superior flow characteristics of the new pipe. The reconnection of laterals and service lines in conjunction with sliplining of gravity pipelines usually necessitates excavation. Excavation must take place and the lateral must be disconnected before grouting. Electrofusion is commonly used to connect laterals to PE liners in the same way as new installations. For glass-fiber reinforced polyester resin (GRP) pipe, laterals may be typically reconnected to the new liner pipe using "tees."

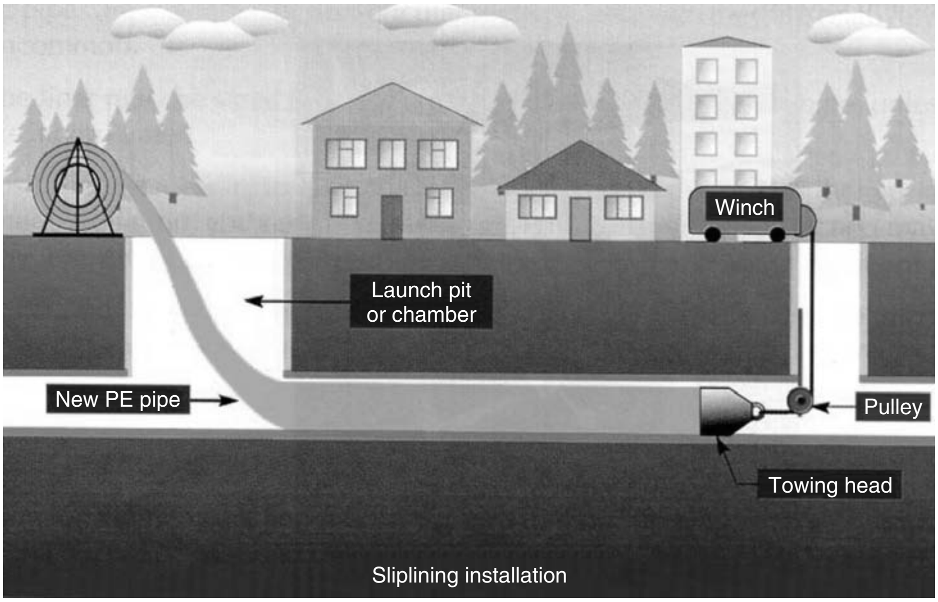

Figure 1. Continuous sliplining.

Cured-In-Place Lining (CIPP)

The main alternative to sliplining and its variants in the non-man-entry pipeline renovation market is the cured-in-place lining (CIPP), sometimes referred to as "*in situ* lining." Although several patented systems are currently available, the common feature of CIPP is the use of a polyester or epoxy resin impregnated fabric tube. The tube is inserted into the existing host pipe and inflated against the wall of the host using a hydrostatic head or air pressure (Fig. 2). The inflated liner is cured by recirculating hot water or steam. The CIPP process creates a "close-fit" pipe that has quantifiable structural strength and can be designed for specific loading conditions.

The chief advantages of CIPP is that it minimizes the reduction in cross section and the liner pipe can conform to noncircular cross sections. The laterals can be reopened remotely after lining by using a remote controlled robotic cutter. The chief disadvantage of this method is the need to take the host pipe out of service during installation and curing. Diversion or bypass pumping adds to the installation cost. CIPP is not cost-effective for large diameters.

As in all trenchless renovation systems, thorough cleaning and preparation are essential. In non-man-entry pipelines, CCTV inspection should be carried out prior to and after installation. All silt and debris should be removed completely by jetting or other means prior to installation. Intruding connections, encrustation, and other deposits should be removed by mechanical means or high-pressure jetting, followed by cleaning to remove debris. There may be short-term environmental implications with CIPP systems when using polyester resins. The solvents in the systems can give off strong odors and in high concentrations, the vapor can pose a health risk. Such levels are not typically found in CIPP installations; nonetheless, adequate ventilation of a CIPP work site is essential. This problem applies only until the resin is cured.

Close-Fit Pipe

The use of liners that are deliberately deformed prior to insertion, and then revert to their original shape once

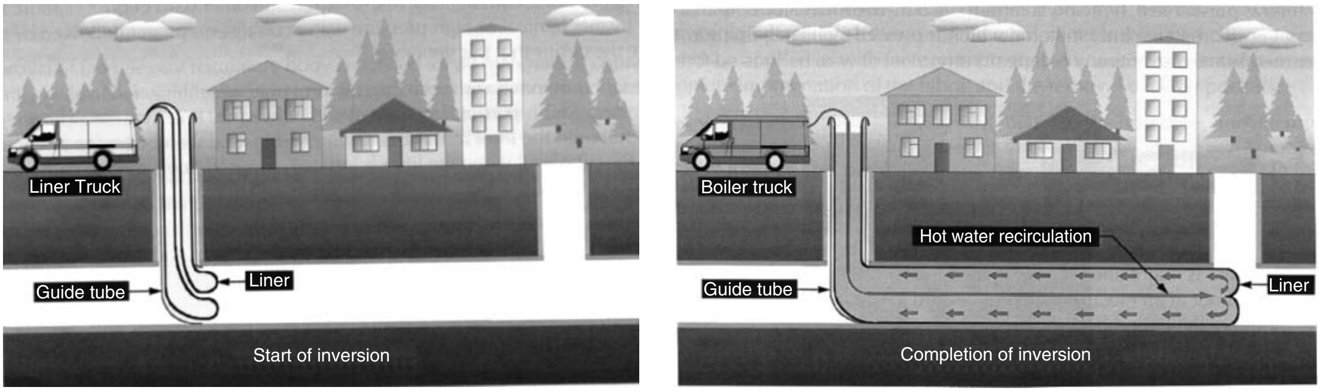

Figure 2. Cured-in-place pipe (CIPP) lining.

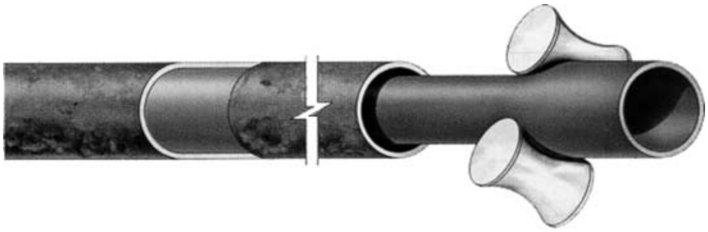

The pipe is reduced in diameter by passing it through rollers or dies, and is reverted to its original size after insertion

Figure 3. Swaged liner. Diagram courtesy of Subterra.

in position, so that they fit closely inside the host pipe, is called "close-fit lining." Such techniques are a logical development of basic sliplining described previously. The close-fit pipe method takes two principal forms, both of which take advantage of the built-in memory of some polymeric pipe materials. In one method, the diameter of the liner is temporarily reduced by drawing it through a set of rollers, a process referred to as "swaging," so that it can be inserted into the existing pipe (Fig. 3). Once installed in place, the liner is restored to its original size by pressurizing the line. Due to the limitations on size reduction, this technique is better suited to pressure pipes than to gravity sewers that have dimensional irregularities. The second method involves folding the liner into a "U" or "C" shape prior to insertion (Fig. 4), and then using heat and/or pressure to restore its original shape. This technique is often described as "fold-and-form." The liner diameter and wall thickness are the main limitations of this process, but it can be used for both pressure pipes and gravity sewers. Some versions of the spirally wound lining technique described previously offer the facility to expand the liner to provide a close fit with the host pipe. During installation, the joint between the adjacent turns of the helix is prevented from slipping by a locking wire. Once the liner is in position, the locking wire is pulled back progressively to allow the joint to slip and the helix to increase in diameter (Fig. 5).

Close-fit lining minimizes the need for cross-sectional reduction. Theoretically speaking, in this type of method, there is no annulus and therefore no need for annulus grouting. The curing time is reduced compared with a cured-in-place (CIPP) liner. As in CIPP, the lateral connections can be reopened remotely after lining by using a remote controlled robotic cutter. The chief disadvantage is the size limitation (for non-man-entry pipe sizes).

The spirally wound liner is expanded after insertion by allowing slippage between adjacent turns of the helix

Figure 5. Spirally wound liner being installed in a host pipe.

Spray-On Linings

Spray-On linings have a long history in potable water pipelines, where the principal objective is to remove the scale and corrosion of old pipelines, generally made of cast iron, and then apply a coating that inhibits further deterioration and seals minor leaks and cracks. The most common materials used for this purpose are *cement mortar linings* or *epoxy resin linings*. For small-to medium sized pipelines this can be achieved by a robotic spraying machine that is winched through the pipeline at a constant, predetermined rate. Development continues in achieving a cost-effective application of spray-on linings in non-man entry sewer pipeline renovation, but so far no method has commercial prominence. This may be partly due to the differing requirements for sewer renovation, where the aim is to increase the structural strength of the pipe, rather than prevent corrosion, and partly due to the practical difficulty of ensuring that the inflow into the system is completely stopped while the material is being applied and cured. For large, man-entry pipelines, the application of a mortar lining can be done manually or mechanically.

Spray-on linings are usually intended as protective coatings and rely on the bond to the host pipe for their function. Hence the preparation of the host pipe is critically important. Old water mains, particularly those made of cast iron, often have heavy internal deposits of corrosion and scale. Cleaning techniques include high-pressure water jetting, scraping, pigging, etc. There is often a balance drawn between removing all traces of corrosion and avoiding damage to the pipe wall; some of the more aggressive cleaning techniques should be used with caution.

Pipe scrapers are designed to remove hard deposits. Spring-loaded steel blades are mounted on the central shaft of a scraper. A towing eye is fitted to each end allowing the scraper to be pulled through the pipe in either direction. Wire brush pigs consist of circular wire brushes mounted on a central shaft and are used to remove the debris loosened by the scrapers or by themselves to remove loose debris from the pipe. Cleaning pigs are available in a wide range of designs and are normally driven through the pipe under water pressure. In a heavily encrusted pipe, pigging may be carried out in stages, using pig sizes of increasing diameters. Pull-through pigs, also known as "squeezes," remove fine material and fluids from pipes. They consist of rubber disks fitted to the central shaft that are towed through the pipe. Pull-throughs are often used in the final stage of pipe preparation to produce a clean, dry surface, to which the spray-on lining is applied.

The application of a *cement mortar lining* is a common and a relatively inexpensive method for water main renovation. The cement mortar serves two important functions: the alkalinity of the cement inhibits corrosion of an iron pipe, and the relative smoothness improves flow characteristics. Note that cement mortar linings are applied to many new cast iron and ductile iron pipes to inhibit corrosion. Application is generally by a spraying machine that is either fed by a hose from the surface or, for large pipes, may have its own hopper containing premixed mortar. The forward speed of the sprayer is controlled to achieve a consistent mortar thickness. Spray application may be followed by troweling. This is often carried out by rotating spatulas fitted to the spraying machine.

For renovation of large diameter brick and concrete pipelines, *shotcrete* is often used as a cost-effective means to enhance the structural integrity of a pipeline. Shotcrete is a process in which mortar or concrete is conveyed through a hose and projected at high velocity onto the surface of a pipe. Shotcrete may be applied dry or wet. The method of applying dry-mix shotcrete through a hose using compressed air is also given the trade name, *Gunite*. There are advantages and disadvantages to both methods. For instance, a wet-mix shotcrete application results in less rebound, less dust, and yields a higher compressive strength. The drawbacks of the wet-mix are limited conveying distance, increased demand on aggregate quality, and increased clean-up costs. As in other lining methods, surface preparation is critical. All deteriorated material from the pipe walls must be removed along with dirt, oil, and other bond inhibiting material. The pipe surface must be dampened in the wet method so as to be saturated surface dry (SSD) prior to application. Prepackaged mixtures of ready-to-use cementitious mortars containing various proportions of silica fume and fiber reinforcement, and admixtures for high-strength, low-shrinkage shotcrete are commercially available. For additional strength, reinforcing bars or welded wire fabrics may be used. Both wet and dry-shotcrete are shot perpendicularly to the pipeline surface to minimize rebound and to create a smooth pattern. After applying the shotcrete, it is allowed to stiffen for about 10 minutes before "bumpy" areas are troweled to give a uniform surface. Shotcrete is applied in layers (approximately 1-inch thick) until the required design thickness is reached. Before applying the next layer, the previous layer must be allowed to reach an initial set. This can take from 45 minutes to several hours depending on mix consistency and ambient temperature.

Epoxy linings are an alternative to cement mortar linings (Fig. 6). The resin bonds to the surface of the pipe, forming a coating, which inhibits water penetration and corrosion. Epoxy coatings are much thinner than cement mortar linings and therefore do not significantly reduce the pipe cross section. However, any defect in the coating may allow corrosion to start and unlike cement mortars, they do not have alkalinity to inhibit chemical deterioration. Epoxy resins are also relatively expensive compared to cementitious materials. Epoxy resins should not be used for lining water lines unless specifically approved by NSF. The resin is applied by a spraying machine with a rotating nozzle. The thickness of the coating is controlled by the flow rate and forward speed of the sprayer. In most systems, the resin base and the hardening agent are fed through separate hoses and are combined by a static mixer just behind the spray nozzle. Ideally, the cure time should be as short as possible to minimize the time during which the pipe is kept out of service. However, too rapid a cure carries the risk of causing blockage in the static mixer or the nozzle. Unlike cement mortar linings, the resin is not smoothed or troweled after spraying, and the

Figure 6. Application of epoxy resin lining.

surface quality depends on the application technique and the properties of the material.

Epoxy linings do not fulfill any structural function and are not recommended for pipes that leak significantly or for pipes with significant structural defects.

Point Source Repairs

Various localized repair systems have been developed, most aimed at sewer renovation but include some that are designed to seal joints in pressure pipes. Many techniques are adaptations of the full-length lining systems seen previously.

The economics of "spot repair" versus renovation of the entire pipe length is assessed by the Design Engineer, but as a general rule spot repair methods may prove economical where defects in the pipe are restricted to less than 25% of the length. Preinspection of the pipeline and cleaning are just as essential to localized repairs as to full-length renovation. There are four broad categories of localized repair systems: robotic, grouting, mechanical seals, and point CIPP. Sometimes point repair systems are classified into two categories, structural and nonstructural. Robotic methods, mechanical seals, and point CIPP produce increased structural strength and are hence regarded as "structural" renovation techniques; chemical grouting is often termed "nonstructural."

Point Source Repairs. Robotic techniques, used mainly in gravity pipelines, consist of a grinding robot and a sealing robot (Fig. 7). The grinding robot can be fitted with various shapes of diamond carbide cutters suitable for clayware, concrete, polymeric pipe, and even steel. The wheels are driven by an electric motor and cooled by a water jet spray. The robotic operation is monitored by a CCTV camera attached to the head. Typically, the grinding robot mills cracks to a width and depth of up to 1 inch, after which the area around the crack is cleaned. A grinding robot can also remove intruding laterals, grout deposits, and hard encrustation. Like the grinding robot, the sealing robot is self-propelled and equipped with an onboard CCTV camera. Epoxy is applied by the sealing robot to completely fill the slot milled by the grinding robot. In addition to filling slots, the sealing robot can apply epoxy around poorly made connections or leaking joints to seal connection and joints.

All robotic functions are controlled from a central console housed in a vehicle, which contains the power pack, hoist for lifting and lowering robots into manholes, and other ancillary equipment. Robotic repairs are versatile, but to be cost-effective, a consistent program of work is needed.

Grouting. Resin injection systems fall into two categories: those whose principal function is to seal the pipeline against infiltration and exfiltration and those that restore structurally damaged pipe.

A common method of sealing leaking joints in gravity pipelines is by using a special packer that combines the functions of leakage testing and grout injection. A packer with inflatable elements is positioned across a pipe joint and pressurized to isolate the joint. The joint is tested for pressure loss and if necessary a sealing gel is injected through the packer to seal the joint. The grout has little intrinsic strength but turns the ground around the leaky joint into an impermeable mass thereby enhancing the structural stability of the pipe.

In the past, the use of acrylamide grouts was commonplace. However, these grouts have been banned in the United States because the unreacted components pose a serious health risk. Today the use of polyurethane (PU) grouts is common. PU grouts react with the free water in the soil to form a viscous gel that hardens over time. Many PU grouts contain acetone to reduce viscosity. The flammability of acetone should be considered during storage and handling.

For leak sealing the entire system—main sewer, laterals, and manholes—a different approach is taken, often referred to as "fill and drain." The section of the sewer to be sealed is first isolated and then filled from manhole to manhole with an environmentally safe chemical solution (usually *sodium silicate*). After a predetermined interval to allow the chemical to permeate through leaking joints and cracks, the solution is pumped out quickly, and the section filled once again with a second chemical solution

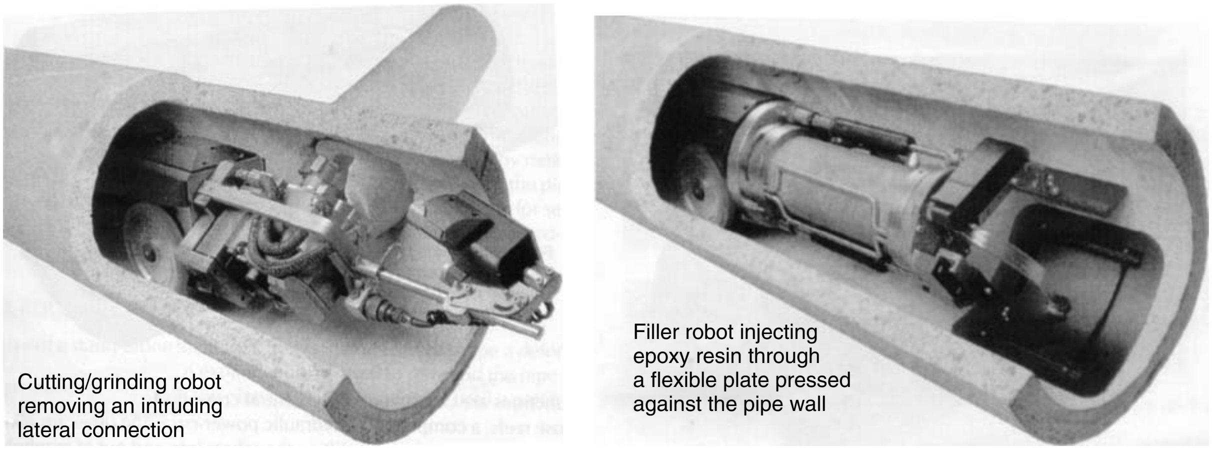

Figure 7. Robotic repairs using grinding and filling remotely controlled robots.

(usually *proprietary*), which reacts with the residue of the first chemical to form a waterproof gel. The second chemical is then pumped out and the pipe cleaned before returning it to service.

An epoxy resin system is used to address structural defects in pipes. An inflatable packer isolates the defect and injects a rapid-setting epoxy resin into the crack, fracture, or hole in the pipe wall. The packer is left in position until the resin has cured, thus forming an internal collar inside the pipe.

Mechanical Seals. Mechanical seals are used primarily for sealing leaking joints. This method involves installing a metal band or clip (usually stainless steel) faced with an elastomeric material across the joint. The elastomeric material forms a seal with the inner surface of the pipe. Repair modules are installed by an inflatable packer which expands the clip and presses the elastomeric material against the pipe wall. The packer is then deflated and withdrawn. Systems of this type are available for gravity and pressure pipe. Mechanical sealing systems have the advantage of being quick and easy to install; however, the material cost is higher than in other methods. Tapered versions are available to seal between pipes of varying diameter and to seal the annulus at the ends of sliplined pipes.

Point CIPP. Most point or "patch" repairs with cured-in-place (CIPP) liner sections entail impregnating a fabric with suitable resin, pulling the patch into place within a sewer by using an inflatable packer or mandrel, and then filling the packer with water, steam, or air under pressure to press the patch against the existing sewer wall while the resin cures. After curing, the packer is deflated and removed. The repair is then inspected by CCTV, and any lateral connections present are reopened using the same techniques as for full-length CIPP liners.

Both thermal and ambient cure systems are currently available. In many respects, point repairs are a short version of cured-in-place liners, although often the fabrics and resins are specialized to achieve greater structural strengths in the patch. The fabric is commonly polyester needle-felt (unwoven), either on its own or in combination with glass fiber. Some systems use a multilayer sandwich; the glass fiber provides strength, and the felt acts as a resin carrier. Although polyester resin is used in full-length liners for economy, epoxy resins are a common alternative for local repair systems. Epoxies, unlike polyester resins, are not affected by the presence of water. This is especially relevant in techniques designed for installation without diverting the flow in the pipeline. Impregnation of the fabric is usually, but not always, carried out on site. In this case, care is needed to avoid health risks and the spillage of chemicals, some of which are toxic in the unreacted stage. During mixing and impregnation of the resin, it is important to remove all entrapped air because air can weaken the material and in severe instances results in porosity. To overcome this, some systems use vacuum impregnation.

In both ambient and thermally cured systems, it is essential to limit the rise in the temperature of the material until the patch is inflated within the host pipe. Exothermic cure begins as soon as the resin components are mixed, and the rate of temperature rise depends on the volume of resin mixed. One of the most common causes of point system failure is premature cure, where the patch has started to harden before it is in position.

BASICS OF MANHOLE RENOVATION USING TRENCHLESS TECHNIQUES

Trenchless manhole renewal methods offer several advantages over conventional dig and repair/replace methods. These advantages are similar to those in trenchless pipeline renovation, explained previously.

There are four basic methods of manhole rehabilitation:

- spot repairs (chemical grouting, plugging, and patching);
- cementitious coatings (spray and troweled);
- protective coatings (epoxy and polyurea); and
- structural repair systems (monolithic *in situ* liners)

Spot Repairs. Most injection processes use materials similar to those employed in pipe joint sealing, polyurethane or acrylic grouts. The primary purpose of pressure grouting is for I/I control and stabilization of voids around manholes.

The process generally involves drilling injection holes in a predetermined pattern, through which the grout is injected to create a flexible external membrane. Polyurethene grouts are water-reactive and can be injected without a catalyst if there is sufficient free water in the surrounding ground.

Rapid setting hydraulic cements may be used for plugging holes and cracks and are generally used prior to grout injection to prevent washout of the grout. Some hydraulic cements have a setting time of just a few seconds.

Careful inspection of the contractor's work during the actual grouting operation is necessary to ensure adequate coating of the exterior of the manhole structure. A follow-up dye test is recommended for each manhole.

Cementitious Coatings. Cementitious coatings are typically used to inhibit I/I and are not structural. Cementitious coatings are typically made of portland cement, finely graded mineral fillers, and proprietary chemical additives. Cementitious coatings are generally brushed on in two applications, one gray and one white, to provide a visual indication of the coverage of each layer, to a total thickness of about 1/2 inch. Before applying the cementitious coatings, it is essential to prepare the interior by washing with high pressure jets and plugging and patching as required.

Protective Coatings. Protective chemical coatings, such as epoxies and polyureas, are used as barriers to bacterial corrosion on new or recently installed precast manholes. They are not used in rehabilitating badly deteriorated or structurally unsound manholes. The recommended coating thickness differs greatly among products and manufacturers, although the typical range is from 60 to 200 mils. A combination of semistructural cementitious liners with epoxy coatings has recently been introduced to provide surface restoration and protection.

Structural Repair Systems. Cementitious liners have been widely used over the past 5 years for structural enhancement of brick manholes which have lost some of their mortar joints but remain basically sound. The liners are made of high-strength, quick-setting mortars of portland or high alumina cements. Thorough preparation of the internal surface is essential, and a bonding or stabilizing agent may be necessary depending on the condition of the manhole. Structural rehabilitation generally requires a cementitious liner thickness of between 1 to 4 inches (Fig. 8).

In situ structural replacement systems fall into two categories: inserts and *in situ* lining systems. A variety of inserts made of fiberglass, polyurethane, PVC, etc., can be installed inside existing manholes and then back-grouted to create a new structure inside the host manhole. The concept is similar to sliplining in pipeline renovation. This method requires excavating the ring and the cone to allow placing the insert inside. If the manhole is tapered, it may be necessary to excavate several feet before the insert can be positioned. Careful attention is required around pipe inlets because it is difficult to make a seal when the material composition of the liner is different from that of the inlet pipe.

In situ lining systems are reconstruction techniques that require no excavation and are not disruptive. These systems use a variety of spiral-wound, cured-in-place, etc., materials to create a liners inside existing deteriorated manholes. Cured-in-place liners are generally recommended for structural rehabilitation of manholes where future corrosion is expected. A felt or a glass-reinforced “bag” is custom-made to the size of the manhole. Resin is impregnated into the bag at the job site. The bag is then lowered into the manhole, steam pressure injected for 1–2 hours to achieve curing, and holes are cut at the invert and pipe inlet locations before returning the manhole to service. Surface preparation is crucial to the success of this method. All voids and recesses need to be filled prior to undertaking cure-in-place lining. The helically wound lining technique described previously for pipeline renewal can also be used for renovating manholes. PVC strips are fed into the manhole opening and spirally wound by a winding machine into the existing manhole. Preparation involves removing ladders, step-irons, and internal backdrops before cleaning the surface by high pressure water jetting. Annulus grouting is carried out to bond the liner to the walls of the manhole.

Figure 8. Application of one-coat cementitious structural liner.

BASICS OF UNDERGROUND WATER AND SEWER PIPELINE ASSESSMENT, REPAIR, AND REHABILITATION

Sanjiv Gokhale
Vanderbilt University
Nashville, Tennessee

In March 2001, ASCE released a Report Card for America’s Infrastructure. The wastewater and drinking water infrastructure categories received a discouraging D+ overall and an estimated need for an investment of $1.3 trillion to bring conditions to acceptable levels. In September 2003, ASCE released a Progress Report (http://www.asce.org/reportcard/) that examines the current trends for addressing the nation’s deteriorating infrastructure. ASCE determined that the conditions and performance had not changed significantly in 2 years.

America’s industries rely on clean water to carry out activities that contribute over $300 billion to our economy each year. However, the challenge to continue providing clean water remains because our existing national wastewater infrastructure is aging, deteriorating, and in need of repair, replacement, and upgrading. In fact, EPA has reported that without improvements to the nation’s wastewater treatment infrastructure, we face the very real risk of losing the environmental gains we have achieved during the last three decades since the passage of the Clean Water Act of 1972. Drinking water quality remains good, but the infrastructure of the nation’s 54,000 drinking water systems is aging rapidly. Federal funding remains flat, and the infrastructure needs continue to increase. There is an annual shortfall of $11 billion needed to replace or rehabilitate facilities that are nearing the end of their useful lives and to comply with federal water regulations.

The nation’s 16,000 wastewater systems face enormous needs. Some sewer systems are 100 years old and many treatment facilities are past their recommended life expectancies. For the fiscal year 2001, Congress allocated $1.35 billion for wastewater infrastructure, but currently there remains a $12 billion annual shortfall in funding for infrastructure needs. Sewer overflows and discharge of untreated or undertreated flows into streams and rivers has made more than one-third of U.S. surface waters fail to meet water quality standards.

The forecast for our nation’s drinking water systems indicates a downward slope. Drinking water received a D on the 2001 Report Card, yet the situation continues to worsen as aging systems—some developed more than a century ago—continue to service our ever-growing population.

Traditionally, municipalities have constantly been a "step behind" in managing the municipal, and this is especially true of sewer systems. Municipalities have addressed the design, construction, maintenance, and rehabilitation of sewer systems by a "crisis-based" approach. Sewers are not built and/or rehabilitated until a major failure (i.e., overflow, collapse) occurs. This reactive management practice has led to inefficient use of funds and causes more frequent sewer failures, which end in difficult and costly repairs. For municipalities to be a "step ahead" in managing sewer systems, they need to have a better understanding of the existing condition of the network, which in turn will help them plan and manage maintenance to prevent major failures.

PIPELINE ASSESSMENT

A variety of ways and means exist by which existing underground pipelines may be evaluated:

- ground penetrating radar (GPR)
- sonar
- televising
- smoke testing
- dye testing
- flow monitoring
- walk-through
- pressure leak tests
- electronic leak testing

Ground Penetrating Radar

Ground penetrating radar (GPR) works by launching pulses of electromagnetic energy into the soil under investigation. These pulses propagate through the ground and are reflected by subsurface targets or at interfaces between different media. The radar measures the time taken for a pulse to travel to and from the target, which indicates its depth and location. The transit time of the pulse depends on the dielectric properties of the material. In addition, the depth and penetration obtained may vary considerably with soil conditions; for example, loam is an easy medium to penetrate, whereas clay is more difficult.

The difficulty with GPR lies in selecting the correct frequency; different types of soil respond differently to radar frequency. A large study undertaken in Canada to detect leaks in buried plastic water distribution pipes was inconclusive. However, more recent advances in GPR technology and in particular the use of multisensory systems seem to hold promise. Field trials indicate that multisensory systems are more accurate, faster, and capable of working in a variety of ground conditions. At present, however, the effectiveness of this technology in pinpointing inactive leaks in underground pipes is undocumented.

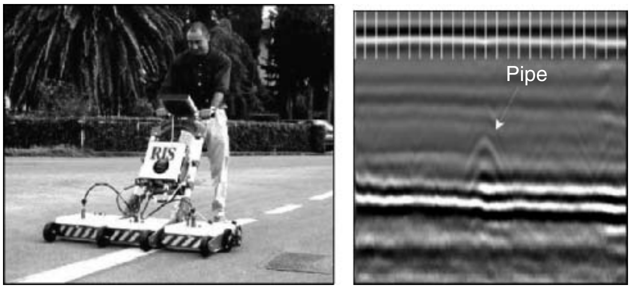

Figure 1. Multisensory ground penetration radar (GPR) used in locating underground pipe.

GPR is used today primarily to locate underground pipelines. GPR equipment is dragged across the surface in a precise fashion, and the output (radar signal) is stored and later graphed after filtering out the "noise" (Fig. 1). Computer enhancements have allowed GPR technology to become very effective in situations where an underground discontinuity (e.g., a pipeline) is known, but the plan location of a buried pipeline is unknown. However, GPR may be able to indicate that a discontinuity exists underground, but there is often an uncertainty about what the discontinuity actually is and also what is the exact depth at which this discontinuity exists.

GPR technology is an evolving field and it is expected that in the future this may very well become the most dominant method of pipeline location and assessment.

Sonar

Sonar can give a relatively accurate picture of the profile of a pipe wall and surrounding soil. The results, however, are very much open to interpretation, and a highly skilled operator is vital. Sonar techniques can, however, show flow regimes under water and are thus useful in detecting infiltration into surcharged pipes.

Televising

Pipeline televising is used to identify problems primarily in sanitary and storm sewer pipe. It is usually referred to as closed-circuit television inspection (CCTV) and consists of a remote television camera passing through a pipe that sends the live picture to a screen aboveground. The remote television camera unit is composed of a camera mounted on a skid or equipped with wheels (Fig. 2). The camera can be directed through the pipe using manholes as access points to insert cables that connect to the remote TV unit. Other cables connected to the remote TV unit carry the signal back to the screen, which is usually mounted in a truck. The screen mount in the truck incorporates a videocassette recorder slot so that data can be saved and viewed by others.

The sizes and types of pipe that can be televised are virtually unlimited, especially with newer technologies that allow smaller TV units to be pushed through small diameter pipe such as house laterals. The line televising crew usually consists of an operator stationed in the truck and one or two operators stationed near the manhole(s).

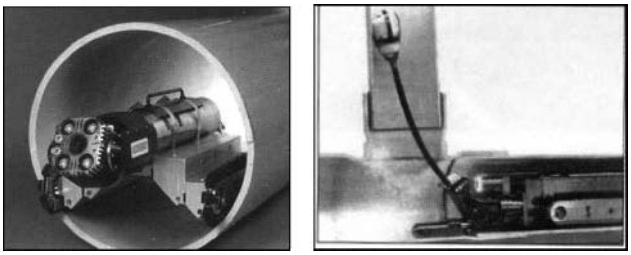

Figure 2. CCTV Systems: Mainline inspection and lateral inspection (left to right).

In most cases, the line televising crew is employed by the local utility, although private contractors perform this service as well.

Line televising is performed as part of routine operation and maintenance by most wastewater utilities. It provides a good indication of the structural integrity of the pipe and can pinpoint problems in a way that was not possible before its invention (Fig. 3).

A utility may also require postconstruction televising at the completion of a new sewer or storm pipe to determine adequacy of joint connections, service connections, or other indications of proper pipe installation. A further application might be the review of lined sewer pipe to ensure that services were properly reinstated. The applications of line televising are numerous. The information generated, in conjunction with proper consultation with the Engineer, will guide the utility toward better decisions regarding the maintenance and operation of the network.

Smoke Testing

Smoke testing is a simple test used to identify unauthorized connections to a sanitary sewer system. In systems where the sanitary and storm sewers are separate, unauthorized connections include roof leaders, downspouts, and yard drains. Smoke testing can also identify direct connections between the sanitary and storm sewer system and, to a lesser extent, locations of broken sewers or “lost” manholes. In these latter two cases, line televising is more effective.

To smoke test, a blower unit is inserted over a manhole to allow smoke to be blown into the sewer (Fig. 4). Pipe plugs are inserted into adjacent manholes to isolate a section of sewer before “smoke bombs” are inserted into the manhole where the blower is located. The smoke blown into the sewer then, in theory, has no place to escape except through unauthorized connections, direct connections from the storm sewer, plumbing vents, or defects in the sewer system. However, there is a potential that smoke can enter homes or businesses if the plumbing that connects the building to the sewer is defective or was installed improperly or if the traps are dry. For example, the absence of a vent pipe in a home may cause smoke to enter the house. For these reasons, advance warning to the residents potentially impacted is not only a good idea, but also a necessity. Further, coordination with the local Police and Fire Departments is necessary to avoid panic or alarm with the potential of smoke detected in resident’s homes. Smoke testing can be a valuable tool in determining who is connected to the sanitary, or storm, sewer system.

Dye Testing

Dye testing, like smoke testing, can be used to determine connections to a sanitary, or storm, sewer system or interconnections between the two. It can also be used to determine leaking sewers that may be discharging to creeks or other bodies of water. Improper connections, such as yard drains discharging to a sanitary sewer, can be effectively identified by a dye test. It can also be used to identify positively whether a house is actually connected

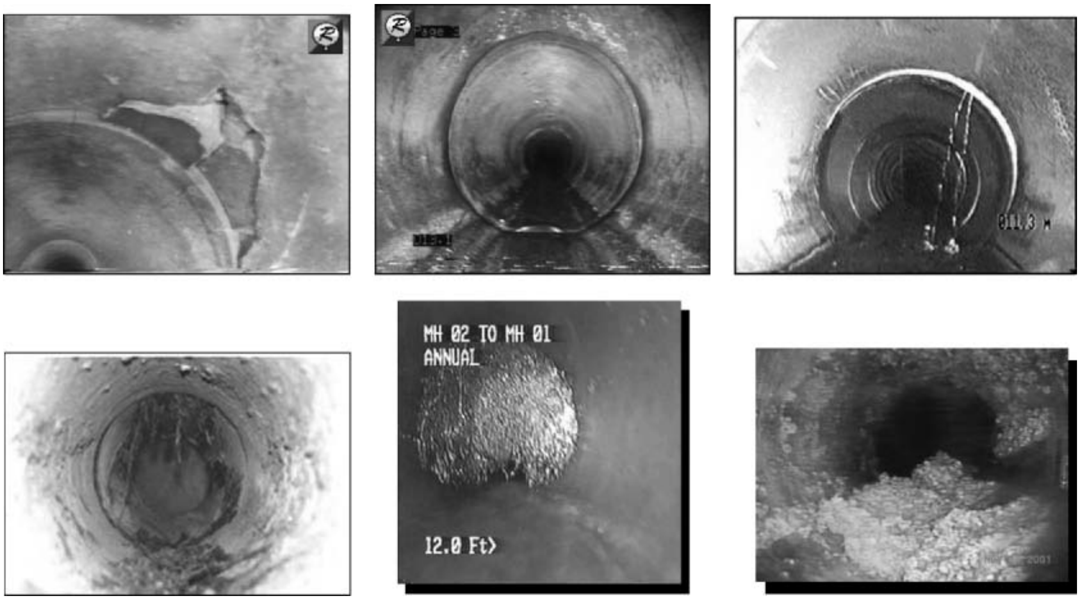

Figure 3. Pipeline Defects: Cracked pipe, offset joint, infiltration root intrusion, root blockage, and grease blockage (clockwise from top left).

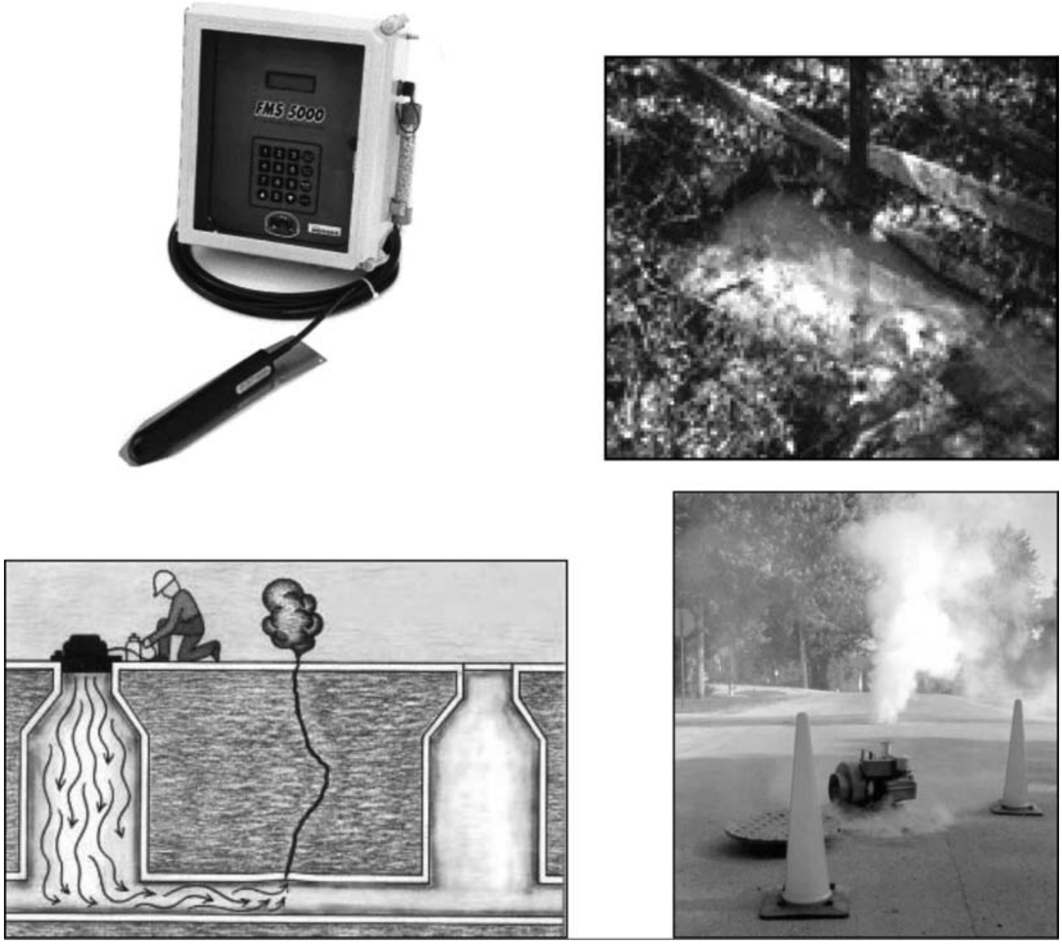

Figure 4. Flow monitoring device, dye testing, and smoke testing in sewers (clockwise from top left).

to the sanitary sewer. Rare instances where house laterals were either inadvertently not connected or wrongly connected to the storm sewer system, unfortunately, sometimes occur. A dye test is a good tool for these cases.

The dye can be in powder, tablet, or liquid form and is simply inserted into the sewer (Fig. 4). Although safe and harmless, the wastewater utility should be contacted to ensure that no regulations against the dye are in place and as a “heads-up” if appreciable quantities of the dye reach the treatment plant. Similarly, the local environmental agency should be contacted if dye testing is proposed in storm sewers. Some dyes can be mistaken for things such as “antifreeze” spills and can cause undue alarm and attention. Like smoke testing, public education is a necessity in most applications. Where access to households is necessary to test for positive connections of laterals or drains, it is probably best to work through local city or town officials.

Flow Monitoring

Flow monitors (or meters) are useful as part of a statistical modeling exercise for I&I (Fig. 4). Data on water use, and hence discharge to sewers, can be obtained through a few strategically placed flowmeters and when combined with network modeling, can present a very accurate overall picture of the system operation.

Walk-Through

The walk-through method of pipe assessment is obviously used only for large diameter pipes or large storm sewer box structures. This method can yield important information on the structural integrity of the pipe and structure, especially if trained personnel perform the inspection. The Construction Inspector must be fully aware of the safety implications of entering these pipes or structures. The decision on whether to enter a pipe or structure should be made with full regard for Occupational Safety and Health Administration (OSHA) confined space entry regulations http://www.osha.gov/.

Pressure Leak Testing

For pressure pipe, the methods of assessment for pipe in service are limited. One method used is leak testing using sound waves to pinpoint the location of the leak. The test is primarily on water mains and is usually performed by specialized firms. However, the cost of leak detection equipment has decreased to the point where most medium to large water utilities have invested in this methodology.

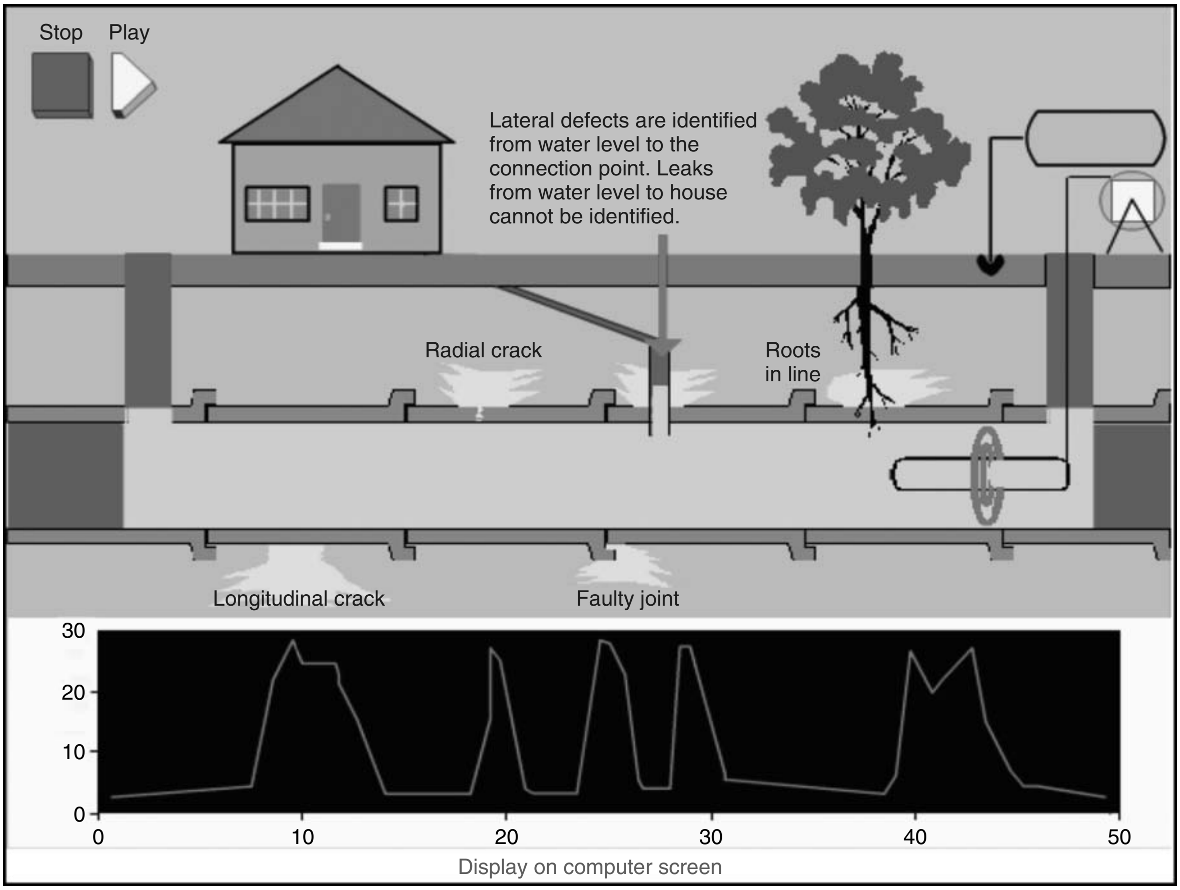

Figure 5. The FELL system.

Leak testing uses sound waves to identify the point in the pipe where a leak has occurred. The technology has evolved to a point where digital readouts can specify the exact location of the leak relative to the wire connections on water main appurtenances, usually valves. This technology could be useful when recently installed or repaired pipe cannot pass specified pressure tests.

Electronic Leak Testing

The focused electrode leak location (FELL) system measures electrical current flow between a probe that travels in a pipe and a surface electrode. Pipe defects that allow liquids to flow into or out of the pipe cause a spike in the electrical signal, thereby locating the sources of infiltration or exfiltration. The intensity of the measured current can be correlated with the magnitude of the leaks.

The FELL test system uses a specially constructed electrode called a “sonde” that generates an electric field. The sonde is 30 in. long and 3 in. in diameter. The electric field is focused into a narrow disc, 1 in. wide set normal to the longitudinal axis of the sonde. A surface electrode (usually a metal stake) is put into the ground at the surface. When the sonde is placed in a *nonconducting* pipe that contains sewage (and/or water), the electric current flow between the sonde and the surface electrode is very small. Defects in the pipe that would allow flow of fluid either *into* or *out of* the pipe provide an electrical pathway from the sonde, through the wall of the nonconducting pipe, and through the ground, to the surface electrode. When the sonde is close to such a defect, the current between the sonde and the surface electrode increases. Figure 5 illustrates the operation of the FELL system.

PIPELINE REPAIR AND RENEWAL—EXCAVATION

Sanitary and storm sewer systems and water distribution systems develop defects over time. Defects occur from a variety of causes including improper initial installation, freeze/thaw damage, and cutting by another contractor. Pressure lines typically exhibit failures rapidly; it may take years for a defect in a gravity line to be obvious. A failing pipe system can be repaired or renewed by replacing the entire pipe or manhole or by replacing only the defective portion. Construction requirements for repair and renewal are similar to original construction requirements. The following discussion highlights the different methods of repairing or renewing pipes and manholes.

PIPELINE REPAIR AND RENEWAL—WHOLE PIPE

Gravity Sewers

When the Engineer has determined that a pipe and/or manhole has deteriorated beyond trenchless rehabilitation, replacement is typically the prudent alternative. To replace a whole segment (structure to structure), the Contractor must excavate to the pipe. Paved surfaces must be saw cut prior to excavation to prevent damage beyond the construction limits. The original backfill is removed; if it is acceptable material by today's standards, it can be reused; otherwise, it must be removed. When the pipe is exposed, it is removed along with the bedding material. Lateral connections should be cut before the pipe is removed to prevent fracturing the lateral. Once enough of the pipe is removed, new segments of pipe may be installed following procedures for new pipe installation. Bedding, haunching, and backfilling are all important components of successful pipe replacement. Although it is often more difficult to prepare the bedding below the pipe because water may be flowing in the trench, proper bedding is essential for proper pipe installation. In addition, if the original pipe settled, the bedding remaining under the existing pipe will not be on grade for the installation of the new pipe. It is important to check the grade of the bedding prior to laying the new pipe.

Force Mains

If the line to be replaced is a force main, it may be designed in a new location so the existing force main can remain in service until the latest possible time. In this case, the force main installation is the same as new construction until it is time to make the final connection to the pump end of the force main. If the new force main connects to the existing force main, a pressure coupling must be used. If the new force main is connected at the discharge of the pumps, properly sized spool pieces must be on hand to complete the final connections as rapidly as possible.

Couplings to join the new force main to the old force main must be designed for the pressure the line will undergo. Pressure couplings typically have a rubber sealing sleeve surrounded by a steel or stainless steel sleeve. The sleeve is fastened to the pipe by tightening bolts provided on the clamp.

All testing of the force main must be completed prior to putting it into operation. The same tests required for new force mains must be completed on replacement force mains.

The Contractor may have to provide external pumping capacity or temporary piping to allow pumping the wastewater or storm water downstream. This can also be accomplished by a vacuum truck, with appropriate permissions to discharge into a downstream manhole.

Manhole Connections

The rubber gasket or boot used to create a watertight seal between the manhole and the pipe may need to be replaced. The importance of the gasket, whatever type is used, is to prevent groundwater from entering the pipe–manhole joint. The gasket must seal tightly to the manhole and to the pipe.

Lateral Connections

The Engineer will specify if the laterals are to be replaced to the right-of-way or easement limits or only within the trench. In either case, the lateral wye or tee must be installed in the main line approximately at the same location as the previous one. The Contractor must excavate along the lateral until sound (not broken or cracked) pipe is found and replace the lateral from that point to the main. The connection between the new pipe and old pipe is made with a special coupling. These couplings are manufactured to fit various pipe sizes and materials. They are manufactured from rubber compounds and have some type of clamp to seal the coupling to the pipe. Some of the couplings have a stainless steel sleeve to prevent misalignment of the pipe.

Testing

Testing requirements are specified in the Contract Documents. Rehabilitated pipe may be tested similarly to a new pipe installation with a low-pressure air test and a deflection test. If the main has lateral connections, the lateral connection coupling must be removed and the lateral plugged prior to the air test. To help reduce the cost of testing, the pipe can be air tested (if permitted by Contract Documents) once the pipe has been bedded and backfilled up to the elevation of the lateral couplings. Deflection testing should be completed after the required waiting time. In special circumstances, the Engineer may specify joint testing in lieu of air testing of the whole pipe. The Engineer may also specify deflection and/or television inspection of the main after the repair has been completed. Television inspection after installation is similar to the inspection described in assessment of pipes earlier in this article.

Sewage Control

The Contractor may choose (or the Engineer may require) to plug the upstream sewer line and pump the flow around the segment being replaced. This creates easier working conditions for preparing the bedding for the new pipe. As work progresses on the line segment, the Contractor may have to cope with flow from laterals. If the flow is light, the Contractor may choose to "just work in it" and let the sewage flow through the trench. This is acceptable as long as the crew is able to compact the bedding and backfill properly. If the Contractor does not bypass the wastewater, workers need to be aware of the potential for disease transmission. Rubber boots, gloves, and eye protection should be provided. Facilities must be provided for washing hands.

PIPELINE REPAIR AND RENEWAL—POINT REPAIRS FOR GRAVITY SEWERS

Gravity Sewers

If a sewer or force main has a small section that is deteriorated, it may be replaced while leaving the remaining line in service. The Contractor saw cuts pavement as necessary and excavates down to the pipe. The bad section of pipe is exposed. The pipe must be cut with a saw past the limits of the damage. It is important that the pipe is cut back to sound pipe for the repair coupling to seal against. A new section of pipe is cut to the same length as the piece removed. Repair couplings are placed on the replacement piece and the new piece is inserted into place.

Bedding

The repair piece must be bedded properly to prevent settlement or heaving of the new piece of pipe. If flexible couplings are used, this is all the more critical because the flexible couplings will deflect rapidly creating an offset in the pipe or a tear in the coupling if the offset is severe enough. If couplings with a steel sleeve are used, the offset may cause the pipe to crack if it is not bedded properly. Lean concrete or flowable fill may be used to bed the pipe.

Repair Clamps

- *Flexible Repair Coupling*: these clamps are manufactured to fit snugly on various sizes and types of pipe. Clamps can be purchased to fit VCP on one end and PVC on the other because they have different outside diameters. The proper clamp must be used to ensure a watertight connection. The rubber sleeve is tightened onto the pipe by tightening the clamps supplied with the repair coupling
- *Repair Couplings with Sleeves*: these clamps are similar to the flexible clamps described above, but they have a stainless steel (usually) sleeve that wraps around the rubber sleeve to prevent the pipes sections from being misaligned or offset.
- *PVC Repair Clamps*: these clamps can be used to repair PVC pipe with PVC pipe. The clamp is a double bell.

Testing

The most common tests for point repairs are

- *Segmental Low-Pressure Air Test*: a testing ring is inserted into the line and positioned over the repair. The positioning is observed with a television camera. The testing ring is inflated to the required test pressure.
- *Mandrel Deflection Test*: Completed in the same manner as new construction.
- *Television Inspection*: Completed in the same manner as assessment.

PIPELINE REPAIR AND RENEWAL—POINT REPAIRS FOR FORCE MAINS

Force Mains

Force mains may be point repaired by methods similar to those for gravity lines. The main difference is in the type of repair clamp and testing. If the defect in the force main is a single crack, a repair clamp of the proper pressure rating and length may be used without replacing any pipe. If the damaged section cannot be repaired by one clamp, a section of the force main may be removed by saw cutting. A new section of pipe is then secured into the line with one or two clamps (one if it is possible to use a push-on or bolt-on joint). The bedding must be moved away from the pipe to install the clamp. The pipe must be cleaned to allow the clamp to seat properly.

Bedding

The replaced section of pipe or the clamped area must be rebedded to support the pipe properly. Lean concrete or flowable fill may be used for support under the repaired area.

Repair Clamps

The surface of the existing pipe and the replacement piece must be relatively clean to allow the repair clamp to seal completely on the pipe. The clamp will leak if there is debris on the pipe.

- *Bolt-On Flanges*: for most pressure pipe, flanges can be bolted onto the existing pipe and a new flanged piece (or bolt-on flanges on the repair piece) bolted into place.
- *Pressure Couplings*: these couplings are typically made from a sheet of rubber to create the sealing surface and a stainless steel band with multiple clamps to hold and tighten the clamp onto the pipe. They are manufactured for various pressure ratings.

Testing

Typically, the repair is tested after the pipe is bedded but before backfilling is completed. The pressure is returned to the line; if no leaks are observed, backfilling is completed.

MANHOLE REPAIR AND RENEWAL

Manholes

To replace a manhole or storm structure, the Contractor must saw cut the existing pavement and excavate around the manhole. When the excavation reaches the elevation of the sewers, the excavation must follow along the pipes to allow the pipes to be saw cut. Once all lines have been freed from the manhole or structure, the manhole can be removed. The Contractor will have to provide a means of controlling wastewater flow into the excavation, as described earlier in this section.

Once the manhole has been removed, the bedding can be removed and replaced. The bedding must be compacted well, leveled, and brought up to the correct elevation. The new manhole is set similarly to new construction. Once the manhole is set, the pipes must be reconnected. New sections of pipe are inserted into the manhole, and the other end is connected to the existing pipe with a coupling as, described in the Point Repair section.

Testing

Replaced manholes are typically vacuum tested and the line connections are tested, as described in the Point Repair section.

WATER MAIN REPAIR AND RENEWAL—POINT REPAIRS FOR FORCE MAINS

Point Repairs of Water Mains

Point repairs on water mains are similar to repairs on force mains, except that water mains may be under constant pressure. Normally, a sufficient number of valves in the water distribution system can be closed to reduce or eliminate any pressure in the water main. Point repairs can be completed using a repair clamp or sleeve with the proper pressure rating and size for the pipe to be repaired. Water main pipe materials vary from ductile iron, cast iron, old sand cast iron with variable diameters and rough surfaces to asbestos cement and concrete to smooth wall PVC and polyethylene plastic. Repair clamps are normally stainless steel with rubber gaskets and seating surfaces. Repair sleeves are usually ductile iron with rubber gaskets.

If the portion of the water main to be repaired is large enough, sections of pipe may need to be removed, replaced, and connected with one or two repair clamps/sleeves. If a new bell joint can be used at one end of the repair, only one clamp/sleeve would be needed.

Pipe bedding must be removed below the clamp/sleeve for proper cleaning and preparation of the pipe to receive the repair clamp/sleeve. Once repairs have been made, the repaired section may be pressurized to check for leaks at the joints and repair clamps/sleeves.

After satisfactory testing or observation of the repair under pressure, pipe joints and repair clamps/sleeves need to be properly bedded. After bedding of the entire repair section, the trench is backfilled and compacted, as it would be for new construction. Backfill materials may be excavated soil, granular materials, and flowable fill.

Line Stops

At times, there may not be an adequate number of valves in the existing system to isolate the water main to be repaired. In these instances, it may be necessary to install line stops to complete the repair. A line stop consists of a tee installed on the water main to provide access to install a flexible rubber plug in the water main that acts as a closed valve. Line stops can be installed in a water main while the water main is still pressurized.

The tee is bolted to the water main and a specially constructed valve is installed on the branch of the tee. A cutting tool is inserted through the valve and a circular hole is cut into the existing water main. The cutting tool is retracted, the valve is closed, and the cutting tool is removed. The rubber stopper or plug is inserted through the valve and pushed into the water main, filling the entire pipe with a rubber plug. The line stop acts as a temporary closed valve. Repairs are completed to the water main using normal pipe repair methods, and once the repairs are complete, the plug and valve are removed from the line stop tee. A threaded cap is installed in the tee to close the tee. The tee is backfilled as part of the pipe but can be used again in the future if a temporary closed valve is necessary.

Insertion Valves

At times, there may not be an adequate number of valves in the existing system to isolate the water main to be repaired. In these instances, it may be desirable to insert a permanent valve to allow making the repair and to provide a way to isolate water main sections in the future. The procedures to insert a valve are similar to those for installing a line stop.

An insertion valve body consisting of at least two sections is bolted to the water main and a temporary valve is installed on top of the valve body. All work to cut the wall of the water main and to install the valve gate is done through the temporary valve. A cutting tool is inserted through the valve and a circular hole is cut in the existing water main. The cutting tool is removed and the valve gate and operator are installed in the valve body and water main. The valve body and operator are fastened together and the temporary valve is removed.

The insertion valve and joints are tested for leaks and once accepted, can be bedded and backfilled as new construction of a water main valve.

Freezing and Clamping of Service Pipes

Repair of service pipes can sometimes be completed by freezing or by clamping a service line. Wrapping dry ice around the entire circumference of the pipe usually completes freezing. For freezing to work, there must be no flow through the pipe, so one end of the service line must be plugged or crimped to stop all flow. Once the water in the service pipe is frozen, the plugged/crimped end can be cut off and repairs made.

Clamping a service line is limited to use on polyethylene plastic service pipe. Polyethylene can be completely clamped tight and once the clamp is removed, it rebounds to match its original shape closely.

Testing

As discussed before, testing usually consists of physically observing the repaired section of pipe and any valves and fittings for leaks after pressure is restored to the water main. Any leaks must be repaired to the satisfaction of the water utility or municipal personnel. It is advantageous to have the circumference of all joints exposed so any dripping on the bottom of the pipe can be observed.

Disinfection

Under normal repair conditions, the repaired water main cannot be disinfected by methods used for new construction. Repairs and water in the water main are not usually disinfected after the repair is complete because the water mains usually serve existing customers. Instead, the repair pipe, valves, fittings, line stops, etc., are cleaned and disinfected during repair procedures. Cleaning and disinfecting is done by swabbing the materials with a strong solution of chlorine prior to installation.

After the repair is complete, the water main is usually flushed with a high flow rate of water by opening one or several fire hydrants near the repair section. Many water utilities and municipalities also issue a “boil order” to have customers boil their water for 1 or 2 days following a water main repair.

Public Notification

Customers affected by reduced pressure or a water main shutdown should be notified of the repairs being made and precautions to take once water service is restored. "Boil orders" are often used to protect public health and welfare. Boil orders are issued by personal contact, door-to-door notice, daily newspaper articles, and radio/television notice. The water utility or municipality normally takes responsibility to notify its customers of repairs and precautions.

WATER HAMMER: QUANTITATIVE CAUSES AND EFFECTS

Rathnavel Ponnuswami
Care2
Redwood City, California

Water hammer is a hydraulic phenomenon that has to be considered for the safe design of water-carrying pipes. It is basically a pressure fluctuation that would result in disturbing noises and, more importantly, rupture of pipes and fittings (1,2).

DEFINITION

Water hammer can be defined as a transitory increase in pressure in a water system when there is a sudden change of direction or velocity of the water. Water hammer may also be known by names like shockwave effect or hydraulic shock.

If the velocity of water flowing in a pipe is suddenly checked, the energy given up by the water will be utilized in compressing the water itself. This pressure energy is transferred to the pipe wall and this leads to the setup of shock waves in the system. These shock waves travel backward (with a speed similar to the speed of sound), until encountering a solid obstacle (the valve), and crash into the obstacle back and forth repeatedly. This repeated crashing produces an undesirable sound and may lead to rupture of valves and pipes.

The concept of water hammer is normally explained by drawing an analogy to the movement of a train. Assume a real train, instead of slowing to a stop, hits into a mountainside. The back of the train continues forward even though the front cannot go anywhere. Similarly, the hammer occurs because an entire train of water is being stopped so fast that the end of the train hits up against the front end and sends shock waves through the pipe.

EFFECTS OF WATER HAMMER

Water hammer cannot be ignored as another hydraulic effort in water conveyance, as it poses undesirable effects during water conveyance. The major effects of water hammer are the following:

1. Water hammer will cause disturbing noises that tend to be highly problematic in houses and industrial areas.
2. Water hammer may account for the malfunctioning of pipe appurtenances like pressure relief valves, mud valves, backflow preventers, or stop valves.
3. Water hammer may also lead to rupture of the pipes and connected fittings.
4. Water hammer may at times lead to minor flow losses.

CAUSES OF WATER HAMMER

The problem of water hammer can be encountered in varied places like houses, irrigation systems, domestic water supply, and industries. The causes for water hammer (i.e., causes for sudden change in flow velocity/direction) are varied, yet they can be grouped under five major cases:

- Rapid opening or closing of control valves.
- Starting and stopping of pumps.
- Recombination of water after water column separation.
- Rapid exhaustion of all air from the system.
- Power failure in water pumping system.

COMPUTATION OF WATER HAMMER

The pressure rise caused by the water hammer should be quantified to understand its impact and to sort out remedial measures. The rise in pressure due to water hammer can be attributed to pipe velocity, pipe diameter, and pressure wave travel in the pipe. The maximum pressure caused by water hammer can be obtained by the expression

$$H_{\max} = a \times V_n/g$$

where $H_{\max}$ is the maximum pressure rise due to water hammer, V_n refers to the velocity of flow in the pipe, g refers to the acceleration due to gravity, and a is the velocity of pressure wave travel, which in turn can be obtained by the expression

$$a = 1425/(1 + kd/EC)^{1/2}$$

where k is the bulk modulus of water, d is pipe diameter, C is wall thickness of the pipe in meters, and E is the modulus of elasticity of the pipe material.

The pressure exerted due to water hammer is taken into consideration for the structural design of pipelines for public water supplies. In case of unavailability of data and as a rule of thumb, Table 1 presents the extra pressures taken depending on pipe size.

Table 1. Water Hammer Pressure for Different Pipe Diameters

Diameter of pipe, mm	<250	300	400	500	600	750	>750
Water hammer pressure, kg/cm^2	8.50	7.75	7.00	6.30	5.75	5.60	4.90

Today there are a lot of computational facilities also available for the quantification of water hammer pressure.

CONTROL OF WATER HAMMER

As a hydraulic effect, water hammer is undesirable but inevitable. However, there are a lot of techniques to minimize the pressure rise due to the water hammer, which need to be exercised for proper flow profile.

1. The best and simplest technique would be to close or open the valves slowly. Even the first 80% of the valve travel may be executed conveniently, but the last 20% should be done at a snail's pace to avoid problems. The usage of flywheels for this purpose is advisable, and automatically controlled valves with slow closing are desirable.
2. The provision of check valves, surge relief valves, and similar instruments may help in reducing the water hammer. Today, specialized water hammer arrestors are commercially available for this purpose. Apart from these surge-absorbing water hammer arrestors, pressure regulation devices can also be used. An example is a pressure snubber, a device for slowing the rate of change of system flow that will protect from water hammer damage if installed (using a proper size) near the input of a pressure sensor.
3. The pumps are also a matter of concern. Pump startup problems can usually be avoided by increasing the flow slowly to collapse or flush out the voids gently. Also, an uninterrupted power supply for pumps would prevent water hammer. The above arrangements may also contribute to lower horsepower and maximum operating efficiency.
4. Great care should be taken to incorporate the pressure rise due to water hammer during the structural design of pipelines.

There has not been much study about the phenomenon of water hammer and its significance in the design and performance aspects of a water system, but the current scientific forum is coming up with better descriptions.

CONSTRUCTED WETLANDS

Guenter Langergraber
BOKU—University of Natural
Resources and Applied Life
Sciences
Vienna, Austria

The term constructed wetlands describes artificial wetlands designed to improve water quality. A constructed wetland is a complex mixture of water, substrate, plants, litter (fallen plant material), and a variety of microorganisms (most importantly, bacteria). The mechanisms for improving water quality include settling of suspended particulate matter; filtration and chemical precipitation; chemical transformation; adsorption and ion exchange on surfaces of plants, substrate, and litter; breakdown, transformation, and uptake of pollutants and nutrients by microorganisms and plants; and predation and natural die-off of pathogens.

Constructed wetlands provide the optimal treatment conditions found in natural wetlands but have the flexibility of being constructed. For optimal support of the treatment mechanisms, various types of constructed wetlands optimized for different applications are used. Free-water-surface constructed wetlands and subsurface-flow constructed wetlands are the main types of constructed wetlands. The applications include treatment of domestic, industrial, and agricultural wastewaters, storm water, and landfill leachate.

Wetland treatment systems are effective in treating organic matter, nitrogen, phosphorus, and additionally for decreasing the concentrations of heavy metals, organic chemicals, and pathogens. A good pre-treatment for suspended solids is essential for long-term operation.

MECHANISMS FOR WATER QUALITY IMPROVEMENT

Organic Matter

Treatment wetlands receive large external supplies of carbon. Degradable carbon compounds are utilized in wetland processes. At the same time, degradation processes produce biodegradable carbon compounds. Microorganisms use degradable organic matter as a substrate for respiration and growth.

In general, wetlands are efficient in reducing organic matter. Organic matter exists in particulate and dissolved form at the influent of constructed wetlands. The concentration of organic compounds is often reduced to the background level at the effluent.

In aerobic zones where dissolved oxygen is available, organic matter is decomposed by respiration of heterotrophic organisms that produce carbon dioxide (CO_2) and water. Under anoxic conditions (no dissolved molecular oxygen is available), nitrate is used as an electron acceptor and is reduced to dinitrogen (denitrification). In anaerobic zones (neither molecular nor bound oxygen is available), degradation of organic matter is a multistep process in which CO_2 and methane (CH_4) are produced. Under anaerobic conditions, organic matter can also be reduced by sulfate and iron. However, these pathways play a minor role in subsurface-flow constructed wetlands.

Particulate matter in subsurface-flow wetlands has a large impact on the porous substrate. Particles settle into the pores, and the settled matter is degraded as described before. If the decomposition rate of the particulates is less than the settling rate, the pore volume is reduced, and this causes clogging. The potential for clogging is higher near the inlet of subsurface-flow systems. To prevent clogging, only pre-treated wastewater can be used in combination with subsurface-flow constructed wetlands.

Nitrogen

Nitrogen compounds are among the most important constituents of wastewater due to their role in eutrophication, their effect on the oxygen content of receiving waters, and their toxicity to aquatic organisms and animals. The most important inorganic forms of nitrogen in wetlands are ammonia (NH_4^+), nitrite (NO_2^-), nitrate (NO_3^-), and dissolved elemental nitrogen or dinitrogen gas (N_2). Nitrogen is also present in many organic forms, including urea, amino acids, amines, purines, and pyrimidines. Organic nitrogen compounds are also a fraction of the dry weight of plants, microorganisms, detritus, and soils.

The various forms of nitrogen are continually involved in biochemical transformations. The major processes involved in the nitrogen cycle are ammonification, nitrification, denitrification, nitrogen fixation, nitrogen assimilation, and ammonia volatilization (Fig. 1).

Ammonification. Ammonification is the transformation of organic nitrogen to ammonia. This process occurs during the breakdown of organic matter. The rate of ammonification is directly related to the rate of degradation of organic matter.

Nitrification. Nitrification is the process of oxidizing ammonia to nitrate. The oxidation is done by autotrophic bacteria, which are entirely dependent on generating energy from nitrification. Nitrification is strictly an aerobic process (the presence of oxygen is indispensable) and takes place in two steps. *Nitrosomonas sp.* are responsible for the first step of nitrification: ammonia is oxidized, and nitrite is produced. The nitrite produced is further oxidized to nitrate by *Nitrobacter sp*. Due to the high oxygen demand of the nitrification process (4.57 g oxygen are required for 1 g of ammonia nitrogen), the elimination of ammonia nitrogen is one of the major requirements of wastewater treatment to guarantee a sufficient oxygen concentration in receivers.

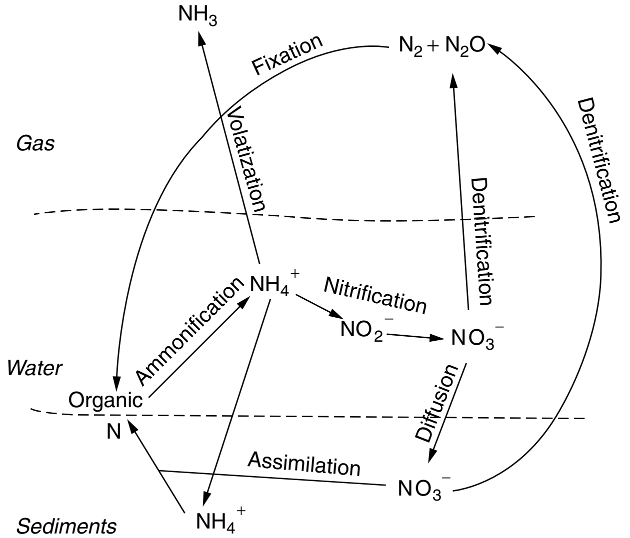

Figure 1. Simplified wetland nitrogen cycle.

Denitrification. Under anoxic conditions and if easily biodegradable organic matter is present, heterotrophic bacteria reduce nitrate to molecular dinitrogen by denitrification. Besides dinitrogen, small amounts of nitrous oxide (N_2O) and nitric oxide (NO) are produced. These dissolved gases are released to the atmosphere, and this reduces the total nitrogen content of treated water. Denitrification and nitrification occur simultaneously in soils where both aerobic and anoxic zones exist nearby. The lack of carbon in the anoxic zones where nitrate is available is the limiting factor for denitrification in wetlands.

Nitrogen Assimilation. Nitrogen assimilation refers to a variety of biological processes that convert inorganic nitrogen into organic compounds. Ammonia uptake is more favored by wetland plants and bacteria than nitrate uptake. In general, the amount of nitrogen taken up by plants and incorporated into the bacterial biomass is small compared to the nitrogen influent load of constructed wetlands for wastewater teatment.

Other Processes. Bacteria, blue-green algae, and plants can fix nitrogen. Nitrogen gas in the atmosphere diffuses into solution and is reduced to ammonia. However, this is generally not observed in constructed wetlands because fixation is more effective in nitrogen-poor environments.

Un-ionized ammonia (NH_3) is relatively volatile, so it can be removed from solution to the atmosphere via diffusion. Usually less than 1% of the total ammonia is present in un-ionized form.

Ammonium can be adsorbed onto active sites of a soil matrix. Only intermittent loading of a system will show rapid removal of ammonia by adsorption due to depletion of ammonia on the adsorption sites during resting periods.

Phosphorus

Phosphorus is typically present in wastewater as orthophosphate and organic phosphate. Phosphorus is released during the degradation of organic matter. Orthophosphate is incorporated into the biomass of organisms during growth. Phosphorus removal in wetland treatment systems occurs by adsorption, plant uptake, complexation, and precipitation.

Plant uptake is not a suitable measure of the net removal rate in a wetland because most of the stored phosphorus is returned to the water by decomposition processes. Due to the limited sorption sites in the soil matrix, phosphorus removal via adsorption is time dependent. After a phosphorus removal rate of almost 100% at the start-up of the operation of the constructed wetland, the removal rate becomes very low, once all sorption sites are filled. During times of low phosphorus influent concentration, also a release of phosphorus can be observed.

Other Substances

Besides the main constituents of wastewater, organic matter, nitrogen, and phosphorus, other pollutants such as heavy metals, specific organic compounds, and pathogens can be removed from water using constructed wetlands.

Heavy Metals. Wetlands interact strongly with heavy metals in a number of ways and thus are capable of significant metal removal. The three major mechanisms are

- binding to soil, sediments, particulates, and soluble organic matter;
- precipitation as insoluble salts, principally sulfides and oxyhydroxides; and
- uptake by plants and bacteria.

A criterion for heavy metal removal is the contact time between dissolved metals and the soil matrix. The longer the contact time, the more exchange processes occur. A particularly significant effect can be observed on the adsorbed metal concentration in the rhizosphere by using different plant species. The plant organisms can, however, become stressed at high heavy metal concentrations, so that the treatment is more appropriate to low metal influent levels. Harvesting the plants used for metal removal then provides a means to prevent metals cycling in the wetland ecosystem and a sustainable means of disposal, if the harvested plants are then appropriately dealt with. Experimental evidence has shown that heavy metal concentrations are highest in the plant roots, followed by the stems, and then the leaves, so that the whole plants must be harvested, not just the foliage.

Specific Organic Compounds. Many constructed wetlands deal with domestic wastewater where BOD and DOC are used as a sum parameter for organic matter. However, other special organic compounds can be removed by using constructed wetlands. Experience exists with waters containing surfactants, solvents, mineral oils, and pesticides. Some specific compounds that were successfully treated by constructed wetlands are, for example, MTBE, trichloroethane, BTEX, cyanide, and explosives (e.g., TNT). Major removal mechanisms are volatilization, photochemical oxidation, sedimentation, sorption, and microbial degradation by fermentation or aerobic and anaerobic respiration. Bioaugmentation of the sediment and sorption by macrophytes is particularly important. In general, there is a lack of knowledge on the detailed removal pathways for organic compounds.

Pathogens and Parasites. Human pathogens are typically present in untreated wastewater. Their populations are highly variable and depend on the health of the human population contributing to the waste. Typical pathogen populations in wastewater include viruses, bacteria, fungi, and protozoa. Parasites such as helminth worms are also common.

Natural treatment technologies can reduce populations of human pathogens by filtration, natural die-off rates, and hostile environmental conditions. Constructed wetlands reduce pathogen populations at varying but significant degrees of effectiveness. The elimination efficiency varies with macrophyte type and increases with the retention time of the wetland.

The Role of Plants

Macrophytes growing in constructed wetlands have several properties in relation to the treatment process. This makes plants an essential part of the design of constructed wetlands.

The most important effects of the macrophytes ragarding the treatment process are physical effects. The roots provide surface area for attached microorganisms, and root growth maintains the hydraulic properties of the substrate. The vegetation cover protects the surface from erosion, and shading prevents algae growth. Litter provides an insulating layer on the wetland surface (especially for operation during winter).

As far as is known, the effect of plant uptake plays a minor role in common wastewater parameters compared to the degradation by microorganisms. For other pollutants such as heavy metals and special organic compounds, the selection of different plant species can, however, play a major role in enhancing treatment efficiency. Both plant productivity and pollutant removal efficiency are relevant in finding an appropriate plant for a given application.

If the wetland is not harvested, the substances incorporated in the plant will be returned to the system during decomposition of the plants. When dead plants are degraded, the organic constituents can act as an additional carbon source for denitrification. Some plants also release organic compounds from their roots, which can also be used for denitrification.

Oxygen release from roots into the rhizosphere is well documented but *in situ* release rates, still are a matter of controversy. Compared to the amount of oxygen brought into the system from the atmosphere via convection and diffusion, the release of oxygen from plant roots can be neglected.

Plants also have other functions not directly related to the treatment process. They provide a habitat for wildlife (including birds and reptiles in large systems) and give the treatment system a more aesthetic appearance.

TYPES OF CONSTRUCTED WETLANDS

Surface-Flow Constructed Wetlands

Surface-flow (SF) or free-water-surface (FWS) wetland technology is strongly related to natural wetlands. Wetlands have been used for wastewater discharge for as long as sewage has been collected. When monitoring was initiated at some of the discharges, an awareness of the water purification potential of wetlands began to emerge. The ‘technology’ started in the 1970s in North America with ecological engineering of natural wetlands for wastewater treatment.

In surface-flow wetlands (Fig. 2), water flows over the soil surface from an inlet to an outlet point. Inflow water containing particulate and dissolved pollutants slows down and spreads through the area of shallow water. The main removal mechanism for particulates is settling. Particulates contain organic matter and enter the biogeochemical cycle in the water column and wetland soil surface. Dissolved pollutants are sorbed by plants, soil, and active microbial populations throughout the wetland and then also enter the overall mineral cycles of the wetland ecosystem. The amount of sorption processes is related to the area where these processes can take place. Due to

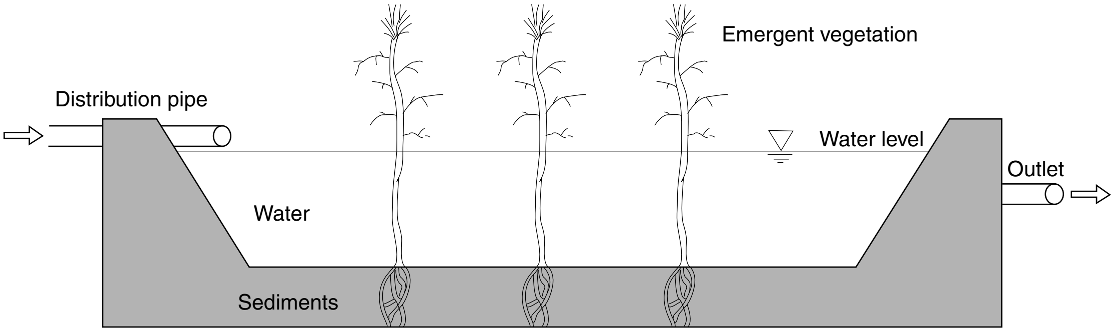

Figure 2. Surface-flow wetland containing emergent macrophytes.

the small surface area of the wetland soil, surface-flow constructed wetlands require a large area to reach good elimination rates of dissolved pollutants.

Surface-flow constructed wetlands can be classified by the plants that are used. Most treatment wetlands use emergent macrophytes (e.g., common reed—*Phragmites australis*), plants whose parts extend above the wetland waters (Fig. 2). Other types use free-floating macrophytes (e.g., water hyacinth—*Eichornia crassipes*), floating-leaved, bottom-rooted macrophytes (rooted in the soil, but their leaves float on the water surface, e.g., water lilies—*Nymphea* spp.), submersed macrophytes (plants that are buoyant and suspended in the water column), or floating mats (some emergent macrophytes can form floating mats, e.g., cattails—*Typha* spp. and common reed—*Phragmites australis*).

Summarizing, one can say that the main disadvantages of free-water-flow constructed wetlands are that they require a large area, they may freeze in temperate climates, and they provide a breeding ground for mosquitoes.

Subsurface-Flow Constructed Wetlands

Subsurface-flow (SSF) constructed wetlands can be subdivided into horizontal flow (HF) and vertical flow (VF) systems depending on the direction of water flow through the porous medium (soil or gravel). The use of subsurface-flow constructed wetlands is limited to pre-treated water, which contains only a low particulate content. Compared to surface-flow systems, the contact area of water with bacteria and substrate is much larger. This enhances the process rates of the system and therefore decreases the area requirement of the treatment system. Pathogen reductions for SSF compared with SWF for similarly sized and managed systems are higher. Subsurface-flow constructed wetlands are frequently planted with common reed (*Phragmites australis*). Therefore a common term is a reed bed treatment system. Other emergent plants like cattails (*Typha* spp.) and bulrushes (*Scirpus* spp.) are also used.

Horizontal-Flow Constructed Wetlands. In a horizontal-flow constructed wetland (Fig. 3), water is fed in at the inlet and flows slowly under the surface through the porous media until it reaches the outlet zone, where it is collected and discharged. Despite regular topography and homogenous plant growth, obtaining an ideal flow is not guaranteed, so that tracer studies are advisable to ensure good hydraulic design. During the passage through the system, water comes in contact with a network of aerobic, anoxic, and anaerobic zones in the substrate. Aerobic zones occur in the upper parts of the water table, anaerobic conditions at the bottom of the wetland.

Oxygen required for aerobic processes is supplied mainly from the atmosphere via diffusion. The oxygen transport from the roots into zones under the water table is too weak to facilitate aerobic processes. Therefore, anoxic and anaerobic processes play an important role in horizontal-flow constructed wetlands. Organic matter is decomposed aerobically and anaerobically and is, therefore, removed well. Due to the poor oxygen supply, only incomplete nitrification can take place.

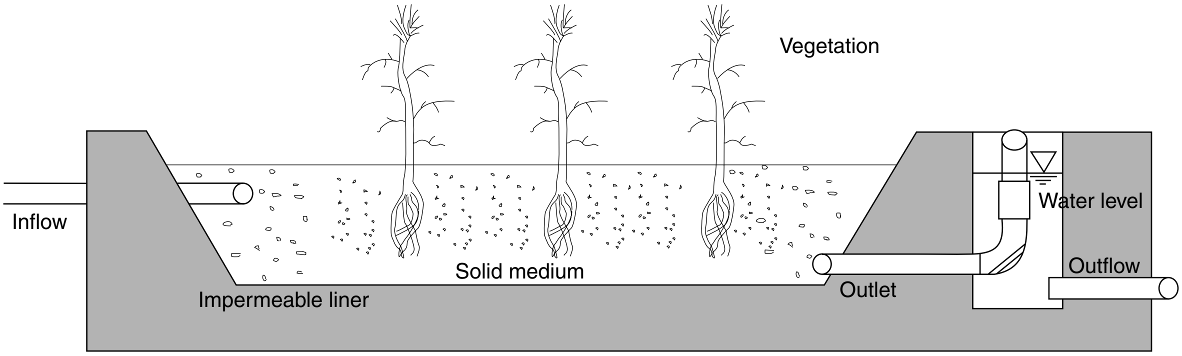

Figure 3. Longitudinal cross section of a horizontal subsurface-flow constructed wetland.

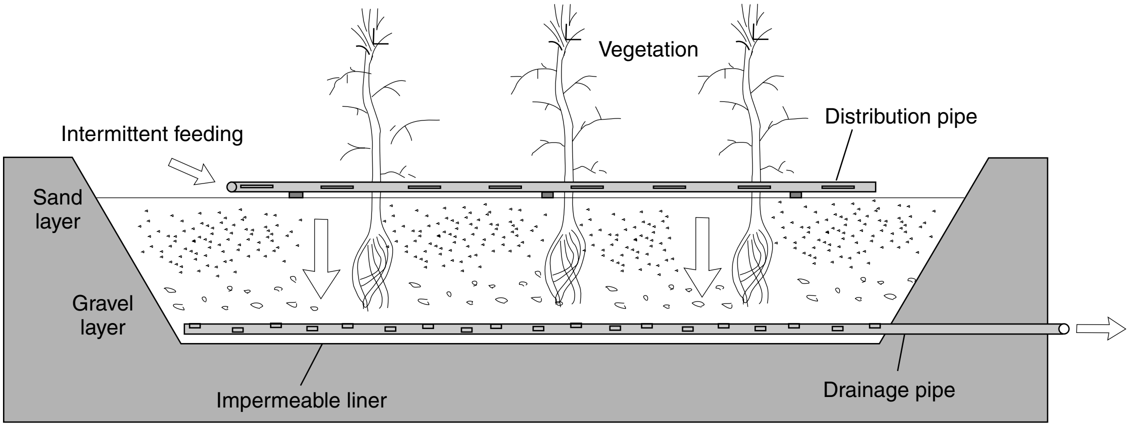

Figure 4. Typical construction of a vertical-flow constructed wetland.

Vertical-Flow Constructed Wetlands. Vertical-flow constructed wetlands look like the system shown in Fig. 4. Water is fed to the system intermittently. The large amount of water from a single feeding causes flooding of the surface. The water infiltrates into the substrate, then gradually drains down vertically, and is collected by a drainage network at the base. Until the next loading, oxygen re-enters the system, and good oxygen transfer into the system is possible. Vertical-flow constructed wetlands are, therefore, suitable when nitrification and other strictly aerobic processes are important factors in the treatment process. When high ammonia nitrogen elimination is required, only vertical-flow constructed wetlands intermittent loading can be used.

APPLICATION OF CONSTRUCTED WETLANDS

The applications of constructed wetlands for water treatment are widespread and include treatment of domestic wastewater, stormwater management in urban areas, treatment of surface water and industrial wastewater, including special wastewater (e.g., from hospitals), and sludge consolidation. Some of these of are discussed more fully here.

Domestic Wastewater. Constructed wetlands for domestic wastewater treatment are generally applied as a main or tertiary treatment stage. For use as a main treatment stage, only subsurface-flow constructed wetlands are used. For tertiary treatment, both surface and subsurface-flow constructed wetland are widely used.

As a main treatment stage, either horizontal-flow or vertical-flow constructed wetlands can be used, depending on the effluent quality desired. Good pre-treatment is necessary to reduce the loading of suspended solids. If low ammonia effluent concentrations are required, only vertical-flow constructed wetlands with intermittent loading fed can guarantee good nitrification. To improve denitrification rates, combined systems with horizontal and vertical types of SSF constructed wetlands can be used.

Sufficient oxygen supply is the main factor for good performance of vertical-flow constructed wetlands. Design recommendations can be based on calculations of oxygen demand and oxygen supply. Considerations of long-term operation of vertical-flow constructed wetlands should, in particular, consider pore size reduction from influent inorganic suspended solids.

Agricultural Wastewater and Food Wastes. Constructed wetlands were used to treat agricultural wastewater from farms with animal production. Crop runoff and pesticides such as atrazine have also been effectively treated Food processing wastes usually have high organic loads that are easily biodegradable. Constructed wetlands have been used to treat potato processing water, olive oil mill water, and dairy wastewater.

Industrial Wastewater. Constructed wetlands can be used to treat several kinds of industrial wastewater: coal and metal mining water, oil extraction, refinery effluents, oil-sand processing water, and wastewater produced by the pulp and paper industries. Many organic and heavy metal wastes have been effectively retained or removed. Constructed wetland technology was also successfully applied to treat hospital wastewater.

Landfill Leachate. Landfills generate highly pollutant leachates as they decompose anaerobically over many years. Constructed wetlands are used for leachate treatment due to their long-term sustainable treatment and low operating and maintenance costs. The retention capacity of wetlands can also be sufficient to prevent contamination of downstream water sources in a heavily contaminated area.

Stormwater and Runoff Management. Uncontrolled urban stormwater has been identified as a major contributor to the nonpoint source pollution of surface waters. Small amounts of rainwater often carry large amounts of pollutants. Three approaches are used to control urban stormwater using constructed wetlands: dry and wet detention ponds (where the ponds remain dry or wet between floods) and stormwater wetlands. Detention ponds collect stormwater and release it during dry weather. The main removal mechanism is settling.

Surface Water. Heavily polluted surface water can also be treated using constructed wetland technology. The treated water can be used, for example, for groundwater recharge and for restoring contaminated surface waters. However, it is not possible to produce an effluent quality that allows direct use as drinking water.

SUMMARY

Constructed wetlands are artificial wetlands designed to improve water quality. They provide the optimal treatment conditions found in natural wetlands but have the flexibility of being constructed. Wetland treatment systems are effective in treating organic matter, nitrogen, phosphorus, and additionally for decreasing the concentrations of heavy metals, organic chemicals, and pathogens. Various types of constructed wetlands optimized for different applications are used for optimal support of the treatment mechanisms. The main types are free-water-surface constructed wetlands and subsurface-flow constructed wetlands with horizontal or vertical flow.

In general, the use of constructed wetlands provides a relatively simple, inexpensive, and robust solution for treating water. Compared to other treatment options, constructed wetlands usually need less operation and maintenance. Additional benefits include their tolerance to fluctuations in flow, the facility of water reuse and recycling, the provision of habitat for many wetland organisms, and the more aesthetic appearance of a natural system compared with technical treatment options.

USING ECOSYSTEM PROCESSES IN A CONSTRUCTED WETLAND TO TREAT MINE WASTEWATER IN IRELAND

Aisling D. O'Sullivan
Marinus L. Otte
University College Dublin
Belfield, Ireland

WASTEWATER GENERATION

The development and expansion of industrial and agricultural activities in the Western world has led to a corresponding increase in the release of potentially toxic chemicals into the environment. Although growth has had many socioeconomic benefits, it has also led to negative implications for wetland ecosystems. For instance, the intensive farming practices developed in Ireland in the 1970s led to eutrophic (overenriched) rivers and lakes as a result of inadvertent inputs of excess nitrogen and phosphorus. This resulted in algal blooms, subsequent fish mortality, and reduced biodiversity of aquatic systems. The breaching of tailings dam walls in mine storage ponds has also resulted in catastrophic impacts on neighboring watersheds, which in many circumstances has led to irreversible ecosystem damage. Therefore, a balance is sought between reducing undesirable impacts while facilitating positive economic progress. By understanding the complex processes that affect the biogeochemistry and cycling of contaminants in aquatic ecosystems, innovative treatment technologies can be applied to mitigate and treat these wastes.

During metal mining, the oxidation of ores frequently results in increased reactivity and bioavailability and possibly toxicity of heavy metals (1). Many contaminants such as heavy metals and radionuclides cannot be chemically degraded, but microbial deactivation (mainly through immobilization) is most suitable for the treatment of these types of wastes (2). Other pollutants that prove difficult to dispose of are polychlorinated biphenyls (PCBs) which were used liberally as additives in the manufacture of paints and plastics until their toxicity was realized in the mid-1960s. PCBs have very high chemical, thermal, and biological stability; these properties resulted in their bioaccumulation in sediments and biota. Excess plant nutrients such as nitrogen and phosphorus are typically easier to treat in waters because they can be easily assimilated by plants and algae.

CURRENT TREATMENT PRACTICES AND ALTERNATIVE OPTIONS

Conventional practices for treating wastewater in Ireland adopt predominantly chemical applications that require high energy demands. These traditional technologies typically include the chemical manipulation of contaminants and subsequent physical precipitation of suspended solids in the water. Other means of treating wastewater contaminated with biodegradable organic wastes have proven very successful in the past few decades as wastes are biologically converted into gaseous and solid forms. Treatment practices relying on biological processes include continuous activated sludge reactors, which operate either aerobically or anaerobically. In suspended reactor vessels, microorganisms are kept in suspension in the wastewater, whereas in attached systems, microbial masses adhere typically to an inert medium. Various modifications of the aerobic treatment processes have been developed, including stabilization ponds, aerated waste reservoirs, and rotation and filtration techniques (3). These treatment techniques rely principally on activated processes, that is, they require substantial energy inputs and risk failure without continuous energy inputs.

Nonactivated biological processes employed to degrade contaminants are a more recent practice in wastewater treatment. Worldwide, particularly in North America and Australia, emerging practices for treating wastewater include constructed wetlands. These systems operate by using natural processes and usually do not require substantial energy inputs. The biological processes are typically solar-driven and use carbon and nutrients in the substrate to drive the microbial and plant processes. Therefore, constructed wetlands can be economical and ecologically acceptable. Typically, constructed wetlands are designed specifically for the type of wastewater being treated. Nutrients can be removed in aerobic systems, and sulfates and metals can be removed from wastewater under chemically reducing conditions. Wastewater contaminated by metals has usually been treated primarily to reduce acidity, but some treatment options for this type of waste have shown that substantial metals can be removed concurrently (4).

THE TARA MINES CASE STUDY

Tara Mines Ireland, a subsidiary of the Finnish company Outokumpu-Zinc, is the largest producer of zinc in Europe and the fifth largest lead-zinc mine worldwide. They have been operating since 1977 and supply approximately 20% of the European demand for zinc (5). The local bedrock from which the ore is extracted is classified as Lower Carboniferous calcite ($CaCO_3$) and dolomite ($CaMgCO_3$), which buffers the wastewater used in the processing operations to a pH of approximately 7.8 (5). Spent water is pumped to large storage ponds for treatment at a site about 5 km from the ore extraction site. Some of this wastewater is fed to the experimental treatment wetlands described here.

Treatment wetlands were engineered on-site at Tara Mines in 1997. These wetlands, built specifically to treat sulfate and metal-enriched wastewater emanating from the mine, are the only treatment wetlands of this kind in Europe at this time. Most applications employing microbes to reduce levels of contaminants in wastewater have focused on metal removal (6); the research at Tara Mines was concerned primarily with removing sulfate from the alkaline mine water.

Construction Design at Tara Mines Wetlands

Two similar experimental treatment systems were built adjacent to large tailings ponds. Each system measured 12 m (length) × 3 m (width) × 2 m (depth) or 72 m^3 with a 4:1 (length to width) aspect ratio (7) and comprised three 12 m^2 in-series surface-flow cells: inflow, wetland, and outflow (see Fig. 1 for details). Both systems were lined with a 2000 gauge (light-insensitive) impermeable PVC sheet, and each wetland cell was planted with cattails (*Typha latifolia*), reed (*Phragmites australis*), and floating sweetgrass (*Glyceria fluitans*) in the ratio of 4:9:7 per m^2. Three wooden baffles coated with an industrial-grade waterproof varnish were also placed in each wetland cell to increase the length of the flow path of the water. Mesocosm experiments indicated that an optimal combination of plant growth and substrate permeability was achieved by using a medium containing spent mushroom substrate and fine grit in a 1:3 ratio by volume of. Each cell was filled with a similar mix of this substrate to a depth of about 50 cm (Fig. 1).

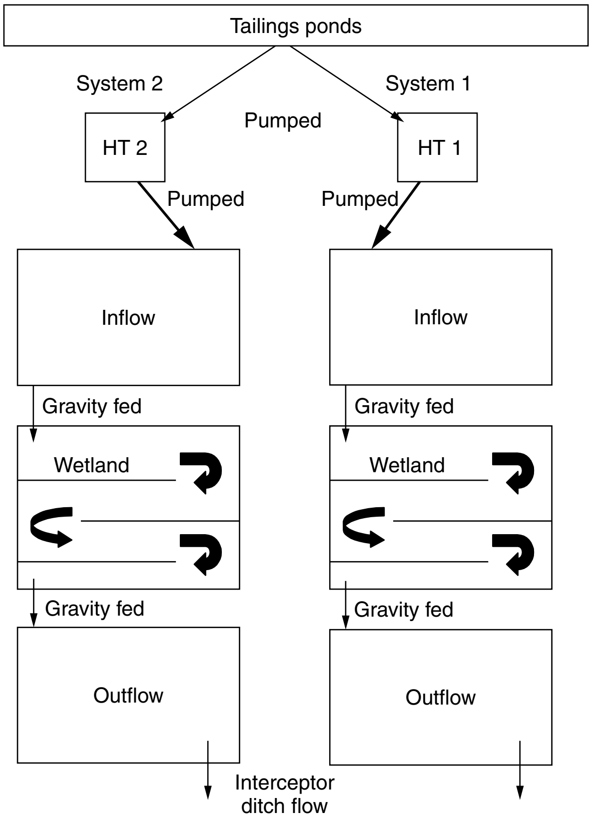

Figure 1. Schematic representation of the experimental treatment wetlands at Tara Mines, Ireland. Arrows indicate the flow path of the water, which was pumped from the storage ponds to the header tanks (HT 1 and HT 2) and subsequently to the inflow cells of each system. From there on, water traveling between cells was gravity fed (by head differences between cells) to the wetland cells and then finally to the outflow cells.

BIOGEOCHEMISTRY—THE KEY TO REMEDIATION

Wetland plants can remove pollutants from contaminated soils and water through uptake, translocation, and compartmentalization in storage tissues (2,8). However, the more significant influence of plants on metal removal from wastewater is indirect by accumulation of metals in the sediments surrounding the roots (8,9). Sufficient organic matter, provided by seasonal plant dieback, is also important in treatment systems that operate on natural biological processes. The accumulation of these contaminants is governed by microbial reactions mediated in suitable substrates and under appropriate conditions. For instance, the substrates used in the treatment wetlands at Tara Mines contained indigenous populations of sulfate-reducing bacteria, identified as the genera *Desulfovibrio, Desulfobulbus, Desulfotomaculum*, and *Desulfoccus*. The systems were permanently flooded and this provided net anaerobic substrate conditions conducive to the chemical reduction of sulfate (SO_4^{2-}) to sulfide (S^{2-}). This reaction occurred as the microorganisms assimilated sulfate in the absence of oxygen, thus reducing it to sulfide through the transfer of electrons produced by the simultaneous oxidation of the organic substrate. Sulfide anions resulting from the reaction are very unstable and readily react with free or sorbed metal cations to form metal sulfides such as zinc sulfide (ZnS), lead sulfide (PbS), and iron sulfide (FeS) (10). However, sulfide can also react with hydrogen to form hydrogen sulfide. Once the overlying water became saturated with hydrogen sulfide, it evolved to the atmosphere as a gas. Although evolution of this gas has not yet been quantified, it appears that substantial amounts were produced in the Tara Mines treatment wetlands, as evident from the frequent detection (olfactory). This may be a concern in the application of a larger scale treatment wetland and has not yet been fully addressed. Nonetheless, in the Tara Mines case study, the capacity to treat metal and sulfate contaminated wastewater using natural ecosystem processes was successfully demonstrated.

SUCCESS STORY—IN MANY WAYS

Treatment Capacity

The experimental treatment wetlands were modeled on the surface-flow design previously established in North America. Effectively, treatment occurred through bioimmobilization of the contaminants in the water as substrate, vegetation, and microbial assemblages interacted at the sediment–water interface. Although sulfate concentrations exiting the treatment systems did not comply with acceptable discharge levels (of 200 mg L^{-1}) stipulated in national legislation, up to 69% of the influent concentration (900 mg L^{-1}) was removed, and this equaled a removal rate of 29 g m^{-2} day^{-1}. Similarly, zinc and lead were removed by up to 99% and 64%, respectively, of the original concentrations supplied of 1.8 mg Zn L^{-1} and 0.2 mg Pb L^{-1}. Concentrations of these metals and of sulfides in the sediments were significantly greater than those in the original substrates, and concentrations in the soil water were also elevated compared to background water levels. Plants contained less than 1% of sulfur in their tissues, in accordance with other studies. Vegetation (including algae that voluntarily colonized the systems) sequestered metals to some extent, but plant roots had almost double the concentration of metals, compared to plant shoots. This may be explained by selective uptake and translocation mechanisms exhibited by some plants that can prevent contaminants from traveling to their shoots. The effect may also be explained by metal hydroxides that can form on plant roots (11). These hydroxides form when localized oxygenation by wetland plant roots and rhizomes induce precipitation of metals. Once metals are precipitated from solution, they become relatively immobile and thus generally less available to living organisms. The vegetation was not harvested from the treatment wetlands, so metals in these tissues were not actually removed from the systems because plant uptake and decay result in cycling of metals within such ecosystems. The most important attributes for ensuring long-term success and sustainability of constructed wetlands that treat these kinds of wastes appear to be wetland size and chemical loading rates. Therefore, these considerations must be clearly evaluated before constructing treatment wetlands.

Ecological and Societal Benefits

Wetlands are recognized for their hydrologic, economic, ecological, and aesthetic values. Natural, restored, and constructed wetlands have become the focus of many scientists in recent years for their capacity to treat wastewater in an ecologically and economically cost-effective way (12). The ecological benefits provided by the Tara Mines treatment wetlands were diverse and innumerable. Soon after they were constructed, macroinvertebrates (35 taxa), plants (6 species), algae, and microorganisms voluntarily colonized the systems. The vegetation afforded refuge to birds (e.g., moorhen) and other wildlife (foxes, rabbits, shrews, etc.), and also provided niches for microbial and invertebrate communities.

It is obvious that surface-flow wetlands offer many ancillary benefits by creating new habitats for wildlife. Initiatives to develop treatment wetlands have frequently involved local communities and educational establishments, thereby integrating educational principles into their goals. Aspects of the study at Tara Mines have been delivered to a wide spectrum of society from high-school teenagers in the local community to undergraduate and postgraduate students in universities in Ireland, Europe, and the United States. Additionally, the work has been well received by industries and local interest groups. By involving communities in the construction of wetlands, awareness of the value of such ecosystems and their capacity to recycle wastes by biological and ecologically acceptable techniques is generated.

TREATMENT SUCCESS COMPARED WITH OTHER SYSTEMS

The performance of the Tara Mines treatment wetlands for sulfate and metal removal was compared with that of other studies. Many of the other investigations quantified removal as a percentage of the influent concentration, but mass removal rates represent a more realistic estimate of the actual amount removed (4). In this instance, contaminant removal is calculated from a loading perspective; considers flow rates, concentrations, and wetland size; and expresses removal per unit time. Sulfate removal at Tara Mines was comparable with that published by Eger (13) of up to 27 g m^{-2} day^{-1}. Metal removal (from a percentage perspective) at Tara Mines was usually greater than that of other studies (e.g., Reference 14; removal of 33% Zn and 26% Pb). However, metal levels in the wastewater treated in the other studies were higher than those in the Tara Mines wastewater, and so higher mass removal rates probably occurred in these other studies.

STIMULUS FOR REVISING WASTE MANAGEMENT PRACTICES

In the past 25 years, most treatment wetland studies were concerned with removing plant nutrients from water. In the last decade, this focus has shifted toward remediating mine wastewater, principally to reduce the impact of acid mine drainage (4). However, constructed wetlands built for treating mine waste were primarily developed in North America, and the scope of similar systems in Europe has yet to be demonstrated. However, the question of long-term reliability of treatment wetlands is still not conclusively answered because most systems of this type have operated less than 15 years. Many scientists will advocate that, once they are appropriately designed and managed, they can remain self-renewing for several decades. The development of constructed wetland technology has demonstrated attractive success rates, and incurred limited financial operational costs. They can also provide ancillary ecological benefits. Increasing pressure in preparing for mine closure following ore exhaustion, coupled with societal concerns regarding environmental quality, is pressuring industries to reevaluate conventional treatment practices. Recent Irish and European Union legislation has contributed in some ways toward increasing the awareness of alternative cost-efficient treatment practices allied with sustainable development. By exploiting this newly found awareness, the possibility of implementing some innovative, ecologically sound waste technologies looks promising.

Acknowledgments
The authors acknowledge the financial support of Tara Mines Ireland and Enterprise Ireland for the research project. Dr. Declan Murray is also acknowledged for his involvement in the research project and our colleagues in the Department of Botany (UCD, Ireland) for their assistance in the field while constructing the treatment wetlands.

WATER AND WASTEWATER PROPERTIES AND CHARACTERISTICS

Absar A. Kazmi
Department of Civil
Engineering
Roorkee, Uttaranchal, India

Water in nature is most nearly pure in its evaporative state. Because the very act of condensation usually requires a surface, or nuclei, water may acquire impurities at the very moment of condensation. Additional impurities are added as the liquid travels through the remainder of the hydrologic cycle and comes into contact with materials in the air and on or beneath the surface of the earth. Human activities contribute further impurities in the form of industrial and domestic wastes, agricultural chemicals, and other less obvious contaminants. Ultimately, these impure waters complete the hydrologic cycle and return to the atmosphere as relatively pure water molecules. However, the water quality in the intermediate stage is of greatest concern because the quality at this stage affects human use of water.

The impurities accumulated by water throughout the hydrologic cycle and from human activities may be in both suspended and dissolved form. Suspended material consists of particles larger than molecular size that are supported by buoyant and viscous forces within the water. Dissolved material consists of molecules and ions that are held by the molecular structure of water. Colloids are very small particles that technically are suspended but often exhibit many of the characteristics of dissolved substances.

Water pollution is the presence of impurities in water in such quantity and of such nature as to impair the use of the water for a stated purpose. Many parameters and characteristics have evolved that qualitatively reflect the impact that various impurities have on selected water uses. Knowledge of properties/characteristics/parameters of water and wastewater treatment processes is essential for environmental scientists and engineers.

PHYSICAL WATER QUALITY PARAMETERS

Physical parameters define those characteristics of water that respond to the senses of sight, touch, taste, or smell. Suspended solids, turbidity, color, taste and odor, and temperature fall into this category.

Suspended Solids

Solids can be dispersed in water in both suspended and dissolved forms. Solids suspended in water may consist of inorganic or organic particles or of immiscible liquids. Inorganic solids such as clay, silt, and other soil constituents are common in surface water. Organic materials such as plant fibers and biological solids (algal cells, bacteria, etc.) are also common constituents of surface waters. These materials are often natural contaminants resulting from the erosive action of water flowing over surfaces. Other suspended material may result from human use of water. Domestic wastewater usually contains large quantities of suspended solids that are mostly organic. Industrial use of water may result in a wide variety of organic or inorganic suspended impurities. Immiscible liquids such as oils and greases are often constituents of wastewater.

Suspended material in water may be objectionable for several reasons. It is aesthetically displeasing and provides adsorption sites for chemical and biological agents. Suspended organic solids may be degraded biologically, resulting in objectionable by-products. Biologically active (live) suspended solids may include disease-causing organisms as well as organisms such as toxin-producing strains of algae.

Suspended solids are likely to be organic and/or biological and are an important parameter of wastewater. The suspended solids parameter is used to measure the quality of wastewater influent, to monitor several treatment processes, and to measure the quality of the effluent. The U.S. Environmental Protection Agency (EPA) has set maximum suspended solids at 30 mg/L for most treated wastewater discharges.

Turbidity

Direct measurement of suspended solids is not usually performed on samples from natural bodies of water or on potable (drinkable) water supplies. The nature of the solids in these waters and the secondary effects they produce are more important than the actual quantity. For such waters, a test for turbidity is commonly used. Turbidity is a measure of the extent to which light is either absorbed or scattered by suspended material in water.

Most turbidity in surface waters results from the erosion of colloidal material such as clay, silt, rock fragments, and metal oxides from the soil. Vegetable fibers and microorganisms may also contribute to turbidity. Household and industrial wastewaters may contain a wide variety of turbidity producing material. Soaps, detergents, and emulsifying agents produce stable colloids that result in turbidity. Although turbidity measurements are not commonly run on wastewater, discharges of wastewaters may increase the turbidity of natural waterbodies.

When turbid water in a small, transparent container, such as a drinking glass, is held up to the light, an aesthetically displeasing opaqueness or “milky” coloration is apparent. The colloidal material associated with turbidity provides adsorption sites for chemicals that may be harmful or cause undesirable tastes and odors and for biological organisms that may be harmful. Disinfection of turbid waters is difficult because of the adsorptive characteristics of some colloids and because the solids may partially shield organisms from the disinfectant.

In natural waterbodies, turbidity may impart a brown or other color to water, depending on the light-absorbing properties of the solids, and may interfere with light penetration and photosynthetic reactions in streams and lakes. Accumulation of turbidity-causing particles in porous streambeds results in sediments that can adversely affect the flora and fauna of the stream.

Color

Pure water is colorless, but water in nature is often colored by foreign substances. Water whose color is partly due to suspended matter is said to have apparent color. Color contributed by dissolved solids that remain after removal of suspended solids is known as true color.

After contact with organic debris such as leaves, conifer needles, weeds, or wood, water picks up tannins, humic acid, and humates and takes on yellowish-brown hues. Iron oxides make water reddish, and manganese oxides make water brown or brackish. Industrial wastes from textile and dyeing operations, pulp and paper production, food processing, chemical production, and mining, refining, and slaughterhouse operations may add substantial coloration to water in receiving streams.

Colored water is not aesthetically acceptable to the general public. In fact, given a choice, consumers tend to choose clear, uncolored water of otherwise poorer quality over treated potable water supplies with an objectionable color. Highly colored water is unsuitable for laundering, dyeing, papermaking, beverage manufacturing, dairy production and other food processing, and textile and plastic production. Thus the color of water affects its marketability for both domestic and industrial use.

Color is not a parameter usually included in wastewater analysis. In potable water analysis, the common practice is to measure only the true color produced by organic acid resulting from decaying vegetation in the water. The resulting value can be taken as an indirect measurement of humic substances in the water.

Taste and Odor

The terms taste and odor define this parameter. Because the sensations of taste and smell are closely related and often confused, a wide variety of taste and odors may be attributed to water by consumers. Substances that produce an odor in water almost invariably impart a taste as well. The converse is not true; many mineral substances produce tastes but no odor. Many substances with which water comes into contact in nature or during human use may impart perceptible taste and odor. These include minerals, metals, and salts from the soil, end products from biological reactions, and constituents of wastewater. Inorganic substances are more likely to produce tastes unaccompanied by odor. Alkaline material imparts a bitter taste to water, and metallic salts may give a salty or bitter taste. Organic materials, on the other hand, are likely to produce both taste and odor in water; petroleum based products are prime offenders. The biological decomposition of organics may also result in taste-and odor-producing liquids and gases in water. Consumers find taste and odor aesthetically displeasing for obvious reasons. Because water is thought of as tasteless and odorless, the consumer associates taste and odor with contamination and may prefer to use a tasteless, odorless water that might actually pose more than a problem of simple aesthetics because some of those substances may be carcinogenic.

Temperature

Temperature is not used directly to evaluate either potable water or wastewater. It is, however, one of the most important parameters in natural surface water systems. The temperature of surface waters governs to a large extent the biological species present and their rates of activity. Temperature has an effect on most chemical reactions that occur in natural water systems. Temperature also has a pronounced effect on the solubilities of gases in water. The temperature of natural water systems responds to many factors, ambient temperatures are the most universal.

CHEMICAL WATER QUALITY PARAMETERS

Water has been called the universal solvent, and chemical parameters are related to the solvent capabilities of water. Total dissolved solids, alkalinity, hardness, fluorides, metals, organics, and nutrients are chemical parameters of concern in water quality management.

Total Dissolved Solids (TDS)

The material remaining in water after filtration for a suspended solids analysis is considered dissolved. Dissolved material results from the solvent action of water on solids, liquids, and gases. Like suspended material, dissolved substances may be organic or inorganic. Inorganic substances that may be dissolved in water include minerals, metals, and gases. Water may come in contact with these substances in the atmosphere, on surfaces, and within the soil. Materials from the decay products of vegetation, from organic chemicals, and from organic gases are common dissolved organic constituents of water. Many dissolved substances are undesirable in water. Some dissolved minerals, gases, and organic constituents are carcinogenic.

Because no distinction is made among the constituents, the TDS parameter is included in the analysis of water and wastewater only as a gross measurement of dissolved material. This is often sufficient for wastewaters, but it is frequently desirable to know more about the composition of the solids in water for use in potable supplies, agriculture, and some industrial processes. When this is the case, tests for several of the ionic constituents of TDS are made.

Akalinity

Alkalinity is the quantity of ions in water that will react to neutralize hydrogen ions. Alkalinity is thus a measure of the ability of water to neutralize acids. The constituents of alkalinity in natural water systems include CO_3^{2-}, HCO_3^-, and OH^-. These ions result from the dissolution of mineral substances in the soil and atmosphere. Phosphates may also originate from detergents in wastewater discharges and from fertilizers and insecticides from agricultural land. Hydrogen sulfide and ammonia may be products of the microbial decomposition of organic material. In large quantities, alkalinity imparts a bitter taste to water. The principal objection to alkaline water, however, is the reactions that can occur between alkalinity and certain cations in the water. The resultant precipitates can foul pipes and other water system appurtenances.

Hardness

Hardness is the concentration of multivalent cations in solution. At supersaturation, hardness cations react with anions in the water to form solid precipitates. The multivalent metallic ions most abundant in natural waters are calcium and magnesium, and for all practical purposes, hardness may be represented by the sum of calcium and magnesium ions.

Soap consumption by hard water represents an economic loss to the water user. Sodium soaps react with multivalent cations to form a precipitate, thereby losing their surfactant properties. Lathering does not occur until all the hardness ions are precipitated, at which point the water has been softened by the soap. Boiler scale, the result of the carbonate hardness precipitate, may cause considerable economic loss through fouling of water heaters and hot water pipes. Changes in pH in water distribution systems may also result in deposits of precipitates. Bicarbonate begins to convert to the less soluble carbonates at a pH above 9.0.

Magnesium hardness, particularly associated with the sulfate ion, has a laxative effect on persons accustomed to it. Magnesium concentrations of less than 50 mg/L are desirable in potable waters, although many public water supplies exceed this amount. Calcium hardness presents no public health problem.

Fluoride

Generally associated in nature with few types of sedimentary or igneous rocks, fluoride is seldom found in appreciable quantities in surface waters and appears in groundwater in only a few geographical regions. Fluoride is toxic to humans and other animals in large quantities, but small concentrations can be beneficial.

Metals

All metals are soluble to some extent in water. Excessive amounts of any metal may present health hazards, but only those metals that are harmful in relatively small amounts are commonly labeled toxic; other metals fall into the nontoxic group. Sources of metals in natural waters include dissolution from natural deposits and discharges of domestic, industrial, or agricultural wastewaters. Metals in water are usually measured by atomic absorption spectrometry.

Organics

Many organic materials are soluble in water. Organics in natural water systems may come from natural sources or may result from human activities. Most natural organics consist of the decay products of organic solids; synthetic organics are usually the result of wastewater discharges or agriculture practices. Dissolved organics in water are usually divided into two broad categories: biodegradable and nonbiodegradable (refractory).

Biodegradable Organics. Biodegradable material consists of organics that can be used for food by naturally occurring microorganisms within a reasonable length of time. In dissolved form, these materials usually consist of starches, fats, proteins, alcohols, acids, aldehydes, and esters. They may be the end products of the initial microbial decomposition of plant or animal tissue, or they may result from domestic or industrial wastewater discharges. Although some of these materials may cause color, taste, and odor problems, the principal problems from biodegradable organics are the secondary effects from the action of microorganisms on these substances.

Nonbiodegradable Organics. Some organic materials are resistant to biological degradation. Tannic and lignic acids, cellulose, and phenols are often found in natural water systems. These constituents of woody plants biodegrade so slowly that they are usually considered refractory. Molecules that have exceptionally strong bonds (some of the polysaccharides) and ringed structures (benzene) are nonbiodegradable.

Nutrients

Nutrients are elements essential to the growth and reproduction of plants and animals. Aquatic species depend on the surrounding water to provide their nutrients. Although a wide variety of minerals and trace elements can be classified as nutrients, those required in most abundance by aquatic species are carbon, nitrogen, and phosphorus. Carbon is readily available from many sources. Carbon dioxide from the atmosphere, alkalinity, and decay products of organic matter all supply carbon to the aquatic system. In most cases, nitrogen and phosphorus are the nutrients that limit aquatic plant growth.

BIOLOGICAL WATER-QUALITY PARAMETERS

Water may serve as a medium in which literally thousands of biological species spend part, if not all, of their life cycles. Aquatic organisms range in size and complexity from the smallest single-cell microorganism to the largest fish. All members of the biological community are to some extent, water quality parameters, because their presence or absence may indicate in general terms the characteristics of a given body of water. As an example, the general quality of water in a trout stream would be expected to exceed that of a stream in which the predominant species of fish is carp. Similarly, abundant algal populations are associated with a water rich in nutrients.

Biologists often use a species-diversity index (related to the number of species and the relative abundance of organisms in each species) as a qualitative parameter for streams and lakes. A body of water that hosts a large number of species with well-balanced numbers of individuals is considered a healthy system. Based on their known tolerance for a given pollutant, certain organisms can be used as indicators of the presence of pollutants.

Pathogens

From the perspective of human use and consumption, the most important biological organisms in water are pathogens, organisms that infect or transmit diseases to humans. These organisms are not native to aquatic systems and usually require an animal host for growth and reproduction. They can, however, be transported by natural water systems, thus becoming temporary members of an aquatic community. Many species of pathogens can survive in water and maintain their infectious capabilities for significant periods of time. These waterborne pathogens include species of bacteria, viruses, protozoa, and helminths (parasitic worms).

Bacteria. Bacteria are single-cell microorganisms, usually colorless, and are the lowest form of life that can synthesize protoplasm from the surrounding environment. Gastrointestinal disorders are common symptoms of most diseases transmitted by waterborne bacteria. Among the most violent waterborne bacterial diseases, cholera causes vomiting and diarrhea that, without treatment, result in dehydration and death.

Viruses. Viruses are the smallest biological structures known to contain all the genetic information necessary for their own reproduction. So small that they can only be "seen" with the aid of an electron microscope, viruses are obligate parasites that require a host in which to live. Symptoms of waterborne viral infections usually involve disorders of the nervous systems rather than of the gastrointestinal tract. Waterborne viral pathogens cause poliomyelitis and infectious hepatitis.

Protozoa. The lowest form of animal life, protozoa are unicellular organisms more complex in their functional activity than bacteria or viruses. They are complete, self-contained organisms that can be free-living or parasitic, pathogenic or nonpathogenic, microscopic or macroscopic. Highly adaptable, protozoa are widely distributed in natural waters, although only a few aquatic protozoa are pathogenic. Protozoal infections are usually characterized by gastrointestinal disorders of a milder order than those from bacterial infections.

Helminths. The life cycles of helminths, or parasitic worms, often involve two or more animal hosts, one of which can be human or animal waste that contains helminths. Contamination may also be via aquatic species of other hosts, such as snails or insects. Aquatic systems can be the vehicle for transmitting helminthal pathogens, but modern water treatment methods are very effective in destroying these organisms. Thus, helminths pose hazards primarily to those persons who came into direct contact with untreated water.

ANAEROBIC WASTEWATER TREATMENT

Look Hulshoff Pol
Lettinga Associates Foundation
Wageningen, The Netherlands

Anaerobic digestion is a natural process in which different microorganisms of the biological kingdoms of Bacteria and Archaea work together to convert organic compounds through a variety of intermediates into biogas, a mixture of methane and carbon dioxide and small amounts of hydrogen sulfide and hydrogen. This ancient process, brought about by living species long before the presence of oxygen in the atmosphere, is presently gaining an increased interest because of its potential in the treatment of solid organic waste, sludge, and wastewater.

HISTORY OF THE APPLICATION OF ANAEROBIC PROCESSES

Volta is considered to be the first to realize that there was a relationship between decaying vegetation and the occurrence of inflammable gas. In 1776 he showed that "combustible air" was formed from sediments in lakes, ponds, and streams (1). The initial use of anaerobic fermentation for pollution prevention has been for the treatment of domestic wastewater using anaerobic filters and hybrid systems, the latter consisting of a combination of an anaerobic tank and an anaerobic filter. The first recorded anaerobic treatment process was an air-tight chamber called the Mouras Automatic Scavenger, which was developed in the 1860s in France (2). Based on this concept Cameron developed a kind of septic tank in England to treat the wastewater of the city of Exeter in 1895, and Talbot developed a similar tank with baffles in Illinois in the United States in 1894.

In the first half of the twentieth century, anaerobic processes were especially applied for the digestion of sewage sludge. During the 1920s and 1930s, interest in the utilization of methane generated in sludge digesters grew, especially in Germany. Gas was used for heating of digesters, and in 1927 the Ruhrverband in Germany started to use sludge gas to generate power for a biological treatment plant. The generated (waste) heat was used for heating the digester. This is now common practice throughout the world.

The development of anaerobic treatment of industrial wastewater started in the second half of the twentieth century, also thanks to extensive studies in the first half of the century by Buswell. To reduce the size of the treatment systems, in the 1950s in South Africa, Stander (3) developed the clarigester, a modified Imhoff tank with an internal settler on top. In the same period, Schroepfer (4) used a reactor with recirculation of sludge from the settling tank, similar to aerobic treatment. This process was called the anaerobic contact process.

The development of anaerobic industrial wastewater treatment got a big boost after the energy crisis in the early 1970s, as anaerobic treatment is more energy efficient than aerobic treatment. A major factor in the development was also the recognition of the importance of sludge retention. New reactor concepts resulted in a further reduction of reactor volumes that could accommodate much higher loading rates than conventional aerobic treatment processes. The most prominent of these new systems is the UASB-process developed by Lettinga in The Netherlands (5).

In the last two decades a renewed interest has emerged in the application of anaerobic pretreatment for domestic wastewater in countries with a warm climate. The anaerobic treatment step is usually followed by an aerobic post-treatment.

THE ANAEROBIC PROCESS

The most important polluting compounds in wastewater are usually organic polymers such as fats, proteins, and carbohydrates. For the degradation of these polymers four main steps can be distinguished in anaerobic fermentation: hydrolysis, acidogenesis, acetogenesis, and methanogenesis (see Fig. 1).

In the hydrolysis step, extracellular complex organic polymers (proteins, carbohydrates, and lipids) are hydrolyzed by exoenzymes into smaller molecules (mono- and oligomers: amino acids, sugars, and long-chain fatty acids), which can pass through bacterial cell membranes for further decomposition. For complex wastewaters, containing a large fraction of polymers, hydrolysis is the rate-limiting factor. During acidogenesis, the mono- and oligomers are acidified, which means that they are converted into simple organic acids, hydrogen, and carbon dioxide. In the third step, called acetogenesis, acetate is formed out of the simple (volatile) acids other than acetate. Under standard conditions, acetogenic conversions are endothermic and cannot take place. Only by immediate consumption of the products of this conversion step (hydrogen and acetate) by the methanogenic Archaea, can this conversion become thermodynamically favorable (exothermic). Finally, in the last step (methanogenesis) biogas is formed, either out of hydrogen and carbon dioxide or out of acetate. Roughly 70% of the biogas is produced via the acetate route. Due to the low growth rates of acetotrophic methanogens (the growth rate $\mu_{\max}$ of *Methanosaeta soehngenii*, which is usually the most predominant methanogen in the anaerobic sludge, is around 0.1 d^{-1}), acetotrophic methanogenesis is a crucial conversion in the total anaerobic digestion process.

If sulfate is present in the wastewater, part of the organic compounds will be degraded by sulfate-reducing bacteria. Sulfate mediates the degradation of organic compounds and will thereby be reduced to hydrogen sulfide, which will partly end up in the biogas.

BIOGAS PRODUCTION

For more concentrated types of wastewater, biogas production forms a welcome source of renewable energy. Theoretically, about 0.5 m^3 biogas can be produced per kilogram of converted COD. The basic principle of anaerobic fermentation is that part of the carbon is completely oxidized to CO_2, whereas the other part is completely reduced to CH_4 with the result that the average oxidation state of the carbon stays the same. N and O will stay completely reduced. Buswell derived an equation to determine the theoretical biogas production for any given organic compound. Assuming that of an organic molecule with the general formula of $C_nH_aO_bN_d$ a fraction x of C goes to CH_4 (oxidation state $C = -4$) and a fraction $(1 - x)$ of C goes to CO_2 (oxidation state $C = +4$) and taking into account that that does not change, it can be derived that the average oxidation state of the organic molecule $(2b + 3d - a)/n$ equals $-4x + 4(1 - x)$. From this the Buswell equation is obtained:

$$\begin{aligned} C_nH_aO_bN_d &+ (n - a/4 - b/2 + 3d/4)H_2O \\ &\rightarrow (n/2 + a/8 - b/4 - 3d/8)CH_4 \\ &\quad + (n/2 - a/8 + b/4 + 3d/8)CO_2 \\ &\quad + dNH_3 \end{aligned}$$

The real amount depends on various factors such as temperature, atmospheric pressure, pH, heat production, biodegradability of the pollutants in the wastewater, amount of COD used for cell maintenance and growth, and sulfate concentration in the wastewater. The CO_2 content is strongly related to the pH: the higher the pH, the lower the partial pressure of CO_2 in the biogas. Sulfate will reduce the CH_4 content of the biogas. Theoretically, sulfate-reducing bacteria will reduce 2 g of COD per gram of sulfate, with the effect that the generated electrons are used for formation of H_2S rather than CH_4. This results in a biogas with lower methane content.

Biogas can be used as a replacement for natural gas in different ways. It can be used directly in burners, in boilers, or in gas engines or fuel cells for electricity generation.

ANAEROBIC TREATMENT TECHNOLOGY

Anaerobic treatment has some clear advantages over conventional aerobic treatment. It has to be noted though that anaerobic treatment still needs further aerobic treatment of the remaining BOD. Most importantly, the aerobic activated sludge process needs energy for aeration (about 100 kWh per 100 kg COD), whereas in anaerobic

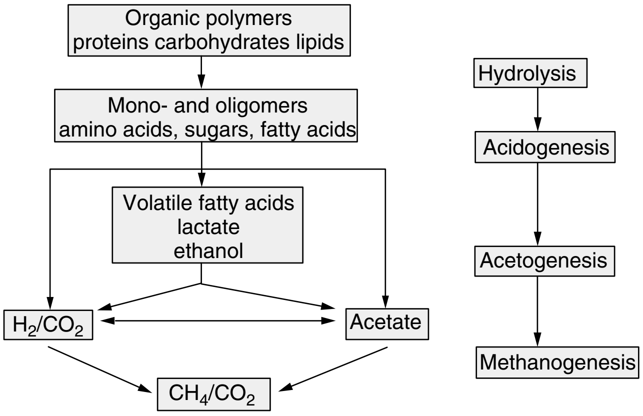

Figure 1. Schematic representation of the anaerobic fermentation of complex organic polymers into biogas.

Table 1. Comparison of Various Characteristics of Aerobic and Anaerobic Degradation of Glucose

Characteristic	Aerobic	Anaerobic
Reaction	$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O$	$C_6H_{12}O_6 \rightarrow 3CO_2 + 3CH_4$
Energy release	$\Delta G^0 = -2840$ kJ/mol	$\Delta G^0 = -393$ kJ/mol
Carbon balance	50% → CO_2 50% → biomass	95% → $CH_4 + CO_2$ (biogas) 5% → biomass
Energy balance	60% → biomass 40% → heat	90% retained in CH_4 5% → biomass 5% → heat
Biomass production	Yield > 0.5 kg VSS/kg COD	Yield = 0.05—0.15 kg VSS/kg COD
Energy input for aeration	1 kWh/kg COD	None

treatment energy is produced in the form of biogas. Over 285 kWh of electrical power can be produced per 100 kg COD.

In aerobic treatment much more sludge is produced than in anaerobic treatment. This is caused by the big difference in sludge yield factors (= grams of biomass formed per gram of degraded COD). For aerobic sludge this factor usually is around 0.5, whereas for anaerobic sludge it is generally below 0.15. As sludge management is a major cost factor in wastewater treatment, a strongly reduced sludge production is a big advantage. Contrary, comparing the effluent qualities of aerobic and anaerobic treatment shows that aerobic treatment is superior to anaerobic treatment in COD removal efficiency. Usually anaerobic treatment needs further post-treatment to meet common effluent discharge standards. However, an anaerobic system with appropriate post-treatment, in which the bulk of the organic pollutants is treated in the anaerobic step, is more cost effective than conventional aerobic treatment. The above mentioned difference between aerobic and anaerobic degradation is further illustrated for glucose as a model pollutant in Table 1.

ANAEROBIC REACTOR SYSTEMS

Key to the worldwide interest in anaerobic treatment is that it allows for an extreme uncoupling of the solid retention time from the hydraulic retention time. This uncoupling can be achieved by various means of sludge retention, such as sedimentation, immobilization on a fixed matrix or moving carrier material, and granulation. Granulation is a form of autoimmobilization typical for anaerobic biomass. Under appropriate conditions, dispersed sludge gradually transforms into a granular type of sludge. Granules are usually 0.5–3 mm in diameter and have high specific methanogenic activities and high settleabilities (up to 60 m/h). They are far more resistant to external shear forces than flocs. In practice, uncoupling of the hydraulic retention time from the solids retention time means that small reactor systems can be applied at high volumetric loading rates.

Tables 2, 3, and 4 give an overview of the most common low rate, high rate, and super high rate processes that are presently applied on full scale.

The anaerobic filter (AF) was used in early applications for domestic sewage treatment. It was further developed in the United States (6,7) for the treatment of industrial wastewater treatment. The reactor is filled with a packing material for bacterial attachment. Sludge retention is also achieved by accumulation of anaerobic biomass in the crevices of the packing. This reactor type can be operated both in an upflow and downflow mode.

In the Upflow Anaerobic Sludge Bed (UASB) reactor (5,8) sludge retention is achieved by sedimentation of granular or thick flocculent sludge in an internal settler located in the upper part of the reactor. This internal settler is also called a gas–liquid–solids (GLS) or three-phase separator. In this separator biogas is captured in a gas hood, creating a quiet zone above this hood, allowing solids to settle and return to the lower reactor compartment where the anaerobic conversion takes place. The water leaves the reactor on top of the reactor as effluent. About 60% of all full-scale anaerobic reactors that have been built worldwide are of the UASB type. Alternative sludge bed processes are the Anaerobic Baffled Reactor (ABR) (9,10) and the Anaerobic Migrating Blanket Reactor (AMBR) (11). UASB and AF reactors are used for the treatment of both industrial and domestic wastewater.

Common super high rate processes are the Expanded Granular Sludge Bed (EGSB) reactor (12) and the Internal Circulation (IC) reactor (13) presented in Table 4. These reactor systems can treat at volumetric loading rates up to 30 kg COD/m^3· d. The EGSB is operated with anaerobic granular sludge. EGSB reactors are more widely applied than fluidized bed (FB) reactors. The upflow velocity in EGSB reactors is up to 10 m/h. Like the UASB reactor, the EGSB system has an internal settler on top of the reactor. IC reactors are also operated with anaerobic granular sludge. In this reactor an internal liquid recycling is created by a so-called gas lift of the water by the generated biogas. This internal recycling results in optimal mixing and an intense contact between wastewater and sludge. Contrary to external recirculation, the internal recirculation does not lead to higher average upflow velocities in the system. EGSB and IC reactors are tall and slim and therefore have a small footprint.

Table 2. Most Common Low Rate Anaerobic Treatment Systems (Volumetric Loading Rate <5 kg COD/m^3·d)

Reactor Type	Characteristics
Completely Stirred Tank Reactor (CSTR)	
	• Suitable for sludge and manure digestion • No sludge retention • Long hydraulic retention times (15–30 days)
Anaerobic Contact Process	
	• Suitable for wastewaters rich in suspended solids • Sludge retention by external sedimentation and sludge recycling
Covered Anaerobic Lagoon	
	• Suitable for wastewaters rich in suspended solids • Sludge retention by sedimentation • Large reactor with large footprint • Long hydraulic retention times
Anaerobic Sequencing Batch Reactor (ASBR)	
	• Suitable for wastewaters rich in suspended solids • Sludge retention by sedimentation

BASIC DESIGN PRINCIPLES

There are three important factors that determine the design of anaerobic reactors:

1. The biological conversion capacity.
2. The maximum allowable hydraulic loading rate.
3. The maximum allowable gas loading rate.

For the design of a system treating concentrated wastewaters the biological conversion capacity is the determining factor. The conversion capacity is determined by the amount of biomass that can be retained in the reactor and the specific methanogenic activity of this biomass. This activity is influenced by various factors such as pH, temperature, intensity of the contact between wastewater and the biomass, COD composition, presence of inhibiting or toxic compounds, and presence of sufficient macro- and micronutrients.

For diluted wastewaters the limiting factor is the hydraulic capacity of the reactor. If the hydraulic load

Table 3. Most Common High Rate Anaerobic Treatment Systems (Volumetric Loading Rate 3–20 kg COD/m^3·d)

Reactor Type	Characteristics
	Anaerobic Filter (AF)
	• Sludge retention by attachment on filter material and entrapment in voids in the filter • Can be operated upward and downward
	Upflow Anaerobic Sludge Bed (UASB) Reactor
	• Sludge retention by granulation and settling • Internal three-phase separator to separate gas, sludge, and water • Optimal contact of water with biomass by gas mixing

Table 4. Most Common Super High Rate Anaerobic Treatment Systems (Volumetric Loading Rates 10–30 kg COD/m^3·d)

Reactor Type	Characteristics
	Expanded Granular Sludge Bed (EGSB) Reactor
	• Suitable for medium to low strength wastewater and low temperatures (<25 °C) • Comparable to fluidized bed reactor • External recirculation • Upflow flow rate in the reactor is up to 10 m/h
	Internal Circulation (IC) Reactor
	• Requires anaerobic granular sludge • Two internal three-phase separators • Internal circulation of water by gas lift principle

exceeds the hydraulic capacity of the system, the sludge washout from the reactor can become higher than the sludge yield by bacterial growth. This will result in a gradual drop in the quantity of active biomass in the reactor and ultimately in reactor failure.

PHYSICAL SEPARATION OF ACIDOGENESIS FROM METHANOGENESIS

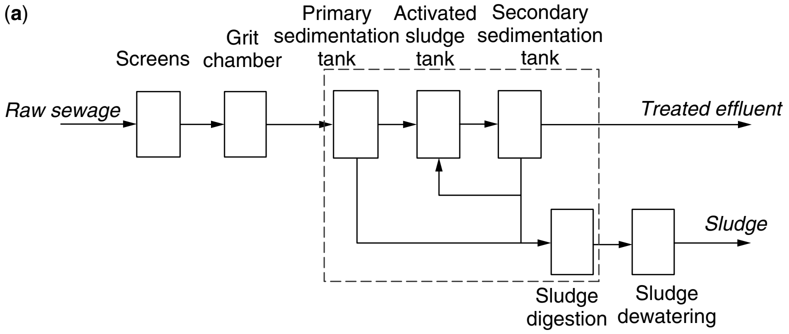
Fairly common in anaerobic treatment is the physical separation of hydrolysis and acidification in an acidifying reactor and acetogenesis and methanogenesis in a second reactor. This phase separation was supported by a school of researchers (14–17), who claimed that such a separation would lead to better control of the overall digestion process. Under optimal mesophilic conditions a slight preacidification of the wastewater is certainly beneficial, but generally this is already accomplished during the transport of the wastewater in the sewer system. For soluble and not or partially acidified carbohydrate-containing wastewaters, phase separation is therefore not required. For the formation of granular sludge it is even better to have no phase separation. However, for treatment of hardly acidified carbohydrates under psychrophilic conditions, the use of a preacidification step is required: the in-growing voluminous acidifying organisms do not decay sufficiently fast, and therefore they will accumulate in the retained methanogenic sludge, creating a bulking type of sludge. As a result, the sludge characteristics will deteriorate (18).

Staging of anaerobic treatment systems can be considered beneficial for the treatment of various types of complex wastewaters, such as domestic sewage or wastewaters containing slowly biodegradable or inhibitory compounds (19). In such staged reactors in principle all phases of the anaerobic degradation process are allowed to proceed to some extent simultaneously in each reactor module. A staged reactor system will provide a higher treatment efficiency, because more difficult compounds like intermediates such as propionate, or possibly even xenobiotic compounds (when present in the wastewater), will find a more optimal environment for degradation due to the development of appropriate microbial communities in each stage. The process stability of a staged system is also substantially higher than in the present commonly practiced one-step systems.

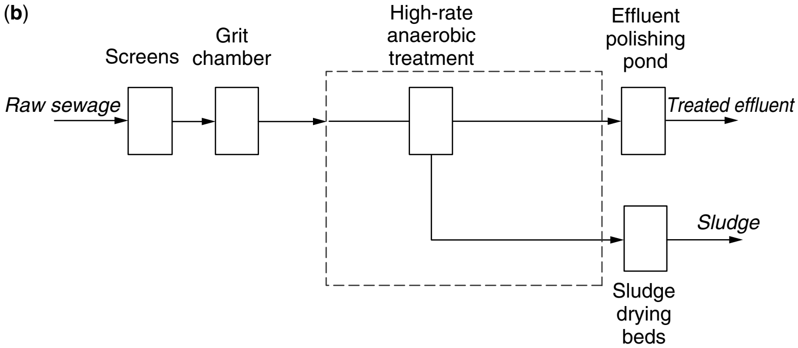
APPLICATION OF ANAEROBIC WASTEWATER TREATMENT

Anaerobic treatment has been applied primarily for medium to high strength wastewaters of (agro-) industrial origin with COD concentrations over 1000 mg/L. Common industries generating wastewater that can be well treated by anaerobic processes are starch factories, breweries, pulp and paper mills, and distilleries. More recently, other industries with wastewater containing organic pollutants have started using anaerobic treatment, such as chemical and pharmaceutical industries.

Since 1985 interest has grown in anaerobic treatment of domestic sewage in countries with tropical or subtropical climates (20). The full-scale plants mostly use UASB reactors for the anaerobic step and they are constructed all over South America and Asia, especially in Brazil and India. As indicated in Fig. 2 the advantage of anaerobic sewage treatment over aerobic treatment is that four components of the latter (primary clarifier, activated



Aerobic sewage treatment



Anaerobic sewage treatment

Figure 2. Flowsheets of aerobic sewage treatment (**a**) using the activated sludge process and anaerobic sewage treatment (**b**) with post-treatment in a polishing pond.

sludge tank, secondary clarifier, and sludge digester) can be combined in one single reactor. In this reactor removal of COD and sludge stabilization takes place simultaneously.

Anaerobic treatment has traditionally been applied under optimal mesophilic temperature conditions (around 30 °C). Anaerobic digestion however, is, feasible under a wide range of conditions, such as temperatures ranging from 4 to 70 °C, high salinity, the presence of recalcitrant or toxic compounds, and for wastewater with very low COD/sulfate ratios.

CONCLUSION

Anaerobic digestion is implemented for the treatment of industrial and domestic wastewater, sludge, and solid waste for the removal of biodegradable compounds from the waste. Anaerobic processes require only a small energy input and a renewable energy source is generated in the form of biogas. Anaerobic treatment is a standard technology for wastewater of agroindustrial origin in the industrialized world. In developing countries, interest in and application of anaerobic treatment of domestic sewage are emerging.

The applicability of anaerobic processes is further extended to hot and cold wastewater as well as wastewater from the (petro-) chemical, pharmaceutical, textile, and mining industries.

SEWERAGE ODORS—HOW TO CONTROL

Bradley A. Striebig
Gonzaga University
Spokane, Washington

WHAT ARE ODORS?

Odors result from the perception of chemicals by the olfactory system. The chemicals are detected in the mouth and nasal passages. Sensations are conveyed to the brain where they may be negatively perceived. The olfactory nerve (first cranial nerve) conveys the perception of chemical odorants to the brain. The trigeminal nerve (fifth cranial nerve) relates the pungency or irritability due to chemical exposure to the brain. Many of the chemicals that cause a negative reaction, bad odors, are related to bacterial emissions that may indicate the presence of pathogenic organisms. The human olfactory system can detect many of these pathogenic indicator chemicals at concentrations of only a few parts per billion (ppb). The chemicals that cause the olfactory response are called odorants. The human olfactory system is capable of detecting a wide variety of odorants.

The human response to odorants present in the air depends on the odor concentration, intensity, persistence, and character. Odor concentration can be measured as a dilution ratio and results may be reported as a detection threshold, recognition threshold, or dilution-to-threshold ratio. Odorants can be measured analytically in the field or laboratory and their concentrations are typically reported in parts per million (ppm) or parts per billion (ppb) by volume. Odor intensity is often related to the equivalent intensity produced by exposing an odor panel to the sample of interest and correlating the odor panel response to a butanol-based standard scale. Odor persistence is interpreted as the duration of exposure and is reported as a dose–response function. The odor character is a descriptive scale, which describes what the odor smells like based on categorical descriptive terms. These terms provide scientists and engineers with the measurement and descriptive techniques relating odorants to odors and hold the key to understanding odor control strategies. Prior to describing control techniques, it is helpful to understand what causes odors and how they are generated in the sewers.

WHAT CAUSES ODORS?

Wastewater or sewage water is a complex mixture of organic and inorganic wastes. The organic wastes consist of a mixture of human wastes, food wastes, and industrial wastes. Simple organic compounds such as sugars and carbohydrates are broken down aerobically into carbon dioxide and water, and anaerobically into methane. More complex organic molecules, such as proteins and amino acids, are also broken down into carbon dioxide, water, and methane; however, the remaining sulfur and nitrogen present in these compounds may result in the production of hydrogen sulfide, ammonia, and other strong odorants as illustrated in Fig. 1.

Aerobic wastewaters commonly contain many odorants, including indole, skatole, organic acids, esters, alcohols, and aldehydes. However, microbial activity in the sewers depletes the oxygen, creating anaerobic conditions. When anaerobic conditions develop, the types and concentrations of odorants in the sewer rapidly increase. Most sewage odor problems are related to the odorants formed under anaerobic conditions, including hydrogen sulfide, mercaptans, ammonia, amines, and volatile fatty acids.

Hydrogen sulfide is typically the odorant of greatest concern in sewers due to its low detection threshold, high concentration, and acidic nature. Hydrogen sulfide is generated from the anaerobic biological reduction of sulfate ($SO_4{}^{2-}$) or thiosulfate. One common mechanism is described by

$$SO_4{}^{2-} + 2C + 2H_2O \xrightarrow{\text{anaerobes}} 2HCO_3{}^{-} + H_2S$$

Hydrogen sulfide is generated in the slime layers and sludge deposits in sewer collection systems as illustrated in Fig. 2. Key parameters that control sulfide generation include the concentration of organic materials and nutrients in the sewage, sulfate concentrations, temperature, dissolved oxygen, pH, and residence time of the sewage and sludge deposits in the sewer system.

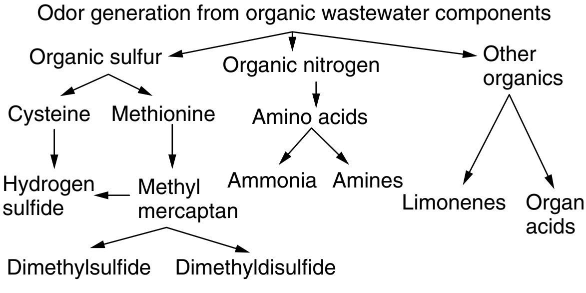

Figure 1. Odorants generation mechanisms from organic wastes.

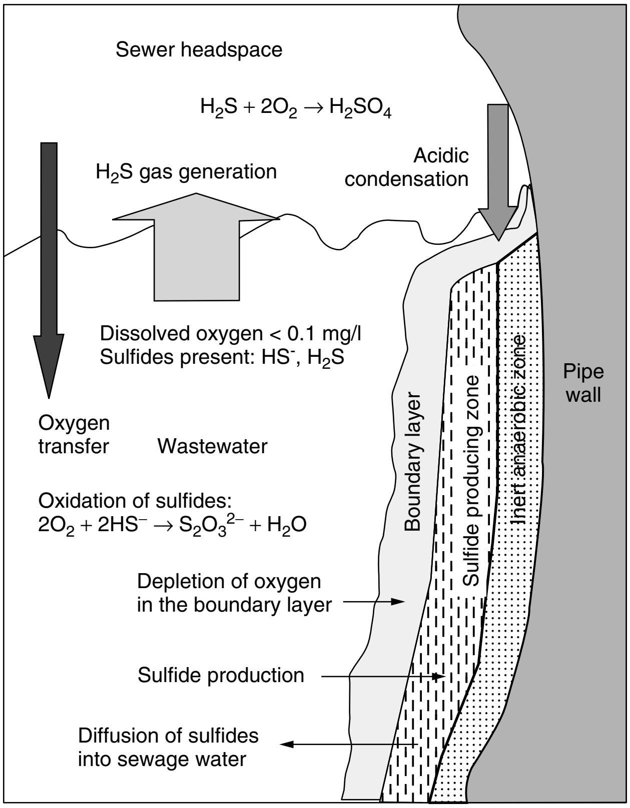

Figure 2. Sulfide generation in sewers (adapted from Ref. 1).

Pomeroy and Parkhurst (1) developed a predictive model for estimating sulfide generation in wastewater collections systems:

For pipes flowing full:

$$S_2 = S_1 + (M)(t)[\text{EBOD}(4/d + 1.57)]$$

For less than full pipes:

$$S_2 = S_{\text{lim}} - \frac{(S_{\text{lim}} - S_1)}{\log^{-1}\left[\dfrac{m(su)^{3/8}t}{2.31d_m}\right]}$$

where S_2 = predicted sulfide concentration at time t_2 (mg/L)
S_1 = sulfide concentration at time t_1 (mg/L)
S_{lim} = limiting sulfide concentration, $S_{\text{lim}} = (M'/m)\ \text{EBOD}(su)^{-3/8}(\text{P/b})$ (mg/L)
M = sulfide flux coefficient, typically 0.5×10^{-3} to 1.0×10^{-3} (m/h)
M' = effective sulfide flux coefficient in gravity sewers, typically 0.32×10^{-3} (m/h)
m = empirical coefficient for sulfide loss, typically 0.96
t = detention time in the sewer reach with constant diameter and flow (h)

EBOD = effective biochemical oxygen demand, EBOD = BOD × $1.07^{(T-20)}$ (mg/L)
d = pipe diameter (m)
T = wastewater temperature (°C)
s = slope (m/m)
u = stream velocity (m/s)
d_m = mean hydraulic depth, equal to area of flow divided by surface width (m)
P = wetted perimeter (m)
b = width of wastewater stream at the surface (m)

Odor emission of other compounds present in the sewage, like hydrogen sulfide, increase with increased turbulence of flow. The solubility of the odorant, concentration, temperature, pH, and mass transfer coefficient are all factors that affect the emission rate of odorant in the sewer. Weirs, junction chambers, and holding tanks may represent significant sources of odor.

Odor emissions are dependent on the chemical nature of the odorant of concern and the composition of the wastewater. Emissions are also dependent on the mechanical operating parameters of the sewer. Odor emissions are of greatest concern when odorants are in close proximity to receptor populations. Nuisance odors are often reported because pressurization of the sewer atmosphere results in odorant emissions from manholes, house vents, and other structures. Pressurized conditions can result from inverted siphons, drop structures, discharges of forces mains, reductions in pipe diameter, and sags in the sewer that restrict air movement.

Odor control measures are designed to prevent the formation of hydrogen sulfide or remove hydrogen sulfide from sewer exhaust. Prevention of hydrogen sulfide formation is usually accomplished by either improving oxygen transfer or the addition of chemical or microbial additives to the sewer.

ODOR PREVENTION

Improving Oxygen Transfer

Ventilation of the sewer system can be improved through proper maintenance or the addition of appurtenances to increase the rate of oxygen transfer. Sewer system ventilation is a dynamic parameter that varies with change in barometric pressure along the sewer, wind velocities past vents, sewage drag, sewage flow rates, and the relative density of sewer and outside air. Partial blockages of flow and buildup of the slime layer within the sewers significantly affect ventilation and increase hydrogen sulfide emissions. These conditions can be mitigated through a regular program of inspections and cleaning. Regular cleaning has been shown to temporarily reduce the rate of sulfide buildup, particularly when sewage deposit buildups are problematic (2).

Oxygen can be transferred mechanically into the sewer to increase the dissolved oxygen concentration in the wastewater and reduce hydrogen sulfide generation. Air or oxygen may be directly injected into the sewer. The rate of air flow required for odor reduction with direct air injection depends on the oxygen uptake rate, detention time in the downstream sewer, temperature and pressure, and degree of odor control required. Direct air injection rates utilized in practice in the United States are highly variable, but typical ranges are 0.75–2.25 m^3 air/m^3 wastewater or 0.7–1.3 m^3/h/cm-pipe-diameter. Other appurtenances used to increase oxygen transfer into the wastewater include venture aspirators, air lift pumps, U-tube injection lines, and pressurized air tanks, which are described in more detail in the referenced literature (1–8). The costs associated with air injection are illustrated in Table 1.

Additives

A variety of chemical additives have been employed to reduce odors from sewers and wastewater treatment facilities. The additives reduce hydrogen sulfide emissions by chemical oxidation, microbial inhibition of sulfate reduction, precipitation, and pH control. The most effective chemical additives for control of sewage odors have been chlorine agents, peroxides, and metal salts.

Chlorine has been used effectively to control hydrogen sulfide emissions from wastewater. Chlorine may be added to wastewater as hypochlorite or as chlorine gas. Hypochlorite solutions may be used for small chlorine dosages, but chlorine gas is more cost effective when 2.3 kg/d of chlorine or more is required. Chlorination systems are designed based on the level of sulfide control required, the characteristics of the wastewater, and the degree of process control required. Sulfide is oxidized to

Table 1. Typical Costs for Increasing Oxygen Transfer in 2003 Dollars[a]

Condition	Small Air Injection System	Large Air Injection System	Small Oxygen Injection System	Large Oxygen Injection System

Oxygen required, kg/d	NA	NA	93	310
Capital cost, $	37,000	96,000	35,000	89,000
Oxygen cost, $/yr	NA	NA	16,000	35,000

[a] Update by the Consumer Price Index from 1984 dollars (1).

sulfate in wastewater when excess chlorine is present:

$$HS^- + 4Cl_2 + 4H_2O \longrightarrow SO_4{}^- + 9H^+ + 8Cl^-$$

At least 8.87 parts by weight of chlorine are required to oxidize sulfide according to the above equation. However, higher dosages are required in full-scale applications due in part to limitation on the amount of mixing. Field application rates typically required 10–15 kg Cl_2/kg H_2S. Full-scale studies should be performed for a period of several weeks to ensure adequate odor control is achieved based on the control system and chlorine dose. Chlorine feed rates may be optimized through monitoring residual chlorine, sulfide, and wastewater flow rate. Table 2 illustrates the typical costs associated with chlorine injection systems.

Hydrogen peroxide has been utilized to oxidize hydrogen sulfide and reduce odorous emissions from sewage. The hydrogen peroxide oxidation occurs rapidly and excess peroxide results in a higher dissolved oxygen concentration. Hydrogen peroxide is also an attractive reagent because it can be used for gravity and pressurized sewers, feed systems are relatively simple, and peroxide provides effective sulfide control for up to 4 h.

The chemical mechanism of sulfide oxidation is dependent on the pH of the wastewater:

$$\text{For pH} < 8.5: H_2O_2 + H_2S \longrightarrow S + 2H_2O$$

$$\text{For pH} > 8.5: 4H_2O_2 + S^- \longrightarrow SO_4{}^- + 2H_2O$$

The stoichiometric peroxide dose required is 1 g H_2O_2/g H_2S. Dosage varies with the BOD, pH, and temperature of the wastewater and the hydraulic characteristics of the sewer. Typical peroxide dosages in practice range from 0.9 to over 3.0 g H_2O_2/g H_2S. The peroxide dose can be optimized by monitoring wastewater flow rates, sulfide concentrations, and chemical feed rates. The costs associated with peroxide addition systems are shown in Table 2.

Many metal ions react with dissolved sulfides to form insoluble salts that precipitate from the solution. Iron and zinc salts have been added for control of sulfur emission. The proposed mechanism of sulfur removal with iron salts is represented by

$$Fe^{2+} + 2Fe^{3+} + 4HS^- \longrightarrow Fe_3S_4 + 4H^+$$

The overall removal mechanism can be expressed as

$$FeSO_4 + H_2S \longrightarrow FeS + H_2SO_4$$

Stoichiometric removal of sulfur requires 1.6 g Fe/g H_2S removed. Actual dosages require field testing to optimize the iron dose required for the desired odor reduction. The costs associated with iron injection for hydrogen sulfide control are shown in Table 2.

Nitrates, alkalis, ozone, and potassium permanganate have been utilized for short-term odor control measures. These additives have been shown to help control short-term odor problems and spikes in odor at specific locations that require only small doses of the additives. However, these chemicals have not been cost effective for long-term sulfide control in large sewers.

Biological additives have been marketed to help control odor emissions from sewage. These products may alter the metabolism of existing microorganisms or be "designer" microorganisms that out-compete odor-producing microorganisms and thus reduce emissions. Metabolic modification with anthraquinone products has been effective in treating small diameter pipes and force mains where there is a large slime layer or septic sediments are problematic. The product is cost effective when used as a preventative measure for small lines with high sulfide concentrations and slow moving gravity lines. Recommended dosages are based on the surface area of the slime layer and are approximately 0.24 kg of the product per 1000 m^2 of surface area. Nitrate and metabolic modifiers may be a cost-effective combination for minimizing odors.

ODOR REMOVAL

If odor prevention is not cost effective or sufficient to control nuisance odors, various odor control technologies are capable of removing odorous compounds exhausted from confined sources. The most common technologies for

[a] Update by the Consumer Price Index from 1984 dollars (1).

treating sewer-related odors are carbon adsorption, biofiltration, absorption, ozonation, and thermal oxidation.

Four major factors need to be considered to select and design a cost-effective system to remove odorants from exhaust air. The concentration and composition of the odorants in the air stream must be determined from sampling and laboratory analysis. The flow rate of the exhaust air stream must be minimized. The cost associated with the control technologies, both capital and operational costs, must be considered. Selection and design of control technologies should include pilot scale testing to ensure odors are adequately removed. Experience and judgment are inherent and necessary parts of designing an effective odor control system.

Adsorption Systems

Carbon adsorption systems utilize the attractive van der Waals forces on porous granulated activated carbon (GAC) surfaces to capture and contain organic pollutants. GAC systems are commonly applied to a wide variety of odor control situations due the simplicity of design, low capital costs, and minimal maintenance requirements. Carbon adsorption systems are ideal for small applications dictated by space and low capital investment.

The activated carbon acts as a capture and control device. The odorants adhere to the surface of the GAC and eventually consume all available surface sites. The mass-transfer zone (MTZ), where odorants are being removed, gradually moves from the inlet side of the carbon bed to the outlet side. As time passes and more odorants are adsorbed, the amount of spent carbon increases. Breakthrough occurs when the zone of mass transfer reaches the exit of the carbon bed and there is no longer an excess of active carbon sites available. When the carbon adsorption bed efficiency decreases, as the bed nears saturation, the carbon must be replaced or regenerated. The vendor of the material typically regenerates the GAC off-site.

Monitoring of the carbon adsorption system is critical to prevent and detect breakthrough of the odorants as the bed nears the end of its useful life span. Regular monitoring of the system allows accurate measurement of cycle times and service contracts should be created to minimize episodes of poor efficiency. The capital costs, illustrated for two different air flow rates in Table 3, and the operational costs may be considerable.

Biological Control Systems

Biofilters have been used for many years in the United States for odor control and have a reputable history for odor control in many European countries. Odorants are degraded by microorganisms in the biofilter. Odorant removal occurs in a thin liquid film or biofilm. The end products of the degradation are carbon dioxide, water, biomass, and (when removing high concentrations of hydrogen sulfide) sulfuric acid. Because biotrickling filters have the ability to "store" the contaminants as a food source, they are often applied to situations that have variable influent loading rates.

Biofilters represent a low cost alternative for treating low concentration, high volume exhaust streams as shown in Table 3. The capital and operational costs for biofiltration systems are relatively low. In addition, biofilters produce no secondary waste if properly operated, except for periodic media replacement. Historically, biofilters were limited in their application due to variable removal efficiencies caused in part by their intolerance to fluctuation in air flow rates, concentrations, and temperatures. In addition, biofilters typically require a very large area footprint compared to other types of organic control technologies.

Absorption Systems

Absorption systems or scrubbers involve the selective transfer of the odorants from the gas phase to a contacting liquid. The odorants must have preferential solubility in the liquid. The soluble odorants diffuse from the gas through a gas–liquid interface and the odorants are dispersed in the liquid.

Absorption systems are ideal for controlling water-soluble odorants, such as hydrogen sulfide, ammonia, and organic acids. The soluble pollutants must be continually destroyed or treated to maintain operational efficiencies. For both ammonia and hydrogen sulfide removal, the pH of the system must be continuously monitored and controlled. Absorption systems are sometimes combined with chemical additives to increase aqueous phase reaction rates. Absorption systems are often used to remove large quantities of hydrogen sulfide prior to a second stage scrubber or carbon bed used to remove less concentrated odorants such as mercaptans and volatile acids, which without treatment would result in nuisance odors.

Ozone Contactors

Ozone is utilized for odor control in the exhaust air as well as preventing odors from forming in the wastewater. Sufficient time and ozone concentrations are required in the contacting chamber to ensure adequate ozone removal. Detailed ozone reaction mechanisms are complex and

Table 3. Typical Costs for Odor Removal from Confined Space Exhaust Air in 2003 Dollars[a]

Air Flow Rate, m^3/min	Adsorption		Biofiltration		Absorption		Ozone Contactor	Thermal Oxidizer
	Capital	Annual	Capital	Annual	Capital	Annual	Capital	Capital
28	53,000	11,000	17,000	500	69,000	4,000	54,000	56,000
280	227,000	85,000	158,000	5,000	136,000	35,000	120,000	91,000

[a] Update by the Consumer Price Index from 1984 dollars (1).

highly dependent on the chemical composition of the treated wastewater or air stream. Examples of overall reactions of ozone with hydrogen sulfide, amines, and mercaptans are illustrated by

$$H_2S + O_3 \xrightarrow{\text{major pathway}} S + H_2O + O_2$$

$$H_2S + O_3 \xrightarrow{\text{minor pathway}} SO_2 + H_2O$$

$$R_3N + O_3 \longrightarrow \underset{\text{(amine oxide)}}{R_3NO} + O_2$$

$$\underset{\text{Methyl mercaptan}}{CH_3SH} + O_3 \longrightarrow CH_3S - SCH_3$$

$$+ O_3 \longrightarrow \underset{\text{methyl sulfonic acid}}{CH_3SO_3H} + O_2$$

Ozone is an unstable gas that must be produced on-site. Ozone is typically generated by corona discharge, which requires significant electrical consumption and excess heat. Three to four ppm of ozone are required in the exhaust air to sufficiently control odors. Reaction times, typically in the range of 10–60 s, vary widely depending on the degree of control required, odorant concentration, humidity, and ozone concentration. The ozone dosage must be controlled to minimize the discharge of unreacted ozone or excess ozone can be discharged into the wastewater. Occupational and environmental health and safety aspects must be considered due to the potential exposure to ozone and electrical currents. Typical costs for ozone contactors are provided in Table 3.

Thermal Oxidation Systems

Thermal oxidation systems reliably maintain nearly complete destruction of odor-causing compounds. Thermal oxidizers are designed based on operating temperature, residence time, and turbulence or mixing in the reactor. Temperature requirements for destruction range from typical design temperatures of 480 to 870 °C. Thermal oxidation systems can maintain high destruction efficiencies even with wide fluctuations in concentration. However, thermal oxidation systems do not tolerate wide flow rate fluctuations well. Thermal oxidation systems also consume large quantities of fossil fuels and as a result they are sources of nitrogen oxides, carbon dioxide, and possibly acid gases for sulfur-containing waste streams. Furthermore, thermal oxidation systems are typically run 24 h/d due to the long start-up and shut-down times required for operation.

The volumetric flow rates of the fuel and air streams along with the size of the reaction chamber are important to ensure adequate retention time and destruction efficiency. For low concentration air streams, additional make-up air is not necessary if there is sufficient oxygen in the polluted air stream to maintain combustion. A mass balance and enthalpy balance should be performed to estimate the required fuel flow rate to maintain the desired operational temperature.

Fuel costs make up the majority of operational costs and must be considered in order to select the most cost-effective treatment systems. Adequate design and operation of thermal oxidation systems is dependent on the temperature, the residence time of the gas, and turbulence or mixing within the reaction chamber. These variables are dependent on one another. The kinetic rate constants increase exponentially with temperature. Reaction times on the order of 0.1–0.5 s are usually sufficient to allow the reactants to reach the desired degree of chemical destruction. Turbulence within the reaction chamber ensures sufficient mixing. Therefore, a higher reaction temperature results in a shorter residence time, a smaller combustion chamber, and lower capital costs. A higher residence time lowers the operating temperature, results in less fuel usage, and in higher capital costs. The operational costs versus capital investment should be considered during selection and design of thermal oxidation systems. Factors that should be considered when determining the capital costs illustrated in Table 3 include the materials of construction, instrumentation, costs of heat exchangers, engineering fees, and construction fees.

CONCLUSION

Odor control requires a comprehensive maintenance program, preventive measures to reduce odor control costs, and possible implementation of control systems where sewage odor is a nuisance. Research, experience, and comprehensive testing programs are important for determining the most cost-effective odor control methods. Regardless of the technologies implemented, there are ongoing costs for preventing and controlling odors that must be included in the operational budget of the wastewater authority.

ULTRAFILTRATION—COMPLEXATION IN WASTEWATER TREATMENT

Raffaele Molinari
Pietro Argurio
Universitá della Calabria
Rende, Italy

GENERAL INTRODUCTION

General

Wastewater treatment represents one of the most important fields of study today in the wide subject of pollution problems solving. A "rational hydrologic resource management" is necessary because of the world's increased demand of water, particularly in these last years, owing to a lack of this resource (1). As a result, the main challenge is to create new resources and to fully reuse the existing ones (2). In particular, water frequently contains numerous ionic solutes, many of which are not desirable, and it is used either for residential or industrial purposes.

In the last fifty years, pressure-driven membrane processes have become a routine technique for the removal of environmentally relevant and hazardous substances from aqueous systems (3–10). A membrane can be defined as a selective barrier between two phases (5,11). Transport through the membrane takes place when a driving force is applied. The main goals of such processes are: a) concentration of a solute by removing the solvent, b) purification of a solution by removing nondesirable components, and c) fractionation of liquid or gaseous mixtures.

The separation of solutes with ionic dimensions can be accomplished by using the reverse osmosis operation, but this will result in high operative costs, low permeate flow rate, and low ions selectivity. In order to overcome these problems, the hybrid ultrafiltration-complexation process was introduced (12–17). It was named polymer-assisted ultrafiltration (PAUF) or polymer-enhanced ultrafiltration (PEUF). This process can be applied for various purposes such as the treatment of waste effluents, groundwater, and seawater (13–15,18,19). The advantages of this method are the low energy requirements involved in UF, the conceptual simplicity, the modularity typical of membrane processes, the high permeate flow rate, the high removal efficiency because of effective binding while reducing the initial waste volume significantly, the selectivity achieved when an appropriate complexing agent is considered, and the optimal quality of treated water (6,16,20–22).

The separation process will be successful if the polymer meets the following requirements: good solubility, high selectivity, regeneration possibility, chemical and mechanical stability, low toxicity, high molecular weight with low viscosity, and low cost (12).

The complexation-ultrafiltration technique is mainly applied today in the separation of metal ions from aqueous solutions, covering processes ranging from production of potable water to leaching and recovery of metals from washing water of contaminated soil or from ores to detoxification of process water and wastewater, also for water recycling and reuse (23–27). Indeed, metal contamination is a dangerous cause of water pollution and it constitutes a big health hazard (28–34). Some metal ions play an essential role in many biological processes, and their deficiency, unusual accumulation or imbalance, may lead to biological troubles, e.g., Cu^{2+} ion is an essential nutrient, but when people are exposed to copper levels of above 1.3 mg/l for short periods of time, stomach and intestinal problems occur. Long-term exposure to Cu^{2+} leads to kidney and liver damage (35,36), producing DNA mutation, evidence of its cancerogeneous character.

In the following, the application of PAUF technique is reported with particular focus on metal removal from water.

Historical Background

In 1980, Nguyen et al. (37) considered the application of ultrafiltration to the concentration and separation of solutes of low molecular weight in water. Their results showed a high rejection of these species by complexing them with a suitable soluble macromolecule. Furthermore, they demonstrated that it is possible to separate a specific cation from a mixture by using a polymer that shows a marked selectivity for one cation.

Another similar approach was published in 1982 by Renault et al. (38), which studied the recovery of chromium from effluents by using ultrafiltration.

In 1984, Buffle and Staub (39) gave a fundamental contribution to increase research interest on PAUF method with a work in which they applied the ultrafiltration for measurement of complexation equilibrium constants of metal ions in water in natural conditions. Thus, the coupling of the terms complexation and ultrafiltration was used.

In successive years, several research efforts were made to study mainly the technical and economical feasibility of PAUF to meet the limits fixed by pollution laws for metal removal from water of various origins.

Tabatabai et al. (17) studied the feasibility in the removal of Ca^{2+} and Mg^{2+} ions from hard water by using the sodium polystyrene sulfonate (PSS) polymer (water softening). They demonstrated (with some economical considerations) that the PSS needs to be recovered from the retentate and regenerated appropriately to be reused.

Juang and Shiau (20) studied the metal removal from aqueous solutions using chitosan-enhanced membrane filtration, and in two other works (2,40), Juang and Chiou considered the problem of technical feasibility on the use of PAUF for brackish water softening and wastewater treatment by using three weakly basic, water-soluble polymers like chitosan, polyethylenimine (PEI), and poly(diallyl dimethylammonium chloride) to remove ions like Ca^{2+}, Mg^{2+}, Na^+, K^+, Cu^{2+}, and Zn^{2+}.

An et al. (28) evaluated the ability of crab shell (practically chitosan) to remove heavy metals from aqueous solutions by comparison with several sorbents. They found, for crab shell heavy metals, removal capacity higher than cation exchange resins, zeolite, powered activated carbon, and granular activated carbon. Besides, this process is selective, removing Pb and Cr in preference to Cd and Cu.

Barron-Zambrano et al. (23) investigated the separation of mercury from aqueous solutions using PEI as polymeric complexing agent. They considered the development of a two-stage process: The first one enables mercury concentration and the production of a purified stream, whereas the second one was required to separate the mercury from the polymer and to recycle the polymer (chemical regeneration).

Steenkamp et al. (35) considered the copper(II) removal from polluted water with alumina/chitosan composite membrane, giving attention prevalently to the problems related to the synthesis of the composite support and to the factors that influence metal removal efficiency, like pore radii variation with temperature and powder mixtures used and chitosan coating thickness.

Vieira et al. (41) studied the metal removal from wastewater of the pulp and paper industry. Zakrzewska-Trznadel et al. (42) tested the application of PAUF for radioactive waste processing purposes. Their results showed that this process could be an alternative to reverse osmosis.

Canizares et al. (18) studied a semicontinuous laboratory-scale application of polymer-enhanced ultrafiltration for the recovery of lead and cadmium from aqueous effluents. They emphasized that this process includes two stages: a) metal retention, where a permeate stream free of heavy metals is obtained and b) polymer regeneration, where the polymer is regenerated in order to be reused. The pH for metal retention and polymer regeneration and the binding capacity to know the metal amount that can be treated are also important parameters.

FUNDAMENTALS OF POLYMER-ASSISTED ULTRAFILTRATION

The idea of the PAUF process is that ultrafiltration can be used for removal of ions from aqueous streams, provided that they are preliminarily bound to water-soluble polymers (2,12,43,44). The unbound ions pass through the membrane, whereas the polymers and their complexes are retained (13,14,42,45).

Low-molecular-weight species such as metal ions can be bound to macromolecules by intermolecular forces, mainly ionic interaction and complex binding, or the combination of both.

Formation of complexes is significantly more selective than ionic interactions. An example of this binding mechanism is the complexation reaction among the polymeric agent (PEI), the proton (H^+), and the metal cation (Cu^{2+}), which is represented by the equilibrium equations:

$$\mathrm{PEI} + \mathrm{n\ H_2O} \Longleftrightarrow \mathrm{PEIH_n^{n+}} + \mathrm{n\ OH^-} \tag{1}$$

$$\mathrm{PEI} + \mathrm{a\ Cu^{2+}} \Longleftrightarrow \mathrm{PEICu_a^{2a+}} \tag{2}$$

where $0 \leq \mathrm{n} \leq \overline{\mathrm{n}}$ and $0 \leq \mathrm{a} \leq \overline{\mathrm{a}}$ with $\overline{\mathrm{n}}$ equal to the number of monomers contained in a single polymeric chain and $\overline{\mathrm{a}}$ representing the maximum complexation ratio of the polymers with copper ions ($\overline{\mathrm{a}} = \frac{\overline{\mathrm{n}}}{4}$ for PEI-Cu complex because of Cu^{2+} tetra-coordination with four nitrogen of PEI). In particular, considering that commercial PEI, widely used in literature, has a polymeric chain of MW 60 kDa and considering that a monomeric unit $-CH_2-CH_2-NH-$has MW 43.062 Da, $\overline{n} = 1393$ is obtained (30).

An ionic interaction mechanism can be described, for example, in the removal of dihydrogen arseniate ion with a polymer R^+Cl^-, by the following reactions:

$$\mathrm{R^+Cl^-} \Longleftrightarrow \mathrm{R^+} + \mathrm{Cl^-} \tag{3}$$

$$\mathrm{R^+} + \mathrm{H_2AsO_4{}^-} \Longleftrightarrow \mathrm{RH_2AsO_4} \tag{4}$$

This is an ion-exchange reaction, similar to that which takes place in anion-exchange resin. In another case, the water-soluble polymers polyacrylic acid (PAA) and polyacrylic acid sodium salt (PAASS) interact with copper cation by ion-exchange reactions, described by the following equations:

$$\mathrm{PAA} + \mathrm{n\ Cu^{2+}} \Longleftrightarrow \mathrm{PAACu_n} + \mathrm{2n\ H^+} \tag{5}$$

$$\mathrm{PAASS} + \mathrm{m\ Cu^{2+}} \Longleftrightarrow \mathrm{PAACu_m} + \mathrm{2m\ Na^+} \tag{6}$$

Ionic exchange interaction mechanism has low selectivity and the disadvantage to release another ion (H^+ or Na^+ in this case) in the feed solution, so that to remove an ion from an aqueous solution, another one must be released. In contrast, reactions such as in Eq. 2 do not present this disadvantage.

It should be taken into account that, in general, solid resins and water-soluble polymers have similar functional groups, which would result in similar chemical properties, e.g., the ability to bind certain ions. These analogies in the properties can be used in order to predict the behavior of an unknown hydrophilic polymer if the properties of the functional group of the resin are known.

The PAUF process can be economically more feasible if the polymer could be regenerated, releasing the metal to separate, and be reused. The general scheme of the overall process is represented in Fig. 1.

Polymer regeneration could be carried out by three major methods (12):

1. *Chemical regeneration* means the change of pH of the retentate in order to cleave the polymer–metal bond (21,30,46);
2. *Electrochemical regeneration* means the electrolysis of the retentate resulting in a deposition of the metal on an electrode, whereas the polymeric agent remains in the solution (44);

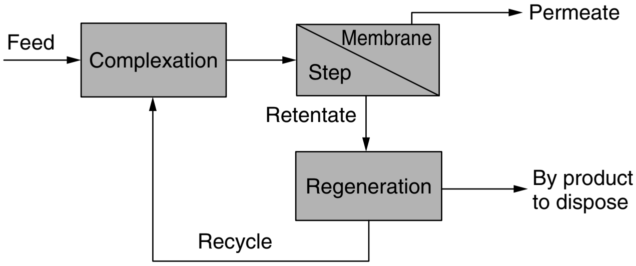

Figure 1. Flowsheet of PAUF separation process.

3. *Thermal regeneration* could be also possible if the polymer-metal bond can be cleaved by heating the retentate, but it has found no practical application so far.

SOME STUDIES OF PAUF IN THE REMOVAL OF METAL IONS FROM AQUEOUS SYSTEMS

In the following, attention will be focused on the application of the complexation-ultrafiltration process in the removal of the model ion copper(II) from aqueous systems, using water-soluble polymers as chelating agents.

Copper(II) Removal from Water by Using Polyethylenimine (30)

The mechanism of the water-soluble polymer PEI—copper interaction can be described by the previously reported equilibrium reactions (1) and (2). In those reactions, a competition exists between Cu^{2+} and H^+ for the polymer because, depending on pH, the PEI is able to complex copper ions by means of Eq. (2), but, at low pH, it stays in aqueous solution in the $PEIH_n^{n+}$ form incapable to interact with copper.

Thus, the first step in the application of the complexation ultrafiltration technique consists in the determination of optimal chemical conditions (pH) for copper complexation (bound) and de-complexation (release) at isothermal conditions (e.g., temperature of 25 °C). To quantify the copper-polyethylenimine (Cu-PEI) complex formation, the spectrophotometric technique was used by reading at 620 nm wavelength.

The complexation-decomplexation process was quantified by plotting vs. the pH the complexation percentage $C\% = (ABS/ABS_{max}) \times 100$, where ABS_{max} is the maximum value of the absorbance that corresponds the maximum amount of complex (100%). The results, reported in Fig. 2, show that PEI is able to complex copper ion at pH 6 or higher, whereas the decomplexation happens at pH < 3.

Similar results were obtained by working at different polymer concentrations observing that maximum binding pH does not depend on polymer concentration. This behavior agrees with the chemical mechanism of polymer-copper interactions (Eqs. 1–2). Indeed, at high pH, the complexation reaction (2) takes place.

To determine the binding capacity of PEI (maximum copper amount (mg) that can be complexed by a fixed amount (1 g) of polymer), some complexation tests were carried out with a polymer concentration of 150 mg/l and changing copper concentration at a fixed pH (~6). The obtained value of the binding capacity was 0.333 mg Cu^{2+}/mg PEI. It must be observed that a high-binding capacity means a lower cost of the PAUF process.

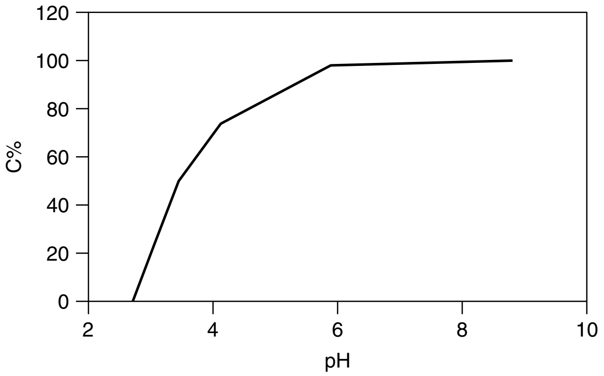

Figure 2. Cu-PEI complex formation $C\%(= (ABS/ABS_{max}) \times 100)$ vs pH in complexation tests of PEI (150 mg/l) with copper (50 mg/l).

Ultrafiltration tests were carried out by using five different membranes (Table 1), two operative transmembrane pressures (2 and 4 bar), pH ca. 6, and five different weight concentrations of PEI and Cu^{2+} with the same ratio (150/50, 270/90, 375/125, 480/160, 600/200).

Working at increasing PEI and Cu^{2+} concentrations and maintaining the same ratio, it is permitted to simulate the increase of retentate concentration in a hypothetical industrial plant where the permeate, free of metals, is withdrawn using the PAUF technique.

It was obtained that simultaneously increasing copper and polymer concentrations (ratio $PEI/Cu^{2+} = 3$ fixed) in the retentate, the separation efficiency (R%) decreased, resulting in an increase of copper and polymer concentrations in the permeate and a little decrease of permeate flux. As a result of increased concentration in the retentate, rejection first decreased, but then increased, because of the formation of a selective dynamic layer (by concentration polarization), which caused a little decrease of permeate flux too, because of mass transfer resistance increase.

It should be observed that an optimal PAUF process should produce a high permeate flux (J_P) and a low copper concentration (C_p). So, in order to compare membrane performances, an appropriate parameter Jp/Cp was introduced. This parameter has no dimensional significance, but it answers the previous requirements to optimize PAUF processes by choosing the membrane that gives the highest ratio.

To evaluate the possibility of polymer regeneration, some UF tests were carried out (operative conditions:

Table 1. Some Characteristics of the UF Membranes Tested in the PAUF Process

Membrane Type	Material	Cut-off (kDa)	Producer	Water Flux [l/h × m^2] (2–4 bar)
Iris 10	Poly ether sulphone (PES)	10	Tech-Sep	33.85–55.00
FS 40 PP	Fluoride-polypropylene	40	Dow	220.0–397.7
GR 40 PP	Polysulphone-polypropylene	40	Dow	220.0–444.3
Iris 30	Poly ether sulphone (PES)	30	Tech-Sep	114.2–207.3
PAN 40	Polyacrylonitrile	40	Tech-Sep	291.1–528.9

PEI = 150 ppm; Cu = 50 ppm; pH = 3) withdrawing the permeate at established time and analyzing copper and TOC (Total Organic Carbon) concentrations. Obtained data showed that all the copper passed through the membrane, whereas the polymer remained in the retentate (rejection of 95% with PAN 40 kDa membrane); that means a good possibility of polymer regeneration, recovery, and reuse.

Comparison of Copper(II) Removal from Waters by Using Various Polymers (21)

Some water-soluble polymers, such as polyetilenimine (PEI), polyacrylic acid (PAA), polyacrilic acid sodium salt (PAASS), and poly(dimethylamine–co–epichlorohydrin–co–ethylenediamine) (PDEHED) as chelating agents (Table 2), have been tested by using the Cu^{2+} as model ion.

Optimal Chemical Conditions. For PAA and PAASS, an ionic interactions mechanism, such as the equilibrium reactions (5) and (6), occurs. It is influenced by the pH: at low pH, the protonation of carboxylic group of the polymer is favored, whereas at higher pH complexation, the reaction is shifted right, meaning macromolecular complex formation with the metal ion. The interaction between the copolymer PDEHED and copper ion is more complicated: both the lone pair of the nitrogen in dimethylamine and ethylenediamine monomers and the oxygen of epichlorohydrin could bind copper with both complex bond and ionic interactions.

From Fig. 3 it can be observed that copper ion is complexed by PEI, PAA or PAASS, and PDEHED at pHs higher than 6, 4.6, and 8, respectively. The decomplexation reactions took place at pH < 3.

Binding capacity was 0.333 mg Cu^{2+}/mg polymer for PEI and PAA. At pH 8.5, working with a polymer concentration of 50 mg/l and changing copper concentration, a binding capacity of 2 mg Cu^{2+}/mg PDEHED was obtained; at higher ratios, a cloud solution was observed, probably because of limited complex solubility.

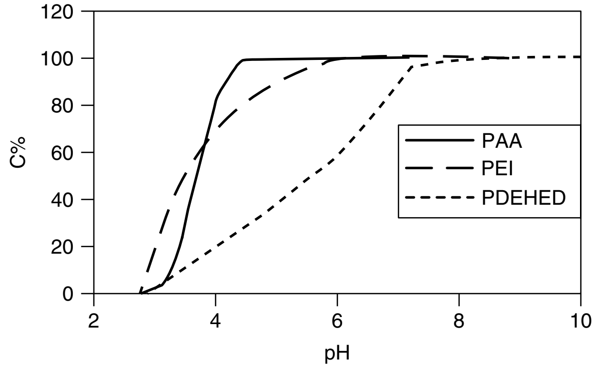

Figure 3. Comparison of Cu-polymer complex formation C% (= $(ABS/ABS_{max}) \times 100$) vs pH in complexation tests of PEI (150 mg/l), PAA (150 mg/l), and PDEHED (150 mg/l) with copper (50 mg/l).

Ultrafiltration Tests. Ultrafiltration tests were realized at two transmembrane pressures (2 and 4 bar), by using five different membranes, and determining flux and rejection. Copper concentration was fixed at 50 mg/l to simulate the treatment of the same pollution load.

The results, summarized in Table 3, show that the fluxes (J_P) obtained with the PDEHED are lower than that registered using PEI and PAA. Regarding the separation efficiency, measured by R%, this is in the order PDEHED > PAA > PEI. This behavior could be caused by the higher membrane fouling and/or polarization concentration caused by the copolymer.

Inspection of membranes at the end of the experimental runs showed a thin layer on the filtering surface: the cake was cerulean with the color of polymer-copper complexes, and it appeared like an incrustation in the case of PDEHED, whereas for PAA and PEI it was a simpler deposit easily removable.

The polymer PDEHED is useful if the objective of wastewater treatment is to obtain a complete copper removal. In opposition, the polymer PAA with the

membrane PAN GKSS HV2/T can be used when very low metal concentration is not required because of the higher flux (rejection 99.6% and permeate flux 275 l/h·m^2 at 2 bar). Indeed, it is better operating at transmembrane pressure of 2 bar rather than at 4 bar because the little increase of the permeate flux obtained at steady state for PEI and PAA polymers does not justify the higher costs (e.g., electrical energy and cooling).

Data of the optimization parameter J_p/C_p for the transmembrane pressure of 2 bar, for the PEI and PAA polymers, showed that PAN GKSS membranes gave the best combination of the two parameters. Furthermore, a higher J_p/C_p for PAA was registered, meaning more interesting performances in copper removal from waters. The optimization parameter for PDEHED has no practical significance, in this case, because of copper concentration next to the zero.

Membrane Washing and Reuse. The possibility of membrane reuse in the complexation-ultrafiltration process was evaluated by carrying out three UF runs in series by using the polymer PDEHED, which gave the highest fouling. Each run was composed by four steps in sequence:

1. membranes characterization;
2. UF test carried out until reaching steady-state conditions;
3. washing of membranes and system with tap water for 2 hours without recycle (open loop);
4. washing of membranes and system with 20 l of demineralized water without recycle; and
5. return to (1).

Steps 3 and 4 were carried out at maximum cross flow and minimum transmembrane pressure to avoid further cake compaction during membrane washing.

The results showed that, after a flux decrease was observed in the second run, membrane performance remained the same in the third run, which is interesting for a long-time use of the same membrane.

CONCLUSION

The experimental work available in the literature on the PAUF process show that satisfactory results were obtained by applying it in the separation and concentration of metallic cations from wastewaters. This technique combines both the advantages of classical adsorption (i.e., ion exchange and complexation interactions) method for metal removal from aqueous systems and of membrane processes.

The chemical fundamentals of the process have to be preliminarly studied in order to find the optimal chemical conditions of: 1) pH for the metal retention stage (complexation) and for the polymer regeneration stage (decomplexation) and 2) polymer-binding capacity (loading ratio = g metal/g polymer).

These results have to be transferred in the realization of the two stages of metal separation and recovery process: (1) metal retention, where a permeate stream free of heavy metals can be obtained, and (2) polymer regeneration, where the polymer is regenerated in order to be recycled.

Several factors influence the separation of the target substance, such as membrane type, composition of water to treat, pH, binding capacity of the polymer, polymer adsorption on the membrane (fouling), and hydrodynamics.

The complexation-ultrafiltration technique could be competitive in the near future provided a significant knowledge on the main process parameters are realized: (1) design and preparation of polymeric binding agents with the desired properties (good solubility, high selectivity, regeneration possibility, chemical and mechanical stability, low toxicity, high molecular weight with low viscosity, and low cost); (2) proper membrane choice; (3) accurate approach to the fluid dynamics and to the chemistry of the process; (4) appropriate study of polymer regeneration; and (5) appropriate study on membrane washing and reuse.

The complexation-ultrafiltration process is a relatively new separation technique, but the results reported in the literature clearly indicate its potential in wastewater treatment with some reasonable technological improvements.

ACID MINE DRAINAGE—EXTENT AND CHARACTER

ARTHUR W. ROSE
Pennsylvania State University
University Park, Pennsylvania

Acid mine drainage (AMD), also known as acid rock drainage (ARD), is an extensive environmental problem in areas of coal and metal mining. For example, the Appalachian Regional Commission (1) estimated that 5700 miles of streams in eight Appalachian states were seriously polluted by AMD. AMD is also serious near major metal mining districts such as Iron Mountain, CA and Summitville, CO (2,3). In streams affected by AMD, fish and stream biota are severely impacted and the waters are not usable for drinking or for many industrial purposes (4). In addition to deleterious effects of dissolved constituents (H^+, Fe, Al) on stream life, Fe and Al precipitates can cover the stream bed and inhibit stream life, and suspended precipitates can make the water unusable. In metal mining areas, heavy metals can add toxicity. General references on chemistry of AMD are Rose and Cravotta (5) and Nordstrom and Alpers (6).

CHEMISTRY OF FORMATION

AMD is formed by weathering of pyrite (FeS_2, iron sulfide) and other sulfide minerals, including marcasite (another form of FeS_2), pyrrhotite ($Fe_{1-x}S$), chalcopyrite ($CuFeS_2$), and arsenopyrite (FeAsS). The following reactions, involving oxygen as the oxidant, occur when pyrite is exposed to air and water:

$$FeS_2 + 3.5O_2 + H_2O = Fe^{2+} + 2SO_4{}^{2-} + 2H^+ \quad (1)$$

$$Fe^{2+} + 0.25O_2 + H^+ = Fe^{3+} + 0.5H_2O \quad (2)$$

$$Fe^{3+} + 3H_2O = Fe(OH)_3 + 3H^+ \quad (3)$$

The sum of these, representing complete oxidation and Fe precipitation, is

$$FeS_2 + 3.75O_2 + 3.5H_2O = Fe(OH)_3(s) + 2SO_4{}^{2-} + 4H^+ \quad (4)$$

In addition, the Fe^{3+} formed in Eq. 2 is a very effective oxidant of pyrite:

$$FeS_2 + 14Fe^{3+} + 8H_2O = 15Fe^{2+} + 2SO_4{}^{2-} + 16H^+ \quad (5)$$

These reactions also generate considerable heat, which tends to increase temperature and reaction rate.

In the above equations, the Fe precipitate is shown as $Fe(OH)_3$, but other ferric Fe phases can precipitate, depending on the conditions. Goethite (FeOOH), hematite (Fe_2O_3), ferrihydrite ($Fe_5HO_8{\cdot}4H_2O$), schwertmannite ($Fe_8O_8(OH)_6(SO_4)$), and jarosite ($KFe_3(SO_4)_2(OH)_6$) are among the products. The latter two products represent "stored acidity" that can react further to release additional acidity. Under evaporative conditions, $FeSO_4$ and other Fe sulfates can precipitate to form stored acidity.

Acid generation is dependent on a large number of factors, including the pH of the environment, temperature, the surface area of the pyrite or other source, the atomic structure of the pyrite, bacterial activities, and oxygen availability.

Oxidation of Fe^{2+} (Eq. 2) is relatively slow at pH below about 5. However, certain bacteria, such as Thiobacillus ferrooxidans, can catalyze the oxidation reaction under acid conditions. Bacterial action increases the reaction rate by a factor of about 10^6 (7). In addition, Fe^{3+}, the most effective oxidant via Eq. 4, has negligible solubility above about pH 3.5. As a result of these effects, severe AMD only develops in conditions where the water in contact with pyrite is highly acid and Fe-oxidizing bacteria are present (8). At higher pH, acid generation is relatively slow.

During natural weathering of pyrite-bearing rocks, the oxidation reactions happen slowly. In contrast, mining and other rock disturbances, such as road building, can result in greatly increased exposure of pyrite to oxidizing conditions, with resulting rapid acid generation. The water flowing from many underground mines is deficient in oxygen, and the above sequence proceeds only as far as reaction (1) [or perhaps reactions (1), (2) and (4)]. As a result, outflowing water contains elevated Fe^{2+} that oxidizes after it reaches the surface and generates additional acid owing to Fe precipitation after exposure to air. In such cases, pH can decrease downstream.

CHEMISTRY OF ACID MINE DRAINAGE

The H^+ generated by pyrite oxidation attacks various rock minerals, such as carbonates, silicates, and oxides, consuming some H^+ and releasing cations. For this reason, AMD commonly contains moderate to high levels of Ca, Mg, K, Al, Mn, and other cations balancing SO_4, the dominant anion. These reactions consume H^+ and increase the pH. If reaction with rock minerals is extensive, the resulting water may have a pH of 6 or even higher, and if oxidizing conditions exist, Fe may be relatively low. If carbonates are present in the affected rocks, the "AMD" may contain significant alkalinity as HCO_3. AMD is characterized by $SO_4{}^{2-}$ as the dominant anion but can have a wide range of pH, Fe, and other cations (Table 1).

The pH of AMD typically ranges from about 2.5 to 7, but the frequency distribution of pH is bimodal, with most common values in the range 2.5 to 4 and 5.5 to 6.5 (5). Relatively fewer values are in the range 4 to 5.5. An extreme value of negative 3.6 is reported (2). Common ranges of other constituents are up to 100 mg/L Fe, up to 50 mg/L Al, up to 140 mg/L Mn, and up to 4000 mg/L SO_4.

A key variable characterizing AMD is "acidity." Acidity is commonly expressed as the quantity of $CaCO_3$ required to neutralize the sample to a pH of 8.3 by reaction (8). The acidity includes the generation of H^+ by reactions (1) and (3), as well as the effects of other cations that generate

Table 1. Analyses of Typical "Acid Mine Drainage" (5)

Constituent	Units	WMB A1	WMS 2K	LMS S2-15
pH		2.6	4.2	6.9
Acidity	mg/L $CaCO_3$	688	270	0
Alkalinity	mg/L $CaCO_3$	0	0	730
Fe	mg/L	174	34	5.7
Mn	mg/L	25.5	67	7.5
Al	mg/L	68.9	26	<0.14
Ca	mg/L	83	270	650
Mg	mg/L	74	280	230
SO_4	mg/L	913	1600	1900
Spec. Cond.	μS/cm	2120	1860	3890

acidity at $pH < 8.3$, such as

$$Al^{3+} + 3H_2O = Al(OH)_3 + 3H^+ \quad (6)$$

In common AMD, acidity includes contributions from H^+, Fe^{2+} (Eqs. 2 and 3), Fe^{3+} (Eq. 3), Al^{3+}, and Mn^{2+}. To accurately measure the contribution of these solutes, the acidity determination should include a step in which Fe and Mn are oxidized, commonly by addition of H_2O_2 and heating (9,10). In waters from metal mining areas, other heavy metals, such as Cu, may contribute to acidity. Acidity of AMD from coal mining areas is commonly up to 1000 mg/L as $CaCO_3$.

THE CONTROL OF ALGAL POPULATIONS IN EUTROPHIC WATER BODIES

Dorchester, Dorset, United Kingdom

INTRODUCTION

Eutrophication is a natural aging process occurring in lakes and reservoirs, which is characterized by increasing nutrient levels in the water column and increasing rates of sedimentation. For water bodies in urban and agricultural landscapes, this process is accelerated by increased nutrient inputs from agricultural fertilizers, sewage effluents, and industrial discharges. Eutrophication is accompanied by increased macrophyte and algal populations, which, without appropriate management, can develop to nuisance proportions.

Algae are microscopic plants that can reproduce rapidly in favorable conditions. Some species can form scum or mats near or at the water surface. The presence of excessive algae can disrupt the use of a water body by restricting navigational and recreational activities and disrupting domestic and industrial water supplies. In particular, algal blooms can have a severe impact on water quality, causing noxious odors, tastes, discoloration, and turbidity. Blue-green algal blooms are particularly undesirable due to their potential toxicity to humans, farm livestock, and wild animals. In addition, algae may block sluices and filters in water treatment plants and reduce water flow rates, which may in turn encourage mosquitoes and increase the risk of waterborne diseases such as malaria and bilharzia (schistosomiasis). Ultimately, the presence of excessive algal populations will limit light penetration through the water column, thus inhibiting macrophyte growth and leading to reduced biodiversity.

Methods for controlling algal populations can be divided into categories as follows:

1. Environmental methods involve limiting those factors, such as nutrients, that are essential for algal growth.
2. Chemical methods involve the application of herbicides, or other products such as barley straw, that have a direct toxic effect on algae.
3. Biomanipulation involves the control of zooplanktivorous fish to favor algal grazing by invertebrates and also describes the use of microbial products.

ENVIRONMENTAL METHODS

As algae are dependent on the availability of limiting nutrients required for growth, namely, phosphorus and occasionally nitrogen, the long-term control of algal populations requires measures to reduce the entry of nutrients from external sources and to reduce the internal release of nutrients from sediments.

Nutrients may enter water bodies from point sources, such as sewage and industrial effluents, and diffuse sources, such as runoff from agricultural land following the application of animal slurries or fertilizers. Methods for reducing external nutrient loading from point sources include diversion, effluent treatment, or installation of artificial wetlands. Methods for reducing loading from diffuse sources include buffer strips and adoption of good agricultural practice.

For many shallow water bodies, attempts to reduce external loading have been less successful due to the internal release of phosphate from the sediment, which delays the decline in the total phosphorus load. Under these circumstances, the successful management of algae requires simultaneous measures to reduce internal phosphate cycling. Techniques available for this purpose include dilution and flushing, hypolimnetic withdrawal, hypolimnetic aeration, artificial circulation, phosphorus inactivation, sediment oxidation, sediment sealing, and sediment removal.

A brief description of each method for reducing external and internal nutrient loading is provided below.

Diversion

Nutrient inputs can be reduced by the diversion of effluents away from vulnerable water bodies to water courses that have greater assimilative capacity. This option is only viable where there is an alternative sink within the vicinity of the affected water body as construction of pipe work to transport water over long distances is prohibitively expensive. Diversion also reduces the volume of water flushing through the water body and, therefore, may not be viable if such a reduction is predicted to significantly affect water body hydrology. Examples where diversion has successfully reduced external phosphate loading, leading to reductions in algal biomass, include Lake Washington in the United States (1). In this case, total phosphorus concentrations were reduced from 64 μg/L prior to diversion in 1967, to 25 μg/L in 1969. This reduction was accompanied by a fivefold decrease in the concentration of chlorophyll *a* over the same period.

Effluent Treatment

Reductions in external nutrient loading can be achieved by removing phosphate and/or nitrates from effluents, prior to their discharge. Phosphorus can be removed from raw sewage or, more commonly, final effluents, by the process of stripping, which involves precipitation by treatment with aluminum sulfate, calcium carbonate, or ferric chloride. The resulting sludge is spread onto land or transferred to a waste-tip. In contrast, removal of nitrates from effluents is more complex requiring the use of ion exchange resins or microbial denitrification. The process of phosphate stripping is a requirement of the Urban Waste Water Treatment Directive in some European countries including Switzerland and The Netherlands. Phosphate stripping has successfully reduced algal biomass in Lake Windermere in the United Kingdom. In this case, total internal phosphate concentrations were reduced from 30 μg/L in 1991 to 14 μg/L in 1997, while biomass of the filamentous algae, *Cladophora*, was reduced by 15-fold between 1993 and 1997 (2).

Constructed Wetlands

External nutrient loads may also be reduced by passing effluents through detention basins or constructed wetlands, which are areas of shallow water, planted with macrophytes, that are designed to retain and reduce nutrient concentrations by natural processes. Wetlands are particularly effective for reducing nitrate concentrations by denitrification and retaining phosphorus that is bound to particles. However, they will not permanently retain soluble phosphorus and may release phosphorus from sediments at certain times of year. The development of artificial wetland systems can also be prohibitively expensive as they require large areas of land and regular maintenance, including sediment dredging and macrophyte harvest, to remain efficient. An example where constructed wetlands have been developed as part of a lake restoration scheme is provided by Annadotter et al. (3).

Good Agricultural Practice and Buffer Strips

External nutrient loading from diffuse agricultural sources can be reduced by the adoption of good agricultural practices designed to minimize fertilizer use and reduce runoff into adjacent water courses. Strategies for reducing nutrient inputs include minimizing fertilizer applications, where possible, and using slow-release formulations. Measures to minimize opportunities for runoff include avoiding applications in wet weather, incorporating fertilizer into soil by ploughing after application, maintaining ground cover for as long as possible to minimize exposure of bare ground to rainfall, and, finally, ploughing along contours.

Nutrient loading from diffuse sources can also be reduced by the creation of buffer strips between cultivated land and vulnerable water courses, in which fertilizer applications are prohibited. The development of semi-natural vegetation within these strips will also serve to intercept and assimilate the nutrients in runoff, as described for constructed wetlands (4). Under current legislation in the European Union, buffer strips are only mandatory in situations where they are essential for protecting drinking water supplies from nitrate inputs and, in particular, in areas where drinking water abstractions have concentrations exceeding 50 mg nitrate per liter. As nitrate concentrations that contribute to eutrophication are much lower than 50 mg/L, this legislation is unlikely to assist in the control of algae. Various schemes exist at member state level to promote adoption of buffer strips as a normal farming practice although experience in the United Kingdom indicates that such schemes have not been widely adopted.

Dilution and Flushing

Dilution and flushing involve the influx of large volumes of low nutrient water into the affected water body, thus diluting and therefore reducing nutrient concentrations, and washing algal cells out of the water body. This approach is dependent on the availability of large volumes of low nutrient water and systems for its transport to the affected water body. Examples where dilution has been successfully used to control algae include Green Lake in Washington State (USA). In this case, phosphorus and chlorophyll *a* concentrations were reduced by 70% and 90%, respectively, within six years of initiation of dilution (5).

Phosphorus Precipitation from the Water Column

Surface water concentrations of phosphorus can be reduced by the application of aluminum salts to the water column. At water pH values between 6 and 8, these salts dissociate and undergo hydrolysis to form aluminum hydroxide, which is capable of binding inorganic phosphorus. The resulting floc settles to the bottom of the water body, where the precipitated phosphorus is retained. The precipitate also effectively seals the sediment, thus retarding the further release of phosphorus from the sediment. At pH values below 6 or above 8, the aluminum exists as soluble ions that do not bind phosphorus. As well as being ineffective for phosphorus precipitation, these forms of aluminum present a toxic hazard to fish and aquatic invertebrates. Therefore, the successful and safe use of aluminum salts requires careful calculation of the necessary dose based on water pH and may require the use of a buffer solution such as sodium aluminate. This technique is widely used in eutrophic water bodies and Welch and Cooke (6) report several case studies. Effects are typically rapid and have been reported to reduce phosphorus release from sediments for between ten and fifteen years, although the effectiveness and longevity of the treatment may be compromised by natural sedimentation and benthic invertebrate activity.

Alternatively, phosphorus can be precipitated from the water column by the application of iron or calcium salts. These salts do not pose such a toxicity hazard as aluminum but their successful use often requires additional management techniques such as aeration or artificial circulation in order to maintain the necessary water pH and redox conditions. Consequently, the use of iron and calcium salts is less widely reported (7,8).

Hypolimnetic Withdrawal, Aeration, and Artificial Circulation

The release of phosphorus from sediment can be inhibited by increasing the concentration of dissolved oxygen in hypolimnetic waters at the water–sediment interface. The hypolimnion is the layer of water directly above the sediment, which, in thermally stratified water bodies, is usually too deep to support photosynthesis. Continued respiration leads to depletion of dissolved oxygen and the concomitant release of phosphorus from iron complexes. In stratified lakes with low resistance to mixing, wind action and the resulting turbulence may cause temporary destratification and movement of phosphorus from the hypolimnion, through the metalimnion, and into the upper epilimnion layers. In susceptible water bodies, this natural process can be circumvented by implementation of hypolimnetic withdrawal, aeration, or artificial circulation processes. By default, these approaches have the advantage of extending the habitat available for colonization by fish and zooplankton.

Hypolimnetic withdrawal involves the removal of water directly from the hypolimnion through a pipe installed at the bottom of the water body. This process requires low capital investment and reduces the detention times of water in the hypolimnion, thus reducing the opportunity for the development of anaerobic conditions. The successful implementation of these systems depends on the availability of a suitable sink for discharge waters and measures to avoid thermal destratification, caused by epilimnetic waters being drawn downward, which would otherwise encourage the transport of hypolimnetic nutrients to surface waters. This risk can be reduced by careful control of the rate of withdrawal and redirection of inlet water to the metalimnion or hypolimnion. Examples where hypolimnetic withdrawal systems have been installed in lakes are reported by Nurnberg (9).

Aeration of the hypolimnion can be achieved by mechanical agitation, whereby hypolimnetic waters are pumped onshore where the water is aerated by agitation before being returned to the hypolimnion. More usually, the hypolimnion is aerated using airlift or injection systems, which use compressed air to force hypolimnetic waters to the surface where they are aerated on exposure to the atmosphere. Water is then returned to the hypolimnion with minimal increase in temperature. In contrast, artificial circulation involves mechanical mixing of anaerobic hypolimnetic water with the upper water body using pumps, jets, and bubbled air. By default, complete circulation causes destratification of the water body, with potential adverse consequences for cold water fish species, but may also serve to reduce the concentration of algal cells in the upper water body by increasing the mixing depth and relocating algal biomass to deeper water with reduced light availability (10). Detailed examples of these processes are provided by Cooke et al. (5).

Sediment Oxidation

The release of phosphorus from sediment can also be inhibited by oxidation of sediment by the “Riplox” process. This process involves the direct injection of calcium nitrate solutions into the sediment in order to stimulate microbial denitrification and thus restore an oxidized state, conducive to the binding of interstitial phosphate with ferric hydroxide. In some cases, where the inherent iron content of the sediment is inadequate, iron chloride is initially added to generate ferric iron. Similarly, calcium hydroxide may also be added in order to raise the sediment pH to levels required for optimum microbial activity (11). This process has been documented to reduce phosphate release by up to 90% under laboratory conditions and by 50–80% following the treatment of Lake Noon in the United States (5). However, sediment oxidation is only suitable for water bodies where phosphate binding is modulated by iron redox reactions. In shallow water bodies where phosphate release is predominantly influenced by fluctuating pH and temperature at the water–sediment interface, sediment oxidation may not significantly reduce phosphorus release.

Sediment Sealing

Sediment sealing involves the physical isolation of the sediment from the water column using plastic membranes or a layer of pulverized fly ash, a solid waste product from coal-burning power stations. These techniques may prove effective at reducing algal biomass in small enclosures used for recreational purposes or industrial water supplies but are unsuitable for conservation or restoration purposes, as fly-ash may contain high levels of undesirable heavy metals and open sediment is required to support aquatic plant growth (12).

Sediment Removal

The release of nutrients from the sediment can be averted by sediment removal either using conventional excavation equipment after drawdown or using a suction-dredger and pump. In both cases, the resulting wet sediment is then transferred to a suitable disposal site. Direct dredging is more commonly practiced but has the disadvantage that phosphates or other toxins adsorbed to sediment may be released into the water column when sediment is disturbed. Furthermore, benthic organisms will inevitably be disturbed and removed during dredging, although recolonization will mitigate any long-term effects. Examples where sediment removal projects have been implemented include Lake Finjasjon in Sweden and the Norfolk Broads in the United Kingdom (3,13).

CHEMICAL METHODS

Herbicides

The availability of aquatic herbicides has been limited by their small market value and the stringent toxicological and technical challenges presented by the aquatic environment. Aquatic herbicides, particularly those used to control algae, must be absorbed rapidly from dilute and often flowing aqueous solution. More recently, the number of products available for use in water has been reduced by the prohibitive cost of meeting the increasingly stringent requirements of pesticide registration. In 2004, the few products that remain on the market for use on a large scale are based on the active ingredients of copper, diquat, endothall, and terbutryn. Additional products based on other active ingredients are available for amateur use in enclosed garden ponds but are not registered for use in larger water bodies.

Use of herbicides to control algal blooms is often limited where water is required for domestic drinking water supply or for the irrigation of crops or livestock. Their use under these circumstances requires strict adherence to label recommendations and observation of recommended irrigation intervals. Despite these restrictions, chemical control may be preferable where immediate control is required or alternative, long-term measures are prohibited due to excessive cost.

Herbicide applications to water are generally made using hand-operated knapsack sprayers operated from bank or boat, or spray booms mounted to boats, tractors, helicopters, or planes. Much of this equipment is modified from conventional agricultural sprayers and nozzles, although the injection of herbicides into deep water or onto channel beds may require the use of weighted, trailing hoses fitted to boat-mounted spray booms.

Disadvantages associated with the use of herbicides include potential adverse effects on nontarget organisms including aquatic invertebrates and fish, development of herbicide-resistant algal strains, and excessive copper accumulation in treatment plant sludges, which may lead to disposal problems. The control of algae with herbicides can also create large quantities of decaying tissue, which cause deoxygenation of the water due to a high bacterial oxygen demand. This may lead to the death of fish and other aquatic organisms, particularly during summer months when deoxygenation is more rapid due to lower dissolved oxygen levels and increased rates of decomposition caused by higher water temperatures. Deoxygenation can largely be avoided by restricting applications to the early growing season. Where later treatments are essential, applications should be restricted to discrete localized areas of a water body, or slow-release formulations should be used to avoid a sudden buildup of decaying tissue.

Barley Straw

Research in the United Kingdom has led to the use of barley straw for the control and prevention of algal blooms in a range of water bodies including lakes, reservoirs, rivers, streams, and ponds (14). During decomposition, barley straw is known to release compounds, including active oxygen and hydrogen peroxide, which are toxic to algae (15). Although similar effects have been demonstrated with wheat, linseed, oil-seed rape, and lavender straw, barley straw provides the most effective and long-lasting control. For effective control, chopped straw is typically added to the water in loosely packed bales enclosed in mesh sacks, netting, or wire cages that are anchored to the bank or to the bottom of the water body. Depending on the type of water body and the severity of the algal bloom, typical application rates vary between 100 and 500 kg/ha. In order to promote the decomposition process and the release and distribution of the algicidal components, bales should be positioned at, or near, the water surface where water temperatures, movement, and aeration are the greatest. Depending on water temperature, the decomposition process may continue for 2–8 weeks after application before the straw releases sufficient quantities of the active components to cause an effect. These chemicals continue to be released until decomposition is complete, which may take up to six months. Therefore, for maximum efficacy, straw is typically applied in spring before algal blooms reach their peak and again in the autumn.

The use of straw has few, if any, adverse effects on nontarget organisms such as macrophytes, invertebrates, or fish. The main disadvantage associated with its use is the risk of deoxygenation caused by the high bacterial oxygen demand of those microorganisms responsible for straw decomposition. Deoxygenation may lead to the death of fish and other aquatic organisms, particularly during summer months when rates of decomposition are increased due to higher water temperatures. This risk can be reduced by early application during the spring and avoiding applications during prolonged periods of hot weather.

BIOMANIPULATION

Removal of Zooplanktivorous Fish

Algal populations may be controlled through the biomanipulation of foodwebs to favor algal grazing by invertebrates, by removing fish (16). Methods for the direct removal of fish include application of the piscicide, rotenone, to anesthetize fish prior to removal or to kill them outright. However, use of rotenone for this purpose is discouraged in some countries, including the United Kingdom, and requires special consent from the appropriate government authority. Alternative methods for fish removal include systematic electrofishing, seine netting, and fish traps. In smaller water bodies, drawdown may be used to concentrate fish into increasingly smaller water volumes to simplify their capture. Even where complete drawdown is possible, elimination of all fish is unlikely and additional measures may be necessary to prevent successful spawning of remaining fish. Spawning can be prevented by nets, placed in traditional spawning areas, to capture eggs, which are then removed.

The long-term success of fish removal schemes also requires measures to prevent recolonization from tributaries and floodwaters. In cases where water can be diverted and tributaries do not carry boat traffic, isolation of water bodies may be possible by the construction of dams. Where boat traffic requires access, the installation of electronic netting gates, which automatically lower to allow access, or engineered locks, which dose the water with rotenone on opening, may be required (12). Recolonization can also be avoided by creating fish-free enclosures, using fishproof barriers, within affected water bodies. Once restoration is complete within an enclosure, more enclosures may be built and eventually joined together until a large proportion of the water body is enclosed. This approach was used during the restoration of Hoveton Broad in the United Kingdom (12).

Alternative methods to control fish populations involve the introduction of piscivorous fish, such as pike or pikeperch in the United Kingdom or American large-mouthed bass in the United States. The addition of piscivores can have immediate and dramatic impacts on invertebrate populations and has been practiced as part of restoration schemes in Lake Lyne in Denmark and Lakes Zwemlust and Breukeleveen in The Netherlands (12). However, the success of this approach is unlikely to be sustained without regular restocking as predation of the fish population will invariably lead to a decline in the piscivore population.

Microbial Products

The use of bacteria to control algal populations is a recent innovation adapted from the wastewater industry. As bacteria have a high surface area to volume ratio and a high uptake rate for nutrients relative to unicellular algae, they can out-compete algae for limiting nutrients, such as nitrogen and phosphorus, and have been demonstrated to suppress the growth of algal cultures under laboratory conditions (17). This observation has led to the commercial development of microbial products, containing bacteria and enzymes, that are designed to supplement natural microbial populations to the levels required to have a significant impact on algae. The number of available products has increased as the use of chemical algicides has become more restricted. However, few researchers report a significant reduction in algal growth following the use of microbial products under experimental conditions and their use on a large scale has yet to be widely documented (18).

CONCLUSIONS

While chemical control methods, such as the application of herbicides or barley straw, can provide rapid, short-term reductions in algal populations, the long-term and sustainable management of algae requires consideration of the cause and source of eutrophication and the implementation of techniques to reduce nutrient loading and to restore natural foodweb interactions. Evaluation of the suitability of the techniques discussed here, for use in individual cases, requires detailed assessments to determine the trophic status of the affected water body and, in particular, the relative contribution of point source, diffuse, and internal nutrient sources to total nutrient concentrations. Only when the causes of eutrophication are clearly identified can the symptom of excessive algal growth be efficiently managed.

ARSENIC COMPOUNDS IN WATER

CORINNA WATT
X. CHRIS LE
University of Alberta
Edmonton, Alberta, Canada

Arsenic is the twentieth most abundant element in the earth's crust; it occurs naturally in the environment in both inorganic and organic forms. Arsenic is also released to the environment by anthropogenic activities such as pesticide use, wood preservation, mining, and smelting. Human exposure to arsenic by the general population occurs primarily from drinking water and food. In areas of endemic arsenic poisoning such as Bangladesh, India, Inner Mongolia, and Taiwan, the main exposure is through drinking water where inorganic arsenic levels can reach concentrations in the hundreds or thousands of micrograms per liter. The arsenic is released from natural mineral deposits into the groundwater in endemic areas. Groundwater is the primary drinking water source in these areas.

Arsenic is present in a variety of inorganic and organic chemical forms in water. This is a result of chemical and biological transformations in the aquatic environment. The specific arsenic compound present determines its toxicity, biogeochemical behavior, and environmental fate.

In natural waters, arsenic is typically found in the +5 and +3 oxidation states (1–6). The most common arsenic compounds detected in water are arsenite (As^{III}) and arsenate (As^{V}). Monomethylarsonic acid (MMA^{V}), monomethylarsonous acid (MMA^{III}), dimethylarsinic acid (DMA^{V}), dimethylarsinous acid (DMA^{III}), and trimethylarsine oxide (TMAO) have also been detected in water (Table 1). Several reviews provide important additional information regarding the cycling and speciation of arsenic in water and the environment (1,3,4,7–12).

Arsenic and arsenic compounds are classified as Group 1 carcinogens in humans by the International Agency for Research on Cancer (IARC). "The agent (mixture) is carcinogenic to humans" and "the exposure circumstance entails exposures that are carcinogenic to humans" (13). Chronic exposure to high levels of arsenic in drinking water has been linked to skin cancer, bladder cancer, and lung cancer, as well as to several noncancerous effects (8,11,14). Noncancerous effects from arsenic exposure include skin lesions, peripheral vascular disease (blackfoot disease), hypertension, diabetes, ischemic heart disease, anemia, and various neurological and respiratory effects (8,11,14). The reproductive and developmental effects of arsenic exposure have also been reported (14). The National Research Council and the World Health Organization have reviewed the most significant studies on arsenic exposure, toxicity, and metabolism (8,11,14). The association of arsenic with internal cancers has led to increased pressure for stricter guidelines for arsenic in drinking water.

Table 1. Arsenic Species Present in Water

Arsenic Species	Chemical Abbreviation	Chemical Formula
Arsenite, arsenous acid	As^{III}	H_3AsO_3
Arsenate, arsenic acid	As^{V}	H_3AsO_4
Monomethylarsonic acid	MMA^{V}	$CH_3AsO(OH)_2$
Monomethylarsonous acid	MMA^{III}	$CH_3As(OH)_2[CH_3AsO]$
Dimethylarsinic acid	DMA^{V}	$(CH_3)_2AsO(OH)$
Dimethylarsinous acid	DMA^{III}	$(CH_3)_2AsOH$ $[((CH_3)_2As)_2O]$
Trimethylarsenic compounds	TMA	$(CH_3)_3As$ and precursors
Trimethylarsine oxide	TMAO	$(CH_3)_3AsO$
Oxythioarsenic acid		H_3AsO_3S

The World Health Organization (WHO) guideline for arsenic in drinking water is 10 μg/L. The Canadian guideline is 25 μg/L and is currently under review. The United States has recently lowered its maximum contaminant level (MCL) for arsenic in drinking water from 50 μg/L to 10 μg/L. The previous MCL was established as a Public Health Service standard in 1942 and was adopted as the interim standard by the U.S. Environmental Protection Agency (EPA) in 1975. The Safe Drinking Water Act (SDWA) Amendments of 1986 required the EPA to finalize its enforceable MCL by 1989. The EPA was not able to meet this request partly because of the scientific uncertainties and controversies associated with the chronic toxicity of arsenic. The SDWA Amendments of 1996 require that the EPA propose a standard for arsenic by January 2000 and promulgate a final standard by January 2001. In 1996, the EPA requested that the National Research Council review the available arsenic toxicity data and evaluate the EPA's 1988 risk assessment for arsenic in drinking water. The National Research Council Subcommittee on Arsenic in Drinking Water advised in its 1999 report that, based on available evidence, the MCL should be lowered from 50 μg/L (8). After much debate on what would be an appropriate MCL (3, 5, 10, or 20 μg/L), the EPA published its final rule of 10 μg/L in January 2001 under the Clinton administration. This was initially rescinded by the Bush administration. The reasons cited for this rejection were the high cost of compliance and incomplete scientific studies. In 2001, the National Research Council organized another subcommittee to review new research findings on arsenic health effects and to update its 1999 report on arsenic in drinking water (14). This second subcommittee concluded that "recent studies and analyses enhance the confidence in risk estimates that suggest chronic arsenic exposure is associated with an increased incidence of bladder and lung cancer at arsenic concentrations in drinking water that are below the MCL of 50 μg/L" (14). The MCL of 10 μg/L was approved later by the EPA and became effective in February 2002. The date for compliance has been set at January 23, 2006.

Most controversies over an appropriate MCL arise from a lack of clear understanding of the effects on health from exposure to low levels of arsenic. There are limited studies available that have examined the increased risk of cancer at low levels of arsenic exposure. Therefore, the National Research Council and the EPA had to base their assessments on epidemiological studies where the arsenic exposure is very high (8,11,14). Extrapolation of health effects from very high exposure data to the much lower exposure scenarios involves large uncertainties. Experimental animal studies were also consulted as well as the available human susceptibility information (8,14). Animal studies are of limited value when examining arsenic effects in humans because of differences in sensitivity and metabolism. Experimental animals are often exposed to very large doses of arsenic that are not representative of typical human exposure. In addition, the studies used to establish the new MCL do not take into account arsenic exposure through food intake and other beverages. Other confounding factors may include nutrition, metabolism, and predetermined genetic susceptibility (8,14).

The exact mechanism of arsenic's tumorigenicity is not clear. Therefore it is difficult to ascertain the risk of cancers from very low exposures to arsenic. Due to the limited information on the cancer risks posed by low-level arsenic exposure and to the unknown shape of the dose–response curve at low doses, the EPA used a default linear dose–response model to calculate the cancer risk. The linear extrapolation to zero assumes that there is no safe threshold of exposure at which health effects will not occur, whereas others argue that a safe threshold level or sublinear dose–response relationship may exist.

The cost of compliance with a lower MCL and the monitoring and treatment technology are other important considerations in setting the new MCL. According to the EPA, water systems that serve 13 million people and representing 5% of all systems in the United States would have to take corrective action at an MCL of 10 μg/L (15). However, the EPA believes that the new MCL "maximizes health risk reduction at a cost justified by the benefits" (15).

INORGANIC ARSENIC

As^{III} and As^{V} are the dominant arsenic species detected in most natural waters. As^{III} and As^{V} have been detected in all forms of natural water including groundwater, freshwater, and seawater (Table 2). In oxygen-rich waters of high redox potential, the As^{V} species H_3AsO_4, $H_2AsO_4^{-}$, $HAsO_4^{2-}$, and AsO_4^{3-} are stable (1,4). As^{III} species, which exist in reduced waters, may include H_3AsO_3, $H_2AsO_3^{-}$, and $HAsO_3^{2-}$ (1,4). However, in most natural waters, As^{III} is present as H_3AsO_3 (as its pK_a values are 9.23, 12.13, and 13.4) (8,16). The pK_a values of As^{V} are 2.22, 6.98, and 11.53 (8). At natural pH values, arsenate is usually present as $H_2AsO_4^{-}$ and $HAsO_4^{2-}$ (1,4,16).

The distribution of As^{V} and As^{III} throughout the water column varies with the season due to changes in variables such as temperature, biotic composition, pH, and redox potential (4,17–28). Biological activity also contributes to changes in speciation (1,3,4,6,20,22–24,29–39). The uptake of As^{V} by phytoplankton and marine animals results in the reduction of As^{V} to As^{III} and the formation of methylated arsenic compounds (4,19,23,24,29,32,34,37–42).

As^{V} is typically dominant in oxygen-rich conditions and positive redox potentials (4,6,33,43,44). As^{V} has been detected as the predominant species in most natural waters (Table 2). As^{III} is expected to dominate in anaerobic environments (4,7,10,25,33,45). As^{III} has been detected as the predominant species in groundwater (46–48) and is significant in the photic zone of seawater (43,45,49). As^{III} has also been associated with anoxic conditions in estuaries (31,50), seawater (33,43), and marine interstitial water (6,30). In lake interstitial water, 55% of the dissolved arsenic was present as arsenite and a few percent as DMA^{V} (51).

The As^{III}/As^{V} ratio typically does not reach thermodynamic equilibrium (1,4,6,20,24,33,50,52,53). This reflects biological mediation. The kinetics of the As^{V}–As^{III}

transformation in natural waters is also known to be chemically slow (5,33,37,52,53). As a result, As^{III} has been observed in oxic waters, and As^{V} has been found in highly sulfidic water (25), contradictory to thermodynamic predictions. As^{III} was present in higher than expected amounts in the oxic epilimnion of the Davis Creek Reservoir (20). As^{III} has been detected in the oxic surface waters of lakes (24,53) and seawater (45,54). As^{V} has also been detected in anoxic zones (24,33,43,53).

The instability of arsenic species in water samples and the procedures used for sample handling and analysis may be the reason that As^{V} is commonly reported as the predominant species in water. Oxidation of As^{III} to As^{V} can occur during sample handling and storage. As^{III} may be present in higher concentrations in groundwater than previously reported (7). Many methods for preservation have been tested to prevent oxidation of As^{III} to As^{V} (55–60). On-site methods of analysis have been developed to avoid the need for preservation (61,62). As^{III} was determined as the predominant species in most groundwater samples measured from tanks and wells in Hanford, Michigan (47). In thirteen of sixteen wells and three of four tanks, As^{III} was present as $86 \pm 6\%$ of the total arsenic (47).

METHYLATED ARSENIC COMPOUNDS

Biological mediation is primarily responsible for the production and distribution of methylated arsenic species (1,3,4,6,19,22,29,31,34,35,37,42,43,45,49,63). MMA^{V}, MMA^{III}, DMA^{V}, DMA^{III}, and TMAO are the methylarsenicals present in natural waters (Table 3). It is estimated that methylarsenicals account for approximately 10% of the arsenic in the ocean (43). Methylarsenicals accounted for up to 59% of the total arsenic in lakes and estuaries in California (20). The pK_a values of MMA^{V} are 4.1 and 8.7, and the pK_a of DMA^{V} is 6.2 (8). At neutral pH, MMA^{V} occurs as $CH_3AsOOHO^-$ and DMA^{V} occurs as $(CH_3)_2AsOO^-$ (4). Trimethylarsenic (TMA) species have also been detected in some natural waters (Table 3). In the contaminated Tagus Estuary, trimethylarsenic was present at 0.010–0.042 μg/L (67). TMAO has been detected in marine interstitial waters (30) but not in surface waters (34). Methylated arsenic species are at a maximum in the euphotic zone of seawater (36,39,43). Similar to inorganic arsenic, the distribution of methylarsenicals is affected by seasonal changes in natural waters (19,20,22–24,27,32,64–66). Methylarsenicals usually occur predominantly in the pentavalent (+5) oxidation state (4).

Pentavalent arsenic species (As^{V}, MMA^{V}, DMA^{V}, and TMAO) are chemically or biologically reduced to trivalent arsenic species (As^{III}, MMA^{III}, and DMA^{III}), and biological methylation results in methylarsenicals. MMA^{III} and DMA^{III} are intermediates in the two-step methylation process. MMA^{III} and DMA^{III} appeared in minor fractions in Lake Biwa (eutrophic zone), Japan, and DMA^{V} was dominant in the summer (28,64).

PARTICULATE ARSENIC

In oxidizing conditions, As^{V} becomes associated with particulate material and may be released in reducing conditions. The amount of arsenic adsorbed to particulate can be substantial (62,68,69). The failure to account for arsenic in particulate results in an underestimation of total arsenic and inefficient treatment and removal of arsenic in water. The particulate matter in natural waters may occur as undissolved mineral (1,4,10) and organic species (70,71). As^{V} readily adsorbs and/or coprecipitates onto Fe^{III} oxyhydroxide particles (1,4,8,10,16,71). As^{V} and As^{III} can also react with sulfide ions to form insoluble arsenic sulfide precipitates (1,8,10,16,72,73). Under highly reducing conditions, the organic/sulfide fraction predominates (16,73).

In groundwater samples in the United States, particulate arsenic accounted for more than 50% of the total arsenic in 30% of the samples collected (69). In the Nile Delta Lakes, the arsenic budget consisted of 1.2–18.2 μg/L dissolved arsenic and between 1.2 and 8.7 μg/g of particulate arsenic (73). Significant amounts of particulate arsenic have also been detected in estuaries and coastal waters (17,23,70). In the drainage waters of an area impacted by mine wastes, particulate matter was greater than 220 times more concentrated than dissolved arsenic. Suspended matter in the deep water of Lake Washington contained up to 300 mg/g arsenic in the summer (51). In the Gironde Estuary, arsenic-containing suspended particulate matter varied with depth (5.1–26.8 μg/g) (29). The level of arsenic in phytoplankton was estimated at 6 μg/g compared to 20–30 μg/g in iron-rich and aluminum-rich terrigenous particles (29).

UNCHARACTERIZED ARSENIC SPECIES

Substantial amounts of arsenic species remain to be characterized. There are many reports of unidentified arsenic species in water (8,21,29,34,74–78). After UV irradiation of surface water from Uranouchi Inlet, Japan, the inorganic arsenic and dimethylarsenic concentrations detected by hydride generation increased rapidly (75). The UV-labile arsenic fractions represented 15–45% and 4–26% of the total dissolved arsenic in Uranouchi Inlet and Lake Biwa, respectively. In sediment porewater of Yellowknife, Canada, there was an increase of 18–420% in total dissolved arsenic concentration observed after irradiation (74). The difference between the sum of known arsenic species and total arsenic in the euphotic layer of an estuary was 13% (29).

In coastal waters, the concentration of total dissolved arsenic increased by approximately 25% following UV irradiation of the samples (78). In a National Research Council of Canada river water standard reference material, approximately 22% of the arsenic was unidentified (76). In estuarine waters, uncharacterized arsenic compounds corresponded to approximately 20% and 19% of the total arsenic content in summer and winter samples, respectively (77). Identification of these compounds is necessary to complete our understanding of the biogeochemical cycling of arsenic in the environment.

ARSENOTHIOLS

There is limited evidence that the precursors to methylarsine species detected by hydride generation may

be arsenic/sulfur compounds (40,74,79). Arsenic/sulfur compounds could dominate in reducing environments (4,34). The presence of arsenothiols in lake sediment porewater has been suggested (74). The presence of oxythioarsenate, $[H_3As^VO_3S]$, in water from an arsenic-rich, reducing environment has been demonstrated (80).

CONCLUDING REMARKS

Ingestion of arsenic from drinking water is a risk factor for several cancers and noncancerous health effects. Arsenic occurs naturally in the environment. Both inorganic and methylated arsenic species have been detected in aquatic systems. Inorganic As^V and As^{III} are predominant in most natural waters; methylated arsenic species occur at lower concentrations. Arsenothiols and uncharacterized arsenic species are also present in some aqueous environments. The relative abundance of various arsenic species in natural waters depends on both biological activity and chemical parameters, such as redox potential and pH.

ARSENIC HEALTH EFFECTS

I. Katsoyiannis
A.I Zouboulis
Aristotle University of
Thessaloniki
Thessaloniki, Greece

INTRODUCTION

The toxicity of inorganic arsenic species depends mainly on their valence state (usually −3, +3, or +5) and also on the specific physical and chemical properties of the compounds in which it occurs. Trivalent (arsenite, As^{III}) compounds are generally more toxic than pentavalent (arsenate, As^{V}) compounds, whereas arsenic compounds that are more soluble in water usually are more toxic and more likely to present systemic effects, in comparison with less soluble compounds, which are more likely to cause chronic pulmonary effects, if inhaled. Among the most toxic inorganic arsenic compounds is arsine gas (AsH_3). Additionally, note that laboratory animals (commonly used for toxicity evaluation) are generally less sensitive than humans to the toxic effects of inorganic arsenic compounds.

The toxicity "scale" of arsenic compounds is as follows (in the order of decreased toxicity):

$$\text{Arsine} > \text{Arsenites} > \text{Arsenates} > \text{Organoarsenic compounds}$$

Humans are usually exposed to arsenic compounds primarily through (contaminated) air, food, and/or water sources. The concentration of arsenic in air is usually in the range of a few ng As/m^3, although the relevant exposure may be higher in highly polluted areas. The consumption of contaminated water for drinking is also an important source of arsenic exposure. The concentration of arsenic is generally higher in groundwater than in surface water, especially when and where specific geochemical conditions favor dissolution of arsenic minerals.

Due to the widespread distribution of this element in major environmental compartments, it should not be surprising that most people experience a (more or less) measurable arsenic intake each day. It has been reported that exposures of the general population to inorganic arsenic are between 5 and 30 μg/day, which come from air, food, and water. In particular, it has been estimated that humans can get around 0.05 μg As/day from the air, 1–10 μg As/day from (drinking) water, and 5–20 μg As/day from food. Another 1–20 μg As/day can be absorbed, when someone is also a smoker. The U.S. Food and Drug Administration (U.S. FDA) has calculated the mean daily intake of inorganic arsenic at about 0.5 μg/kg body weight of an adult; this corresponds to a range of 30–38 μg/day for adults weighing 60–75 kg. The Food and Agriculture Organization (FAO) and the World Health Organization (WHO) have estimated the safe daily doses or tolerable daily intakes of inorganic arsenic. Provisional values for adults are 2.1 μg As/kg body weight, which equals about 126–160 μg As/day for adults weighing 60–75 kg.

From the previous information, it becomes obvious that the recent (up to 1998) maximum concentration limit (MCL) of 0.05 mg/L of arsenic in drinking water is not protective enough. Considering that humans consume about 2–3 liters of water daily, when the water contains about 50 μg/L of arsenic, this results in a daily arsenic intake of 100–150 μg/day, in addition to another 30–38 μg/day, which has been calculated by the U.S. FDA; therefore, the total arsenic intake of humans, who drink water containing 50 μg/L of arsenic, is up to 130–188 μg/day. This might be higher than the safe daily dose for arsenic, as proposed by the WHO. As a result, the concentration limit of arsenic in drinking water has recently been lowered. In Europe, the respective limit, according to the E.C. Directive 98/83, is now 10 μg/L. In the United States, after several discussions of this issue, the arsenic limit in drinking water remained 50 μg/L up to January 22, 2001. Then, the U.S. Environmental Protection Agency (1) published a relevant final rule, which includes the revised standard for arsenic in drinking water, of 10 μg/L.

METABOLISM AND DISPOSITION

Once arsenic compounds are ingested, the soluble forms of arsenic are readily absorbed from the gastrointestinal (GI) tract. Arsenate, whether in inorganic or in organic form, is better absorbed than arsenite because it is less reactive with the membranes of the GI tract.

The absorption of water-soluble inorganic arsenic compounds through the GI tract is very high. In humans, absorption rates of 96.5% for trivalent sodium arsenite and 94% for soluble sodium arsenate have been reported. In contrast, the GI absorption of less soluble trisulfide arsenate was reportedly only 20–30% in hamsters. The absorption of arsenic in the lungs depends on the size of the particles onto which arsenic compounds have been deposited, as well as on their respective solubility; respirable particles (i.e., 0.1–1 μm in diameter) can be carried deeper into the lungs, and therefore they are more likely to be absorbed.

Once absorbed, the blood transports arsenic to different body organs, such as the liver, kidney, lung, spleen, aorta, and skin. It is worth noting that, except for skin, clearance from these organs is relatively rapid. Arsenic also deposits extensively in the hair and nails (2). Arsenic compounds are then subject to metabolic transformation. Pentavalent arsenic compounds are reduced to trivalent forms, and then they are methylated in the liver to the less toxic methylarsinic acids. Typical levels in the blood of people who are not exposed to significant sources of arsenic pollution are in the range of 1–5 μg As/L (3). Finally, arsenic can be removed (cleared) from the body relatively rapidly, primarily through urine. Urinary excretion rates of 80% within 61 h, following oral doses, and 30–80% within 4–5 days following parenteral doses, have been measured in humans (4). Arsenic can also be lost from the body through the hair and nails, because they represent a nonbiologically available arsenic pool. In Fig. 1, the main routes of the fate, distribution, and

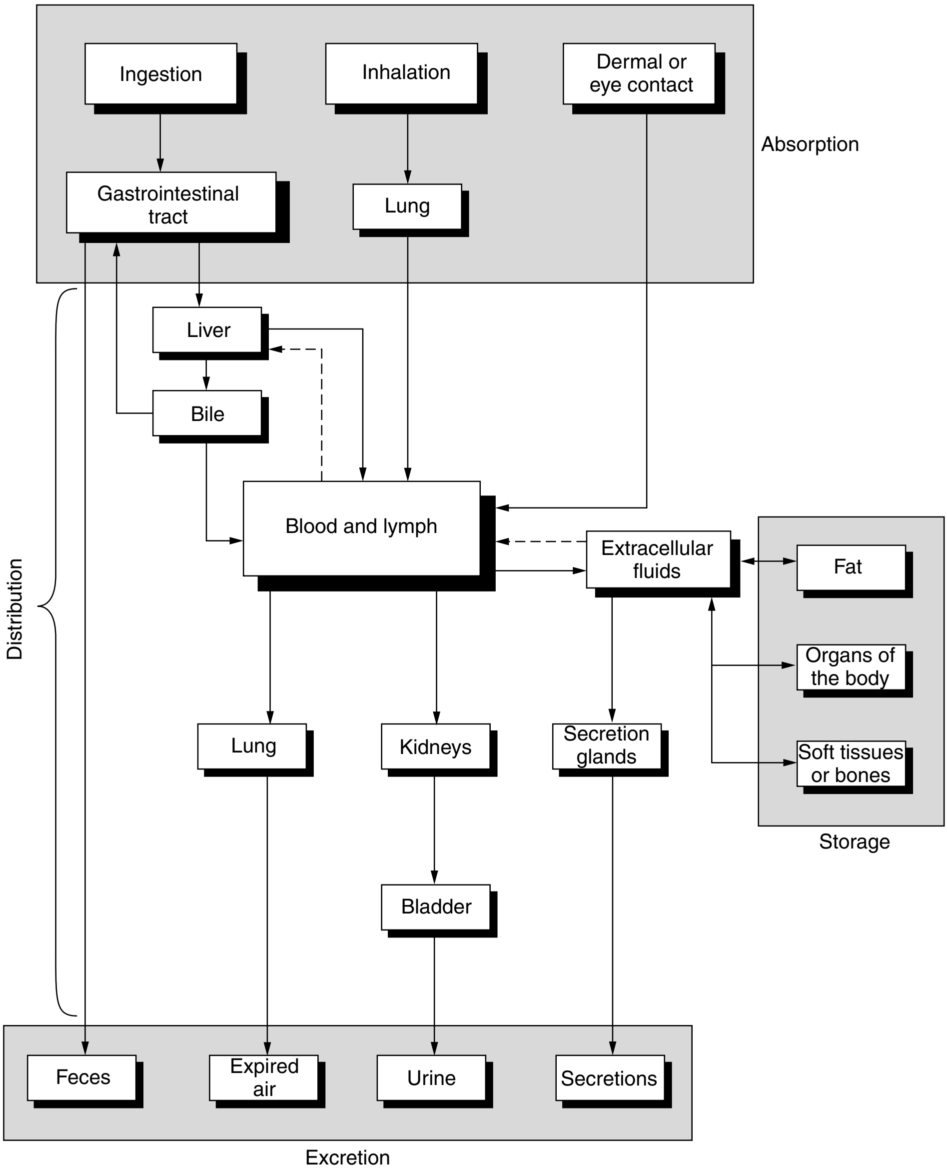

Figure 1. Fate, distribution, and excretion of toxic chemicals in the human body.

excretion of toxic chemicals, such as arsenic, for humans are presented.

MECHANISMS OF TOXICITY

The main inorganic arsenic species (i.e., As^{V} and As^{III}) have different mechanisms of action on which their toxicity depends. Arsenates behave similarly to phosphates. Consequently, they can substitute for phosphates in common cell reactions, whereas arsenites have high affinity for the thiol groups of proteins, causing inactivation of several enzymes.

In particular, the structural similarity of arsenates to phosphates allows them to substitute for phosphates in energy-producing reactions within the cell. First, arsenate can replace phosphate during glycolytic phosphorylation; if this occurs, glycolysis can continue, but ATP-producing reactions do not take place and, therefore, the cell produces less ATP. Second, arsenates can uncouple oxidative phosphorylation by substituting for phosphates in the ATP synthetase enzyme. As electrons are transferred to oxygen, ADP-arsenate (rather than ATP) is formed, which rapidly hydrolyzes. Hence, energy is wasted from the electron transport chain, because it cannot be stored appropriately. In addition, arsenate may also exert its toxic effects indirectly via reductive metabolism to arsenite.

The key to the toxicity of arsenite is its electrophilic nature; arsenite binds to electron-rich sulfydryl groups on proteins. Although such binding exerts adverse effects on structural proteins, such as the microfilaments and microtubules of the cytoskeleton in cultured cells, most of arsenite's toxicity is likely due to the inhibition of enzymes by binding to a thiol-containing active site. In particular, arsenite is known to inhibit enzymes of the mitochondrial citric acid cycle, and cellular ATP production decreases. Arsenite also uncouples oxidative phosphorylation. Arsenic's multipronged attack on the cell's energy production system can adversely affect cellular health and survival (5,6).

In contrast to inorganic arsenic, organoarsenic compounds, such as MMA or DMA, can bind strongly to biological molecules of humans, resulting in less toxic effects.

ARSENIC HEALTH EFFECTS

Acute arsenic exposure (i.e., high concentrations ingested during a short period of time) can cause a variety of adverse effects. The severity of effects depends strongly on the level of exposure. Acute high-dose oral exposure to arsenic typically leads to gastrointestinal irritation, accompanied by difficulty in swallowing, thirst, and abnormally low blood pressure. Death may also occur from cardiovascular collapse. The lethal dose to humans is estimated at 1–4 mg As/kg for an adult (3,7,8). Short-term exposure of humans to doses higher than 500 μg/kg/day can cause serious blood, nervous system, and gastrointestinal ill effects and also may lead to death.

Chronic arsenic uptake may have noncarcinogenic, as well as carcinogenic, effects on humans. Chronic exposure to low arsenic concentrations is of primary interest, when the health significance of arsenic in drinking water is evaluated. The most common signs of long-term, low-level arsenic exposure are dermal changes. These include variations in skin pigments, hyperkeratosis, and ulcerations. Vascular effects have also been associated with chronic arsenic exposure.

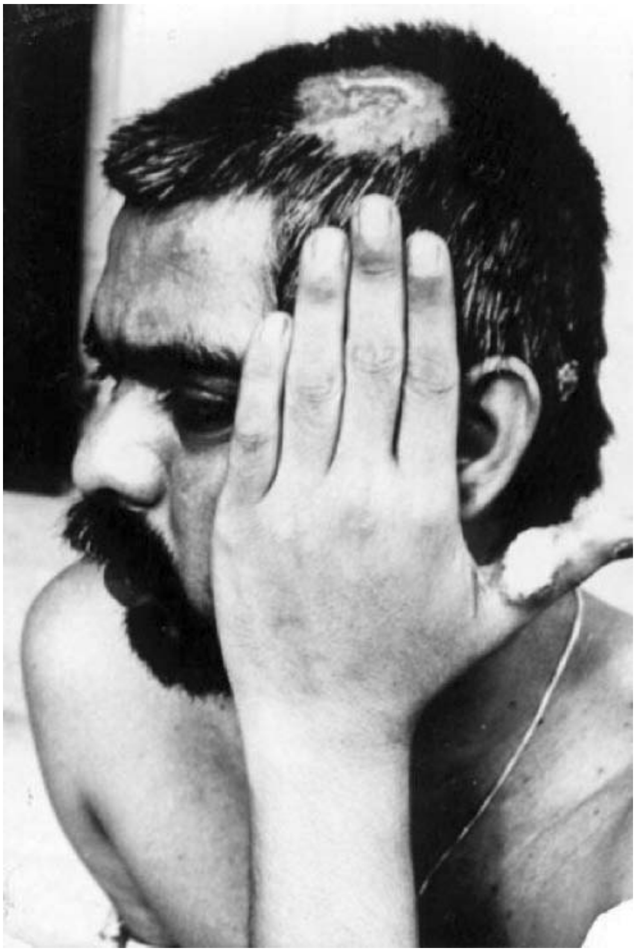

Figure 2. Skin cancer on the head caused by chronic arsenic intake.

Chronic arsenic exposure can also lead to carcinogenesis in humans. Arsenic is classified as a human carcinogen, according to the U.S. EPA. This classification was based mainly on human data because the respective animal data were inadequate. Several epidemiological studies have documented an association between chronic exposure to arsenic in drinking water and skin cancer. A correlation between chronic arsenic exposure and cancer in the liver, bladder, kidney, lung, and prostate has also been documented. Arsenic contamination is of major concern in several countries, such as Bangladesh, Chile, and Taiwan. Figures 2–5, taken of people suffering from arsenicosis in these countries, show the significance of the arsenic problem, mainly due to the consumption of contaminated drinking water, and indicate clearly the urgent need for effective treatment of groundwater to remove arsenic (3,7,8).

As can be noticed in these photos, chronic exposure to arsenic can cause skin cancer in several parts of the human body: on the head, on the hand, and on the foot. In India,

Figure 3. Skin cancer on the foot known as "black-foot" disease, caused by chronic arsenic intake.

Figure 4. Skin cancer on the hand.

in the area of West Bengal, more than 40 million people suffer from different kinds of arsenicosis, and 37% of the water samples, which have been analyzed, contain arsenic concentrations higher than 50 μg/L. In Bangladesh, more than 70 million people suffer from several kinds of cancer due to chronic exposure to arsenic. (9). This problem also exists in several areas of the United States, as well as in Europe. In the United States, more than 3 million people drink water whose arsenic concentrations are higher than 50 μg/L, whereas in Europe, arsenic concentrations over the 10 μg/L concentration limit have often been reported in Germany, Hungary, Finland, and Greece (7).

BACKGROUND CONCENTRATION OF POLLUTANTS

Mário Abel Gonçalves
Faculdade de Ciências da
Universidade de Lisoba
Lisoba, Portugal

The background concentration of an element or compound in a system may be considered as the averaged most common concentration defined from a set of representative samples. Traditionally, statistical techniques, such as moving averages and probability plots, are used to define these values quantitatively, which means that a statistically representative number of samples are required, and that samples represent the same general set of physical and chemical characteristics of the system. These approaches are most common to geochemical exploration surveys, through soil and rock analyses. Characterization of natural waters is based on the same principles, but the difficulties in achieving these principles are markedly different.

Defining background concentrations of pollutants in waters is of fundamental importance to establish water quality standards. Several pollutants occur in surface and groundwaters in a range of concentrations exclusively related to natural phenomena. However, anthropogenic activities induce large perturbations in most water systems. One major difficulty facing chemical characterization of surface and groundwater systems is their dynamic nature, which means that concentration patterns change with time. Once introduced in the water system, the fate and spatial distribution of a pollutant are determined by factors such as advection, diffusion, chemical reactivity, and biodegradation.

The large majority of the U.S. Environmental Protection Agency (EPA) list of priority pollutants refers to organic compounds that are solely due to human activities, and most of the inorganic pollutants occur in the natural waters at trace element concentrations (<1 mg/L). Thus, to define the background concentration of pollutants, one must distinguish those that occur naturally, with or without anthropogenic-induced disturbances, from those exclusively due to anthropogenic activities. Inorganic pollutants are clearly in the former group whereas organic compounds fall into the latter.

FACTORS DETERMINING WATER CHEMISTRY

Factors that influence the natural concentrations of major and minor elements in surface waters include the lithology, relief, climate, atmospheric dry and wet deposition, and human activities. Global river chemistry shows an enormous range in concentrations, ionic ratios, and proportion of ions in cation and anion sums spanning several orders of magnitude (1,2). It is unrealistic to define any kind of average of global water chemistry composition based on the large river basins. Besides, Maybeck (1) notes that river chemistry is very sensitive to alteration by human activities, and that, in the northern hemisphere, it is now difficult to find a medium-sized basin not significantly impacted by human activities. It must also be stressed that, between different chemical elements and species, different degrees of chemical reactivity exist, such as precipitation and incorporation into mineral phases, bonding to organic functional groups, and adsorption onto inorganic solid surfaces. These factors and the amount of colloids and suspended solid material in natural waters determine much of the element dispersion and concentration decay from source. Nriagu and Pacyna (3) estimated that human-induced mobilization of several trace metals far exceeds the natural fluxes, and enrichment factors in the range of 3–24 are reported for such elements as As, Cd, Pb, Se, and Hg.

Groundwaters are less sensitive to some of the external influences as the ones previously mentioned. However, understanding groundwater geochemistry is difficult because of the chemical heterogeneity of most aquifer systems. The residence time of groundwater is a factor that influences its final chemistry and depends on permeability and transmissivity and the amount of recharge of the aquifer. Groundwaters with long residence time in the reservoir become closer to chemical equilibrium with the minerals of the host rocks. In turn, low residence times of waters associated with the slow kinetics of silicate dissolution put severe constraints on groundwater chemistry. Nevertheless, cases where rapid ongoing dissolution and precipitation reactions are taking place, such as in some aquifers, result in relatively unaffected groundwater chemistry, irrespective of flow rate and direction. These are just some examples that illustrate the difficulty in defining acceptable background concentrations of chemical elements in several water systems.

BACKGROUND CONCENTRATION OF INORGANIC POLLUTANTS

Nitrate, ammonia, and trace metals are the most important inorganic pollutants present in waters. Several surface and groundwaters contain natural (background) concentrations of one or more of these and other chemical elements and species exceeding, for example, the U.S. EPA drinking water standards for reasons totally unrelated to human activities. Thus, identifying such natural sources is fundamental for regulatory decisions to avoid the assignment of unrealistic cleanup goals below such natural background concentrations. One of the most striking examples comes from groundwater arsenic contamination in Bangladesh (4), whose mechanisms, although attributable to iron oxide reductive dissolution, are still subject of intense debate. Of the millions of tube wells, about one-third have arsenic concentrations above the local drinking water standard (50 μg/L), and half of them do not meet the 10 μg/L guideline value of the World Health Organization (WHO) (4).

The approach to determine background concentrations of inorganic pollutants in water systems requires the sample of stream waters and/or groundwaters from boreholes in nearby areas in the same geological setting, where water chemistry has presumably not been affected by human activity. Regretfully, this approach is not always possible in several areas. In such cases, it might be reasonable to assume natural background concentrations equal to the measured concentrations in streams and groundwaters in the same general area and similar geologic environments, not forgetting that such factors as climate, relief, and aquifer recharge and hydraulic properties must also be evaluated. Sources of data on the "typical" chemical composition of groundwaters from different rock types also exist [see references in (5)]. However, the factors that influence water chemistry are varied and may differ between similar geological settings, and so the previous approaches are far from being reliable.

Use of cumulative probability plots of all the data for the area of interest can be a way to identify background concentrations, allowing the classification of samples into uncontaminated and contaminated groups (6). Some geostatistical techniques also aim to provide a separation between anomalous and background values in samples, especially factorial kriging (7). However, this does not avoid the need to have truly uncontaminated samples. Another shortcoming is that not all elements spread equally through a surface or groundwater system. Nitrates, for example, are highly mobile because they are not limited by solubility constraints. Adsorption onto solid phases is a mechanism that may rapidly remove trace metals from solution, such as Pb and Cd. Thus, what may be an uncontaminated water sample with respect to a given element may not hold in relation to other elements.

BACKGROUND CONCENTRATION OF ORGANIC POLLUTANTS

Organic pollutants are compounds that were mostly introduced in the environment by anthropogenic activities. Contrary to metals (the most important class of inorganic pollutants), several of these compounds are biodegradable, which, coupled to other mechanisms such as abiotic decomposition (including hydrolysis, oxidation reduction, and elimination), adsorption, dispersion, and dilution, contributes to what is called “natural attenuation.” Their source is varied and includes spilling and leakage from underground storage tanks and landfills, and several commercial and industrial activities, to name but a few. Background concentration of these pollutants is solely the result of human impact on the water system. In this case, organic pollutants should not overcome the maximum concentration level for drinking water standard in agreement with the various national regulations. For water quality assessment, it is important to have a good knowledge of organic pollutant dispersion and persistence in water systems, and the same basic principles presented also apply to sampling in this case. As a result of the previously mentioned mechanisms, these compounds have a complex behavior in water systems. Chlorinated solvents, for example, sometimes behave as conservative solutes that are rapidly transported, but they also undergo several microbial degradation processes causing them to rapidly disappear and be replaced by the lightly chlorinated ethenes. Some case studies describe the development of a dynamic steady state in plumes of hydrocarbons that stopped spreading because the rate of input of soluble hydrocarbons was balanced by biodegradation mechanisms that consumed hydrocarbons in the plume. Thus, knowledge of these processes is fundamental to evaluate and prevent organic pollutant concentrations to build up above levels considered potentially harmful to human and ecological health.

WATERBORNE BACTERIA

Barry H. Rosen
US Fish & Wildlife Service
Vero Beach, Florida

CHARACTERISTICS OF BACTERIA

Bacteria are so widespread that only the most general statements can be made about their life history and ecology. They are everywhere on the earth, even in the most hostile environments, including extremes of temperature, such as freshwater hot springs. Many live in water; however, they are also an important part of soils and live in and on plants and animals; others are parasites of humans, animals, and plants. Only a handful of waterborne bacteria cause diseases, usually by producing toxins. Most bacteria have a beneficial role in decomposing dead material and releasing nutrients back into the environment.

Bacteria are a group of microorganisms that lack membrane-bound organelles and hence are considered simpler than plant and animal cells. They are separated into gram-positive and gram-negative forms based on the staining properties of the cell wall. Most bacteria are unicellular and are found in various shapes: spherical (coccus), rod-shaped (bacillus), comma-shaped (vibrio), spiral (spirillum), or corkscrew-shaped (spirochete). Generally, they range from 0.5 to 5.0 micrometers in size. Motile species (those that can move on their own) have one or more fine flagella arising from their surface. Many possess an outer, slimy capsule, and some have the ability to produce an encysted or resting form (endospore). Bacteria reproduce asexually by simple division of cells and rarely by conjugation.

Bacteria have a wide range of environmental and nutritional requirements. One way to classify them is based on their need for oxygen. *Aerobic bacteria* thrive in the presence of oxygen and require it for continued growth and existence. *Anaerobic bacteria* thrive in oxygen-free environments, as often found in lake or wetland sediments. *Facultative anaerobes* can survive in either environment, although they prefer oxygen. The way bacteria obtain energy provides another means of understanding and classifying organisms. *Chemosynthetic bacteria* are autotrophic and obtain energy from the oxidation of inorganic compounds such as ammonia, nitrite (to nitrate), or sulfur (to sulfate). *Photosynthetic bacteria* convert sunlight energy into carbohydrate energy. Bacteria such as the purple sulfur bacteria, purple nonsulfur bacteria, green sulfur bacteria, and green bacteria have a bacterial form of chlorophyll. Cyanobacteria, commonly called blue-green algae, are a separate group that contains chlorophyll *a*, a pigment that is common to eukaryotic algae and higher plants. *Heterotrophic* bacteria form a diverse group that obtains energy from other organisms, either while they are alive (parasites) or dead (saprophytes).

BACTERIAL IDENTIFICATION

Bacterial size and a lack of visual cues prevent the identification of organisms by traditional microscopic techniques. Typical bacterial identification involves isolating organisms by culturing them on a variety of media that reveal the organism's physiological or biochemical pathways. For example, purple nonsulfur photosynthetic bacteria can be isolated from lake sediments by inoculating a mineral salt–succinate broth and incubating in light at 30 °C in a bottle sealed to ensure anaerobic conditions.

INDICATORS OF BACTERIAL/FECAL CONTAMINATION

One emerging water quality issue is contamination of surface and groundwater by bacteria and other microorganisms that are defined as pathogens—organisms that cause disease in animals or plants. The difficulty in direct detection of bacteria in water has led to the use of fecal bacteria as an indicator of the presence of pathogens and the risk of disease. Rapid, inexpensive techniques have been standardized for determining if fecal material has contaminated water, although the sources of that contamination are numerous. Wildlife, pets and companion animals, agricultural animals, and humans are all possible sources (Fig. 1).

Although indicator bacteria are not pathogenic themselves, high numbers may indicate fecal contamination from leaky septic tanks, animal manure, or faulty wastewater treatment facilities. Some species also live in soil and on plants and are harmless. Total coliform is the broadest category (Table 1) of indicator bacteria, and it was originally believed that it indicates the presence of fecal pollution. Numerous nonfecal sources make this indicator too generic. Fecal coliform, a subgroup of total coliform, originates from the intestinal tract of warm-blooded animals. This subgroup is the most commonly used indicator of bacterial pollution in watersheds. *Escherichia coli* is a member of the fecal coliform subgroup. This subgroup is used because it correlates well with illness from swimming and can cause gastrointestinal problems. Fecal streptococci, also called fecal strep, are another grouping of bacteria, similar to the coliforms that are associated with feces from warm-blooded animals. Enterococci are a subgroup of fecal strep bacteria. This subgroup is used because it correlates well with human illness from recreational waterbodies. Enterococci and *E. coli* are considered to have a higher degree of association with outbreaks of gastrointestinal illness than fecal coliforms, as indicated by the U.S. Environmental Protection Agency. State and local government agencies commonly monitor for total or fecal coliform, and some monitor *E. coli* and enterococci. States and local health agencies may have more stringent standards than national guidelines (Table 1).

Escherichia coli O157:H7 is a potentially deadly fecal bacteria that can cause bloody diarrhea and dehydration in humans. The combination of letters and numbers in the name of this bacterium refers to the specific molecular markers found on its cell surface; they distinguish it from other types of *E. coli,* most of which are part of the normal bacterial flora in warm-blooded animal intestinal tracts. This organism does pose a threat to bathers or others from bodily contact in contaminated waters, although the majority of outbreaks are from contaminated food.

BACTERIAL SOURCE TRACKING

DNA fingerprinting, one tool for bacterial source tracking (BST), consists of a family of techniques that are under development to identify the sources of fecal contamination in various waterbodies. The goal is to identify the source, whether human, livestock, pets and companion animals, or wildlife. In theory, this allows targeting management activities for bacterial reduction on the appropriate sources.

The EPA periodically reports data submitted by states on impairments to rivers, lakes, and estuaries. Bacteria and pathogens, based on fecal indicator bacteria data collected by states, frequently exceed water quality criteria. An individual waterbody or segment of a river that exceeds these criteria is listed by the state [EPA's 303(d) list] and may trigger additional efforts to improve the waterbody. One mechanism for improving water quality that is currently being used by the EPA is the total maximum daily load (TMDL). Microbial source tracking techniques are currently the best technology for tracking sources of fecal contamination and can play an important role in TMDL development. For example, if fecal contamination is a major issue in a particular watershed, BST might show that the contamination originates from humans, not livestock. The TMDL should then reflect an appropriate proportion of reduction in bacterial loading from agriculture and from urban areas (leaky septic systems or ineffective sewage treatment plants).

Understanding the concept of how BST works, including its limitations, can help determine if these techniques can be used in a particular situation. Although DNA fingerprinting has received the greatest amount of attention recently, other BST methods are in use and can play an important part in fecal source tracking.

For most of these techniques, bacteria from known sources (humans, swine, raccoons, deer, cows, etc.) are collected directly from the animal, then isolated and grown

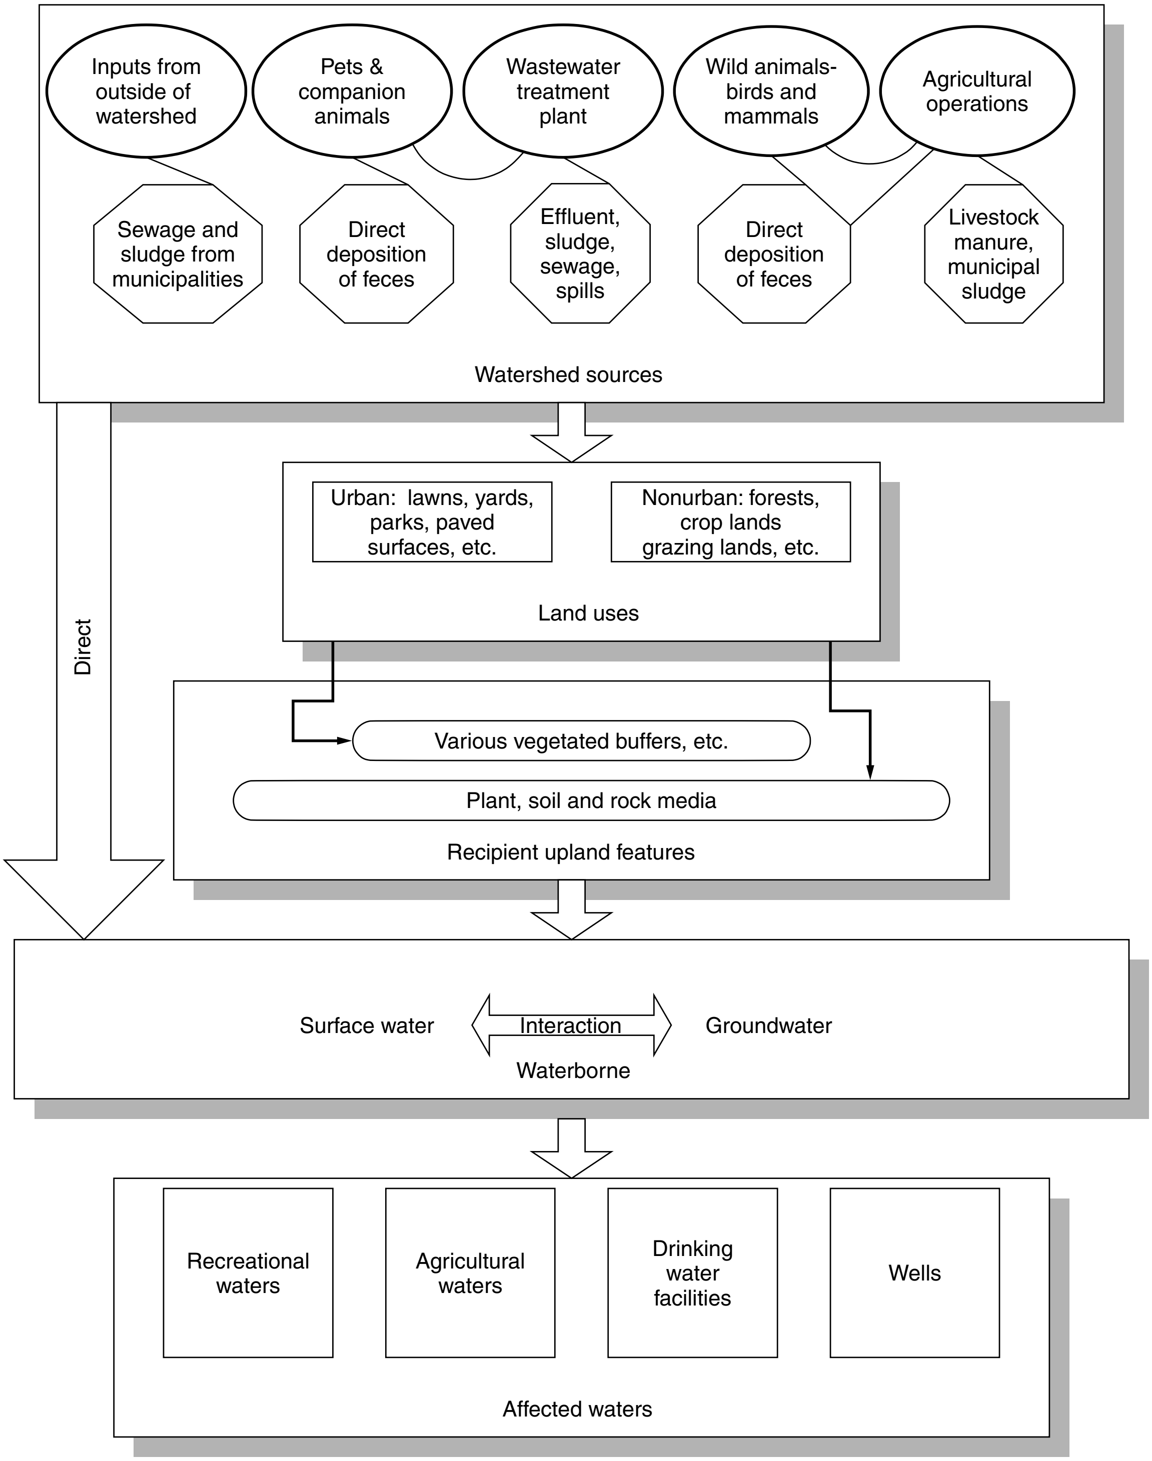

Figure 1. Potential pathways for pathogen movement into water.

in the laboratory. One species of bacteria, *E. coli*, has been extensively used, but others are more likely to be found in particular situations. For example, fecal streps (e.g., *Streptococcus feacalis*) are very numerous compared to *E. coli* in composted poultry litter or in high quality biosolids. These isolates grown in the laboratory are the basis of the library or database for subsequent comparison to unknown samples.

The current state of research normally involves isolating and culturing as many organisms as practical. Financial constraints usually limit this approach; several hundred may be needed from each major source to identify sufficiently the source in a water sample. In addition, regional differences in the genetics of isolates are just coming to light, potentially restricting the broader use of genetic libraries.

Table 1. Comparison of Fecal Bacteria Water Quality Indicators Commonly Used

Microbial Indicator	Properties	Federal Standard[a,b]
Total coliforms (TC)	• originally believed to indicate the presence of fecal pollution • widely distributed in nature: soils, water, flora, fauna • contains members of *Escherichia, Citrobacter, Klebsiella*, and *Enterobacter* identified by incubation at 35 °C	1000 CFU/100 mL
Fecal coliforms (FC)	• subgroup of TC • coliforms that originate specifically from intestinal tracts of warm-blooded animals • cultured by increasing the incubation temperature to 44.5 °C • remains the predominant indicator used to assess bacterial pollution in watersheds	200 CFU/100 mL
Escherichia coli	• member of the FC group • presence correlates with illness from swimming in both fresh and marine waters • has been shown epidemiologically to cause gastrointestinal symptoms • O157:H7 is a toxin-producing strain of this common bacterium	126 CFU/100 mL
Enterococci	• subgroup of the FC, including *Streptococcus faecalis, S. faecium,* and *S. avium* • commonly found in intestinal tracts of humans and other warm-blooded animals • presence correlates well with illness from both fresh and marine waters	33 CFU/100 mL

[a] Individual states may have higher standards but not lower; CFU = colony forming units.

[b] Primary contact water includes recreational use such as swimming and fishing.

CURRENT TECHNIQUES UNDER DEVELOPMENT

Molecular Methods (Genotype)

The overall intestinal environment in each type of animal is different enough to allow selective pressures on the microbial flora, resulting in populations of bacteria that have slightly different genetics from each species. The purpose of these molecular techniques is to find that difference among the genetics of the same type of bacteria isolated from these different animals. Commonly used methods, such as restriction endonuclease and polymerase chain reaction (PCR) used to amplify DNA, are sophisticated molecular techniques that rely on DNA extracted from isolates that have been cultured and purified before analysis.

Ribosomal RNA is the target of several molecular techniques because this portion of the bacterial genome is considered stable. The techniques associated with target ribosomal RNA are called “ribotyping.” Other molecular methods target parts of the bacterial DNA and may use pulse field gel electrophoresis and randomly amplified polymorphic DNA—a technique that amplifies selected portions of the DNA by PCR. Highly qualified personnel trained on rather elaborate equipment must perform all of these molecular techniques, currently limiting the availability and cost of these procedures.

Biochemical Methods (Phenotype)

Biochemical methods have some advantages over molecular techniques in cost and efficiency. Molecular techniques are more precise, but more time-consuming, and are not suitable for analyzing large numbers of samples at this time. A combination of the two approaches may be best, the simpler, quicker, less costly biochemical approach followed by detailed molecular analysis of selected bacterial isolates to confirm the results.

One technique that falls under biochemical methods is antibiotic resistance analysis. The same principle that applied to the discussion of the intestinal tract selecting certain genetics in bacterial flora applies to microbes that acquire resistance to antibiotics or other biochemical traits. Each source is expected to have its own pattern of resistance; the general concept is that human fecal bacteria have developed the greatest diversity of resistance. Recent findings, however, have shown that domestic animals that receive antibiotics are hosts of antibiotic resistant bacteria and these bacteria can be found in waterbodies adjacent to farms.

Other biochemical methods that are being used include the F-Specific (F+ or FRNA) coliphage (although this is targeted at viral sources), sterols or fatty acid analysis from the cell walls and membranes of *E. coli*, and nutritional patterns.

STATUS OF THESE TECHNIQUES

The current set of techniques can distinguish between humans and animal sources. Separation of wildlife from domestic animals is also successful, although less accurate than human–animal separation. Distinguishing different types of domestic animals or different types of wildlife from one another is still under development but likely in the near future.

All of these techniques should be considered under development. Studies are in progress with more than one technique applied to the same set of conditions to determine the extent of similarity, effectiveness, cost, strengths, and weaknesses. Many site-specific studies have proved effective and valuable; however, regional variation needs to be addressed to move beyond these site-specific findings. Most likely, a combination of methods will be useful, based on the particular situation. Other nonbacterial techniques may also indicate the presence of wastewater, such as optical brighteners from laundry detergents and caffeine. Collectively, BST techniques will prove valuable for tracing fecal pollution from a variety of sources. State and local public health officials are increasingly acquiring this technology and may be good resources for information applicable on areawide or watershed scales.

WATER ASSESSMENT AND CRITERIA

Parley V. Winger
University of Georgia
Atlanta, Georgia

INTRODUCTION

Human activities have historically altered aquatic systems to some extent; however, with the Industrial Revolution and the shift from hunting and agricultural use of the land to amassing in population centers, pollution of adjacent waterways reached intolerable levels (1,2). Untreated municipal and industrial wastes were released directly into river, stream, and lake systems, and even with the development of sewage treatment in the mid-1800s, sewage outfalls continued to reduce the quality of downstream waters (1). Federal intervention into activities influencing water quality began in the late nineteenth century (e.g., River and Harbors Act of 1899) and continues today, primarily under the auspices of the Clean Water Act and its amendments (3,4). With the advent of legislative regulation for water quality, procedures for measuring and describing the status and quality of aquatic systems were needed for management and decision making. Developing from this need has been a progressive advancement of practices and procedures used to describe and categorize the quality of aquatic environments, culminating in the present-day regional approach to biological assessment and the development of biological criteria that can be used to evaluate ecosystem health and classify the biological integrity of aquatic systems. Biological assessment is defined as "an evaluation of the condition of a waterbody using biological surveys and other direct measurements of the resident biota in surface waters," and biological criteria are "numerical values or narrative expressions that describe the reference biological condition of aquatic communities inhabiting waters of a given designated aquatic life use and are used as benchmarks for water resources evaluation and management decision making" (5). A mandate of the Clean Water Act was to restore and maintain biological integrity of aquatic systems. Biological integrity encompasses all factors affecting an ecosystem and is defined as the "capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of the natural habitat of the region" (6).

EARLY ASSESSMENTS

An extensive history and subsequent evolution of concepts, procedures, and understanding of processes associated with assessments of aquatic environments in relation to anthropogenic impacts exist (2). Basic to the development of appropriate and effective bioassessment procedures was the recognition that aquatic systems are more than just water and that the biological components represented by the myriad of microbes, plants, and animals are integral to these systems in carrying out the biological processes that ensure water quality. The diverse biological assemblages that reside in aquatic habitats, although generally unique for each system, are characteristic of the indigenous water quality. Early studies and measurements of water quality relied primarily on the chemical characteristics (pH, dissolved oxygen, etc.) of the water, but it was eventually recognized that these measurements provided little insight into the biological health of these bodies of water. Maintenance of clean, healthy, high-quality water is dependent on diverse and fully functional aquatic communities. Conversely, the biological components present in an aquatic system reflect the quality of the water and habitat.

DEVELOPMENT OF BIOASSESSMENT PROCEDURES

A number of factors and activities exist that can adversely impact aquatic systems. Aside from the general features that provide the underlying control of the structure and function of rivers and streams (climate, geology, soil types, etc.), anthropogenic activities can have marked influences on aquatic environments (7). Environmental factors (e.g., water quality, habitat structure, flow regime, energy source, and biotic interactions) influence the biological integrity of aquatic systems and anthropogenic activities generally influence one or more of these factors (5). Physical alterations of the habitat (e.g., agriculture, logging, channelization, flow alterations) can affect erosion, sedimentation, and hydrological characteristics of streams and rivers, and these, in turn, can drastically alter the biological communities. Inputs of contaminants and other pollutants from agricultural runoff and municipal and industrial effluents can also impact the biological components, but generally in a different manner from that elicited by physical disturbance. Similarly, different types of contaminants can adversely impact aquatic communities in unique ways (e.g., impacts from organic pollution are different from that shown by acid-mine drainage or an industrial chemical). Consequently, bioasssements need to be robust enough to be able to detect impairment of aquatic communities, regardless of the cause.

Although early assessments associated with organic pollution relied heavily on chemical analyses (basic water chemistry such as dissolved oxygen), the adverse effects of pollution on aquatic organisms were understood by the mid-1800s (4). However, most early documentation of the biological impacts from pollution in aquatic systems was qualitative. Results from biological measurements were generally lengthy lists of “indicator” organisms associated with zones of pollution or purification. For example, Kolkwitz and Marrson (8,9) identified the zones of purification/decomposition (“saprobia”) downstream from sewage outfalls as poly-, meso-, and oligosaprobia, with each zone characterized by a unique assemblage of organisms.

The use of indicator organisms in categorizing water quality provided a framework for focusing on the biological components of aquatic systems and for the development of more robust bioassessment procedures (10). As “indicator organisms” were more descriptive of organic pollution (sewage) and the tolerances of organisms to the many types of pollution (sewage, metals, industrial contaminants, pesticides, etc.) were not well known, there was an impetus for development of bioassessment programs that incorporated community-based approaches (11,12). Patrick (13) pioneered the concept of using aquatic communities in stream assessments and compared histograms depicting the numbers of species of various taxonomic groups (blue-green algae, oligochaetes and snails, protozoans, diatoms and green algae, rotifers and clams, insects and crustaceans, and fish) comprising the communities in test streams with those from a clean or reference site. Patrick recognized that healthy streams had a great number of species representing the various taxonomic groups and no species were represented by a great number of individuals, whereas streams impacted by pollution had reduced numbers of species and those remaining were in great abundance.

A major drawback, however, of including most of the various biological components (algae, protozoa, benthic macroinvertbrates, and fishes) in these types of bioassessments was the amount of time required and the expertise needed to collect and identify all of the organisms comprising the aquatic communities at sites of concern. As a result of this criticism, aquatic scientists began to specialize or use specific taxonomic groups in bioassessments as representative components or surrogates of the biotic communities (14). Of course, each specialist considered their particular taxonomic group as the most appropriate for use in bioassessments, and for the most part, although each group had its advantages and disadvantages, they each provided meaningful information and generally reflected some level of impairment (5), albeit in much less time than that required for assessment of the full biological complement of taxa. A number of taxonomic groups have been touted as useful in assessing the quality of aquatic systems: diatoms (15), algae (16), protozoa (17,18), benthic macroinvertebrates (19–22), and fishes (23,24). The advantages of using periphyton (algae), benthic macroinvertbrates, and fish are outlined in Barbour et al. (25). The structure and function of specific biotic assemblages or taxonomic groups, such as benthic invertebrates or fish, integrate information about the past and present water quality conditions. Consequently, their inclusion in aquatic bioassessments strengthens the ability to categorize the prevailing water quality.

Refinements to aquatic bioassessment procedures resulted in more widespread use and acceptance, as well as a movement toward standardization of field and laboratory procedures (3,26,27). The inclusion of biotic indices (28–31) and diversity indices (32–34) in the analysis of biological data provided additional measures of community structure and function that aided in the interpretation and identification of impairment from pollution. These indices were also useful in reducing and synthesizing large amounts of data (data that reflected biotic responses to complex interactions and exposures to pollution) into comprehensible numeric values descriptive of water quality. However, bioassessment procedures were still deficient in their ability to fully and accurately describe the overall health of aquatic systems (4).

CURRENT STATE-OF-THE-ART BIOASSESSMENT PROCEDURES

The most useful measures of biotic integrity of aquatic systems reflect the biological responses of organisms and their populations to the prevailing (past and present) environmental conditions. The ability to classify the quality of streams and rivers (with indigenous biological assemblages) provides information that is integral for making management decisions and identifying anthropogenic impacts (35). Development of an “Index of Biotic Integrity” (IBI) using a combination of 12 community parameters (metrics) for fish assemblages provided direction into a new and innovative way of obtaining this type of information (24). The combination of these community attributes (multimetrics) into an IBI provided a classification of the quality of fish communities as a measure of water/habitat quality. The metrics used in the construction of the IBI encompassed several levels of fish community structure and function—species composition/richness and information on ecological factors (trophic structure and health). Successful application of multimetric indices depends on selecting the appropriate metrics used to describe and delineate the biological assemblages (36). The use of multimetrics provides a way of measuring the response of biological assemblages at several levels of organization (e.g., composition, condition, and function) to anthropogenic influences, and these measurable biological attributes can be tested, verified, and calibrated for use in the respective geographical areas of study (37–39). The multimetric concept was expanded on and modified to include benthic macroinvertebrates as well as fish in a set of procedures developed for the U.S Environmental Protection Agency called the Rapid Bioassessment Protocols (RBPs) for use in streams and rivers (40). The RBPs provided a cost-effective framework for bioassessment that could be used by federal, state, and local agencies for management purposes of screening, site ranking, and trend monitoring of the biotic integrity of streams. Modifications, improvements, and additions to these procedures were included in a more recent revision of the RBPs (25). The integrated assessments recommended in the RBPs include information (field collected) on the physical habitat and water quality as well as a number of measures (metrics) describing the biological assemblages of periphyton, benthic macroinvertebrate, and fish.

REFERENCE SITES AND ESTABLISHING BIOCRITERIA

Knowing the organisms that comprise or could comprise the aquatic assemblages in unimpacted streams provides the basis for application of current biological assessment procedures, such as the RBPs, and the development of biological criteria. Consequently, reference streams/sites provide the basis or benchmark for establishing suitable criteria that can be used for comparison with other streams/sites to detect impairment (5,41). Unfortunately, few streams and rivers are pristine anymore because of the widespread influence of anthropogenic activities. Consequently, streams/sites that are the least impacted (minimally impaired) are selected to establish the "attainable" condition or level that is used for comparison with the streams under study.

Reference sites must also be representative of the aquatic systems that are being evaluated. Two types of reference conditions, site specific and regional, are currently used for field bioassessments (25). However, multiple reference sites within a geographical region provide a realistic representation of the community assemblages and compensate for and include the inherent variability associated with individual sites (41). The selection of reference sites on an ecoregional or subregional basis provides an unbiased estimate of the least impacted (attainable) biological assemblages for that particular region of study (41,42). Using a suite (population) of reference streams/sites also allows the use of statistical analyses to establish the natural variability and ranges for each of the metrics and indices to be used for comparison with the study streams. The number of reference sites needed to describe the expected or attainable conditions may vary with the geographical area, but generally 3 to 20 sites are acceptable (41). Once the biological assessments are complete for the reference sites, the suitability and strengths of the metrics included in the analysis and the overall rating index used in detecting impairment can be evaluated using box-and-whisker plots (5) or other statistical analyses (43,44). The box-and-whisker-type plots for the metrics/indices determined for reference streams/sites depict the median, interquartile range (25th and 75th percentiles) and the range (minimum and maximum values). Metric and index values from the study sites that are above (low values for reference conditions) or below (high values for reference conditions) the interquartile range shown by the reference sites demonstrate impairment. The interquartile ranges for the various metrics and combined overall indices (combined scores for the individual metrics) establish the numeric biological criteria for that region.

The reference streams/sites must be representative of the resources at risk. They provide the benchmarks for the expectation or attainable level of biological integrity/water quality that the study areas will be compared with for classification of their level of impairment, and once defined, these biocriteria will describe the best attainable condition (5,37). The acceptable level of difference between the established criteria representing the reference sites and those of the study sites will vary depending on the designated aquatic life use (e.g., cold water fisheries, warm water fisheries, and endangered species) of the study sites (5). The narrative description based on the quantitative database or the numeric criteria (indices) calculated from the database from the reference sites can also be used as the biological criteria for identifying water quality and level of impairment.

An alternative approach to using multimetrics (45,46) in establishing reference conditions relies on multivariate analyses and predictive modeling (47–49). Models are developed that will predict the expected species composition of a "pristine" site given the physical and chemical characteristics (50). The species composition (and associated metrics) from this expected (predicted) community assemblage can be compared with those from the field study sites included in the bioassessments; assessment sites are compared with model-predicted reference conditions. These predictive models require extensive information on the physical and chemical characteristics of pristine streams and the biological organisms that would be associated with them (5). In the absence of field data (or as alternatives for defining reference conditions in the event that suitable sites no longer exist), historical data, simulation modeling, and expert consensus can be used to supplement the data needed for these models (5). Under the multivariate approach, the predicted species compositions (and associated metrics/indices) would establish the biological criteria for streams in that region.

BIOASSESSMENTS CRITICAL IN PRESERVING BIOTIC INTEGRITY

Current practices in biological assessment and the establishment and use of biological criteria based on community structure and function at reference sites (or predicted by models) are effective tools in describing biological integrity and classifying water quality (5,51). As these procedures are used, refinements will most likely be made (particularly at the regional level) as more information is generated and the selection/calibration of metrics is improved. Biological monitoring that includes bioassessment and the establishment of biocriteria on an ecoregional basis (46) is integral to meeting the demands for ecosystem health (52) and measurement of ecological integrity (53) of our nation's aquatic resources.

PHYSIOLOGICAL BIOMARKERS AND THE TRONDHEIM BIOMONITORING SYSTEM

KARL ERIK ZACHARIASSEN
Norwegian University of
Science and Technology
Trondheim, Norway

Poor water quality is frequently the result of the presence of potentially toxic substances. Detection of such substances by chemical analysis may be complicated, time consuming, and expensive, and it does not reveal much about possible toxic effects.

WHAT IS A BIOMARKER?

Biomonitoring of water quality takes advantage of the fact that organisms in the water may be moderately affected by the substances. A biomarker is a cellular, biochemical, or physiological parameter, which may be affected when bioactive chemicals are present in the water. One biomarker can respond to the presence of a wide variety of substances and respond before manifest toxic effects occur. Biomarkers are, therefore, particularly useful in early warning monitoring.

Physiological Biomarkers

However, biomarkers should be used by scientists with care, and an appropriate interpretation of their response requires insight into the integrated functional system they are part of, that is, by considering the biomarkers in a physiological context. In a healthy organism, optimal chemical and physical conditions are maintained by a variety of homeostatic regulatory mechanisms. Well-known examples of regulated parameters are body temperature, body fluid pH, and body fluid concentrations of ions, organic solutes, and hormones. Whenever such parameters, for some reason, are displaced beyond optimal range, regulatory mechanisms are activated to compensate for the disturbing stress.

The impact of a chemical substance on an organism can range from a trivial disturbance, which the organism can compensate for, to a serious and eventually lethal disturbance of a regulated parameter. When an organism is injured or killed by a toxic agent, it is because the agent changes a regulated parameter beyond the tolerated range. Regulated parameters as well as the activity of regulatory mechanisms can be physiological biomarkers to provide information about the severity of the impact of a toxic agent (1). As different toxic agents interfere with organisms in different ways, the combined effect pattern of several biomarkers may be more or less specific to the toxic agents, and the effect pattern may identify the agent in cases when the cause of a toxic impact in the environment is unknown or disputed.

THE TRONDHEIM BIOMONITORING SYSTEM

The Trondheim Biomonitoring System (TBS) was developed to extract the appropriate information out of the changes that occur in an organism affected by a toxic chemical. It is a so-called active biomonitoring system; that is, it uses organisms such as mussels placed individually in chambers where they can be exposed to the water that is to be monitored. It operates with three categories of biomarkers: biomarkers for exposure, biomarkers for evaluation of toxic effects, and fingerprint biomarkers to identify the toxic agent (Fig. 1).

Phase 1, Exposure Biomarkers

Exposure biomarkers are the first changes that occur in an affected organism, and they reflect the mechanisms

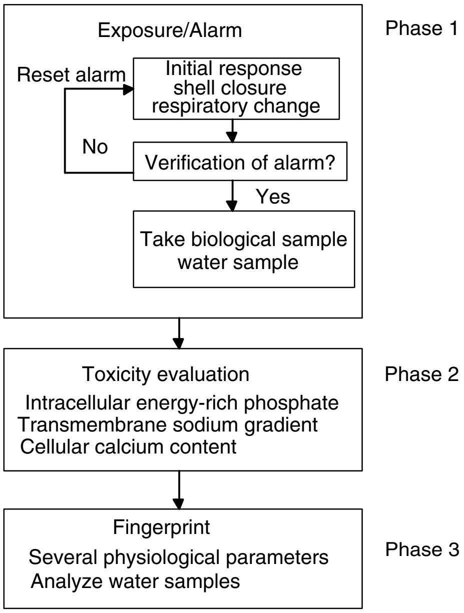

Figure 1. Trondheim Biomonitoring System.

that handle the impact. These changes may be increased activity of homeostatic regulatory mechanisms or the activation of detoxifying mechanisms such as cytochrome P_{450} for certain organic chemicals and metallothioneins (MTs) for certain toxic metals. It should be emphasized that the activation of detoxifying mechanisms such as P_{450} and MT production does not imply that an organism is seriously affected, only that it is compensating for a chemical impact. It should also be emphasized that these systems are activated even by substances of natural origin, and it may be difficult to distinguish natural from non-natural origins.

An ideal exposure biomarker should be sensitive to a wide variety of substances occurring at low concentrations, and it should be possible to monitor the biomarker continuously, for example, online on a computer. As moderate toxic impacts and the activation of many compensatory mechanisms are associated with changes in metabolic rate, the TBS has been using automatic measurement of oxygen consumption as an exposure biomarker. Water from chambers with and without animals is led to a separate chamber with an oxygen electrode connected to a computer, and the oxygen consumption is continuously determined from the difference in oxygen tension of water from chambers with and without animals.

Phase 2, Toxicity Biomarkers

As toxicity biomarkers, the TBS has so far been using tissue levels of energy-rich phosphates and cellular levels of sodium and calcium. The rationale behind the use of these parameters is that many toxic agents inhibit energy metabolism and ionic pumps or affect membrane permeability. Such impacts will affect cellular levels of ATP and active extrusion of sodium and calcium from cells, which will in turn increase the cellular levels of these ions. A substantially reduced transmembrane energy gradient for sodium or high cellular levels of calcium are inevitably lethal, and moderate changes in these parameters indicate that the cells are under serious stress and may become injured if the stress persists (2).

Phase 3, Fingerprint Biomarkers

To obtain pollutant-specific fingerprint biomarkers, a combination of exposure and toxicity stress biomarkers has been used. In addition, intracellular and extracellular concentrations of free amino acids have been included. The specificity of the response of the latter is enhanced because they include more than 20 different substances and they are influenced by a variety of stress factors such as a drop in the transmembrane sodium gradient, anaerobiosis, and cell volume changes. In principle, any measurable parameter may be used, but the number of parameters should be kept at the minimum required to obtain a pollutant-specific effect pattern. The development of an operative system of fingerprint biomarkers is complicated because different pollutants sometimes act together and the changes associated with a single pollutant may depend on its concentration (hormesis).

Toxic agents may also affect a variety of other processes, such as nervous transmission, hormonal control systems and immune responses, osmoregulation, respiration, and heart activity, and effects may be acute or caused by chronic, long-term exposure. Depending on the mechanisms of action of the various toxic chemicals, appropriate biomarkers may be selected and included in the biomarker categories of the TBS.

BIOMARKERS, BIOINDICATORS, AND THE TRONDHEIM BIOMONITORING SYSTEM

Rita Triebskorn
Steinbeis-Transfer Center for
Ecotoxicology and
Ecophysiology
Rottenburg, Germany

Environmental effects resulting from chemical exposure can be traced at different levels of biological organization. In this context, the term “biomarker” is used mainly for functional measures expressed at the organism to suborganism level of biological organization, while the term “bioindicator” refers to effect endpoints at higher biological levels including population and community-level attributes (1).

During the last two decades, interest in using biomarkers or bioindicators as monitoring tools to assess environmental pollution has steadily increased. This is mainly due to the fact that chemical analyses, which are well established in ecotoxicological monitoring programs, can exclusively give information on chemicals present in the environment or accumulated in biota. However, they cannot provide information on exposure-related effects, which possibly occur in exposed organisms. In addition, chemical analyses can often only provide information on a defined spectrum of chemicals (being searched for) available and are mainly "snapshots" of a defined exposure scenario (depending on the time of sampling). Furthermore, low dose effects have received increasing attention during the last few years, especially in the context of endocrine disruption. Therefore, the detection of effects that may be attributed to chemicals present in the environment in concentrations at or beyond the detection limits has become more and more important. On the other hand, it has also become evident that the presence of a chemical in an organism or an environment does not necessarily imply that the organism or the environment is affected or threatened by that chemical.

Biomarkers are suitable not only for delivering information on the health status of exposed organisms (biomarkers of effect), but also on the quality and/or quantity of the exposure situation (biomarkers of exposure). Thus, they can be used both as measures of toxic effects and as fingerprints for chemical exposure (2–4). Depending on the character of biomarkers selected for risk assessment, the evaluator will receive more data on either adverse effects in organisms or on the exposure situation itself (Fig. 1).

Whereas established ecological surveys (e.g., the water quality assessment system) are often based on the disappearance of species under stressed conditions (thus using mortality as the endpoint of toxic effect), the biomarker approach uses responses of organisms (still) living under unfavorable conditions as early warnings before populations or ecosystems are severely damaged (5–7). Since biomarkers respond quickly to environmental stressors before ecological effects become apparent, they serve to detect effects at an early stage. They are highly sensitive and, in addition, integrate effects of animals' exposure to contaminants and confounding factors over time (8–10).

To date, most biomarker research has been conducted in aquatic ecosystems (summarized in Reference 1). In the last decade, however, the field of biomarker application in terrestrial environments has also expanded and several techniques have been adapted for soil organisms (11,12).

A concept to integrate physiological biomarkers into a monitoring system was elaborated by a group of scientists from Trondheim, Norway, ten years ago (2). This "Trondheim Biomonitoring System" (TBS) is a practically operative integrated system for biomonitoring of marine environments using the mussel *Mytilus edulis* as the monitoring organism. The technical setup of this system consists of ten exposure chambers each containing one mussel. The exposure chambers, through which seawater flows, are mounted into a submersible exposure unit and are connected to a respirometer. Thus, data for oxygen consumption can be recorded continuously for each mussel and displayed on a computer screen. In addition, samples (e.g., tissue, hemolymph) for other purposes can be taken from the exposed organisms. The aims of this biomonitoring system are as follows:

1. To detect the presence of environmental pollution at the earliest possible stage in order to enact possible countermeasures before ecological damage becomes obvious.
2. To evaluate the stress status of organisms or ecosystems exposed to environmental pollutants.
3. To identify the pollutants responsible for the detected stress status.

To achieve these aims, the TBS uses physiological biomarkers in three phases. In the first phase, "the

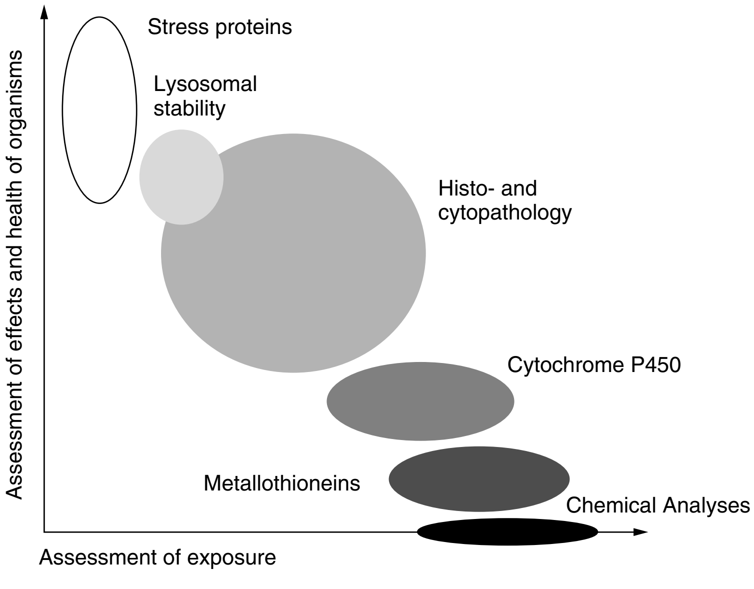

Figure 1. Suitability of different biomarkers to assess effects and health of organisms on the one hand and the exposure situation on the other. Chemical analyses only provide information on the exposure situation.

alarm phase," very sensitive biological parameters (e.g., shell closure or oxygen consumption of mussels) are continuously recorded as "alarm parameters." In the event the alarm is verified as not due to changes in natural environmental parameters, mussel samples are taken for phase 2.

In the second phase, "the toxicity evaluation phase," biomarkers indicating toxicity stress or strain (e.g., intracellular energy-rich phosphates, strombine formation, transmembrane sodium gradient, cellular calcium content) are used to assess the health status of the exposed organisms.

In the third phase, "the fingerprint phase," a set of chemical-specific biomarkers (e.g., transmembrane distribution of free amino acids) are applied in parallel with chemical analyses of samples automatically taken in phase 1. These investigations provide information on the nature of the chemicals responsible for the effects observed in phases 1 and 2.

For freshwater monitoring of pollution, the Multispecies Freshwater Biomonitor (MFB) has been established by LIMCO Int. (13). Similar to the TBS, the MFB uses flow-through exposure chambers for the exposure of limnic organisms including gammarids, chironomids, or fish. As biomarkers/bioindicators, breathing activity and locomotion of animals can be recorded continuously in this system. In case of an incidence, samples can be taken for different analytical purposes.

In order to evaluate biomarker responses with respect to their toxicological and ecological relevance (i.e., their chemical specificity and importance for effects at higher biological levels including populations and ecosystems), an extended monitoring project called VALIMAR (*vali*dation of bio*mar*kers for the assessment of small stream pollution) was conducted at two small streams in southern Germany between 1995 and 2000 using fish as monitoring organisms (10). The project was based on a "middle-up and middle-down" approach using flow-through aquaria in the field as intermediates between controlled lab and uncontrolled field situations.

According to the results of VALIMAR, for stream systems mainly influenced by wastewater release and agricultural activities, a combination of cellular (e.g., histopathology of kidney or liver, ultrastructure of gills or liver) with biochemical biomarkers (e.g., EROD activity, stress protein expression, catalase or esterase activity) can be recommended as useful tools for assessing risk in fish populations. Biomarkers proved to be sensitive early warning sentinels, which indicate the general stress status and the health of fish in streams influenced by different sources of pollution, but also in streams influenced by temporary or locally restricted spills (6,10). In addition, biomarkers are very useful in assessing the recovery of aquatic ecosystems (14). Although in the VALIMAR project the ultrastructure of the gills could clearly be identified as the best discriminator between the two streams in both brown trout and stone loach (15), the use of single biomarkers to assess the holistic effects of pollution, either structural or biochemical, is not recommended. Whereas biochemical biomarkers are sensitive and respond rapidly to stressors, their disadvantage is that they are also highly variable and are quick to recover following removal of stress. Structural responses, on the other hand, are generally less variable, but also less sensitive in response to short-term events. Since structural parameters require more time to recover than biochemical responses, structural responses are useful in understanding past water quality conditions for some days or weeks after a stress event. For the experimental situation of VALIMAR, a combination of biomarkers to discriminate between the two test streams in trout was the gill ultrastructure, esterase, and cytochrome P450 enzymes. A suitable combination of biomarkers in stone loach was gill ultrastructure, acid phosphatase, and alanine aminotransferase (15).

As cellular biomarkers, histological and ultrastructural changes in monitoring organs (e.g., liver or gills of fish, or hepatopancreas or kidney of invertebrates) were shown to be suitable for pollution assessment in terrestrial and aquatic ecosystems (16–18). The *in situ* evaluation of cellular injury allows a direct diagnosis of adverse effects qualitatively but also quantitatively by means of morphometry or different semiquantitative assessment methods (19). Since histology and cytology not only reflect the impact of xenobiotics but also the general metabolic status of an organism, it is essential for an investigator of cellular biomarkers to be aware of the diversity and plasticity of cellular reactions occurring in an organ under unpolluted conditions. Many studies using light and electron microscope techniques as tools of prospective as well as retrospective risk assessment have been conducted. The majority of this work has been done with fish, but experience is also available for molluscs, annelids, mites, diplopods, isopods, and collembolans in response to heavy metals and organic pollutants (reviewed in References 11 and 20).

At the subcellular/organelle level, the lysosomal system has been identified as a very sensitive target for xenobiotics (21). Lysosomes are membrane-bound vesicles containing acid hydrolases. In intact lysosomes, these hydrolases are prevented from reacting with cytoplasmic compounds by an intact membrane. In response to stress, the lysosomal membrane stability decreases and its permeability increases. As a result, hydrolases are released into the cytoplasm. One of the easiest techniques to determine lysosome membrane integrity is the neutral-red retention assay, which is based on the uptake of the dye neutral-red by transmembrane diffusion. The capacity of healthy lysosomes to take up and maintain the dye depends on the efficiency of membrane-bound proton pumps (22). In stressed cells, neutral-red gradually leaks from the lysosomes into the surrounding cytoplasm. The time of dye retention in the lysosomes is the measure for the intensity of stress. In the past, most experience with the neutral-red retention assay exists in the marine field (21); however, a few studies have also been conducted with soil invertebrates exposed to environmental pollutants (23,24).

At the physiological, biochemical, and molecular levels, several biomarkers are well established, which differ with respect to their capability to indicate exposure and/or effects. The most prominent biomarkers are biotransformation enzymes (e.g., cytochrome P450 and glutathione-*S*-transferase), metallothioneins, and stress proteins. In the TBS, respiratory rates, intracellular energy-rich phosphates, strombine formation, the transmembrane sodium gradient, the cellular calcium content, the transmembrane distribution of free amino acids, and other physiological parameters are recommended for evaluation of chemical stress in marine ecosystems. Physiological, biochemical, and molecular biomarkers are very sensitive and respond quickly to environmental stressors. Therefore, they are also useful tools to detect influences on organisms in minor contaminated environments. In contrast to cellular biomarkers, however, which show saturation response kinetics with increasing intensity of the stressor, response kinetics of biochemical and molecular biomarkers often follow an optimum curve (Fig. 2). Thus, low values for molecular biomarker responses are difficult to interpret since they may occur in healthy as well as in moribund organisms, in the latter having already surpassed the optimal biomarker response threshold. Whether these low values result from exposure to very low or very high stressor intensities can only be decided when biochemical markers are combined with markers that are characterized by optimum response kinetics, for example, histopathological diagnostics (25). In addition, the dependence of physiological, biochemical, and molecular marker responses on exogenous and/or endogenous stress factors other than xenobiotics (e.g., temperature or reproduction status) has to be taken into account by the investigator.

The question of whether biomarker responses are relevant for effects at higher biological levels (i.e., populations or ecosystems) can be answered either experimentally (as in Reference 26) or by using a weight of evidence approach (27). Köhler and colleagues (26) studied the relevance of stress protein responses in the slug *Deroceras reticulatum* exposed to metals for different population parameters. They showed that the hsp70 levels in slugs after 2–3 weeks of exposure to the respective metals reflected effects in fecundity, reproduction, and mortality of lifetime exposure. Thus, in this case, biomarker measurements were proved to be early warning tools to predict long range consequences of xenobiotic exposure at the level of life cycle parameters.

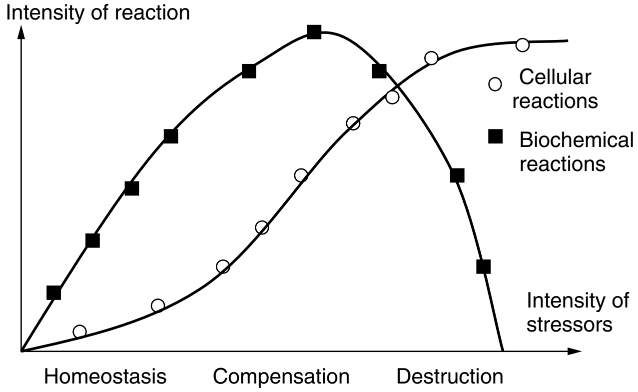

Figure 2. Response kinetics of cellular and biochemical biomarkers.

Since long generation times of many organisms often do not permit such direct evidence of causal relationship between effects at low and high biological levels, a weight of evidence approach commonly used in human medicine is suitable to relate causes and effects on the basis of epidemiological data. By means of Hill's causality criteria (28), for example, the criteria of biological plausibility, strength of association, consistency of association, or experimental evidence, causality can be established even when direct experimental proof of causality is lacking. Based on this, in the VALIMAR project (10), a simultaneous collection of data for responses at different levels of biological organization in combination with a detailed characterization of the exposure situation made it possible to establish causality between different levels of biological organization as well as between exposure and effects (27).

ACTIVE BIOMONITORING (ABM) BY TRANSLOCATION OF BIVALVE MOLLUSCS

Auckland Park, South Africa

DEFINITION

To start with, it is necessary to clearly define what is understood by active biomonitoring (ABM) using bivalve molluscs in this context. Here, the definition that will be used is: "the translocation of bivalve molluscs from one place to another for the purpose of environmental quality monitoring" (1–3).

The use of bivalves obviously indicates that the focus will be on the aquatic environment. However, ABM has also been performed in the terrestrial environment, using, for example, snails (4,5), mosses (6,7), lichens (8), or grasses (9).

Thus, an ABM approach employs organisms that are collected from an (generally) unstressed, unpolluted population and that, afterwards, are translocated to potentially polluted sites. The chemical and biological consequences of this translocation, which usually involves the caging of the organisms, can then be followed in space and time to estimate the effects of exposure on selected endpoints (3,10).

A second approach in which organisms are used to reflect environmental pollution is passive biomonitoring (PBM), which comprises "the collection of organisms from their habitats at sites where a natural population exists" (1–3). Although PBM has also frequently been used, ABM has a number of properties that advocate its use in environmental quality monitoring.

(DIS) ADVANTAGES OF ABM

The advantages of ABM for biomonitoring purposes are:

- Experiments can be performed for a **known exposure period**.
- All organisms have a **similar life history** at the start of the exposure.
- It is easy to **compare different sites**, even if the organisms are not normally present at the exposure locations.
- A **comparison between transplanted and indigenous organisms** can indicate to what extent the indigenous organisms are adapted to the location or can give information about uptake kinetics of pollutants. Indigenous species can be "genetically

protected," and thus the use of transplanted organisms can circumvent this adaptation process, making the comparison among different sites more precise and the use of nonadapted species more sensitive.

- Compared with laboratory-bred organisms, transplanted organisms are **better acclimated** to changing environmental conditions, and thus the impact of field exposure through, for example, climatological shock, will be less pronounced.

Although these advantages advocate the use of ABM under field conditions, a number of drawbacks also exist that have to be kept in mind when evaluating and interpreting the results of ABM studies:

- **Food availability** may skew the results by overestimating or underestimating the instream toxicity. As mussels depend mainly on algae as a food source, exposure in nutrient-poor but clean water may indicate stressful situations not related to pollutants but to a decreased quality of food resources (11,12). On the other hand, high amounts of food in eutrophic streams may mitigate the impact of pollutant exposure on aquatic organisms. Several authors have demonstrated the positive impact of increased food availability on growth and reproduction of pollutant-exposed organisms (13–15).
- The **loss of cages** containing the transplanted animals can make interpretation of the results much more difficult or even impossible.
- Compared with indigenous organisms, ABM might give **an overestimation of effects** because prolonged exposure to low levels of contamination eventually could lead to genetic adaptation of indigenous organisms. ABM does not take this kind of evolutionary processes into account.

WHY USE BIVALVE MOLLUSCS?

ABM studies have been performed with a wide variety of organisms, but bivalve molluscs have a number of important advantages compared with other aquatic organisms, which advocate their usefulness in biomonitoring.

- Although subsequent handling of organisms had a demonstrably negative effect on bivalve growth (16,17), **handling stress** and crowding are less important in bivalves compared with other organisms.
- Many bivalve molluscs are **relatively resistant to pollution**, although this feature is obviously species-dependent. The most commonly used test species for both marine and freshwater environments have a relatively high pollution tolerance, although this does not necessarily mean that they are insensitive to it.
- As filter feeders, mussels are **exposed to water, food, and suspended matter** as potential sources of contamination, which provides an integrated measure of pollution exposure, which is often not the case with other test species.
- Mussels have a **very high bioaccumulation** and a low biotransformation potential for both organic and inorganic contaminants (18,19), which means that there will be no or low transformation of, for example, organic micropollutants, and mussels can thus be used as long-term bioaccumulators.
- Mussels are **sedentary organisms** and are often easily collected. Mostly, they are attached to rocky or woody substrates in high numbers, which makes it easy to collect a large number of organisms from one location.
- Bivalves often have a **commercial value**, which makes them target organisms for environmental protection and legislation efforts.

However, a number of negative features connected to the use of bivalve molluscs as a biomonitoring tool also exist.

- **Reproduction**, an ecotoxicological endpoint with very high ecological relevance, is relatively difficult to measure and is highly dependent on seasonality (20).
- **No clear reference populations** exist, whereas other aquatic organisms (e.g., daphnids or zebrafish) have clearly defined responses under "no stress" or laboratory situations, which might complicate the comparison between different studies when organisms for transplantation are taken from geographically different collection sites.
- Mussels have no or a relatively **low biotransformation potential** (also a benefit, see above), which limits the use of biotransformation enzymes as biomarkers of exposure (18).

THE USE OF BIVALVE MOLLUSCS FOR BIOMONITORING

Biomonitoring is regarded as the regular systematic use of organisms to evaluate changes in the environment or water quality (21). It may take on many forms, from the measurement of chemical residues in tissues of living organisms (i.e., chemical monitoring) to the quantification of biological endpoints (i.e., biological effect monitoring or biomarkers) including changes to various biochemical, physiological, morphological, and behavioral factors (22).

The most popular bioindicator species used in the marine bioaccumulation and biomarker ABM are species from the family Mytilidae (e.g., *Mytilus edulis* and *M. galloprovincialis*) and *Perna* spp. from the family Pernidae. With the subsequent expansion of ABM to freshwater environments, the Dreissenidae (e.g., *Dreissena polymorpha*) and species from the family Unionidae (e.g., *Anodonta cygnea, Elliptio complanata*) are the most used bioindicator organisms. These four families make up over 70% of the bioindicator organisms used in ABM studies worldwide. An evaluation of three databases revealed over 350 references related to the implementation of transplanted bivalves in biomonitoring programs. These studies that were carried out between the early 1980s and 2004 showed two very definite trends in the application of bivalves in ABM.

Chemical Monitoring with Bivalve Molluscs

Physical and chemical measurements of dissolved and particulate bound compounds reveal valuable information concerning the presence and the dispersion of pollutants in aquatic environments. However, important shortcomings exist in predicting the impact of pollution in the environment. Due to changes in water composition and environmental conditions, representative samples cannot easily be obtained (23,24). Furthermore, measurements of pollutants in the water and/or sediments do not necessarily represent their bioavailability. Therefore, measurements of accumulated micropollutants in the biota can help to determine the presence, bioavailability, and impact of pollution in the environment.

During the last three decades, bivalves have widely been employed as biomonitors to evaluate the bioavailability of micropollutants. Marine mussels, such as *M. edulis, M. galloprovincialis*, and *P. viridis*, have been used since 1975 in monitoring programs to evaluate the bioavailability and effects of pollutants present in estuarine and coastal ecosystems (25–29). In several areas of the world, this so-called “Mussel Watch Program” has been implemented (30). Following these marine biomonitoring programs, freshwater mussels have been used since the late 1980s to monitor the quality of freshwater ecosystems. Freshwater bivalves that have been used are, among others, *E. complanata*, the Asiatic clam *Corbicula fluminea*, and *Anodonta* sp. (31,32). In Europe, the most frequently used bivalve species is the zebra mussel, *D. polymorpha* (33–36). One matter that is of special interest when molluscs are used for chemical monitoring involves the question whether concentrations of micropollutants in resident mussels might vary from transplanted mussels. Therefore, comparison of the accumulation of contaminants between transplanted and indigenous mussels is essential to evaluate and validate the applicability of caged organisms as a chemical monitoring tool. Among others, an extensive study by Bervoets et al. (37) showed that transplanted zebra mussels, exposed for a period of 6 weeks in summer, accumulated a broad range of micropollutants up to levels comparable with levels measured in resident mussels.

Table 1 lists a number of selected studies that have used ABM with bivalve molluscs to monitor the presence of pollutants in freshwater, estuarine, and marine environments.

Biological Monitoring with Bivalve Molluscs

The realization, however, that it is virtually impossible to monitor all contaminants present in the environment (both of anthropogenic and natural origin), together with the increased attention that the relationship between chemical body burdens and toxic effects was receiving, led to the application of biomarkers in ABM (59,60). Biomarkers involve the assessment of the overall quality of the aquatic environment by examining biochemical, physiological, behavioral, or population responses that reflect the potential of contaminants to impair biological processes in exposed organisms (61). From the early 1990s, biomarkers became frequently employed in ABM studies as indicators of biological responses, which were related to exposure and toxic effects of environmental chemicals. Various biochemical parameters in bivalves have been tested for their responses to toxic substances and their potential use as biomarkers of exposure or effect (22). The biomarkers that have been investigated the most extensively are related to those biochemical parameters that provide short-term indication of long-term effects, that is, responses at the lower level of biological organization (e.g., antioxidant enzymes, metallothioneins, acetylcholine esterase). However, the technical demands and lack of ecological relevance have been identified as a

Table 1. A Brief Overview of Chemical Monitoring Studies with Bivalve Molluscs

Area	Species	Common Name	Pollutant	Reference
Marine waters	*Mytilus edulis*	Common mussel	Heavy metals	39
	Mytilus edulis	Common mussel	PAHs	40
	Mytilus edulis	Common mussel	PCBs and hydrocarbons	41
	Mytilus galloprovincialis	Bay mussel	Heavy metals	42
	Mytilus galloprovincialis	Bay mussel	PAHs	43
	Mytilus californianus	California mussel	Heavy metals	44
	Macoma balthica	Baltic tellin	Heavy metals	39, 45
	Perna viridis	Green mussel	Heavy metals	46, 47
Estuarine	*Perna perna*	Brown mussel	Hg, MeHg	48
	Ragnia cuneata	Wedge clam	Heavy metals	49

	Elliptio complanata	Eastern elliptio	PAH and PCB,	56, 57
	Hyridella depressa		Heavy metals	58

concern in the application of these biomarkers in ABM. In this regard, energy budgets at different levels of biological organization can potentially link these different levels and provide a holistic and integrative indication of the effects observed within exposed organisms. This concept has been applied from as early as the beginning of the 1980s to demonstrate the scope for growth changes in bivalves along a pollution gradient. In recent years, energetic responses are increasingly used as biomarkers in ABM and have been statistically correlated to negative effects on growth and condition in bivalves transplanted along a pollution gradient and other invertebrate community-related responses (2,3,62,63).

CONCLUSIONS

Bivalve molluscs have a number of properties that advocate their use in both chemical and biological monitoring studies. Active biomonitoring, being the translocation of organisms from one (usually unpolluted) location to another one (usually polluted), can provide valuable information about the state of the environment, the presence and biological availability of pollutants, and the effects of these pollutants on organisms and ecosystems.

BIOCHEMICAL OXYGEN DEMAND AND OTHER ORGANIC POLLUTION MEASURES

Neil F. Pasco
Joanne M. Hay
Lincoln Ventures, Ltd.
Lincoln, New Zealand

Biochemical (also called biological) oxygen demand (BOD) is an empirical test indicator of biological activity and follows a specified laboratory procedure to determine the oxygen requirements of wastewaters, effluents, and polluted waters (1,2). The BOD test measures the amount of oxygen consumed in breaking down organic matter using both aerobic biological and chemical degradation processes, giving an indication of the organic strength of a wastewater. The test has its widest application in measuring waste loadings to treatment plants and in evaluating the BOD-removal efficiency of such treatment systems.

BOD is determined by incubating a water sample in a sealed container for a specified time and measuring the loss of oxygen that occurs between the beginning and end of the test. Samples must often be diluted prior to incubation.

WHAT DOES IT MEASURE?

Biodegradable organic matter is a composite substrate and is difficult to quantify directly. The BOD test estimates the amount of dissolved oxygen used during the degradation of organic waste as a surrogate for measuring the waste itself.

The amount of molecular oxygen measured during the incubation period can accrue from three sources:

1. The oxygen used for the biochemical degradation of organic material (carbonaceous biochemical oxygen demand, CBOD).
2. The oxygen used to oxidize inorganic materials such as sulfides and ferrous iron.
3. The oxygen used to oxidize reduced forms of nitrogen (nitrogenous demand), although a nitrifying inhibitor is often used to suppress the nitrogenous demand.

The earth's surface is mildly oxidizing and a tendency exists for reduced compounds, such as carbohydrates, to react with oxygen to form the more stable endproducts, carbon dioxide and water. BOD is the manifestation of this tendency in an aqueous environment, and two of the three sources listed above, (1) and (3), require microorganisms as the catalyst, whereas in (2), oxygen is capable of directly oxidizing some classes of inorganic materials.

Primarily, BOD values indicate the amount of carbonaceous organic material. The oxygen demand made by the oxidation of ammonia and organic nitrogen can be inhibited using 2-chloro-6-(trichloromethyl) pyridine or allyl thiourea in order to remove the nitrogenous demand and isolate the CBOD value. In the remainder of this article, BOD refers to CBOD only.

HISTORICAL CONTEXT

The complete biochemical oxidation of organic matter in a water sample can take up to 90 days, an impractical duration for an analytical test. The current international regulatory standard method for determining biodegradable organic compounds in wastewaters has been set as a five-day BOD assay (BOD_5). BOD_5 quantifies the amount of dissolved oxygen required for the microbial oxidation of carbonaceous organic material in five days under specified conditions (1). The five-day duration has no theoretical grounding but is based on an historical convention reported in 1912, as follows (3):

> In a report prepared by the Royal Commission on Sewage Disposal in the United Kingdom at the beginning of last century, it was recommended that a five-day, 18.3 °C, BOD value be used as a reference in Great Britain. These values were selected because British rivers do not have a flow time to the open sea greater than five days and average long-term summer temperatures do not exceed 18.3 °C. The temperature has been rounded upward to 20 °C, but the five-day time period has become the universal scientific and legal reference.

The standardized test was first published in the *American Public Health Association (APHA) Standard Methods* in 1917.

UNITS OF MEASURE

BOD is expressed either as milligrams of oxygen per liter (mg O_2/L) or parts per million (ppm).

WHAT IS IT USED FOR?

Despite its dubious ancestry, the BOD_5 test is still the most important and widely used environmental index for monitoring organic pollutants in wastewaters, mainly as proof of compliance with relevant legislation. Most developed countries strictly regulate the permissible BOD loadings of water as it is discharged from a treatment plant into receiving waters (e.g., sea or river), which is typically required to be less than 20 mg O_2/L. The BOD_5 value for potable water is close to zero; domestic wastewater effluent entering a treatment plant typically has a BOD_5 of around 300 mg O_2/L; and industrial effluents can have BOD_5 values greater than 20,000 mg O_2/L.

HOW DOES IT WORK?

Heterotrophic microorganisms require a metabolizable source of organic carbon, such as sugars, amino acids, nucleotides, organic acids, and fats, in order to grow. Depending on their physiology and the prevailing environmental conditions, microorganisms can harness energy from these food sources using either respiratory or fermentative biochemical pathways. Respiration is defined as the oxidation of an energy source (such as organic carbon) in which electrons are removed from the carbon source and donated to an inorganic terminal electron acceptor within the cell. Aerobic respiration uses oxygen as the terminal electron acceptor. Hence, through a complexity of genetics, physiology, and biochemistry, the breakdown of organic carbon is coupled to oxygen reduction and is facilitated by microorganisms.

Natural organic detritus plus organic waste from wastewater treatment plants, agricultural, and urban runoff provides food sources for waterborne microorganisms. The lab-based BOD_5 test is unique in that it simulates the microbial decomposition of organic wastes in the environment, thereby approximating the response of natural ecosystems (4), which helps explain the enduring relevance of the BOD test over so many years.

MEASUREMENT PROTOCOL

The BOD_5 test consists of a sample of wastewater held in a full, airtight bottle (usually 300 mL) (Fig. 1) for five days at 20 °C in the absence of light. The amount of dissolved oxygen present in the sample is measured at the beginning of the test period and at the end of five days using a dissolved oxygen probe (Fig. 2). The difference in dissolved oxygen between the day 0 and day 5 measurements represents the biochemical oxygen demand. The test requires the presence of three key ingredients: dissolved oxygen, organic substrate, and microorganisms, as prescribed by the standard test protocol. For complete specifications on how to set up and calculate a BOD_5 analysis, refer to Reference 1.

Figure 1. Standard 300 mL BOD bottle.

Figure 2. Dissolved oxygen probe.

COMPONENTS OF THE BOD_5 TEST

Dilution Water

The dilution water (saturated with dissolved oxygen) must be free of organic matter and bioinhibitory substances and has a twofold function:

- It ensures that aerobic conditions prevail throughout the test. Water samples with high BOD loadings contain insufficient dissolved oxygen for the complete oxidation of the compounds present in the sample. Without dilution, the sample will become anaerobic at some point during the five-day incubation period, causing the microorganisms to switch from a respiratory to a fermentative mode. Diluting these samples ensures that sufficient oxygen is maintained to oxidize all the organic matter present, with some residual oxygen left at the end of the test.
- It supplies the inorganic nutrients necessary for microbial growth (magnesium sulfate, calcium chloride, ferric chloride) and a buffering capacity in order to maintain a pH suitable for bacterial growth.

Seed (Microorganisms)

The seed refers to the microorganisms responsible for the biodegradation of organic matter in the sample. Although microorganisms occur naturally in the environment, a diluted water sample may require seeding with additional microbes to ensure a sufficient number of microbes are present to degrade the organic matter in the sample. The preferred seed is effluent from a wastewater treatment plant. The seed material has a BOD of its own, which must be measured separately in a control (seed in dilution water with no added substrate) and subtracted from the BOD of the samples. In a 300 mL BOD bottle, the volume of seed is typically 2 mL.

Wastewater Sample

The wastewater is the source of the organic matter to be measured. Given that biodegradable organic matter is a composite substrate, the BOD measurement is an aggregate of the wide range of substances present. It is also dependent on the microbial species present and the relative biodegradability of the substrates present. Depending on the expected BOD strength of the wastewater sample, a known volume is added to the BOD bottle and made up to 300 mL with dilution water.

STANDARDS

Glucose–Glutamic Acid (GGA)

The primary standard for calibrating BOD_5 tests is a glucose and glutamic acid solution (150 mg glucose/L, 150 mg glutamic acid/L). The GGA solution is intended to be a reference point for evaluating the dilution water quality, seed effectiveness, and analytical technique.

Organization for Economic Cooperation and Development (OECD)

The GGA solution has increasingly been questioned as a valid standard, particularly for the developing rapid BOD tests (see later). Many microorganisms preferentially use simple sugars like glucose and will actively repress the metabolism of other carbon sources when glucose is present, which has led to an underestimation of BOD values of samples containing compounds that are less readily biodegradable. A more appropriate standard solution with similar biodegradative properties to the sample being analyzed may be warranted, especially for rapid BOD tests. The OECD-defined wastewater standard solution (5) has been proposed as an alternative and more appropriate choice of standard for analysis of treated wastewater (6,7). The OECD solution, however, is not currently recognized as a regulatory standard.

QUALITY CONTROLS

No absolute BOD value of a sample exists, and BOD results are test defined, meaning BOD values are based on the parameters of the test method, not on any “true” BOD value. Some specific requirements exist that must be met for a BOD_5 analysis to be valid and which ensure that the methodology used is correct. Controls to be included each time a BOD_5 test is performed are a dilution water blank, a seed (the microorganisms) sample, and a GGA standard. If any of these quality control checks fall outside the recommended ranges (specified below), the results of the BOD_5 test should be rejected.

- *BOD blank* (bottle containing only dilution water and no seed) must not show a dissolved oxygen depletion of more than 0.2 mg O_2/L after five days.
- *Seed blank* (microorganisms added to water sample) should contribute between 0.6 and 1.0 mg O_2/L uptake per BOD bottle.
- *The glucose–glutamic acid standard* should report a BOD of 198 ± 31 mg O_2/L after a five-day incubation (i.e., the oxidation of the glucose–glutamic acid solution consumes 198 mg O_2/L over five days).

Sample dilutions should report a 50% decrease in dissolved oxygen over the five-day incubation period. At minimum, there should be an oxygen depletion of at least 2 mg O_2/L between the initial and final reading, plus a residual dissolved oxygen reading of at least 1 mg O_2/L.

HOW MUCH IS MEASURED?

Wastewater contains both biodegradable and non-biodegradable material, the latter not being represented in the BOD measurement. However, in general, the BOD_5 test does not represent the total biodegradable fraction of organic material present. Depending on the type of wastewater, the rates at which the biodegradable material in a given sample can be oxidized over five days can be between 50% and 90%.

Where the composition of the organic substrate is chemically defined, as is the case for the primary GGA standard, the amount of oxygen required for its complete oxidation can be calculated from a stoichiometric equation.

For example, the stoichiometric equation for the oxidation of glucose ($C_6H_{12}O_6$) is

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_20$$

For the complete oxidation of 1 mole of glucose, 6 moles of oxygen is required. A 150 mg glucose/L is reported to have a BOD_5 of 99 mg/L (1). On a molar basis, 150 mg glucose/L corresponds to 0.83 mmol/L, and the stoichiometric oxygen requirement is 5 mmol/L. The BOD_5 glucose requirement of 99 mg/L converts to 3.094 mmol O_2/L, and therefore the biological oxidation occurring after five days equates to 61.9% conversion. A similar exercise with glutamic acid, excluding the oxidation of nitrogen, equates to 58.4% conversion; thus the mean molar conversion of the standard glucose and glutamic acid mix in a one-hour BOD_5 test is 60.5% (8).

PROBLEMS

Although the BOD_5 test sounds simple, practical difficulties associated with it exist, and it has significant limitations. Although the test has been refined over the years, the basic approach of using a dilution technique has remained unchanged. Unfortunately, these dilutions reduce the concentration of substrates and microorganisms in the samples, thereby decreasing the overall kinetics. This decrease, along with the arbitrary time period of five days, means the actual BOD of the sample may not be reflected. The presence of toxic substances, such as copper, mercury, or chromium, even at low concentrations, in the wastewater can affect, or kill, the bacteria. A decrease in BOD_5 values may be because of a decrease in organic load or may be because of the presence of a toxin in the sample. The test is also insensitive and imprecise at low concentrations; the method requires experience and has an accepted margin of error of 15–20%, possibly because of the heterogeneity of the microbial populations in wastewater treatment systems and their widely differing responses to substrates.

However, the major drawback of the traditional BOD test continues to be the five-day measurement time. Such a delay is unacceptable for any form of active intervention for environmental monitoring and/or process control. It is suggested that the low solubility of oxygen in water is rate-limiting in the BOD_5 test; an O_2 saturated solution at 20 °C contains 9.07 mg O_2/L. The limited oxygen storage capacity of water is responsible for aqueous environments being so susceptible to nutrient deoxygenation and is why wastewater samples are often required to be substantially diluted to keep the oxygen depletion within the 1–9 mg O_2/L working range of the BOD_5 test.

ALTERNATIVE MEASUREMENT TECHNOLOGIES

In an attempt to overcome the difficulties in achieving rapid, reproducible results, a number of analytical wet chemical techniques have been developed to monitor organic pollution, as alternatives to BOD_5 measurements (9).

Chemical Oxygen Demand (COD)

The COD test measures the chemical oxidation of wastewater by using a strong oxidizing agent under acid conditions. As for BOD, it measures the amount of oxygen required as a surrogate for measuring the organic waste component directly. However, the COD test does not differentiate between biologically available and inert organic matter and measures the total quantity of oxygen required to oxidize all organic matter into carbon dioxide and water. COD values are always greater than BOD values, but the results can be obtained within two hours and the presence of toxic compounds in the sample do not affect COD measurements. In many cases, the BOD/COD ratio is used to provide an indication of the biodegradability of the wastewater. However, the chemicals used, such as acid, chromium, silver, and mercury, produce liquid hazardous waste that requires careful handling and disposal. Finally, the precision and accuracy of the COD test are questionable at low BOD values.

Total Organic Carbon (TOC)

This test measures carbon, where the carbon is oxidized by catalytic combustion (either at low temperatures by ultraviolet light and the addition of persulfate reagent, or by using a catalyst at high temperatures) to carbon dioxide, which is then measured. However, good correlations between BOD and TOC measurements have not been demonstrated, and again, the test is unable to differentiate between biodegradable and nonbiodegradable matter. The main advantage of the TOC test is its speed; determinations can be made within minutes, facilitating a greater number of measurements compared with either BOD or COD tests.

RAPID BOD TECHNOLOGIES

Oxygen-Based Sensors

In response to the restrictive five-day time lag inherent in the traditional BOD_5 test, a number of rapid BOD techniques have been devised. They have evolved down two development paths, both respiratory-based: microbial biosensors and respirometers.

Microbial BOD biosensors consist of a microbial biofilm immobilized onto a dissolved oxygen probe. Since the first BOD biosensor of this sort was developed (10), various sensor designs have been reported, and their response time ranges from 3 to 30 minutes. In all reported cases, the decrease in dissolved oxygen forms the basis of the analytical signal. One consequence of oxygen limitation for these sensors is that the amount of organic material biodegraded in a short-time assay is a very small fraction (~1%) of the total biodegradable organic content, and they can only respond to the easily assimilated compounds in the wastewater.

Commercially available respirometers, such as RODTOX®, BIOX®, BIOMONITOR®, and RACOD®, are designed to replicate the operation of a wastewater treatment plant, rather than the methodology of the

BOD test. They consist of one or more activated-sludge bioreactors maintained at steady-state conditions by continuous stirring. The inclusion of organic material increases microbial respiration, in turn increasing the rate of oxygen uptake, which is recorded by an oxygen sensor. Oxygen consumption is then correlated with BOD; these devices also report a short-term BOD estimation in 3–30 minutes.

Nonoxygen-Based Sensors

A second generation of rapid BOD sensors have been reported based on the measurement of charge transfer, either to an alternative electron acceptor, such as a synthetic redox-active mediator (8,11), or directly to an electrode (12), rather than the depletion of oxygen.

Mediated Sensors

The oxidation (loss of electrons and the concurrent transfer of charge) of organic substrates can be coupled to the reduction of a redox mediator, such as potassium hexacyanoferrate. These mediators readily accept or donate (i.e., shuttle) electrons in biochemical reactions. In a BOD application, the redox mediator substitutes for oxygen as the terminal electron acceptor during aerobic oxidation and transfers the electrons to an electrode, generating an analytical signal that can be converted to a BOD value. By replacing oxygen with a more soluble synthetic mediator, higher numbers of microorganisms can be incorporated into the assay, significantly reducing the incubation time to one or two hours (8).

Direct Electron Transfer

Direct electron transfer to an electrode is exhibited by some microorganisms, such as *Shewanella putrefaciens*, thereby eliminating the need for a redox mediator. The direct reducing action of the electrochemically active microorganisms can be exploited in a microbial fuel cell device, and the current produced has been shown to be dependent on the concentration of organics in the wastewater water sample (12).

CONCLUSION

For all its shortcomings and the availability of a number of related measurement techniques, the BOD_5 assay remains the preferred test for reporting the oxygen requirements of wastewaters, effluents, and polluted waters, which is, in part, because of its international regulatory status, but also because it uniquely characterizes the impact of oxygen depletion developing from biological activity in breaking down organic matter on receiving waters.

Concern over water quality continues to increase and has led to the implementation of stricter environmental pollution control legislation worldwide. Legislation, such as the European Urban Wastewater Treatment directive, is framed in terms of compliance with BOD_5 and will entrench the test even further. Although the need for a more rapid test is well recognized, the success of these alternative tests will remain limited until they can demonstrate robust comparability with the BOD_5 measurement.

BIODEGRADATION

Christian D. Frazar
Silver Spring, Maryland

The beginnings of life on this planet arose during a time of extreme conditions. For life to arise in an inhospitable world, the first organisms needed to be simple but hearty. The life forms of today considered most similar to those early ancestors of life are bacteria and archaea—simple, primitive organisms. Despite their primitive nature, these organisms have a diverse and powerful metabolic potential.

As life and other processes transformed the earth's air, land, and water, early organisms were in a new and changing environment. A wider variety of ecological niches became available. For five-sixths of the earth's existence, it was inhabited exclusively by microorganisms (1). Given their short generation time, microorganisms have had unfathomable generations to adapt to earth's many chemicals. As a result it is quite possible that for every natural compound that exists, there is a microorganism that has evolved to metabolize it and use it for growth.

Microorganisms are at the base of the food chain and play a key role in both secondary production and in decomposition. The ability of microorganisms to decompose or break down compounds is known as biodegradation. This term is often used to refer to the degradation of environmental pollutants by bacteria or fungi. This discussion will focus on the degradation process itself and the factors that influence and limit biodegradation.

MICROBIAL DIVERSITY AND METABOLIC POTENTIAL

The use of biodegradation to remove a contaminant from the environment is known as bioremediation. Understanding microbial diversity and metabolic potential is essential to understanding how to use biodegradation for remediation projects. During the twentieth century, a vast number of synthetic and natural compounds were released into the environment. A complex community of microorganisms often has the mechanisms to use or detoxify many of the compounds that humans have released.

Some organisms have a very narrow range of metabolic potential, and others have a wider capacity. For example, it has been demonstrated that the organism *Pseudomonas putida,* strain F1, degrades approximately 105 compounds, and it has been suggested that it can degrade many more (2). Other compounds, many of which are synthetic, are resistant to microbial degradation. Resistant compounds are known as recalcitrant compounds; many factors contribute to a compound's recalcitrance, which will be discussed later.

Many synthetic compounds are considered xenobiotics. The term xenobiotic is often used to refer to compounds that are foreign to biological systems. The term originates in mammalian systems, not microbial systems. It does not always describe a compound accurately in microbial terms, because microbial diversity is so vast. What is foreign to one group of bacteria may be readily metabolized by a different group.

Microorganisms benefit from biodegradation by metabolizing a compound to yield carbon and energy. Energy is derived from the transfer of electrons and the conservation of that energy in the form of molecules such as adenosine triphosphate (ATP) and nicotinamide-adenine dinucleotide (NAD^+). ATP conserves this energy through high energy phosphate bonds and is used to drive energy-requiring reactions in the cell. NAD^+ is an electron carrier involved in oxidation–reduction reactions. If metabolism results in complete breakdown of a compound to inorganic products such as CO_2 and H_2O, this is referred to as mineralization. As the compound of concern disappears from the environment, the number of organisms that use this compound as a substrate for metabolism increases. This is known as growth-linked biodegradation, and mineralization is a common result.

ENRICHMENT CULTURES AND BIODEGRADATION RESEARCH

When research scientists attempt to identify an organism capable of degrading a particular compound, they collect microorganisms from the environment and inoculate them into a culture flask containing minimal medium, and the compound of interest provides the sole carbon source. The minimal medium provides other nutrients, such as nitrogen and phosphorus, that are necessary for microbial growth. Organisms unable to use this compound will not be able to grow, whereas those that can metabolize the compound will flourish. The organisms for this enrichment culture are often collected from a site where the compound of interest is found naturally or as a contaminant. For instance, if a researcher were attempting to isolate a xylene-degrading microorganism, a sample might be collected from an area of a gasoline spill because xylene is a component of gasoline.

Scientists need to be cautious of optimism because one organism may seem to degrade a chemical efficiently under laboratory conditions, but the actual environment where the degradation is to take place may have many inhibiting factors that cannot be controlled.

It is important for researchers to identify degradation products because some products are more toxic than the parent compound. For example, the hydrolysis of the herbicide 2,4-D is catalyzed by soil microorganisms, which yields a form of the compound toxic to plants (3).

FACTORS LIMITING BIODEGRADATION

The mere presence of a compound and a capable microorganism does not guarantee the compound's degradation. Microbial growth requires water, nitrogen, phosphorus, trace elements, carbon, energy, temperature, and suitable pH conditions. Biodegradation commonly supplies the carbon or energy or both. But growth may be inhibited by other toxins or limited by other essential elements or conditions. Under environmental conditions, predation can also be a factor that limits biodegradation. Protozoa consume bacteria; bacteriophages are viruses that can infect and lyse bacteria.

If no organisms can use the compound as the sole carbon or energy source, a compound may still be cometabolized. Cometabolism involves the degradation of a compound by an organism without providing carbon, energy, or any other factors required for growth. Unlike mineralization, cometabolism is not growth-linked. Even though the compound is not functioning as the carbon or energy source, it is possible for degradation to be quite rapid (4). Often other organic molecules in the environment provide the carbon or energy source, which leads to an increase in the microbial population that is responsible for the increased rate of degradation.

ENZYMATIC MECHANISMS

The proper enzyme must exist for metabolism or transformation of a compound. Over geologic time, microorganisms have adapted to compounds and structures to which they are exposed regularly. It is often believed that microbial enzymes have not evolved rapidly enough to cope with the onslaught of synthetic compounds that have been released into the environment in the last century (2).

Biodegradation may occur inside or outside the cell. Intracellular enzymes require the organism to have some means of transporting the compound inside the organism for degradation. Extracellular enzymes are released by the organism and degrade the compound before the products are transported into the cell, where the final degradation occurs. This is a common microbial tactic when the carbon or energy source is too large to internalize. Extracellular enzymes are manufactured in comparatively high concentrations compared to intracellular enzymes.

Degradative enzymes are often highly specific for a particular reaction. The enzyme must be able to fit the correct molecular structure into its active site. The active site of an enzyme is responsible for the cleavage or molecular rearrangement of a portion of the compound. The three-dimensional structure of the functional group fits neatly into the active site of the enzyme. Functional groups are often the targets of these enzymes (Table 1). Compounds can have a combination of functional groups, and the transformation of these compounds will depend on the spatial arrangement of the functional groups and the enzyme's ability to catalyze the degradation products. If it is known that an organism can degrade a structurally similar compound, then it may be possible to enrich for an organism capable of degrading the compound of concern.

ACCLIMATION PHASE

Initially, the organisms in the environment that can degrade a particular compound will often be insufficient to cause a noticeable change in the quantity of compound present. This initial period, referred to as the acclimation phase, can vary in length among compounds, environments, and organisms. Bioavailability and compound concentration can influence the length of the acclimation phase. If the compound is present in the environment at a concentration that is too high, then it can be toxic to organisms that would break it down (5).

Table 1. Common Functional Groups in Contaminants

Name	Structure	Example(s)
Halogen	R–X where X=Cl, Br, or F	Metolachlor
Aromatic ring		Benzene, toluene, ethylbenzene, xylenes (BTEX), polyaromatic hydrocarbons (PAHs)
Carboxcylic acid	 $R_1{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}OH$	Picloram
Alkene	$R_1{-}C{=}C{-}R_2$	Aldrin, dieldrin, and heptachlor
Alcohol (hydroxyl group)	$HO{-}R_1$	2,4-D
Ester	 $R_1{-}O{-}\overset{\displaystyle O}{\overset{\|}{C}}{-}R_2$	Malathion
Ether	$R_1{-}O{-}R_2$	2,4-D, MTBE

Research has shown that organisms that have been exposed to a particular compound can respond more quickly to a second exposure to the same compound (6). The first exposure selects for a community of organisms capable of degrading the compound. Upon reintroduction of that same compound, the community is already capable of degrading the compound, and the acclimation phase is shortened. The shortened acclimation phase can be attributed either to a more metabolically active community or a more rapid increase in the number of organisms capable of degrading the compound (6). This response has been identified among organisms capable of degrading several different pesticides (6).

RECALCITRANCE

Recalcitrant molecules are either resistant to degradation or are degraded at a very slow rate. There are several reasons that this occurs. As suggested previously, it is possible that the necessary enzyme does not exist. It is also possible that the correct enzyme may exist, but it cannot reach the active site and catalyze the necessary reaction. Finally, the enzyme necessary for the degradation of the compound may never be turned on by the organism. In this case, the enzyme is encoded on the organism's DNA, but no signal induces enzyme production. Some compounds, such as 2,4-D, are readily degraded under aerobic conditions but not under anaerobic conditions (4). Other compounds, such as the organophosphate herbicide, fenitrothion, are preferentially degraded under anaerobic conditions (4). Thus, the environment can play a role in a compound's recalcitrance.

BIOAVAILABILITY

A compound must be bioavailable before degradation will occur. The organism and its enzymes must be capable of coming into contact with the compound. To understand fully the limitation that bioavailability presents, we need to examine the microscopic scale on which microorganisms exist. Most bacteria are no longer than 10 μm, and the distance between one soil particle and another may be a journey that a bacteria never makes. Most bacteria in soil or sediment are attached to particles, but some are motile. These motile organisms often simply pass through pore spaces and do not really contribute to the microenvironment. If examined in great detail, it would be possible to see that the surfaces of soil and sediment particles consist of depressions and valleys, which provide habitats for native microorganisms. Some microorganisms will never leave these tiny spaces. These organisms rely on the movement of compounds and nutrients for survival. Some pores are too small for microorganisms but are large enough to provide a protective area for the compound.

Over time, the bioavailability of a compound tends to decrease due to sequestration of the compound. When the compound is plentiful, microorganisms will use the molecules that are easiest to obtain. Available compound is used, whereas the excess becomes bound to soil and sediment particles. Compound bioavailability then limits biodegradation. Researchers have attempted to model the diffusion and sorption of a compound to soil or sediment (7). One model is the diffusion–sorption bioavailability model that attempts to describe the rate of biodegradation in the presence of soil or sediment aggregates (7). Many biodegradation studies are done in flasks and do not take into account environmental factors such as diffusion and sorption.

NONAQUEOUS PHASE LIQUIDS AND COMPOUNDS OF LOW WATER SOLUBILITY

Nonaqueous phase liquids (NAPLs) generally have low water solubility. Dense nonaqueous phase liquids can be found below an aquifer, whereas light nonaqueous phase liquids are found on the surface of the water. A very small fraction of a NAPL is soluble in water, and this quantity is available to microorganisms for biodegradation. The vast majority of NAPLs are not in the aqueous phase, so they are often considered unavailable to the organisms capable of degrading or metabolizing them, thus presenting a factor limiting biodegradation. NAPLs that have polluted the environment include hydrocarbons (mainly from oil spills) and industrial solvents.

Microbial growth on compounds of low water solubility is generally slow; however; in some cases, exponential growth has been observed (8). There are several ways by which a compound that has low water solubility can be degraded. The small fraction of the compound that enters the aqueous phase is readily accessible to the organism. The organism also can come in direct contact with the compound at the water–compound interface (9). Finally, some organisms can make the compound more accessible through a process known as pseudosolubilization (9). Pseudosolubilization occurs via compounds released by the organism, which act as carrier molecules (10). The compound becomes enclosed in a micelle, which may diffuse through the aqueous phase (10). Microorganisms in the aqueous phase can then use the carbon source within the micelle. Surface active compounds can also be released by the organism. These compounds are composed of various lipids and interact with low solubility compounds such as hydrocarbons to facilitate their uptake by the organism (11,12).

GROUNDWATER BIOREMEDIATION

Groundwater contamination is of high priority because so many people rely on groundwater as a source of drinking water. Porosity, the empty space between soil and sediment grains, determines how much water an aquifer can hold. Water moves slowly through underground aquifers and that movement is a function of the type of soil or rock that composes the aquifer. Darcy's law allows scientists to approximate the discharge of water from an aquifer and takes the material that makes up the aquifer and the hydraulic gradient into consideration. Once the plume is located and the concentration of compound has been determined, removing it can be difficult and costly.

For *in situ* biodegradation to occur, it is often necessary to supply oxygen and nutrients to the microorganisms. The absence or presence of oxygen can make a substantial difference to the active microbial community and its ability to degrade the contaminant. The contaminated groundwater can also be pumped from the ground into a reactor, where microorganisms degrade the contaminant (for a review, see Reference 13). These reactors function similarly to sewage treatment plants. Contaminated groundwater and nutrients are pumped into a reactor where microorganisms are grown so that they are attached to the reactor. As the contaminated groundwater passes the microorganisms, they degrade the compound. The water is then disposed of or returned to the aquifer. Bioreactors are often limited by their high costs. Pumping of NAPLs is often difficult due to their low solubility in water.

MARINE OIL SPILLS

Marine oil spills can be remediated by bioremediation. Dispersants are used to spread the nonaqueous phase contaminants across the water's surface to create more favorable biodegradation conditions. The dispersants themselves are biodegraded in the process. It is estimated that 50% of the oil from the *Exxon Valdez* spill was biodegraded on the water surface, on the shore, or in the water column (14). Fertilizers are often used to enhance the rate of oil degradation and to supply otherwise limiting nutrients.

ALGAL BIOREMEDIATION

Biodegradation is not limited only to bacteria. Fungi play an important role in soil systems; in many aquatic systems, algae can play an important role. Several algal species are capable of degrading some pesticides in freshwater systems (15). Algae can be used to clean industrial pulp mill effluent before the effluent is discharged. They are effective in removing both the dark color of the effluent and organic halides (16). Some algae can bioaccumulate some polycyclic aromatic hydrocarbons in marine systems (17). Bioaccumulation is the sequestration of a compound by an organism, where the compound remains unchanged and the organism is unharmed by its presence. Over time, significant quantities of compound can be accumulated by the organism.

The metabolic diversity of microorganisms is a powerful tool for degrading unwanted compounds. Numerous sources are available to provide additional information regarding biodegradation processes. The journal *Biodegradation*, published quarterly, contains scientific advancements in biodegradation. Biodegradation databases are available that provide information on biodegradable compounds and the enzymes and microbial species that degrade them. A useful database is the University of Minnesota Biocatalysis/Biodegradation Database, found on the web at: www.umbbd.ahc.umn.edu/index.html.

BACKGROUND

This article summarizes recent developments in whole cell bioluminescent biosensors for estimating toxicity at wastewater treatment plants (WWTPs). This started with the use of natural marine bioluminescent bacteria, and there is now at least a 20-year history of toxicity testing with these organisms. Molecular biology has given rise to many new bioluminescent strains for toxicity testing to overcome some specific limitations of *Photobacterium (Vibrio) fischeri*. Luminescence decay toxicity tests have also been developed in higher organisms, up to *Caenorhabditis elegans* (1), to try to improve the relevance of these tests. Custom-made biosensors for protecting wastewater treatment plants are already in development. These developments coincide with the pattern of environmental legislation in Europe.

LEGISLATIVE DRIVERS

The Urban Wastewater Treatment Directive and the Water Framework Directive

In the European Union, under the Urban Wastewater Treatment Directive (2), the functioning of wastewater treatment works is considered important, and reaching nontoxic levels is of primary concern (3). In common with most legislation in the area, the Directive is directed toward regulating discharges to the environment, rather than to the WWTP itself. The more recent EU Water Framework Directive (4) is concerned mostly with protecting receiving waters from pollution and toxic discharges.

IPPC

The Integrated Pollution Prevention and Control Directive, adopted in 1996 (5), is one of the cornerstones of the EU's environmental legislation. It is likely that fines based on toxicity levels, in addition to the current physicochemical parameters, will be assessed on companies that discharge industrial effluents at concentrations above guidelines (6).

ENVIRONMENTAL QUALITY STANDARDS

Industrial effluents tend to contain more toxic substances than domestic wastewater, and numerical limits are set for discharges to ensure compliance with Environmental Quality Standards (EQSs). Compliance is then monitored by chemical analysis. There are several problems in this approach:

- There are many substances for which there is no EQS (over 99%).
- There are no ecotoxicological data for thousands of chemicals, and most EQSs are based on limited data.
- Difficulties are experienced in predicting the interaction of chemicals with each other and the subsequent effect on the environment.
- There are analytical difficulties for many chemicals, and great cost in separating and identifying all constituents.

TOXICITY CONSENTS AND DIRECT TOXICITY ASSESSMENT

In 1993, the predecessor to the U.K. Environment Agency, the National Rivers Authority (NRA), began research into setting discharge consents based on toxicity. This became known as Direct Toxicity Assessment (DTA). DTA provides a direct measure of acute toxicity, and it is not necessary to identify the substances causing effluent toxicity to treat or reduce it (7); a property can be measured and treated directly. If toxicity is detected but considered acceptable, a toxicity consent can be derived and applied. If the toxicity of the effluent is unacceptably high, however, remedial action may be needed, and then a toxicity consent can be derived (Fig. 1). In the United States, a similar process is applied to discharges to receiving waters; the process is called Whole Effluent Toxicity (WET).

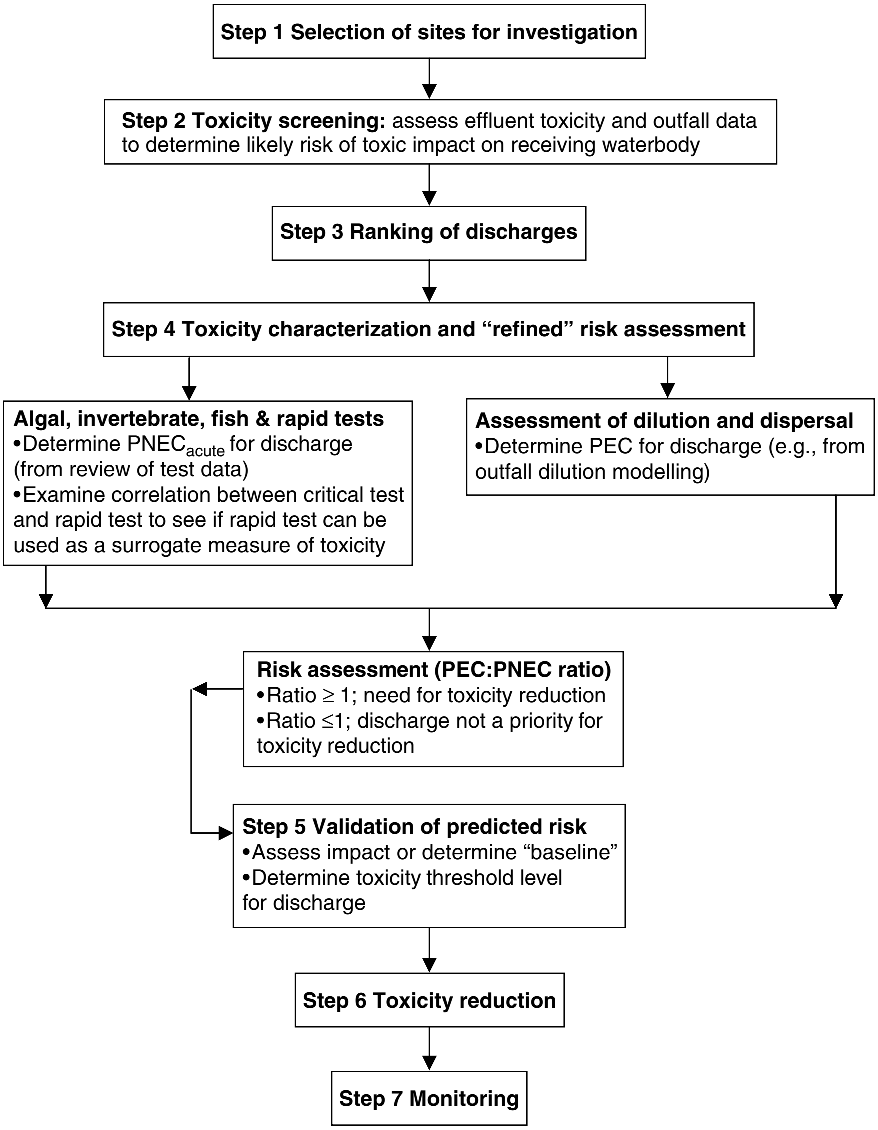

Figure 1. The Direct Toxicity Assessment process.

Two Types of "Legislative" Toxicity

From the above, it can be recognized that there is a need to measure toxicity in two different senses. On the one hand, there is the need to protect the biological WWTP, especially the activated sludge plant, from toxic influents that can kill the treating biomass, leading to loss of treatment and concomitant financial and regulatory implications. On the other hand, there is the need to measure the toxicity of the treated effluent from the WWTP for environmental protection.

Toxicity, An Imperfect Analyte

Toxicity is not a well-defined analyte for a biosensor. Acute toxicity refers normally to lethality as a result of exposure to a high concentration of a toxicant for a short period. Chronic toxicity may be lethal or sublethal but refers to exposure to a low dose for a long period. Although chronic toxicity does not necessarily cause death, it can result in long-term debilitation of some form.

Nevertheless, to make meaningful comparisons, it is necessary to put numbers to toxicity. These are some of the most commonly encountered numbers:

- LC_{50}: the concentration that produces 50% mortality in test organisms;
- LD_{50}: the dose that produces 50% mortality in test organisms;
- IC_{50}: the concentration at which 50% of growth or activity is inhibited;
- EC_{50}: concentration at which 50% of the predicted effect is observed;
- LOEC (the lowest observable effect concentration): the concentration at which the lowest effect is seen;
- NOEC (the no observable effect concentration): the maximum concentration at which no effect is observed.

In bioluminescence tests, the figures quoted are usually EC_{50} or IC_{50}. Their direct correlation with lethality (e.g., LC_{50}) in higher organisms is fraught with difficulty. It should be expected that the EC_{50} will be lower than the LC_{50} because impairment of function should precede total inhibition (8).

THE RELATIONSHIP BETWEEN BACTERIAL BIOLUMINESCENCE AND TOXICITY

The bacterial bioluminescence reaction involves oxidation of a long-chain aldehyde (RCHO) and reduced flavin mononucleotide ($FMNH_2$), resulting in the production of oxidized flavin (FMN) and a long-chain fatty acid (RCOOH), along with the emission of light (Fig. 2).

$FMNH_2$ production depends on functional electron transport, so only viable cells produce light. This relationship between cellular viability and light endows bioluminescence with the ability to report bacterial injury and recovery. It can be established readily that any substance that impairs the biochemistry will lead to a reduction in light output. Of crucial importance to the commercial development of the bacterial bioluminescence toxicity tests was the fact that the change in light output is proportional to the concentration of the toxicant. Thus, it was possible to develop quantitative tests and compare the results to toxicity tests with higher organisms (Fig. 3).

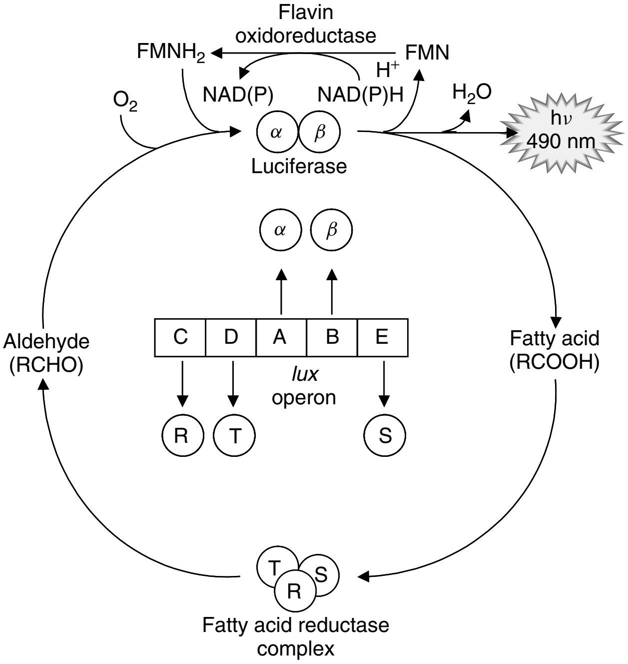

Figure 2. Genetics and biochemistry of bacterial bioluminescence. The rectangles represent genes and the circles represent enzymes or enzyme subunits.

BIOLUMINESCENT TOXICITY BIOSENSORS: POTENTIAL FOR USE IN DTA

What is required of these sensors is not necessarily greater sensitivity, resulting in lower EC_{50} values. The real value to DTA of treated effluents discharged to receiving water bodies would be relevance (good correlation) to the results of toxicity tests with higher organisms. The tests based on naturally occurring marine bioluminescent bacteria as used in the Microtox® test or the ToxAlert® test are in widespread use, and they correlate inhibition of luminescence with toxicity (9–12).

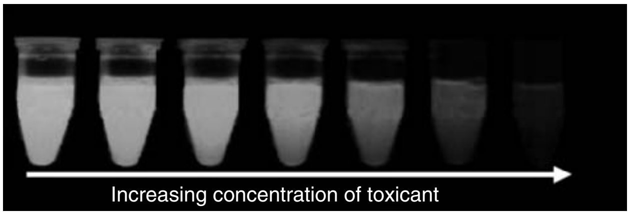

Figure 3. A series of tubes containing bioluminescent bacteria responding to increasing concentrations of toxicant by producing less light. (Courtesy of Remedios Ltd, http://www.remedios.uk.com/.)

The tests are rapid, and reliable toxicity testing has been demonstrated (13–19). Their use has resulted in extensive databases on the toxicity of pure chemicals (18). The potential for using the Microtox test as an alternative to animal testing has been demonstrated (19). It was found more sensitive and less prone to false positives than two common toxicity tests, the L-929 Minimal Eagle's Medium (MEM) elution cytotoxicity test and the Draize rabbit eye irritancy test. It offers the often quoted advantages of low cost and convenience, and it is far less controversial than these latter tests.

Despite these advantages, application to environmental samples has not always been successful (20,21), and correlation with other toxicity assays may require much more intrusive modification. In particular, the marine origin of these natural bacteria may act as a barrier to their use in DTA. For example, they are sensitive to pH and osmotic conditions. The revolution in genetic engineering, however, has made it routine to transfer genes for bioluminescence to other bacteria. This has opened up new possibilities for biosensor design.

BIOLUMINESCENT TOXICITY BIOSENSORS: MONITORING THE PERFORMANCE OF WWTPs

The limitations of marine bioluminescent bacteria become much more apparent when the biosensor is to be used for predicting toxicity in WWTPs. Then, it is not the treated, biodegraded effluent that is to be monitored, but the toxic influent before treatment; so the concentrations of pollutants are much higher, depending on the particular industrial wastewater. The issues for the plant operator are somewhat similar to those of DTA, regulatory and financial if a fine is levied for noncompliance. However, the situation for the operator is more serious if the influent to a biological wastewater treatment plant is toxic to the microbial community that performs the purification.

LOSS OF TREATMENT SPELLS REGULATORY AND FINANCIAL TROUBLE

Partial or complete loss of treatment through toxicity to mean liquor suspended solids (MLSS) will cause out-of-compliance and can also result in serious operational problems (such as sludge bulking and foaming) and the attendant need for untreated disposal or storage. In the event of total loss of viability, restoring the biological plant can take weeks to months, with very serious financial and regulatory consequences. Until recently, total loss of viability has been considered anecdotal, but real instances have been recorded. Much more frequent occurrences are instances of partial or chronic toxic events. For example, up to 50% inhibition of nitrification has been attributed to toxicity from industrial wastewater (22).

MARINE BIOLUMINESCENCE TOXICITY TESTS ARE NOT FIT FOR THE CHALLENGE

The irrelevance of marine bioluminescent biosensors can be demonstrated with phenol as an example. During coal coking, an aqueous effluent is produced containing several hundred mg/L of phenols. Biological treatment of these wastewaters is an accepted full-scale practice; high efficiencies of removal are achievable, but occasionally treatment fails through toxicity to the treating biomass. However, the 5-minute EC_{50} for phenol to the Microtox strain is 18 mg/L (23). Used as a toxicity biosensor upstream of such an activated sludge plant, this strain would cause continuous false alarms while the biodegrading community functioned normally.

ENTER GENETIC ENGINEERING

Thus, there is a need for biosensor strains that are more relevant to the wastewater treatment system under consideration. The best correlations between toxicity tests and the actual behavior of an activated sludge plant are obtained when microorganisms from the activated sludge plant are used in toxicity tests (24). In this manner, Kelly et al. (20) developed a bioluminescent toxicity biosensor by inserting the *luxCDABE* genes from *V. fischeri* into a *Pseudomonas* strain from an activated sludge plant. By similar means, a wide range of alternative luminous bacteria has been developed for use in toxicity testing of contaminated waters (25–30).

MEASURING LIGHT PRODUCTION AND DECAY

One reason for the popularity of bioluminescence biosensors is the ease of detecting and quantifying light. Light does not accumulate or diffuse and facilitates real-time and *in situ* measurements. It can be measured linearly over several magnitude orders, an extremely important consideration. As a result, different techniques are available for detection. The most widely used is luminometry.

Luminometry is rapid and sensitive, and its sensitivity is increasing with time due to technical innovations. Laboratory-based luminometers generally rely on high sensitivity photomultiplier tubes and have a range of advanced features. For field deployment of toxicity biosensors, a more portable instrument is required. The choice is normally silicon photodiode technology, which has advanced rapidly in the last 10 years, so that very inexpensive, compact, and sensitive photodiodes are now available, making them suited to field use. The technology has advanced to the stage where an instrument is available with 24 individual photodiodes so that a 24-well microtiter plate can be read in an instrument that is small enough to be handheld (Fig. 4).

Example Data

A generic example is presented here, where a handheld instrument was used to measure bioluminescent decay from a genetically modified biosensor designed to respond to phenol (30). The data in Fig. 5a show the response of the sensor to different concentrations of a toxicant (in this case trichlorophenol) with time. The instrument measured light every second, and each decay curve represents a concentration of toxicant. Note that an increasing concentration of toxicant depresses the end point of the

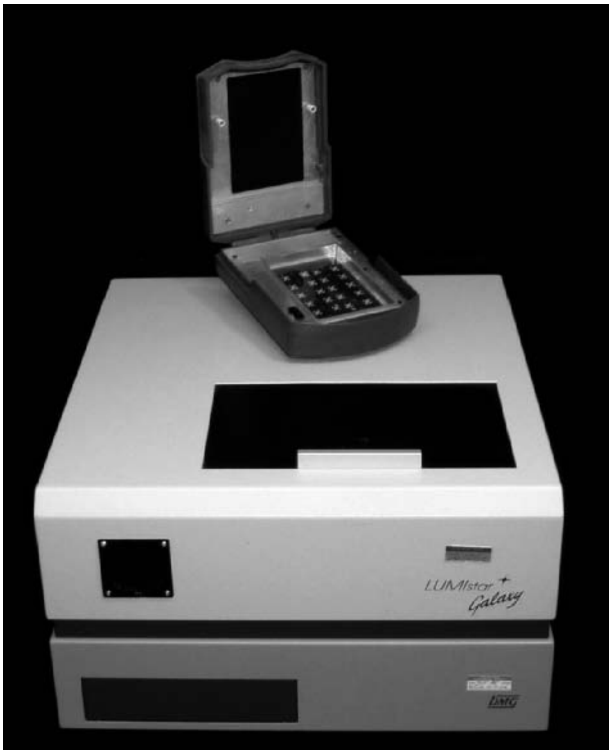

Figure 4. Two types of luminometer. On the bottom is a research laboratory instrument based on photomultiplier technology. reaction with reference to a nontoxic control. These data were then manipulated to give a mean endpoint figure, which was then plotted against concentration (Fig. 5b).

BIOMANIPULATION

Masaki Sagehashi
University of Tokyo
Tokyo, Japan

Biomanipulation is a currently used lake purification method, which modifies a lake ecosystem to an ideal state. Prior to discussing biomanipulation, lake purification methods are reviewed, and the principles and current status of biomanipulation are described afterward.

CLASSIFICATION OF LAKE RESTORATION METHODS

Some measures have been designed and implemented to prevent the eutrophication of lakes. These methods can be divided into two types, the "temporary type" and the "sustainable type." The separation of artificially aggregated algae (1–4) and aeration (5–7) are temporary types of purification methods. These methods are always immediately and strongly effective, and special knowledge of the methods is not required because the mechanisms are relatively simple. These methods, however, do not sustain their effects, and whenever algal blooms appear, we should use these methods. Therefore, this type of method is not essentially a lake purification method. On the other hand, external nutrient loading reductions (8), flow control (9), dredging of sediments (10), and "biomanipulation" are the sustainable type. There are many unclear points as to the effects of these types of methods; however, they restore a lake ecosystem, and long-term stable effects can be expected in contrast to the temporary types of methods. External nutrient loading reductions are the most effective methods; however, it is difficult to prevent completely external nutrient loading due to the considerable amount of so-called nonpoint nutrient loading sources. Furthermore, internal nutrient elution from sediments is always abundant. In other words, it is difficult to prevent on algal bloom with only external nutrient loading or flow control. On the other hand, dredging of sediments is costly. That is why interest in "biomanipulation" has been growing.

PRINCIPLES OF BIOMANIPULATION

The theoretical possibility that ecosystems have more than one equilibrium has been discussed (11). Lakes make complicated ecosystems (Fig. 1) (12) and also have alternative equilibria, a clear one and a turbid one (13, 14). This idea is based on the observation that the restoration of turbid eutrophic lakes by nutrient reduction seems to be often prevented by ecological feedback mechanisms; moreover, the clear state also possesses a number of stabilizing feedback mechanisms (15). The negative effect of the vegetation of aquatic macrophytes on turbidity has been one of the reasons to expect alternative stable states in freshwater ecosystems. Scheffer (15) showed a schematic representation of the effect of vegetation on the nutrient–turbidity relationship and consequences for system equilibria if the vegetation completely disappears from a lake at a critical turbidity (Fig. 2). The equilibrium curve is also affected by the depth of the lake (Fig. 3). Scheffer summarized the relationship using his model and proposed the "marble-in-a-cup" theory (Fig. 4). The minima of the resulting curves represent stable equilibria, whereas the hilltops are unstable breakpoints. The hysteresis behavior of lake ecosystems (13) is thus derived from this relationship. At a low nutrient level, the system has one globally stable equilibrium, a clear water state. Any increase in the nutrient level gradually changes the shape of the stability landscape and gives rise to an alternative turbid equilibrium. However, no major disturbances occur, and

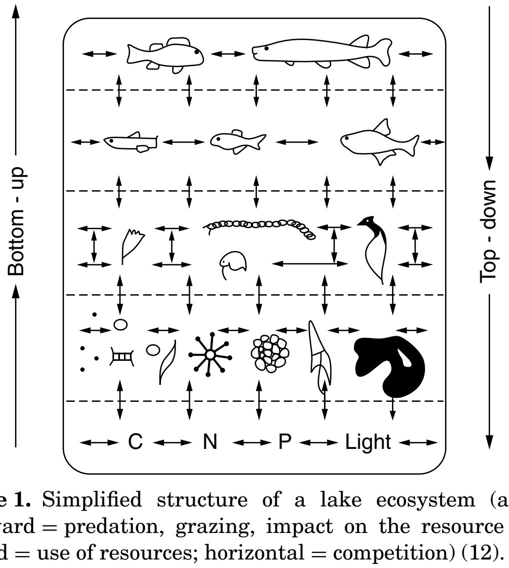

Figure 1. Simplified structure of a lake ecosystem (arrows: downward = predation, grazing, impact on the resource basis; upward = use of resources; horizontal = competition) (12).

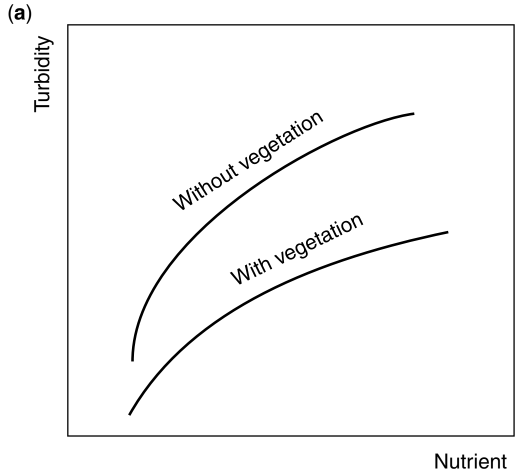

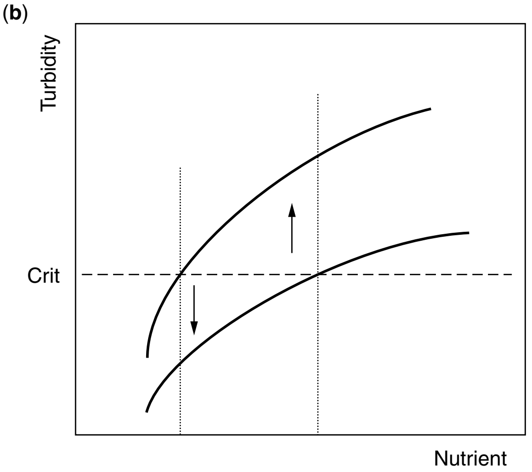

Figure 2. Schematic representation of (**a**) the effect of vegetation on the nutrient–turbidity relationship and (**b**) consequences for systems equilibria if vegetation completely disappears from a lake at a critical turbidity (crit) (15).

the system will stay in its current state, responding only slightly to enrichment. If the nutrient level is further raised, the stability of the clear state decreases, and slight perturbations are enough to cause a switch in the turbid equilibrium. At still higher nutrient levels, the clear water equilibrium disappears, inevitably causing an irreversible jump to a turbid state. Efforts to restore the system by decreasing the nutrient level change the stability landscape again, but even if the nutrient level at which the system was formerly clear is realized, there will hardly be a response to the measures. An alternative clear equilibrium may be present, but the locally stable turbid state is sustained. Only a severe reduction in nutrient level results in a switch to the clear state.

The reduction of the nutrient level as a measure to restore a lake ecosystem, which has the alternative equilibria mentioned before, gives poor results, but "biomanipulation" (16) as an additional measure can have significant effects, provided that the nutrient level has been sufficiently reduced to allow the existence of a stable alternative clear water equilibrium. A schematic diagram of the restoration of water quality by biomanipulation is shown in Fig. 5. Biomanipulation may be defined as the restructuring of a biological community to achieve a favorable response, usually a reduction in the algal biomass, attainment of clear water, and promotion of a diverse biological community (17). The theory of biomanipulation is based on the prediction that increased piscivore abundance results in decreased planktivore abundance and that increased zooplankton grazing pressure leads to reductions in phytoplankton abundance and improved water clarity (18).

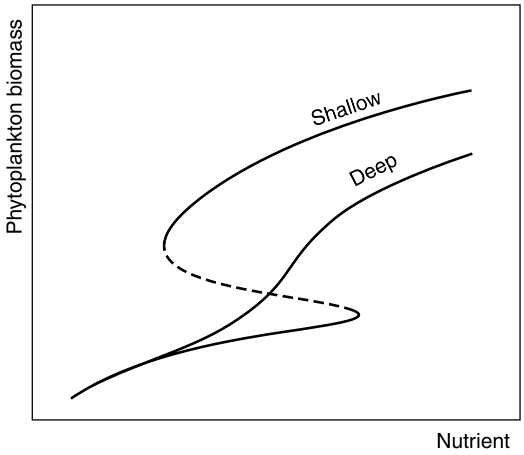

Figure 3. Equilibrium density of phytoplankton as a function of nutrient level computed from Scheffer's model for a shallow lake of homogeneous depth ("shallow") and for a deep lake with gradually declining slopes ("deep"). The dashed part represents unstable "breakpoint" equilibria (15).

REVIEW OF TRIALS OF BIOMANIPULATION AND ITS PERSPECTIVE

A number of fish manipulations in lakes and ponds have been done in various water ecosystems around the world. Some researchers have reviewed them (17,18,20). Based on these reviews, the biomanipulation trials so far attempted are summarized in Table 1. The manipulations, lake size, and outcomes are mentioned in this table. Table 1 shows that there has been a considerable spectrum of fish manipulation occurring throughout the world. Note that not every manipulation was aimed at algal growth suppression. Some of them were an unexpected change in fish biomass. In early stages, such as Hrbácek et al. described (21), little attention was given to reducing the algal biomass by manipulating the fish biomass.

These trials can be divided into several groups based on their results. The following categories are used for classifying the trials:

A: biomass of phytoplankton decreased ("successful")
B: dominated by larger zooplankton species or an increase in the biomass of zooplankton/obvious change in phytoplankton community was not observed ("insufficient")
C: no obvious changes in both the phytoplankton and zooplankton communities ("failure")
D: harmful algal dominance was observed ("risky")
E: others ("others")

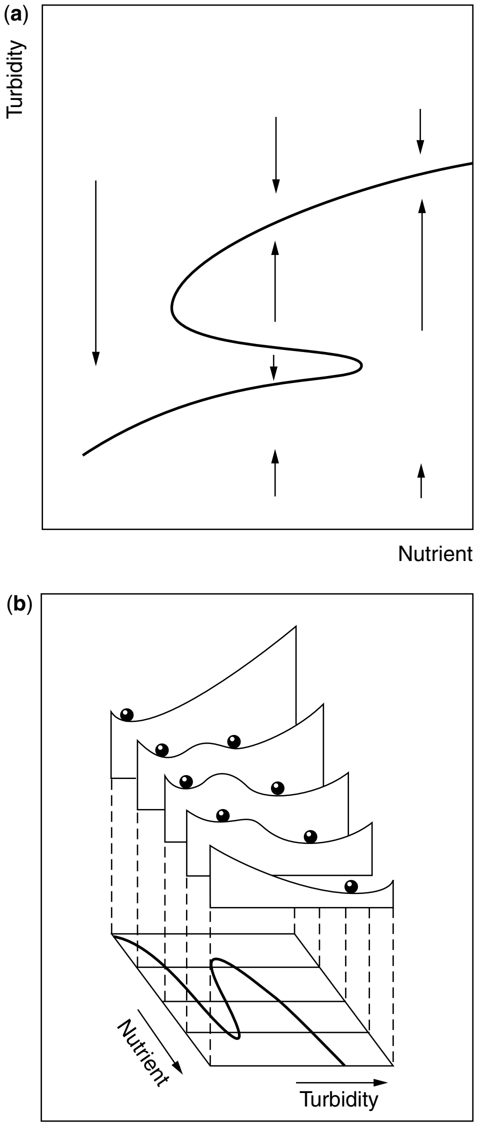

Figure 4. (**a**) Equilibrium turbidity as a function of nutrient level; direction and speed of change are indicated by arrows (example computed from vegetation–phytoplankton model). (**b**) "Marble-in-a-cup" representation of stability at five different nutrient levels. The minima correspond to stable equilibria; the tops to unstable breakpoints (15).

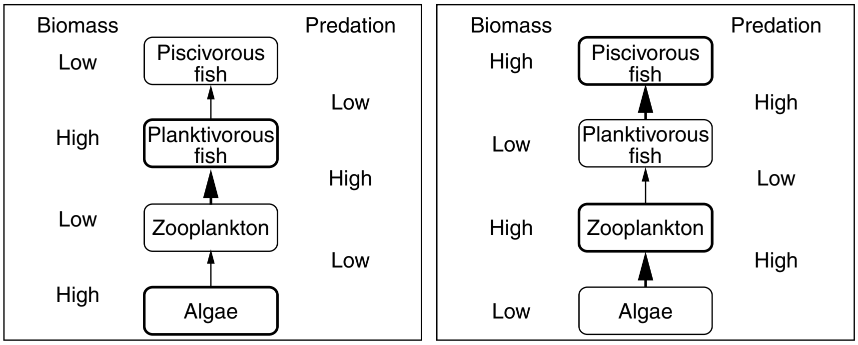
There are 35 trials listed in Table 1. Twenty cases of "success" (57.1%), five cases of "insufficient" (14.3%), three cases of "failure" (8.6%), four cases of "risky" (11.4%), and three cases of "others" (8.6%) are categorized. Categories A and B can be considered "positive cases"; C and D are the "negative cases." Based on this consideration, there are 71.4% positive and 20.0% negative results.

There are various manipulations in the "positive" cases. A-1, A-2, and B-3 are the cases that are naturally caused. Case A-2 was also affected by summer stratification. A-6–8, and B-4 are enclosure experiments, which examined the effect of planktivorous fish (A-6–8: bluegill, bream, roach, and crucian carp) or piscivores (B-4: walleye). Fish were killed by fish toxin (mainly rotenone) in A-4, 9, 10, 13, and 14, and B-1 and B-2. Selective catchment, which is more theoretical than poisoning, was found in cases A-12 and A-16–20. The stocking of piscivores was tried in cases A-3, 5, 11, 13, 15, 16, and 19 and B-1, 2, and 5. The piscivores stocked were pike, pikeperch, rudd, salmonine, trout, bass, and walleye. Case A-15 is one of the most perfect biomanipulation trials because the lake was emptied by pumping, and daphnids and macrophytes were stocked as well as piscivores.

Some reasons could be postulated for the "no effect" cases. In general, the removal of fish was not enough (53). This means that the calculation of sufficient biomass removal of fish to improve water quality is essential for successful biomanipulation.

The transition to an ecosystem dominated by harmful algae, which is the most undesirable result, was observed in cases D-1–4. In these cases, large size blue-green algae, which could not be predated by zooplankton, dominated the phytoplankton community. This is one of the contradictions in the effect of biomanipulation. Increased zooplankton predate small, edible phytoplankton. Large, inedible algae such as filamentous blue-green algae then occupy the phytoplankton's niche. Hosper and Meijer (48) pointed out that filamentous blue-green algae and the possible development of invertebrate predators (*Neomysis, Leptodora*) on *Daphnia* are uncertain factors for successful biomanipulation. Therefore, it should be determined whether or not inedible phytoplankton will increase in a waterbody prior to the biomanipulation.

The long-term stability of biomanipulation still needs to be investigated because these trials were performed over relatively short periods. Hosper and Meijer (48)



Algal-blooming state due to eutrophication

Preferable state created by biomanipulation

Figure 5. The paradigm of biomanipulation (19).

Table 1. Biomanipulation Trials Reported in the Literature

			Appearances	
Type #	Manipulation	Waterbody	Premanipulation[a]	Postmanipulation[a]
A-1	**Natural case: 1960s** decrease in *Neomysis mercedis* (planktivores) perhaps due to increase in long-fin smelt (22)	**Lake Washington**, Washington, USA	<1950s> **F:** large amount of *Neomysis* **P:** dominance of *Oscillatoria*	<1970–1980> **F:** abruptly scarce of *Neomysis* **Z:** daphnid dominance **P:** decrease in *Oscillatoria*
A-2	**Die-off (winterkill): in winter, 1964–65** DO depletion due to ice cover (23)	**Lake Severson**, Minnesota, USA area = 10.4 ha $z_{\max} = 5.3$ m; $z_{\text{ave}} = 2.2$ m	<1955–1965> **Z:** small species **P:** 300–600 mg chl.$a \cdot$m^{-3} water bloom of blue-greens **O:** summer stratification	<1965> **Z:** large species **P:** <30 mg chl.$a \cdot$m^{-3}; small greens **F:** disappearance of planktivores **M:** increased **O:** disappearance of stratification
A-3	**Stocking (piscivores): 1972** ca. 200 ind.$\cdot$ha^{-1} of trout (24)	**Hubenov Reservoir**, the Czech Republic area = 92.5 ha $z_{\max} = 31.5$ m $z_{\text{ave}} = 8.93$ m control; Klicana; Vrchlice res.	<1976> (control reservoirs) **F:** dense population: roach, perch, other small cyprinids **Z:** small cladocerans **P:** 10.5(annual);11.4 (summer) mg chl.$a \cdot$m^{-3} **S:** 2.1 (annual); 2.5 (summer) m **fit well to the Dillon–Rigler regression**	<1976> (Hubenov Reservoir) **Z:** large daphnids **P:** 2.4(annual);2.3 (summer) mg chl.$a \cdot$m^{-3} **S:** 4.9 (annual); 5.0 (summer) m **half or even less than half the value expected from the Dillon–Rigler regression**
A-4	**Poisoning (rotenone): Nov. 1973** (25,26)	**Lake Lilla Stocke-lidsvatten** Sweden area = 1 ha $z_{\max} = 8$ m;	<1973> **Z:** small cladocerans (*Bosmina*) **P:** 400 mm$^3 \cdot$m^{-2} (in August) **S:** 1.2 m (in August) **PP:** 18 mg C$\cdot$m$^{-3} \cdot$h^{-1} (average, surface)	<1975,76> **Z:** large copepods (*Eudiaptomus*) **P:** 25 mm$^3 \cdot$m^{-2} (in August) **O:** Secci: 5.8 m (in August) **PP:** 2 mg C$\cdot$m$^{-3} \cdot$h^{-1} (average, surface)
A-5	**Piscivore stocking: 1975–** An aggressive salmonine stocking program (27)	**Lake Michigan**, Wisconsin, USA area = 58,188 km^2 $z_{\max} = 285$ m $z_{\text{ave}} = 84$ m	<1975> **F:** Alewife = 110, 000 t total **Z:** calanoid copepods dominant **P:** 0.7–3.5 mg chl.$a \cdot$m^{-3} **S:** 3–8 m	<1983,84> **F:** alewife = 18, 000–20,000 t total **Z:** large daphnids dominant **P:** 0.2–2.5 mg chl.$a \cdot$m^{-3} **S:** 5–15 m
A-6	**Enclosure exp. (fish stocking): June 15–25, 1975** bluegill (0–4 ind.$\cdot$encl.$^{-1}$) (28,29)	**Enclosures in Pleasant Pond**, Minnesota, USA area = 0.25 ha $z_{\max} = 2.5$ m 1 m in diamter; 1.8 m in depth; closed bottom	[with fish] **Z:** small cladocerans **P:** increased with the biomass of fish (20—80 mg chl.$a \cdot$m^{-3})	[without fish] **Z:** large daphnids **P:** low (<5 mg chl.$a \cdot$m^{-3})
A-7	**Enclosure exp. (fish stocking): 1976** without fish and with fish (90 g m^{-2} of bream and roach) from June to October (30,31)	**Enclosures in Lake Trummen**, Sweden; enclosure: 3 m in diameter 2.2 m in depth open for sediments	[with fish] **Z:** rotifers, cyclopoid copepodites; **P:** 440 mg chl.$a \cdot$m^{-3} (in August) *Microcystis* dominant (in summer; 83 g fresh$\cdot$m^{-3}) [lake] soft-water, dense fish population (bream, roach, and pike)	[without fish] **Z:** large daphnids **P:** 20.4 mg chl.a m^{-3} (in August) a mixed population of cryptomonads, small blue-greens, and diatoms

evaluated the long-term studies of biomanipulation in The Netherlands. They surveyed nine trials (Lakes Zwelmust, Bleiswijkse Zoom, Noorddiep, Breukeleveense plas, Klein Vogelenzang, IJzeren Man, Sondelerleijen, Wolderwijd, and Duinigermeer). Their survey indicated that six cases (Lakes Zwelmust, Bleiswijkse Zoom, Noorddiep, IJzeren Man, Wolderwijd, and Duinigermeer) showed positive results; however, only three lakes (Noorddiep, IJzeren Man, and Wolderwijd) showed long-term (>5 years) stability of clear water. Thus, long-term stability resulting from biomanipulation must be examined. In other words, the ecological sustainability of treated lakes determines their long-term stability. One of the essential methods for elucidating long-term stability is to quantify the material flow in a lake ecosystem as a means of numerical modeling. For this purpose, some numerical models that describe the lake ecosystem and predict the effect of biomanipulation are available in the literature (19,61).

GENOMIC TECHNOLOGIES IN BIOMONITORING

Michael J. Carvan III
Matthew L. Rise
Rebecca D. Klaper
University of Wisconsin–Milwaukee
Milwaukee, Wisconsin

Biological monitoring, or biomonitoring, is defined as using measurements of the resident biota in surface waters to evaluate the condition of the aquatic environment (1). In part, biological monitoring in the United States is designed to satisfy the goals of the Clean Water Act, which aims to protect wildlife in and on the water and eliminate discharge in toxic amounts into navigable water. Biomonitoring has inherent advantages over simply measuring the presence or concentration of a particular stressor or toxin due to the fact that organisms represent an integrated response to factors in their environment over time. Biomonitoring in aquatic habitats traditionally involved measuring the diversity within the community of macroinvertebrates, fish, or periphyton using species diversity, composition with respect to functional groups, or genetic diversity (2). Community indices have inherent problems. For example, streams can include a large spatial variance that is not correlated with problems in habitat. In addition, sampling effort can affect diversity measurements, resulting in an increase in the number of species sampled with longer or more frequent sampling times (3). Identification of species is time consuming and can increase the costs associated with these types of measurements due to personnel-hours required (4).

As one alternative, measurement of the concentration of chemicals has been used as a surrogate for biological criteria. These chemical water quality criteria (TMDL or total maximum daily load) have been developed by determining concentrations of compounds that cause acute toxicity to standard test organisms. However, simply measuring the concentration of a chemical present in a system in one snapshot of time does not indicate the actual exposure of any particular organism to that chemical, neither to the organism as a whole nor to a target of action. Variation in exposure within a single species may be influenced by habitat utilization in the environment, feeding behaviors, and metabolism and physiology. To provide this information, chemical data can be used in conjunction with biomarkers, which are enzymes, proteins, or other products that can indicate an organism has been exposed to a toxin or that a toxic response has occurred. This involves sampling one or several species in a community to collect tissues, or whole organisms, for detection of the biomarker. A problem with this method in the past has been that biomarkers, for the most part, indicate a general response that can occur with exposure to several different compounds and are not specific enough to indicate a particular exposure or toxic response.

Genomic tools could potentially solve some of the problems with each of these techniques, while at the same time complementing traditional methods of monitoring. Examining the genes that are being expressed within an organism, or across several organisms, in the community provides hundreds to thousands of potential biomarkers for exposure and effects (5,6). As the number of biomarkers is several orders of magnitude greater, there is also the capability of differentiating exposures and effects to provide a more specific indicator, even from a complex mixture. Here, we provide an overview of the technologies of genomics (and other -omics) and provide a few examples of the development of their use for environmental monitoring.

HIGH THROUGHPUT TECHNOLOGIES AND THEIR APPLICATION TO BIOMONITORING

Genomics

There are a number of high throughput genomic technologies with application to environmental biomonitoring. Quantitative reverse transcription polymerase chain reaction (qRT-PCR) is one of the most sensitive techniques for detection of low abundance mRNA. The reverse transcription process creates a complementary DNA molecule (cDNA) from an mRNA template. The PCR process amplifies the gene-specific cDNA target in a series of thermal cycles that include DNA denaturation, target-specific primer binding, and primer extension using a thermostable polymerase. Utilization of fluorescent labeling allows the quantitative detection of cDNA molecules following each round of amplification. Gene-specific fluorescent labeling of targets can be accomplished using TaqMan® (Applera Corporation) or molecular beacon (7) probes that are designed to anneal to an internal sequence of the PCR product. This approach allows multiple target sequences to be analyzed using multiple fluorescent labels in the same reaction (multiplex qRT-PCR). Intercalating agents like SYBR green are used as nonspecific probes that bind DNA and track the accumulation of PCR product. These assays are less expensive and very flexible because SYBR green will bind to any target. SYBR green can also be used to detect multiple targets if used in conjunction with melting point analysis of the PCR products (8).

Relative quantitation of the PCR products compares fluorescent intensity and the number of cycles required for the fluorescent signal to reach a fixed threshold (generally multiple standard deviations above background fluorescence) generally in the logarithmic portion of the amplification cycle. The parameter Ct (cycle threshold) is defined as the cycle number at which the fluorescence emission exceeds the fixed threshold. Ct is proportional to the number of target molecules in the sample and is used to derive mRNA abundance estimates (Fig. 1). The use of a normalizer gene, expressed at approximately the same level in the experimental and control samples used in microarray and qRT-PCR studies, corrects for technical inaccuracies (i.e., slight differences in amounts of RNA template due to pipetting error, or variability in efficiency of reverse transcriptase reactions). While there are no perfect normalizer genes, a number of transcripts are commonly reported in the literature, including glyceraldehyde-3-phosphate dehydrogenase, beta actin, major histocompatibility complex I, cyclophilin, various ribosomal proteins, and ribosomal RNA. Comparative quantitation uses Ct data to determine the relative abundance of specific transcripts in different samples. A new approach for the relative quantitation of targets in qRT-PCR (9) takes into account primer-dependent differences in the efficiency of amplification resulting in more accurate relative estimates of target abundance. Absolute quantitation of mRNA abundance in a sample requires comparison of Ct for the target gene to that of samples with known quantities of target. A standard curve can be generated using a dilution series of known targets and can then be used to estimate the number of target molecules in a particular sample. Some real-time PCR systems (e.g., Stratagene Mx3000P) include user-friendly software for performing data analyses such as conversion of Ct values to fold differences using comparative or absolute quantitation methods corrected with normalizer gene data.

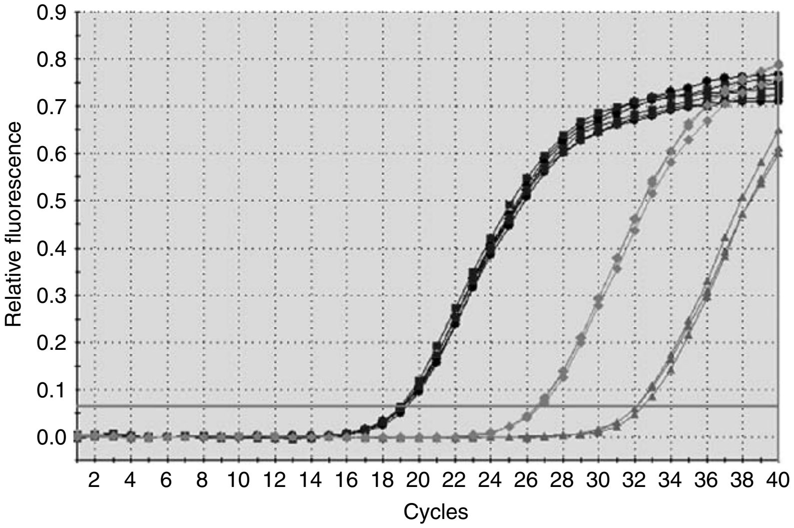

Figure 1. qRT-PCR amplification plots. Curves show amplification from template A (control, non-exposed tissue) and template B (exposed tissue). The horizontal line is the threshold. The Ct values for the amplification plots are virtually identical, indicating that the normalizer gene is expressed at approximately the same level in control and exposed tissues. Analysis of these triplicate data using Mx3000P software (Stratagene) and the relative quantification method (9) revealed that the gene of interest (GOI) was 44-fold downregulated in the exposed sample relative to the control sample.

DNA arrays (also known as Gene Chips®, DNA chips, or gene arrays) have revolutionized the way scientists think about biological problems. DNA arrays allow the simultaneous detection and quantitation of hundreds to thousands of DNA targets within a single complex mixture. The unlabeled probes for DNA arrays are printed (spotted) using high speed robots and immobilized on a solid substrate (generally nylon membranes, glass slides, or quartz wafers). Macroarrays are low density DNA arrays that are usually printed on nylon membranes or glass slides with spot diameters generally greater than 300 μm. Microarrays are high density DNA arrays that are usually printed on glass slides or quartz wafers with spot diameters generally less than 200 μm. The highest density microarrays utilize tens of thousands of oligonucleotide probes applied to, or synthesized directly on, quartz wafers. For DNA array analyses, the targets in a single sample are generally labeled with a fluorescent (or radioactive) tag and hybridized to the immobilized probes (spots on the DNA array). Hybridization of specific targets is quantified relative to standard genes on a typical one-color (or radioactive) array. Two- (or multi-) color arrays utilize multiple fluorescent labels, one for each sample to be compared, and allow the quantitation of the relative abundance of each of the specific targets in each sample. The most common experimental approach is to use the fluorescent dyes Cy3 and Cy5 to label cDNA from the control and experimental samples (or vice versa), which are then hybridized to the DNA array. This process is diagrammed in Fig. 2. Through competitive hybridization, the abundance and proportion of bound target in the two samples should reflect the abundance and proportion of corresponding transcripts in the original samples. Images of the hybridized microarray are generally acquired by laser confocal scanning using dye-specific lasers and/or filters. Quantitation of the data at each spot requires sophisticated image analysis and statistical software and the final output depicts the ratio of cDNA abundance between the two samples for each probe by scatter plot, dendrogram, heat map, or Venn diagram. The differential gene expression data from microarray experiments are usually confirmed by qRT-PCR.

Microarray analysis is an extremely sensitive technique for the analysis of mRNA abundance, and small variations in the experimental conditions may lead to dramatically different results and conclusions. As a result, the Microarray Gene Expression Data (MGED) Society was formed as an international organization of biologists, computer scientists, and data analysts that aims to facilitate the sharing of microarray data generated by functional genomics and proteomics experiments. The MGED has established a set of guidelines called the Minimum Information About a Microarray Experiment (MIAME) with the goal that such information will allow one to "interpret unambiguously and potentially reproduce and verify an array-based gene expression monitoring experiment" (www.mged.org) (10). Adherence to the MIAME guidelines and submission of all microarray images and data to a public data repository such as Gene Expression Omnibus (http://www.ncbi.nlm.nih.gov/geo/) are required by most of the top scientific journals in the United States and Europe.

Serial analysis of gene expression (SAGE) is a powerful tool that allows the analysis of overall gene expression patterns (11). SAGE can be used to identify and quantitate genes from model organisms with a sequenced genome (12) and from those with few known genes (13). The SAGE technique is based on the concept that short sequence tags (10–14 bp) can contain sufficient information to uniquely identify a transcript. Sequence tags are linked together in concatamers, which are then sequenced. Quantitation of the number of times a particular tag is observed provides the expression level of the corresponding transcript. SAGE has contributed to our understanding of numerous biological processes including differentiation, development, carcinogenesis, and responses to environmental chemicals and stressors (14).

Massively parallel signature sequencing (MPSS) technology generates sequence information from millions of DNA fragments without the need for individual sequencing reactions and the physical separation of DNA

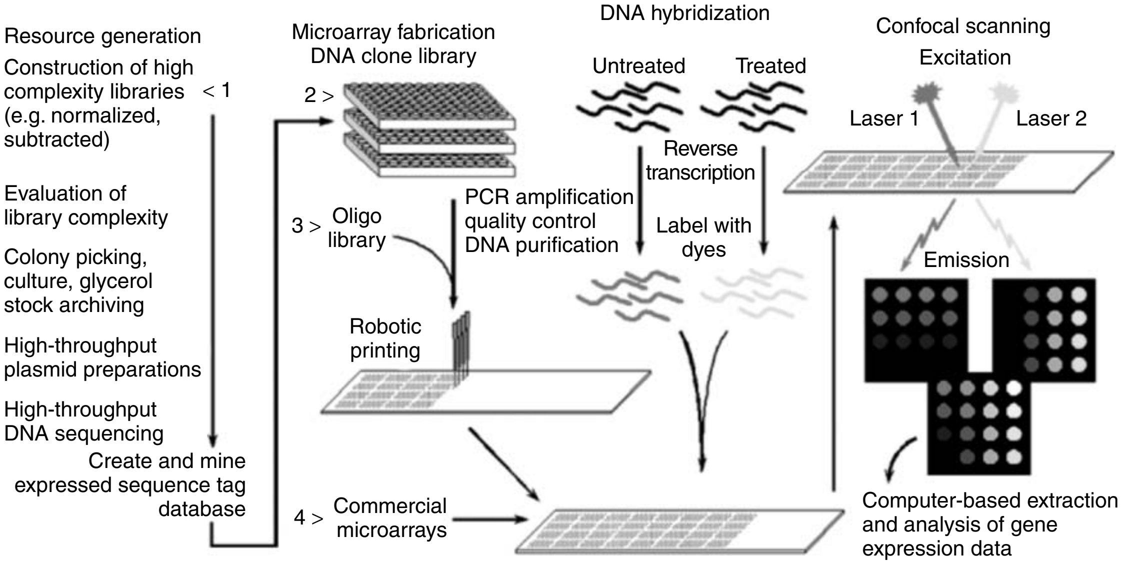

Figure 2. Microarray fabrication and utilization for transcriptional profiling. There are a number of entry points into the microarray fabrication process that are indicated by the arrows (>). The utilization of transcriptional profiling and other functional genomic technologies will require the generation of genomic resources for the vast majority of ecologically important species. This process begins, at step <1, with construction of high complexity libraries and expressed sequence tag (EST) databases. Investigations that utilize organisms for which DNA clone or oligonucleotide (oligo) libraries are available (entry points 2> and 3>, respectively) can derive fragments from these libraries for spotting on prepared glass slides. Investigations using human, mouse, *Drosophila*, yeast, or sequenced microorganisms can purchase commercial slides and enter at step 4>.

fragments (15,16). Amplified DNA molecules are bound to Megaclone™ microbeads, which are arrayed in a flow cell, and the reagents required for sequencing flow over the microbeads. The proprietary protocol elicits sequence-dependent fluorescent responses from the microbeads, which are recorded by a CCD camera after each cycle, to construct a short 17–20 bp signature sequence. The sequences are then grouped to determine abundance and compared to public and private databases to identify the gene represented by the individual signature sequences and to determine putative function of the gene product (17,18).

Proteomics

High throughput protein expression analysis is primarily performed using three techniques: two-dimensional (2D) gel electrophoresis, mass spectrometry, and protein arrays. Two-dimensional gel electrophoresis separates labeled proteins from a biological sample by their isoelectric point and electrophoretic mobility (size), producing a 2D fingerprint of protein content. Changes in protein expression can be determined by analyzing 2D gels from different samples and isolation of the elements that vary with experimental conditions. N-terminal protein sequencing can be used to identify the protein represented by a single element of a 2D gel (19). Alternatively, the isolated element can be analyzed by mass spectrometry to determine peptide mass and/or sequence, leading to its identification. The primary types of mass spectrometry used for protein expression analysis are matrix-assisted laser desorption ionization time of flight (MALDI-TOF) and Electrospray ionization MS quadrupole (ESI-MS). MALDI-TOF allows peptide fingerprinting of a protein sample following tryptic digestion. The peptide fingerprint is then compared to a database with data from known proteins or computationally derived data for theoretical peptides (20). ESI-MS provides peptide sequence information in addition to any post-translational modifications, for example, acylation, phosphorylation, or glycosylation (21).

Protein arrays are assay systems using immobilized probes on a solid support, which include glass, membranes, microtiter wells, and mass spectrometer plates. Protein arrays are used to assay a biological sample for a number of interactions including ligand binding, protein–protein, protein–DNA, protein–drug, receptor–ligand, and enzyme–substrate (22–24). Depending on the design of the array, proteins of interest can be either immobilized probes or labeled targets for binding to immobilized high affinity probes (antibodies, engineered scaffolds, single protein domains, peptides, or nucleic acids). Since this field is very new and rapidly evolving, a variety of methods are under development for utilization of protein from a number of sources, application to different formats and surfaces, immobilization of probes, fabrication of arrays, and detection of signal. Many of the techniques available today rely on adaptation of DNA array technologies and the bioinformatics tools developed for data analysis. We now know that the number of proteins produced by a given organism is, on the average, an order of magnitude greater than the number of genes in the genome. Many of the protein array technologies are focused on specific pathways and do not try to analyze the entire proteome.

Metabolomics

The foundation of metabolomics is the ability to detect changes in metabolic processes that are initiated in response to cellular stressors and enzyme system inhibitors. A number of analytical techniques can be used to generate metabolomic databases, including liquid chromatography in conjunction with mass spectrometry, high resolution nuclear magnetic resonance spectroscopy, high pressure liquid chromatography, and optical spectroscopic techniques (25–27). These techniques produce a comprehensive profile of small molecule signals. When samples derived from stressed tissues (diseased, toxicant exposed, etc.) are compared with appropriate control tissues, relatively small stresses can result in dramatic changes in metabolite profiles (28).

DEVELOPING TOOLS FOR ECOTOXICOGENOMIC RESEARCH AND BIOMONITORING

Genomics is defined as the comprehensive study of an organism's genes and their functions. Toxicogenomic research is aimed at understanding how changes in gene expression, elicited by chemical exposures, contribute to toxicological effects. DNA microarrays, important tools in toxicogenomic research, allow the relative expression of thousands of genes to be evaluated simultaneously. A primary goal of ecotoxicological research is to shed light on the mechanisms by which toxins exert their effects on various wildlife species, and ecotoxicogenomics involves the use of genomic resources and methods in ecotoxicological research.

Expressed sequence tag (EST) databases and DNA microarrays are important tools in ecotoxicogenomic research. EST databases, generally arising from high complexity (e.g., subtracted, normalized) cDNA libraries, allow researchers to identify the genes expressed in a given tissue under select conditions and at a particular point in time. For example, a suppression subtractive hybridization (SSH) cDNA library construction kit (e.g., from Clontech) could be used with mRNA from two tissues (e.g., toxin-exposed liver and control nonexposed liver) to generate reciprocal SSH libraries. One of these libraries would be enriched for genes upregulated in toxin-exposed liver relative to nonexposed liver, and the other library would be enriched for genes suppressed by the exposure. Characterization of these libraries, involving colony (clone) picking and overnight culture, plasmid DNA preparation, and automated sequencing of clone inserts (generally from one end, hence the term "tag" in EST) is generally performed in 96- or 384-well format. EST databases are designed by bioinformaticians to perform quality control such as trimming of poly A tails, low quality sequence, and vector. In addition, EST databases are generally designed to perform assemblies to identify ESTs contributing to contiguous sequences (putative transcripts). Assembled ESTs and their putative translations are aligned (BLASTN and BLASTX, respectively) with public nucleic acid or amino acid sequence databases (e.g., NCBI nt or nr, respectively) for identification. The top (most negative E-value) BLAST hits (gene names, regions of sequence overlap, percent identity/similarity, and significance of hit) and functional annotations associated with these genes (gleaned from public databases such as Gene Ontology Consortium or Swiss-Prot) may be linked to sequences within an EST database (4,29). With steadily decreasing costs associated with DNA sequencing, EST projects for ecologically important (e.g., indicator) species are now relatively affordable.

An EST project usually precedes design and construction of DNA microarrays (see Fig. 2). For model organisms (e.g., *D. rerio, X. laevis, C. elegans, Drosophila*, rat, and mouse) and some organisms of agricultural importance (e.g., rice, barley, cow, Atlantic salmon), genomic resources (e.g., EST databases and DNA microarrays) have been developed and are available. However, ecotoxicogenomic researchers generally wish to study wildlife species for which little or no genomic data previously exist. If a researcher has access to a fully equipped molecular biology laboratory, it is possible to develop genomic reagents for an ecologically important species for under \$50,000, not including personnel costs. Reciprocal SSH libraries can be constructed for about \$5000; 10,000 sequences from these high complexity libraries (likely representing approximately 5000 different transcripts) can be obtained for under \$20,000; 1000–2000 selected transcripts (e.g., relevant to xenobiotic metabolism) can be PCR amplified, cleaned, and spotted onto glass slides for under \$20,000; reagents for conducting preliminary microarray experiments (50 chips) would cost approximately \$5000. An example of such a project might be to study the effects of atrazine exposure on gene expression in a larval amphibian. Reciprocal SSH libraries could be constructed from atrazine-exposed versus nonexposed larval tissues. Transcripts of interest could be selected from the resulting EST database for inclusion on a microarray. It is now affordable for a researcher to partially characterize a nonmodel organism's transcriptome, generate genomic tools (EST database and DNA microarray), and acquire meaningful data on how the sentinel organism responds transcriptomically to a particular insult. The cost of constructing custom DNA microarrays will decrease as the number of array facilities increases. Methods for construction depend on whether the research desires a cDNA or oligonucleotide microarray.

A typical, simple toxicogenomic experimental objective might be to evaluate the impact of a single dose of toxin (e.g., atrazine) on global gene expression in a specific organ (e.g., liver) at various time points (Fig. 3). An alternative experimental approach would use microarrays to evaluate gene expression changes in a tissue associated with various toxin doses at a single time point (e.g., 24-h exposure). For all genes represented on the DNA microarrays used, expression can be compared in the exposed versus unexposed tissues. Microarray experiments are generally run on pooled samples (e.g., pooled $n = 5$ exposed liver versus

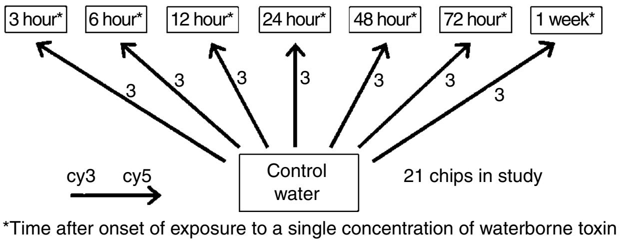

Figure 3. Microarray experimental design for determining expression of candidate molecular biomarkers of toxin exposure over time. All RNA samples are from a single toxin (e.g., atrazine) challenge at a single concentration (e.g., 10 ppb).

pooled $n = 5$ control liver), followed by real-time qRT-PCR for select transcripts of interest on individual fish samples to validate microarray results and reveal biological variability in expression of informative genes. Validated toxin-responsive genes can be functionally annotated using public sequence databases such as Swiss-Prot (http://us.expasy.org/sprot/). The example microarray experiment (Fig. 3) would be relatively easy to run, and statistical analyses of resulting data would be straightforward (e.g., K mean clustering of background-corrected, Lowess-normalized Cy5/Cy3 ratio values using software such as GeneSpring by Silicon Genetics, Fig. 4). It is important to note, however, that organisms in nature generally do not encounter a single toxin in a single dose for an extended period of time. Actual toxin exposures in the wild (e.g., exposure of larval amphibians to agricultural runoff) are continuums with fluctuating toxin concentrations and dynamic ambient conditions (e.g., temperature, pH). Furthermore, ecologically important organisms often encounter mixtures of toxins, such as effluents or automobile exhaust. Realistic modeling of this type of complexity will require extremely well-designed ecotoxicogenomic experiments supported by collaborations with mathematicians, statisticians, and computer scientists.

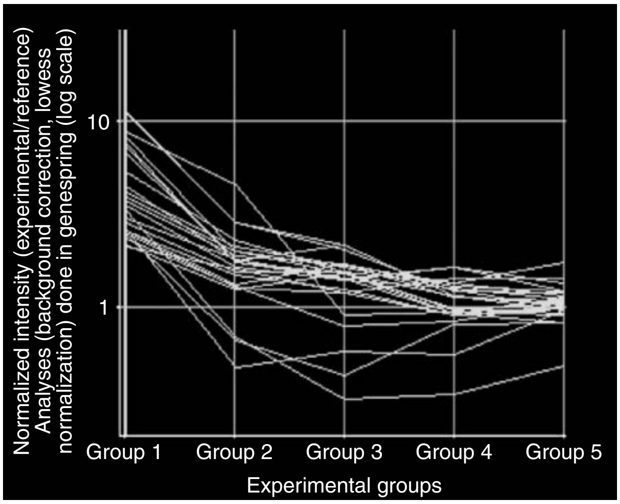

Figure 4. K means clustering identifies suites of genes having similar expression profiles.

RECENT APPLICATION OF GENOMIC TOOLS IN BIOMONITORING

Only very recently have genomic tools been used to understand environmental processes or to determine environmental quality, and we will present a few examples. Random shotgun sequencing of DNA from an environmental sample (e.g., a natural biofilm) can be used to determine species composition and provide evidence of survival strategies in these harsh environments (30). The relatively small number of dominant bacterial species in many harsh environments allows for extensive analyses without culturing organisms in the laboratory or having a previously sequenced genome to aid analyses (30).

Stressor-specific signatures in gene expression profiles can be used to diagnose which stressors are impacting populations in the field (31). Consensus PCR primers can be designed using sequence information from several animal sequences. It may then be possible to amplify some of these well-characterized stress-induced genes from organisms of interest in ecotoxicology. cDNAs representing stress-induced genes from a number of species can be arrayed on a single glass slide for rapidly screening environmental samples (31).

A few cDNA microarrays are available for fish species important in the aquaculture industry. These arrays are valuable for expression profiling following exposure to specific toxicants (32) or bacterial infection (28). While these studies are laboratory based, they demonstrate the potential for cDNA microarrays to provide insight into organism health as part of a larger biomonitoring effort. Currently available microarray resources can also be used to analyze samples from many closely related species (33,34). Thus, biomonitoring projects may be able to take advantage of genomic resources developed for model organisms in other fields and may not need to generate a species-specific microarray for every organism of interest. Targeted low density macroarrays from a few environmentally relevant species can detect alterations in gene expression following exposure to "environmental estrogens" (35,36). This technology is useful for identifying endocrine disruption; however, it may have limited utility in the analysis of the multiple stressors found in complex environments.

It is important to note that genomic information must be tied to traditional measures of toxicity to be useful. Gene expression profiling provides a picture in a snapshot of time where toxic endpoints are an accumulation of exposure and effect (5,37). To include microarray and other types of genomic data in risk assessments will involve measurements of gene expression over time and over several tissues and organisms.

MACROPHYTES AS BIOMONITORS OF TRACE METALS

Shimshon Balanson
Tarun K. Mal
Cleveland State University
Cleveland, Ohio

INTRODUCTION

Aquatic macrophytes are macroscopic aquatic plants that play an important role in the health of aquatic ecosystems. Not only do macrophytes provide vital structural support in aquatic ecosystems (1), but they also contribute toward food production, nutrient regeneration, and habitat for a wide range of organisms. Because of their roles in aquatic ecosystem health, aquatic macrophytes can be utilized as indicators of stream health (2). In fact, aquatic macrophytes may be indicative of a variety of ecosystem stressors including nutrient runoff, changes in hydrologic regime, and exotic species invasion (3,4). Therefore, species richness of aquatic macrophytes, their composition, and density have all been incorporated into different macrophyte indicators (5,6). As such, bioindicators estimate the pollutants affecting the biota in an ecosystem and are purely qualitative in nature.

BIOINDICATORS VERSUS BIOMONITORS

Of course, the use of aquatic macrophytes as *qualitative* bioindicators of stream health does not reveal the amount of pollutants in the water column and sediments. Therefore, another technique must be utilized when attempting to *quantify* the direct impact of in-stream pollutants on aquatic macrophytes. The use of biota as monitors of ecosystem health relies on changes in the morphology, biochemical pathways, and life cycle of the organisms being tested as well as direct measurement of pollutant levels in the tissues (2,7,8). Biomonitors have been preferred to abiotic monitors in many instances. Abiotic monitors such as water and sediments do detail the amount of a pollutant in the ecosystem but do not reveal the quantities that are actually *available* to organisms living in an ecosystem (9).

In some ways, however, bioindicators and biomonitors share many of the same purposes. Like bioindicators, biomonitors can be utilized to identify changes in plants over the course of time, especially morphological and biochemical changes (8,10–12). Changes can be quantified at contaminated sites and patterns compared to those in plants unaffected by pollutants. Experiments can also be conducted to explore what pollutants and at what level are causing the changes in the organism. Furthermore, small discrete changes can be indicative of low contamination levels and can serve as early warning signs (12).

TRACE METAL POLLUTION IN THE AQUATIC ENVIRONMENT

Pollution is a global crisis and affects both terrestrial and aquatic environs. In aquatic ecosystems, pollution can enter through various vectors. Agricultural and industrial pollutants enter aquatic ecosystems through point sources and nonpoint sources. Atmospheric deposition, runoff, groundwater seepage, precipitation, and direct discharge are the pathways by which pollutants enter aquatic ecosystems. Trace metals are important pollutants that infiltrate aquatic ecosystems. Because many of them are essential nutrients for biota at low concentrations in certain forms and deadly at high concentrations in other forms (13), trace metals can affect aquatic ecosystems in a way akin to that of phosphorus and nitrogen.

Trace metals, in excessive quantities, have serious health ramifications for humans and other organisms. In many areas of the world, where industrial pollution is less regulated and sophisticated water treatment facilities are not in place, trace metal pollution can significantly impact drinking water and food supplies (14,15). The effects of certain trace metal species or high concentrations of essential trace metals on human health include and are not limited to: increased rates of cancer, allergic reactions, behavioral problems, lower cognitive function, lowered immunity, reduced fertility, and central nervous system dysfunction (13,16–20). Therefore, it is imperative that water resources utilized for recreation, irrigation, and drinking water supply be investigated for potential impacts of trace metal contamination on human health and ecosystem function.

AQUATIC MACROPHYTES AS BIOMONITORS

Aquatic macrophytes are prime candidates as biomonitors of trace metals in aquatic ecosystems. Their ability to accumulate trace metals many times the background levels in the environment is a significant instrument for assessing the availability of trace metals to biota (14,21–23). Aquatic macrophytes can amass trace metals by accumulation of metal ions in tissues through the roots, shoots, and leaves or through adsorption of metals to the surface of plants (21,22,24–27). The ability to bioaccumulate in roots, shoots, and leaves, termed hyperaccumulation, allows aquatic plants to be utilized as biomonitors in three distinct ways.

The tissues of aquatic macrophytes can be analyzed for trace metal concentration. Through a rather elaborate sample preparation process, with special attention to avoid introducing outside contaminants to the sample, tissue can then be tested for the concentrations of various metals generally using atomic absorption spectrophotometry (8,22,25,27–29). The direct testing of metal concentration in macrophyte tissues delivers a quantitative value regarding the accumulation potential of a given plant and can help identify the potential impact of trace metals to biota in the ecosystem (30,31). This is of primary importance when monitoring aquatic ecosystems utilized for agricultural and drinking water purposes (14). Direct testing also allows for quantification of accumulated trace metals in plant parts. This information is especially useful for plants that may be consumed. Active *in situ* experiments are preferred over passive ones by allowing temporal impacts and controlling background concentration (2).

However, that is not to say that direct tissue testing is not without its difficulties. The cost of directly testing plant tissues can be extraordinarily high and the results may not be indicative of current ecosystem conditions (32). Time-dependent accumulation and adsorption must also be taken into account (24,32). Background metal concentration also impacts uptake potential for aquatic plants. As such, *in situ* experiments must monitor sediment and water column metal concentrations and pay special attention to local environmental conditions. Finally, metal concentration is influenced by pH and other factors relating to sediment/soil composition (33).

Beyond direct testing for metal concentration in plant tissues, there exists the potential to indirectly monitor the concentration of metal through its impact on plants. Trace metals can be indirectly monitored by analyzing biochemical changes in aquatic macrophytes. Various trace metals, cadmium (Cd), lead (Pb), copper (Cu), and chromium (Cr), have been shown to reduce carbohydrate, protein, and chlorophyll production in aquatic macrophytes (see Fig. 1) (10,34). Reduction in essential nutrient uptake has also been observed in plants affected by trace metals (35), which may account for the decrease in production of other compounds in plants. Additionally, biomarkers of metal stress can indicate the presence of metal, and through research a stress-response pattern can be elucidated (36). Toxicity studies are quite similar in approach and may also help estimate levels of trace metal contamination that significantly reduce survivorship in aquatic macrophytes. Laboratory studies are far more reliable sources of information regarding indirect effects since *in situ* experiments may be confounded by synergistic effects of various compounds in the water column or other unidentifiable factors (32).

The third mechanism for testing the effects of trace metals on aquatic macrophytes is through studies of morphological changes. Changes in plant height, biomass, shoot length, and structural symmetry may all be indicative of metal stress (7,11,35,37,38). The goal in biomonitoring is to relate the degree of morphological changes in organisms to metal concentrations in the environment and available to biota. Thus, the long-term goal of utilizing morphological changes is linked to direct testing. Morphological monitoring is significantly limited,

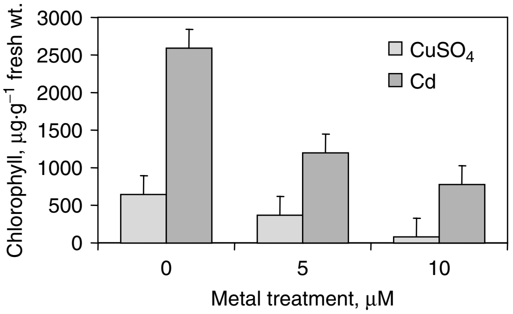

Figure 1. Changes in chlorophyll concentration as a function of trace metal treatment after eight days ($CuSO_4$, copper sulfate; Cd, cadmium). (Adapted from Refs. 10 and 34.)

much like indirect testing, to laboratory media where metal-specific responses can be controlled.

HYPERACCUMULATION POTENTIAL OF VARIOUS AQUATIC MACROPHYTES

Laboratory and *in situ* experiments on the hyperaccumulation capability of various aquatic macrophytes have yielded a wide range of results. Figure 2 exhibits the maximum observed accumulation potential of various metals by aquatic macrophytes. While aquatic macrophytes as a whole may accumulate significant levels of trace metals from the water column and sediments, no single species accumulates all metals well enough to be utilized as a single biomonitor for aquatic ecosystems (39). Figure 2 also indicates the maximum accumulation potential of various trace metals by different aquatic macrophytes. Please note that the greatest concentration of different metals has been observed in different aquatic macrophytes. However, the concentrations of metal in the tissue are not adjusted for background concentration.

While different aquatic macrophytes accumulate metals in different concentrations, it also has been found that different tissues vary in metal accumulation. In general, roots hyperaccumulate the greatest concentration of trace metals (28,30). Additional studies have shown metal concentrations in inflorescence and fruiting bodies of plants to be at startling levels especially considering their importance as food for both humans and other organisms (Fig. 3) (14,40).

Since roots are shown to be the greatest accumulators of heavy metals, it would seem obvious that rooted aquatic macrophytes would be preferred to floating macrophytes. However, this is not true in all cases. Floating macrophytes of the genus *Lemna* are utilized frequently in phytotoxicity studies (34,41). Ease of use and consistency with previous studies often influence the species of macrophytes to be used, especially for laboratory studies. *In situ* studies generally rely on the available local species, although submerged rooted species of the genus *Potamogeton* almost always have been investigated.

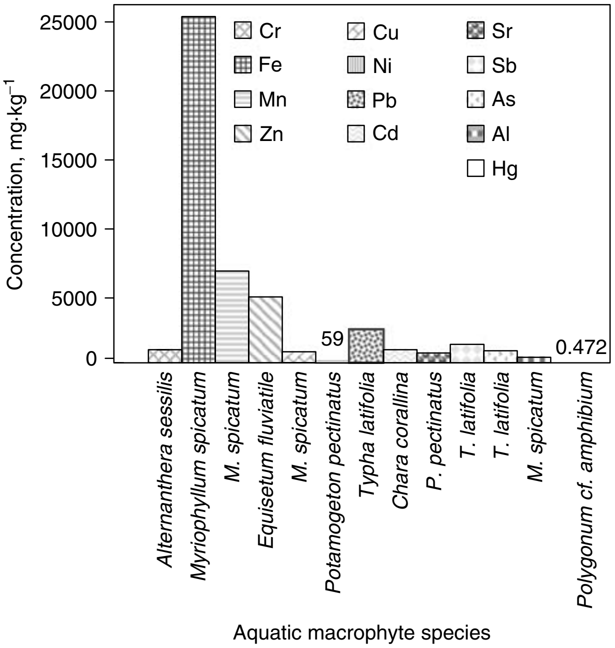

Figure 2. Maximum accumulation of trace metals by aquatic macrophytes (Cr, chromium; Fe, iron; Mn, manganese; Zn, zinc; Cu, copper; Ni, nickel; Pb, lead; Sr, strontium; Sb, antinomy; As, arsenic; Al, aluminum; Hg, mercury). (Adapted from Refs. 15, 21, 22, and 25.)

MACROPHYTES AS BIOMONITORS OF INDUSTRIAL POLLUTANTS

Aquatic macrophytes are already being utilized as keystone monitors of industrial pollutants in various bodies of water (15,21,22,42). For instance, aquatic macrophytes have been used to monitor pollutants in discharge of water from mines and ore processing facilities. Aquatic macrophytes, living in such highly polluted places, have adapted to extreme conditions and therefore are more likely to survive than any new species introduced as a monitor.

Aquatic macrophytes are also utilized as biomonitors of drinking water in parts of India (15). In instances where the indigenous population relies on streams and lakes for drinking water, industrial pollution can significantly harm the human population. In such cases, the concentration of metal in aquatic macrophytes can indicate to resource managers and decision-makers that something must be done to protect the residents. Direct testing of aquatic macrophytes can also indicate to farmers that irrigating crops from a specific body of water may have ramifications on human health down the line. Additionally, aquatic macrophytes may be a vital link in the foodweb dynamics of a region and significantly impact the health of animals as well as humans (22).

FUTURE RESEARCH OPPORTUNITIES

Before aquatic macrophytes can be fully employed as biomonitors of trace metals, various avenues of research must be undertaken. Direct correlations between biochemical changes and metal concentration in both plant tissues and background environments must be fully realized through intensive research. Synergistic effects of various metals should also be assessed. Studies of morphological changes due to heavy metal accumulation can be undertaken in both laboratory and *in situ* settings. Additionally, time-dependent mechanisms relating to hyperaccumulation of trace metals and their impacts on morphology and biochemical processes should be investigated. Those utilizing biomonitoring for practical purposes must know how long macrophytes retain metals in their tissues and if they are re-released into the water column in any significant way. Studies should also take into account the implication of introducing new aquatic macrophyte species as biomonitors and their potential impact on the aquatic ecosystem in general.

IMPORTANCE OF BIOMONITORING TO OTHER AREAS OF SCIENTIFIC RESEARCH

Biomonitoring of aquatic macrophytes can provide additional insight into other areas of science. The information on hyperaccumulation of heavy metals has a profound impact on the use of plants in bioremediation (8,15,42). Plants may be of vital use in extracting pollutants from a given site. Additional research on the re-release of trace metals back into the water column and sediment will have tremendous value for developing bioremediation programs as well.

Furthermore, understanding biomonitoring potential for aquatic macrophytes can also provide insight into the mechanisms and factors that influence the metal ion accumulation in aquatic plants (43). Metal accumulation by macrophytes is also a significant component of metal cycling in aquatic ecosystems (44). Thus, the scientific knowledge gained through research on aquatic macrophytes as biomonitors may have far-reaching impacts on other important realms of scientific exploration.

BIOSORPTION OF TOXIC METALS

M.X. Loukidou
A.I. Zouboulis
Aristotle University of Thessaloniki
Thessaloniki, Greece

GENERAL ASPECTS

Metals may be disseminated in the environment "naturally" by geochemical and biological activities, but anthropogenic actions today produce a greater input. Several industrial activities, such as the mining, electroplating, and metal finishing industries, have intensified environmental pollution problems, as well as the discharge of heavy metals in the environment. It is well known that metals are not biodegradable and can be transformed from one chemical form to another. Growing attention is being given to the potential hazard shown by their increased concentrations in the environment because their accumulation in living tissues throughout the food chain may pose a serious human health problem. Therefore, metal-laden waste sources should be effectively treated (1).

Different factors, such as the degree of environmental risk assessment, the probable future increase in market price, and the depletion rate of reserves are usually applied to set them into different categories—high, medium, or low priority. Under public and media pressure, the European Union and the U.S. EPA have introduced and progressively enforced stricter regulations on metal discharges, particularly for effluents from industrial operations. Currently available techniques for treating metal-bearing effluents, including mainly precipitation, evaporation, adsorption, ion exchange, membrane processing, and solvent extraction, are not effective enough, or rather expensive and occasionally inadequate, considering the large wastewater quantities produced. The main performance characteristics of common heavy metal wastewater treatment technologies are summarized in Table 1 (2).

The method that consists of oxidation/reduction, chemical precipitation, and solid/liquid separation has been traditionally the most commonly applied. Depending on the volumes involved, this treatment can be operated either in batch or continuous mode. It is also essential to control carefully the addition of chemical agents, as well as the pH. One of the main problems of this method is the production of toxic sludge; it transforms an aquatic pollution problem into another of subsequent safe solid waste disposal.

As a consequence, research efforts are intensive to apply more efficient and cost-effective treatment technologies. Biosorption promises to fulfill these requirements because it is a competitive, effective, and rather cheap method.

Generally, biosorption is a treatment process that uses inexpensive biomass, usually by-product, to sequester toxic metals from contaminated effluents. Biosorbents can

Table 1. Performance Characteristics of Common Heavy Metal Removal Technologies to Treat Industrial Wastewater

Method	Disadvantages	Advantages
Chemical precipitation	• Difficult separation • Disposal of resulting toxic sludge • Not very effective	• Simple • Relatively cheap
Electrochemical treatment	• Applicable for high metal concentrations • Sensitive to specific conditions, such as the presence of certain interfering compounds	• Metal recovery
Reverse osmosis	• Application of high pressures • Membrane scaling/fouling • Expensive	• Pure effluent/permeate (available for recycling)
Ion exchange	• Sensitive to the presence of particles • Expensive resins	• Effective • Possible metal recovery
Adsorption	• Not very effective for certain metals	• Conventional sorbents

be prepared from natural abundant biomass sources, such as seaweeds, or from waste biomass of algae, fungi, or bacteria (Fig. 1) (3–6).

The unique capabilities of certain types of biomass to concentrate and immobilize particularly heavy metals can also offer some degree of selectivity. This property depends on the following parameters:

- the specific type of biomass,
- the mixing conditions of the suspension,
- the type of biomass preparation, and
- the specific physicochemical conditions.

Broad-range biosorbents can collect most of the heavy metals from an aqueous solution (wastewater), presenting rather a smaller degree of selectivity among them. A specific metal can be separated either during sorption uptake, by manipulating the properties of a biosorbent, or upon desorption during the regeneration cycle of the biosorbent.

Metal uptake by living or dead cells can consist of two different modes (5). The first, independent of metabolic activity, is referred to as *biosorption* or *passive uptake*. The second mode of metal uptake into the cell (and across the cell membrane) depends on cell metabolism and is referred to as *bioaccumulation, active uptake*, or *intracellular uptake*. Both living and dead cells can take up metals. The use of dead cells seems to be the preferred alternative for the majority of studies. The wider acceptability of dead cells is devoted to the absence of toxicity limitations, as well as of requirements for growth media and nutrient supplements in the solutions to be treated. The biosorbed metals can also be easily desorbed, creating a more concentrated solution, from which metals can be recovered for subsequent reuse by using convenient technologies, such as electrolysis; simultaneously, the regenerated biomass can also be

Table 2. The Main Characteristics of Metal Biosorption and Bioaccumulation

Feature	Biosorption	Bioaccumulation
Metal affinity	High under favorable conditions	Toxicity will affect metal uptake
Rate of metal uptake	Rapid	Slower than biosorption
Selectivity	Poor	Better than biosorption
Temperature tolerance	Within a modest range	Inhibited by relatively low or high temperatures
Versatility	pH dependent, affected by anions or other molecules	Requires an energy source; dependent on plasma membrane

reused. The main characteristics of metal biosorption and bioaccumulation processes are presented in Table 2.

Biological processes to remove toxic metals can be more effectively used to treat metal solutions of low concentration (in the range of few mg/L), as a final polishing step to remove any residual metal. Therefore, the appropriate pretreatment of metal-laden wastewater containing elevated concentrations (in the range of several mg/L) is considered necessary and is usually done by common methods, such as chemical precipitation.

Although the use of living organisms is often successful for treating even highly toxic organic contaminants, living microorganisms in conventional biological treatment systems have not been found particularly useful for treating wastewater containing heavy metal ions. When the metal concentration becomes high enough, then the metabolism of the microorganism is disrupted, causing its death. The defense mechanisms of living microorganisms are responsible for the observed decrease of metal sorption. This disadvantage is not operative when nonliving microorganisms, or biological materials derived from microorganisms, are used to remove metal ions from dilute aqueous solutions.

DESORPTION

Whenever the biosorption process is used as an alternative treatment method for metal-laden wastewater, regeneration of loaded biosorbent is an important issue, to keep the process costs low and to establish the possibility of recovering the metal extracted from the liquid phase (4,7). The desorption process could result in a more concentrated metal solution, keeping the metal uptake high upon subsequent reuse of the biomass and when appropriately performed, without causing physical changes in or damaging the biosorbent. The use of dilute acids was found quite effective, and careful control of pH may also provide a simple means to increase the selectivity of metal recovery. Carbonates and/or bicarbonates were also suggested as desorptive agents; they appear to have the most commercial potential, though carbonates may sometimes affect the biomass structure.

The selection among possible metal recovery methods, subsequently applied to the resulting concentrated metal solutions, depends on the ease of metal removal from the biomass and on the commercial (or environmental) value of the metal or the biomass, as a reusable entity. When the waste biomass is relatively cheap or when it is used to accumulate valuable metals, destructive recovery by incineration or strong acid/alkali dissolution of the biomass may be considered economically feasible. The recovery method also depends on the mechanism of metal accumulation. Biosorption is often reversible, whereas metabolism-dependent intracellular accumulation is usually irreversible and, hence, necessitates the use of destructive treatment to recover metals.

MECHANISMS OF METAL BIOSORPTION

The complexity of a microorganism's structure implies that there are many different ways for the metal to be captured by a (living or dead) cell. Therefore, biosorption mechanisms can be varied, and in some cases, they are still not very well understood. They may be divided into several categories, according to the dependence on cell metabolism, metabolism-dependent and nonmetabolism-dependent, as well as on the location, where the metal will be removed from the solution, through extracellular accumulation/precipitation, cell surface sorption/precipitation, or intracellular accumulation, as shown in Fig. 2 (3).

Transport of the metal across the cell membrane yields intracellular accumulation, which depends on cell metabolism; this implies that this kind of biosorption may take place only with the viable cells. It is often associated with the active defense system of microorganisms, which react in a toxic environment (in this case, the metal).

In physicochemical interaction between a metal and the functional groups on a cell surface that takes place during physical adsorption, ion exchange, and/or surface complexation mechanisms, sorption onto a cell surface would not depend on metabolism. Cell walls of microbial biomass, composed mainly of polysaccharides, proteins, and lipids, can offer several metal-binding functional groups, such as carboxylate, hydroxyl, sulfate, phosphate, and amino groups. Biosorption of metals through physicochemical interaction occurs relatively rapidly and can be reversible. In this case, biomass has the major characteristics of an ion exchange resin, or of an activated carbon, implying certain advantages, such as lower cost, in the industrial application of biosorption.

Precipitation of metals may depend on cellular metabolism or may be independent of it. Metal removal from solution is often associated with the active defense system of microorganisms. Metal removal by precipitation, which does not depend on cellular metabolism, may be a consequence of the chemical or physical interaction

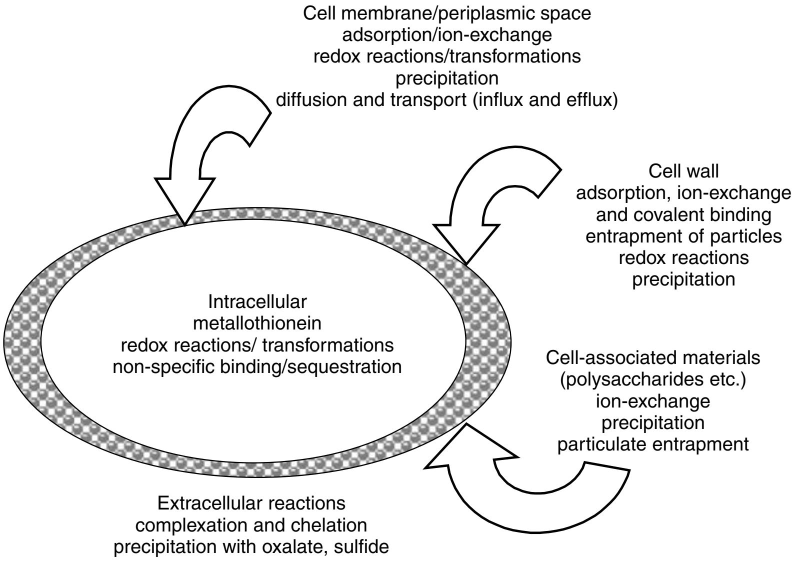

Figure 2. Several processes that contribute to microbial uptake and detoxification of aqueous solutions containing toxic metals.

between the metal and the cell surface. It becomes evident that the biosorption mechanisms are varied, and they can also take place simultaneously.

Generally, biosorption by living microorganisms consists of two basic steps. First, an independent metabolism binding step to cell walls and second, metabolism-dependent intracellular uptake, whereby metal ions are transported across a cell membrane into the cell (8). Cadmium, zinc, copper, and cobalt biosorption by the dead biomass of algae, fungi, and yeasts takes place mainly through electrostatic interactions between the metal ions in solution and cell walls. Cell walls of microorganisms contain polysaccharides as basic building blocks. The ion exchange properties of natural polysaccharides have been studied in detail, and it is well established that bivalent metal ions may exchange with the counterions of polysaccharides. Alginates of marine algae usually occur as natural salts of K^+, Na^+, Ca^{2+}, and/or Mg^{2+}. These metallic ions can be exchanged with counterions, such as Co^{2+}, Cu^{2+}, Cd^{2+}, and Zn^{2+}, resulting in biosorptive uptake of the metals. Knowledge of metal biosorption mechanisms could lead to the development of economically attractive sorbent materials.

MODELING

Mathematical modeling of biosorption offers an extremely powerful tool for a number of tasks on different levels; it is essential for process design and optimization. The biosorptive capacity and required contact time are two of the most important parameters. Sorptive equilibrium is established when the concentration of sorbate in the bulk solution is in dynamic balance with that on the interface. An equilibrium analysis is the most important information required to evaluate the affinity or capacity of a biosorbent. However, thermodynamic data can predict only the final state of a system from an initial nonequilibrium mode. It is important to determine how sorption rates depend on the concentrations of solution and how these rates are affected by sorptive capacity. From kinetic analysis, the solute uptake rate, which determines the residence time required to complete the sorption reaction, may be established (9). Equilibrium and kinetic analyses allow estimation of sorptive capacities and rates and also lead to suitable rate expressions that are characteristic of possible reaction mechanisms.

A wide range of equilibrium-based models has been used to describe the sorption of metals onto solid particles. They include the common isotherm equations, such as those developed by Langmuir and Freundlich. The Langmuir equation models monolayer sorption onto surfaces that contain a finite number of accessible sites:

$$q_{\mathrm{e}} = \frac{q_{\max} b C_{\mathrm{e}}}{1 + bC_{\mathrm{e}}} \tag{1}$$

where $q_{\max}$ is the maximum quantity of metal ions per unit weight of biomass to form a complete monolayer on the surface (mg/g) and b is a constant related to the affinity of binding sites for the metal ions (sorbate, L/mg). Note that $q_{\max}$ represents a practical limiting adsorptive capacity corresponding to the surface of a sorbent fully covered by metal ions. This quantity is particularly useful for assessing adsorption performance, especially when the sorbent does not reach its full saturation, because it enables an indirect comparison between different sorbents (10).

The empirical Freundlich equation accounts macroscopically for sorption onto heterogeneous surfaces:

$$q_e = K_{\mathrm{F}} C_{\mathrm{e}}^{1/n} \tag{2}$$

where K_{F} is an indicator of adsorptive capacity (L/g) and n is adsorptive intensity (dimensionless) (10).

Table 3 lists several types of biomass examined for their ability to remove Cd(II), Ni(II), Cu(II), and Cr(VI), which are metals considered of high environmental priority. The values of specific metal uptake q (mg of metal biosorbed per gram of biomass) are quite high in several cases

Table 3. Selected Literature Survey: Comparison of Different Biosorbents for Cd(II), Cu(II), Ni(II), and Cr(VI) Removal Capacity

Metal	Biosorbent	$q_{\max}$, mg/g	pH	T, °C	Biomass Concentration, g/L	Reference
Cd(II)	*B. licheniformis*	142.7	7	20	1	11
	B. laterosporus	159.5	1	25	1	11
	Sphaerotilus natans	115	6	25	0–1	3
	Sargassum fluitans	101.4	7	25	—	3
	Rhizopus arrhizus	26.8	7	26	3	11
	Saccharomyces cerevisiae	0.56	5	25	2	8
Cu(II)	*Chlorella vulgaris*	37.6	4	25	0.75	16
	Spirulina platensis	10	6	25	1	3
	Synechocystis sp.	23.4	4.5	25	1	3
Cr(VI)	*Chlorella vulgaris*	24	2	25	1	11
	Zooglera ramigera	3	2	25	—	3
	B. laterosporus	72.6	1	25	1	11
	Rhizopus arrhizus	62	2	25	1	13
	Rhizopus nigricans	123.45	2	25	1	13
Ni(II)	*Ascophyllum nodosum*	70	6	25	1	16
	Chlorella vulgaris	42.3	5	25	1	16
	Synechocystis sp.	15.8	5	25	1	16

and showed that selected biosorbents can be effective for removing heavy metals.

Sorption kinetics may be controlled by several independent processes that can act in series or in parallel, such as (i) bulk diffusion, (ii) external mass transfer (film diffusion), (iii) chemical reaction (chemisorption), and (iv) intraparticle diffusion (9). Any of these four steps, or any combination among these steps may be the rate-controlling factor. Transport in the solution is sometimes the rate-determining parameter in large-scale field processes. At sufficiently high agitation speed in the reaction vessel, the bulk diffusion step can be safely ignored because then sorption onto sorbent particles is decoupled from mass transfer in the bulk mixture.

IMMOBILIZATION

In the industrial application of biosorption, an immobilization procedure for biosorbent materials is often necessary to improve subsequent solid/liquid separation. The immobilization of biomass within appropriate solid structures creates a new sorptive material that has the appropriate size, mechanical strength, rigidity, and porosity necessary for use in conventional unit operations, such as fixed beds, adsorption columns, or mixing tanks. The principal techniques for the application of biosorption are based on entrapment in a strong, but rather permeable matrix, such as encapsulation within a membrane-like structure and bonding of smaller particles. It has been recognized that immobilizing biomass in a polymer matrix may improve the biomass performance and capacity, and, simultaneously, there is no need for the solid–liquid separation of a metal-laden biomass from the treated solution (11). Many polymeric matrices have been used for biomass immobilization, including polysulfone, polyurethane, alginate, polyacrylamide, and polyethyleneimine (PEI) (3). Several modifications of biomass immobilization have been used for metal removal, such as *Chlorella homosphaera* immobilized by sodium alginate; *Sargassum fluitans* and *Ascophyllum nodosum* cross-linked with formaldehyde, glutaraldehyde, or embedded in polyethylene imine; sphagnum peat moss immobilized in porous polysulfonate beads; and *Rhizopus arrhizus* immobilized in reticulated polyurethane foam (5). Modified polyacrylonitrile (denoted as PAN) was also examined as an efficient binder of fungal biomass (dead cells of *P. chrysogenum*, a waste by-product during antibiotic production) (12).

BIOSORPTION OF HEAVY METAL ANIONS

Several studies were carried out and highlighted that biosorptive removal of metal cations from aqueous solution depends mainly on the interactions between metal ions and specific groups, which are associated with the biosorbent surface. The uptake of anions by biosorption has become a growing concern, because they cannot be easily removed as insoluble hydroxides or salts by the common application of chemical precipitation.

Several chemically modified sorbents were examined for their enhanced ability to bind anions (3). The selective modification of *Rhizopus nigricans* using cetyl trimethylammonium bromide was also examined; polyethyleneimine improved the biosorptive efficiency to high levels (13). The modification of *P. chrysogenum* with common cationic surfactants (amines) or with a cationic polyelectrolyte overcame the low capacity of biomass for treating arsenic-contaminated wastewater (14). Extensive studies were carried out and reported on the biosorption of molybdate or (hexavalent) chromium anions (15). The removal of these anions can be related to the various functional groups of biomass surface, such as amino groups or proteins, which can provide positive surface charges, therefore, causing the electrostatic attraction of anions.

BIOSORPTION TREATMENT PLANTS

Following equilibrium and dynamic sorption studies, the quantitative basis for the sorption process can be established, including process performance models. Biosorption process feasibility is assessed for well-selected cases. It is necessary to realize that there are mainly two types of pilot plants, which eventually can be run side by side (Fig. 3) (4):

- biomass processing pilot plant
- biosorption pilot plant

The process of biosorption for removing metals can show performance comparable to its closest commercially used competitor, ion exchange treatment. Effluent qualities of the order of only a few ppb (μg/L) of residual metal can be achieved. Commercial ion exchange resins are rather costly, and the price tag of biosorbents can be an order of magnitude cheaper, only 10% of the ion exchange resin cost. The main attraction of biosorption seems to be the cost-effectiveness of this process. Biosorption is in its early developmental stages, and further improvements in both performance and costs can be expected in the near future.

EXISTING TECHNOLOGIES

Several biosorption processes have been developed and introduced for removing metal contaminants from surface water and groundwater. The BIOCLAIM® process employs microorganisms, principally bacteria of the genus *Bacillus*, which have been treated with strong caustic solution to enhance the accumulation of metal, washed with water to remove residual caustic, and immobilized in extruded beads using polyethyleneimine (PEI) and glutaraldehyde (3). The AlgaSORB™ process is a proprietary family of products that consists of several types of nonliving algae in different immobilization matrices. The BIO-FIX® process includes several types of biomass, including sphagnum peat moss, algae, yeast, bacteria, and/or aquatic flora, which are immobilized in polysulfone. Immobilized *Rhizopus arrhizus* has also been evaluated for recovering uranium from an ore bioleach solution. The application of flotation for the subsequent separation of metal-laden biomass, when applied in suspension, was also suggested (17).

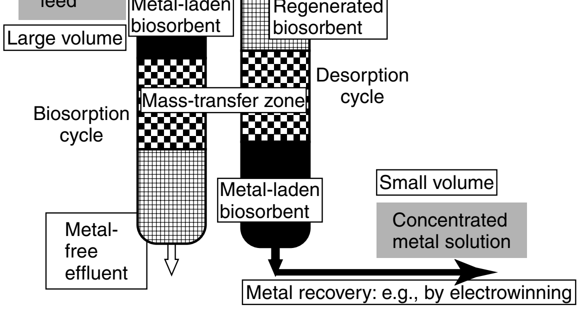

Figure 3. Schematic diagram of possible biosorption implementation, using packed bed columns for biosorption and desorption (4).

FUTURE ASPECTS

It should be evident from this brief survey that the possibilities for microbial metal removal and recovery are abundant. Biosorption is a multidisciplinary scientific area extending into several sciences, such as biology, chemistry, and engineering. The biosorption process could be used, even with a relatively low degree of understanding of its metal-binding mechanisms, but better understanding is necessary to increase the effectiveness and to optimize the relevant applications. Regarding technological development, scientific investigation should result in new families of products, as well as of biosorbents. The accompanying services should involve:

- assessing the type of problem to be remedied,
- assessing the applicability of biosorption,
- developing a customized biosorption process,
- designing and building the plant, and
- recovering the removed metals for subsequent reuse (4).

BROMIDE INFLUENCE ON TRIHALOMETHANE AND HALOACETIC ACID FORMATION

Shankar Chellam
University of Houston
Houston, Texas

INTRODUCTION

General Background

Chemical disinfectants are added to drinking water primarily to kill or inactivate microorganisms, as discussed in other sections of this encyclopedia. However, an undesired and unintentional consequence of their use is that they react with natural organic matter (NOM) to form disinfection by-products (DBPs) (1,2). DBPs have been studied extensively since the first reports of trihalomethanes (THMs) and haloacetic acids (HAAs) in drinking water by Rook (3) and Christman et al. (4), respectively. THMs and HAAs constitute the two most important classes of DBPs measured on a weight basis in chlorinated drinking water (5). Because of length limitations, this section can only succinctly describe the important influence of the bromide ion on THM and HAA formation and speciation. The reader is directed to the references cited to obtain more detailed information. Additionally, only DBPs formed because of the application of free chlorine will be considered herein because most municipalities around the world use it for disinfection.

Simplistically, the formation of organic DBPs including THMs and HAAs can be written as follows:

$$\text{NOM} + \text{chlorine} + \text{bromide} \rightarrow \text{THMs} + \text{HAAs} + \text{other halogenated DBPs} \quad (1)$$

In the absence of the bromide ion, the only THM that can be formed is $CHCl_3$ (chloroform) whereas three HAAs, namely, chloroacetic acid (ClAA), dichloroacetic acid (Cl_2AA), and trichloroacetic acid (Cl_3AA), can be formed. However, bromide can be present in drinking water supplies due to natural geological occurrence, salt water intrusion, or human activities such as coal mine drainage or re-injection of oil field brine (6). When Br^- is present in water along with NOM, addition of chlorine can also result in formation of three additional THMs, namely, dichlorobromo methane, chlorodibromo methane ($CHClBr_2$), and bromoform ($CHBr_3$), and six additional HAAs, namely, bromo acetic acid (BrAA), dibromo acetic acid (Br_2AA), tribromo acetic acid (Br_3AA), bromochloro acetic acid (BrClAA), dichlorobromo acetic acid (Cl_2BrAA), and chlorodibromo acetic acid ($ClBr_2AA$). Hence, a total of four THMs and nine HAAs contain bromine and chlorine. As can be inferred from Equation 1, changes in the concentration of the reactants (including Br^-) will influence both the formation and relative speciation of the four THMs and nine HAAs.

Health Effects and Regulations

Epidemiological studies suggest a slightly increased risk of bladder, colon, and rectal cancers after long-term exposure to chlorinated water because of the presence of DBPs (7), warranting their designation as "primary" drinking water contaminants. However, partially because of limited data available for the occurrence, formation, and toxicology of the mixed chlorobromo acetic acids and Br_3AA, current federal regulations (8) simplistically address the sum of mass concentrations of THMs and only five HAAs (HAA5, viz, ClAA, Cl_2AA, Cl_3AA, BrAA, and Br_2AA) expressed in μg/L.

Literature reports indicate that increasing concentrations of the bromide ion cause a general shift from chlorinated toward brominated THMs (9–14), HAAs (15–18), as well as other DBPs classes (19). These studies have unequivocally established the formation of the unregulated mixed bromochloro HAA species (ClBrAA, Cl_2BrAA, and $ClBr_2AA$) and Br_3AA when chlorine is added to waters containing bromide. Importantly, recent evidence points to the increased cytotoxicity, mutagenicity, and genotoxicity of brominated acetic acids and nitromethanes compared with their chlorinated counterparts (20,21). Hence, an expressed need exists to delineate the role of bromide ion in controlling THM and HAA9 speciation, with the ultimate aim of reducing health risks associated with DBPs in drinking water.

CHEMISTRY OF BROMINATED THM AND HAA FORMATION

The relative proportion of individual THM and HAA species depends on several water chemistry factors including the concentrations of Br^- and NOM (quantified often as dissolved organic carbon, DOC), Cl_2 dosage, temperature, pH, and contact time (22). Additionally, NOM characteristics, such as polarity and molecular weight distribution, also influence THM and HAA speciation (23,24). Hence, seasonal variations in NOM characteristics, temperature, and bromide levels can be expected to induce changes in THM and HAA formation with season.

The oxidation of bromide by free chlorine (hypochlorous acid) to hypobromous acid is a very fast second-order reaction:

$$\text{HOCl} + \text{Br}^- \rightarrow \text{HOBr} + \text{Cl}^- \quad (2)$$

Note that this reaction also demonstrates that Br^- could exert a chlorine demand in natural waters. The simultaneous and parallel reactions of HOBr and HOCl with NOM results in the formation of halogenated DBPs. A higher fraction of HOBr ($pK_a = 8.8$) will remain undissociated at pH values commonly encountered in drinking water treatment than of HOCl ($pK_a = 7.5$), which allows increased formation of halogenated DBPs in bromide-containing water supplies. Starting from the early report of THM formation (3), bromine has been understood to be more reactive than chlorine in forming THMs and HAAs (13,14,16).

Trihalomethanes

Several investigations have shown that, for fixed NOM concentrations and chlorine doses, increasing bromide substantially increases total THM formation on a mass basis (9,12,13). This phenomenon is corroborated by the positive exponents for bromide ion in empirical THM models (25–29). Hence, Br^- is a THM precursor in addition to NOM. The increase in total THM levels is smaller when calculated on a molar basis because bromine has a higher atomic weight (79.9 g/mole) than does chlorine (35.5 g/mole).

Increasing Br^-/DOC ratio also induces changes in speciation under most circumstances, wherein $CHCl_3$ mole fraction monotonically decreases and $CHBr_3$ mole fraction monotonically increases. In contrast, $CHCl_2Br$ and $CHClBr_2$ mole fractions first increase and then decrease. The chlorine dose has to be increased to adjust for increasing chlorine demand for higher DOC waters in order to obtain a constant residual at the end of the predetermined incubation time when performing tests under simulated distribution system (30) or uniform formation conditions (31). These changes in Br^-/Cl_2 ratios also influence THM formation and speciation. Simultaneous changes in Br^-/DOC and Br^-/Cl_2 ratios may confound analysis of THM speciation and formation, even though the above-mentioned trends are generally observed (9,10,12–14). In general, high pH favors the formation of THMs (2,32) possibly because they are the end products of hydrolysis of several DBPs (33).

The degree of bromine substitution in THMs can be quantified for the bromine incorporation factor n (34):

$$n = \frac{\sum_{k=0}^{3} k \times [\mathrm{CHCl}_{3-k}\mathrm{Br}_k]}{\sum_{k=0}^{3} [\mathrm{CHCl}_{3-k}\mathrm{Br}_k]} \tag{3}$$

where each THM species is expressed in μM. If $CHCl_3$ is exclusively formed $n = 0$, whereas $n = 3$ corresponds to a situation when only $CHBr_3$ is formed. In most water treatment scenarios, $0 < n < 3$, which corresponds to the simultaneous formation of all or several THM species. As can be anticipated, increasing Br^-, decreasing DOC, and decreasing Cl_2 dose generally result in increasing THM bromine incorporation factor (9,10,12–14).

Haloacetic Acids

In contrast to the numerous THM studies available in the literature, investigations on the role of bromide ion on HAA9 formation and speciation had been limited until relatively recently by the nonavailability of commercial standards for the mixed chlorobromo and tribromo species. Early HAA9 studies employing instrumental standards for several mixed chlorobromo species synthesized in academic laboratories revealed a gradual shift from the chlorinated to the mixed bromochloro and then to the brominated species with increasing Br^- concentration (15,16). However, unlike the THMs, the molar yield of HAA9 does not appear to strongly depend on Br^- (15,16), which indicates that Br^- may not necessarily be a precursor for HAAs. Studies that only monitored HAA5 or HAA6 (HAA5 and BrClAA) have indicated a decrease in the regulated HAAs with increasing Br^- (10,35), which should be interpreted with caution because shifts toward the unmonitored and more brominated species would cause this phenomenon rather than a decrease in the total molar concentration of all nine HAAs. These patterns are consistent with the negative exponent for Br^- in empirical power law functions derived to model HAA6 formation (26) and purely chlorinated HAAs (27) and positive exponent for BrAA and Br_2AA (27).

Monohalogenated HAAs (ClAA and BrAA) are typically formed at very low levels after chlorination of drinking water supplies, whereas the di- (Cl_2AA, ClBrAA, Br_2AA) and trihalogenated (Cl_3AA, Br_3AA, Cl_2BrAA, and $ClBr_2AA$) HAAs are the dominant species. Their relative dominance may depend on specific ultraviolet absorbance at 254 nm and pH (16,36). As a general rule, HAAs are preferentially formed at low pH values partially because trihalogenated HAAs undergo base catalyzed hydrolysis at high pH values (33).

Equation 3 can be extended to define a HAA9 bromine incorporation factor n':

$$n' = \frac{\begin{array}{c}[\mathrm{BrAA}] + [\mathrm{BrClAA}] + [\mathrm{BrCl_2AA}] \\ +2 \times [\mathrm{Br_2ClAA}] + 2 \times [\mathrm{Br_2AA}] + 3 \times [\mathrm{Br_3AA}]\end{array}}{\begin{array}{c}[\mathrm{ClAA}] + [\mathrm{Cl_2AA}] + [\mathrm{Cl_3AA}] + [\mathrm{BrAA}] + [\mathrm{BrClAA}] \\ +[\mathrm{BrCl_2AA}] + [\mathrm{Br_2ClAA}] + [\mathrm{Br_2AA}] + [\mathrm{Br_3AA}]\end{array}} \tag{4}$$

Similar to the THM bromine incorporation factor, $0 \leq n' \leq 3$ and n' increases with the degree of bromine substitution.

EFFECTS OF TREATMENT PROCESSES ON SPECIATION

During drinking water purification, changes in the relative amounts of Br^- and DOC are most often brought about by decreases in NOM rather than by increases in Br^-. In other words, the Br^-/DOC ratio is increased by decreasing the denominator rather than by increasing the numerator, as in most previous investigations of bromide effects on THM and HAA formation and speciation (9,12,13,15,16,35). This result is because processes such as coagulation, precipitative softening, nanofiltration (NF), biological filtration, advanced oxidation, and granular activated carbon (GAC) treatment are capable of DBP precursor (or NOM) removal, whereas Br^- passes almost conservatively through them (37). These changes in Br^-/DOC inherent to drinking water treatment processes will induce changes in THM and HAA formation and speciation as discussed next. Because of length limitations, only NF and GAC will be considered herein. Additional information on other treatment processes can be found elsewhere (1,33,38).

Effects of Granular Activated Carbon Treatment

Granular activated carbon treatment has been designated as one of the best available technologies for DBP precursor removal by the U.S. Environmental Protection Agency and is widely employed for NOM removal. Several excellent reviews of GAC use in drinking water treatment are available including its use for DBP control (39,40). However, changes in DBP speciation have not been emphasized in these reviews. Hence, this section focuses primarily on speciation issues and the reader is directed elsewhere for a more holistic understanding of GAC use for DBP control.

Figure 1 depicts several aspects of THM and HAA precursor removal and changes in speciation after GAC treatment for a pretreated surface water. The breakthrough curves corresponding to a gradual increase in effluent DOC and UV_{254} values are shown in Fig. 1a. Consequently, the effluent Br^-/DOC ratio decreases (Fig. 1e) because GAC treatment has very little effect on bromide ion. Figure 1e also depicts decreasing Br^-/Cl_2 decrease with progressive breakthrough of NOM, which is caused by increasing disinfectant demand, which necessitates higher Cl_2 doses to maintain a ~1 mg/L residual at the end of the 24 h incubation time (SDS testing conditions). These changes result in an increase in the formation of brominated THMs and HAAs in the effluent with operating time (Fig. 1b and 1c). Note that after ~3200 bed volumes, $CHBr_3$ concentrations were greater in the effluent than in the influent. Similar changes in THM speciation have been discussed earlier (41,42). Importantly, it should be noted that even though each individual THM and HAA increased on mass basis in the effluent (Fig. 1b and 1c), only the mole fraction of chloroform increased substantially (0.10 to 0.27). This result was accompanied by a significant decrease in $CHBr_3$ mole fraction (0.33 to 0.13). Mole fractions of $CHCl_2Br$ remained approximately constant, whereas that of $CHClBr_2$ increased slightly from 0.18 to 0.23. Of the unregulated HAAs, two mixed chlorobromo species (ClBrAA and Cl_2BrAA) were detected in both the GAC influent and effluent, whereas Br_3AA and $ClBr_2AA$ were never formed (probably because of the relatively low influent levels of $Br^- = 72$ μg/L). In the feed water ($Br^-/DOC = 5.8$ μM/mM), the speciation of the detectable HAAs was in the order: $Cl_2AA > BrClAA > Cl_3AA \sim Br_2AA > Cl_2BrAA$. After 4800 bed volumes ($Br^-/DOC = 13.4$ μM/mM), the speciation changed to $Cl_2AA \sim Br_2AA > BrClAA > Cl_2BrAA \sim Cl_3AA$ because the DOC was reduced to 0.8 mg/L with Br^- remaining at 72 μg/L. This change in Br^-/DOC ratio increased the mole fraction of Br_2AA from 0.13 in the influent water to 0.21 in the effluent. It should be noted that different speciation patterns should be expected if Br^- levels in the influent were higher.

Decreasing Br^-/DOC with GAC operation (increasing bed volumes) reduced both THM and HAA bromine incorporation factors as shown in Fig. 1(d). Another method of analyzing halogen incorporation is to calculate DBP-X/DBP, which refers to the molar concentration of Cl or Br incorporated in THMs or HAAs divided by

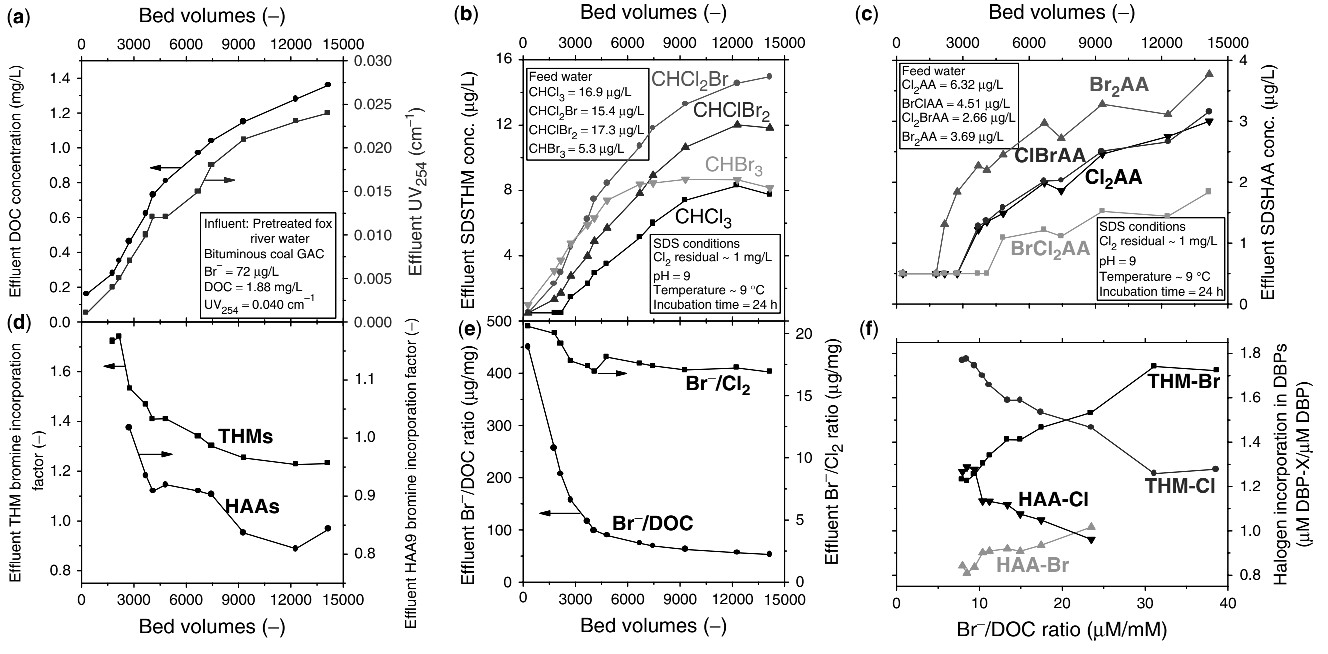

Figure 1. Several aspects of DBP control using GAC. (**a**) DOC and UV_{254} breakthrough curves; (**b**) and (**c**) formation of individual THMs and HAAs in the effluent, respectively; decreasing THM and HAA bromine incorporation factors (**d**) are caused by decreases in Br^-/DOC and Br^-/Cl_2 ratios (**e**). Increasing Br incorporation and decreasing Cl incorporation in GAC effluent for both THMs and HAAs with Br^-/DOC is shown in (**f**).

the total molar concentration of THM or HAA (Fig. 1f). Bromine incorporation into THMs and HAAs formed in GAC effluent was the highest at early times (high Br^-/DOC ratio) and decreased progressively with bed operation. As may be anticipated, the opposite trend was observed for chlorine incorporation. Bromine and chlorine incorporation in both THMs and HAAs were found to be equal at Br^-/DOC of ~20 μM/mM, corresponding to a Br^-/Cl_2 molar ratio of 15.5, which confirms that HOBr is more reactive than HOCl is in forming THMs and HAAs.

Effect of Nanofiltration

The early work by Taylor and co-workers simply documented that NF membranes were capable of very high NOM removal and capable of allowing municipalities to easily meet or exceed federal DBP regulations even if chlorine is employed for both primary and secondary disinfection (43). As demonstrated in more recent investigations (44–46), DBP precursor rejection decreases with increasing feed water recovery (Fig. 2a), which indicates that diffusion is the controlling mechanism of NOM and DBP precursor removal by NF membranes. Hence, increasing recovery reduces the Br^-/DOC ratio (Fig. 2f), which consequently increases the formation of the more chlorinated THMs ($CHCl_3$ and $CHCl_2Br$) while decreasing the more brominated ones ($CHClBr_2$ and $CHBr_3$) as depicted in Fig. 2c. Importantly, decreasing HAA9 and THM4 formation as recovery is lowered (increasing Br^-/DOC) indicates that NF waters are precursor limited.

Because NF achieved >90% removal of DOC (Fig. 2a) while allowing the almost complete passage of Br^-, a substantial increase in more brominated THM and HAA species was observed in the permeate compared with the feed water at a fixed operating recovery (70%) (Fig. 2b and 2e). Such speciation changes also decrease n and n' values with increasing recovery (Fig. 2d). Note that the mixed chlorobromo species were all detected in the permeate water. Similar to Fig. 1e, the Br^-/Cl_2 ratio also decreased with increasing DOC because greater Cl_2 doses were necessary to maintain a ~2 mg/L residual at the end of the 24 h holding time. Formation and speciation trends in Fig. 1 are qualitatively similar to those reported earlier (44,47).

Importantly, chlorination conditions (pH, temperature, incubation time, and dose) have been shown to influence THM and HAA speciation more than the membrane material and molecular weight cutoff or source water location (35,47).

Figure 3 depicts individual THM species formed in the permeate water normalized by the corresponding value in the feed water for three different NF membranes. Under the SDS conditions employed, NF preferentially reduced $CHCl_3$ and $CHCl_2Br$ concentrations, whereas NF increased concentrations of the more brominated species ($CHClBr_2$ and $CHBr_3$). Cumulatively, even though ~90% of THM precursors were removed by the same 400 Da molecular weight cutoff membrane shown in Fig. 1, it

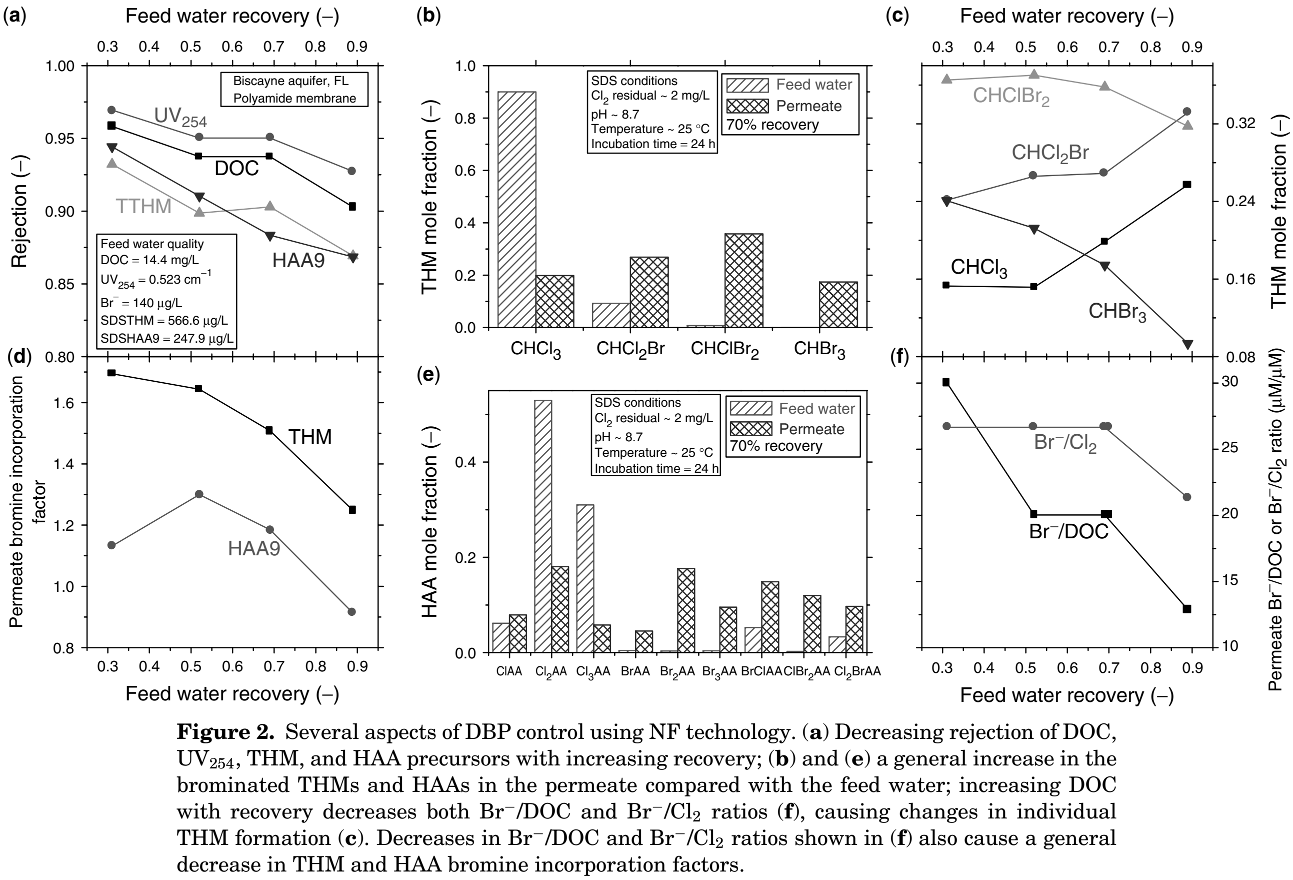

Figure 2. Several aspects of DBP control using NF technology. (**a**) Decreasing rejection of DOC, UV_{254}, THM, and HAA precursors with increasing recovery; (**b**) and (**e**) a general increase in the brominated THMs and HAAs in the permeate compared with the feed water; increasing DOC with recovery decreases both Br^-/DOC and Br^-/Cl_2 ratios (**f**), causing changes in individual THM formation (**c**). Decreases in Br^-/DOC and Br^-/Cl_2 ratios shown in (**f**) also cause a general decrease in THM and HAA bromine incorporation factors.

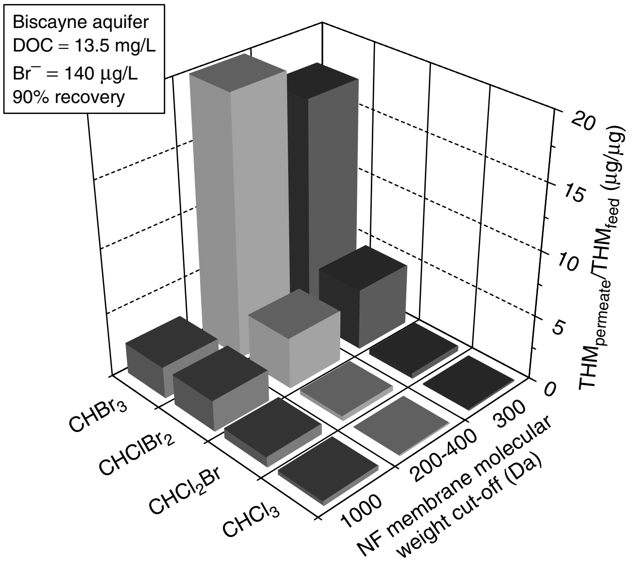

Figure 3. Effects of nanofiltration and membrane molecular weight cutoff on THM speciation for a naturally brominated groundwater measured under simulated distribution system conditions mentioned in Fig. 2.

also induced a fourfold increase in $CHClBr_2$ and a 20-fold increase in $CHBr_3$. As reported earlier (37), the shift toward the more brominated THMs was generally consistent with a decrease in MWCO, which increases Br^-/DOC ratio.

In summary, Figs. 1–3 as well as other investigations (44,47) unequivocally demonstrate the formation of the unregulated HAAs after advanced treatment. In fact, one study showed that the mole fraction of unregulated HAAs could be as high as ~50% following NF (47). Such substantial changes in speciation are not captured in existing DBP regulations, which only limit the sums of mass concentrations of four THMs and five HAAs. This important pitfall should be considered in formulating more equitable DBP regulations designed to protect human health.

ACTIVATED CARBON: ION EXCHANGE AND ADSORPTION PROPERTIES

Basu Saha
Loughborough University
Loughborough, United Kingdom

INTRODUCTION

The importance of environmental pollution control has increased significantly in recent years. Environmentalists are primarily concerned with the presence of heavy metals, pesticides, herbicides, chlorinated hydrocarbons, and radionuclides in groundwater, surface water, drinking water, and aqueous effluents because of their high toxicity and impact on human and aquatic life.

Several techniques have been developed and used to remove and/or recover a wide range of micropollutants from water and a variety of industrial effluents. Adsorption using activated carbon is well established for the removal of organic molecules from aqueous solution, but to a much lesser extent for the removal of toxic heavy metals.

Here, the preparation, properties, and metal sorption performance of a range of as-received and oxidized samples of granular activated carbon that were either prepared or modified in the author's laboratory are discussed. Samples were evaluated for the removal of trace toxic metal ions from aqueous solutions. Batch and column experiments have been performed to elucidate the relationship between sorptive performance and the physical and chemical structure of these materials. A detailed discussion of adsorption and ion-exchange properties of engineered activated carbons and carbonaceous materials can be found in a recent publication by Streat et al. (1).

ACTIVATED CARBONS

Activated carbon is the generic name given to amorphous carbonaceous materials with an extensively developed internal pore structure. The characteristics of activated carbons depend on the carbonaceous precursor and the technique of activation used in their production. Activated carbon is obtained by thermal decomposition, combustion, and partial combustion of different carbonaceous substances. The carbonaceous substances are usually cheap vegetable material high in carbon content and low in ash content. The raw material can be wood, peat, fruit stones, nutshells, or sawdust. (2). Nonvegetable sources include blood, bones, leather waste, fish, petroleum products, and by-products (3). Currently, a bulk of the activated carbon comes from natural coal, which is because of its low cost and availability.

Activated carbons have proved versatile adsorbents mainly because of their large surface area and surface reactivity. They also possess favorable pore size, which makes the internal surface accessible, enhances the adsorption rate, and enhances mechanical strength (2). According to the International Union of Pure and Applied Chemistry (IUPAC) system, the pore structures are divided into three categories, namely, micropores (<2 nm in diameter), mesopores (between 2 and 50 nm in diameter), and macropores (>50 nm). The pores exist in different shapes, which can be V-shaped pores, tapered pores, capillary shaped with one end closed or open at both ends, contracted entrance pores, and so on.

Micropores constitute the bulk of the area, and their sizes are usually comparable with the adsorbate molecules. The mechanism of adsorption in micropores is micropore filling, and it comes as a result of the adsorption force field that encompasses the whole volume of micropores. This type of mechanism leads to higher heat of adsorption energy as compared with the adsorption energy on surface or mesopore regions. Mesopores have a dual function that involves adsorption and channels for the adsorbate to access the interior of the adsorbent. The mechanism of adsorption is via capillary condensation. Macropores serve as passages for the adsorbate to access the interior of the adsorbent, and they do not contribute significantly to the adsorption capacity.

Activated carbon is a microcrystalline, nongraphitic form of carbon and can be produced in the form of powders, granules, and shaped products satisfying any modern engineering requirements. Its exceptional adsorptive properties are attributed to the controlled size and distribution of pores within the carbon matrix. The strong market position of the activated carbons relates to their unique properties and lower cost compared with that of other possible competitive adsorbents.

Through the choice of precursor, the method of activation, and control of processing conditions, the adsorptive properties of activated carbons can be specially designed for many diverse applications such as the purification of potable water and adsorption of various emissions from motor vehicles. In drinking water treatment, the carbon is used to remove dissolved organics with molecular weights in excess of 45 g/mol (4).

HISTORICAL BACKGROUND

The use of activated carbon as an adsorbent dates back to the Egyptians in about 1500 B.C. (2). It was used in the form of carbonized wood mainly for medical purposes as well as a purifying agent. However, the basis of its industrial production and use was established in the late eighteenth century and its uses have broadened since then. The first industrially manufactured activated carbons were Eponit decolorizing carbons. They have been produced since 1909 by heating wood charcoal with steam and carbon dioxide in a furnace specially designed for this purpose. Activated carbons are now produced industrially by several different methods, as many new production technologies have appeared.

Granular activated carbon found uses for purification of gases and extraction of vapors from gas streams, recovery of liquid petroleum from natural gas, extracting benzene from manufactured coal gas, and recovering volatile solvents from various industrial applications. Activated carbon has also been applied to the removal of color, odor, taste, and many chemical undesirable species from aqueous solutions either by adsorption or ion exchange (1). It is now extensively used for potable, domestic, and industrial waste water purification, sugar refining, and metal recovery (2,3,5,6).

Over the last two decades, an interest has developed in activated carbon, and applications continue to evolve in response to growing demands for environmental protection and emerging technologies.

PRECURSORS

The materials used for the production of activated carbon are of high carbon content and contain a low concentration of inorganic substances. Precursor materials include wood, animal bones, nutshells, coconut shell, fruit stones, brown coal, bituminous coal, charcoal, peat, lignin, lignite, pitch, mineral oil products, and petroleum and lubricant wastes (3,7). However, only wood, bones, coal, lignite, coconut shell, and peat have been used on an industrial scale because they are currently the only economically viable raw materials (3,4).

As already mentioned, many potential raw materials exist for the production of activated carbon, but not all of them produce activated carbon of high quality. The reason behind this lies in the high amount of inorganics that exist in the structure of the raw materials as well as in their scarcity. Poor quality can also result from poor storage conditions and difficult workability of the raw materials.

The principal properties of manufactured active carbons depend on the type and properties of the raw material used. The properties of the final product will also depend on the nature of the raw material but mostly on the nature of the activating agent and the conditions of the activation process, which makes the carbonization and activation processes the most important factors in producing a good quality activated carbon. The next section gives a brief review on how activated carbon is produced and discusses how the activation of the carbon can result in a material suitable for specialized applications.

CARBONIZATION

The first stage of production of the activated carbons is the carbonization process, where the properties of the activated carbon can be modified. The carbonization process involves thermal decomposition and elimination of the noncarbon species and can introduce a simple pore structure that depends principally on the physical properties of the precursor and can be controlled by the rate of heating.

Generally, carbonization is conducted by heating the initial material up to 973 K in the absence of oxidizing gases. During this process, the raw material is dehydrated, that is, oxygen- and hydrogen-containing compounds are decomposed and eliminated from the precursor to produce a skeleton possessing a latent pore structure. If the temperature of carbonization is low, impurities such as tar may be left in the pores without decomposition. The presence of impurities, which block the pores, may result in a low surface area and limited surface activity. The mechanical and adsorptive properties of an activated carbon can also be introduced and controlled by various additives introduced during the stabilization and carbonization process.

ACTIVATION

The activation process is the second stage of production, where any disorganized carbon from the surface and the carbon from the aromatic sheets under the surface are burned off by contacting the carbonized material either with gases or with chemical reagents, which results in wider pores and new porosity with an oxidized surface.

Generally, two main activation processes are used by industry to manufacture activated carbon: physical (or thermal) and chemical activation. The main difference between the two is that in physical activation, the process is done at high temperature and the yield of activated carbon is low, whereas in chemical activation, the process is carried out at a lower temperature and results in a much higher yield.

Physical activation involves carbonization of the raw material and the activation of the carbonized product. Carbonization is generally performed at temperatures around 873–923 K in the absence of oxidizing gases (8). The resulting material is enhanced by activation via partial gasification with mild oxidizing agents such as steam, carbon dioxide, or a mixture of both at 1073–1273 K (9). In the case of activation with air or oxygen, excessive burning of the carbon exists and the reaction is difficult to control, which is the main reason that these oxidizing agents are not used for activation purposes. Generally, microporosity is introduced when activation is done using carbon dioxide, whereas meso- or macroporosity develops if steam is used for the activation.

Chemical activation, on the other hand, involves the reaction of a carbon precursor with a reagent. The contact of the raw material with the reagent takes place while the temperature increases from 623 K to 1173 K. The commonly used reagents for chemical activation in industry until 1970 were zinc chloride, sulfuric acid, and phosphoric acid. The preferred precursors exposed to this type of activation are lignocellulosic materials, wood being the most common. Today, only nonmineral precursors can be applied successfully, with wood and olive stones the most commercially used. Jankowska and Swiatkowski (10) reported that this activation process produces a carbon matrix that contains a considerable amount of heteroatoms (including residual of phosphates, sulfates, and zinc).

PHYSICAL AND CHEMICAL PROPERTIES OF ACTIVATED CARBONS

The structure of activated carbon is best described as a twisted network of defective carbon layer planes, cross-linked by aliphatic bridging groups (11). The lattice is composed of pores sizes whose size distribution can be controlled by the choice of carbon feedstock and mode of preparation. The surface of activated carbons is not uniform in either structural or in energetic respect. Atoms at the carbon surface are in a different electronic state than those in a pore phase, especially on the edges of the carbon layers; where defects, dislocations, and discontinuities of the layer planes are present. Such sites, called the “active” sites, are associated with high concentration of unpaired electron spin centers and are therefore expected to play a significant role in chemical and adsorptive interaction of the activated carbon with different compounds (12).

Today, it is well established that almost all types of activated carbons are covered with oxygen complexes, unless special care is taken to eliminate them. Therefore, the adsorptive properties of an activated carbon are not only determined by its porous structure but also by its chemical composition. These complexes are often the source of the properties, which make an activated carbon useful or effective in certain applications. Two main types of surface functional groups exist: acidic and basic surface groups, which are discussed in the following section.

ACID SURFACE FUNCTIONAL GROUPS

Several types of oxides having an acidic character have been identified to exist on the surface of activated carbons by different types of techniques: specific organic reactions, potentiometry, Fourier transform infrared (FTIR), and X-ray photoelectron spectroscopy (XPS). The structures presented in Fig. 1 are the oxygen containing groups that are found at the edges of the graphene layers. The most important ones are the carboxyl (a), carbonyl (f), and single hydroxyl (phenolic) (e) groups.

Other groups can then be generated from a combination of these three because the simultaneous presence of various types of organic groups may lead to more complex surface structures. Thus, carboxylic anhydrides (b) can be produced when carboxyl groups are close together, lactone groups (c) when hydroxyl and carboxyl groups are joint, and lactoles (d) when carboxyl and carbonyl groups come close enough (Fig. 2). Carbonyl groups can also be present on the surface of the carbon as conjugated structures called quinones (g). Lastly, ether type structures (h), which are stable even at high temperatures, can also be found on the activated carbon surface.

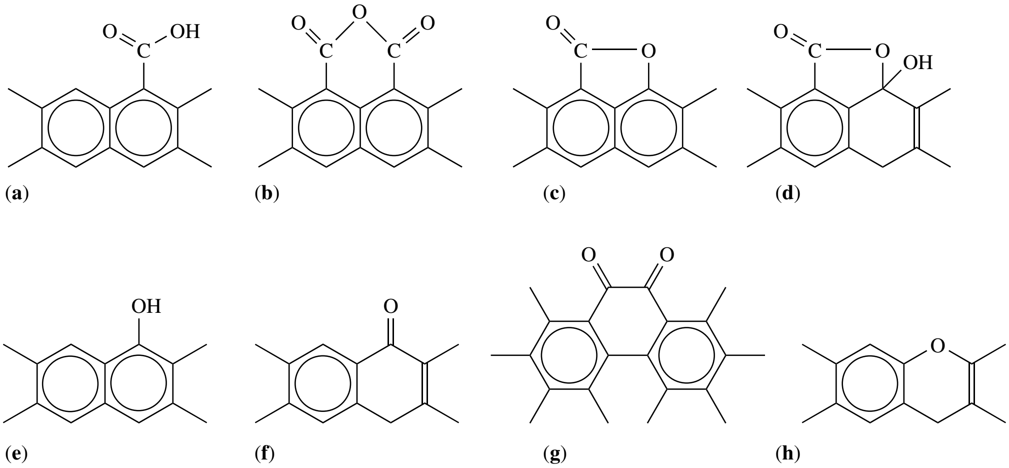

Figure 1. Possible structures of surface oxygen groups (redrawn from Ref. 13).

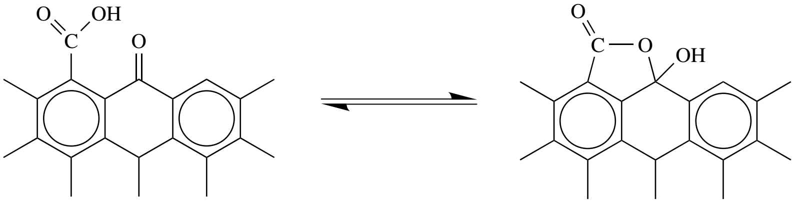

Figure 2. Possible interaction of oxygen-containing groups (redrawn from Ref. 13).

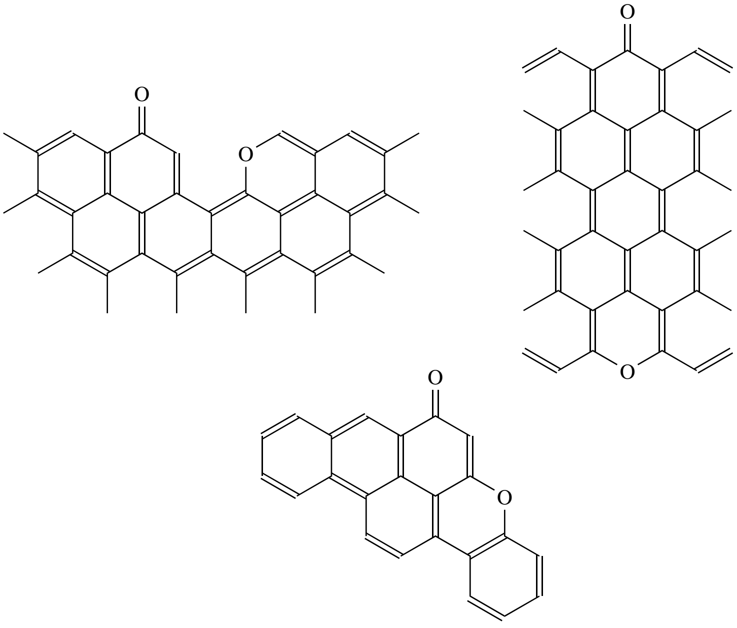

Figure 3. Possible structures of basic surface sites on a graphene layer (redrawn from Ref. 16).

BASIC SURFACE FUNCTIONAL GROUPS

Very scant information is available about basic surface functional groups. They are formed when a carbon is heat treated above 973 K, cooled in an inert atmosphere, and reexposed to oxygen at room temperature. In order to explain the uptake of acids, Garten et al. (14) and Garten and Weiss (15) proposed a chromene structure, but g-pyrone-like structures are more likely (16). These structures are schematically shown in Fig. 3, and they characteristically possess two oxygen groups situated on different rings of the graphitic layer.

Evidence also exists that protons can be adsorbed on basal planes either by reaction with pyrones or by donor–acceptor interactions. The end result is the formation of basic surface structures, which can be represented by pyrone-like structures with oxygen atoms, in general, located in two different rings of a graphite layer; the positive charge being stabilized by the resonance (Fig. 4).

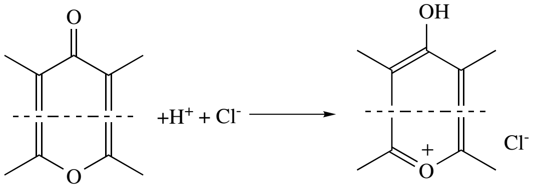

Figure 4. Reaction of proton with pyrone-like structure (redrawn from Ref. 16).

PREPARATION AND PROPERTIES OF ACTIVATED CARBON

The synthesis, structure, and adsorption properties of engineered activated carbons with reference to the body of work carried out in the author's research laboratory are reviewed. The main emphasis is granular activated carbon (GAC). The majority of engineered carbons discussed here have graphitic or disordered graphitic microstructures. Also, for most engineered carbon materials, the originating precursor is organic and the materials develop from heat treatment of the precursor in inert atmospheres (carbonization). A selection of technically important carbons developing from solid, liquid, and gaseous organic precursors are presented in Table 1.

The role of pore structure and surface area of engineered carbons and their impact on adsorbent performance are discussed elsewhere (1,17,18). The surface chemical structure affects interaction with polar and nonpolar molecules because of the presence of chemically reactive functional groups (see Fig. 1). The adsorption is a complex interplay between the chemical and porous surface structure of the carbon. Important factors including the nature and relative amounts of surface functional groups, the surface area, and pore size distribution, as well as the characteristics of the adsorbate molecule (e.g., size and

Table 1. Starting Precursors for Carbons (Adapted from Ref. 1)

Primary	Secondary	Example of Carbons
Hydrocarbon gases		Pyrocarbons, carbon blacks, vapor grown carbon fibers, matrix carbon[a]

nature of the cation/anion, polarity and chemical structure of the molecule, molecular/ionic dimensions) are discussed by Streat et al. (1). The importance of precise characterization of the surface and structure of engineered carbons in order to tailor adsorbents for specific applications is outlined by Saha et al. (17–19).

Granular oxidized carbon samples showed similar ion-exchange properties to active carbon fibers with respect to influence of solution pH on ion-exchange behavior. The pH dependence may be attributed to acidic surface groups that dissociate as a function of solution pH. The point-of-zero charge (PZC) plays an important role in the ion-exchange behavior of the carbon adsorbents in removing metal ions from solution (17).

SORPTION OF TRACE METALS ONTO ACTIVATED CARBON

Previous publications have discussed the adsorption of heavy metal ions from aqueous solutions by carbonaceous materials (20–24). It is widely accepted that surface acidic functional groups are responsible for metal ion binding (20). Chemical oxidation is commonly used to introduce these functional groups onto the surface of carbons.

The results of detailed minicolumn experiments to determine breakthrough characteristics and regeneration performance of selected oxidized activated carbons are outlined in this section. Samples of BGP (a wood-based activated carbon) were tested using solutions containing target metals to determine overall performance criteria, which consisted of testing samples of BGP against solutions containing copper, nickel, zinc, or cadmium. All breakthrough capacities were calculated based on the total amount of metal removed before 5% or 50% of the feed concentration of metals was detected in the outlet, which was to give an indication of uptake performance of each material for the four metals used. The results of the minicolumn experiments are summarized in Table 2.

Table 2. Uptake Capacity of Carbons from 1 mM Metal Solutions (pH 4.7)

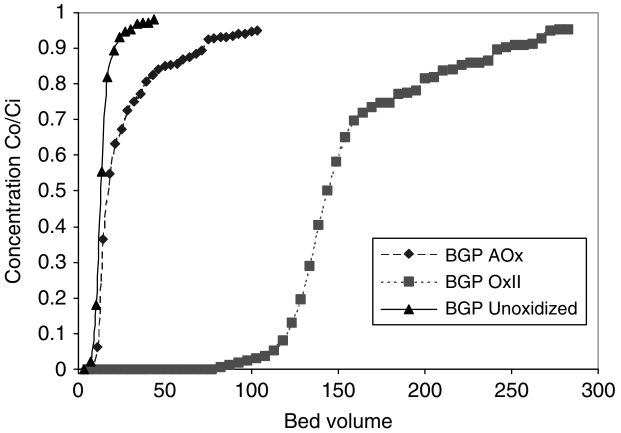
			Breakthrough Capacity (mmol/g)	
Sample[a]	Metal	pH	5%	50%
BGP OxII	Cu	4.7	0.35	0.42
BGP AOx	Cu	4.7	0.04	0.05
BGP Unoxidized	Cu	4.7	—	0.004
BGP OxII	Zn	4.7	0.13	0.16
BGP AOx	Zn	4.7	—	0.13
BGP OxII	Ni	4.7	0.14	0.20
BGP AOx	Ni	4.7	0.03	0.06
BGP OxII	Cd	4.7	0.16	0.21
BGP AOx	Cd	4.7	—	0.02

[a] AOx, air oxidized; OxII, alkali washed, acid oxidized for 9 h.

An unoxidized sample of BGP was used to generate a breakthrough curve to compare copper sorption capacity with oxidized samples. The copper breakthrough curves can be seen in Fig. 5.

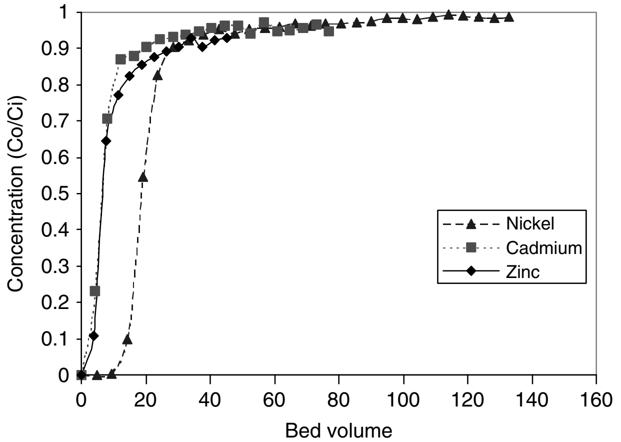
Results show that significant improvement occurred in copper sorption capacity on oxidation of the original sample. The copper sorption capacities increased by a factor of up to 100 by oxidizing the original material. This change can be attributed to oxygen surface groups introduced onto the surface of Ceca BGP. The 5% copper breakthrough capacities of BGP OxII and BGP AOx were 0.35 mmol/g and 0.04 mmol/g, respectively. Over 100 bed volumes of 1 mM solution were passed before any copper could be detected leaving the column using the acid oxidized sample, BGP OxII.

BGP AOx was also used to generate breakthrough curves for removal of nickel, zinc, and cadmium. Results for these experiments can be seen in Fig. 6. It shows that the metal sorption capacity of air-oxidized samples was much less than acid-oxidized samples for a feed concentration of 1 mM and pH of 4.7. Breakthrough capacities at 5% were 0.02 mmol/g for nickel, and for other samples, the 5% breakthrough was instantaneous. The low capacity of BGP



Feed concentration = 1 mM copper, feed pH = 4.7, flow rate = 5 BV/h

Figure 5. Copper breakthrough curves for samples of BGP.

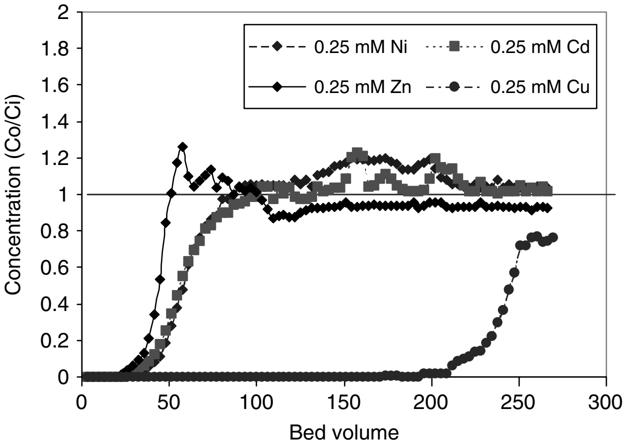


Feed concentration = 1 mM Ni, Zn or Cd, feed pH = 4.7, flow rate = 5 BV/h

Figure 6. Breakthrough curves for nickel, zinc, and cadmium using BGP AOx sample.

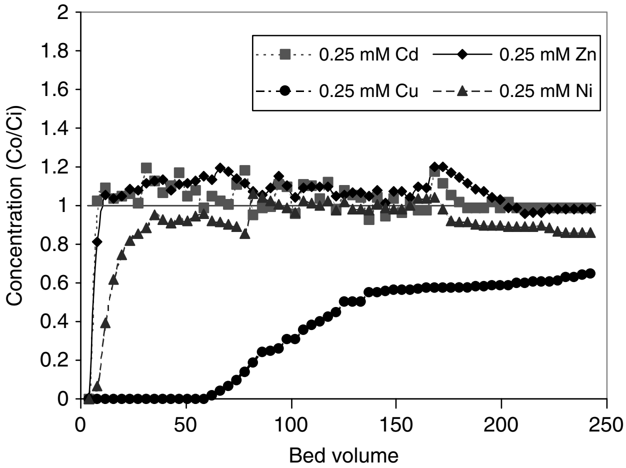
AOx sample can be partially attributed to the high reaction temperature during the oxidation rising above 723 K, which would have resulted in desorption of some oxygen surface groups. Very poor breakthrough performance was obtained for the BGP AOx sample with the exception of the nickel experiment when 10 bed volumes were treated before any metal was detected in the outlet.

A combined feed containing all four metals, copper, zinc, nickel, and cadmium, was passed through the column containing 1 g of BGP OxII (see Fig. 7). The feed concentration of all metals was 0.25 mM and the feed pH was 4.7, which indicate the following selectivity series: $Cu^{2+} > Ni^{2+}, Cd^{2+} > Zn^{2+}$. The increase in the concentration above the feed was because of chromatographic elution. A solution containing copper, zinc, nickel, and cadmium was used to obtain the selectivity of BGP AOx. The results shown in Fig. 8 indicate a selectivity order of $Cu^{2+} > Ni^{2+} > Zn^{2+}, Cd^{2+}$. These studies confirm that both materials are highly selective toward copper in the presence of other metal ions.



Feed concentration = 0.25 mM each of Cu, Ni, Zn and Cd, feed pH = 4.7, flow rate = 5 BV/h

Figure 7. Breakthrough curve using a feed solution containing copper, nickel, zinc, and cadmium with a sample of BGP OxII.



Feed concentration = 0.25 mM each of Cu, Ni, Zn and Cd, feed pH = 4.7, flow rate = 5 BV/h

Figure 8. Breakthrough curve using a feed solution containing copper, nickel, zinc, and cadmium with a sample of BGP AOx.

The BGP OxII elution results are shown in Fig. 9. Most of the metals were eluted with 0.1M HCl in the first 10 bed volumes except for cadmium. All the copper was recovered, but only 86% of nickel, 90% of zinc, and 85% of cadmium were eluted. Elution efficiency of BGP AOx was 100% for all metals. The results show that most of the metals were recovered before 10 bed volumes of eluant had been passed through the columns.

The sorptive capacity and selectivity of oxidized carbons vary for different metal ions, and higher valency metal ions are usually preferred to those of lower valency (20,21). It has also been observed that selectivity differs even within a series of metals with the same valency. Among divalent metals, Cu^{2+} is generally the most preferred ion. However, the reason for the higher affinity of oxidized carbons toward this particular metal ion has not been clearly identified. The formation of metal surface complexes on the oxidized carbon involving cooperative action seems quite likely (see Fig. 10).

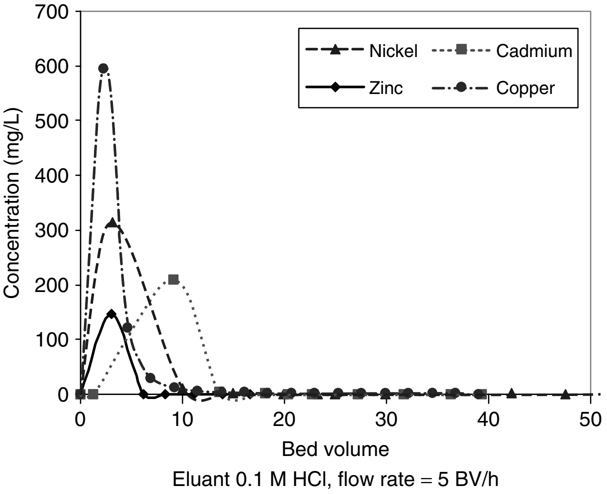


Figure 9. Elution curves of BGP AOx.

It can be concluded that air and acid oxidation significantly enhance the sorption capacity of Ceca BGP. BET and Langmuir surface areas were relatively unchanged by air oxidation, but some surface area was lost during acid oxidation. Acid-oxidized samples have a much higher copper uptake capacity than the as-received material. Air-oxidized samples show lower metal uptake capacity compared with acid-oxidized samples. Acid-oxidized samples are heat treated and alkali washed to remove organic by-products that are formed during the oxidation. At every stage, some material is lost, reducing the yield of material based on weight of as-received material compared with the final product. The sorption capacity of the materials was reduced by these treatments, indicating the metal binding capacity of these organic by-products formed during oxidation. Equilibrium capacity of modified samples decreased with a reduction in the pH because of the weakly acidic nature of the sorbents. Kinetic experiments indicate that about 80% of the metals are removed in the first twenty minutes for all samples. Minicolumn experiments show that modified carbons are efficient sorbents for the removal of trace metal ions from solution. After initial breakthrough, complete loading of carbons occurs slowly, which is most likely because of the presence of micropores and small mesopores within the structure of the materials. All samples are regenerated using 0.1 M HCl solution. Both modified samples demonstrated good regeneration efficiencies with 100% of the copper recovered during elution cycles compared with the amount of metal removed during the sorption experiments.

CONCLUSIONS

Engineered activated carbons can be manufactured in a range of physical forms and from a wide variety of starting precursor materials. Pyrolysis and activation combined with further surface pretreatment results in a range of adsorbent materials with widely varying physicochemical properties. It is argued that liquid-phase sorption of solutes on carbon surfaces involves a complex interplay between the delocalized π-electron system developing from the aromatic backbone of the graphite microstructure and the electron withdrawing surface functional groups (e.g., oxygen functional groups). This interplay not only lowers the point-of-zero charge of the surface but also reduces the dispersive adsorption potential by decreasing the π-electron density in the graphene layers (2). Optimization of the physical properties of carbonaceous adsorbents, that is, surface area and a well-developed pore structure, are essential for the application of the adsorbents in conventional water treatment technologies (e.g., using fixed-bed adsorbers). In addition, it is vital that the chemical properties of the adsorbent surface must be tailored to suit the individual application. Carbon surface functional groups influence the selectivity of the adsorbent for metal ions in solution. Oxidation treatment of commercially available carbons dramatically enhances their ion-exchange properties and results in reversible adsorption of metal ions from solution. Design of adsorption systems using engineered carbons requires careful optimization of process parameters with due attention to the speciation chemistry of metal ions and the solution pH that markedly influences the interaction of the solute species with the adsorbent surface. We are now in a position to reverse-engineer tailored structured carbonaceous adsorbents with optimized physicochemical properties suited for selective separation of solutes from aqueous streams.

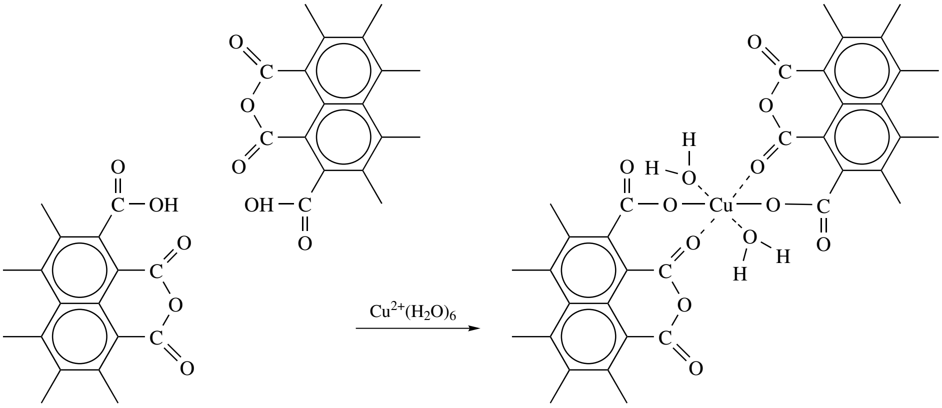

Figure 10. Postulated complexation reaction between copper (II) and oxidized carbon surface.

Acknowledgments

I would like to express my sincere gratitude to Professor Michael Streat for his support, continuous encouragement, and advice for conducting the research in the area of adsorption and ion exchange and development of tailored sorbent materials for environmental remediation. I am indebted to Dr. Hadi Tai, Purazen Chingombe, and Eleni Karounou for their painstaking experimental work. Funding from European Community, EPSRC, Severn Trent Water Ltd., and Commonwealth Scholarship Commission is gratefully acknowledged.

ACTIVATED CARBON—POWDERED

Absar A. Kazmi
Nishihara Environment
Technology
Tokyo, Japan

INTRODUCTION

The most commonly used adsorbent in water and wastewater treatment is activated carbon. Activated carbon is manufactured from carbonaceous material such as wood, coal, or petroleum residues. A char is made by burning the material in the absence of air. The char is oxidized at higher temperatures to create a very porous structure. The "activation" steps provide irregular channels and pores in the solid mass, resulting in a very large surface-area-per-mass ratio. Surface areas ranging from 500 to 1500 m^2/g have been reported, and all but a small surface area is in the pores. Once formed, activated carbon is pulverized to a very fine powder (Fig. 1). The size is predominantly less than 0.075 mm (200 sieve). Dissolved organic material adsorbs to both exterior and interior surfaces of the carbon. The characteristics of powdered activated carbon are summarized in Table 1.

APPLICATION IN WATER TREATMENT

Seasonal application of powdered activated carbon (PAC) at the raw water intake or rapid mix unit is used by some plants to correct short-term raw water quality problems such as algal blooms. PAC is used to correct taste and

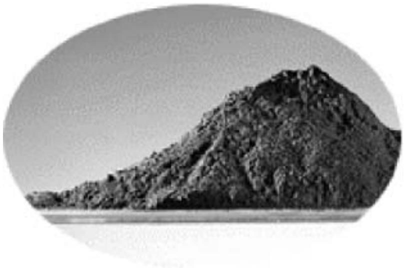

Figure 1. Powdered activated carbon.

Table 1. Characteristics of Powdered Activated Carbon

Parameter	Unit	Values
Total surface area	m^2/g	800–1800

Ash	%	≤ 6
Moisture as packed	%	3–10

odor problems, which are primarily aesthetic qualities of water. Contact time is needed to allow adsorption to occur. Powdered activated carbon is contacted with water in open vessels where it is maintained in suspension for the necessary contact time and then removed by conventional solids removal processes (Fig. 2). The general feeling among water treatment plant operators is that, when everything else fails, it is time to use PAC. It is quite reliable, but its effectiveness depends on the type of carbon, the dosage, and the point of application. Usual carbon dosage ranges from 0.5 to 5.0 mg/L.

Normally, the PAC dose is based on operator experience, although laboratory tests may provide more precise dosages. In these tests, a series of carbon dosages is added to odorous water and the residual odor levels are determined. When a single odorous chemical is present, the initial and residual concentrations can be measured by using advanced laboratory identification techniques. Where such equipment is not available, the odor source is unknown, or numerous compounds are involved, the threshold odor number (TON) method may suffice. These data then can be plotted in one of several ways to clarify the removal response, to produce a predictive trend, and to determine the dosages to achieve acceptable water quality.

A simple plot of carbon dose versus TON (or the residual concentration) might be sufficient to highlight the relationship; however, the preferred method is to identify constants in an equation for removal and apply these to dosage calculations. The Freundlich and Langmuir isotherm equations are commonly used. The primary difference is that the Freundlich isotherm equation is strictly an empirical approach, accepted as standard; the Langmuir isotherm has a theoretical basis and has wider applicability.

The Freundlich isotherm is expressed by Eq. 1 and its corollary by Eq. 2

$$\frac{X}{M} = kC^{1/n} \tag{1}$$

$$\ln\left(\frac{X}{M}\right) = \ln(k) + \frac{1}{n}\ln C \tag{2}$$

X/M = mass of adsorbate per unit mass of adsorbent, mg adsorbate/g activated carbon
C = final or equilibrium concentration of the adsorbate, mg/L
k = empirical constant (y intercept)
n = slope inverse constant

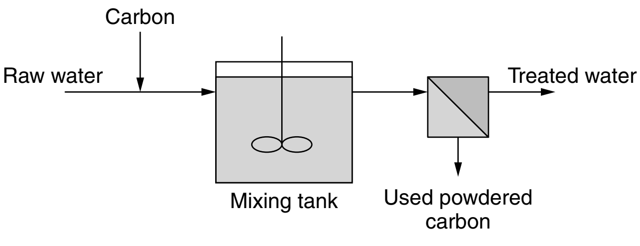

Figure 2. Powdered activated carbon for water treatment.

Similarly, the Langmuir isotherm is defined by Eqs. 3, 4, and 5:

$$\frac{X}{M} = \frac{abC}{1+bC} \tag{3}$$

$$\frac{C}{XM} = \frac{1}{ab} + \left(\frac{1}{a}\right)C \tag{4}$$

$$\left(\frac{1}{X/M}\right) = \left(\frac{1}{ab}\right)\left(\frac{1}{C}\right) + \frac{1}{a} \tag{5}$$

where a = maximum number of moles adsorbed per mass of adsorbent at monolayer saturation
b = empirical constant, L/mg

The Langmuir isotherm can be plotted in terms of $C/(X/M)$ versus C or $1/(X/M)$ versus $1/C$. The plot that produces a clear trend provides more accurate constants.

ANALYSIS AND DESIGN OF POWDERED ACTIVATED CARBON CONTACTOR

For a powdered activated carbon (PAC) application, isotherm adsorption data can be used in conjunction with a material mass balance to obtain an approximate estimate of the amount of carbon that must be added, as illustrated below. Here again, because of the many unknown factors involved, column and bench tests are recommended to develop the necessary design data. If the mass balance is written around the contactor (i.e., batch reactor) after equilibrium has been reached, the resulting expression is

$$\text{Amount absorbed} = \text{initial amount of absorbate present} - \text{final amount of absorbent present}$$

$$q_e m = VC_o - VC_e, \tag{6}$$

where q_e = adsorbate phase concentration after equilibrium, mg adsorbate/g adsorbent
m = mass of adsorbent, g
V = volume of liquid in the reactor, L
C_o = initial concentration of the adsorbate, mg/L
C_e = final equilibrium concentration of the adsorbate after absorption

If Eq. 6 is solved for q_e, the following expression is obtained:

$$q_e = \frac{V(C_o - C_e)}{m} \tag{7}$$

The equation can be rewritten as

$$\frac{V}{m} = \frac{q_e}{C_o - C_e} \tag{8}$$

The term V/m, defined as the specific volume, represents the volume of liquid that can be treated with a given amount of carbon. The reciprocal of the specific volume corresponds to the dose of adsorbent that must be used.

APPLICATION IN WASTEWATER TREATMENT

A proprietary process, “PACT,” combines the use of powdered activated carbon with the activated-sludge process. In this process, when the activated carbon is added directly to the aeration tank, biological oxidation and physical adsorption occur simultaneously. A feature of this process is that it can be integrated into an existing activated sludge system at nominal capital cost. The addition of powdered activated carbon has several advantages, including (1) system stability during shock loads, (2) reduction of refractory priority pollutants, (3) color and ammonia removal, and (4) improved sludge settleability. In some industrial waste applications, where nitrification is inhibited by toxic organics, the application of PAC may reduce or limit this inhibition.

The use of powdered activated carbon in secondary wastewater systems results in an inseparable mixture of biological solids and carbon. Thermal regeneration of the carbon also results in destruction of biomass, eliminating the need for other sludge processing and disposal techniques, but increases the size of the carbon regeneration system.

The dosage of powdered activated carbon and the mixed liquor–powdered activated carbon suspended solids concentration are related to solids retention time as follows:

$$X_\mathrm{p} = \frac{X_i \mathrm{SRT}}{\tau} \tag{9}$$

where X_p = equilibrium powdered activated carbon–MLSS content, mg/L
X_i = powdered activated carbon dosage, mg/L
SRT = solids retention time, days
τ = hydraulic retention time, days

Carbon dosages typically range from 20 to 200 mg/L. At higher SRT values, the organic removal per unit of carbon is enhanced, thereby improving process efficiency. Reasons cited for this phenomenon include (1) additional biodegradation due to decreased toxicity, (2) degradation of normally degradable substances due to increased exposure time to the biomass through adsorption on the carbon, and (3) replacement of low molecular weight compounds with high molecular weight compounds, resulting in improved adsorption efficiency and lower toxicity (Fig. 3).

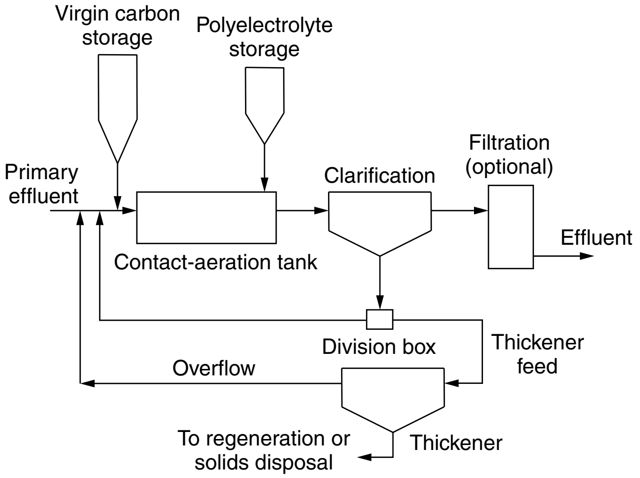

Figure 3. Schematic for the application of powdered activated carbon.

CHLORINATION

Absar A. Kazmi
Nishihara Environment
Technology
Tokyo, Japan

INTRODUCTION

Chlorine is added to water to kill disease-causing bacteria, parasites, and other organisms. At low concentrations, chlorine probably kills microorganisms by penetrating the cell and reacting with the enzymes and protoplasm. At higher concentrations, oxidation of the cell wall destroys the organism. Chlorination also removes soluble iron, manganese, and hydrogen sulfide from water.

CHLORINE COMPOUNDS

The principal chlorine compounds used in water treatment are chlorine (Cl_2), sodium hypochlorite (NaOCl), and calcium hypochlorite $Ca(OCl)_2$. Chlorine gas can be liquefied by compression and shipped to the site in compact containers. Because it can be regasified easily and has a solubility of approximately 700 mg/L in water at the pH and temperatures generally found in water treatment plants, this form of chlorine is usually preferred. Hypochlorites tend to raise the pH, thus driving the reaction more toward the less effective OCl^-. Commercially available calcium hypochlorite contains approximately 70–80% available chlorine, whereas NaOCl contains only 3–15% available chlorine. Some practical difficulty is involved in dissolving $Ca(OCl)_2$, and both hypochlorites are more expensive on an equivalence basis than liquefied Cl_2. There are other considerations, however, that sometimes dictate using hypochlorites.

CHLORINATION CHEMISTRY

Chlorine may be applied to water in gaseous form (Cl_2) or as an ionized product of solids [$Ca(OCl)_2$, NaOCl]. The reactions in water are as follows:

$$\mathrm{Cl_2 + H_2O \longrightarrow H^+ + HOCl} \tag{1}$$

$$\mathrm{Ca(OCl)_2 \longrightarrow Ca^{2+} + 2OCl^-} \tag{2}$$

$$\mathrm{NaOCl \longrightarrow Na + OCl^-} \tag{3}$$

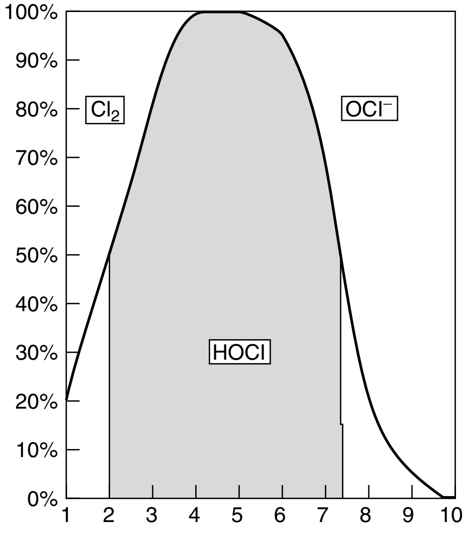

Figure 1.

The hypochlorite (HOCl) and the hypochlorite ion (OCl^-) in these equations are further related by

$$\mathrm{HOCl} \rightleftharpoons \mathrm{H^+ + OCl^-} \tag{4}$$

A relationship governed primarily by pH is shown in Fig. 1.

The sum of HOCl and OCl^- is called the free chlorine residual and is the primary disinfectant used. HOCl is a more effective disinfectant. As indicated in the previous equations, HOCl is produced on a one-to-one basis by the addition of Cl_2 gas, along with the reduction of pH, which limits the conversion of OCl^-. Cell membranes are rapidly penetrated by HOCl because lipid structures accept nonpolar materials. Passage of OCl^- is much slower, and this mitigates its killing. Although a low pH is best for disinfection by chlorine, the pH is often adjusted upward to reduce the chlorine-like odor and because swimmers suffer eye irritation when the concentration of HOCl is high.

AFFECTING FACTORS

Factors affecting the process are:

1. *Form of Chlorine.* Hypochlorous acid is more effective than the hypochlorite ion by approximately two orders of magnitude.
2. *pH.* Because the free-chlorine species are related to pH, one would expect a relationship between efficiency and pH. Empirically, it has been found that chlorine dosages must be increased to compensate for higher pH.
3. *Concentration, Contact Time.* The chlorine concentration and contact time relationship is often expressed by

$$C^n t_p = k, \tag{5}$$

C = concentration of chlorine, mg/L
t_p = time required for given percent kill, min
n, k = experimentally derived constants for a given system

4. *Temperature.* The effects of temperature variations can be modeled by the following equation derived from the van't Hoff–Arrhenius equation:

$$\ln \frac{t_1}{t_2} = \frac{E'(T_2 - T_1)}{R_{T_1,T_2}} \tag{6}$$

where t_1, t_2 = time required for given kills
T_1, T_2 = temperature corresponding to t_1 and t_2, K

E' = activation energy related to pH

CHLORINATION PROCESS

Chlorine is a strong oxidant and reacts with almost any material that is in a reduced state. In water, this usually consists of Fe^{2+}, Mn^{2+}, H_2S, and organics. Ammonia (NH_3) is sometimes present in small quantities or may be added for purposes to be presently discussed. These oxidizable materials consume chlorine before it has a chance to act as a disinfectant. The amount of chlorine required for this purpose must be determined experimentally because the exact nature and the quantity of oxidizable material in water are seldom known. A typical titration curve is shown in Fig. 2.

The products of organics oxidized by chlorine are undesirable. Organic acids (humic, fulvic) form chlorinated hydrocarbons or trihalomethanes (THMs) that are suspected of being carcinogenic. Because THMs are very seldom associated with groundwater, they are a primary concern where surface water is used. Lifetime consumption of water with THMs at a level greater than 0.10 mg/L is considered a potential cause of cancer by the Environmental Protection Agency. Minute quantities of phenolic compounds react with chlorine to form severe taste and odor problems. The original organics must be removed before chlorination, and undesirable compounds must be removed after chlorination, or the compounds must be prevented from forming. The compounds can be removed by adsorption onto activated carbon, or their formation can be prevented by the substitution of chloramines, which do not react with organics or phenols, for free chlorine. Chloramines can be formed by adding a small quantity of ammonia to the water. The reactions of chlorine with ammonia are as follows:

$$\mathrm{NH_3 + HOCl} \longrightarrow \mathrm{NH_2Cl}\ \text{(monochloramine)} + \mathrm{H_2O} \tag{7}$$

$$\mathrm{NH_2Cl + HOCl} \longrightarrow \mathrm{NHCl_2}\ \text{(dichloramine)} + \mathrm{H_2O} \tag{8}$$

$$\mathrm{NHCl_2 + HOCl} \longrightarrow \mathrm{NCl_3}\ \text{(nitrogen dichloride)} + \mathrm{H_2O} \tag{9}$$

These reactions are dependent on several factors; the most important are pH, temperature, and reactant quantities. At a pH greater than 6.5, monochloramine is the predominant species. Combined residuals

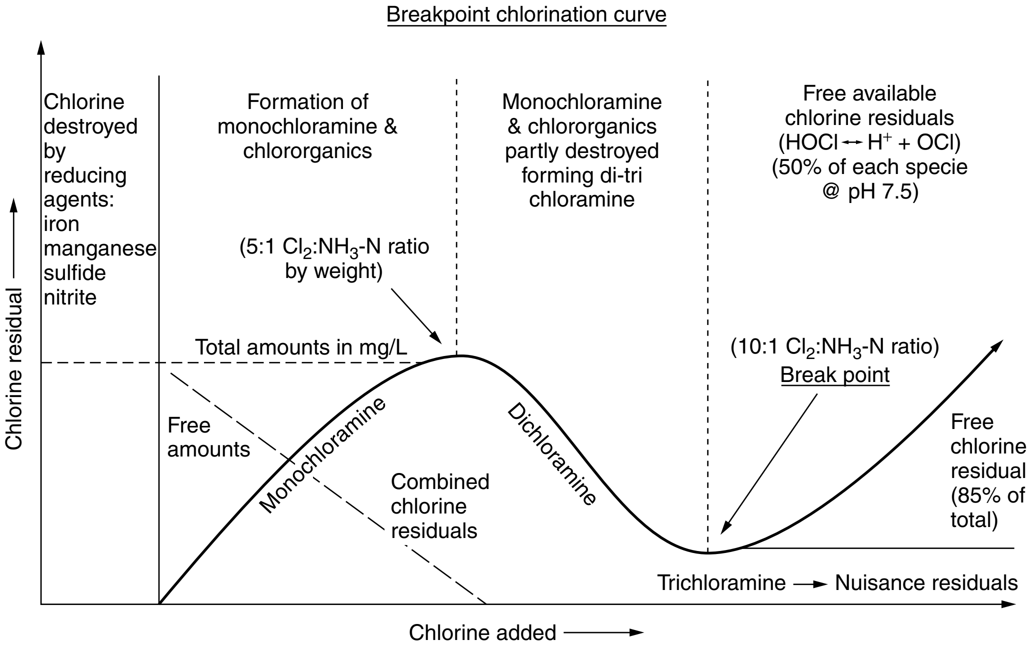

Figure 2.

are less effective as a disinfectant, so a concentration of 2–3 mg/L and contact time in excess of 30 min are often required. Chloramines are persistent and provide continued protection against regrowth in the distribution system.

APPLICATION AND DESIGN CONSIDERATIONS

Provision may be made for applying chlorine at several points within the water treatment processes. When treating raw water of good quality, no early application may be necessary, yet it is advisable to design a plant to allow for easy addition of early applications later, should future conditions require them.

Chlorine may be added to the incoming flow (prechlorination) to assist in oxidizing inorganics to arrest biological action that may produce undesirable gases in the sludge at the bottom of clarifiers. Chlorine is frequently added prior to filtration to keep algae from growing at the medium surface and to prevent large populations of bacteria from developing within the filter medium.

Mixing is one of the most important aspects of the chlorination process. The velocity gradient must be sufficient to ensure a uniform concentration of chlorine throughout the water and to break up any remaining flocculant material that might shield microorganisms from contact with chlorine. A contact chamber must be provided to ensure adequate kill time. In water treatment plant operations, mixing and contact operations may be accomplished by sectioning off part of the clear well.

CHLORINE GAS SAFETY CONSIDERATIONS

Chlorine gas is a very strong oxidant that is toxic to humans. It is heavier than air, so it spreads slowly at ground level. Therefore, extreme care must be exercised in its manufacture, shipping, and use. Accounts of evacuations of populated areas because of rail or barge accidents involving chlorine gas are common news items. The use of hypochlorite is often mandated when large quantities of chlorine are needed in treatment plants in highly populated areas.

Safe and effective application of chlorine requires specialized equipment and considerable care and skill on the part of the plant operator. Liquefied chlorine is delivered to water treatment plants in tanks containing from 75 to 1000 kg. Large plants may be designed to allow using chlorine directly from a tank car. In such cases, designers should be aware of the Interstate Commerce Commission (ICC) and Occupational Health and Safety Agency (OSHA) regulations for shipping and handling chlorine.

Safety considerations mandate storing chlorine tanks in a separate room. Storage and operating rooms should not be directly connected to other enclosed areas of the treatment plant. All doors to these facilities should be open to the outside, and windows should be provided for visual inspection from the outside. Safety equipment, including masks with air tanks, chlorine detection devices, and emergency repair equipment, should be provided in strategic locations.

BACKGROUND

Disinfection of drinking water is considered one of the most successful public health interventions, effectively eliminating many waterborne diseases (e.g., cholera) from many parts of the world. In 1908, chlorine was the first disinfectant to be used on a continuous basis to treat water in the United States (1). Chlorine can be used for primary or secondary disinfection via gaseous chlorine, sodium hypochlorite, or calcium hypochlorite. According to an American Water Works Association (AWWA) survey of medium (10,000–100,000 people served) and large (>100,000 people served) water systems in the United States, chlorine gas was used for disinfection by 84% of the surveyed utilities (2). Chlorination was also the predominant choice for small systems (<10,000 people served) surveyed by the AWWA, with all of the groundwater users relying on chlorine gas or sodium/calcium hypochlorite for disinfection (3). Chlorine is the primary disinfectant used for water treatment worldwide, but chlorine dioxide and ozone are also common in many European countries (see Alternative Disinfectants chapter).

Chlorination is a well-defined and fairly cost-effective treatment process. Chlorine provides adequate residual for treatment throughout the distribution system to combat bacteria, viruses, and some protozoa (e.g., *Giardia*) but may not efficiently inactivate resistant pathogens, such as *Cryptosporidium* (4). Gaseous chlorine is explosive and can present safety concerns, so many U.S. systems are switching to less hazardous types of application (5). An additional disadvantage of chlorine disinfection is the formation of potentially hazardous disinfection by-products (DBPs).

DBP FORMATION AND OCCURRENCE

In 1974, the trihalomethanes (THMs) were the first DBPs to be identified (6,7). DBPs are formed when organic or inorganic matter present in water combines with disinfectants such as chlorine. DBP formation can vary seasonally and is influenced by numerous water quality and treatment parameters, including contact time, pH, temperature, natural organic matter, chlorine dose and residual, and bromide levels (8). As shown in Table 1, different water treatment processes will influence the type and amount of DBPs formed. Recent analytical improvements have led to the identification of over 600 DBPs in laboratory scale studies and another 250 DBPs in distribution system samples (17). While numerous halogenated DBPs have been identified, they account for less than half of the total organic halide concentrations detected in chlorinated water (18).

The main chlorination DBPs include halogenated species such as the THMs, haloacetic acids (HAAs), haloacetonitriles (HANs), haloacetaldehydes (HAs), haloketones (HKs), and halonitromethanes (HNMs). The

Table 1. By-products Formed During Disinfection of Drinking Water

Disinfectant	Organohalogenated DBPs[a]	Inorganic DBPs	Nonhalogenated DBPs
Chlorine	THMs,[b] HAAs,[b] HANs, HAs, HNMs, HKs, NDMA, bromohydrins, chlorophenols, MX and brominated MX analogues	Chlorate, iodate	Aldehydes, cyanoalkanoic acids, alkanoic acids, carboxylic acids, benzene
Chloramines	THMs[b], HAAs,[b] HAs, NDMA, HKs, MX, cyanogen chloride, organic chloramines	Chlorate, nitrate, nitrite, hydrazine	Aldehydes, ketones
Chlorine dioxide	HAAs, HANs, HAs, HKs, MX	Chlorate, chlorite	Carboxylic acids
Ozone	Bromoform, monobromoacetic acid, dibromoacetic acid, dibromacetone, cyanogen bromide	Bromate, chlorate, iodate, ozonates, hydrogen peroxide, hypobromous acid, epoxides	Aldehydes, ketones, ketoacids, carboxylic acids, iodic acid, aldo acids

[a] Abbreviations: DBPs, disinfection by-products; THMs, trihalomethanes; HAAs, haloacetic acids; HAs, haloacetaldehydes; HANs, haloacetonitriles; HNMs, halonitromethanes; HKs, haloketones; NDMA, *N*-nitrosodimethylamine; MX, 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5*H*)-furanone.
[b] Includes the iodinated DBPs.
Source: References 9–16.

two most predominant groups of DBPs include the THMs and the HAAs (19). Chloroform (TCM) is typically the most prevalent THM found in chlorinated water, although the brominated THMs can predominate in bromine-rich water. Dichloroacetic acid (DCAA) and trichloroacetic acid (TCAA) are the most prevalent of the nine HAAs typically measured in drinking water.

THM and HAA concentrations found in U.S. finished water are usually less than 0.1 mg/L, while the HANs, HKs, HAs, and HNMs rarely exceed 0.01 mg/L (15,20,21). 3-Chloro-4-(dichloromethyl)-5-hydroxy-2(5*H*)-furanone (MX) is typically found at an order of magnitude less than most other halogenated DBPs (22,23), but recent findings in the United States and Russia have detected MX levels exceeding 300 ng/L (15,24). Other chlorinated DBPs such as *N*-nitrosodimethylamine (NDMA) are found in chlorinated and chloraminated water at concentrations usually below 10 ng/L (25,26).

DISINFECTION AND DBP REGULATIONS

As part of the Stage 1 Disinfection By-products Rule (DBPR), the U.S. EPA (27) established maximum residual disinfectant levels in water distribution systems for chlorine (4 mg/L as Cl_2), chloramines (4 mg/L as Cl_2), and chlorine dioxide (0.8 mg/L). Stage 1 also established maximum contaminant levels (MCLs) for bromate (0.010 mg/L), chlorite (1.0 mg/L), and HAA5 [sum of monochloroacetic acid (MCAA), DCAA, TCAA, monobromoacetic acid, and dibromoacetic acid] (0.060 mg/L) and reduced the THM4 [sum of chloroform (TCM), bromodichloromethane (BDCM), dibromochloromethane (DBCM), and bromoform (TBM)] MCL to 0.080 mg/L. The Stage 2 DBPR proposes to change the monitoring requirement for DBPs from a running annual average to a locational running annual average (28).

Members of the European Union are required to regulate total THMs at 0.1 mg/L and bromate at 0.25 mg/L, based on the Council of the European Union directive from 1998. As shown in Table 2, member countries have the discretion to establish other standards or set lower maximum acceptable concentrations (MACs) for individual DBPs. Canada has a similar MAC for THM4 and has recently proposed a MAC of 0.016 mg/L for BDCM (31). Australia has nonenforceable national guidelines for several DBPs, including 0.25 mg/L for THM4 (32). The World Health Organization (16) drinking water guidelines include values for TCM (0.20 mg/L), BDCM (0.06 mg/L), DBCM (0.10 mg/L), TBM (0.10 mg/L), dibromoacetonitrile (0.07 mg/L), MCAA (0.02 mg/L), TCAA (0.20 mg/L), cyanogen chloride (0.07 mg/L), formaldehyde (0.90 mg/L), and trichlorophenol-2,4,6 (0.20 mg/L). WHO provisional guideline values include DCAA (0.05 mg/L), bromate (0.01 mg/L), chloral hydrate (0.01 mg/L), dichloroacetonitrile (0.02 mg/L), chlorite (0.70 mg/L), and chlorate (0.70 mg/L).

Table 2. Standards for Disinfection By-products in Drinking Water

	Disinfection By-product Standards,[a] mg/L				
Country	THM4	BDCM	HAA5	Bromate	Chlorite
United States	0.08		0.06	0.01	1.00
Canada	0.10	0.016[b]			
United Kingdom	0.10			0.01

HEALTH EFFECTS OF CHLORINE AND CHLORINATION BY-PRODUCTS

Existing toxicologic data on chlorine carcinogenicity is equivocal. No dose–response relationships have been observed, but positive findings for lymphoma and leukemia were detected among female rats (34,35). Chloroform is the most studied DBP and was the first to be recognized as a carcinogen in 1976. Liver and kidney cancer in mice and rats and central nervous system depression in mice have been reported following administration of high doses of chloroform (36,37). Similar effects have been noted in animals following exposure to BDCM (37–40). Other DBPs reported to be carcinogenic in animals include DBCM, TBM, MX, NDMA, the HANs, and the HAAs (41–45). Despite exposure assessment limitations, epidemiologic studies have also reported associations between DBP exposure and bladder cancer (46,47).

Much of the ongoing DBP research is focused on potential reproductive and developmental toxicity. Previous studies showed teratogenic effects in animals following administration of HAAs and HANs (48–53). Full litter resorptions were reported in rats following dosing with BDCM and bromoform, and sperm abnormalities have also been reported in male rats following ingestion of BDCM in water (54,55). Klinefelter and colleagues (56) and Tyl (57) have reviewed most of the existing reproductive and developmental toxicity data. Associations between DBPs and a variety of reproductive and developmental outcomes reported in the epidemiologic literature have also been reviewed in detail elsewhere (58–61). Overall, the weight of evidence for reproductive and developmental effects of DBPs is mixed for many endpoints. Toxicological and epidemiological studies examining various effects are ongoing and may further elucidate the relationship between DBP exposures and potential health effects.

ROUTES OF EXPOSURE

The main route of exposure for nonvolatile chlorinated DBPs (e.g., HAAs) is from ingestion of water or water-based beverages. Exposure to volatile DBPs, such as the THMs, can occur through inhalation, dermal absorption, or ingestion. Since inhalation and dermal exposures to volatile DBPs may be greater than from ingestion, activities such as bathing, showering, and swimming need to be considered when determining overall exposure levels (62). Point-of-use filtration devices can be used to minimize DBP ingestion exposures (24). Boiling water prior to consumption is also effective at removing many DBPs, especially the volatile compounds (63,64). In addition to point-of-use treatment, DBPs can be reduced from a variety of changes in water treatment processes or from source water protection efforts (see Alternative Disinfectants chapter). Changes in water treatment implemented to reduce DBPs need to be carefully balanced with protection against microbial pathogens, so that drinking water supplies are not compromised.

CLASSIFICATION AND ENVIRONMENTAL QUALITY ASSESSMENT IN AQUATIC ENVIRONMENTS

Huan Feng
Victor Onwueme

Lewis Schneider
North Jersey District Water
Supply Commission
Wanaque, New Jersey

Water plays an important role in our daily life. Natural water in each compartment on Earth is balanced

through a hydrological cycle. With the population increase, industrialization, and rapid urbanization, water quality has been affected and an increased demand for water use has occurred. Anthropogenic substances are discharged into our aquatic environment. As a consequence, water contamination has been found in many rivers, streams, and lakes globally. Facing our current water environmental problems, water resources management and aquatic environmental protection and restoration are important issues to us. In the United States, water quality has been improved significantly since 1972 when the Clean Water Act was enacted by the U.S. Environmental Protection Agency. In this article, we introduce the classification of waters based on the reservoir they reside in and discuss the water quality, water pollution, and aquatic environmental legislations. This article gives a general overview of water classification, quality assessment, and legislations. Greater efforts are still needed to protect the aquatic environment and improve water quality.

INTRODUCTION

Water is essential to human life. A water molecule is made up of two positively charged atoms of hydrogen and one negatively charged atom of oxygen ($2H^+ + O^{2-} = H_2O$). Each hydrogen atom of the water molecule is linked to the oxygen atom by a covalent bond. It is a polar molecule. Because of the distribution of the charges, the molecules interact with each other by forming hydrogen bonds between the molecules. Therefore, the water molecule is stable. The properties of water are determined by the structure of the water molecule. It has a high specific heat (1 calorie $^\circ C^{-1}$ g^{-1}), a high latent heat of fusion (80 calories), and evaporation (540 calories). Light can only travel a maximum of a few hundred meters through water, sound can travel thousands of kilometers through water, and water is essential to life. Pure water freezes at 0 °C and boils at 100 °C at 1 atmosphere pressure. The maximum density of freshwater is at 4 °C (for seawater it is at its freezing point −1.9 °C) at 1 atmosphere pressure. The pH ($pH = -\log_{10}[H^+]$) value of pure water is pH = 7, rainwater pH = 5.0–5.6, river water pH = 6–7 (6.8 on average), and seawater pH = 7.5–8.5 (7.8 on average).

CLASSIFICATION OF WATER AND HYDROLOGIC CYCLE

Based on their physical and chemical properties and their storage reservoirs, the waters on Earth are classified as follows (1–3):

Rainwater—Precipitation from the atmosphere when water vapor in the air condenses and water droplets grow sufficiently large.

River (Stream) Water—Precipitation that does not evaporate or infiltrate into the ground runs off the surface and flows back toward the ocean. Best measure of water volume carried by a river is discharge that is defined as the amount of water that passes a fixed point in a given amount of time. Usually, it is expressed as cubic meter per second.

Lake and Pond—Lakes are inland depressions that hold standing freshwater year-round. Ponds are generally considered as small bodies of water.

Groundwater—The second largest reservoir of freshwater. The source of groundwater is caused by infiltration, a process of water percolating through the soil and into fractures and permeable rocks. Presently, groundwater is being removed faster than it can be replenished in many areas.

Seawater—Oceans contain more than 97% of all liquid water in the world. In open ocean, seawater has approximately 35 g of salts in 1000 g of seawater; thus, salinity = 35‰.

The hydrological cycle keeps the water balance on Earth. It describes the circulation of water when it evaporates from land, water, and organisms or transpires from plants, enters the atmosphere and condenses, and then precipitates back to the Earth's surface. Water can move underground by infiltration or overland by runoff into streams, rivers, lakes, and oceans. Renewable water supplies are made up of surface runoff and infiltration into accessible freshwater aquifers. It is estimated that 1.5 billion people lack access to an adequate supply of drinking water and nearly 3 billion lack acceptable sanitation (3). Regarding the water use in each sector, on the worldwide average, agriculture consumes about 69% of total water withdrawal and industry accounts for about 25% of all water use (3).

ENVIRONMENTAL QUALITY ASSESSMENT

Water Pollution

Since industrialization, many inorganic and synthetic organic chemicals have been used to make pesticides, plastics, pharmaceuticals, pigments, and so on. They are highly persistent and toxic and tend to bioaccumulate in food chains. These characteristics are also true of many heavy metals such as mercury, lead, cadmium, and nickel. The two most important sources of toxic inorganic and organic chemicals in water are improper disposal of industrial and household wastes and runoff of pesticides from high-use areas (such as fields, roadsides, and golf courses). It was reported that more than 25% of the mass of all materials dumped into the ocean is dredged materials from ports and waterways (2,4). Industrial waste is one major waste dumped at sea. Between 1890 and 1971, for example, 1.4×10^6 m^3 solid waste has been dumped into the water of the New York Bight (5,6). In 1972 the U.S. Marine Protection, Research, and Sanctuaries Act (the Ocean Dumping Act) prohibited dumping of all types of materials into ocean waters without a permit from the EPA. In fact, the United States has stopped its ocean dumping except for uncontaminated dredged materials with a permit from the U.S. Corps of Engineers.

Any physical, biological, or chemical change in water quality that adversely affects living organisms can be considered pollution. Pollutants can be from point sources (i.e., discharge pollutants from specific locations such as factories) and non-point sources (i.e., no specific location of discharge, such as agricultural fields and feedlots). At present, at least 2.5 billion people in less developed countries lack adequate sanitation, and about half lack access to clean drinking water (7). Sewage treatment plants and pollution-control devices can greatly reduce pathogens (8,9). To remove intestinal bacteria, drinking water is generally disinfected via chlorination.

Most urban sewer systems in the United States were built in the late 1800s and early 1900s. In 1972, the Federal Clean Water Act, in an effort to make U.S. water "fishable and swimmable," mandated the upgrade of sewage treatment to the secondary treatment level by 1977 (8,9). Although the discharge flow has been increasing over the years because of a population growth and an increasing discharge of waste by industry, total suspended solids, 5-day biochemical oxygen demand (BOD), and oil and grease have decreased in the waste stream. In most areas, heavy metal concentrations in the waste stream have been reduced as a result of enhanced sewage treatment and more strict federal and state policies and criteria that prevent these contaminants from entering the waste stream (10,11). The amount of dichlorodiphenyltrichloroethane (DDT) shows a dramatic decrease with time, although it is being gradually flushed from the land. Because of their toxic effect, polychlorinated biphenyls (PCBs) are also no longer used in a large quantity at present. Nutrient concentrations in coastal waters have been changed with land practice change, and the increasing supply of nutrients results in deoxygenation in some coastal waters as the surplus plant material decays (12–14).

Water Legislation

Water legislation in the United States was designed primarily to protect the nation's water from pollution, which included the Clean Water Act (CWA) (1972), a major revision of the prior Federal Water Pollution Control Act; and the Safe Drinking Water Act (1974) to protect populations consuming water and prevent groundwater contamination; as well as other laws such as the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) to prevent and mitigate contaminated groundwater. "The objective of this act (CWA) is to restore and maintain the chemical, physical and biological integrity of the Nation's waters." A major concern of the CWA was to prevent discharges to navigable water bodies of the United States. The CWA did this by making it illegal to discharge to a navigable waterway without a permit. The National Pollutant Discharge Elimination System (NPDES) defines this permitting process and implements the requirements for a point source discharger to monitor conventional, toxic, and nonconventional pollutants. Reduction (conventional pollutants) or limiting (toxicants) of these effluent discharges is achieved by the discharger through pollution control technologies. Pretreatment standards for indirect dischargers are also required in the CWA. Industries discharging indirectly to a publicly owned water treatment work (POTW) through a wastewater collection system must also comply with pollutant limits. Section 404 of the CWA includes permits oversighted by the U.S. Army Corp of Engineers to discharge dredged spoils to waters of the United States. Section 404 has been interpreted to protect adjacent and nonadjacent waterbodies that covers wetlands. Water quality standards are imposed to maintain the goal of "fishable/swimable waters," which are adopted by states with prior approval from the EPA. The water quality standards include designated use(s) of the waterbody, an antidegradation policy, and numerical and narrative criteria. Non-point source pollution is a key concern for the waterways of the United States and is addressed in the 1972 amendments to the CWA, which include state primacy in land use planning and regulations to control non-point source pollution. Storm water discharges may be considered point source discharges when conveyed through storm sewers. In 1987, the CWA amendments required discharges from municipal storm sewers to meet criteria under the act.

The primary goals of the SDWA were to ensure potable water at the consumer's tap and protect groundwater from contamination. The act applies to public water systems (PWSs), those servicing over 15 service connections or at least 25 persons. PWSs are in turn divided into community and noncommunity systems. The differentiation of community versus noncommunity is that community systems are used year-round, whereas use of noncommunity systems may vary from at least 60 days to more the 6 months. To protect the public health, the SDWA establishes primary and secondary standards. The primary standards are based on specific feasible maximum contaminant levels (MCLs) and maximum contaminant level goals (MCLGs) for the future. The primary standards include microbiological monitoring, inorganics (primarily metals and nitrate/nitrite), volatile organic compounds, synthetic organic compounds and pesticides, asbestos, and radionuclides. The SDWA establishes monitoring frequencies and analytical reporting, public notification, recordkeeping, and remediation requirements and procedures for these primary standards. Secondary contaminants are based on aesthetics, which include taste, odor, and appearance of the water, and adversely affect public welfare. Recommended ranges and limits are given for secondary standards that include physical, chemical, and biological characteristics. Similar to the primary standards, secondary standards establish monitoring requirements, public notification, and remediation. State underground injection wells are also regulated by the SDWA. Sole source aquifers are protected as well as wellhead areas and defined watersheds for surface water sources. Amendments to the SDWA, particularly in 1996, included grant and loan funding, a consumer confidence report designating water quality for annual customer distribution, and the use of risk assessment and cost–benefit analysis for adding new contaminant standards.

Water Quality Today

Significant progress in water protection and quality improvement has been made since the early 1970s. Most progress is from municipal sewage treatment facilities. In the United States, the Environmental Protection Agency has focused more on watershed-level monitoring and protection since 1998. States are required to identify waters not meeting water quality goals and develop total maximum daily loads for each pollutant and each listed waterbody. However, some problems remain. Greatest impediments to achieving national goals in water quality are sediment, nutrients, and pathogens, especially from non-point source discharges. Globally, according to Cunningham et al. (3), sewage treatment in wealthier countries of Europe generally equals or surpasses the United States. In Russia, only about half of the tap water supply is safe to drink. In urban areas of South America, Africa, and Asia, 95% of all sewage is discharged untreated into rivers. Two-thirds of India's surface waters are contaminated sufficiently to be considered dangerous to human health.

Pollution control has been advocated and practiced for many years, which includes source reduction and wastewater treatment. The public has recognized that the most effective way to reduce pollution is not producing it or not releasing it into our environment. To reduce the water pollution in our living environment, the wastewater treatment technologies have been developed, which include primary treatment (i.e., physical separation of large solids from the waste stream), secondary treatment (i.e., biological degradation of dissolved organic compounds), and tertiary treatment (i.e., removal of plant nutrients from secondary effluent) (8,9). The present water remediation technologies include oxidation, reduction, neutralization, or precipitation of polluted water. Bioremediation technologies mainly use living organisms to effectively break down contaminants in polluted waters (15).

CONCLUSION

Natural water is essential to our human life and living plants and organisms on Earth. The global hydrological cycle keeps the water balance in all compartments on Earth. Water resources management is important in regulating water use, discharge, and protecting the environment. With human population growth and increasing urbanization, demand on the water supplies is becoming increasingly high. Because of industrialization and economic development, water quality in some regions is becoming a serious environmental problem. Some rivers and streams are polluted by various anthropogenic contaminants. Since the 1970s, water pollution has been realized as a serious concern and water protection has received more and more attention. Since then, water quality has been improved to varying degrees in different countries. Overall, great efforts are still needed to conservatively use our water resource and protect the aquatic environment.

COAGULATION AND FLOCCULATION IN PRACTICE

Alper Ozkan
Selcuk University
Konya, Turkey

INTRODUCTION

All waters, particularly surface waters and process wastewaters, contain both dissolved and suspended particles. Very fine particles only a few microns in diameter settle extremely slowly by gravity alone. Therefore, several methods are used to increase the size of solid particles in solid/liquid separation. The processes of coagulation and flocculation are the major techniques used to aggregate particles. Solid particles can be flocculated into relatively large lumps, called flocs, that settle out more rapidly and thus particles are separated more easily from water (1,2). Although the terms coagulation and flocculation are often used interchangeably, or the single term "flocculation" is used to describe both, they are two different processes. Fine particles can be aggregated by neutralizing the electrical charge of the interacting particles, which is "coagulation," and bridging the particles with polymolecules is called "flocculation" (3,4).

COAGULATION

The major interactive forces between suspended particles are of two kinds, attractive and repulsive. The stability of particle suspensions depends on the properties of these forces. Attractive forces arise from van der Waals forces, which are effective only at very close range, whereas repulsive forces are due to the overlap of similarly charged electrical double layers of particles. Aggregation between particles can occur if the magnitude of the interparticle repulsive force does not exceed the corresponding attractive force. Electrostatic forces are responsible mostly for repulsion, so if suspension properties are adjusted to minimize such forces, particles can be coagulated (4,5).

Most solid particles suspended in water have a negative charge; since they have the same type of surface charge, they repel each other when they come close together. Repulsive forces prevent coagulation of particles and also retard their settlement. The specific surface charge of a particle and its magnitude, measured as zeta potential, are indicative of the strength of the repulsive forces due to charge. The charge on particle surfaces can be controlled by suspension pH. At some pH, called point-of-zero charge (PZC), the particles have no net charge and are unstable with respect to coagulation. pH control is a simple method for destabilizing suspensions. However, it may be impractical if the PZC occurs in an inconvenient pH range. Therefore, coagulants are often used to eliminate the negative charge on particle surfaces (4,6). Coagulants have a charge opposite to that of the particle surfaces; this causes charge neutralization that allows particles to come into contact and start to associate in bunches. Inorganic salts, such as $CaCl_2$, $MgCl_2$, $FeCl_3$, $AlCl_3$, $FeSO_4$, and $Al_2(SO_4)_3$, are used as coagulants. However, aluminum and iron salts are the most commonly used in wastewater treatment. The ability of most inorganic salt ions to compress the electrical double layer or the magnitude of the zeta potential is related to the valence of the ionic charge itself. In addition, hydroxy complexes of these are very active; thus they adsorb strongly on solid surfaces and can reverse the sign of the zeta potential. When hydrolyzable metal ions are used in the pH range and at the concentration level where the metal hydroxide is precipitated, sweep coagulation of suspension occurs by precipitating hydroxides. This effect leads to overall destabilization of a particle suspension (4–7).

FLOCCULATION

Polymeric flocculants are used effectively to destabilize fine particle suspensions. The advantage of polymeric flocculants is their ability to produce large, stronger flocs compared to those obtained by coagulation. The flocculating action of polymeric flocculants proceeds via either "charge patch attraction" or "polymer bridging." Charge patch attraction occurs when the particle surface is negatively charged and the polymer is positively charged. On the other hand, bridging is considered a consequence of the adsorption of segments of flocculant macromolecules onto the surfaces of more than one particle. Such bridging links the particles into loose flocs, and incomplete surface coverage ensures that there is sufficient unoccupied surface on each particle for adsorption during the collisions of chain segments attached to the particles. Most flocculants are synthetic polymers based on repeating units of acrylamide and its derivatives, which may contain either a cationic or anionic charge. Both anionic and nonionic polymers can be manufactured at very high molecular weights and thus can form large, rapid-settling, good-compacting flocs. They are widely used in industrial applications (2,4,8).

The kind of initial adsorption of polymers onto a particle varies, depending on the respective charges of both polymer and particle. It may be purely electrostatic if these charges are opposite in sign. If not, then other physicochemical reactions may take place. A cationic polymer, positively charged, can adsorb on the surface of negatively charged particles via electrostatic bonding. The most likely mechanism of adsorption for nonionic polymers is through hydrogen bonding. Anionic polymers and negatively charged suspensions may also adsorb via hydrogen bonding. In suspensions to which a cation has been added, polymer adsorption often also occurs through cation bridging; that is, the cations can form an electrostatic bridge between the negatively charged particle surface and the negatively charged polymer (4,5).

Theoretically, flocculants may be used either after destabilization of the suspension by coagulation, that is, predestabilization, or without destabilization. Polymeric flocculants are more effective in destabilized fine particle suspensions and so the first option that involves predestabilization by coagulation is always better. Destabilization prior to flocculant addition can usually be accomplished by eliminating the charge barrier by pH control or by adding an inorganic salt. This permits small flocs to form; the bridging action of the polymer links them into substantially larger units (2,6,9,10).

COLLOIDS AND DISSOLVED ORGANICS: ROLE IN MEMBRANE AND DEPTH FILTRATION

Gary G. Leppard
National Water Research Institute
Burlington, Ontario, Canada

Jacques Buffle
University of Geneva
Geneva, Switzerland

INTRODUCTION

A colloid is operationally defined as any particulate with a least dimension in the range of 1.0–0.001 μm; the range includes macromolecules, but not conventional dissolved substances, which tend to be smaller (1,2). For environmental scientists, aquatic colloids are being redefined as any particulate that provides a molecular milieu into and onto which chemicals can escape from bulk water and whose movement is not significantly affected by gravitational settling (3). In practice, colloids and dissolved substances are often defined by a filter operation (4,5). Living microbes, when sufficiently small, can also be considered colloids, albeit colloids capable of very complex behavior (2).

Filtration for water scientists is the separation of particulates from a liquid, achieved by passing a suspension through a porous solid. Through the application of membrane filters and/or depth filters, filtration protocols are commonly used (1) to concentrate or remove particulate matter and (2) to separate suspended particulates into size classes for subsequent biological, chemical, or physical analyses. In water treatment, one discriminates between membrane filters, which are porous membranes that concentrate particulates at or close to the upper filter surface, and depth filters. The latter are relatively inexpensive filters with high collection efficiencies and flow rates that entrap particulates within the filter interior.

Filters for use in the analysis of aquatic samples may be separated into three categories:

1. filters made of a random assembly of fine fibers;
2. filters made of an impermeable material, which has discrete cylindrical holes traversing it and which acts as a true sieve; and
3. "depth filters," which have a spongy structure.

These three categories of filters and their relationships to applicable size ranges and to standard sieves and dialysis membranes are shown in Fig. 1. The various filters in use are complementary in pore size ranges, pore size distributions, and chemical nature, thus providing versatility in minimizing sample perturbation by filters.

PRACTICAL ADVANTAGE OF BETTER UNDERSTANDING

Understanding better the roles of colloids and dissolved organics in a filtration process is particularly useful when considering the following goals:

1. understanding the processes of fouling and biofouling as they relate to water treatment filters (6,7);
2. optimizing the design of filters for improved performance in specific situations (5,6), focused on filters designed to be cleaned *in situ*; and
3. improving the quality of size fractionations for limnologists and oceanographers focused on capturing and analyzing natural microbiological consortia with minimal artifact (7).

Some specific concepts and advances are noteworthy. Biofouling of filters is an unwanted progressive deposition of microorganisms and their consequent formation of biofilms, which clog filter pores and eventually establish an additional (but different) filter at the upper surface

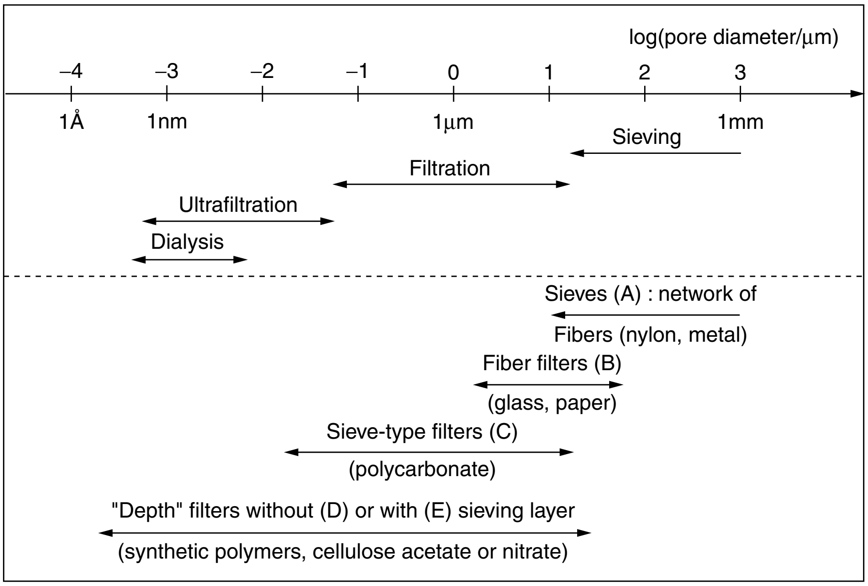

Figure 1. Size ranges for sieving and filtration, including depth filters, and for application of the most important filter types. Reproduced with permission from Buffle et al. (5).

of a membrane filter. The economic consequences of this process are considerable (6). New technology is leading to the identification of specific nanoscale organic entities that microorganisms produce to facilitate their attachment to filter surfaces (8). Such research may lead to better methods for cleaning filters *in situ*. In general, fouling may also result from purely physicochemical interactions between organic and inorganic colloids and a membrane surface, leading to colloid coagulation (5). In such cases, controls over the flow rate and physicochemical conditions are essential.

As realization increases of the many biogeochemical processes dominated by certain abundant living colloids in the oceans, the need to analyze isolated important biological species grows in importance (7). To isolate these microbes and separate them according to size (and then possibly according to dominant species) for subsequent characterization and assessment of their biogeochemical roles, there is a requirement for well-controlled filtration procedures. An additional and valuable consideration is filter selection according to filter compatibility with various techniques of analytical optical microscopy for studying fresh isolates and their minimally perturbed natural consortia while they sit on filters.

ABUNDANT COLLOIDS AND DISSOLVED ORGANICS

In natural waters, the most commonly encountered colloids are fractal aggregates of fulvic and humic acids, living cells of colloidal size, viruses, fibrils (linear aggregates of biopolymers rich in polysaccharide), refractory skeletal fragments of organisms, clay minerals, and oxyhydroxides of iron and manganese (9). Three major groups enable one to describe colloid coagulation properties: inorganic (compact) colloids, fibrillar (rather rigid) large biopolymers, and small (nanometers) fulvic acids (1). Fulvic and humic acids are at the borderline between dissolved and colloidal organics, whereas organic metabolites emanating from leaky cells, lysing cells, or excreta are usually dissolved. In engineered aquatic ecosystems, such as water treatment facilities, the same colloids and dissolved organics tend to be present but in different relative amounts. These colloids and dissolved organics can have an impact on the biological activities and clarity of both natural and engineered waters through their influences on flocculation (10,11). The impact on filtration processes of those most abundant can be considerable, leading to defective filter performance and misleading information (5).

KINDS OF FILTERS AND THEIR APPLICATION: GENERAL CONSIDERATIONS

An in-depth review of the various kinds of filters, used currently for water treatment and for the size fractionation of aquatic particles and colloids, is beyond the scope of this article. Water treatment plants and their apparatus are evolving toward greater cost-effectiveness through design changes, which are adaptations to the specific properties of the water being received. Thus, different sites are likely to have different kinds of membrane filters and use different flow rates, and changes are made continually. General considerations are found in Buffle et al. (5) and in Droppo (4). General research needs are outlined well in a 1998 Committee Report of the AWWA (12). For water treatment, there is a strong research effort to develop plastic filters with well-controlled properties, an ongoing work that is progressing well. Coupled to this are considerable interests in developing filters that can be cleaned *in situ* and improved filters for removing waterborne pathogens. Filtration can be used in conjunction with chemical aids, such as flocculants, to minimize fouling. This is a research topic that is likely to expand quickly.

BIOPHYSICOCHEMICAL INTERACTIONS BETWEEN FILTERS AND COLLOIDS/DISSOLVED ORGANICS

As stated earlier and revealed by Figs. 1 and 2, the various types of filters are complementary in properties. The nature of filtration problems, however, varies from one filter type to another, in particular because flow rates through the various membrane types differ.

Filters with a large pore size (>0.1 μm) are used for sieving and filtration (Figs. 1 and 2). A large solution flow rate can be achieved, even though a rather low pressure is applied to the filter. At a large flow rate, the concentration of colloids at the filter surface may become orders of magnitude larger than in the bulk solution (the so-called concentration polarization effect), leading to instantaneous coagulation (Fig. 3) and consequent clogging of the filter (5). Under such conditions, the nature of the membrane is not very relevant. The way to minimize clogging is to use minimum flow rates. Although very low flow rates are usually required to avoid surface coagulation, they cannot be so low as to permit bulk coagulation (Fig. 3).

Filtration membranes with pore sizes in the range 1–100 nm are used for ultrafiltration. High pressure (1–4 atm) must be applied to the membrane because of the small pore size, but flow rates are never large. When the effective hole size is of the same order of magnitude as the molecule, dialysis or reverse osmosis occurs, whereby the solvent does not move through the membrane. With such membranes and techniques, clogging due to surface coagulation is low or negligible, and it decreases with the membrane pore size. On the other hand, when molecules and pore sizes become more and more similar, interactions between the solute (the organics especially) and the membrane body become increasingly important (Fig. 3). In

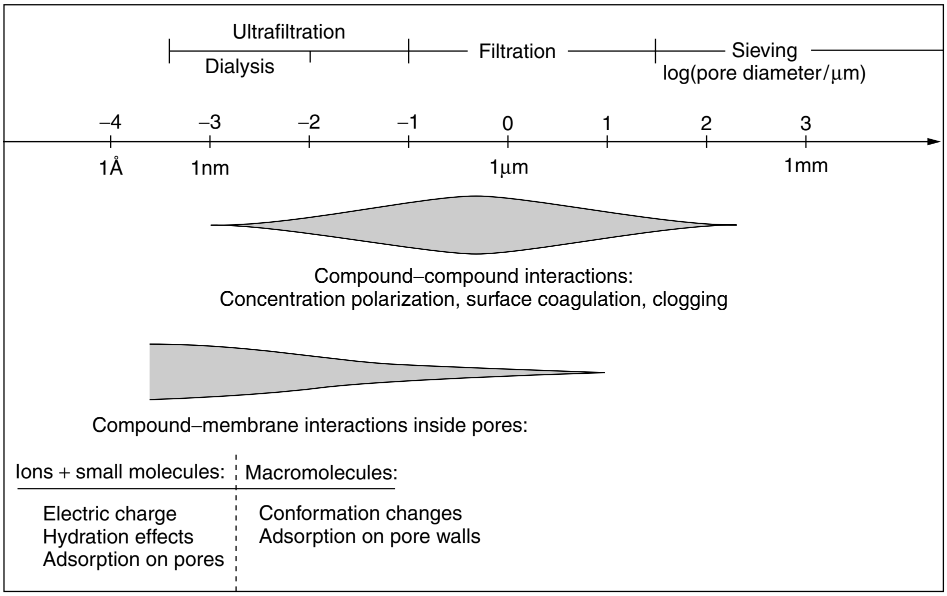

Figure 2. Schematic of size ranges where important secondary filtration effects are expected to play a significant role. The thickness of hatched zones reflects the relative importance of the corresponding factors. The word "compound" designates any component different from water, be it particulate or colloidal or dissolved. Reproduced with permission from Buffle et al. (5).

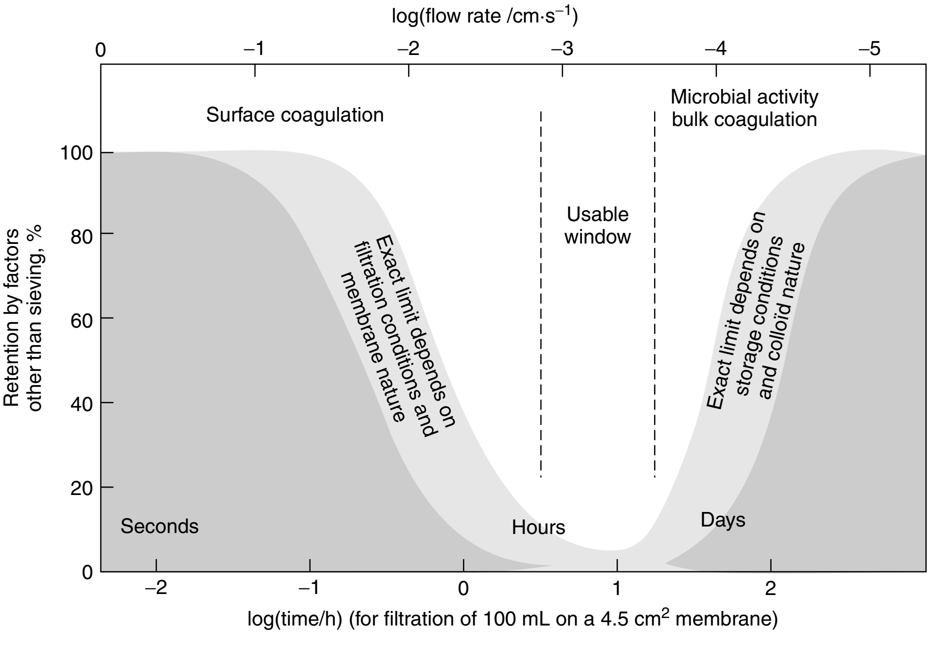

Figure 3. Semiquantitative representation of the change in retention with flow rate and with aggregation in the filtration cell, revealing the flow rate window of minimal artifact. Reproduced with permission from Leppard and Buffle (2).

such cases, the chemical nature of the membrane plays an important role. Thus it must be realized that the problems encountered in sieving and filtration are rather different from those in ultrafiltration, dialysis, and reverse osmosis. Detailed descriptions of the various types of interactions are given in Buffle et al. (5). The concept of the optimal flow rate window is illustrated in Fig. 3.

In addition to the aforementioned physicochemical interactions between membranes, suspended colloids, and dissolved organics, biological effects may play an important role. In particular, once microorganisms have been collected on the membrane filter, some of them secrete adhesive organic macromolecules (as cell attachment devices) directly onto membrane surfaces, leading to the development of a biofilm (an attached consortium of individual colloidal cells enmeshed in a porous matrix of their extracellular biopolymers). Attempts to identify specific important bioadhesives are receiving an impetus from transmission electron microscopy examinations of colloid/filter associations, using fouled membrane filters (8).

SIZE FRACTIONATION

Various sequential size fractionation procedures have been subjected to comparative analysis. In analytical applications, one can use either washing (also called diafiltration) or concentration techniques and, for each case, either sequential (also called cascade) or parallel filtration. In the concentration technique, the solution is pushed through the membrane by applying pressure. In the washing technique, a constant volume is maintained over the filtration membrane by compensating with synthetic solution. It has been found that the washing technique is more reliable because it avoids concentrating the particles in the retentate, thus minimizing coagulation problems. In a sequential filtration procedure, the same solution is filtered successfully through a series of membranes of decreasing pore size; the filtrate of one cell is filtered on the following membrane. The proportion of colloids in each size fraction is obtained by analyzing the various filtrates. In the parallel procedure, aliquots of the same sample are filtered through several membranes of different pore size. The proportions of colloids in the size fractions are obtained, based on the analysis of the filtrates and calculations. Because the reproducibility of filtration is not better than 5–10% error, the accumulation of errors becomes exceedingly large over five filtration steps in all cases, but sequential filtration is preferred because it minimizes aggregation problems. The rate of coagulation increases with particle concentration and heterogeneity.

OPTIMIZATION

The factors that affect the retention of colloids are summarized in Fig. 3. At large flow rates ($>3 \times 10^{-3}$ cm/s), large concentration polarization occurs and retention is due mostly to surface coagulation, which often leads to clogging. At very low flow rates, such surface coagulation is not important, but coagulation in the bulk solution becomes an important factor (for flow rates $<10^{-4}$ cm/s) because filtration times can be exceedingly long (days). For this reason, in chemical analysis, it is also preferable to avoid dialysis for which very long equilibration times are required. At intermediate flow rates ($10^{-4} - 3 \times 10^{-3}$ cm/s), the separation of colloids is effectively based on sieving and depends on membrane pore size.

The aforementioned limiting values of flow rates are valid for stirred conditions with a diffusion layer thickness (δ) of 10 μm. However, surface and bulk coagulation strongly depend on hydrodynamic conditions, which influence the value of δ (and thus surface coagulation), and on the bulk coagulation rate. Thus, both surface and bulk coagulation depend on the filtration mode (batch filtration with stirring, cross-flow filtration, pulsed filtration, filtration on rotary cylinders or disks, hollow fiber filtration). Decreasing δ below a few micrometers, to minimize surface coagulation, is very difficult; thus the schematic curves of Fig. 3 can be seen as the upper limits for both surface and bulk coagulation. It is interesting to note that the actual pore size of a membrane filter might not play a direct role in particle retention; the actual pore size might influence only the flow rate and thus the coagulation efficiency.

NEW VISTAS

In the last few years, novel chemical treatments have been applied to both porous and nonporous surfaces to create modified surfaces that kill bacteria on contact (13). The treatments are especially advantageous because they are not expected to exacerbate the problem of growing bacterial resistance to antibiotics. In practice, an antibacterial chemical (which disrupts drastically the integrity of the bacterial surface to kill bacteria before they can establish a biofilm) is bonded to the surface of interest so that it can neither be washed away nor modified upon interaction with oncoming bacteria. The treatments are currently applicable to glass surfaces, polymer surfaces, and carbohydrate-based porous materials. Can their use with membrane and depth filters be far behind? Considering the explanations given previously, this membrane treatment should be combined with a physicochemical means to minimize “cake” formation at the surface of filters by surface coagulation.

An interesting complementary idea is the creation of living filters in which a biofilm is purposely formed at the surface of the pores of a filter. Even though the concept needs considerable development, it can be envisioned that such a filter could be used (1) selectively to extract certain valuable substances from water for recovery or (2) selectively to degrade organic contaminants that become bound within the biofilm matrix (and thus are subject to enzymatic activities of nearby microorganisms).

COLUMN EXPERIMENTS IN SATURATED POROUS MEDIA STUDYING CONTAMINANT TRANSPORT

WOLFRAM SCHUESSLER
Institut für Nukleare Entsorgung
Karlsruhe, Germany

ROBERT ARTINGER
TÜV Industrie Service GmbH
München, Germany

Column experiments are one key technique to investigate transport phenomena of contaminants in water-bearing porous media. The main applications of column experiments are the determination of (1) sorption coefficients for contaminants in different porous media (e.g., aquifers), (2) transport phenomena of dissolved matter (e.g., filtration of aquatic colloids), and (3) reaction mechanisms of dissolved matter (e.g., dissociation kinetics of aquatic complexes).

The typical setup of a column experiment is given in Fig. 1. From a reservoir a fluid (e.g., groundwater or contaminated water) is pumped through a column and the effluent of the column is analyzed online or by collecting individual samples. To control the flow-through either a flowmeter or a balance is used. A second reservoir can be used to switch from one feeding solution to another [e.g., from a groundwater solution to a contaminated (spiked) groundwater]. In addition to the analysis of the effluent, the distribution of sorbing tracers or filtrated colloids in the column can be analyzed, either online or postmortem. Depending on the samples under investigation the whole experiment can be performed in a glove box, for example, for radiation protection reasons or to control the ambient air composition.

Most of the column experiments found in the literature fall into three categories: experiments with (1) intact natural porous media to the greatest possible extent, (2) artificially packed natural porous media, and (3) artificial porous media (e.g., ion exchange resins).

For the experiments in category 1 the most difficult task is to get an undisturbed (or least disturbed) column from the field site into the lab and to maintain the natural boundary conditions.

Category 2 experiments somehow represent a compromise between categories 1 and 3. The natural material can be well characterized before using it in the column experiment. During the process of column packing the natural steady state between the solid and the liquid phase is disturbed. Therefore, prior to a column experiment under “near natural” conditions the whole system, porous medium and feed solution, has to be equilibrated until a steady state is reached. This new steady state is not necessarily the one found in nature. To come as close as possible to natural conditions, parameters such as surrounding gas atmosphere or redox state have to be monitored and, if possible, controlled.

Categories 1 and 2 aim at the quantitative determination of parameters “directly” applicable to the natural systems under investigation. However, even being as close as possible to the natural conditions, one has to be aware of possible artifacts and the problems of upscaling, relevance, and transferability (1).

Category 3 experiments are used to investigate properties of dissolved matter like aquatic complexes of contaminants and aquatic colloids. Here the main goal is to identify and quantify processes under well defined conditions, which normally is not possible in a complex natural system. In these experiments well defined standard porous media (e.g., quartz sand) or porous media with special characteristics (e.g., ion exchange resins) are used.

COLUMN PREPARATION

The best preparation method strongly depends on the properties of the system under investigation. Therefore,

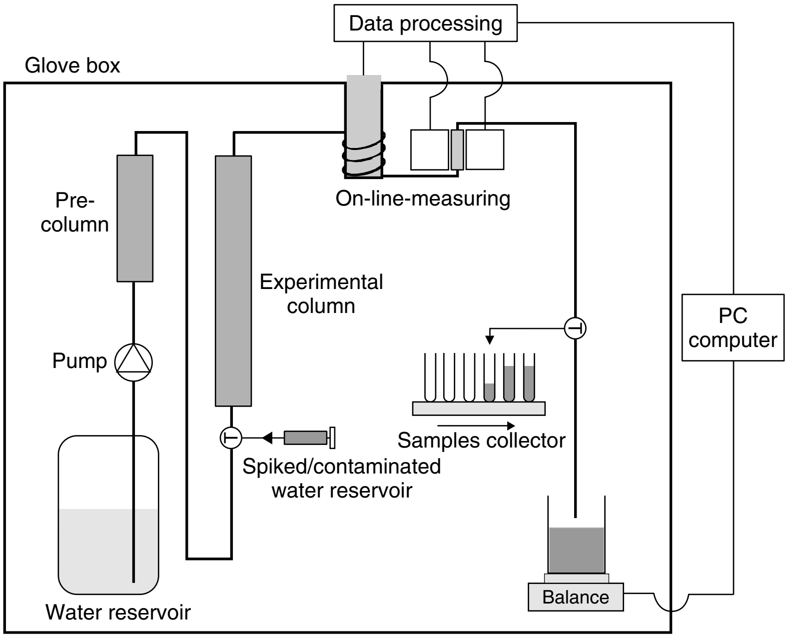

Figure 1. Experimental setup for column experiments.

only a few main hints, resulting from the long experience with column experiments of D. Klotz (2) and our own experiments with radionuclides, are given here.

The dimensions of the column are determined by the porous medium under investigation. It turned out that the column diameter should be at least 30 mm and larger than 25 mean grain diameter; the length should be larger than four times the column diameter. This setup enables evaluation of the experiments assuming an almost homogeneous distributed porous medium (not necessarily meaning homogeneous grain size) and minimizes the influence of boundary effects at the inlet and the outlet of the column.

Suitable materials for the columns are stainless steel or acrylic glass. The use of acrylic glass enables eye inspection of the readily prepared column. The disadvantage in case of experiments with natural samples is the growth of algae if the experiment is not run in the dark and at limited pressure. If the column is kept in the dark except for short periods of light (e.g., for sample taking), the growth of algae is prevented. At the inlet and the outlet of the column a frit is used in order to keep the porous medium inside the column and to distribute or sample the water over the whole cross section of the column.

As examples, two preparation methods (2) for columns are given here. In preparing a column with a cohesive medium, a slurry of one part porous medium and one part water is made. The slurry is filled into the vertical adjusted column up to a height of 1 cm. Then the water is extracted from the bottom of the column with a slow flow rate (1 cm^3/h or less). A second batch of slurry is put on top of the condensed porous medium in the column and the water is again extracted. This procedure is applied until the column is filled to the top. In the case of a sandy porous medium, the vertical adjusted column is filled with 1 cm of water and then 1 cm of the sandy medium is put into the column. The sandy medium is compacted by stamping with a bead-molding in the column and knocking with a rubber mallet from outside the column. Next, the supernatant is discarded and the process is continued unless the column is filled. This procedure guarantees a tightly packed reproducible bed inside the column.

EXPERIMENTAL PROCEDURE

In general, the flow through the column should be directed from the bottom to the top. Remaining gas bubbles originating from the packing procedure in the column are driven by the water flow and the buoyant force toward the outlet and are thus removed from the column during the equilibration process. If the column is operated from the top to the bottom, the buoyant force is always directed toward the column inlet and thus always some bubbles remain in the column, influencing the flow characteristics in an uncontrollable way.

In the case of sandy media, a pump is located at the inlet of the column and the effluent is recovered in an open sample reservoir at the outlet. For cohesive media, at the column outlet pressure is applied to extract the effluent from the column. At the outlet a sample collector can be used to allow solution analysis of individual fractions of the effluent. Flow-through can easily be monitored using a balance and a data acquisition program. In addition, online detection methods can be applied, for example, radiometric or spectroscopic methods or ion-sensitive electrodes.

Initially, the column is manipulated until a steady state in chemical composition of the effluent and hydraulic properties of the column is reached. The hydraulic properties are determined and monitored by using conservative tracers. When the steady state is reached, either a short pulse injection or a continuous step injection may be applied for a contaminated water. Which method is used depends on the system under investigation. Experiments with radioactive contaminants often use the pulse injection method to keep the activity introduced into the column as low as possible (3). In contrast, experiments with water contaminated by heavy metals frequently use the step injection method. However, the corresponding breakthrough curves of the tracers in both experiments contain the same information although they look very different at first glance (4).

A column may be used several times. However, one has to make sure that the subsequent experiments are not influenced by the preceding ones. This has to be kept in mind for the analysis of the breakthrough curves as well as for the postmortem analysis of the tracer distribution in the column.

EXAMPLES

Sorption Coefficient of Cadmium onto Sea Sand

The sorption coefficient of cadmium (Cd) onto sea sand (5) in a synthetic groundwater is determined using a plexiglas column (length 500 mm, diameter 50 mm) (Fig. 2). The column is equilibrated with the water for a period of 3 weeks. Bromide is applied as a conservative tracer for the determination of the hydraulic properties of the column. Cd breakthrough curves are determined from pulse injection (300–800 mL) experiments with initial Cd concentrations of 8.9×10^{-6} mol/L. The Cd concentration in the eluate is determined online as a function of time, that is, the Cd breakthrough curve, by means of a Cd-sensitive electrode and after collection of individual fractions by ICP-MS.

In the case where all chemical reactions involved in the experiment are in equilibrium, the sorption coefficient can be determined from the breakthrough curve according to

$$R_f = 1 + \gamma K_d V / V_p$$

where γ is the density of the packed column (here 1.7 $\text{g}\cdot\text{cm}^{-3}$), V is volume of the column (here 1000 cm^3), V_p is pore volume of the column (here 400 cm^3), and the retardation factor $R_f = v_\text{D}/v_t$ with v_D being the Darcy velocity and v_t the pore water flow velocity. Here $R_f = V_\text{max}/V_p = 8000/400 = 20$ and therefore $K_d = 4.5\ \text{g}\cdot\text{cm}^{-3}$. V_max is the solution volume eluted from the column corresponding to maximum tracer concentration in the effluent (maximum of the breakthrough curve).

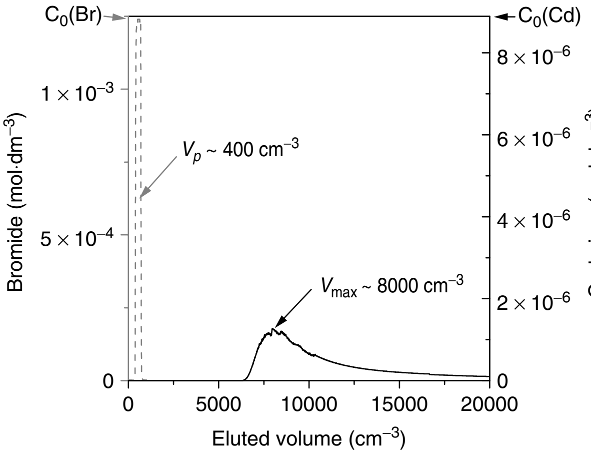

Figure 2. Column experiment to determine the sorption coefficient of Cd onto sea sand.

Transport Phenomena of Dissolved Matter, Size Exclusion of Humic Colloids

Column experiments (6) were carried out to investigate the influence of humic colloids on subsurface uranium migration (Fig. 3). The columns were packed with well characterized aeolian quartz sand and equilibrated with groundwater rich in humic colloids (DOC: 30 $\text{mg}\cdot\text{dm}^{-3}$). U migration was studied under an Ar/1% CO_2 gas atmosphere. Precolumns (250 mm long, and 50 mm in diameter) were used as filters to remove possibly generated larger particles and to pre-equilibrate the groundwater. The whole system was equilibrated with groundwater over a period of at least three months. Tritiated water (HTO) was used as a conservative tracer to determine the hydraulic properties of the column. The breakthrough curve of HTO was measured using a flow-through monitor for β-radiation; U was determined using single fraction analysis. The uranium-spiked groundwater was prepared by adding aliquots of an acidic U(VI) stock solution to the groundwater. The U concentration in the spiked groundwater was 10^{-6} $\text{mol}\cdot\text{dm}^{-3}$.

The breakthrough curves (Fig. 3) indicate that U was transported as a humic colloid-borne species with a velocity up to 5% faster than the mean groundwater flow (monitored by HTO). This could be attributed to size exclusion of the humic colloids from small water-bearing pores within the column.

Dissociation Kinetics of Am-Humic Colloids

The column experiments (3) were performed using the same groundwater/sand system as described for the U experiment (Fig. 4). The breakthrough curves of HTO and Am were measured using flow-through monitors for β and γ radiation and additionally by single fraction

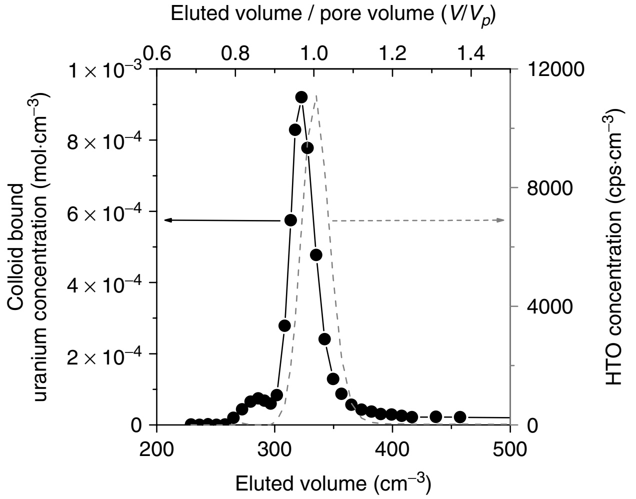

Figure 3. Column experiment investigating the size exclusion of humic colloids in a sandy aquifer.

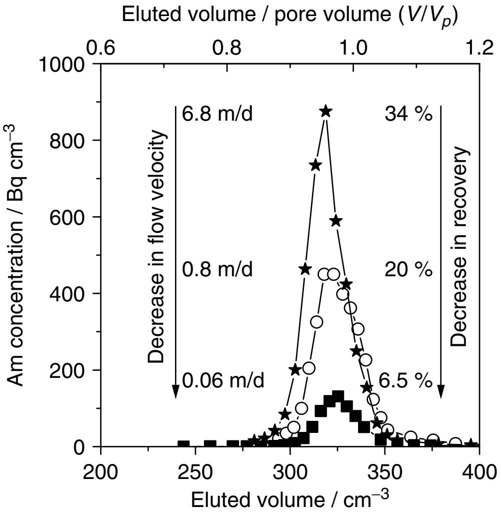

Figure 4. Column experiment investigating the dissociation kinetics of Am-humic colloids.

analysis. The ^{241}Am concentrations in eluate fractions and batch experiments were further determined by liquid scintillation counting. The Am-spiked groundwater was prepared in the same manner as described for U. The Am concentration in the spiked groundwater was 2×10^{-8} mol $\cdot$ dm^{-3}. The breakthrough curves again indicate that Am was transported as a humic colloid-borne species with a velocity up to 5% faster than the mean groundwater flow (monitored by HTO).

By varying the groundwater flow velocity about two orders of magnitude (0.06–7 m/d), an increase of the Am recovery (ΣAm injected into the column/ΣAm recovered from the column) is obtained ranging from 6% to 34% (Fig. 4). That means the longer the residence time of humic colloid-borne Am in a column, the higher is the amount of Am sorbed onto sand. The significant dependence of the Am recovery on the groundwater flow velocity is due to time-dependent turnover of Am from humic colloids onto the sand surface. These types of experiments were further used to investigate the actinide humic colloid interaction kinetics (7–10).

CYTOCHROME P450 MONOOXYGENASE AS AN INDICATOR OF PCB/DIOXIN-LIKE COMPOUNDS IN FISH

HANNAH AOYAGI
OLADELE A. OGUNSEITAN
University of California
Irvine, California

POLYCHLORINATED BIPHENYL AND DIOXIN-LIKE COMPOUNDS AS ENVIRONMENTAL TOXICANTS

Polychlorinated biphenyls, dioxins, and furans are ubiquitous and persistent organic pollutants (POPs). These three categories of chemicals are among the 12 priority POPs that have been scheduled for global phase-out according to the Stockholm Convention on Persistent Organic Pollutants (SCOPOP). SCOPOP was inaugurated in May 2001, and it has been ratified by more than 100 countries under the auspices of the United Nations Environment Program (1). Despite the stringent regulatory restrictions now placed on the manufacture and distribution of polychlorinated biphenyls and dioxin-like compounds, their recalcitrance in polluted aquatic environments necessitates the continuation of monitoring programs that have been implemented to reduce negative impacts on biotic and abiotic components of vulnerable ecosystems.

Polychlorinated biphenyls (PCBs) include 209 congeners consisting of two to ten chlorine atoms attached to a biphenyl structure. PCBs are highly soluble, clear, oily liquids at room temperature. They are chemically inert and thermally stable. These properties make them useful as insulators and coolants for capacitors and transformers in a variety of industries. Monsanto began production of PCBs in 1930, marketing congener mixtures under the brand name Aroclor. PCBs were also sold under the names Clophen (Germany), Kanechlor (Japan), Fenchlor (Italy), and Phenochlor (France). PCB production was banned in the United States in 1977 due to potential carcinogenicity (2,3).

PCBs tend to deposit in sediments and soils where they persist and bioaccumulate; their half-lives are in the range of months to decades. Due to their high affinity for lipids, PCBs have been detected in the adipose tissues of animals worldwide, including humans (3). Consumption of contaminated fish is the primary route of exposure for adults, whereas infants can be exposed to high concentrations of PCBs in breast milk (4).

The adverse health effects associated with PCB exposure include neurological impairment, developmental effects, carcinogenicity, hepatotoxicity, thyroid problems, dermal and ocular abnormalities, and changes in immune function (3). Occupational studies provided the first evidence of chloracne (skin eruptions) and neurological impairment, but detailed acute and chronic health effects of PCB exposure in the general population were provided by the Yusho and Yu-cheng poisoning incidents in Taiwan where 1843 adults, children, and pregnant women consumed PCB-contaminated rice oil (5,6).

The increasing recognition of human health effects due to PCB exposure has led to suspicions of their ecotoxicological impacts on various organisms inhabiting polluted ecosystems (7). Aquatic animals and their predators are at risk of cancer, neurotoxicity, reproductive toxicity, immune impairment, and endocrine effects. Due to the bioaccumulative nature of PCBs, health risks are highest for the top predators in the food chain (7). No threshold level of exposure has been identified for immune effects in animals. Moreover, it has been found that reproductive impairment can endure long after exposure in some organisms, indicating that PCBs may pose a serious threat to the fundamental survival of many species (2).

Chlorinated Dibenzofurans

CDFs are a class of chemicals composed of 135 congeners; each consists of a furan ring surrounded by two benzene rings, and one to eight chlorine atoms are attached to the benzene structures (Fig. 1). They are colorless solids, soluble in organic solvents, and do not interact with acids or alkalis. However, they are less stable than PCBs and degrade at a temperature of 700 °C (4). CDFs are not manufactured for commercial use, but they are by-products of PCB and chlorinated herbicide manufacturing, solid waste incineration, and bleaching processes. Currently there are no specific regulations pertaining to CDFs (8). They have been detected in the atmosphere and in surface waters but tend to adhere to sediments where they can bioaccumulate in fish and other aquatic organisms (4). Human exposure routes include eating contaminated fish and drinking milk from cows that have ingested feed contaminated by CDFs from atmospheric deposition. There are no data on the human health effects of CDFs alone because exposures have typically occurred simultaneously with PCBs and other similar compounds. Animal studies indicate that exposure to CDFs leads to adverse health outcomes similar to those of PCB exposure, including hepatotoxicity, thyroid alterations, and reproductive effects (8).

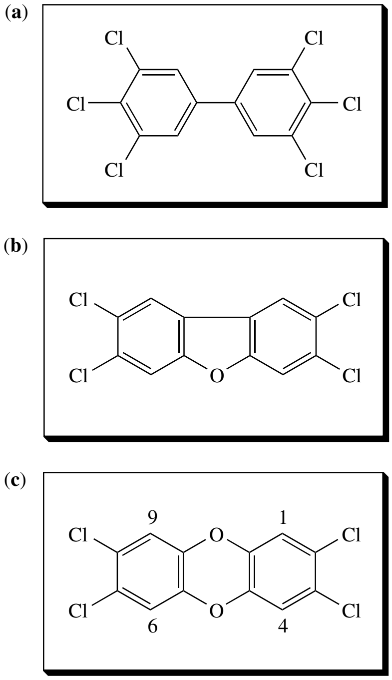

Figure 1. Schematic diagram of the structure of polychlorinated biphenyls (**a**), chlorinated dibenzofurans (**b**), and chlorinated dibenzo-*p*-dioxins (**c**) compounds.

Chlorinated Dibenzo-*p*-dioxins

CDDs comprise a group of 75 congeners; each consists of two benzene rings connected by two oxygen bridges, and one to eight chlorine atoms surround the structure (Fig. 1). CDDs are colorless solids or crystals of low solubility. They readily partition in air, water, and soil (4). CDDs were originally produced as herbicides, such as Agent Orange. In 1983, the Environmental Protection Agency (EPA) banned the use of chlorophenoxy herbicides on agricultural lands. CDDs are still emitted from incineration and chlorine bleaching processes in paper and pulp mills, as well as from the combustion of fossil fuels, wood, and cigarettes. Recent regulations have attempted to reduce paper and pulp mill effluents, as well as reducing dioxin emissions from incineration (9). CDDs are found worldwide in small concentrations, in the atmosphere (incinerator emissions), surface water (paper and pulp mill effluents), and in soils and sediments (herbicide spraying and atmospheric deposition). CDDs in soil and sediments can bioaccumulate through the food chain and reach humans through fish, meat, and milk. Occupational exposures can occur during the manufacture of pesticides and herbicides. Human and animal health effects are similar to PCBs, including cancer, immunosupression, reproductive and endocrine effects, chloracne, and neurotoxicity (9).

CYTOCHROME P450 ENZYMES

The cytochrome P450 superfamily (P450s) of microsomal hemoproteins is a set of oxygen activating terminal oxidases that catalyze several biosynthetic and metabolic processes. The monooxygenase activity of P450 enzymes is expressed through a series of electron transfer reactions involving the heme moiety (Fig. 2). The overall reaction can be summarized by the schematic equation

$$\mathrm{RH} + \mathrm{O_2} + 2\mathrm{H^+} + 2\mathrm{e^-} \longrightarrow \mathrm{ROH} + \mathrm{H_2O}$$

Figure 2. Amino acid sequence of salmon P4501A, and the three-dimensional structure of eukaryotic cytochrome P450 monooxygenase. The amino acid sequence was recovered from the National Center for Biotechnology Information database (http://www.ncbi.nlm.nih.gov/) (12). The image was generated from another P450 sequence imported into the Cn3D4.1 software program. The string and barrel structure shows the position of the essential iron atom.

The RH substrate represents a wide variety of compounds, including chlorinated aromatic pollutants. More than a hundred different P450 enzymes have been identified in animals, plants, fungi, and microorganisms, although they appear to play the most complex role in animals (10).

P450s perform a variety of functions, including the capacity to hydroxylate different structural types of organic molecules. They were first identified in liver tissue and later in tissues such as the adrenal gland and lymphocytes (10). In the liver, P450s catalyze the first step in metabolizing environmental toxicants as well as endogenous steroid hormones and drugs. These reactions have important implications for the use of cytochromes P450 as biomarkers of environmental toxicant exposures (12).

In the typical metabolic reaction, cytochrome P450 binds with the substrate, oxygenates it, and transforms it into a reactive state. In the second step of metabolism, the substrate undergoes a conjugation reaction (glucuronidation) and eventually elimination. In the reactive state, the substrate has the potential to form DNA adducts, thereby initiating carcinogenesis. However, ecotoxicologists are more interested in the mechanism of P450 induction and how changes in enzyme synthesis can be used as an indicator of exposure to specific environmental toxins. Cytochrome P450 assays are useful because genetic regulation of the enzyme can be induced by certain substrates (12).

There are two types of P450 induction; one requires phenobarbitone as a substrate, and the other requires carcinogenic polycyclic hydrocarbons such as PCBs, CDDs, and CDFs as a substrate. This second type of induction occurs with cytochrome P450 1A1 (CYP1A1), which is believed to have evolved at least 800 million years ago as a way for animals to metabolize plant chemicals (12). Cytochrome P450 1A1 can be induced in animals by planar molecules such as planar PCBs and CDDs; 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) is the most potent inducer known (12). These specific planar molecules bind readily to the cytosolic aryl hydrocarbon receptor (AhR) due to a similarity shared in the number of chlorine atoms present at the para and meta positions of the chemical structure. Although the main function of the AhR is unclear, it allows planar molecules to be translocated into the nucleus and induce CYP1A1 by suppressing normal genomic control of transcription (12).

Cytochrome P450 1A1 induction is a potent biomarker of ecosystem-wide exposure to PCBs and dioxin-like compounds due to its occurrence in most animal species. CYP1A1 induction is quantifiable, it indicates specific types of exposure, and its induction is manifested as a reversible subclinical effect (14). Rather than assessing the toxicological endpoints of PCB and dioxin exposure, CYP1A1 provides a measurement of alterations that affect the bioavailability and metabolism of carcinogens and other toxins (14). Sustained CYP1A1 induction can lead to an increase in the rate of metabolism and activation of carcinogens and mutagens, leading to increased formation of oxidative DNA adducts (12). Activated metabolites can also be transported to distant tissues where they cause oxidative damage and other adverse effects (15).

ECOLOGICAL IMPACTS OF PCBS AND DIOXIN-LIKE COMPOUNDS ON FISH

PCBs and dioxin-like compounds have impacted aquatic ecosystems through paper mill effluents, other industrial discharges, urban runoff, and atmospheric deposition (4). These contaminants persist in sediments and bioaccumulate, causing chronic exposure in many fish species (Table 1). Of all fish studied to date, salmonids are the most sensitive to chlorinated hydrocarbons, especially in regard to reproductive effects. They are thus useful as test organisms for the many possible physiological effects of exposure to PCBs and dioxin-like contaminants (16).

Chronic exposure to TCDD increases adult mortality in female rainbow trout (*Oncorhynchus mykiss*) in a dose-dependent fashion after a relatively long exposure of at

Table 1. Chemical Properties of PCBs, CDFs, and CDDs

Compounds	Commercial Uses and Sources into the Environment	Estimated Environmental Half-Life[a]
Polychlorinated biphenyl	Insulators, coolants in capacitors and transformers	Vapor phase: 12.9 days for monochlorobiphenyl to 1.31 years for heptachlorobiphenyl Freshwater: 6.8–9 years
Chlorinated dibenzofuran	By-product of heating PCBs, incineration, and chlorine bleaching	Surface water: 7 days–4 weeks Soil: 7 days–4 weeks Aerobic aquatic: 7 days–4 weeks Anaerobic aquatic: 28 days–16 weeks
Chlorinated dibenzo-*p*-dioxin	Herbicides, by-product of incineration and bleaching	Surface water: 1.15–1.62 years Soil: 1.15–1.62 years Aerobic aquatic: 1.15–1.62 years Anaerobic aquatic: 4.58–6.45 years

[a] References 4, 11.

least 26 weeks (16). TCDD exposure, it is also believed affects behavior in rainbow trout, making them less active and responsive (17). Reproductive outcomes are manifested in the decreased survival of young and a large number of deformities, although egg characteristics such as weight, lipid content, and total number of eggs produced do not differ from those of unexposed populations. TCDD-exposed rainbow trout young experience an unusually high incidence of yolk sac edema, a disease rarely seen in unexposed fish (17).

Chlorinated hydrocarbon exposure can also lead to AhR-mediated induction of CYP1A1 in rainbow trout and in many other species of fish, making it one of the most consistently observed outcomes in fish toxicology. CYP1A1 levels naturally fluctuate in female rainbow trout and decline as they approach their reproductive phase. It has been observed that the fluctuations are associated with the health of the fish and its environmental conditions. Although it is unclear exactly what role the enzyme plays in the life cycles of fish, it may be involved in mitigating yolk sac edema and a number of other adverse health effects, both directly and indirectly (16).

Several factors affect the intensity of cytochrome P450 induction and PCB/dioxin toxicity in fish. The potency of the compound, or mixture of compounds, determines the extent of induction and subsequent toxicity. In addition to being the most potent CYP1A1 inducer, 2,3,7,8-TCDD is considered the chlorinated polycyclic hydrocarbon most toxic to all life and thus has a toxic equivalency factor (TEF) of 1. In rainbow trout and carp, TCDD is followed in toxicity by CDFs, whose TEFs range from 0.359 to 0.028, and nonortho PCBs, whose TEFs range from 0.00016 to 0.000041 (17,18).

Lipid levels also play a role in CYP1A1 induction, toxicant bioavailability, and baseline health conditions of fish. Linoleic acid (18:2) controls hepatic cytochrome P450 concentrations, high levels of 18:2 decrease enzymatic activity (19). Chlorinated polycyclic hydrocarbons have high affinity for lipids and can be readily stored in the adipose tissues of fish. This type of storage is believed beneficial by reducing chronic exposure, although it can be harmful if the tissue is mobilized.

METHODS FOR ASSESSING CYP1A INDUCTION AND THE RATIONALE FOR INCLUDING IT IN ECOTOXICOLOGICAL ASSESSMENTS

CYP1A1 induction is an appropriate biomarker of PCB/dioxin exposure in fish because it is easily and rapidly quantified, specific, and has a temporary, reversible effect. There are various methods for assaying cytochrome P450 induction, using well-established criteria to characterize accurately the extent of induction in the liver and other tissues of interest. The level of induction may be used as a measure of potential adverse health effects in fish, without the manifestation of disease end points. Ideally, a biomarker should quickly signal adverse effects before they become serious and irreversible (14). CYP1A1 induction fits this criterion; it is not a disease end point itself, but an indicator of potential DNA damage through carcinogen activation, and may be reversed once exposure ends (15).

Induction can be examined in terms of mRNA production, protein synthesis, or enzymatic activity, and there are methods for assessing cytochrome P450 induction at each of these stages: mRNA quantification, immunologic protein determination, and assays of enzymatic activity (20). mRNA quantification is a relatively simple and rapid method compared to immunodetection and enzyme assays and may be a more useful tool for measuring aquatic pollution through cytochrome P450 induction. One process involves isolating CYP1A RNA from tissues of interest, synthesizing cDNA, designing primers to amplify specific regions of CYP1A cDNA, and quantifying using reverse transcription-polymerase chain reaction (RT-PCR) and gel electrophoresis techniques (20,21). Other studies have used slot blot analysis and RNA spectrophotometry to quantify CYP1A induction (22).

Immunodetection methods, such as Western blotting or immunohistochemistry, require identifying antibodies for specific cytochromes P450; monoclonal antibody 1-12-3 is specific to CYP1A1 and can detect CYP1A in all fishes studied thus far (23). The antibody and developer are applied to tissue samples and incubated until staining has developed. The resulting staining pattern indicates which cells have expressed CYP1A1 and to what degree. The intensity of CYP1A staining is measured on a scale of 0 to 15, where zero indicates no induction of the enzyme (23). The advantages of immunodetection methods are that they have the sensitivity to detect very small quantities of cytochrome P450 in all types of cells (15). The drawbacks are that these methods require a longer induction time than mRNA quantification, and it is uncertain whether appropriate antibodies can be found for all species of fish (20).

Enzyme assays measure the biotransformational activities of induced CYP1A on specific substrates. One type of assay examines the deethylation of 7-ethoxyresorufin (EROD) to resorufin, which can be compared to a resorufin reference (12). The dealkylation of 7-pentoxyresorufin (PROD) and UDP-glucuronosyltransferase activity (UDP-GT) are also used, and all three types of biotransformation may be quantified by using fluorescence spectrophotometry (24). Enzyme assays provide a good quantitative method for determining CYP1A induction, but the induced enzyme is subject to denaturation prior to EROD, potentially underrepresenting the extent of induction. Furthermore, certain pollutants may inhibit EROD, masking their effect on CYP1A1 induction (20).

CASE STUDIES USING P450 AS AN INDICATOR OF POLLUTANTS IN FISH

The Atlantic Tomcod in the Hudson River Estuary of the United States

The Hudson River contains aromatic hydrocarbon contaminants released from industry, municipal wastewater treatment plants, and sewage outflows. During a span of 30 years, hundreds of thousands of pounds of PCBs were released from two major sites impacting the Hudson River estuary (22). CDDs and CDFs were released during a 20-year period by a company manufacturing the herbicide 2,3,4-T, and from municipal waste incineration. Therefore, the estuarine sediments contain high levels of contaminants that have bioaccumulated in fish, including the Atlantic tomcod (22).

Yuan and co-workers (22) used Atlantic tomcod to compare hepatic CYP1A1 mRNA expression in relationship to sediment levels and hepatic burdens of chlorinated aromatic hydrocarbons and to evaluate CYP1A1 as a biomarker for mapping sediment contaminant concentrations in the Hudson River estuary. Previous studies had linked tomcod body burdens of PCBs, CDDs, and CDFs to regions of high sediment contamination and linked body burden of chlorinated aromatic hydrocarbons to CYP1A1 induction. The authors observed significant differences in CDD and CDF body burdens that varied across the estuary and sediment contamination levels. They also found that CYP1A1 induction varied significantly across sediment contamination levels. However, CYP1A1 induction did not correspond to the type of chlorinated aromatic hydrocarbon or to the TEF. The authors hypothesized that polyaromatic hydrocarbons (PAHs)—also present in the Hudson River estuary but not included in the study—were partially responsible for the observed CYP1A1 induction. Additionally, chronic exposure to PCBs, CDFs, and CDDs, it was shown, depletes AhR cells, thereby lowering the level of CYP1A1 inducibility and restricting the ability to predict exposure in fish based on enzyme levels.

Carp Fish in Hikiji River, Kanagawa Prefecture, Japan

Between 1992 and 2000, dioxin-contaminated raw sewage was released into the Hikiji River, Japan from an industrial waste incinerator (25). The toxic equivalent (TEQ) of 3.0 g of TCDD was released, and water concentrations ranged from 0.93–8.7 pg-TEQ/L in the year 2000. Agricultural runoff and municipal incinerators contributed a variety of other CDDs as well as CDFs. Sakamoto and co-workers examined the level of CYP1A induction in carp from the Hikiji River, both upstream and downstream from the effluent discharge, in conjunction with indicators of their reproductive health (25).

Muscle tissue analysis of carp from the contaminated downstream region showed higher concentrations of several different CDDs, CDFs, and coplanar PCBs. Liver microsomal CYP1A content was significantly higher in the exposed male and female carp, although EROD activity was increased only in females. Serum estrogen levels, an important factor in the initial stages of oocyte development, were low in the exposed fish and significantly correlated with CYP1A content. Reproductive health markers were also correlated to estrogen levels; exposed females produced fewer oocytes containing yolk protein, although the difference was not statistically significant. The investigators noted that estrogen poses a problem in interpreting CYP1A induction due to its interactions with the enzyme. It is known that, of all endogenous compounds, estrogen has the largest impact on CYP1A activity. High estrogen levels during fish reproductive phases are associated with low CYP1A levels. However, the study found a consistent pattern of increased CYP1A induction in exposed carp across all serum estrogen levels.

PROSPECTS FOR USING CYTOCHROME P450 AS A BIOINDICATOR

Though its mechanisms are not fully understood, CYP1A induction, it has been shown, is a very effective biomarker for fish exposure to PCBs and dioxin-like compounds. As Yuan et al. demonstrated, it is difficult to distinguish the effects of PCBs from those of CDDs, CDFs, and PAHs, and thus it is not yet possible to use CYP1A1 induction as a direct measure of one particular aquatic contaminant or class of chemicals. Nor are there adequate data on the level of response for all fish species residing in contaminated waterways. Future research must better quantify the dose–response relationship between exposure and induction across species and elucidate the various modifications of CYP1A induction by endogenous agents, fish health status, and other environmental conditions. Toward this end, the development and breeding of genetically engineered indicator fish with reporter genes such as bioluminescence or green fluorescent protein linked to the inducer locus of cytochrome P450 genes may ultimately prove indispensable.

WATERBORNE DISEASE.

See Water Related Diseases

WATER RELATED DISEASES

Mark J. Walker
University of Nevada
Reno, Nevada

Water related diseases can be placed into four categories: (1) water-based disease, (2) waterborne disease, (3) water vectored disease, and (4) water washed disease. Infectious microbes that cause disease within these categories include bacteria, enteric viruses, parasitic protozoans, helminthes, and algae. The health effects of infection vary considerably, from symptomless to temporary mild illness to prolonged illness to death. Each category represents a distinct pathway and mechanism for infection by a microbial pathogen. Symptoms of infection, such as gastrointestinal upset, may be common across categories.

The categories represent differences in strategies that can be applied to control the prevalence of infection.

Water-based diseases are caused by microorganisms whose reproductive cycles involve passage through an aquatic animal. If the aquatic animal is not present, the microorganism cannot reproduce and, consequently, cannot infect humans. As an example, trematodes, *Shistosoma* spp. (blood flukes), cause the disease schistosomiasis. This disease occurs in China, Japan, the Philippines, Indonesia (infection with spp. *japonica*), throughout Africa (spp. *haematobium*), in Southeast Asia (spp. *mekongi*), and in western and central Africa (spp. *intercalatum*). Shistosomes must pass through a snail in the aquatic environment to develop to a form that infects people (the cercacia). The cercacia enters the bloodstream by passing through skin when people come in contact with contaminated water. The parasite is reintroduced into water as an egg contained in human feces. Control programs to prevent water-based diseases are often designed to eliminate the intermediate aquatic host, using molluscicides, snails that compete for the same habitat but do not act as intermediate hosts, or snail eating fish or birds. The most effective control programs include education about the life cycle, including proper disposal of human wastes.

Waterborne diseases are part of the fecal–oral cycle of infection. This type of disease may be transmitted by many routes, including water contaminated by feces from an infected host. Microorganisms, in a life cycle stage that may infect a new host, are excreted and enter water that is then consumed. Common waterborne microbial pathogens include protozoa (such as *Cryptosporidium* and *Giardia*), viruses (such as *hepatitis*), bacteria (such as *Salmonella* and *Shigella*), helminthes (such as *Ascaris*) and algae (such as *Schizothrix*). The likelihood of infection upon consumption depends upon the virulence of the strain present, survival in the aquatic environment, the number of organisms ingested, the estimated infectious dose, and the susceptibility of the host. As an example, cryptosporidiosis is a gastrointestinal upset caused by ingestion of the environmentally resistant stage of *Cryptosporidium parvum,* the oocyst. This parasitic protozoan has a wide range of hosts, including domesticated animals and wildlife. Oocysts of *Cryptosporidium* spp. are found in surface waters throughout the world. The disease is usually self-limiting, unless the infected subject is immunocompromised.

Immunocompetent hosts develop an immune response to the parasite which dramatically diminishes the likelihood of illness after initial exposure. Control measures for waterborne diseases include water treatment, using flocculants, settling and filtration processes, followed by application of disinfectants such as sodium hypochlorite. Education is an important component of strategies for reducing the prevalence of waterborne diseases, especially education about the fecal–oral route of infection and the role of proper human waste disposal and personal hygiene in preventing disease transmission.

Water vectored diseases are caused by microorganisms that have intermediate hosts in insects that reproduce in aquatic environments and transmit pathogenic microorganisms as part of feeding on human blood. If the aquatic environment needed for the insect to reproduce is not present, the prevalence of the disease is reduced. Malaria, yellow fever, and onchocerciasis are water vectored diseases associated with mosquitos and black flies, respectively. The parasitic microorganisms that initiate disease in humans undergo a portion of their life cycles in the insect host and are transmitted during the bite directly into the human bloodstream. In malaria, the protozoan species of genus *Plasmodium* must develop in an anopheline mosquito. When the female mosquito bites an infected person, it draws blood containing forms of the parasite that develop further within the mosquito, eventually entering the salivary glands. The infected mosquito then injects the developed form into the next human host in saliva secreted during the bite. The anopheline mosquito requires standing, fresh waters for reproduction. Common habitats for breeding include ponds and marshes. Control programs to prevent water vectored diseases focus on eliminating aquatic habitat for insect hosts and reducing the prevalence of disease in human hosts. Activities for this include draining perennially wet areas to remove standing water and application of pesticides or oils designed to kill developing mosquito larvae.

Water washed diseases are caused by contact with water contaminated with fecal material and microorganisms that colonize and reproduce in skin lesions or vulnerable tissues. Common microbial pathogens that cause this type of infection include *Pseudomonas* spp. and *Staphylococcus* spp. This type of water related illness is most associated with lack of adequate supplies, which leads to inadequate personal hygiene. Typical water washed diseases include skin irritations and ulcers, conjunctivitis, and trachoma. Increased supply, coupled with improved sanitation and education, often reduces the prevalence of water washed disease.

DISHWASHING WATER QUALITY PROPERTIES

Eva Ståhl Wernersson
Erik Johansson
GS Development AB

Håkan Håkanson
University of Lund
Lund, Sweden

INTRODUCTION

Water is used as a rinse medium in dishwashing to remove soil from the dishes. An important requirement of the process is that the consumption of fresh water should be moderate, because the supply of fresh water in many countries is limited. Furthermore, the dishwater should reduce the microbiological activity (even when a dishwasher is not used) to diminish the risk of cross-contamination from the dishwater to the dishware.

In dishwashing, it is not only the dishwater that contributes to the cleaning of the dishware, but also the dishwashing process and the detergents. The dishware covers a range from glasses to pots and pans, which consist of a variety of materials such as glass, china, ceramics, thermostable plastics, stainless steel, and aluminum. The dishwashing processes use techniques from hand dishwashing or machine dishwashing to granule-assisted pot washing. For hand dishwashing, the dishware is soaked in water with hand dishwashing detergents (pH 7 to 8) before cleaning. The contact time between the dishware and the dishwater is in the range of 20 to 60 minutes, whereas in dishwashers, the contact time between dishwater and dishware is on the order of 1 to 10 minutes. The dishwashers use detergents with a pH from 12 to 14 that in the dishwater solution becomes pH 9 to 11. In all dishwashing processes, the importance of rinsing the dishware with fresh water is unquestionable (1). In the international standards (2,3), either hot fresh water at a temperature of 85 °C or cold fresh water with additives of disinfecting chemicals such as chlorine should be used to achieve hygienically clean dishware.

The microbiological status of the dishwater is of great importance, because this could cause cross-contamination and thereby the spread of infections (4,5). Therefore, this subject will be addressed more thoroughly.

CHARACTERIZING DISHWATER QUALITY

Dishwater consists of fresh water, detergent, and food residues. Depending on the hardness of the fresh water supply, detergents with more or less complex-acting properties are used. In hand dishwashing, the concentration of the washing-up detergent is around 0.05% (6), and in dishwashers, it is normally about 0.2% (7). The soil in the dishwater can be anything ranging from lipstick residues on glasses to carbohydrates like starch or vegetable fibers, proteins, animal or vegetable fats, and microorganisms from food residues.

There are several parameters to consider when characterizing dishwater, such as the conductivity, the pH, the temperature, the chemical oxygen demand (COD), the general microbiological level expressed as aerobic plate count (APC), and the characterization of the microbiological content. The amount of solid substances in dishwater is low; it varies from 5 mg/L (dishwasher for glasses and cutlery) to 5000 mg/L (pots and pans machine) according to Harpel (8) and our own measurements.

The conductivity is commonly used to monitor the concentration of the detergent used in dishwashers. However, the conductivity can be affected by the ions of the soil dispersed in the dishwater, and this could cause a malfunction of the dosage of the detergent.

The pH is a result of the amount and type of detergent used and the soil on the dishware. The organic soil in the dishwater is hydrolyzed by the high pH into smaller components. The influence of the pH on the microbiological growth in dishwater is shown in Fig. 1. From the figure, it can be seen that a change of the pH from 7 to 9 at 65 °C has a relatively small influence on the reduction of the concentration of the investigated bacteria, *Enterococcus feacium*. The samples were taken and analyzed 30 minutes after the addition of the bacteria, where the initial concentration was measured to be 50000 cfu/mL (^{10}log 4.7). The detergent used in the experiment was Gigant (Diskteknik, Sweden), an ordinary alkaline dishwasher detergent used in professional kitchens. The chosen test microorganism in this investigation is a rather thermostable bacteria, used in international standards (3) and in literature (8).

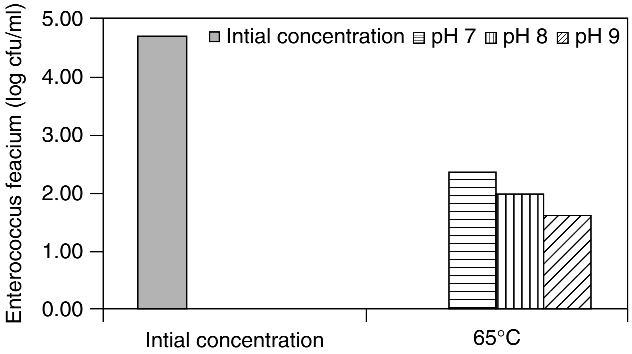

Figure 1. The reduction, 30 minutes after injection of *E. faecium* in dishwater, as a function of pH at 65 °C dishwashing temperature.

The temperature of the dishwater is determined by the process used. For hand dishwashing, the temperature is normally 40–45 °C (9), and for dishwashers, the temperature is 55–65 °C (7). The influence of the temperature is vital for the reduction of the concentration of bacteria in dishwater (see Fig. 2). For this microorganism, the reduction after 30 minutes is negligible for temperatures lower than 55 °C. However, at 65 °C there is a noticeable reduction of the concentration of *E. feacium*. For comparison, in Fig. 2, the reduction of the concentration of the bacteria for the conditions in

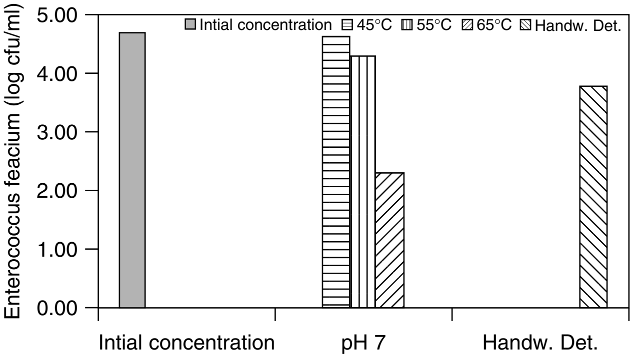

Figure 2. The reduction of *E. faecium,* 30 minutes after injection in dishwater, as a function of temperature of the dishwaters. The pH was kept to 7. For comparison, the reduction of *E. faecium* for the same time, using hand dishwashing detergent at 45 °C dishwashing temperature.

hand dishwashing is included. The decrease in microbiological activity depends solely on the antibacteriological properties of the detergent (Dizzy, Diskteknik, Sweden). Even with longer exposure times of microorganisms in dishwaters containing hand dishwashing detergents, the reduction rate will be low (6,10). Because of safety regulations in many countries, hand dishwashing cannot be performed at temperatures above 55 °C.

Another important factor of the temperature is the emulsion of fats into dishwater, which is considerably more effective at higher temperatures.

The COD depends mainly on the type and the amount of soil on the dishware. Also, the detergent adds to the value of the COD for dishwater. Values ranging from 500 to 5700 mg/L are reported in literature (8) and confirmed by our own measurements (see Fig. 3). Dishwater samples were taken in a professional kitchen from a pot and pan machine. The first sample was taken before the changing of dishwater. The second sample was taken after draining and filling the dishwater tank with fresh water and detergent, and the following ones after each dishwashing cycle. In this experiment, the increase of the COD is about 270 mg/L for each cycle. The manufacturers of one-tank machines recommend changing the dishwater after about 20 dishwashing cycles.

The microbiological content of the dishwater is more difficult to predict. There are several types of active bacteria in dishwater. In the studies of Mattick et al. (9) and Mospuye and van Holy (11), it is obvious that the distribution of the species found in the food residues are transferred to the dishwater. The most frequently reported microorganisms are *Bacillus cereus, Bacillus* spp., *Campylobacter* spp., *Clostridium prefringens, E.coli*, Enterobacteriaceae, *Salmonella* spp., and *Staphylococcus* spp. (9,11–13). Some of these are foodborne pathogens that pose a considerable risk of the spread of infection, if cross-contamination occurs (4).

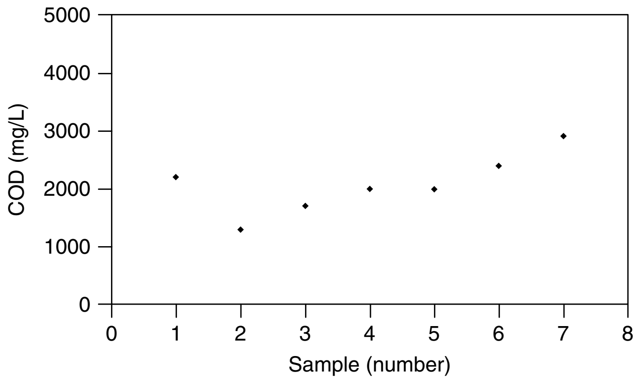

Figure 3. COD of dishwater samples as a function of sample numbers.

Reported values of the APC in dishwater show that hand dishwashing exhibits higher values of the APC than does dishwater from dishwashers (see Table 1) (9,12,13). The content of Enterobacteriaceae and *Bacillus cereus* in the dishwaters from the studies can also be seen in the same table. The level of the APC ranges from $^{10}\log 2.6 \pm 0.8$ to $^{10}\log 4.0 \pm 1.2$. The observations confirm that in hand dishwashing conditions, with a lower temperature and less aggressive detergents, the microbiological activity is higher than in dishwater from dishwashers.

ENVIRONMENTAL ASPECTS

An important factor from an environmental point of view is the consumption of water. The largest consumption of water is for hand dishwashing. In professional dishwashers, the dishwater is reused up to 20–30 cycles, and only diluted with fresh water from each rinse cycle with about 10% of the tank volume. The tank volume ranges from 50 to 250 L in dishwashers. In dishwashers, where the cleaning process is assisted by plastic granules, the granules are reused for about 2000 dishwashing cycles.

To reduce the microbiological activity in dishwater, several methods can be used, for instance, ozone, high temperature and high pH, and disinfecting chemicals such as chlorine (14). From an environmental point of view, high temperature is the most agreeable and efficient parameter to use (see Fig. 2). In many countries, detergents containing aggressive chemicals, like chlorine, are not recommended, which is consistent with an environmental approach. Even the use of ozone is questionable because its general reactivity is well documented.

Table 1. The APC, Entereobacteriaceae, and *Bacillus cereus* Found in Different Dishwaters (cfu/mL) from Professional and Domestic Kitchens

Type of Establishment	Domestic Homes (9)	Hospices (9)	Street-Vended Food (11)	Professional Kitchens (13)
Dishwashing process	Hand dishwashing	Hand dishwashing	Hand dishwashing	Dishwasher
Number of samples	52	10	18	16
APC				
Mean	$1.3 \cdot 10^5$	$2.3 \cdot 10^4$	$1.0 \cdot 10^4$	$2.7 \cdot 10^2$
Range	10^1 to $>3 \cdot 10^5$	$3 \cdot 10^3$ to $1 \cdot 10^5$	$3 \cdot 10^3$ to $3 \cdot 10^6$	<10 to 10^4
Enterobacteriaceae				
Mean	$7.1 \cdot 10^4$	$7.2 \cdot 10^2$	ND	1.2
Range	<1 to $>3 \cdot 10^5$	<1 to $>6 \cdot 10^3$	ND	<1 to 10^2
Bacillus cereus				
Mean	ND	ND	46% of 65 isolates were determined	$2.7 \cdot 10^2$
Range				<10 to 10^4

ND: not determined.

CONCLUSIONS

The temperature is the most important factor in maintaining a low level of microbiological activity in the dishwater. This parameter is also from an environmental point of view less harmful than ozone or detergents containing other oxidizing chemicals. According to the international standard, the heat load on dishware should exceed 3600 HUE (Heat Unit Equivalence) to achieve hygienically clean dishware.

To shorten the dishwashing cycle time, granule-assisted dishwashing could decrease the energy and detergent consumption in the cleaning process. The rinsing procedure with fresh water must follow the above-mentioned standard.

Hand dishwashing consumes more fresh water than do dishwashers. It also uses a lower temperature, which has a considerably lower effect on the reduction of the microbiological activity of the dishwater. It is important to keep an acceptable quality level of the reused dishwater, because otherwise the dishwashing process and the rinse process will not be able to obtain clean dishware. To improve the dishwater quality, some manufacturers have integrated cyclones or filters into their dishwashers.

BACKGROUND

Water is one of Earth's most important natural resources, and its role in our everyday life cannot be ignored. Civilizations began and were centered within regions of abundant water supplies. However, water present in our natural environment is not always potable for human consumption. Many lives have been lost as recently as the early part of last century because of waterborne diseases such as cholera and typhoid fever. Tragically, this battle still continues elsewhere in developing countries where infant mortality is often the result of waterborne diseases (1). To be "potable," water needs to be disinfected with a method such as chlorination, which has been successfully practiced in the United States for over a century.

However, chlorinated disinfection by-products (DBPs) have been a concern for many years because of their adverse effects on human health. A great deal of research has been conducted on these chlorinated by-products. Several chlorinated DBPs have already been identified since the discovery of trihalomethanes (THMs) in 1974 (2). Other chlorinated disinfection by-products include haloacetic acids (HAAs), chloral hydrate, haloketone, and haloacetonitriles. One way to identify the total amount of chlorinated DBPs is to measure the total organic halide (TOX) concentration. However, if all identified chlorinated DBPs were considered, they would only account for about 50% of the TOX (3). The unidentified

DBPs may be too large (nonvolatile) or too small (polar) in molecular weight to be detected by currently accepted analytical methods such as gas chromatography.

In recent years, other alternative disinfectants have been discovered and used by scientists, including chloramines, chlorine dioxide, ozone, potassium permanganate, and ultraviolet irradiation. However, because of proven reliability, cost, and availability, chlorine has remained the chemical of choice. As a result, of all the municipal water supplies that are being chemically disinfected, at least 70% use chlorine (4). Unfortunately, in the process of attacking these unwanted microorganisms, the chlorine reacts with other impurities such as natural organic matter (NOM) and bromide, and it can lead to the formation of carcinogenic DBPs (5). Alternative disinfectants may help to minimize these DBPs. However, these oxidants/disinfectants may produce other DBPs, which may also be harmful (4).

Health-related studies on these carcinogenic by-products suggest that the presence of as low as 6 μg/L of chloroform (chlorinated DBP) can have a lifetime cancer risk of 10^{-6} (6). Another recent DBP-related risk study (7) showed that as the bromide concentration increases from 50 μg/L to 200 μg/L, it substantially increases overall DBP-related cancer risk. To reduce the public health risk from these toxic compounds, the U.S. Environmental Protection Agency (EPA) has regulated THMs since 1979, with a maximum contaminant level (MCL) of 100 μg/L. In view of recent studies, the EPA has proposed a more stringent disinfection/disinfection by-products (D/DBPs) rule, which will be implemented in two stages. Stage 1 (effective from 1998) of the D/DBP rule would reduce the current MCL for THMs from 100 μg/L to 80 μg/L, with a new MCL restriction of 60 μg/L for HAA_5 (sum of five HAA species). Stage 2 (effective from 2002) would further reduce both of these MCLs for THMs and HAAs (as HAA_6) by an additional 50% (8). However, the success of water utilities in meeting these stringent and challenging MCLs will require a better understanding of the DBP precursor material, NOM, and its reactivity with chlorine in forming DBPs.

The most effective strategy to decrease the formation of DBPs would be to reduce the amount of NOM, which is the main precursor of DBPs, before chlorination. The processes that are available to remove this precursor material include membranes, granular activated carbon adsorption, biofiltration processes, and chemical treatment by coagulation. Coagulation has remained the most widely accepted method by utilities to remove NOM from natural waters.

PRECURSOR REMOVAL BY COAGULATION

Coagulation

Coagulation is an age-old practice in water treatment and has not changed much over the years. Until recently, coagulation has primarily removed color (e.g., NOM) and turbidity from water. More attention has been given to NOM removal from water. In the early 1990s, the EPA proposed the enhanced coagulation (EC) rule to further reduce health-related risks from these DBPs and compelled utilities to practice EC to further remove NOM. In enhanced coagulation, NOM removal is based on raw water total organic carbon (TOC) and alkalinity content (Table 1). EC has already been evaluated by several researchers and has been found to be effective in both NOM removal and DBP minimization. Other benefits include reduction in chlorine demand in finished water (9). The main objective of EC is to achieve 15% to 50% removal of organic matter before disinfection. However, some of the disadvantages of EC also reported from these studies include increased chemical use, which translates into higher operational cost; higher sludge production; and additional chemical costs associated with pH adjustments. Thus, more research is still needed to overcome these disadvantages.

Table 1. Percent of Organic Removal for Enhanced Coagulation Requirements Proposed for the DBP Rule

	Alkalinity, mg/L as $CaCO_3$		
TOC, mg/L	<60	60–120	>120
2–4	35%	25%	15%
4–8	45%	35%	25%
>8	50%	40%	30%

Coagulants Used for NOM Removal

Various types of metal coagulants are available to remove NOM. However, two of the most common conventional metal coagulants in water treatment are aluminum sulfate ($Al_2(SO_4)_3 \cdot 14H_2O$, commonly referred to as alum) and ferric chloride ($FeCl_3 \cdot 6H_2O$, commonly referred to as iron salt). Alum is currently the most widely used. However, over the past years, the application of iron salt as a coagulant has increased dramatically (10). Conventional coagulants of other types include aluminum-based sodium aluminate, aluminum chloride, and ferric sulfate (11). However, the application of these coagulants in potable water has been limited. Recently, various other types of (alternative) coagulants have been introduced. These specialized coagulants are more common in Europe and Japan than in the United States (12). These coagulants (patented products) are claimed to be more effective than the conventional coagulants. Conventional coagulants are basically salts of a strong acid (e.g., HCl or H_2SO_4) and a weak base ($Al(OH)_3$ or $Fe(OH)_3$). Thus, it is a mixture of cations (from bases) and anions (from acids). However, alternative coagulants are specially prepared and may include additional anions as additives (i.e., anions such as sulfate).

Effectiveness of Coagulation in Precursor Minimization

Numerous studies have focused on removal of the "humic" fraction of NOM that is believed to be the precursor for THMs. Thus, most of the research has focused on the removal of this fraction by coagulation and other processes. Oliver and Lawrence (13) studied raw water samples collected from treatment plants in the Great Lakes Basin to investigate the effect of alum coagulation in haloform reduction and reported a dramatic drop in haloform formation by alum coagulation. Chadik and Amy

(14) studied natural waters in six different geographical locations to evaluate the effectiveness of metal coagulants (alum and ferric chloride) in removing THM precursors. THM formation potential (THMFP) reduction by alum was in a range between 36% and 66%, whereas the reduction by iron was in a range between 33% and 77%. Alum was found to be more effective than iron in reducing TOC and THMFP. Jodellah and Weber (15) investigated THM precursor removal by alum coagulation, lime softening, and activated carbon adsorption, and they found that precursor removal was variable and concluded that greater removal of organic matter does not necessarily indicate greater reduction of THMFP. No correlation was found between TOC removal by these treatments and overall THMFP reduction. It can be concluded that the reduction of THMFP is dependent on the qualitative nature of the organic matter, rather than on the quantitative amount of organic matter. Thus, a careful assessment of the physical and chemical composition remaining after different treatments of NOM mixtures is required before a mechanistic explanation can be provided.

Hubel and Edzwald (16) studied the THM precursor removal by alum, high-molecular-weight polymers, cationic polymers (usually used as coagulant aids), and various combinations of these coagulants. In this study, it was concluded that cationic polymers were less effective in precursor removal as compared with alum when used as a sole coagulant, where alum removed 50% to 60% more organic matter than did cationic polymers. This study also indicated that the type of polymers used (polyacrylamide versus polyquaternary amine) (i.e., charge density and molecular weight) had slight effects on precursor removal. Cationic polymers as sole coagulants were found not to be effective in THM precursor removal, but they were effective in turbidity removal by forming denser and better settling flocs than alum alone. Knocke et al. (17) studied the effect of seasonal temperature variation in precursor removal in natural water by alum and ferric sulfate. The results showed that lower temperature (coagulation at pH 5.0) significantly reduced the rate of THM formation (2 °C versus 22 °C) for equivalent organic content.

SUMMARY

This study provides a general overview on coagulation and its effectiveness in removing NOM from natural waters for DBP minimization with various metal coagulants. Although other technologies such as activated carbon adsorption and membrane filtration are available to reduce DBP precursors, these alternative technologies are comparatively expensive processes (18). For the time being, coagulation may remain the technology of choice for DBP minimization. In addition, identification of DBP precursors based on detailed NOM characterization and fractionation techniques can provide mechanisms for how these precursor materials could effectively be controlled in natural waters. Once identified, these potential precursor materials could then be effectively removed by in-depth knowledge of coagulants and coagulation techniques.

INTRODUCTION

Disinfection of public water supplies is required in many countries to inactivate microbial pathogens and protect public health. Chlorine is the predominant disinfectant used worldwide for this purpose, and while chlorine provides significant benefit, it can create by-products that may cause adverse health effects. Disinfection by-products (DBPs) have been linked to bladder and rectal cancers and to adverse reproductive outcomes (1,2). The Safe Drinking Water Act amendments of 1996 required the United States Environmental Protection Agency (U.S. EPA) to develop regulations that balanced the conflicting goals of pathogen control with DBP minimization. The Stage 1 Disinfection By-products Rule established standards for trihalomethanes (THMs), haloacetic acids (HAAs), bromate, and chlorite in U.S. drinking water (3).

The use of alternative disinfectants in the United States has received increasing attention in light of DBP regulatory changes. The formation of DBPs depends both on the type of disinfectant used and the presence of precursors. Thus, there are essentially three approaches to reduce the occurrence of any particular DBP: (1) alternative disinfection, (2) other treatment options (e.g., that reduce either the presence of DBP precursors or the amount of disinfectant needed), and (3) approaches aimed at source water, such as watershed protection to limit the addition of DBP precursors to waterways, or the use of source water with naturally low precursor levels. The advantages and disadvantages of these options are briefly outlined below, including usage information, operational concerns, disinfectant properties, and potential impact on the occurrence of specific DBPs in drinking water supplies.

ALTERNATIVE DISINFECTANTS

A number of disinfectants are appropriate to treat drinking water on a large scale. Chlorine, chloramine, chlorine dioxide, ozone, and ultraviolet radiation are among the most widely used disinfectants. Ozone and chlorine dioxide are more common in some European countries, but most water systems use chlorine for either primary (predistribution) or secondary (residual) disinfection (4). Of all the choices, only chlorine and chloramine are suited for secondary disinfection to maintain residual protection in the distribution system.

Chloramine

Chloramines were first used to treat water in the United States and Canada in 1917 (5). Chloramination is increasing in the United States, with about 30% of medium and large utilities reporting its use in 1998, compared to 20% in 1989. Chloramination involves the addition of ammonia to chlorinated water; aqueous chlorine reacts with ammonia to form inorganic chloramines (6). A principal operational consideration is that the chlorine/ammonia dosage ratio must be monitored carefully to prevent the growth of nitrifying bacteria in distribution systems and storage reservoirs (7).

Chloramines are weaker disinfectants compared to chlorine, ozone, or chlorine dioxide. Chloramine *CT* (product of disinfectant concentration and contact time) values to control *Giardia*, *Cryptosporidium*, or viruses are up to four orders of magnitude higher than for the other disinfectants, making chloramines an impractical choice for primary disinfection (Table 1). Chloramines are therefore typically used only for secondary disinfection; the maximum residual disinfectant level (MRDL)

Table 1. *CT* (Concentration × Time) Values[a] for Alternative Disinfectants

		Virus			*Giardia*			*Cryptosporidium*
Disinfectant	Units	2 log	3 log	4 log[b]	1 log	2 log	3 log[b]	2 log[b]
Chlorine	mg · min/L	3	4	6	35	69	104	>4,000
Chloramine	mg · min/L	643	1067	1491	615	1230	1850	>25,000
Chlorine dioxide	mg · min/L	4	13	25	8	15	23	40[c]
Ozone	mg · min/L	<1	<1	1	<1	<1	1	3.9–10
UV radiation	mJ/cm^2	40	N/A[d]	N/A	N/A	N/A	N/A	12

[a] All values are at 10 °C, pH 6–9.

[b] Required removal for large public drinking water systems in the United States.

[c] Chauret et al. (8) report variable *CT* values for 2 log inactivation of *Cryptosporidium* at 21 °C, ranging from 75 to 1000 mg·min/L.

Source: References 6, 8–10.

for chloramines is 4 mg/L. Compared to chlorine, chloramines are more stable secondary disinfectants and may reduce taste and odor complaints. Chloramination may also be more effective than chlorine at inhibiting biofilm and bacterial regrowth in distribution systems (11).

The use of chloramines reduces the formation of two of the major regulated DBP groups—trihalomethanes and haloacetic acids. However, some DBPs, including dihalogenated acids and NDMA (*N*-nitrosodimethylamine), may increase in chloraminated systems (12,13). Source water chemistry and ammonia application timing influence the formation of chloramination by-products. For example, in one chloraminated system, high levels of iodoacids were attributed to the simultaneous application of chlorine and ammonia to source water high in iodide. When ammonia application is applied after significant free chlorine contact time, iodoacid formation is minimized (14).

Chlorine Dioxide

During the 1940s, the Niagara Falls, New York water treatment plant was the first North American utility to use chlorine dioxide for water treatment (15). Chlorine dioxide was used by 8% of medium and large utilities in the United States in 1998, more than triple the proportion that utilized it in 1989 (7). Chlorine dioxide must be generated on site, which requires significant operator skill; thus, it is relatively expensive in comparison to chlorine. Chlorine dioxide is flammable and explosive, and its use therefore requires significant safety precautions.

Compared to chlorine, chlorine dioxide is more effective at inactivation of *Cryptosporidium* and *Giardia* but less effective for *E. coli* and rotaviruses (see Table 1). Although chlorine dioxide CT values of 40 mg · min/L at 10 °C are reported to accomplish 2 log removal, (i.e., 99%) of *Cryptosporidium* (6), highly variable CT values have been reported at other temperatures (8). An advantage of chlorine dioxide is that disinfection efficiency is not dependent on pH or the presence of ammonia (16). However, the half-life decreases at $\text{pH} > 9$ and with increasing chlorine dioxide concentrations (17). The MRDL for chlorine dioxide is 0.8 mg/L (6).

Chlorine dioxide is effective at controlling DBP formation, since it can destroy precursors to trihalomethanes and haloacetic acids and does not oxidize bromide ion to bromate. The predominant DBPs formed by chlorine dioxide are chlorate and chlorite, which may lead to adverse human health effects (see the chapter entitled Health Effects of Commonly Occurring Disinfection By-products in the Municipal Water Supply). Chlorine dioxide can produce other DBPs such as dihalogenated HAAs and haloacetaldehydes (18). Due to the inability of chlorine dioxide to remove hydroxyfuranone precursors, high levels of MX and the brominated MX analogues have been found in waters with elevated total organic carbon and bromide (19).

Ozone

Ozonation was first used in The Netherlands in 1893 and remains a popular disinfection method in Europe (6). While ozonation was used for disinfection by less than 10% of large water utilities in 1998, its use is increasing in the United States (7). In the proposed Stage 2 Disinfectants and Disinfection By-products Rule, the U.S. EPA reported that in 2000 there were 332 plants of various sizes using ozone and 58 plants that were planning to install ozonation (20). Ozone is one of the strongest oxidants used to disinfect water and is the predominant choice of the bottled water industry. Although ozonation is a fairly expensive and complex treatment process, it has several operational advantages. These advantages include short contact time, taste and odor control, and improved coagulation and filtration efficiency. Ozone is very effective at microbial inactivation and is effective against viruses, *Giardia*, and *Cryptosporidium* (see Table 1). Because ozone can also degrade more complex organic matter that may promote microbial regrowth in distribution systems (21), and because ozone does not provide a protective residual, it must be used in combination with chlorine or chloramine in systems where residual disinfection is necessary.

Use of ozone limits the formation of chlorinated DBPs, but it can combine with bromide in water to form bromate, brominated organics, and other brominated by-products (22,23). Ozonation can also produce organic DBPs such as the aldehydes, ketones, ketoaldehydes, carboxylic acids, aldo acids, keto acids, hydroxy acids, alcohols, esters, and alkanes (23). Furthermore, if ozonation is followed by chlorination, the formation of aldehydes and ketones may allow subsequent formation of their halogenated derivatives (e.g., chloropicrin and other halonitromethanes) (19,21,24).

Ultraviolet Radiation

Ultraviolet (UV) radiation is not widely used to treat drinking water in the United States, but has been used extensively to treat wastewater (20). UV radiation can inactivate viruses, bacteria, and protozoans (9). The use of UV radiation is somewhat limited by intensive operational and maintenance requirements, and it is most effective in low turbidity waters. Advantages of UV radiation include a very short detention time requirement, so dedicated contact chambers are not necessary (25). However, a slow flow rate is required, and this may pose operational constraints. UV disinfection does not provide residual protection against bacterial regrowth in the distribution system. UV radiation alone forms few DBPs but DBP formation can still occur when UV disinfection is combined with secondary disinfectants (26).

OTHER TREATMENT OPTIONS

In addition to alternative disinfection, many treatment options are available to water utilities to reduce DBP formation. These include pH adjustment, disinfectant timing or treatment process changes, and physical or oxidative removal of DBP precursors. Changes to these complex treatment processes can have different effects on the various types of DBPs.

The impact of pH on DBP concentrations is reported by a number of researchers (27–32). In general, the concentrations of THMs increase while those of HAAs, HANs, and haloketones decrease with increasing pH. Many of the halogenated DBPs are hydrolyzed above pH 8, reducing their formation (33).

Treatment plant operators may be able to limit DBP formation by reducing contact time or the initial disinfectant dose. Changing the order of disinfectant application within the treatment chain should also be considered. This may include moving the primary disinfectant step to follow filtration, or changing the application point for the secondary disinfectant application (34). Distribution system maintenance may decrease residual disinfectant demand, allowing operators to use smaller amounts of disinfectant.

The major precursors to DBPs of concern are organic substances (e.g., humic and fulvic acids), bromine, and iodine. If treatment processes or primary disinfection methods that reduce DBP precursors are used, then secondary disinfection with chlorine or chloramine will produce lower levels of their associated by-products. Precursor removal can be accomplished by coagulation, filtration, or oxidative processes.

Coagulation is an important step in converting soluble precursors to particulate, which can then be removed by filtration or settling (35). Enhanced coagulation and enhanced softening processes are those that improve removal of DBP precursors over conventional treatment. Coagulants specified by the U.S. EPA as appropriate for precursor removal to achieve compliance with the Stage 1 Disinfection By-Products Rule include aluminum or iron salts, polyaluminum chloride, and cationic polymers, as well as anionic and nonionic polymers (36).

Physical removal of precursors includes processes such as microfiltration and biofiltration, which are used primarily in larger plants. Biofiltration through the use of sand filters or granulated activated carbon can reduce formation of halogenated DBPs (37). Passage of ozonated and chlorinated water samples through a rapid sand filter reduced the concentration of aldehydes by 26–62%, due to biological activity in the sand filters (38,39). However, removal of organic contaminants through biofiltration does not affect bromide concentrations in the treated water and results in greater formation of brominated DBPs (39). Other physical precursor removal techniques like electroporation (40) show promise but are in the early stages of development for practical use.

Oxidative precursor removal is another effective means of reducing DBPs. Ozone is effective at destroying precursors to MX and trihalogenated HAAs (19). Potassium permanganate is very effective at removing DBP precursors, both by oxidation and by enhancing coagulation (6). Some advanced oxidation processes (AOPs) that combine oxidation techniques show promise for utilities (10). Typical AOPs include combinations of ozone, hydrogen peroxide, UV radiation, solid catalysts, or sodium hypochlorite. Titanium dioxide photocatalysis, a combination of titanium dioxide and UV radiation (26), may be applicable for smaller utilities.

WATER QUALITY PROTECTION MEASURES

In the third edition of its guidelines for drinking water quality published in 2004, the World Health Organization (WHO) emphasized source water quality protection as a critical element to providing safe drinking water (41). Source water quality is highly variable, with some regions having high quality source waters and naturally low levels of DBP precursors. For example, some waters contain low bromide levels and low levels of total organic carbon. Such high quality waters are less likely to form certain by-products upon disinfection and may require minimal treatment to remove DBP precursors.

Source water protection, such as covered reservoirs, may help reduce DBP levels by limiting the amount of runoff of organic matter into surface water supplies. Other watershed management practices can reduce the amount of dissolved organic carbon in a water source and concomitant production of DBPs (42). Highly protected source waters, such as naturally filtered groundwater, may require minimal disinfection to remove microbial pathogens.

Providing safe, palatable water necessitates the use of a multiple barrier approach in which watershed protection, water filtration and disinfection, and maintenance of the water distribution system are addressed (43). Future trends in drinking water treatment in developed countries may shift the focus from water treatment to pollution prevention (44) and concentrate resources on maintaining outdated distribution systems and protecting the quality of source water.

WATER QUALITY ASPECTS OF DREDGED SEDIMENT MANAGEMENT

Anne Jones-Lee
G. Fred Lee
G. Fred Lee & Associates
El Macero, California

INTRODUCTION

The United States has 25,000 miles of navigable waterways, which include coastal waterways, such as the Intercoastal Waterway along the Eastern and Gulf Coasts; the major inland rivers, such as the Mississippi and Ohio; and major ports and harbors, such as New York, Galveston, Houston, Los Angeles, San Diego Bay, San Francisco Bay, Puget Sound, and those of the United States–Canadian Great Lakes. The U.S. Army Corps of Engineers (COE) is charged by the U.S. Congress with maintaining the navigation depth of these waterways as they fill with sediment. Maintaining navigation depth is considered to be of national importance to minimize transportation costs of bulk materials. To accomplish this, the COE dredges, or issues permits for contractors to dredge, about 500 million yd^3/yr of sediment from major waterways as well as smaller harbors, marinas, ports, and channels.

In the 1960s, it was beginning to be recognized that the sediments of some U.S. waterways were highly contaminated with chemicals that have the potential to be pollutants—that is, to impair the beneficial uses of waterbodies as domestic water supply sources or for aquatic life/fisheries. As the conventional method of disposal of dredged sediment was to dump it in deeper open water, concern developed about the solubilization and desorption of chemical constituents that were associated with sediment particles when sediments were dredged and then introduced into a watercolumn at a disposal site. In response to water quality impact concerns, the U.S. Army Corps of Engineers developed a $30 million five-year Dredged Material Research Program (DMRP) to investigate the water quality significance of potential pollutants in dredged sediments. As part of that program, the authors conducted extensive laboratory and field studies to investigate the release of sediment-associated contaminants and their impacts associated with open water disposal of dredged sediment (1–3), results of which are summarized or referenced herein.

IMPACT OF TYPE OF DREDGING/DISPOSAL OPERATION

The development of an approach to evaluate and regulate potential water quality impacts of dredging and dredged sediment disposal requires an understanding of what transpires during such operations. In his *Handbook of Dredging Engineering*, Herbich (4) described the various methods of dredging and dredged sediment disposal. Dredging is typically accomplished by either mechanical or hydraulic means.

Mechanical Dredging/Barge Disposal

Mechanical dredging typically employs a clamshell or dragline bucket to remove sediments, which are then deposited onto a barge. Water introduced during dredging drains off the barge. After the barge is towed to the designated disposal site, the sediment is released and drops as a fairly cohesive mass to the bottom. As limited mixing occurs of the sediments being dredged with water, mechanical dredging results in limited opportunity for release of constituents from the sediments to the water, which limits the potential for sediment-associated contaminants to adversely impact water quality.

Hydraulic Dredging

Hydraulic dredging involves sucking up the sediment as a slurry (Fig. 1) and pumping it to an open water or confined on land disposal area or into the holding hoppers of a hopper dredge for transport to an open water disposal site. The sediment:water ratio of the slurry is characteristically 1:4 by volume. The slurrying results in the mixing of the sediments with water, which tends to promote the release of constituents associated with the sediment and interstitial water into the slurry water. If hopper dredge is used, the excess water is typically allowed to drain off at the dredging site or during transport to the disposal site to optimize efficiency of sediment removal.

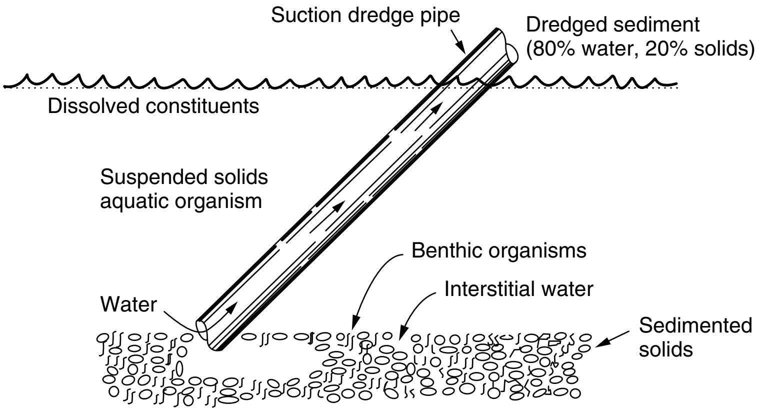

Figure 1. Diagrammatic representation of hydraulic dredging.

Hopper-Dredge Disposal

Figure 2 illustrates the watercolumn during disposal of dredged sediment from a hopper dredge. When the hopper dredge is at the designated disposal location, the hopper doors are opened and the sediment is released. Most of the sediment rapidly descends to the bottom as a fairly cohesive mass. As indicated in Fig. 2, the descent of the dredged sediment from the hopper to the bottom of the watercolumn forms a turbid cloud in the waters of the region.

In their evaluation of the nature and water quality impacts of dredging and dredged sediment disposal, Lee et al. (1) and Jones and Lee (2) monitored the watercolumn during more than 10 open water disposal operations by measuring more than 30 physical and chemical parameters at various depths in the watercolumn before, during, and after the passage of the turbid plume for each. Figure 3 shows the characteristic pattern of turbidity marking the passage of the turbid plume during open water disposal of dredged sediment. As indicated in Fig. 3, near the surface (2-meter depth) the turbidity persisted at a location a few tens of meters downcurrent from the dump for about 2 minutes. Near the bottom, at 14 meters, the turbid plume turbidity persisted for about 7 minutes. The plume typically dispersed to indistinguishable from ambient turbidity of the disposal area in about one hour.

Lee et al. (1) found that, in some instances, some increase occurred in concentration of some chemical constituents in this turbid cloud as well as some decrease in the dissolved oxygen (DO) concentration, as is shown in Fig. 4.

In the studies conducted by Lee et al. (1), the only constituent of potential concern that was released was ammonia. The potential impact of ammonia on aquatic organisms at an open water disposal site would have to be reviewed on a site-by-site basis, because it would be controlled largely by the sensitivity of the organisms there and the rate of dilution.

The turbid plume associated with open water dumping of mechanically dredged sediment is even less pronounced than with hopper-dredge disposal, because the

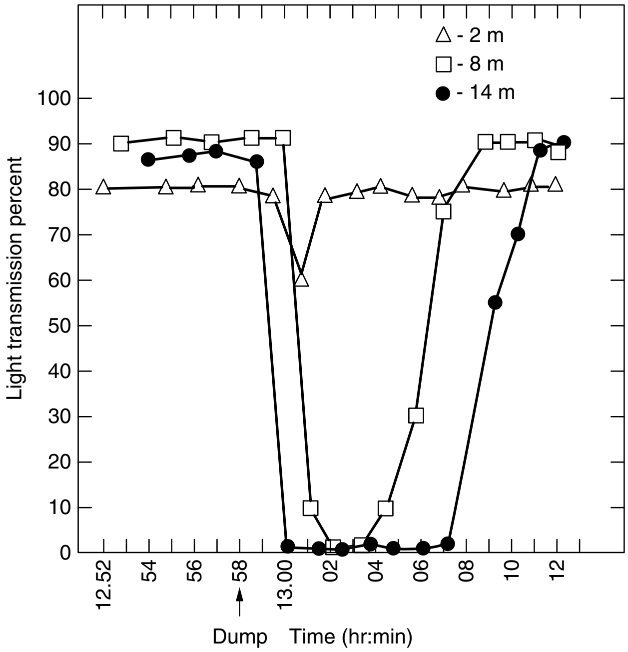

Figure 3. Percent light transmission with depth during passage of turbid plume from open water disposal of hopper-dredged sediment.

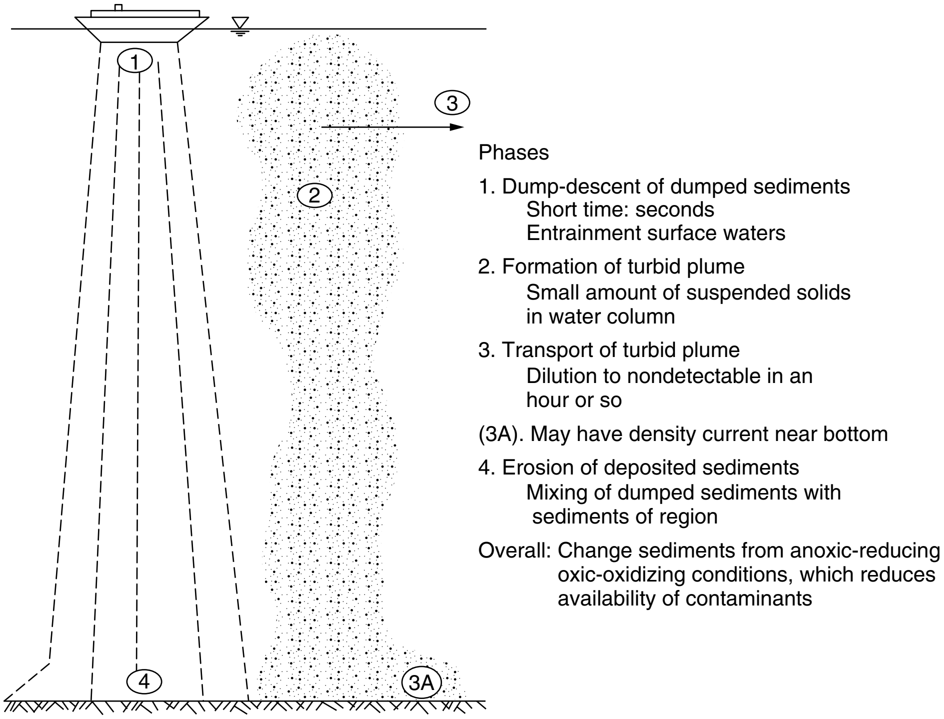

Figure 2. Hopper-dredge disposal of dredged sediment.

mechanically dredged sediment is a more cohesive mass. It was concluded by Lee et al. (1) that open water disposal of even contaminated sediments would not be expected to cause water quality problems in the disposal site water-column because of the limited releases and the short exposures that aquatic organisms could experience from such releases.

Pipeline Disposal

The open water pipeline disposal of hydraulically dredged sediments, illustrated in Fig. 5, presents a situation significantly different from that of dumping of mechanically or hopper-dredged sediments in open waters. In this process, the dredged sediment slurry is transported via pipeline to the discharge location where it is discharged. The slurry sinks to the bottom and moves downcurrent as an approximately one-meter-thick density current along the bottom. This density current has been found to persist for thousands of meters from the point of discharge during disposal operations. As this dredged sediment density current is typically characterized by low DO and/or the release of constituents such as ammonia, its presence at a location for extended periods of time (many hours to a day or so) could represent a significant adverse impact on aquatic organisms residing on the bottom in the path of the current. Ordinarily, however, such density currents do not persist in one location for extended periods because of the intermittent nature of pipeline disposal operations owing to frequent mechanical adjustments and the movement of the dredge. Further, the point of discharge is frequently moved because of the accumulations of sediments near the point of discharge.

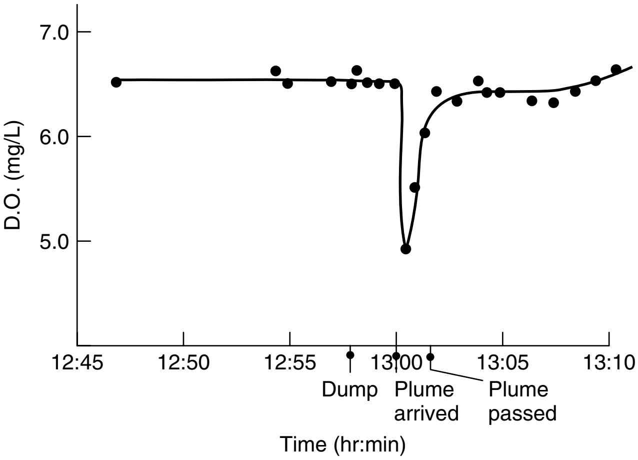

Figure 4. Dissolved oxygen concentration in near-surface waters during passage of turbid plume from hopper-dredge disposal of dredged sediment.

Upland-"Confined" Disposal of Dredged Sediments

It has been commonly assumed that "confined" disposal of dredged sediment on land or behind a dike to form an island in water is less environmentally damaging than open water disposal. This assumption misjudges the adverse impacts of open water disposal and misjudges the water quality protection afforded by "confined" disposal. It is now more widely recognized that upland disposal of contaminated dredged sediments has a greater potential for causing adverse environmental impact than open water disposal of dredged sediments.

As generally practiced, "confined" disposal does not truly confine deposited sediment or eliminate adverse impact. Rather, it provides a settling area where the larger, denser particles settle and the supernatant water and fine materials from the hydraulic dredging overflow the confinement and enter the nearshore areas of the nearby watercourse. Ironically, it is this overflow water that would represent a threat to water quality. It is the fine materials that do not readily settle in the disposal area that contain chemicals that could become available to adversely affect water quality. The area where the confined disposal overflow occurs (i.e., nearshore) is generally the

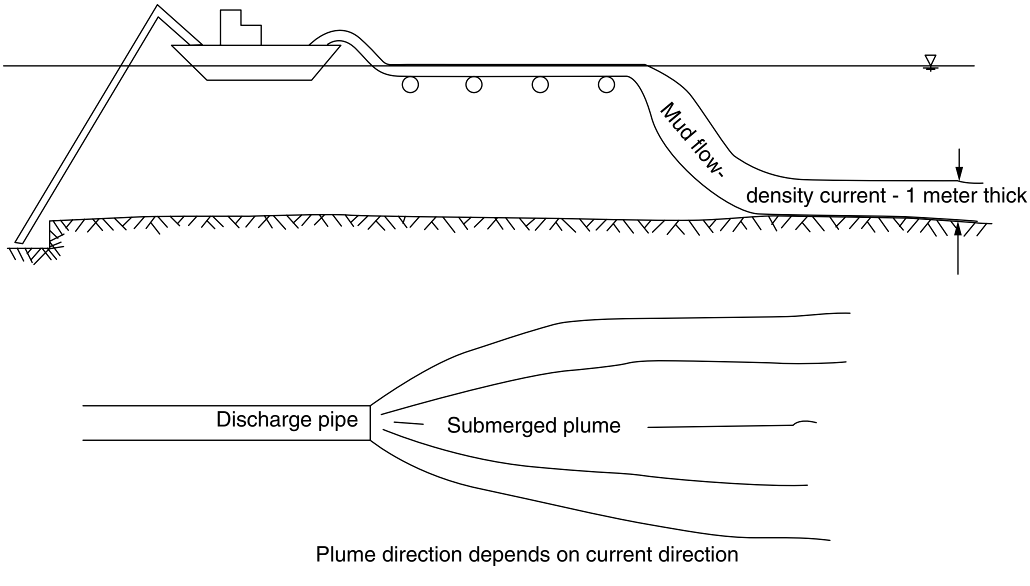

Figure 5. Hydraulic dredging with open water pipeline disposal.

most ecologically sensitive area of the waterbody. Thus, rather than being more protective of ecological/water quality, "confined" disposal operations pose a potentially greater risk than open water disposal.

Potential adverse impacts associated with the materials that remain in the confined area also exist. Studies conducted at the COE Waterways Experiment Station (5) have shown that when the sediments in a confined disposal area dry, they tend to release constituents such as heavy metals, which appears to be related to the oxidation of the amorphous sulfides present in the sediments, which keep the heavy metals in particulate form while the sediment is wet, and the development of acidic conditions. It may also be related to the aging of the ferric hydroxide precipitate (hydrous oxides). Although freshly precipitated ferric hydroxide has a substantial holding power for constituents, aged precipitates, especially those that dry out, lose some of this holding power. It is therefore not surprising to find that dredged sediments that dry in a confined disposal area release appreciable heavy metals when the area is subjected to precipitation or receives additional dredged sediment. The contaminants released then drain from the confinement area to the nearby nearshore waters. The potential for chemicals released from the confined dredged sediments to pollute area groundwater also exists. It is important, therefore, that those who advocate upland disposal of contaminated dredged sediments conduct a proper, critical review and evaluation of the potential adverse impacts of the constituents associated with the sediments that leave the confined disposal area during overflow during dredging operations or via drainage or seepage from the disposal site.

Contaminant Release from Redeposited Sediment

In addition to concern existing about the potential watercolumn impacts of contaminants in dredged sediment, a need exists to evaluate the potential for chemicals in the redeposited dredged material to be released to the watercolumn at the disposal site at sufficient rate to be adverse to water quality. In order to assess whether measured or unmeasured chemicals could have an adverse impact on watercolumn organisms or organisms that might colonize the redeposited dredged sediments shortly after deposition, Lee et al. (1) developed a dredged sediment elutriate screening toxicity test. The dredged sediment toxicity screening test involves introduction of standard test organisms into the settled elutriate from a standard oxic elutriate test procedure (oxic mixing of 1 volume sediment with 4 volumes water and oxic settling). Grass shrimp (*P. pugio*) were used for marine conditions and daphnids were used for freshwater. Lee et al. (1) and Jones and Lee (2) found that sediments collected near urban and industrial areas showed toxicity to aquatic life under the conditions of the laboratory test. Typically, in tests in which toxicity was found, from 10% to 50% of the test organisms were killed in the 96-hour test period. Toxicity was substantially less than may have been expected based on the elevated concentrations of the myriad measured and unknown contaminants in the sediments. Thus, although many of the sediments tested had high concentrations of heavy metals and chlorinated hydrocarbons of various types, those constituents were present in the sediments largely in unavailable, nontoxic forms. In the case of contaminated New York Harbor sediments, Jones and Lee (6) and Jones-Lee and Lee (7) found that the toxicity discovered in the toxicity testing was because of ammonia. Other investigators are also finding that ammonia is one of the principal causes of sediment toxicity to aquatic life. In general, however, it has been found that disposal sites are of sufficiently high energy and the rates of release of pollutants sufficiently slow that water quality problems in the watercolumn do not occur from redeposited sediments.

However, the bioaccumulation or buildup of chemical contaminants in higher trophic-level aquatic organisms that recolonize the disposal site is of concern. A few constituents exist, including methylmercury, PCBs, and PAHs, that have the potential for trophic magnification in aquatic environments. The bioaccumulation of constituents within organisms occurs from both direct uptake of constituents from the water and the consumption of particles that have constituents associated with them as well as the consumption of other organisms. The bioaccumulation and subsequent impact of chemical contaminants cannot be predicted based on their concentration in the sediment. Evaluation of this potential impact needs to be made on a site-specific basis using organism bioaccumulation tests of the type described by the U.S. EPA and COE (8,9).

REGULATING DREDGED SEDIMENT DISPOSAL

In the 1972 amendments to the Federal Water Pollution Control Act (PL 92–500), Congress specified in Section 404 that the disposal of dredged sediments in U.S. waters may take place, provided that an avoidance of "unacceptable effects" exists. It further stated that the disposal of dredged sediments should not result in violation of applicable water quality standards after consideration of dispersion and dilution, toxic effluent standards, or marine sanctuary requirements, and should not jeopardize the existence of endangered species. In order to implement these regulations, the U.S. EPA and Corps of Engineers developed two dredged sediment testing manuals, *Evaluation of Dredged Material Proposed for Ocean Disposal - Ocean Testing Manual* (8), and *Evaluation of Dredged Material Proposed for Discharge in Waters of the U.S. - Inland Testing Manual* (9). The Ocean Testing Manual was developed to implement Section 103 of Public Law 92–532 (the Marine Protection, Research, and Sanctuaries Act of 1972). These manuals prescribe testing procedures to assess biological effects such as toxicity and bioaccumulation of hazardous chemicals from dredged sediments.

The reliable evaluation of the potential adverse effects that may occur from dredging and dredged sediment disposal in a particular manner requires effort and understanding of the biological, chemical, and physical processes involved. It has been long recognized that potential adverse impacts cannot be determined based on the bulk chemical composition of the sediment; this understanding had, in fact, led to the DMRP studies of the 1970s. However, in an attempt to simplify the process and make determinations more administratively expedient, the U.S. EPA and other regulatory agencies have again attempted to regulate dredged sediment disposal based on chemical concentration-based "sediment quality criteria." One such approach that has been advanced is based on the "co-occurrence" in a sediment of a total concentration of a chemical and a biological response not even necessarily caused by the chemical of concern. Lee and Jones-Lee (10) reported on their reviews of co-occurrence-based so-called sediment quality guidelines and discussed why they are technically invalid and cannot provide a reliable evaluation for any purpose. Lee and Jones-Lee (11) recommended that a "best professional judgment" triad, weight-of-evidence approach be used to evaluate the water quality significance of chemicals in aquatic sediments. This approach is based on the integrated use of aquatic toxicity, bioaccumulation, organism assemblage information, and physical and chemical information focused on identifying the cause of aquatic life toxicity. Additional information on the water quality impacts of chemicals in sediments is available from Jones-Lee and Lee (7), DOER (12), and in the U.S. Army Corps of Engineers bulletin, "Dredging Research," available on request from www.wes.army.mil/el/dots/drieb.html.

DREDGING FOR SEDIMENT CLEANUP

In addition to dredging for maintaining navigation depth of waterways, dredging is being undertaken to remove (remediate) contaminant-laden sediments from Superfund and other sites. Evison of the U.S. EPA Office of Emergency and Remedial Response summarized the magnitude of the problem of contaminated sediments at Superfund sites in a presentation entitled, "Contaminated Sediment at Superfund Sites: What We Know So Far" at a U.S. EPA and U.S. Army Corps of Engineers national workshop (13). At the same workshop, Ellis (14), Sediments Team Leader with the U.S. EPA Office of Emergency and Remedial Response, presented a discussion entitled "Superfund Cleanup Issues at Contaminated Sediment Sites." The dredging of contaminated "Superfund" sediments and their disposal require attention to the same water quality/environmental quality, and contaminant availability, transport, and impact issues that are faced in dredging of contaminated sediment for channel depth maintenance.

An example of the use of dredging for sediment remediation is the current cleanup of PCB-contaminated sediments in the Hudson River in New York State. The Hudson River sediments from Hudson Falls to New York City (a distance of 200 miles) were contaminated by PCBs discharged for decades in wastewaters by General Electric Company. U.S. EPA (15) provides information on the past and proposed dredging of the PCB-contaminated sediments in that area. Another example of Superfund dredging is the dredging of PCB-contaminated sediments from the Wisconsin Fox River (16). There, an issue of considerable concern is the appropriateness of placing PCB-contaminated sediments in municipal landfills.

THE ECONOMICS OF WATER QUALITY

Keith O. Keplinger
Texas Institute for Applied
Environmental Research
Stephenville, Texas

The role of economics in water quality decision-making is a topic receiving increasing attention today. A number of factors have spurred this interest. On the policy front, the total maximum daily load program has emerged as a premier water quality program in the United States, engendering fresh opportunities for economic analysis, because the means of attaining ambient targets are not prescribed. The increased relevance of economic analysis in the policy arena has been accompanied by a blossoming of the discipline of environmental economics and greater public and governmental acceptance of pursuing cost-effective and market-based solutions to environmental problems.

The theory of environmental economics has been extensively developed, but the utility and form of policy instruments are highly influenced by the institutional landscape. Consequently, this report begins with a brief assessment of water quality policy in the United States, focusing on the landmark legislation that constitutes the lion's share of current water quality policy, the 1972 Clean Water Act (CWA). Next, the meaning of costs and benefits in a water quality context are discussed, and the merits of two commonly used economic instruments in water quality assessments are explored: cost–benefit analysis and cost-effectiveness analysis. Finally, equity issues and the economic implications of water quality policy alternatives are discussed, with particular emphasis on the historical development and potential for incentive-based mechanisms.

WATER QUALITY POLICY IN THE UNITED STATES

Federal water quality policy in the United States can be succinctly characterized as initially state-based and ambient-based, then switching to a federal system dominated by technology standards with passage of the 1972 CWA. More recently, federal water quality policy has seen a return to the ambient-based approach for impaired waters as the total maximum daily load (TMDL) program has emerged. An ambient-based water quality approach targets the attainment of a specified level of ambient (in-stream) water quality as its objective. Loads or concentrations of pollutants are typically used as water quality measures. Ambient-based water quality approaches contrast with technology-based approaches, which specify the application of controls (e.g., best available technology), based on industrial classification, without explicit regard for the ambient conditions of receiving waters.

A legal scholar has noted that the breathtakingly ambitious goals of the CWA suggest a virtually cost-blind determination to control water pollution (1). It might also be added that the CWA takes a benefits-blind approach as well. Although not completely absent, references to costs or benefits in the CWA are few. The major regulatory mechanism of the CWA, the National Pollutant Discharge Elimination System (NPDES), focuses on technical feasibility as the overriding factor in establishing pollution controls. Considering the political and historical context surrounding the passage of the CWA, this largely prescriptive approach to restoring water quality can be considered neither surprising nor irrational. After years of inaction under prior national clean water legislation in the face of deteriorating water quality and mounting political pressure, the Senate was keen to pass legislation that forced action (2).

Portney (3) opines that

> When the U.S. Congress drafted the environmental legislation of the early 1970's, these and other problems were thought to be so obvious and so serious—and, in fact, they were—that members simply could not envision directing EPA to address them only if it was affordable to do so. As a consequence, most of the early laws effectively directed the agency's administrator to disregard cost altogether in setting ambient air quality standards and some water quality standards.

Houck (2) attributes the CWA's shift in focus to technology standards to “a new ethical premise, that water should simply be clean.”

Unlike the former state administered ambient water quality approach, the prescriptive NPDES approach largely dispensed with the need for scientific endeavor and did not require the monitoring of water quality, estimation of the environmental impacts of control actions, or the estimation of economic costs and benefits.

During debate of the 1972 amendments, classic economic arguments were put forth in favor of continuing ambient-based federal water quality legislation. For example, in House testimony, the Chairman of the Council of Economic Advisors (CEA) stated:

> CEA is in agreement with the use of water quality targets appropriate to the conditions and expected uses of water in particular areas of the country. That is basic to the concept of relating the costs of programs to the benefits received from them. To abandon that concept for a nationally legislated standard which focuses on the level of pollutants removed and is unrelated to water quality uses and standards is economically unwise because it means a necessary misallocation of our inevitably scarce economic resources (4).

Countering this line of argumentation was a consensus, which ultimately prevailed, that the existing state-based water quality approach, which relied on ambient standards, had been given ample time to succeed, but had overwhelmingly failed. “The Senate found the standards weak, late, widely disparate, scientifically doubtful, largely unenforced, and probably unenforceable” (2). Thus, whatever the economic and scientific demerits of the prescriptive NPDES approach, it was at least viewed as an approach that could be effectively implemented and would actually produce cleaner water—the benefits of which were, presumably, greater than the administrative and social costs of the program.

Of the two approaches, it can be argued that the NPDES approach was preferable only because it actually produced quantifiable water quality improvements, whereas the former federal legislation was largely effete. Tietenburg (5) concludes, “the wrong inference was drawn from the early lack of legislative success [in achieving water quality],” suggesting that equal or greater water quality gains could have been made at a lesser cost if correctly structured and adequately enforced incentive-based programs had been implemented. It can also be argued, however, that prescriptive regulation may be preferable when the problem is dire, the benefits great, and when scientific data are lacking, conditions which appear to have largely existed when NPDES was drafted. The National Research Council (6), however, concludes, “the data and science have progressed sufficiently over the past 35 years to support the nation’s return to ambient-based water quality management.” The initial implementation of NPDES and subsequent return to an ambient water quality approach can also be seen within a historical context. Ackerman and Stewart (7) suggest that the prescriptive technology approach “made some sense as a crude first-generation strategy.” Portney (3) attributes the growing role of economics in environmental decision-making to often much higher costs and fewer benefits of additional pollution reduction, the impact of global integration, and to the loss (since the 1970s) of moral imperative status for pollution control.

It is also likely that Congress and the American public believed that effluent limitations based on best available technology applied to point sources would largely solve the nation’s water quality problems. Nonetheless, Section 303(d) of the CWA, the legislation establishing the TMDL program, was included as a backup measure to achieve state water quality criteria if technology measures failed. Reminiscent of and in fact modeled after the 1965 Clean Water Act, Section 303(d) enumerates a number of steps designed to achieve ambient water quality targets consistent with designated uses. The TMDL program, thus, exemplifies an ambient-based approach to water quality.

Largely ignored for the first two decades after passage of the 1972 CWA, a series of lawsuits starting in the 1980s forced both the states and the U.S. Environmental Protection Agency (EPA) to gear up and prepare for the onslaught of TMDL activity to come. The trickle of TMDLs seen in the 1980s has swelled to the point where TMDLs have become a prominent (and controversial) component of CWA compliance. Recent state lists indicate in excess of 21,000 impaired water bodies throughout the nation requiring in excess of 40,000 TMDLs (6). These figures suggest that the ambient-based TMDL program will continue as a major component of water quality control for decades to come.

Although Section 303(d) does not explicitly mention cost considerations, the nature of the legislation facilitates an important role for economic analysis. The goal of attaining quantitative water quality targets is paramount, but the means of attainment are unaddressed, thereby permitting a potentially broad array of attainment strategies; each has its own unique set of control measures and associated economic costs. Consequently, an analysis of viable alternatives, including their economic consequences, can play an important role within the TMDL paradigm.

AN ECONOMIC CHARACTERIZATION OF WATER QUALITY

Water pollution is a classic externality produced by various types of economic activity. An industrial facility, for example, may discharge toxic effluent into a river causing fish kills and environmental impairment further downstream. Because the fisherman and recreationists that suffer harm are not parties to the plant’s decision to discharge, that harm is external to the decision process. Another key feature of water pollution is that, in almost all cases, it harms many users and nonusers simultaneously; hence, in economic lingo, it is a *public* bad. From the reverse perspective, clean water is a public good that produces benefits to often-large groups of users but requires costs to attain it. The externality and the public good nature of water quality/water pollution often lead to market failure—a situation where market forces alone do not result in socially desirable outcomes. The major causes for market failure in water quality are undefined water quality rights and control obligations, and the practical obstacles that discourage numerous individuals who receive relatively small water quality benefits from coordinating their efforts and directly contracting with discharges. Societies have sought to correct market failures through various forms of social intervention. Although not exhaustive, alternative externality correction devices include market emergence, merger, economic incentives, regulation, prohibition, pseudomarkets, and moral suasion.

COMPONENTS OF ECONOMIC ANALYSIS

The two fundamental components of applied microeconomic analyses are costs and benefits. Water pollution involves sacrifices for some groups (costs) and economically benefits others. The benefits of attaining clean water are equivalent to the costs of water pollution, whereas the cost of attaining clean water is equivalent to the benefits that accrue to the production of water pollution. To avoid confusion, the following sections discuss costs and benefits from a water quality perspective.

Costs

Water quality is a public good requiring costs for its attainment. Due to the constraints imposed by nature and current technology, producing more of one good, including water quality, is typically accomplished only at the expense of producing less of other goods. Occasionally, analyses suggest that management or structural measures designed to improve water quality may also result in net benefits to dischargers. Such “win–win” solutions are the exception but might occur for one of two reasons: (1) current technology and resources are not being efficiently utilized, or (2) recent technology has opened up new opportunities for improving water quality while simultaneously producing benefits in other areas. Numerous water pollution control measures have been identified for municipalities, industry, and agriculture. Economic and engineering studies often estimate the costs of implementing specified measures and typically express those costs in monetary units, for example, dollars, which represent the foregone opportunity of producing and consuming other goods.

Benefits

The benefits of mitigating water pollution can be classified as environmental and economic. Environmental benefits are measured by a large number of environmental indexes, such as biological diversity and increased fish populations. Economic benefits are the monetary values society is willing to pay for the associated environmental benefits. Numerous studies have quantified the economic benefits of water quality (8,9). Following Freeman’s taxonomy, benefits include improvements in (1) recreation (swimming, fishing, boating, water fowl hunting), (2) nonuser benefits (amenity, aesthetic, and ecological benefits not directly associated with activities on or near a waterbody, but for which households may be willing to pay), (3) diversionary uses (reducing risk to human health and decreased costs for municipal water supply treatment), and (4) commercial fisheries. Many of the benefits listed above are nonmarket; that is, they are not purchased or sold in ordinary markets and therefore have no observable price. Lack of organized markets for water quality complicates the estimation of water quality benefits (10), though a number of indirect methods have been developed.

ECONOMIC INSTRUMENTS FOR INFORMING WATER QUALITY POLICY

Cost–Benefit Analysis

Applied to water quality, cost–benefit analyses generally estimate and compare both the economic costs and benefits of a water quality project. Such analyses are nominally prescriptive; benefits that exceed costs may represent a sufficient condition for proceeding with a project. A more exacting and universally accepted welfare economic criterion is the Pareto criterion, which states that everyone should be made at least as well off while nobody is made worse off. A policy producing net benefits (total benefits exceeding total costs) is considered a *potential* Pareto improvement because, in theory, the gains of the policy action can be redistributed such that everyone is made at least as well off as before. In practice, a strict Pareto improvement is difficult to achieve and seldom attempted. Thus, a potential Pareto improvement, that is, the generation of positive net benefits, is often used as a decision rule.

In theory, the optimal level of ambient water quality is such that the benefits produced by one additional unit of water quality just equals the costs to attain it. Thus, to fully assess the merits of a water quality project, detailed information on both its benefits and costs is required. Significant difficulties, limitations, and complications inherent in environmental and economic benefit estimation techniques, as described in succeeding sections, suggest one reason why cost–benefit analysis has not factored more prominently in water quality policy.

It is noteworthy that authors of environmental economics textbooks, for the reasons cited, typically exhort students to be cautious in their interpretation of cost–benefit analyses. For example, “Although cost-benefit analysis, with its reliance on numbers and economic theory, may seem as if it might be a precise science, this is not the case” (11). On somewhat of a counterpoint, Hartwick and Olewiler (12) argue, “Cost benefit analysis has been maligned by those who say that it is useless because the numbers are so bad. This criticism misses the point of the exercise. ... The estimate of the benefits of environmental control is crucial if we are to evaluate the tremendous costs of reducing pollution and make informed judgments about the social value of improving environmental quality.”

When benefits cannot be adequately quantified because of uncertainty or other technical hurdles, benefits can only be described. By contrast, estimating the costs of structural or managerial pollution control measures is relatively straightforward and generally involves much less uncertainty. Comparing quantified costs to descriptive, though potentially large, benefits can unduly discount benefits. Although they broadly support the use of cost–benefit analysis, a group of highly respected economists also highlighted some of its limitations in a draft set of principles (13). One of many caveats was that “care should be taken to assure that quantitative factors do not dominate important qualitative factors in decision-making” (14).

Another factor hindering the use of formal cost–benefit analyses as a decision-making tool is the perception that such analyses are prone to manipulation, especially when gaps in knowledge and sources of uncertainty are substantial. Recounting his experience as the senior economist for environmental and resource policy at the Council of

Economic Advisors, Jason Shogren (15) comments: “But now I understand that some people see our orthodoxy as not just simply confining but as downright prehistoric. . . .Because after all, cost–benefit analysis is just naked self-interest dressed up in banker’s pajamas, isn’t it?” Many studies, for instance, have indicated that the nonuse or existence value of environmental amenities may far outweigh their commercial and use value, while other studies omit the estimation of these values altogether.

A final factor discouraging the more widespread use of cost–benefit analysis for water quality is that the estimation of benefits has no practical relevance in either technology-based or ambient-based water quality policy. NPDES technology-based controls, for instance, are mandated on the basis of industrial classification and available technology , while TMDL ambient-based controls are designed to achieve ambient criteria, regardless of the economic benefits produced.

Estimating the Economic Benefits of Water Quality. Three linkages must be established and quantified to estimate water quality benefits: (1) the link between a pollution mitigation strategy and water quality indicators, (2) the link between water quality indicators and environmental benefits, and (3) the translation of environmental benefits into economic benefits. The first linkage is often estimated by simulating a pollution mitigation strategy by using a water quality model. Biophysical models may also be employed to estimate environmental benefits such as increased fish populations. Estimating economic benefits requires knowledge of both environmental benefits and how society values those benefits.

When water pollution causes direct damage to a market commodity resulting in either a decrease in production (e.g., in fisheries) or an increase in expense (e.g., increased treatment cost for municipal drinking water), calculating the value of water quality improvements is relatively straightforward. Because of the public good nature of many water quality benefits, however, many benefits are not directly reflected in markets. Economists have developed a number of indirect methods for estimating nonmarket values of water quality improvement. The hedonistic technique is often used to reveal a lower bound on amenity or aesthetic value. This technique infers the value of a nonmarket commodity by analyzing the value of a commodity whose value is influenced by the nonmarket commodity, for example, comparing waterfront property values across regions experiencing different levels of water pollution. Differences in human behavior, such as increased recreation, due to water quality improvements, can also be used in conjunction with travel cost models to estimate the value of recreational water quality benefits. The travel cost model assumes that the willingness to pay for a recreational trip is at least equal to the cost incurred in traveling to the recreational site. Hedonic and travel cost models can be classified as revealed preference methods because their estimation techniques depend on observable (or revealed) behavior.

If values for water quality are not intimately related to use, for example, the desire to provide clean water environments to current and future generations, they are not necessarily revealed through either changes in market prices or other aspects of human behavior, such as travel to a recreational site or home location. Observational methods, thus, cannot reveal nonuse valuations. Researchers have circumvented this hurdle by describing hypothetical markets to respondents who are asked to indicate (or state) their willingness to pay for a nonmarket commodity (16). This relatively recent benefits estimation methodology has come to be known as the contingent valuation (CV) method, because willingness to pay values are contingent upon the particular hypothetical market described. Because the situation is hypothetical and an actual transaction or observable behavioral pattern has not been effected, value estimates based on surveys are controversial. Participants may answer strategically, for example, may indicate too high a value because they think it will improve the chance that a water quality improvement will be made, or indicate too low a value if they think that their reported willingness to pay might result in increased taxes. If participants are convinced that their responses will have no effect on actual outcomes, the incentive to reveal an inaccurate valuation is reduced (8).

The public good nature of water quality improvements also complicates benefits estimation and adds to data collection expense (10). The value of water quality improvements is typically spread across a wide population of users, and researchers must determine the relevant population for a particular improvement. Another obstacle in estimating nonmarket benefits is that most people do not have well-formed values for the vast array of environmental resources and therefore may resort to heuristics and simple protocols to construct dollar value estimates. These protocols, however, vary widely among individuals, and many irrelevant issues, such as the appropriateness of the payment vehicle or who should pay, often influence responses (17). A few experiments suggest that stated willingness to pay for existence values may be two to ten times higher than actual contributions or payments (18).

Despite the theoretical and methodological difficulties, quantifying the benefits of achieving clean water has often changed the character of debate (18). It is typical that the costs required to achieve water quality are highly concentrated but that benefits are widely distributed. Because benefits to any one user may be quite small, only bearers of costs would have a great incentive to change the outcome of a debate. Given the public good nature of many water quality improvements, however, a CV analysis may show that benefits, though widely dispersed, far outweigh costs.

In sum, certain benefits of water quality are reflected in markets, but many are not. The nonmarket benefits of water quality are important and potentially very large. Measuring these benefits, however, presents unique challenges and methodological difficulties, which have been addressed by a number of ingenious nonmarket benefits estimation techniques; CV is among the most promising. The accuracy, completeness, and potential bias of such techniques, especially CV, however, remain controversial issues.

Cost-Effectiveness Analysis

Cost-effectiveness analysis circumvents the difficulty and controversy of estimating economic benefits by focusing on the costs of achieving a quantified noneconomic objective. Once an objective has been chosen, costs of alternative strategies that reach the objective, for example, a water quality indicator, can be compared. Because the estimation of water quality indicators is generally considered more reliable than estimating the economic benefits of different levels of those indicators, cost-effectiveness analyses generally engender less controversy than cost–benefit analyses.

Cost-effectiveness analyses, in a water quality context, estimate the costs and environmental effectiveness of defined control measures or combinations of measures. Effectiveness is often measured as a reduction in the ambient load or concentration of a pollutant. Cost-effectiveness ratios can be calculated by dividing the cost of a control measure by its effectiveness. This ratio quantifies the cost of achieving a one-unit improvement in the effectiveness measure. Cost-effectiveness ratios can be easily compared across control measures to determine the most cost-effective measures—those measures that have the lowest ratios. To achieve a water quality target when any one control measure does not single-handedly achieve the target, the most cost-effective solution is typically found by applying the most cost-effective measure first, followed by the second most cost-effective measure, and so on, until a specified water quality target is achieved.

Cost-effectiveness analysis is particularly adapted to TMDL deliberations for the following reasons. First, numerical water quality targets are an essential component of TMDL plans. Second, estimating the environmental effectiveness of control measures is also central to TMDL stakeholder deliberations. Descriptions of control measures and their effectiveness are required elements of TMDL implementation plans (19). Third, the means of attaining water quality targets are not prescribed, allowing the comparison of alternative strategies. Fourth, although not a requirement, there is no prohibition on considering the costs of alternative strategies and individual control measures in determining which set of measures to implement. The EPA has characterized the TMDL process as a "cost-effective framework" for achieving water quality and has endorsed cost-effectiveness assessments (20). Fifth, from a welfare economic perspective, reducing or minimizing the cost of achieving a given water quality target increases social welfare. Sixth, compared to estimation of economic benefits, the calculation of pollution mitigation costs is relatively straightforward and less controversial. TMDL assessments, thus, are natural candidates for the application of cost-effectiveness analyses. Despite the suitability of cost-effectiveness analysis within the TMDL framework, rigorous analyses have been pursued for relatively few TMDLs, and there remains a large potential for improving the economic performance of TMDL (and other ambient-based water quality program) allocations.

Cost Minimization. Cost-effectiveness ratio analysis, as outlined above, minimizes costs within the limitations imposed by ratio analysis, for example, linearity and additivity. Under more complex (and realistic) assumptions, cost-effectiveness analysis requires more completely defined relationships among costs, water quality indicators, and control measure adoption. When costs and control measure are not additive, combinations of control measures should be assessed to capture interactive effects. Control measure costs are not necessarily linear. The same control measure at different locations or implemented at different levels can involve different unit environmental responses and entail different unit costs. More sophisticated forms of analyses are needed to analyze partial and site-specific implementation of control measures. Nonlinear and nonadditive relationships among varying levels and combinations of control measures can be addressed by employing a generalized cost minimization framework capable of solving for cost minimizing levels of control measures.

EQUITY CONSIDERATIONS

The scope of equity considerations within technology-based programs, such as NPDES, is rather limited because the procedures for prescribing water quality remedies are highly delineated within the law and regulation. Equity considerations, however, can become highly important within the ambient-based TMDL approach because particular remedies are not prescribed. In many cases, numerous entities that often belong to two or more industries are responsible for exceeding ambient standards. Loads can be reduced to TMDL targets by any combination of control responsibilities as long as the load reductions sum to the total reduction needed to achieve the TMDL target. Cost minimization can be used as the sole criterion for assigning loads, but such assignments may be rejected because they are not perceived as equitable. Hence, the flexibility of the TMDL approach creates challenges to promulgating implementation plans that are deemed equitable. Solutions deemed equitable, however, may compromise economic efficiency, that is, implementing the most cost-effective solution.

Control costs are generally concentrated in particular industrial sectors or entities. The fairness of assigning control costs is almost always at issue in water quality deliberations. Subsidizing water quality improvements by transferring mitigation costs from a small group of dischargers to broader publics is sometimes viewed as an equitable means of distributing control costs. State and federal funds are often appropriated to defray additional expenses of new control obligations. Such transfers can promote the acceptance of new controls. When such funding is not available, the legality of mandating new control obligations, especially for nonpoint sources, is often challenged.

Equity criteria can be analyzed by rigorous analytical methods, such as the attainment of a Pareto optimal. More generally, however, equity issues are dealt with subjectively; nonetheless, concern for fairness is an important driver that influences many water quality decisions. This is particularly true within the TMDL program, where attaining ambient standards often necessitates additional efforts by industry and agriculture. Most states assemble advisory boards of watershed stakeholders, typically composed of public servants, environmental interests, and industry representatives, to recommend key TMDL decisions, including load allocations. Concern for fairness is an important factor influencing load assignments. Recommended load assignments are a product of the internal dynamics of advisory board deliberations, but appeals to equity or fairness are repeatedly raised in these deliberations and undoubtedly play a large role in determining load assignments. It may be deemed equitable for each identified source, or group of sources, to reduce its water quality impact by roughly the same percentage or absolute amount. There are many potential equity criteria, however, and often no concensus on which one is best. Imposing pollution reduction obligations on small businesses and family farms, especially when economic viability is jeopardized, may be deemed unfair (as well as politically infeasible). Even if concensus if reached rearding equitable control assignments, implementation strategies deemed equitable may significantly depart from cost-effective solutions, although a correctly structured incentive-based mechanism can potentially overcome this limitation.

WATER QUALITY POLICY INSTRUMENTS

Poor water quality is symptomatic of market failure and provides a rationale for social intervention. This intervention can take the form of direct regulation, prohibition, or one of a variety of incentive-based mechanisms. Complete prohibition of discharge is sometimes resorted to for extremely toxic substances, when even a very small amount might cause harm. Regulatory approaches, often referred to as “command and control” regulation, typically prescribe control remedies that allow little flexibility in the means for achieving goals. By contrast, incentive-based mechanisms encourage behavior that reduces pollution through market forces and signals and allow at least some degree of flexibility in the means for achieving goals.

The NPDES permit system for point sources, which bases acceptable discharges on best available technology, exemplifies the regulatory approach. The regulatory approach, and NPDES in particular, have been criticized in recent years for reasons that relate mostly to questions of economic efficiency: that it is overly prescriptive and lacks flexibility, that it seeks to regulate inputs rather than outputs (water quality), that it does not adequately consider costs, and even that it has reduced real incomes (7,21). Whether or not a particular market- or incentive-based policy is, more efficient in practice, than a particular “command and control” policy is, however, an empirical question. Alternative policy instruments possess unique biophysical and economic implications, and the efficacy of any given policy depends on a number of site-specific behavioral, environmental, and economic factors that may be difficult to establish a priori. Nonetheless, incentive-based mechanisms for achieving water quality have attracted considerable academic interest because of their theoretical efficiency characteristics, and a number of incentive-based programs have been initiated.

Incentive-Based Mechanisms for Improving Water Quality

Incentive-based mechanisms are advocated primarily as a means of reducing the financial burden of control costs while maintaining or making further progress on water quality. The defining hallmark of incentive-based systems is that they are designed to be incentive compatible, that is, by pursuing self-interests, such as profitability, environmental goals are simultaneously achieved. Unlike prescriptive regulation, incentive-based mechanisms also promote the development and implementation of new pollution control technology. Though recommended by environmental economists for the past several decades, environmental organizations have more recently promoted incentive-based mechanisms (particularly effluent trading) for achieving water quality (22–24).

While generally viewed as a cost saving measure, making pollution control more affordable can also enhance its political acceptability and, hence, promote additional pollution control. Tietenburg (25), for instance, maintains that “with the inclusion of a tradable permits program for sulfur in the [acid rain bill], the compliance cost was reduced sufficiently to make passage politically possible.” Incentive-based mechanisms for improving environmental quality include emission fees or taxes, tradable permits, deposit-refund systems, subsidies for pollution control, removal of subsidies with negative environmental impacts, reductions in market barriers, and performance standards (26–28). We focus here on the two most prominent incentive-based mechanisms, pollution taxes and tradable permits.

Pollution Taxes. Economists have long recognized the allocational inefficiencies of environmental externalities. In the early part of the twentieth century, the noted economist Arthur Cecil Pigou (29) recognized that “when the divergences between private and social costs are pervasive throughout the economy, market prices cannot be used as measurements of consumer satisfaction.” Pigou proposed an externality tax on pollution to internalize the damages caused by pollution. During his time, Pigou’s pollution tax was regarded as an academic exercise and did not gain practical significance. The environmental consciousness of the 1970s, however, spurred a revival of interest in pollution taxes as a solution to environmental externalities, and several European countries and Japan adopted pollution taxes. The consensus among economists is that these fees have typically not had noticeable effects on pollution because they have not been set at levels that affect behavior (27).

Simple models of pollution abatement costs and benefits suggest that pollution taxes yield results identical to those of tradable permits within a cap if the cap or tax is appropriately set. This conclusion can be drawn from a simple graph where pollution is represented on the horizontal axis, control costs are represented on the

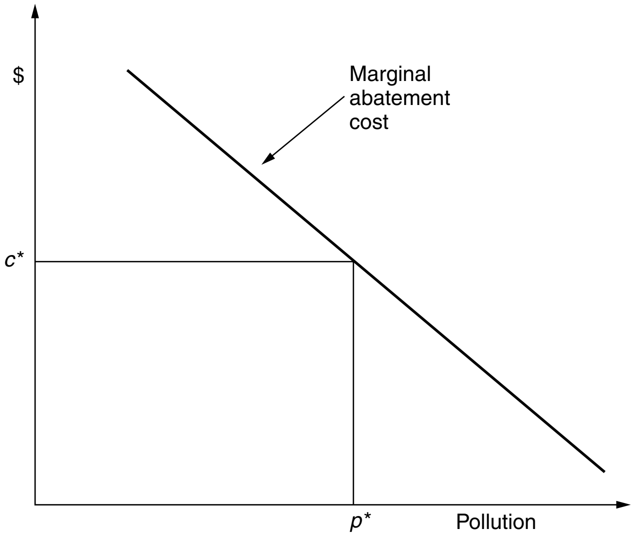

Figure 1. Theoretical equivalence of a pollution tax (c^*) and a pollution cap (p^*).

vertical axis, and declining marginal abatement costs are plotted within the graph (Fig. 1). Any point on the marginal abatement cost function can be mapped to a level of pollution (p^*) and a control cost (c^*). A pollution cap is represented as a vertical line and the equivalent pollution tax by a horizontal line, each intersecting the marginal abatement cost function at the same point. For a given pollution tax, the firm would have an incentive to reduce pollution up to the point where control costs exceed the tax, which could also be achieved by specifying a pollution cap at this level of pollution. Despite the theoretical equivalence of pollution taxes and "cap and trade" programs for the simple model portrayed in Fig. 1, a number of practical advantages are often cited in favor of tradable permits, especially when attaining ambient standards is the overriding consideration.

Tradable Permits. The theoretical underpinnings of a tradable permits system has been attributed to Coase (30), who, in his classic work, *The Problem of Social Cost*, forcefully argued the importance of clear liability rules and bargaining between parties to achieve socially desirable levels of harmful effects (31). Practical applications of Coase's basic premise were extended to air (32) and water pollution (33). Whereas Coase envisioned the bargaining of social harms between the producer and recipient of those harms (regardless of who was liable), Dales set out the parameters of the type of "cap and trade" program in widespread use today. The basic components of the program involve setting a cap on total waste, issuing emission permits, the aggregate of which equals the cap, and allowing the sale and purchase of permits among polluters (33). Marketable credits are formed when dischargers who have low mitigation costs reduce loads below permitted levels. These credits can in turn be sold to entities that have high mitigation costs so that both parties gain, thereby providing an incentive to trade.

Historical precedent for tradable permit systems for water quality is found in the allocation of natural resources, in water supply and fisheries (34). Tietenberg (25) traces the acceptance of tradable permits in the United States to the introduction of "pollution offsets" by the U.S. Congress in 1977, which opened the door to emissions trading in the air arena. In the years since, tradable emission permit systems have been successfully implemented at the federal level for the lead phaseout program, to reduce ozone-depleting chemicals under the Montreal Protocol, and for the sulfur allowance program (25). A number of programs have also been developed at the state level. Emissions trading in the air arena has generally been deemed quite successful. Burtraw and Mansur (35), for instance, estimate that trading of sulfur dioxide emissions resulted in a 13% reduction in compliance costs and produced health related benefits of nearly $570 million in 1995. The actual use of tradable permits for water quality control is of recent origin. In 1992, Willey wrote, "no water emissions markets exist yet," whereas several functioning effluent trading programs were operating by the late 1990s (26,36). Of the 37 trading and offset programs summarized by Environomics (36), 11 were considered well along in being implemented; trades were under way or completed; 5 had specific trading mechanisms approved and were very near implementation; 6 had completed the development and program approval process, but no specific trades had yet been identified; 12 were in various stages short of program approval, including study, discussion, planning, and/or development; 1 was exclusively a study; and 2 were inactive or discontinued.

The advantages of "cap and trade" programs relative to pollution taxes are, first and foremost, that a new pollution tax on industry may be politically unacceptable whereas the issuing of permits produces a potentially valuable property right. A revenue-neutral tax would reduce or eliminate this advantage, although such programs are rarely considered. Second, under conditions of uncertainty, a permit system would guarantee the attainment of the specified pollution level, whereas a large degree of guesswork would be involved in setting the appropriate tax level. Several adjustments of the tax might be required to find the level that would produce the sought for level of pollution control. Third, the amount of pollution reduction achieved by a given pollution tax is also unstable over time. Other things being equal, economic growth would foster increased emissions, as more pollution producing products and services were demanded and produced, because the pollution tax is a variable component of production costs. On the other hand, given expected advances in technology, levels of pollution might decrease if more cost-effective pollution technology were implemented over time. In summation, pollution taxes and tradable permits have relative advantages and disadvantages, but tradable permits systems are considered preferable when achieving quantitative pollution targets is the paramount consideration. Consequently, tradable effluent permits are conceptually well suited to achieving ambient water quality standards.

Because of numerous factors, TMDL and other ambient-based control allocations typically do not exhibit the greatest degree of cost-effectiveness. A tradable permit system holds the promise of reallocating any initial set of load assignments so that a least cost allocation may be attained. Whether or not a tradable permit system, in practice, is more efficient than its absence depends on the level of transactions costs relative to the gains from trade. In general, a trading system is deemed advisable only if the benefits attributable to trading exceed associated transactions costs. Transaction costs include the costs to industry of quantifying their mitigation costs, finding trading partners, initiating a trade, and bargaining, as well as the administrative costs (often borne by the public) of setting up and maintaining a market for pollution credits. If load allocations and implementation strategies are initially made in a relatively efficient manner, there is little potential for further reducing compliance costs that might be realized by a tradable permit system.

Trading has the most potential when there are large differences between marginal pollution control costs and potentially large amounts of pollution credits that can be traded. For these reasons, some researchers see the greatest potential in trades between point and nonpoint sources because the cost of nonpoint mitigation is often believed much less than that of point source mitigation (37,38). Point/nonpoint source trading, however, entails an additional set of challenges, including monitoring and measuring nonpoint pollution and uncertainty regarding the effectiveness of nonpoint controls (38,39).

Within a water quality context, effluent trading is most attractive for waterbodies where pollutants are well mixed and where there are at least several large dischargers and large differences in control costs. Spatial characteristics of water pollution can pose challenges to the development of viable markets. If pollutants are not well mixed, likely in a stream or river, the waterbody may need to be broken into several markets, or conditions to trading would need to be applied so that improvements in one area would not lead to unacceptable degradation in other areas. For this reason, it is also likely that sale of pollution credits downstream would be more likely than upstream sales for streams and rivers. Trading programs for water pollution control reflect the fact that pollution in waterbodies is generally more localized and spatially isolated than in air sheds. The potential for viable water pollution trading programs depends on various site-specific factors, many of them dictated by nature. Under the right conditions, however, a properly structured trading program can be a useful tool for achieving cost-effective water pollution control, either within or outside the TMDL process.

Having achieved some notable successes in the air arena, economists and policy makers have investigated the potential of applying the tradable permit concept to water pollution control and several programs have been developed (26,38). In 1996, the EPA issued a *Draft Framework for Watershed-Based Trading* designed to promote, encourage, and facilitate trading wherever possible, provided that equal or greater water pollution control could be attained at an equal or lower cost (40). Despite considerable effort by the EPA and the states to implement watershed trading, programs have been developed at relatively few locations, and trading within these programs has been limited, probably less than anticipated. It remains to be seen whether efforts by EPA to vigorously implement the TMDL program will greatly increase the use of watershed trading, as suggested by EPA (26), or if spatial and administrative challenges will continue to limit its adoption to a small percentage of impaired or potentially impaired waters.

SUMMARY

Like all environmental issues, the maintenance and attainment of water quality involves intrinsic economic dimensions. For a long time, however, the economic dimensions of water quality have been subordinated by prescriptive water quality policy. The emergence of an ambient-based water quality approach in the United States (in the form of the TMDL program), however, has opened the door to a more flexible approach to water quality attainment. While both benefits and costs are important elements of water quality, benefit estimation is fraught with inherent complexity and controversy. Neither technology-based nor ambient-based policy relies on cost–benefit criteria. Control costs and their estimation, however, are often important elements in TMDL (and other ambient-based program) deliberations. Hence, cost-effectiveness analyses are particularly well adapted to ambient-based water quality approaches.

Equity considerations can increase the costs of achieving water quality targets. A correctly structured incentive-based mechanism, however, can achieve both equity and economic efficiency. Pollution taxes and tradable permits are two incentive-based mechanisms that can, in principle, achieve water quality targets at lower cost. Because maintaining a quantified level of water quality (often measured by loads) is a paramount feature of ambient-based approaches, a tradable permit (cap and trade) system is better suited to TMDLs and other ambient-based programs than pollution taxes. Whether a "cap and trade" program is more efficient in practice than its absence is highly dependent on site-specific factors and the magnitude of transaction costs. The potential for viable tradable permit systems for water quality and the extent to which they may eventually be adopted remain to be seen. What is quite apparent, however, is the increasing use of economic analysis in the planning and implementation of individual water quality projects and the more prominent role that economic assessments have played in forming and evaluating water quality policy.

INTRODUCTION

Escherichia coli is a facultative anaerobe that commonly inhabits the gastrointestinal tracts of humans within hours of birth. This gram-negative bacillus of the family Enterobactericeae is normally a harmless commensal that helps the host by suppressing pathogenic bacteria (due to competition) and by producing vitamin K and vitamin B complex (1). Individuals who suffer severe immunosuppression (both acquired and due to chemotherapy) or a breached gastrointestinal barrier can experience infection by nonpathogenic *E. coli*. More likely, however, are instances of infection by pathogenic *E. coli* that can include urinary tract infections, sepsis/meningitis, or diarrhea. Within the pathogenic *E. coli* responsible for diarrheagenic disease, differentiation of the strains has led to development of five classes (virotypes): enteropathogenic *E. coli* (EPEC), enterohemorrhagic *E. coli* (EHEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), and enteroaggregative *E. coli* (EAEC) (2). Differentiation of pathogenic strains of *E. coli* is based on the organism's surface antigen profiles of O (somatic), H (flagellar), and K (capsular). This serological classification was originally proposed by Kauffman in 1944 and a modified form is still in use today. Although this serotyping of *E. coli* is a reproducible mechanism for identifying *E. coli* associated with particular clinical disease, the serotypes themselves are not responsible for virulence but are only identifiable chromosomal markers for virulence factors (2).

This article focuses on *E. coli* O157:H7, a member of the EHEC class of diarrheagenic *E. coli*, and specifically discusses transmission routes, particularly focused on the waterborne route and the methods that may be employed for detecting contamination.

HISTORY

Escherichia coli O157:H7 was first identified in 1975 by the Centers for Disease Control (CDC) but did not gain widespread attention until 1982 from the investigation of two outbreaks of gastrointestinal disease. Individuals were experiencing severe cramping, abdominal pains, watery diarrhea leading to bloody diarrhea, and low-grade fever. The illness, hemorrhagic colitis (HC), was associated with the consumption of undercooked hamburgers from a fast food restaurant, and examination of stool cultures from affected individuals revealed the presence of a rare *E. coli* serotype, O157:H7 (3). In addition, sporadic cases of hemolytic uremic syndrome (HUS) were reported by Karmali et al. (4), who found fecal cytotoxins and cytotoxin-producing *E. coli* in stool samples. Karmali et al. (5) also reported that verocytotoxin/Shiga-like toxins were the common virulence factor between HC and HUS. This led to the recognition of *E. coli* O157:H7 as an emerging enteric pathogen that was responsible for both intestinal and renal disease. To determine whether *E. coli* O157:H7 was really an emerging pathogen (rather than one that had not been detected previously), retrospective studies were conducted by the CDC and Public Health Laboratory Services (PHLS) in the United Kingdom, which indicated the presence of *E. coli* O157:H7 in only 1 of 3000 samples from 1973 to 1983 and in 1 of 15,000 samples from 1978 to 1982, respectively (2). It has been suggested that the reason for this pathogenic emergence was the acquisition of virulence factors such as the Shiga toxin gene by horizontal gene transfer and recombination (6). *Escherichia coli* O157:H7 produces Shiga-like toxins that allow categorizing it among other Shiga toxin-producing *E. coli* (STEC), alternatively called verocytotoxin-producing *E. coli* (VTEC). These terms are synonymous and are seen in the literature interchangeably. Various strains of *E. coli* O157:H7 can produce Shiga toxin 1 (stx1) and/or Shiga toxin 2 (stx2). Stx1 is virtually identical to the toxin produced by *Shigella dysenteriae* whereas stx2 is approximately 56% homologous to stx1 (6).

CLINICAL FEATURES AND TREATMENT

Infection by *E. coli* O157:H7 brings a wide range of clinical manifestations ranging from asymptomatic carriage to HC and HUS. The incubation period between exposure and disease onset ranges from 1 to 8 days. The illness typically presents with abdominal cramps and nonbloody diarrhea that progresses to bloody diarrhea after 1–2 days in 70% of cases. Blood content in stools can vary from low levels to almost entirely blood (7). Fever occurs in 30% of patients and vomiting in 30–60% of infected individuals (6). Most cases of HC resolve themselves within 1–2 weeks, and the treatment focuses on supportive care, emphasizing nutrition and hydration. It is not generally recommended to treat with antimotility agents, as this could delay O157 from being voided from the body, thus potentially increasing toxin exposure (8).

From 3% to 20% of the more severe cases of HC progress to HUS. Factors that may contribute to this progression include fever, age related susceptibility (i.e., children and the elderly are more susceptible); elevated serum leukocyte count; and treatment with antimotility agents (6). The role of antibiotic treatment in the progression to HUS remains controversial. Conflicting studies have shown both increased and decreased levels of HUS among patients who receive antibiotic therapy for HC. Death can occur in 3–5% of those infected with HUS, whereas 12–30% can experience various long-term complications, including permanent renal damage (2). There is no therapy for abatement of HUS, but dialysis and transfusions are supportive treatment, along with careful management of fluids, electrolytes, and blood pressure.

One highly touted treatment drug was Synsorb-Pk, which consists of a synthetic analog of the receptor for the Stx toxins (Gb3) linked to diatomaceous earth. This compound binds stx1 and stx2 from the intestines of affected patients, and by preventing additional toxin damage, it had the potential to limit the progression from HC to HUS. Initial clinical trials showed promise (2) but final phase III trials showed no effect of stx-binding Synsorb-Pk on the severity of HUS (9).

In some HUS patients, particularly the elderly, the disease also progresses to thrombotic thrombocytopenic purpura (TTP). TTP involves a greater incidence of fever and neurological deficits and involves organs other than the kidneys, specifically the heart and brain (7). There is also a distinct skin darkening that occurs with TTP in 90% of cases. Patients suffering from TTP typically have reduced platelet and red blood cell counts compared with HUS patients. Neurological findings in TTP range from confusion and headaches to coma and seizures. Cardiac involvement ranges from simple rhythmic disturbances to sudden cardiac arrest. Both cardiac and neurological problems are likely to be due to the occurrence of a classic TTP clinical finding: hyaline thrombi (clots composed of platelets and fibrin) that occlude the small arterioles and capillaries. Treatment of TTP consists largely of plasmapheresis (plasma volume exchange) or plasma infusions that continue until the platelet count stabilizes and hemolysis ceases. The increased use of two preventive measures has assisted in reducing mortality rates to 30%; however, some patients (11–28%) may experience a recurrent episode (10). Due to the lack of effective therapies for O157 infections, using vaccines to reduce colonization of the human intestine has been attempted by targeting proteins involved in attachment and effacement or by specifically targeting stx or the O157 lipopolysaccharide. Usually, children are most highly affected by O157 infections and implementation of vaccines in these populations can be difficult. Nonetheless, vaccination of cattle, which can be a major primary source of contamination in food and water, could reduce environmental burdens from this organism. The large numbers of cattle needing vaccination as well as the rapid turnover of these cattle may make such large-scale vaccination programs challenging (11).

PATHOGENESIS OF *E. COLI* O157:H7

Escherichia coli O157:H7 is highly acid resistant, survives the stomach environment, and passes into the gut (8). There, it adheres to the large intestine and disrupts the brush border, causing the characteristic attachment and effacing lesions of O157 infections. *Escherichia coli* O157:H7 strains can produce stx1 and/or stx2; the latter is more damaging to human renal cells (12) and leads to a greater number of HUS cases (13). The Shiga toxins are bacteriophage encoded and consist of five B subunits and one A subunit. The B subunits bind to globotriaosylceramide (Gb3), a glycolipid found in high levels in the human kidney (14), especially in infants and children (13). Upon binding to the cell membrane, the A subunit is internalized by receptor-mediated endocytosis. Within the cell, the A subunit is disrupted and produces a fragment that has RNA N-glycosidase activity, which then acts on the 28S rRNA of the 60S ribosomal subunit. This prevents the peptide chain elongation step of protein synthesis and results in cell death (8). It is believed that this process is the primary cause of renal cell damage in HUS (7).

Although the Shiga toxins produced by O157 are the most frequently discussed virulence factors, other factors can also be responsible for host pathogenesis. The presence of a 60-MDa plasmid that encodes for an enterohemolysin may cause lysis of erythrocytes as seen in the bloody diarrhea of HC. The heme and hemoglobin released from lyzed erythrocytes could be a source of iron for O157 (2,6). A second virulence factor important in O157 pathogenicity is the locus of enterocyte effacement (LEE). The LEE contains the *eaeA* and *tir* genes. The *eae* gene encodes for intimin, a bacterial cell surface protein, which along with a translocated intimin receptor, encoded by *tir*, allows O157 to adhere to intestinal mucosa. This produces the attachment and effacing lesions seen in *E. coli* O157 infections (7,15).

EPIDEMIOLOGY

The CDC estimated that the annual disease burden due to *E. coli* O157:H7 is around 20,000; up to 250 deaths occur at a cost of $250–350 million (16). However, the true incidence may be underestimated due to the failure of laboratories to isolate or detect this pathogen successfully. Some researchers estimate that the incidence is as high as 73,000 annually; 11,000 of those are from waterborne transmission (17). The disease is of greater importance in the developed countries of the Northern Hemisphere, where 80% of all STEC infections are caused by *E. coli* O157:H7 (13). Within the United States, more cases are reported in the northern states, specifically the Northeast, than in southern states. There is also an association with seasonality; most cases are reported in the summer months when peak shedding of O157 in animals has been noted (6).

Stx-producing *E. coli*, specifically O157:H7, are found in the flora of various animals, including cattle, sheep, goats, deer, pigs, cats, dogs, chickens, gulls, and even flies. Cattle are recognized as the important animal species responsible for harboring *E. coli* O157:H7; infection rates typically range from 2% to 16%, however, incidence rates up to 87% have been identified (18). Farm animals are likely reservoirs of human infection because the organism can survive for extended periods in animal feces (19), soil (20,21), and water (22,23).

In human infections, there is a wide variation in the shedding patterns of *E. coli* O157:H7; 66% of stool samples are negative for *E. coli* O157:H7 7 days after diarrhea, despite a lack of antibiotic therapy (24). A later study noted a median shedding period of 17 days (range 2–62 days) (25). Others found a median shedding period of 21 days (range 5–124 days, during which most of the patients were asymptomatic). In addition, changes in the *E. coli* profile of two patients were noticed over 2 weeks of shedding, specifically a loss in the Shiga toxin (Stx) gene, as noted by pulsed field gel electrophoresis (PFGE). This occurrence has important implications for epidemiological studies based on molecular techniques (26).

TRANSMISSION ROUTES

Enterohemorrhagic *E. coli* (EHEC) can be transmitted by any route where fecally contaminated material is ingested by a susceptible host. Epidemiological investigations during outbreaks have found that the infectious dose for EHEC is low (i.e., 10–200 organisms) (27). This low infectious dose combined with the possibility of asymptomatic carriage of *E. coli* O157:H7 allows direct person-to-person transmission. This is especially likely in institutional settings such as day-care facilities and hospitals (25). Incidences of infection from both recreational and occupational exposure to farm animals have been reported (28) as well as occupational exposure of healthcare and laboratory personnel (2,29). A documented outbreak of *E. coli* O157:H7 infection was linked to exposure from a contaminated building. Infected individuals had visited a county fair building, in which *E. coli* O157:H7 was isolated from the dust within the rafters. No other links were established, so this suggested airborne dispersion of the organism (30).

A common route of transmission is food, and a number of outbreaks have been reported from consumption of undercooked ground beef either in restaurants or within individual homes. This suggests important implications for modern food processing practices, where beef from various sources is ground together and distributed statewide or nationwide. In addition to meat, other foods were implicated, including mayonnaise, unpasteurized apple juice, fermented hard salami, lettuce, radish sprouts, and alfalfa sprouts. Indirect contamination of these foods may have occurred due to improper hygiene among food handlers or by contact between uncooked foods and raw meats contaminated with *E. coli* O157:H7. There is also the possibility of direct contamination of produce in the fields by manure from infected animals (6). Foodborne outbreaks have also occurred following consumption of yogurt and milk (31,32).

WATERBORNE TRANSMISSION

A number of *E. coli* O157:H7 outbreaks have been linked to recreational waters. Outside Portland, Oregon, 59 individuals were infected after swimming in a recreational lake in 1991 (33). Similarly, water from a children's paddling pool was responsible for transmitting infection to two other children in Scotland, UK, in 1992 (34). Epidemiological investigations did not reveal conclusive information; however, it was postulated that a child with diarrhea contaminated the pool with *E. coli* O157:H7, and as the pool water was not changed or disinfected, it served as the vehicle of infection for the other two children, who in turn infected others by person-to-person contact. A water park outbreak in Georgia in 1998 resulted in dozens of infections and the death of one child and was linked to low chlorine levels in the pool water (35).

The first municipal waterborne *E. coli* O157:H7 outbreak occurred in Missouri in 1989 (36); more than 240 people were infected and four individuals died. The outbreak, it was suspected, occurred from backflow during two water main breaks, leading to intrusion of the pathogen. In Wyoming, 157 people were infected by *E. coli* O157:H7 during the summer of 1998 as a result of a community water system supplied by a spring and two wells under the influence of surface water. The water in this system was not chlorinated, and the outbreak may have occurred from fecal contamination by wildlife near the spring (37). Another large waterborne outbreak occurred in New York in 1999 where an untreated well at a county fair was contaminated by an adjacent septic system. A total of 127 confirmed cases of *E. coli* O157:H7 infection occurred that led to 14 cases of HUS and 2 deaths (38).

The most publicized waterborne outbreak of *E. coli* O157:H7 occurred in May 2000 in Walkerton, Ontario. Approximately 1350 cases of gastroenteritis were reported in individuals exposed to Walkerton municipal water: overall, it was estimated that the number of cases associated with Walkerton exceeded 2300 individuals. Stool samples confirmed 167 cases of *E. coli* O157:H7 infection; 65 individuals were hospitalized, and 27 individuals developed hemolytic uremic syndrome. Four deaths were directly due to the *E. coli* outbreak in Walkerton, and *E. coli* O157:H7 was a contributing factor that led to three additional deaths. During the outbreak, a supply source well was contaminated with coliforms and *E. coli* O157:H7. This well was prone to surface contamination, especially following flooding conditions, which is what preceded the Walkerton incident. Furthermore, environmental testing of livestock farms, especially a farm adjacent to this well, indicated the presence of *E. coli* O157:H7 infections in the livestock. Had appropriate chlorine residuals been maintained during the flooding and well contamination, it would have prevented the widespread outbreak (39,40).

SUSCEPTIBILITY OF *E. COLI* O157:H7 TO CHLORINATION

The susceptibility of various strains of *E. coli* O157:H7 to chlorine disinfection has been examined in a number of studies, and, except for an occasional resistant strain (41), the organism can be rapidly inactivated by low levels of disinfectant. For example, in the study reported by Zhao et al. (41), free chlorine concentrations of 0.25, 0.5, 1.0, and 2.0 mg/L at 23 °C and sampling times of 0, 0.5, 1.0, and 2.0 min resulted in >7 log reduction. It was determined that a 0.25 mg/L free chlorine concentration required only 1 min to achieve these levels of inactivation, suggesting that this organism had no unusual tolerance to chlorine. In another study, Rice et al. (42) compared the chlorine susceptibility of *E. coli* O157:H7, isolated from two waterborne outbreaks, with four wild-type *E. coli* isolates and reported approximately 4 log inactivation using a chlorine residual of 1.1 mg/L and exposure times up to 120 s. The biocidal activity of chlorine is temperature dependent, and the temperatures used in the Rice et al. (42) study (5 °C) were intended to represent worst case conditions for both groundwater or winter surface water. This was probably a factor leading to lower inactivation levels in this study compared to those reported by Zhao et al. (41).

According to a Water Quality Disinfection Committee survey (1992), it was determined that United States water utilities maintain a median chlorine residual of 1.1 mg/L and a median exposure time of 45 minutes before the point of first use in the distribution system. This suggested that *E. coli* O157:H7 is unlikely to survive conventional water treatment in the United States at these levels of chlorination. In nondisinfected drinking water, *E. coli* O157:H7 has environmental survival or chlorine susceptibility similar to wild-type *E. coli* (43), which suggests that wild-type *E. coli* can be an adequate indicator organism of fecal contamination of water.

DIAGNOSTIC PROCEDURES

Biochemical

Unlike the majority of other *E. coli* isolates, most strains of *E. coli* O157:H7 do not ferment sorbitol within 24 h (44). This allows easy identification of O157 on sorbitol-containing media, such as sorbitol-MacConkey (sMAC) agar. Colonies of O157 appear colorless whereas sorbitol fermenters are pink or mauve. The use of sMAC agar is one of the primary screening methods used in the clinical laboratory to analyze patient specimens for the presence of serotype O157:H7 (45). It has been reported that sMAC agar has a detection sensitivity of 50–60% (14) and the use of sMAC agar is most successful early in the disease; the detection rate declines further (down to 33%) as the infection progresses. The use of cefixime-tellurite sorbitol-MacConkey agar (46) increases sensitivity and inhibits other nonsorbitol fermenting organisms. *Escherichia coli* O157:H7 also does not produce β-glucuronidase and therefore is negative by the methyl-umbelliferyl glucuronide (MUG) assay (47). A variety of selective media have been formulated to use these two biochemical characteristics by adding fluorogenic or chromogenic compounds (2). Although many of these selective media are useful, isolating and identifying *E. coli* O157:H7 by these methods has limitations. One of the greatest limitations involves the time-consuming procedures. Current USDA methods involve four enrichment and culturing steps followed by 10 biochemical confirmation tests that require a minimum of 3 days (17). In addition, there may be misidentification of *E. coli* O157:H7 because other intestinal bacteria (i.e., *E. hermanii* and *Hafnia* spp.) share similar phenotypes and resemble serotype O157:H7 on a sorbitol-containing medium. In addition, there are O157 that are not the H7 serotype or pathogenic and also cannot ferment sorbitol (48). There is also evidence to indicate that serotype O157:H7 in sorbitol-containing foods can mutate to become a sorbitol-fermenting phenotype (49). Isolation of sorbitol-fermenting *E. coli* O157 from HUS patients has also been reported (50) and these strains were also MUG assay positive. These findings were initially considered atypical, but an increasing prevalence of sorbitol-fermenting *E. coli* O157:H7 from HUS patients has been reported (51). There is also the issue of other flora within an environmental or clinical sample that mask low levels of O157:H7. In addition, it has been shown that *E. coli* O157:H7 can enter a viable but nonculturable state, especially when present for a long time in cold water. In such a situation, these culture techniques would not detect the organism isolated from water samples (22).

Immunologic

Currently, a number of tests are available commercially for detecting *E. coli* O157:H7; the majority of these assays are antibody based, using polyclonal, preadsorbed, affinity purified or monoclonal antibodies that target the surface-expressed antigens of O157 and H7, although some tests are specific for stx toxins. These antibody based tests have been used primarily in an enzyme-linked immunosorbent assay (ELISA); the most common assay is the "sandwich" type ELISA, where the same antibody is used both to capture and to detect the specific antigens. Such antibodies have also been effective for use in agglutination or latex agglutination tests and enable rapid screening or serological confirmation of isolates. Anti-O157 antibodies have also been coupled to paramagnetic beads (Dynal, Inc., Lake Success, NY) to isolate this pathogen selectively from the sample matrix by immunomagnetic separation (IMS) (52). IMS procedures have also been combined with ELISA, using colorimetric or fluorometric detection procedures. Simpler procedures have used lateral flow immunoassays, where the antibody–antigen complex is allowed to migrate along a membrane and then captured by a second antibody that is immobilized in a specific region of the membrane. The lateral flow format, which is similar to pregnancy test kits, produces a visual signal (with the aid of colloidal gold or dye encapsulating liposomes) when samples are positive and can be conducted without specialized skills or equipment. Obviously, using antibody based isolation and detection procedures can be prone to cross-reactivity with other organisms (i.e., *Citrobacter freundii*, *E. hermanii*, *Yersinia enterocolitica*) or other non-H7 serotypes; however, these can be reduced either by preadsorption procedures or by selecting specific target antigens (53).

Molecular

Molecular assays typically do not have the limitations of immunologic and biochemical methods. Molecular methods may include pulsed field gel electrophoresis (PFGE), ribotyping, and polymerase chain reaction (PCR). A number of PCR conditions have been developed for identifying *E. coli* O157:H7 based on virulence factors such as the stx, enterohemolysin, and intimin genes (2,14,15). Some multiplex PCRs have been developed that are more specific, namely, a PCR based assay that amplifies an allele in the *uidA* gene that is unique to serotype O157:H7, including phenotypic variants of serotype O157:H, that are sorbitol and methyl-umbelliferyl glucuronide positive (53). Coupled with primers specific for *stx* genes, this multiplex PCR assay simultaneously identifies isolates of serotype O157:H7 and the type of Shiga toxin they encode (54).

The advantages of molecular methods include specificity, sensitivity, and the ability to detect phenotypic variants of serotype O157:H7. However, the complexity and expense of these assays may limit their application in routine water microbiological analysis. Fortunately, some molecular detection procedures, such as the BAX® system by Dupont-Qualicon, do offer a user-friendly molecular assay. In this procedure, primers target sequences derived through random amplified polymorphic DNA (RAPD) analysis and all the PCR components are provided in a tablet format. Simple rehydration of the tablet with the lyzed test sample, followed by sample incubation in a thermal cycler (under preset thermocycling conditions) enables specific detection of *E. coli* O157. Although this assay provides a user-friendly format for specific detection of *E. coli* O157:H7, a drawback is that it uses proprietary equipment and software that necessitate an initial capital outlay of approximately $25,000.

CURRENT STATUS OF *E. COLI* O157:H7 MONITORING IN WATER

Currently, monitoring for microbial contamination of public water systems is regulated under a number of different United States Environmental Protection Agency (U.S. EPA) regulations such as the Safe Drinking Water Act (SDWA) of 1974, and amendments introduced in 1986 and 1996. A list published every 5 years contains contaminants that are known or anticipated in public water systems and could possibly require regulation. Microbial contaminants within this list are regulated by the Surface Water Treatment Rule and Total Coliform Rule of 1989. According to U.S. EPA regulations, a system that operates at least 60 days per year and serves 25 people or more or has 15 or more service connections is regulated as a public water system. Under the Total Coliform Rule, routine monitoring of tap water is required for all public water systems; the frequency and number of samples vary with the size of the system and the number of people that are served. The presence of total coliforms indicates that the system is contaminated or vulnerable to fecal contamination. For any size system, two consecutive total coliform positive samples from one site and one fecal coliform or *E. coli* positive sample result in an acute violation of the Maximum Contaminant Level (MCL) and lead to mandatory immediate notification of the public. Various procedures have been documented in *Standard Methods for the Examination of Water and Wastewater*, 20th ed. (55) to determine the presence of total coliforms, fecal coliform, and *E. coli*. However, *E. coli* O157:H7 has biochemical characteristics that do not allow detection by the techniques used for these broader groups.

The occurrence of waterborne or water-associated outbreaks has demonstrated the need for rapid user-friendly methods for isolating and detecting *E. coli* O157:H7 from source and finished water samples. The absence of such methods has hampered the accumulation of epidemiological information, the effectiveness of water treatment plants for removal or inactivation, and limited timely responsiveness during outbreak investigations, thus delaying employment of adequate control strategies to prevent further disease transmission. In a recent study, Bukhari et al. (56) evaluated four lateral diffusion (pregnancy type test kits) immunologic assays (Reveal®, Eclipse™, ImmunoCard STAT!, and Mionix) and one molecular assay (BAX). They determined that the Reveal test was the most promising and had a sensitivity level of 1×10^4 CFU. Using a molecular detection procedure (BAX® *E. coli* O157:H7 assay), a sensitivity level of 10 CFU was ascertained. Both the Reveal and BAX *E. coli* O157:H7 detection procedures, combined with an overall method, consisting of 200 mL water sample concentration (membrane filtration), enrichment in tryptic soy broth, and simultaneous capture by immunomagnetic separation, enabled rapid detection (less than 8 h) of 0.03–0.12 CFU/mL. The sensitivity and reproducibility of this overall procedure were determined by using spiked environmental water samples in multilaboratory round-robin trials, which indicated that the Reveal assay was more sensitive and reproducible when using spiked finished water samples; however, the BAX method had greater specificity, an important factor when evaluating raw water samples. It is anticipated that user-friendly procedures such as these will allow water utilities to employ these methods routinely to confirm the presence of *E. coli* O157:H7 rapidly in all total or fecal coliform positive samples. Alternatively, water providers could use these methods directly to gather epidemiological information, assess environmental survival, develop treatment strategies, or investigate risks during outbreak situations.

CONCLUSION

In conclusion, numerous waterborne outbreaks of human *E. coli* O157:H7 infection have occurred in the past; however, employing routine monitoring programs and coupling them with adequate disinfection would help reduce the risk of waterborne disease transmission. Historically, routine monitoring was not feasible for water utilities because the methods available were tedious and time-consuming; however, it has become viable with the methods recently described by Bukhari et al. (56), which would allow water utilities to rapidly arm themselves with the relevant information to use appropriate contingency measures to ensure continued safety from this significant human pathogen.

EUTROPHICATION AND ORGANIC LOADING

Scott A. Lowe
Manhattan College
Riverdale, New York

The connection between eutrophication and organic loading was first realized in the 1870s by engineers in London. They concluded that when sewage was discharged into local rivers, the level of dissolved oxygen (DO) dropped, and the amount of algae increased. In other words, the rivers were eutrophied.

Raw sewage contains organic matter (including pathogens that make it so harmful when mixed in drinking water). The typical composition by weight of raw sewage is about 42% carbon (C), 7% nitrogen (N), and 1% phosphorus (P). The remaining 50% is water. This is also our human stoichiometry.

When discharged into a receiving water such as a lake, river, or estuary, the sewage begins to break down into its components. The sewage carbon, for example, oxidizes to CO_2:

$$C \rightarrow CO_2 \tag{1}$$

Stoichiometrically, it can be seen that $2 \times 16\,\mathrm{g\,O}$ is required to oxidize 12 g of carbon, or expressed as a ratio, 2.67 g O/g C. Similarly, for sewage nitrogen, which is mainly bound up as ammonia, NH_3:

$$NH_3 \rightarrow NO_3{}^- + H_2O + H^+ \tag{2}$$

The stoichiometry is 4×16 g O for every 14 g N; as a ratio, 4.57 g O/g N.

Phosphorus in raw sewage is bound up mainly as orthophosphate, PO_4, which is already in an oxidized state and so remains unchanged.

The oxygen that is consumed in this degradation process is supplied by the receiving water DO—hence the drop in DO that was observed in those London rivers. The other observed consequence of high levels of organic loading is excessive algal activity. To understand this phenomenon, one must consider what algae, typically phytoplankton, require to grow.

Phytoplankton have an internal stoichiometry that is similar in proportion to that described above for sewage, that is, 42% C, 7% N, and 1% P. The rest is water. To grow, they need to consume C, N, and P in this proportion. Being plants, they obtain their carbon from dissolved CO_2 in water, in the well-known process of photosynthesis. This also means that phytoplankton require sufficient light to grow.

The N and P that phytoplankton require come from dissolved N and P in the water. This N and P results from the breakdown of organic matter, as described before. If all four items (light, C, N, and P) are supplied in excess, then extreme algal growth occurs. This creates obvious visual effects such as "pea soup" in a pond or lake or "red tides" in the ocean.

To control this phenomenon, C is not important because there is always excess dissolved CO_2 in the water compared to the other nutrients, N and P. Light is also considered uncontrollable in natural systems. Therefore, control efforts center around N and P. The ratio at which algae need N and P is called the nitrogen to phosphorus ratio, simply N/P. It is approximately 7; algae need approximately seven times as much N as P, per their internal composition (7%N and 1%P). Therefore, if N and P in the water are measured (N as dissolved NH_3 and NO_3 and P as dissolved PO_4), then the ratio of actual N/P can be compared to the algal N/P ratio of 7.

The implication of this comparison is that if the measured N/P ratio is greater than, say, 10, then there is excess nitrogen in the water and the lack of phosphorus is limiting algal growth. Conversely, a low N/P ratio would imply that a lack of nitrogen is limiting algal growth. This is known as the limiting nutrient concept. Once the limiting nutrient (either N or P) for a system is identified, then efforts at eutrophication control will focus on further restricting inputs of this nutrient to the system. If the system is relatively balanced in both N and P, then whichever of the two is easier and more cost-effective to control is focused on.

In general, it has been found that freshwater systems are P limited, whereas marine systems, including estuaries, are N limited. Some real world examples of attempts to control eutrophication include:

- the ban on phosphorus in detergents and fertilizers in the watersheds that drain to the Great Lakes, which are P-limited;
- the upgrading of wastewater treatment plants to remove N that discharge to Long Island Sound, which is N-limited;
- the installation of tertiary treatment to remove P in wastewater treatment plants on watersheds that drain into New York City's drinking water reservoirs, which are P-limited; and
- the upgrading of wastewater treatment plants to remove N that discharge to Chesapeake Bay, which is N-limited.

Two final points—first, organic loads can come from raw sewage, and also from a myriad of other sources such as

- agricultural runoff
- industrial discharges
- forests
- urban runoff
- stormwater
- wastewater treatment plants

Second, sediment often contains large amounts of organic matter as a result of organic loading. One consequence of this is that even when the external organic load is reduced, for example, by treating raw sewage in a wastewater treatment plant, there still remains an internal source of nutrients for algal growth. Additionally, sediments with high organic content also exert an oxygen demand on the water, known as SOD—sediment oxygen demand.

TRACE ELEMENT CONTAMINATION IN GROUNDWATER OF DISTRICT HARDWAR, UTTARANCHAL, INDIA

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

The trace element contamination in the groundwater of District Hardwar in the state of Uttaranchal (India) has been assessed to find the suitability of groundwater for drinking purposes. Forty-eight groundwater samples from shallow and deep aquifers were collected during both pre- and postmonsoon seasons in 2002 and analyzed for Fe, Mn, Cu, Ni, Cr, Pb, Cd, and Zn. The presence of trace elements in groundwater was recorded in all samples, but these were not significantly higher. Water quality standards were violated for iron and manganese at certain locations. The concentration of iron varies from 210 to 7004 μg/L during the premonsoon season and from 163 to 6555 μg/L during the postmonsoon season against the maximum permissible limit of 1000 μg/L; that of manganese varies from 7.5 to 839 μg/L during the premonsoon and from 9 to 859 μg/L during the postmonsoon season against the limit of 300 μg/L. The concentration of copper, chromium, lead, cadmium, and zinc were well within the permissible limits in all samples from District Hardwar.

INTRODUCTION

The contamination of groundwater by trace elements has received great attention in recent years due to their toxicity and accumulative behavior. These elements, in contrast to most pollutants, are not biodegradable and undergo a global ecobiological cycle in which natural waters are the main pathways. The major sources of trace elements in groundwater include weathering of rock minerals, discharge of sewage and other waste effluents on land, and runoff water. The water used for drinking should be free from any toxic elements, living and nonliving organisms, and excessive amounts of minerals that may be hazardous to health. Some trace elements are essential for humans, for example, cobalt and copper, but large quantities of them may cause physiological disorders. Cadmium, chromium, and lead are highly toxic to humans even in low concentrations.

The creation of the new state of Uttaranchal has posed many challenges for planners and policy makers. Problems such as drinking water, transportation, power sector, housing and construction, and safety from natural hazards are very serious and require immediate attention. For sustainable development of a society, it is essential that the natural resources are used judiciously for the benefit of the existing population and also to meet the needs and aspirations of future generations. Drinking water is one such precious commodity for which a planned strategy is needed for immediate demands and for sustainability for future needs also. A large part of the state of Uttaranchal lies in the hills, where distribution of the drinking water supply and its quality are major problems needing immediate attention. The physicochemical and bacteriological characteristics of the groundwater of District Hardwar in the state of Uttaranchal have been described in an earlier report (1). In this article, the groundwater quality is examined with reference to trace elements.

STUDY AREA

District Hardwar is part of the Indo-Gangetic plains that lie between latitude 29°30′ and 30°20′ N and between longitude 77°40′ and 78°25′ E in the state of Uttaranchal (Fig. 1). It is the largest district (populationwise) of Uttaranchal State and occupies an area of about 2360 km^2. Per the 2001 census, the population of the District Hardwar is 14,44,213 and the population density is 612 per km^2.

Physiographically, the area is generally flat except for the Siwalik Hills in the north and northeast. The area is devoid of relief features of any prominence except for deep gorges cut by ravines and rivers flowing through the area. The area is bounded by River Yamuna in the west and River Ganga in the east. The climate of the area is characterized by a moderate type of subtropical monsoon. The average annual rainfall in the region is about 1000 mm; the major part is received during the monsoon period. The major land use is agriculture, and there is no effective forest cover. The soils of the area are loam to silty loam and are free from carbonates. The most common groundwater use is by hand pumps and tube wells. Based on the lithologic logs and water table fluctuation data, two types of aquifers have been delineated in the area. The upper is a shallow unconfined aquifer that generally extends to depths around 25 m. The deeper is confined to semiconfined and located about 25 to 150 m below ground level separated by three to four aquifers at average depths of 25 to 55, 65 to 90, and 120 to 150 m. Water table contours in the area indicate the southward trend of groundwater flow in both unconfined and confined aquifers.

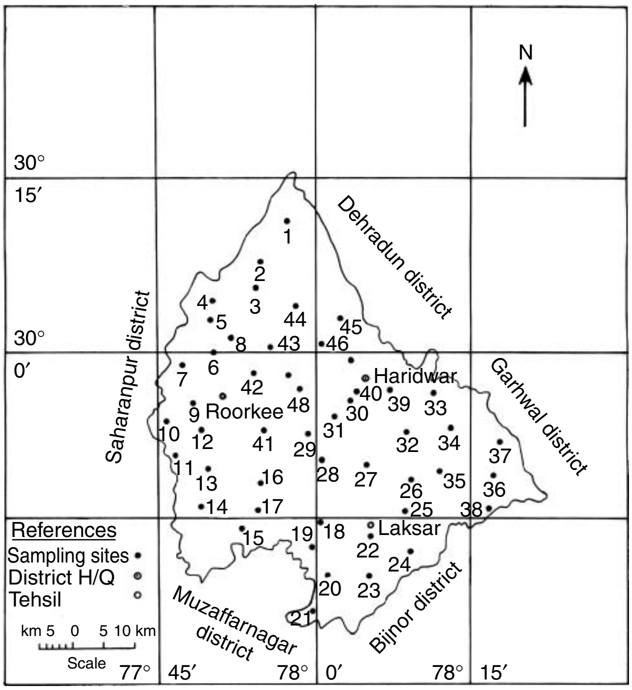

Figure 1. Study area showing location of sampling sites (District Hardwar).

EXPERIMENTAL METHODOLOGY

Forty-eight groundwater samples from District Hardwar were collected during both pre- (June 2002) and postmonsoon (October 2002) seasons from various abstraction sources at various depths covering extensively populated area, commercial, industrial, agricultural, and residential colonies, so as to obtain a good areal and vertical representation; they were preserved by adding ultrapure nitric acid to a pH of 2.0 (2,3). The hand pumps and tube wells were continuously pumped prior to sampling to ensure that groundwater sampled was representative of the groundwater aquifer. The details of sampling locations and source and depthwise distribution are given in Tables 1 and 2, respectively.

Metal ion concentrations were determined by atomic absorption spectrometry using a Perkin-Elmer Atomic Absorption Spectrometer (Model 3110) using an air–acetylene flame. Operational conditions were adjusted in accordance with the manufacturer's guidelines to yield optimal determination. Quantification of metals was based upon calibration curves of standard solutions of respective metals. These calibration curves were determined several times during the period of analysis. The detection limits for iron, manganese, copper, nickel, chromium, lead, cadmium and zinc are 0.003, 0.001, 0.001, 0.004, 0.002, 0.01, 0.0005, and 0.0008 mg/L, respectively.

RESULTS AND DISCUSSION

The Bureau of Indian Standards (BIS), earlier known as the Indian Standards Institution (ISI), laid down standard specifications for drinking water during 1983; they have been revised and updated from time to time. To enable the users to exercise their discretion toward water quality criteria, the maximum permissible limit has been prescribed especially where no alternate source is available. The national water quality standards describe essential and desirable characteristics that must be evaluated to assess the suitability of water for drinking (4). The trace element data for the two sets of samples collected during pre- and postmonsoon seasons are presented in Figs. 2–9. The toxic effects of these elements and the

extent of their contamination in the groundwater are discussed in the following sections.

Iron (Fe)

The concentration of iron in the groundwater of District Hardwar ranges from 210 to 7004 µg/L during the premonsoon season and from 163 to 6555 µg/L during the postmonsoon season; its distribution at different sites is shown in Fig. 2. The Bureau of Indian Standards has recommended 300 µg/L as the desirable limit and 1000 µg/L as the maximum permissible limit for drinking water (4). It is

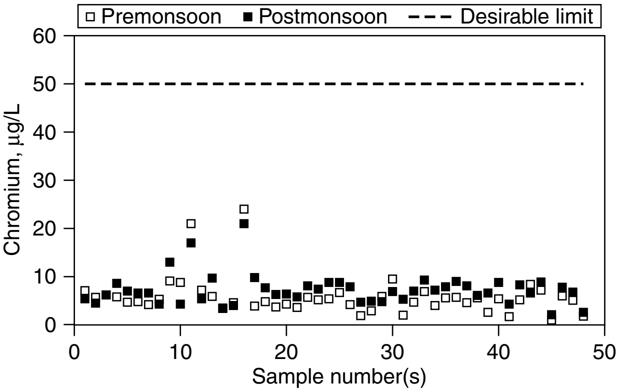

Figure 6. Distribution of chromium at different sampling locations.

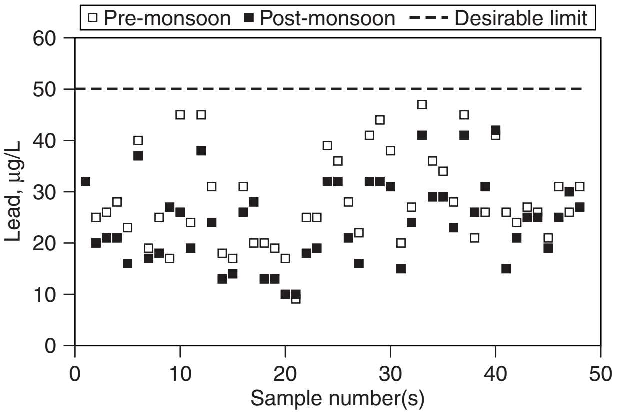

Figure 7. Distribution of lead at different sampling locations.

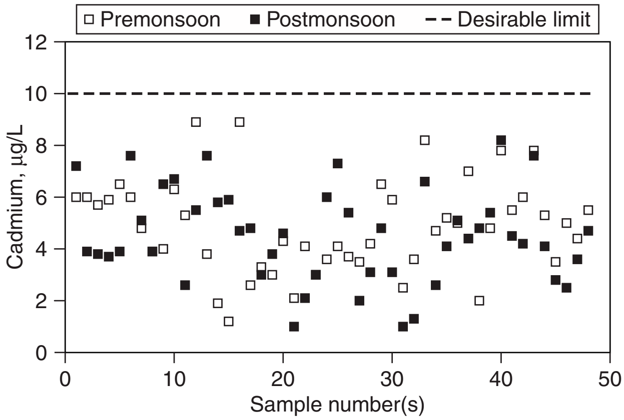

Figure 8. Distribution of cadmium at different sampling locations.

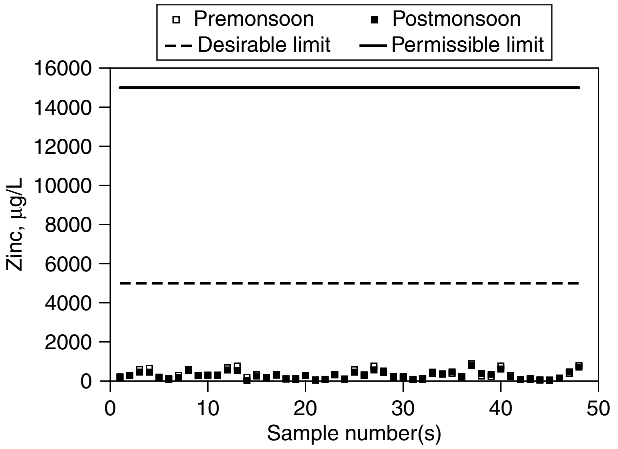

Figure 9. Distribution of zinc at different sampling locations.

evident from the results that only about 15% of the samples fall within the desirable limit of 300 µg/L and about 35% of the samples even cross the maximum permissible limit of 1000 µg/L. High concentrations of iron generally cause an inky flavor and a bitter, astringent taste. It can also discolor clothes and plumbing fixtures and cause scaling, which encrusts pipes. Excessive concentration may promote bacterial activities in pipe and service mains, causing objectionable odors and red-rot disease in water. Well water containing soluble iron remains clear while pumped out, but exposure to air causes precipitation of iron due to oxidation and a resulting rusty color and turbidity.

The increase in iron concentrations during the postmonsoon season may be due to mixing phenomena of recharge water that has more oxygen to react with iron ore, which may be available in clay lenses in the aquifer. The limits of iron in water supplies for potable use have not been laid down from health considerations but are due to the fact that iron in water supplies may cause discoloration of clothes, plumbing fixtures, and porcelain ware. The "red-rot" disease of water, caused by bacterial precipitation of hydrated oxides of ferric iron that give an unaesthetic appearance to water, clog pipes, pit pipes, and cause foul smells, is due to the presence of relatively high iron in water. The concentration of iron in natural water is controlled by both physicochemical and microbiological factors. The weathering of rock and discharge of waste effluents on land are generally considered the main sources of iron in groundwater. Iron migrates adsorbed to suspended matter, as insoluble hydrated iron compounds complexed to inorganic and organic ligands, and also as hydrated ions. Dissolved carbon dioxide, pH, and E_h of water affect the nature of aqueous iron species in the water. In groundwater, iron generally occurs in two oxidation states, ferrous (Fe^{2+}) and ferric (Fe^{3+}) forms.

Manganese (Mn)

The concentration of manganese was recorded at a maximum level of 839 μg/L during the premonsoon season and 859 μg/L during the postmonsoon season; its distribution at different sites is shown in Fig. 3. Manganese is an essential element, which does not occur naturally as a metal but is found in various salts and minerals frequently in association with iron compounds. In general, the concentration of manganese in groundwater is low due to geochemical control. A concentration of 100 μg/L has been recommended as a desirable limit and 300 μg/L as the permissible limit for drinking water (4). The WHO has prescribed 500 μg/L as a provisional guideline for drinking water (5). The presence of manganese above the permissible limit in drinking water often imparts an alien taste to water. It also has adverse effects on domestic uses and water supply structures.

It is evident from the results that about 35% of the samples from District Hardwar fall within the desirable limit of 100 μg/L, 50% of the samples cross the desirable limit but are within the permissible limits, and about 10–15% of the samples exceed the permissible limit of 300 μg/L. The high concentration of manganese at few locations may be attributed to the reducing conditions of the water and dissolution of manganese bearing minerals from the soil strata. Manganese may gain entry into the body by inhalation, consumption of food, and through drinking water.

Copper (Cu)

The concentration of copper was recorded at a maximum level of 47 μg/L during the premonsoon season and 41 μg/L during the postmonsoon season. The distribution of copper at different sites during the pre- and postmonsoon seasons is shown in Fig. 4. The Bureau of Indian Standards has recommended 50 μg/L as the desirable limit and 1500 μg/L as the permissible limit in the absence of alternate sources (4). Beyond 50 μg/L, the water has an astringent taste and causes discoloration and corrosion of pipes, fittings, and utensils. The World Health Organization has recommended 2000 μg/L as the provisional guideline for drinking water (5).

All samples from District Hardwar fall below the desirable limit of 50 μg/L. As such, the groundwater of District Hardwar can be safely used as a source of drinking water supplies. In general, the principal sources of copper in water supplies are corrosion of brass and copper pipe and addition of copper salts during water treatment for algae control. The toxicity of copper to aquatic life depends on the alkalinity of the water. At lower alkalinity, copper is generally more toxic to aquatic life. Copper, if present in excess amount in public water supplies, enhances corrosion of aluminum and zinc utensils and fittings. High intake of copper may result in damage to the liver. The industrial sources of copper that enhance the concentration in groundwater include industrial effluents from electroplating units, textiles, paints, and pesticides.

Nickel (Ni)

The concentration of nickel in the study area was recorded at a maximum level of 61 μg/L during the pre- and postmonsoon seasons; its distribution at different sites is shown in Fig. 5. The World Health Organization has recommended 20 μg/L as the guideline for drinking water (5).

More than 50% of the samples from District Hardwar exceed the WHO limit of 20 μg/L during pre- as well as postmonsoon seasons. The violation of the BIS limit could not be ascertained as no permissible limit of nickel has been prescribed in BIS drinking water specifications. Nickel at trace levels is essential to human nutrition, and no systemic poisoning from nickel is known in this range. The level of nickel usually found in food and water is not considered a serious health hazard. Some of the important nickel minerals include garnierite, nickeliferous limonite, and pentiandite. Certain nickel compounds have carcinogenic effects on animals; however, soluble compounds are not currently regarded as human or animal carcinogens.

Chromium (Cr)

The concentration of chromium in the study area was recorded at a maximum level of 24 μg/L during the premonsoon season and 21 μg/L during the postmonsoon season; in this range, it is not harmful to humans. The distribution of chromium at different sites during pre- and postmonsoon seasons is shown in Fig. 6. A concentration of 50 μg/L has been recommended as a desirable limit for drinking water (4). The WHO has also prescribed 50 μg/L as the guideline for drinking water (5). All samples from the study area fall well within the desirable limit for drinking water.

The two important oxidation states of chromium in natural waters are +3 and +6. In well-oxygenated waters, Cr(+6) is the thermodynamically stable species. However, Cr(+3) is kinetically stable and could persist bound to naturally occurring solids. Interconversions of Cr(+3) and Cr(+6) occur in conditions similar to those in natural waters. Municipal wastewater releases a considerable amount of chromium into the environment. Chromium is not acutely toxic to humans due to the high stability of natural chromium complexes in abiotic matrices. In addition, the hard acid nature of chromium imparts a strong affinity for oxygen donors rather than sulfur donors present in biomolecules. However, Cr(+6) is more toxic than Cr(+3) because of its high rate of adsorption through intestinal tracts. In the natural environment, Cr(+6) is likely to be reduced to Cr(+3), thereby reducing the toxic impact of chromium discharges.

Lead (Pb)

The concentration of lead in the study area was recorded at a maximum level of 47 μg/L during the premonsoon season and at 42 μg/L during the postmonsoon season. The distribution of lead at different sites during the pre- and postmonsoon seasons is shown in Fig. 7. The Bureau of Indian Standards has prescribed 50 μg/L lead as the desirable limit for drinking water (4). Beyond this limit, water becomes toxic. WHO has also prescribed the same guideline for drinking water (5).

All samples from District Hardwar fall within the permissible limit for drinking water during the pre- as well as the postmonsoon seasons, and therefore, the groundwater in the study area can be safely used as a source of drinking water supplies. The major source of lead contamination is the combustion of fossil fuel. Lead is removed from the atmosphere by rain, falls back on the earth's surface, and seeps into the ground. Lead passes from the soil to water and to plants and finally into the food chain. In drinking water, it occurs primarily due to corrosion of lead pipes and solder, especially in areas of soft water. Dissolution of lead requires extended contact time, so lead is most likely to be present in tap water after being in the service connection piping and plumbing overnight.

Cadmium (Cd)

Cadmium is a nonessential, nonbeneficial element known to have a high toxic potential. The cadmium content in the study area varies from 1.2 to 9.0 μg/L during the premonsoon season and from 1.0 to 8.2 μg/L during the postmonsoon season. The distribution of cadmium at different sites during the pre- and postmonsoon seasons is shown in Fig. 8. The Bureau of Indian Standards has prescribed 10 μg/L cadmium as the desirable limit for drinking water (4). Beyond this limit, water becomes toxic. WHO has prescribed 3 μg/L cadmium as the guideline for drinking water (5).

All samples from District Hardwar were within the desirable limit of 10 μg/L, as prescribed by BIS. It is obvious, therefore, that the groundwater of District Hardwar does not present any cadmium hazards to humans. The levels of cadmium in public water supplies are normally very low; generally, only small amounts exist in raw water, and many conventional water treatment processes remove much of the cadmium. Drinking water that contains more than 10 μg/L of cadmium can cause bronchitis, emphysema, anemia, and renal stone formation in animals. Cadmium can also enter the environment from a variety of industrial sources, including mining and smelting, electroplating, and pigment and plasticizer production. Drinking water is generally contaminated by galvanized iron pipe and plated plumbing fittings of the water distribution system. The U.S. EPA has classified cadmium as a probable human carcinogen based on positive carcinogenicity testing. However, no such health hazard is expected in the groundwater of District Hardwar.

Zinc

The concentration of zinc in the study area ranges from 44 to 878 μg/L during the premonsoon season and from 15 to 787 μg/L during the postmonsoon season. The distribution of zinc at different sites during the pre- and postmonsoon seasons is shown in Fig. 9. The Bureau of Indian Standards has prescribed 5000 μg/L zinc as the desirable limit and 15,000 μg/L as the permissible limit for drinking water (4). The WHO has prescribed 3000 μg/L as the guideline for drinking water (5). In the study area, all samples analyzed were within the desirable limits prescribed by the BIS (4) and the WHO (5).

CONCLUSIONS AND RECOMMENDATIONS

The groundwater quality in District Hardwar varies from place to place and with the depth of the water table. The water drawn for domestic applications should be tested and analyzed to ensure the suitability of groundwater for human consumption. The heavy metals except iron and manganese, which are present in appreciable concentration in groundwater, have been below the prescribed maximum permissible limits. The concentration of iron varies from 210 to 7004 μg/L during the premonsoon season and from 163 to 6555 μg/L during the postmonsoon season compared to the maximum permissible limit of 1000 μg/L; that of manganese varies from 7.5 to 839 μg/L during premonsoon and from 9 to 859 μg/L during the postmonsoon season compared to the 300 μg/L limit. The concentration of copper, chromium, lead, cadmium, and zinc were well within the permissible limits in all samples from the study area.

IRON BACTERIA

Baikun Li
Pennsylvania State University
Harrisburg, Pennsylvania

GENERAL INTRODUCTION

Iron is one of the most abundant elements found in nature, accounting for at least 5% of Earth's crust. On the surface of Earth, iron exists naturally in two oxidation states, ferrous (Fe^{2+}) and ferric (Fe^{3+}). Dissolved or ferrous iron is usually found only in groundwater supplies that have not been exposed to oxygen. Water containing ferrous iron is clear and colorless. At contact with the air, the dissolved ferrous iron reacts with oxygen and forms insoluble ferric oxide, also known as iron oxide or "red rust." Water containing ferric iron has undesirable odors and tastes. Iron staining has caused problems in well systems and water distribution pipelines. With the presence of iron bacteria, iron may cause the corrosion of steel piping components.

Iron bacteria are found in all parts of the world, with the exception of the southern polar region. The "true" iron bacteria are microorganisms in which the oxidation of iron is an important source for their metabolic energy. This group is most often associated with filamentous and stalked forms that are encrusted with iron *(Thiobacillus*, *Leptothrix*, *Clonothrix*, *Gallionella*, *Sphaerotilus)*. During the oxidation, soluble ferrous iron (Fe^{2+}) is transferred to insoluble ferric iron (Fe^{3+}), which then precipitates out of solution. The overall reaction of spontaneous ferrous iron oxidation is

$$Fe^{2+} + 0.25\ O_2 + 2.5\ H_2O \rightarrow Fe(OH)_3 + 2H^+$$

The energy released from this reaction promotes the growth of thread-like slimes, which, with the ferric iron, form a voluminous mass that has caused clogging in the water supply system.

Thiobacullus ferrooxidans (Fig. 1) and *Leptothrix ferrooxidans* (Fig. 2) are the best-known iron-oxidizing bacteria. Both of them can grow autotrophically with ferrous iron (Fe^{2+}) as the electron donor. They are very common in acid-polluted environments such as coal-mining dumps. Also, acidophilic iron bacteria exist, such as *Ferrobacillus ferrooxidans* and *Ferroplasma acidophilum* (archaeon), which can oxidize iron in low pH environments (even $pH = 0$) at high temperature (50 °C), and are most commonly found associated with acid mine waste. The acidophilic bacteria are not commonly found in drinking water supplies.

Iron bacteria also cause the majority of problems in water pumps and pipes, blocking them with a brown, slimy, clay-like material (Fig. 3). Sometimes a bad odor comes from the water, like rotten eggs. Iron bacteria are not harmful to humans, but they are harmful to pipelines and pumps. If left untreated, they will cause the eventual blockage of the bore and failure of the pump.

Normally, iron bacteria refer to those in which the oxidation of iron is an important source for their metabolic energy, but another type of iron bacteria exists: iron-reducing bacteria, which get metabolic energy by reducing ferric iron to ferrous iron under anoxic or anaerobic condition with the presence of organic matters or other electron donors. Important ferric reducers include *Shewanella*, *Geobacter*, *Geospirillum*, and *Geovibrio*. Iron-reducing bacteria are important at natural cleanup and energy production.

Figure 1. *T. ferrooxidans* cell suspension viewed by an electron microscope (magnified 30,000 times) (1).

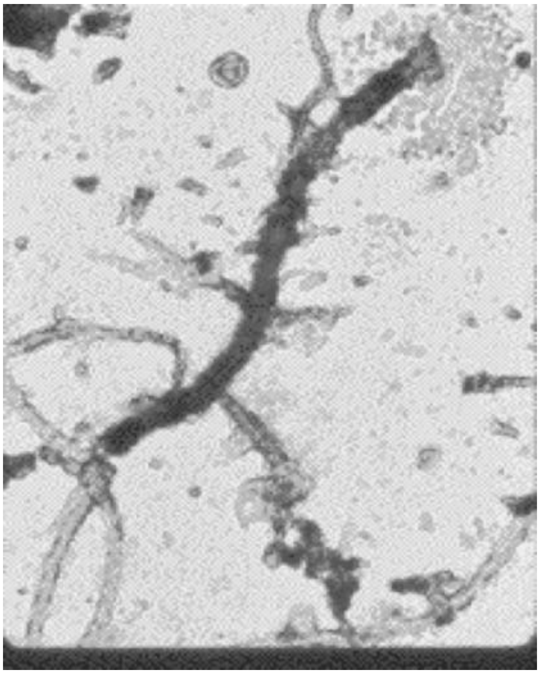

Figure 2. Iron and manganese oxide precipitants deposited on filaments of *Leptothrix ferrooxidans* (2).

IRON-OXIDIZING BACTERIA

Most iron-oxidizing bacteria grow and multiply in water and use dissolved iron as part of their metabolism. They oxidize ferrous (Fe^{2+}) iron into its insoluble ferric state (Fe^{3+}) and deposit it in the slimy gelatinous material that

Figure 3. The cut section of a cast-iron pipe shows a severe iron bacteria buildup on the pipe walls.

surrounds their cells. These filamentous bacteria grow in stringy clumps and are found in most iron-bearing surface waters. They have been known to proliferate in waters containing iron as low as 0.1 mg/L. To carry out the oxidation function, these aerobic bacteria need at least 0.3 ppm of dissolved oxygen in the water.

Iron-Oxidizing Bacteria in Groundwater and Surface Water System

Although iron bacteria do not cause health problems in people, they may have the following unpleasant and possibly expensive effects: cause unpleasant odors and tastes in water, corrode plumbing equipment, reduce well yields (clog screens and pipes), and increase chances of sulfur bacteria infestation for pipeline corrosion. Iron bacteria can build up in a stagnant section of the water supply system, such as the quick disconnect fittings of recoil hoses that are not regularly flushed. If the iron bacteria buildup becomes thick enough, anaerobic conditions may develop at the wall of the fitting or pipe that can cause corrosion of stainless steel or growth of sulfate-reducing bacteria.

The growth of iron bacteria also causes biofouling and blockage in groundwater bores. Although most groundwater contains some iron, iron bacteria do not affect all bores in the absence of oxygen. When iron bacteria infect a bore, the resulting growth may be suspended in water or deposited onto the bore hole equipment. Iron oxide (because of the oxidation by iron bacteria) suspended in the bore water is usually exhibited as biofouling in the irrigation pipes, which will deteriorate the pipeline surface and cause corrosion and shorten the pipeline lifetime. Bacterial growth deposits impact the bore hole equipment as well as the irrigation plumbing.

Normally, the presence of iron and oxygen in water triggers the growth of iron bacteira. Although iron is present in water, it is seldom found at concentrations greater than 10 mg/L or 10 parts per million (ppm). The U.S. Environmental Protection Agency (EPA) did not include iron in the National Primary (health-related) Drinking Water Regulations, but they did set a Secondary Regulation limit of 0.3 mg/L based on aesthetic and taste considerations. Surface water supplies usually have concentrations below the standard level (0.05–0.20 mg/L), although higher levels may be present because of corrosion of pipes. Higher iron levels (1.0–10 mg/L) are most common in groundwater supplies.

Iron-Oxidizing Bacteria in Acid Mining Drainage (AMD)

Mine drainage is metal-rich water formed from chemical reaction between water and rocks containing sulfur-bearing minerals. The runoff formed is usually acidic and frequently comes from areas where ore- or coal-mining activities have exposed rocks containing pyrite—a sulfur-bearing mineral with the major component of FeS. When pyrite is exposed to air and reacts with oxygen and water, sulfuric acid and dissolved iron (Fe^{2+}) are produced (Reaction 1). Ferrous iron is oxidized to ferric (Fe^{3+}) when reacting with oxygen (Reaction 2) and forms ferric hydroxide ($Fe(OH)_3$, Reaction 3). Ferric hydroxide precipitates to form the red, orange, or yellow sediments in the bottom of streams containing mine drainage. The acid runoff further dissolves heavy metals such as copper, lead, and mercury into ground or surface water. In the natural environment, the formation of acid mine drainage would take a long time to develop. But the rate and degree by which acid mine drainage proceeds can be dramatically sped up by the action of certain bacteria (e.g., *Thiobacillus ferrooxidans*).

$$4FeS_{2(s)} + 14O_{2(g)} + 4H_2O_{(l)} \rightarrow 4Fe^{2+}{}_{(aq)} + 8SO_4{}^{2-}{}_{(aq)} + 8H^+{}_{(aq)} \quad (1)$$

$$4Fe^{2+}{}_{(aq)} + O_{2(g)} + 4H^+{}_{(aq)} \rightarrow 4Fe^{3+}{}_{(aq)} + 2H_2O_{(l)} \quad (2)$$

$$4Fe^{3+}{}_{(aq)} + 12H_2O_{(l)} \rightarrow 4Fe(OH)_{3(s)} + 12H^+{}_{(aq)} \quad (3)$$

The overall reaction for pyrite oxidation and precipitation (Reaction 4) is as follows:

$$4FeS_{2(s)} + 15O_{2(g)} + 14H_2O_{(l)} \rightarrow 4Fe(OH)_{3(s)} + 8SO_4{}^{2-}{}_{(aq)} + 16H^+{}_{(aq)} \quad (4)$$

In acid creeks in mining regions like Contrary Creek, VA (Fig. 4), iron-rich precipitates often contain sulfur and are yellow. Many iron-oxidizing bacteria such as *T. thiooxidans* and *T. ferrooxidans* produce this "yellow boy," a yellowish-orange precipitate that turns the acidic runoff in the streams to an orange or red color and covers the stream bed with a slimy coating.

Although iron-oxidizing bacteria play a nuisance role in acid mine drainage, they are the central role for microbial mining, in which the leaching of copper from low-grade ore can recover copper from the drainage water of mines and improve the copper content and ore grade. Many ores that are sources of metals (copper) are sulfide (HS^-), which are highly insoluble minerals. If the concentration of metal in the ore is low, it may not be economically feasible to concentrate the mineral by conventional chemical means. On the other hand, the oxidized status of sulfide–sulfate ($SO_4{}^{2-}$) forms a water-soluble mineral, which can improve

Figure 4. Acid creeks in mining regions at Contrary Creek, VA (picture from USGS website) (3).

the copper content in ores. The natural oxidization from sulfide to sulfate is slow, but it could be catalyzed with the presence of iron-oxidizing bacteria (e.g., *T. ferrooxidans*), thus aiding in the solubilization of the metal (Reactions 5 and 6). Through these processes, the soluble copper sulfate can be recovered from ore (4).

$$Fe^{2+} + \tfrac{1}{4}O_2 + H^+ \rightarrow Fe^{3+} + \tfrac{1}{2}H_2O \quad \text{(by } \textit{T. ferrooxidans}\text{, or } \textit{L. ferrooxidans}\text{)} \qquad (5)$$

$$CuS(\text{insoluble copper}) + 8Fe^{3+} + 4H_2O \rightarrow Cu^{2+}(\text{soluble copper}) + 8Fe^{2+} + SO_4{}^{2-} + 8H^+ \qquad (6)$$

IRON-REDUCING BACTERIA IN BIOREMEDIATION AND ENERGY PRODUCTION

Besides aerobic iron-oxidizing bacteria (normally referred to as iron bacteria), another type of bacteria exists: anaerobic iron-reducing bacteria, which use ferric iron as an electron acceptor for energy metabolism. A wide variety of both chemoorganotrophic and chemolithotrophic bacteria can have this feature. Ferric reduction can be coupled to the oxidation of several organic and inorganic electron donors. Various organic compounds, including aromatic compounds, can be oxidized anaerobically by iron-reducers. Much research on the energetics of ferric iron reduction has been done in the gram-negative bacterium: *Shewanella putrefaciens*, in which ferric-dependent anaerobic growth occurs with various organic electron donors. Other important ferric reducers include *Geobacter, Geospirillum*, and *Geovibrio*.

Geobacter metallireducens has been a model for study of the physiology of Fe^{3+} reduction. This organism can oxidize acetate with Fe^{3+} as an acceptor as follows:

$$\text{Acetate} + 8Fe^{3+} + 4H_2O \rightarrow 2HCO_3{}^- + 8Fe^{2+} + 9H^+$$

Geobacter can also use H_2 or other organic electron donors including aromatic hydrocarbon toluene as the electron donor, which may be environmentally significant because toluene from accidental spills or leakage from hydrocarbon storage tanks often contaminates ferric-rich aquifers, and it has been suggested that organisms like *Geobacter* may be natural cleanup agents in such environments (4).

Another distinct feature of the *Geobacter* species is that it has the ability to directly transfer electrons onto the surface of electrodes, which has made it possible to design novel microbial fuel cells that can efficiently convert waste organic matter to electricity. It has been found that dissimilatory metal-reducing microorganisms, such as *Geobacter* and *Rhodoferax* species (5,6), have the novel ability to directly transfer electrons throughout the cell membrane onto the surface of electrodes, which has led to the construction of microbial fuel cells that are more efficient than are traditional microbial fuel cells in that previously described microbial fuel cells depended on the toxic electron shuttling mediator (e.g., thionine, benzylviologen, phenazines, and phenoxazines) (7,8) to transfer electrons from cell membrane to electrode. As *Geobacter* can transfer electrons onto the electrodes by themselves, no electron shuttling mediator is needed, which can reduce the toxicity to bacterium and make microbial fell cells more cost-effective (Fig. 5). In addition, because *Geobacter* can biodegrade many contaminants, it is possible to harvest electricity from many types of waste organic matter or renewable biomass (5).

SOLUTION FOR BIOFOULING AND WATER COLOR CAUSED BY IRON BACTERIA

Because of the expensive cost incurred by biofouling, corrosion, and red water in the water supply system, efficient approaches should be employed to prevent and control the growth of iron bacteria in water supply and groundwater systems. Currently, chemical and mechanical methods for treating iron bacteria problems are available.

Chemical Treatment

Because it is difficult to get rid of iron bacteria once they exist in well systems, prevention is the best safeguard against accompanying problems. For well drillers, prevention means disinfecting everything that goes into the ground with a strong chlorine solution (250 ppm). As iron bacteria are nourished with the presence of carbon and other organics, it is essential

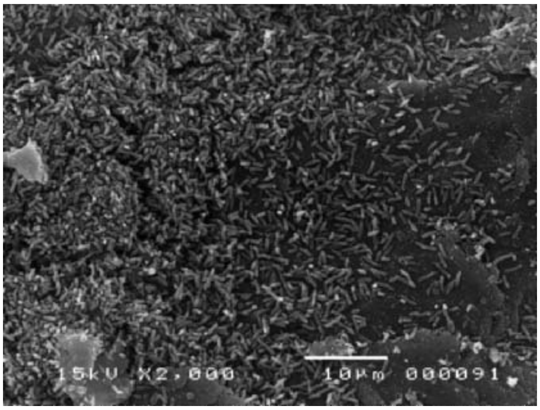

Figure 5. *Geobacter* colonizing a graphite electrode surface in a microbial fuel cell (9).

that these are not introduced into any part of the well system during the drilling process. Also, temperature is normally low in groundwater drilling systems, which leads to the much slower chemical reactions in wells. Therefore, bacterial cells need a long exposure to the chemical for the treatment to be effective.

Mechanical Treatment

In addition to the chemical treatment, mechanical approaches are available to control the iron bacteria in community water systems. Stagnant water conditions can be avoided by looping dead-end plumbing lines and periodically flushing low-flow lines to reduce bacteria. Forcing hot water or steam into a well to disperse the slime and kill the bacteria has also worked well. In addition, flushing large quantities of heated water into the aquifer has been found successful in field tests.

CARTRIDGE FILTERS FOR IRON REMOVAL

D.V. Vayenas
G. Lyberatos
University of Ioannina
Agrinio, Greece

INTRODUCTION

The presence of iron in a water supply at concentrations that exceed the secondary drinking water standards of 0.2 mg/L (1) is undesirable for the following reasons (2): (1) iron precipitates give water a reddish color when exposed to air, (2) iron gives water an undesirable metallic taste, (3) deposition of iron in the distribution system can reduce the effective pipe diameter and eventually clog a pipe, and (4) iron is a substrate for bacterial growth in water mains. When iron bacteria die and slough off, bad odors and unpleasant tastes may result. Consequently, it is very important to remove iron from surface water before it may be used. Iron may be removed from water through a physical-chemical method, a biological method, or a combination of the two.

The oxidation state of iron may be either +2 (ferrous) or +3 (ferric). Surface water iron is generally found in its precipitated ferric form and does not require any further treatment to oxidize it. Groundwater iron is in its ferrous state in the deeper layers of some water reserves that lack oxygen, or in groundwater, in which case it is in a reduced dissolved form (Fe^{2+}) and often chelated. The oxidation state of iron in water depends on the pH and the redox potential. A dissolved form of iron (Fe^{2+} or $FeOH^-$) can be transformed to a precipitated form [$FeCO_3$, $Fe(OH)_2$, or $Fe(OH)_3$] by increasing either the oxidation potential, the pH, or both (3).

Aeration followed by solid–liquid separation is the most commonly used physical-chemical treatment method for iron removal. Aeration is generally recommended for oxidizing ferrous iron in water with high iron concentrations (>5 mg/L), so that costs for chemicals can be avoided (4). Sedimentation and/or filtration (sand or dual-media filtration) are used for the solid–liquid separation. If necessary, other treatments may be added, such as pH correction (lime softening), chemical oxidation by adding an oxidizing agent (such as chlorine, potassium permanganate, or ozone), ion oxidation, settling, and biological oxidation. Unfortunately, several problems are associated with physical-chemical treatments for iron removal that lead to relatively low iron removal rates. Substances such as humic acids, silicates, phosphates, and polyphosphates inhibit oxidation, precipitation, and filtration of ferric hydroxide. Thus, adding reagents is often necessary for pH correction and flocculation. The iron is not retained in a compact form, thus leading to low removal capacity, low filtration rates, large amounts of wash water, and difficult sludge treatment. The effective size of the filter medium can be between 0.5 and 1 mm and filtration rates between 5 and 15 m/h.

The rates of ferrous iron oxidation by air increase with pH; about 90% conversion may be achieved in 10–20 min at pH 7 (5). Iron oxidation is substantially slower at a pH below 6 and reduced forms may persist for some time in aerated waters (6). The rates of ferrous iron oxidation may be increased by the action of microorganisms.

Several genera of bacteria oxidize dissolved iron by different mechanisms. *Gallionella* sp., *Leptothrix ochracea*, and *Crenothrix polyspora* cause intracellular oxidation by enzymatic action; extracellular oxidation is caused by the catalytic action of polymers excreted by the filaments comprising the stalks produced by *Gallionella* sp.; and the sheaths from *Leptothrix* sp., *Crenothrix* sp., *Clonothrix* sp., and *Sphaerotilus* sp. Secondary extracellular oxidation is also caused by the catalytic action of polymers, excreted by the microscopic filaments of capillary appearance that are abandoned by the gliding trichomes of *Toxothrix thrichogenes* and extracellular polymers that are excreted by various Siderocapsaceae (7).

Biological iron removal systems have the following advantages compared with physicochemical iron removal systems: they require smaller installations because higher filtration rates may be used and/or because aeration and filtration can take place simultaneously in the same vessel; they allow longer lasting filtration runs because the retention time of iron in the filter increases due to the formation of denser precipitates and the use of coarser media; they generate denser backwash sludge that is easier to thicken and dewater; they lead to higher net production of clarified water because less water is required for backwashing, though it is possible to use raw water for backwash; they require no added chemicals; they do not deteriorate water quality over time; and they require lower capital and operating outlays (8).

The metabolic activities of iron bacteria are not fully understood, but it is believed that the same oxidation of iron is carried out by some variation in the physical-chemical reaction,

$$4Fe^{2+} + O_2 + 10H_2O \rightarrow 4Fe(OH)_3 + 8H^+ + \text{energy}$$

Whatever the metabolic pathway for the iron oxidation reactions, the biological process is catalytic and causes rapid oxidation. The red insoluble precipitates are all slightly hydrated iron oxides that, beneficially, are forms more compact than the precipitates formed when using physical-chemical processes. This feature partially explains the greater iron retention capacity between backwashes of biological filters compared to physical-chemical treatment filters.

It is important to recognize that iron bacteria catalyze oxidation reactions under conditions of pH and E_h that are intermediate between those of natural groundwater and those required for conventional treatment. The range of conditions allowing biological iron oxidation thus straddles the theoretical boundaries between the fields of Fe^{2+} and Fe^{3+} stability expected strictly by chemical thermodynamics. This can be visualized in a stability diagram, using pH and E_h as ordinates, as shown in Fig. 1.

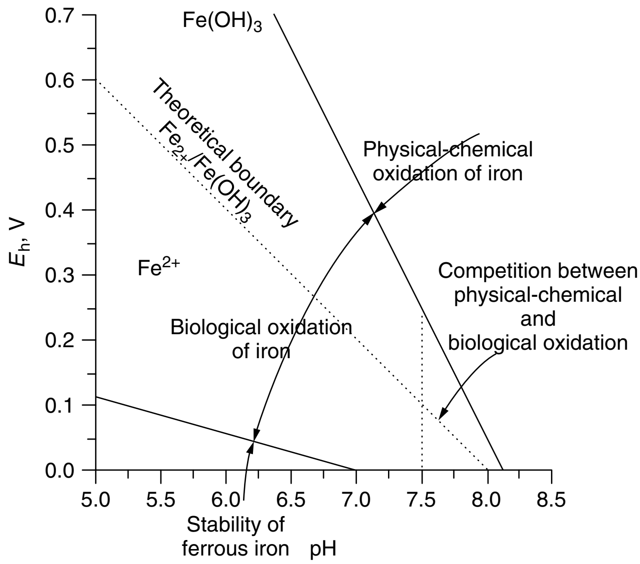

Figure 1. Stability diagram for biological iron removal.

By aerating the raw water and raising the dissolved oxygen concentration, the raw water's rH can be increased into the pH and E_h range where biological oxidation can take place. By controlling the quantity of supplied air, the rH can be adjusted to a level that is ideal for iron removal.

Once a biological iron removal plant is constructed, the system must be given time to "seed" with bacteria naturally present in the water source. This seeded biomass is naturally and continuously regenerated during the life of the plant and is periodically removed partially by backwashing. For iron removal plants, the seeding period is from 1 day to 1 week. At the end of the seeding period, the metal concentration in the effluent falls to near detection levels. The seeding period is affected by the temperature of the water source and is generally longer for cold water sources.

Iron bacteria are generally robust, and because of the variety of species involved, one type or another can thrive under most environmental conditions. Given the correct pH, from 6–8, and E_h, the bacteria can normally oxidize iron at temperatures ranging from 5 to 50 °C. Inhibition of the biological process can, however, be caused by H_2S, chlorine, NH_4^+, and some heavy metals normally not present in water sources.

AMMONIA AND MANGANESE INHIBITION OF BIOLOGICAL IRON REMOVAL

Water sources that contain iron often also contain ammonia and manganese. Ammonia, iron, and manganese may be removed chemically or biologically from a water supply. Biological removal of these pollutants is preferable because there is no need to add extra chemicals and the volume of sludge generated is appreciably smaller and hence easier to handle (9). Simultaneous biological removal of the three elements is very difficult mainly due to the different redox potential values needed to oxidize them. Mouchet (7) summarized the methods for iron and manganese removal from potable water and concluded that due to the different values required for dissolved oxygen concentration, redox potential, and pH, the basic design of plants for iron and manganese removal is substantially different. He also concluded that it is generally not possible to achieve simultaneous removal of Fe^{2+} and Mn^{2+} in a single filter, except in some cases of extremely low filtration rates. Gouzinis et al. (10) studied the simultaneous removal of ammonia, iron, and manganese from potable water using a pilot-scale trickling filter and the influences these pollutants have on filter performance and efficiency. They concluded that iron has a strong negative effect on ammonia removal and ammonia has a very low impact on iron removal. They also concluded that iron has a strong effect on Mn removal and manganese seems to have a much lower effect on iron removal. The main conclusion of that work was that iron should be removed before ammonia and manganese oxidation. For low iron concentration, oxidation by extended aeration could reduce iron at very low levels, and subsequent biological ammonia and manganese removal could be carried out without any problems. For higher iron concentration, an initial biological iron oxidation stage should be necessary.

FILTERS FOR IRON REMOVAL

A key feature of biological iron removal lies in the high rate of iron oxidation. Thus, the engineering systems that have been developed for biological iron removal can be classified by the type of water flow and by aeration into pressurized filters, gravity-flow units (9), and trickling filters.

Pressurized Filters

In a pressurized unit, the main components of the plant (Fig. 2) are the reactor, which is a filter specially designed to operate at high rates and contains sand somewhat coarser than normal for conventional filters; a calibrated raw water aeration system where oxygen is supplied either by an air injector fitted with a rotameter (to adjust the air flow rate, thereby ensuring that E_h and dissolved oxygen concentrations in the preaerated raw water are conducive to optimum growth of iron bacteria) or by recirculating a portion of the treated water, aerated near saturation (this configuration is selected when the dissolved oxygen content at the filtration inlet must be very low and tightly controlled); and an optional aeration system for filter effluent, followed by an optional nonchlorinated washwater storage tank and a storage tank for chlorinated water (7).

Filters can be backwashed by using raw water (in which case, the need for a washwater storage tank is eliminated) or treated water, always beginning with a simultaneous air scour. Aeration systems are simple baffle mixers. Filtration rates can in certain cases attain 40 or even 50 m/h.

Gravity-Flow Units

Gravity-flow units contain an atmospheric pressure aeration system followed by an open or closed filter (Fig. 3). Filtration can also be carried out by gravity flow in these units. The atmospheric pressure aeration system may be cascade aeration (designed to supply water that features optimum oxidation conditions for biological iron removal, as determined by the raw water pH) or spray aeration. These types of open aeration systems are particularly recommended when the raw water contains H_2S. Gravity filtration is usually designed for plants of high capacity.

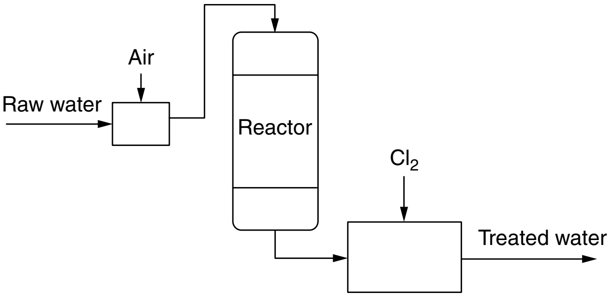

Figure 2. Process flow diagram for biological iron removal in a pressurized filter.

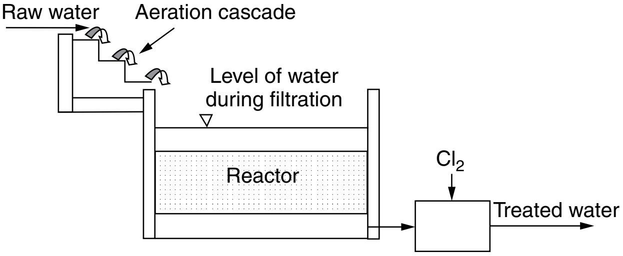

Figure 3. Process flow diagram for biological iron removal in a gravity plant.

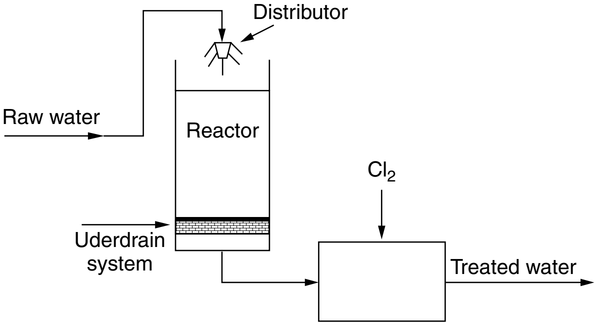

Figure 4. Process flow diagram for biological iron removal in a trickling filter.

Filtration rates can in certain cases attain 20–23 m/h. The filter medium is usually sand of an effective size between 1.0 and 1.5 mm (7).

Trickling Filters

The modern trickling filter consists of a bed of a highly permeable medium to which microorganisms are attached and through which water is percolated or trickled (Fig. 4). The filter media usually consist of either rock or a variety of plastic packing. Filters are constructed with an underdrain system for collecting the treated water and any biological solids that have become detached from the media. This underdrain system is important both as a collection unit and as a porous structure through which air can circulate. The collected liquid is passed to a settling tank where the solids are separated from the treated water (11).

An adequate flow of air is of fundamental importance to the successful operation of a trickling filter. The principal factors responsible for air flow in an open top filter are natural draft and wind forces. In natural draft, the driving force for airflow is the temperature difference between the ambient air and the air inside the pores. If the water is colder than the ambient air, the pore air will be cold and the direction of flow will be downward. If the ambient air is colder than the water, the flow will be upward. The latter is less desirable for mass transfer because the partial pressure of oxygen (and thus the oxygen-transfer rate) is lowest in the region of highest oxygen demand. Thus, a trickling filter has the advantage that it does not require an external air supply or an aeration system. If, in addition, the mean diameter of the filter media is sufficiently small (up to 5 mm), then complete aeration and very good filtration may be effected at the same time (12). Filtration rates are intermediate between those of pressurized filters and gravity-flow plants.

ADVANTAGES AND DISADVANTAGES OF FILTERS FOR IRON REMOVAL

Pressurized Filters

These filters are specially designed to operate at high rates and use particles of small mean diameter as support material, thus increasing the specific surface area available for ferrous iron oxidation. As a result, this type of filters exhibits high iron removal rates. On the other hand, the small particles lead to small pores, which may be clogged quite easily due to bacterial growth and iron precipitate filtration. Consequently, frequent backwashing is necessary. Finally, an external air supply is necessary, leading to increased operating cost.

Gravity Units

These filters are designed for plants where large quantities of drinking water have to be treated. The flow rates are quite low compared to the flow rates in pressurized systems. The support material is usually fine sand, which enables very good filtration but also needs frequent backwashing. The use of cascade aeration keeps the operating cost low and makes the system ideal for H_2S removal from drinking water. The capital cost of these systems is relatively high.

Trickling Filters

Trickling filters are quite simple constructions and do not require an external air supply or an aeration system, leading thus to low capital and operating costs. The support material is larger than that for pressurized systems to secure adequate air circulation. Filtration also takes place simultaneously with oxidation but a separate settling tank may be needed to ensure complete removal of iron precipitates. The rates in these filters lie between the high rates of pressurized systems and the low rates of gravity plants. Figure 5 presents typical iron concentration profiles along the depth of a pilot-scale trickling filter.

Technology offers various solutions for iron removal from drinking water. Cartridge filters combine physical-chemical and biological iron removal. The type of filter that is used depends on the physicochemical characteristics of the water, iron concentration, volumetric flow rate, and, of course, the costs. Thus, a feasibility study is necessary before deciding on the type of cartidge filter that will be used.

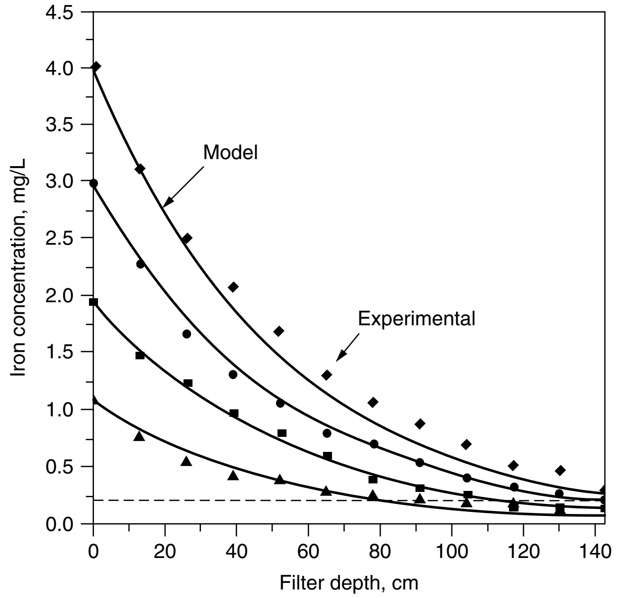

Figure 5. Typical iron concentrations profiles along the depth of a pilot-scale trickling filter (13).

IRRIGATION WATER QUALITY IN AREAS ADJOINING RIVER YAMUNA AT DELHI, INDIA

Chakresh K. Jain
Mukesh K. Sharma
National Institute of Hydrology
Roorkee, India

The groundwater quality of areas adjoining the River Yamuna in Delhi (India) has been assessed for the suitability of groundwater for irrigation. Thirty-eight

groundwater samples from shallow and deep aquifers were collected each during pre- and postmonsoon seasons in the year 2000 and analyzed for various parameters. The suitability of groundwater for irrigation has been evaluated based on salinity, sodium adsorption ratio (SAR), residual sodium carbonate (RSC), and boron content. According to the U.S. Salinity Laboratory classification of irrigation water, more than 50% of the samples fall in water type C3-S1 (high salinity and low SAR). Such water cannot be used on soils that have restricted drainage. Even with adequate drainage, special management for salinity control may be required and plants with good tolerance should be selected. About 30% of the samples fall in water type C3-S2 (high salinity and medium SAR). Such water will induce an appreciable sodium hazard in finely textured soils that have good cation exchange capacity, especially under low leaching conditions.

INTRODUCTION

Groundwater plays an important role in agriculture for both watering crops and for irrigating dry season crops. It is estimated that about 45% of the irrigation water required is from groundwater sources. Unfortunately, the availability of groundwater is not unlimited, nor is the groundwater protected from deterioration. In most instances, the extraction of excessive quantities of groundwater has resulted in drying up of wells, damaged ecosystems, land subsidence, saltwater intrusion, and depletion of the resource. Groundwater quality is being increasingly threatened by agricultural, urban, and industrial wastes. It has been estimated that once pollution enters the subsurface environment, it may remain concealed for many years, disperses over wide areas of the groundwater aquifer, and renders groundwater unsuitable for consumption and other uses. The rate of depletion of groundwater levels and the deterioration of groundwater quality are of immediate concern in major cities and towns of the country.

The National Capital Territory (NCT) of Delhi is facing severe problems in managing groundwater quality and quantity (1). Surface waterbodies play a significant role in groundwater flow. The hydraulic gradient plays a significant role in the lateral and vertical migration of contaminants in groundwater aquifers. Therefore, the present study has been carried out to assess the suitability of groundwater for irrigation in areas adjoining the River Yamuna at Delhi.

STUDY AREA

Delhi generates about 1900 MLD of sewage against installed capacity of 1270 MLD of sewage treatment. The balance of untreated sewage along with a significant quantity of partially treated sewage is discharged into the River Yamuna every day. The river receives sewage and industrial wastes through sixteen drains, which join River Yamuna between Wazirabad and Okhla. Thus Delhi is the largest contributor of pollution to the River Yamuna, which receives almost 80% of its pollution load through these drains.

The climate of Delhi is influenced mainly by its inland position and the prevalence of the continental type air during the major part of the year. Extreme dryness with an intensely hot summer and cold winter are the characteristics of the climate. During the monsoon months, air of oceanic origin penetrates to this area and causes increased humidity, cloudiness, and precipitation. The normal annual rainfall in the National Capital Territory of Delhi is 611.8 mm. The rainfall increases from southwest to northeast; about 81% of the annual rainfall is received during the three monsoon months of July, August, and September; the balance of the annual rainfall is received as winter rains and as thunderstorm rain during pre- and postmonsoon months.

METHODOLOGY

Groundwater samples were collected in polyethylene bottles during the pre- and postmonsoon seasons during the year 2000 from areas adjoining the River Yamuna at Delhi and were preserved by adding an appropriate reagent (2,3). All samples were stored in sampling kits maintained at 4 °C and brought to the laboratory for detailed physicochemical analysis. The details of sampling locations are given in Table 1. The physicochemical analyses were performed following standard methods (2,3).

RESULTS AND DISCUSSION

The hydrochemical data for the two sets of samples collected from the areas adjoining the River Yamuna at Delhi (Fig. 1) during the pre- and postmonsoon seasons are given in Table 2. The pH of the groundwater of areas adjoining the River Yamuna are mostly within the range of 6.7 to 8.3 during the premonsoon season and 6.6 to 8.2 during the postmonsoon season; most of the samples point toward the alkaline range in both seasons. The total dissolved solids (TDSs) in the groundwater vary from 402 to 2266 mg/L during the premonsoon season and from 397 to 2080 mg/L during the postmonsoon season. Higher values of TDSs in areas nearby the River Yamuna indicate high mineralization of the groundwater.

Alkalinity varies from 116 to 380 mg/L during the premonsoon season and from 106 to 310 mg/L during the postmonsoon season. From the view point of hardness, only one sample exceeds the maximum permissible limit of 600 mg/L. The concentration of chloride was within the permissible limit. The sulfate content limit in groundwater is exceeded at two locations (Himmat Puri and Golf Course). The nitrate content in drinking water is considered important because of its adverse health effects. The nitrate content in the groundwater of areas adjoining the River Yamuna varies from 1 to 286 mg/L during the premonsoon season. The higher level of nitrate at certain locations may be attributed to surface disposal of domestic sewage and runoff from agricultural fields. It has also been observed that the groundwater samples collected from hand pumps at various depths have a high nitrate

Table 1. Description of Groundwater Sampling Locations

Sample No.	Label*	Location	Type of Well (Depth in ft)[a]

content, which may be attributed to wellhead pollution. The fluoride content was within the maximum permissible limit of 1.5 mg/L in all samples.

WATER QUALITY EVALUATION FOR IRRIGATION

Irrigation water quality refers to its suitability for agricultural use. The concentration and composition of dissolved constituents in water determine its quality for irrigation. The quality of water is an important consideration in any appraisal of salinity or alkali conditions in an irrigated area. Good quality water can result in maximum yield under good soil and water management practices. The most important characteristics of water that determine the suitability of groundwater for irrigation are as follows:

1. Salinity
2. Relative proportion of sodium to other cations
3. Residual sodium carbonate
4. Boron content

The safe limits of electrical conductivity for crops of different degrees of salt tolerance under varying soil textures and drainage conditions are given in Table 3. The quality of water is commonly expressed by classes of relative suitability for irrigation with reference to salinity levels. The recommended classification with respect to electrical conductivity, sodium content, sodium absorption ratio (SAR), and residual sodium carbonate (RSC) are given in Table 4. The values of SAR, % Na, and RSC for groundwater samples collected from areas adjoining the River Yamuna are given in Table 5.

Salinity

Salinity is broadly related to total dissolved solids (TDSs) and electrical conductivity (EC). A high concentration of TDSs and electrical conductivity in irrigation water may increase the soil salinity, which affect the salt intake of the plant. The salts in water affect plant growth directly and also affect the soil structure, permeability, and aeration, which indirectly affect plant growth. Soil water passes into the plant through the root zone by osmotic pressure. As the dissolved solid content of the soil water in the root zone increases, it is difficult for the plant to overcome the osmotic pressure and the plant root membranes are unable to assimilate water and nutrients. Thus, the dissolved solids content of the residual water in the root zone also has to be maintained within limits by proper leaching. These effects are visible in plants by stunted growth, low yield, discoloration, and even leaf burns at the margin or top.

Relative Proportion of Sodium to Other Cations

A high salt concentration in water leads to the formation of saline soil, and high sodium leads to the development of an alkaline soil. The sodium or alkali hazard in the use of water for irrigation is determined by the absolute and relative concentration of cations and is expressed in terms of the sodium adsorption ratio (SAR). If the proportion of sodium is high, the alkali hazard is high; conversely, if calcium and magnesium predominate, the hazard is lower. There is a significant relationship between SAR values of irrigation water and the extent to which sodium is absorbed by soil. If water used for irrigation is high in sodium and low in calcium, the cation-exchange complex may become saturated with sodium. This can destroy the soil structure owing to dispersion of clay particles. A simple method of evaluating the danger of high-sodium water is the sodium adsorption ratio (SAR) (4):

$$\mathrm{SAR} = \frac{\mathrm{Na}^+}{\sqrt{(\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+})/2}} \tag{1}$$

The percentage sodium is calculated as

$$\%\mathrm{Na} = \frac{\mathrm{Na}^+ + \mathrm{K}^+}{\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+} + \mathrm{Na}^+ + \mathrm{K}^+} \times 100 \tag{2}$$

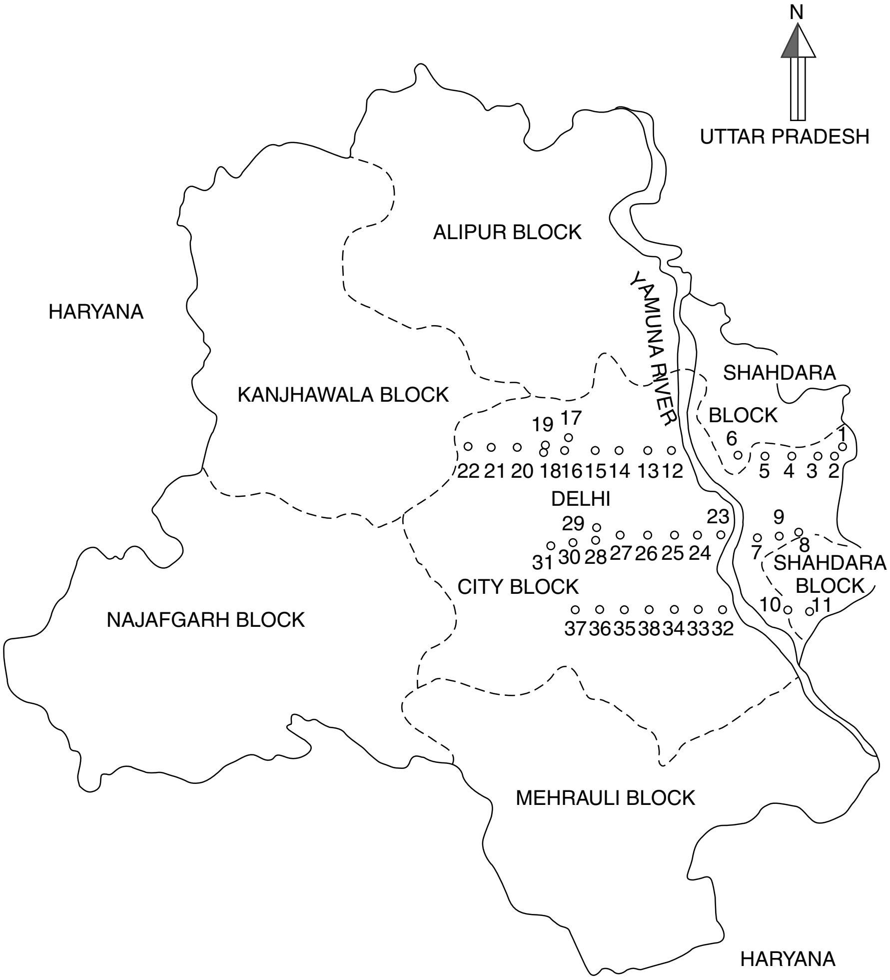

Figure 1. Study area showing sampling locations.

where all ionic concentrations are expressed in milliequivalents per liter.

The values of SAR and percentage sodium of the groundwater samples collected from the area adjoining the River Yamuna are given in Table 5. Calculation of SAR for a given water provides a useful index of the sodium hazard of that water for soils and crops. A low SAR (2 to 10) indicates little danger from sodium; medium hazards are between 7 and 18, high hazards between 11 and 26, and very high hazards above that. The lower the ionic strength of the solution, the greater the sodium hazards for a given SAR (4).

Table 2. Hydrochemical Data on Groundwater Samples from Delhi (Pre- and Postmonsoon, 2000)

Parameter	Minimum[a]		Maximum[a]		Mean[a]	
pH	6.7	(6.6)	8.3	(8.2)	7.1	(7.1)

Potassium, mg/L	4.2	(2.2)	121	(103)	26	(20)
Calcium, mg/L	25	(21)	240	(227)	59	(59)
Magnesium, mg/L	9.0	(7.0)	64	(56)	21	(19)

[a] Values in parentheses represent postmonsoon data.

Table 3. Safe Limits of Electrical Conductivity for Irrigation Water

Sample No.	Nature of Soil	Crop Grown	Upper Permissible Safe Limit of EC in Water, μS/cm
1	Deep black soil and alluvial soils having clay content of more than 30% that are fairly to moderately well drained	Semitolerant	1500
		Tolerant	2000
2	Textured soils having clay content of 20–30% that are well drained internally and have good surface drainage	Semitolerant	2000
		Tolerant	4000
3	Medium textured soils having clay of 10–20%, internally very well drained, and having good surface drainage	Semitolerant	4000
		Tolerant	6000
4	Light textured soils having clay of less than 10% that have excellent internal and surface drainage	Semitolerant	6000
		Tolerant	8000

The SAR values in the groundwater of the study area ranged from 1.70 to 12.06 during the premonsoon season and from 1.65 to 11.24 during postmonsoon. As evident from the SAR values, the groundwater of the study area falls in the category of low sodium hazard except for two samples (Civil Lines and Sardar Patel Road), which reveals that the groundwater in the study area is free from any sodium hazard. The percentage sodium in the study area varied from 30.4 to 83.7 during the premonsoon season and from 34.5 to 82.9 during postmonsoon. More than 50% of the samples in the study area exceeded the recommended value of 60% during both pre- and postmonsoon seasons.

Residual Sodium Carbonate

In addition to total dissolved solids, the relative abundance of sodium with respect to alkaline earths and boron and the quantity of bicarbonate and carbonate in excess of alkaline earths also influence the suitability of water for irrigation. This excess is denoted by residual sodium carbonate (RSC) and is determined by the following formula:

$$\mathrm{RSC} = (\mathrm{HCO_3}^- + \mathrm{CO_3}^-) - (\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+}) \qquad (3)$$

where all ionic concentrations are expressed in equivalents per mole (epm). Groundwater containing high concentrations of carbonate and bicarbonate ions tends to precipitate calcium and magnesium as carbonate. As a result, the relative proportion of sodium increases and is fixed in the soil, thereby decreasing soil permeability. If the RSC exceeds 2.5 epm, the water is generally unsuitable for irrigation. Excessive RSC causes the soil structure to deteriorate because it restricts water and air movement through soil. If the value is between 1.25 and 2.5, the water is of marginal quality; values less than 1.25 epm indicate that the water is safe for irrigation. During the present study, the RSC values were mostly negative. The RSC values clearly indicate that the groundwater in the study area does not have a residual sodium carbonate hazard.

Table 4. Guidelines for Evaluating Irrigation Water Quality

Water Class	Sodium (Na), %	Electrical Conductivity, μS/cm	SAR	RSC
Excellent	<20	<250	<10	<1.25
Good	20–40	250–750	10–18	1.25–2.0
Medium	40–60	750–2250	18–26	2.0–2.5
Bad	60–80	2250–4000	>26	2.5–3.0
Very bad	>80	>4000	>26	>3.0

Boron

Boron is essential to the normal growth of all plants, but the concentration required is very small and if exceeded may cause injury. Plant species vary both in boron requirement and in tolerance to excess boron, so that concentrations necessary for the growth of plants having high boron requirements may be toxic for plants sensitive to boron. Though boron is an essential nutrient for plant growth, generally it becomes toxic beyond 2 ppm in irrigation water for most field crops. It does not affect the physical and chemical properties of the soil, but at high concentrations, it affects the metabolic activities of plants.

U.S. Salinity Laboratory Classification

The sodium concentration is an important criterion in irrigation water classification because sodium reacts with soil to create sodium hazards by replacing other cations. The extent of this replacement is estimated by the sodium adsorption ratio (SAR). A diagram for studying the suitability of groundwater for irrigation is based on the SAR and the electrical conductivity of water expressed in μS/cm.

The chemical analysis data of groundwater samples collected from the area adjoining the River Yamuna in Delhi has been processed per the U.S. Salinity Laboratory classification (Fig. 2), and the results have been summarized in Table 6. It is evident from the results that during the premonsoon season, only three samples (7.8%) fall into water type C2-S1 (medium salinity and low SAR). Such water can be used if a moderate amount of leaching occurs, and plants with moderate salt tolerance can be grown in most cases without special practices for salinity control. More than 50% of the

samples fall into water type C3-S1 (high salinity and low SAR). Such water cannot be used on soils with restricted drainage. Even with adequate drainage, special management for salinity control may be required, and plants with good salt tolerance should be selected. About 30% of the samples fall into water type C3-S2 (high salinity and medium SAR). Such water cannot be used on soils with restricted drainage. Even with adequate drainage, special management for salinity control may be required, and plants with good salt tolerance should be selected. The water will also present an appreciable sodium hazard in finely textured soils that have good cation exchange capacity, especially under low leaching conditions. Three samples (7.8%) fall into water type C3-S3 (high salinity and high SAR). Such water cannot be used on soils with restricted drainage. Even with adequate drainage, special management for salinity control may be required, and plants with good salt tolerance should be selected. The water will also produce harmful levels of exchangeable sodium in most soils and will require special soil management, good drainage, high leaching, and organic matter additions. One sample falls into water type C4-S2 (very high salinity and medium SAR). Such water is not suitable for irrigation. High salinity is harmful to plant growth and changes soil structure, permeability, and aeration, which in turn affect plant growth and yield considerably. An almost similar trend was observed during the postmonsoon season.

CONCLUSIONS

The quality of groundwater varies from place to place with the depth of the water table. It also shows significant variation from one season to another. The U.S. Salinity Laboratory classification for irrigation water indicates that more than 50% of the samples fall into water type C3-S1 (high salinity and low SAR). Such water cannot be used on soils with restricted drainage. Even with adequate drainage, special management for salinity control may be

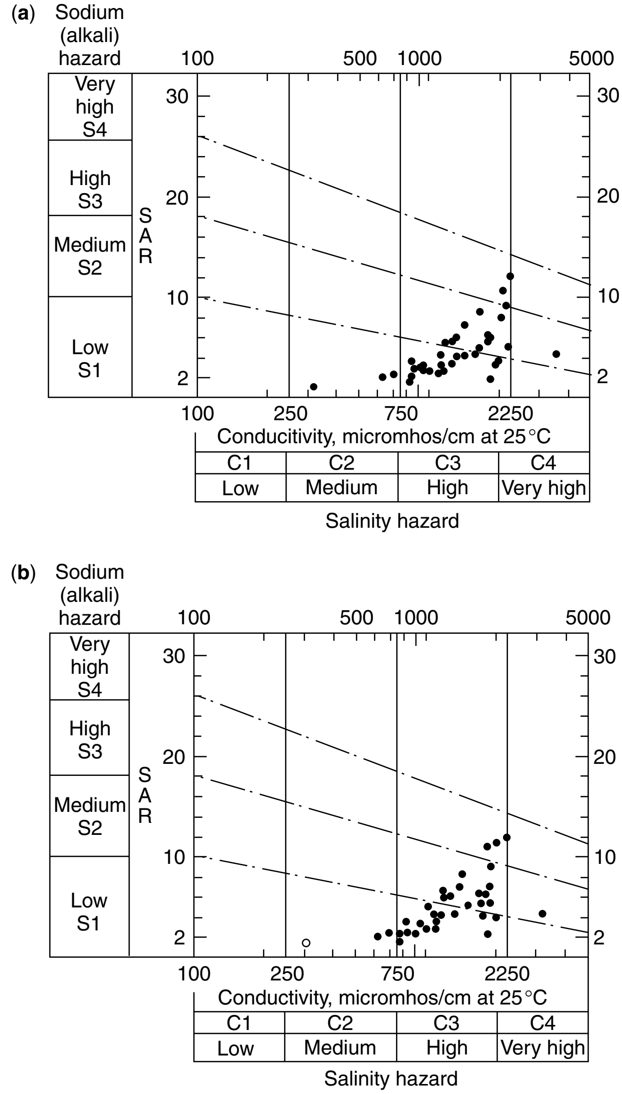

Figure 2. (**a**) U.S. Salinity Laboratory classification (premonsoon 2000). (**b**) U.S. Salinity Laboratory classification (postmonsoon 2000).

required, and plants with good salt tolerance should be selected. About 30% of the samples fall into water type C3-S2 (high salinity and medium SAR). Such water will also induce an appreciable sodium hazard in finely textured soils that have good cation exchange capacity, especially under low leaching conditions.

WATER SAMPLING AND LABORATORY SAFETY

Timothy J. Ryan
Ohio University
Athens, Ohio

Water sampling is done for a wide variety of reasons, including water quality, thermal effluent assessments, point and nonpoint industrial source impacts, microbial contamination from human wastes, and accidental releases. For example, samples can be taken from rivers, lakes, streams, and oceans to determine the level of a specific chemical component, such as nitrates or sulfates. Or tests may be done to investigate the biological oxygen demand (BOD) of the water, as an indicator of the overall health of the water body. Water is routinely sampled for the presence of harmful pathogens, which potentially pose a risk not only to the end user but to the sampling personnel as well. Because sampling may place the person in unsafe locations or even perilous environments, and because sample collection represents a significant allocation of time and resources, safeguards for personnel and samples alike are important.

The first decision in water sampling methodology is the categorical type of sample to be collected: general survey or site-specific. For general survey sampling, locations and analyses should be selected that are representative of the water source, treatment plant, storage facilities, distribution network, or points of use to be characterized. At a minimum, duplicate samples should be collected at each site. To accurately assess large or widely distributed bodies of water, consideration should be given to the use of a statistically sound sampling algorithm.

Table 6. Results of U.S. Salinity Laboratory Classification

	Sample Numbers	
Classification/Type	Premonsoon 2000	Postmonsoon 2000
C2-S1	21,28,29	3,21,28
C3-S1	2,3,4,5,6,7,13,14,15,16,17,18, 19,20,22,23,25, 27,30,32	2,4,5,6,7,8,13,14,16,17,18, 19,20,23,25,27,29,30,32
C3-S2	1,8,9,10,11,24,26,31,34, 35,38	1,9,10,11,15,22,24,26,31, 34,35,36,38
C3-S3	12,36,37	12,37
C4-S2	33	33

A site-specific sampling regimen is inherently simpler in that the sampling location and analysis parameters are known, easily anticipated, or even proscribed by a regulatory agency.

Actual procedures for sampling and analysis frequently depend on the type of analysis to be conducted. As a general truism, the following items are essential to conduct an effective sampling trip: labeled bottles appropriate for the analysis to be run, field equipment for commonly determined parameters (pH, water temperature, etc.), and sampling collection tools. Additional useful and typical equipment might include preservatives, ice packs and coolers, personal gear suitable for all weather conditions and intense insect exposure, a camera or video equipment (if needed to document the actual sampling operation), and laboratory chain-of-custody and analysis requisition forms. All sampling equipment and material should be checked before departing on the collection campaign, and real-time instruments, such as dissolved oxygen spectrophotometers should be calibrated, have their batteries fully charged, and be packed securely to avoid damage. Of all items taken on a sampling trip, the field log book is perhaps the most important. Although it will slow the sampling mechanics, all information pertinent to the sampling trip should be fastidiously recorded in it. Special bound books with water-resilient paper and bindings are available for such use, and they are well worth their added cost because of the increased information security they provide.

Immediately before sample collection, the sampling site should be adequately described in the log book. The use of global positioning satellite (GPS) transponders for precise location identification is always a sound practice and is in fact critical if repeated sampling in the same location on different dates is a possibility. Still-frame or video photographic documentation may be helpful in this regard in that readily identifiable landmarks can easily be recorded and communicated to third parties at a later date. The log book should also document the specific sampling collection information, such as time of day, prevailing wind direction, and weather conditions. Water-related aspects that may be important to the interpretation of specific sampling results include ambient temperature, water temperature, dissolved oxygen, pH, and salinity. Any unusual aspects about the site or water being sampled, such as oil slicks, excessive algae growth, or unusual color or odor, should be noted in the log, along with both typical or atypical human activities in the sampling vicinity. Such activities might include logging, commercial fishing with nets, dredging, industrial permitted point sources, construction work, aerial agricultural spraying, and utility company line clearing or defoliant operations.

The physical security and integrity of water samples is essential to ensuring the accuracy and legal defensibility of their analysis results. Toward this end, there are several things that one can to do assure and maintain sample quality in the field. First and foremost, one must take all necessary precautions to protect samples from contamination and deterioration. Maintaining the sterilized state of the bottle in which biological samples are to be collected is obviously important. Any specific sampling instructions from the analysis laboratory for handling sample containers must be closely followed. After samples are collected, they are normally kept refrigerated and care must be exercised that this does not result in the sample actually freezing. Unless specifically instructed otherwise, all samples should be place in a dark place away from other contaminant sources while awaiting transport or analysis. The person conducting the sampling should have clean hands and abstain from eating, gum chewing, or smoking while working with sampling media or other equipment that could be cross contaminated by such habits. To prevent sample or site confusion, bottles for particular sample types (e.g., volatile organics, chloride, total organic halides) can be color coded for more confident identification.

Sample collection can take place from a variety of locations, including from shore, a boat, access from a bridge, adjacent to the effluent stream, and from receiving waters. Different procedures and safety precautions should be taken with each situation. In general, it is best to take samples from mid-stream rather than near the shore to reduce the possibility of local shore effects contaminating the sample. It bears reiteration to note in the sampling log book the exact spot of sampling, so that if further sampling is needed (e.g., in response to a contested sample result), the identical location can be found for further rounds of testing. Water samples can also be taken in the home or business, such as from a water faucet, well head, or septic system. During these samplings, the same precautions need to be taken concerning the physical security and integrity of the sample. As for outdoor samples, notes should be kept in a log book about pertinent aspects of the water such as location in the building where the sample was collected, temperature of the water, time of day, and overall appearance of the water (e.g., turbid, milky, clear).

After field sample collection, precautions must also be taken by the individual handling water samples in the laboratory. As in the field, normal prohibitions against eating and smoking should be followed, both for the safety of personnel as well as for the integrity of the sample because contamination can result from such sources. Ensuring a hygienic laboratory environment when testing biological samples is a high priority, primarily as a safeguard against cross contamination but also to safeguard the health of the laboratory staff. Because water samples are most often collected in specially cleaned glass bottles (e.g., a standard 300 milliliter BOD bottle), containers should routinely be transported in shock-absorbent carriers to protect them from breakage, resultant sample loss, and possible injury. Note that even when using plastic bottles, precautions should be taken because such containers can break, leak, be punctured, or fail under pressure or heat.

In approximately 25 states and territories, laboratories handling water samples may be subject to federal Occupational Safety and Health Administration (OSHA) standards; laboratories in other states must comply with similar regulations promulgated under state authority. Regardless of their origin, laboratory safety regulations and hazard communication rules are to be followed by persons handling, processing, and otherwise analyzing water samples. Such work can involve exposure to highly corrosive agents (e.g., potassium chromate for chloride analyses), highly reactive catalysts (e.g., metallic sodium for total chlorine), or moderately toxic reagents (e.g., mercuric nitrate for total chlorine). Accordingly, basic minimal protective clothing should be mandatory for handling water samples. This personal protective equipment should include a laboratory coat or chemically resistant apron, gloves impermeable to the reagents handled, and an appropriately selected and worn respirator (where airborne hazards exist, and fumehoods are not available). Perhaps of most importance, protection of the eyes from chemical splashes is required, preferably in the form of chemical goggles or as safety glasses in conjunction with a face shield.

MUNICIPAL SOLID WASTE LANDFILLS—WATER QUALITY ISSUES

G. Fred Lee
Anne Jones-Lee
G. Fred Lee & Associates
El Macero, California

INTRODUCTION

Here we provide information on significant shortcomings inherent in the management of municipal solid waste (MSW) and industrial "nonhazardous" waste by the Subtitle D "dry tomb" landfilling practiced today. Focus is on why following the prescriptive measures outlined for such landfills cannot be relied on to provide protection of public health, groundwater resources, or the interests of nearby property owners.

Historically, the goal of municipal solid wastes and industrial "nonhazardous" waste management has been to get the wastes out of sight in the least costly manner. Solid wastes from urban areas were deposited on nearby low-value lands, frequently wetlands, to create waste dumps. This approach evolved into the deposition of wastes into areas excavated for greater disposal capacity. Wastes in the dumps were often burned to reduce volume. Beginning in some areas in the 1950s, wastes placed in dumps were covered daily with a layer of soil to reduce odors and access to the wastes by vermin, flies, birds, and so on, which was the beginning of the "sanitary landfill." Although the design of sanitary landfills diminished some environmental and public health concerns, it did not address issues of the potential for the wastes to cause groundwater pollution, for the gas generated in the landfill to cause explosions, or for the waste to cause other public health or environmental problems. The pollution of groundwater by landfill leachate from conventional sanitary landfills was recognized in the 1950s (2), but it was not until the 1990s that national regulations existed directed at control of groundwater pollution by landfills.

U.S. EPA SUBTITLE D DRY TOMB LANDFILLING

Recognizing the pollution of groundwaters by sanitary landfills, Congress passed the Resource Conservation and Recovery Act (RCRA) that directed the U.S. EPA to address the issue. As this was not accomplished in a timely manner, the U.S. EPA was sued; in response to that suit, the U.S. EPA developed the dry tomb approach to landfilling of MSW. Despite its acknowledgment of technical shortcomings in the approach, but under the pressure of the lawsuit, the U.S. EPA delineated the prescriptive standards for dry tomb landfills in Subtitle D of RCRA. These prescriptive standards have been adopted by some state regulatory agencies as minimum design standards for MSW landfills.

The concept of dry tomb landfilling was built on the premise that because water in contact with the wastes led to the formation of leachate that traveled to groundwater, isolation of the wastes in dry tombs would prevent groundwater pollution by landfill leachate. A dry tomb landfill, as implemented by the U.S. EPA, is illustrated in Fig. 1. It relies on a liner and cap to keep the wastes dry, leachate collection and removal systems to keep the wastes from polluting groundwater, and gas collection and removal systems. It also relies on groundwater monitoring to signal incipient pollution of groundwater by landfill leachate and specifies a "postclosure" period of 30 years, during which time the facility is to be maintained and monitored.

These provisions notwithstanding, the U.S. EPA realized in its development of these requirements that such a system would not, in itself, ensure the protection of groundwaters forever. As part of adopting the RCRA Subtitle D regulations, the U.S. EPA stated in the draft regulations (3),

> First, even the best liner and leachate collection system will ultimately fail due to natural deterioration, and recent improvements in MSWLF (municipal solid waste landfill) containment technologies suggest that releases may be delayed by many decades at some landfills.

Further, the U.S. EPA (4) Criteria for Municipal Solid Waste Landfills states,

> Once the unit is closed, the bottom layer of the landfill will deteriorate over time and, consequently, will not prevent leachate transport out of the unit.

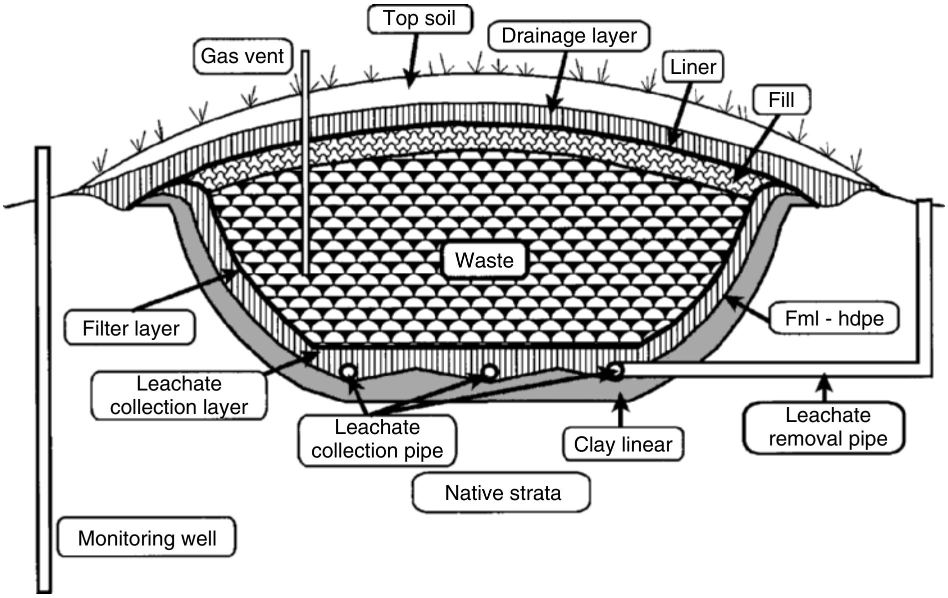

Figure 1. Single-composite liner landfill containment system.

Thus, even if the dry tomb system could be installed without flaw, it will eventually fail to isolate the wastes, which is significant because many of the contaminants in MSW landfills do not decompose to inert forms (e.g., heavy metals) and are hence a threat forever. Furthermore, although many organics can eventually be bacterially decomposed, such decomposition requires water, which is excluded from the landfill under ideal dry tomb landfill conditions. It is therefore important to consider the characteristics and shortcomings of the components of a dry tomb landfill to provide protection of groundwater quality for as long as the wastes in the landfill remain a threat, and how they can be improved to provide more reliable protection.

LANDFILL COVER

Allowed closure of Subtitle D landfills is begun by covering the waste with soil that is placed and shaped to serve as the base for a low-permeability plastic sheeting layer. The plastic sheeting is overlaid by a one- to two-foot deep drainage layer. The drainage layer is overlaid by a few inches to a foot or so of topsoil that serves as a vegetative layer designed to promote the growth of vegetation to reduce erosion of the landfill cover. In principle, water that enters the vegetative layer would either be taken up by the vegetation or penetrate through the root zone to the porous (drainage) layer. When the moisture reaches the low-permeability plastic sheeting layer of the cover, it is supposed to move laterally to the outside of the landfill (see Fig. 1).

However, in addition to deficiencies introduced during the installation of the plastic sheeting, landfill covers are subject to a variety of factors that can breach their integrity, including burrowing animals, differential settling of the wastes beneath the cover, and deterioration of the plastic sheeting. The typical approach to monitoring landfill covers for integrity in keeping moisture out of the landfill, that is advocated by landfill owners and operators and allowed by regulatory agencies, involves visual inspection of the surface of the vegetative soil layer of the landfill cover. If cracks or depressions in the surface are found, they are filled with soil. Such an approach, however, will not detect or remediate cracks in or deterioration of the plastic sheeting layer, which is the basis for the moisture removal system for the cover. As a result, moisture that enters the drainage layer and comes in contact with the plastic sheeting layer will penetrate into the wastes rather than be directed off the landfill. If this occurs during the postclosure care period, the increased leachate generation could be detected. However, it could also readily occur in year 31 after closure or thereafter, when there could well be no one monitoring leachate generation.

LEACHATE COLLECTION AND REMOVAL SYSTEM

The key to preventing groundwater pollution by a dry tomb landfill is collecting all leachate that is generated in the landfill, in the leachate collection and removal system. As shown in Fig. 1, a Subtitle D system prescribes a relatively thin (0.06 inch) plastic sheeting layer (high-density polyethylene—HDPE) and a 2-ft thick compacted soil/clay layer, which together, in intimate contact, form a “composite” liner beneath the wastes. Atop the liner is the leachate collection system consisting of gravel or some other porous medium, which is intended to allow leachate to flow rapidly to the top of the HDPE liner for removal. This porous layer is overlaid by a filter layer, which is supposed to keep the solid waste from migrating into the leachate collection system. Thus, in principle, leachate that is generated in the solid waste passes through the filter layer to the leachate collection layer beneath. Once it reaches the sloped HDPE liner, it is supposed to flow across the top of the liner to a collection pipe, where it would be transported to a sump from which it could be pumped from the landfill. According to regulations, the maximum elevation of leachate ("head") in the sump is to be no more than 1 ft.

However, leachate collection and removal systems, as currently designed, are subject to many problems. Biological growth, chemical precipitates, and "fines" derived from the wastes all tend to cause the leachate collection system to plug. This, in turn, increases the head of the leachate above the liner upstream of the area that is blocked, which further stresses the integrity of the system. Although the potential exists to back-flush some of these systems, this back-flushing will not eliminate the problem.

One of the most significant problems with leachate collection systems' functioning as designed is that the HDPE liner, which is the base of the leachate collection system, develops cracks, holes, rips, tears, punctures, and points of deterioration. Some of these are caused at the time of installation, and HDPE integrity deteriorates over time. When the leachate that is passing over the liner reaches one of these points, it starts to pass through the liner into the underlying clay layer. If the clay layer is in intimate contact with the HDPE liner, the rate of initial leakage through the clay is small. If, however, problems existed achieving or maintaining intimate contact between the clay and HDPE liner, such as the development of a fold in the liner, the leakage through the HDPE liner hole can be quite rapid. Under those conditions, the leachate can spread out over the clay layer and can leak at a substantial rate through the clay. As noted above, even in the establishment of the Subtitle D regulations, the U.S. EPA recognized that such a liner will deteriorate over time.

GROUNDWATER MONITORING

U.S. EPA Office of Solid Waste Emergency Response senior staff members have indicated that the fact that HDPE liners will fail to prevent leachate from passing into the underlying groundwaters does not mean that the Subtitle D regulations are fundamentally flawed because of the groundwater monitoring system requirement. They claim that when leachate-polluted groundwaters first reach the point of compliance for groundwater monitoring, they are detected by the groundwater monitoring system with sufficient reliability so that a remediation program can be initiated. The point of compliance for groundwater monitoring at Subtitle D landfills is specified as being no more than 150 meters from the downgradient edge of the waste deposition area and must be on the landfill owner's property. However, serious technical deficiencies exist in that position.

It was pointed out by Cherry (5) that initial leakage through HDPE-lined landfills will be through areas where there are holes, rips, tears, or points of deterioration of the HDPE liner, which, as illustrated in Fig. 2, can lead to relatively narrow plumes of polluted groundwaters at the point of compliance for groundwater monitoring. The typical groundwater pollution plume in a sand, gravel, or silt aquifer system will likely be on the order of 10 to 20 ft wide at the point of compliance. In order to detect incipient leakage from a Subtitle D landfill, therefore, these narrow plumes would have to be detected by the groundwater monitoring well array at the point of compliance. Typically, federal and state regulatory agencies allow monitoring wells to be placed 100 or more feet apart at the point of compliance; each monitoring well has a zone of capture of about 1 ft. Thus, if the wells were 200 ft apart, 198 ft would exist between wells where a 10- to 20-ft wide plume of leachate-polluted groundwater could pass undetected. It is virtually impossible to reliably monitor groundwater for leachate contamination in fractured rock or cavernous limestone areas. There, leachate can travel great distances and in unexpected directions via cracks and caverns.

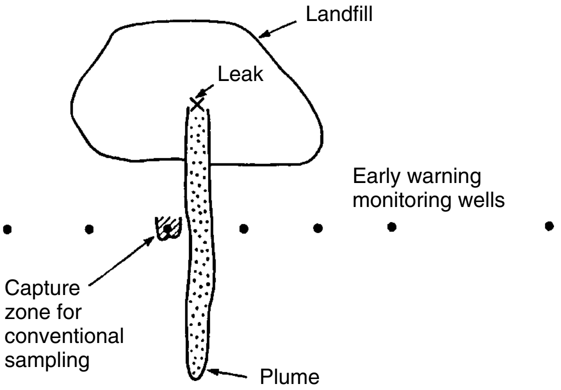

Figure 2. Leakage from HDPE-lined landfill (adapted from Ref. 5).

It is because of the unreliability of groundwater monitoring systems that are based on vertical monitoring wells at the point of compliance that some states (such as Michigan) require that a double-composite liner be used at municipal solid waste landfills. In that system, a leak detection system is in place between the composite liners to detect leakage through the upper composite before the lower liner is breached. Although this approach is not foolproof in its ability to detect when both liner systems fail, it has a much greater probability of detecting when the upper composite liner fails. It is for this reason that Lee and Jones-Lee (6) recommended that all Subtitle D landfills incorporate a double-composite liner with a leak detection system between the two liners.

LANDFILL GAS

Some organics in municipal solid wastes can serve as a source of food for bacteria that will, in a moist landfill environment, produce methane and CO_2 (landfill gas). MSW landfills also release a number of other volatile chemicals, including highly hazardous volatile organic compounds (VOCs) and odorous compounds, which are a threat to the health and welfare of those within the sphere of influence of the landfill. This sphere can extend for several miles, depending on the topography of the area and the tendency for atmospheric inversions to occur.

Although landfill advocates claim that the practice of daily cover of the wastes will reduce the gaseous (odorous) releases from landfills, even diligent covering does not prevent them. Further, when landfill owners/operators become sloppy in operations, greater-than-normal landfill gas emissions occur, which are typically detected through landfill odors. Although some attempt to minimize the significance of smelling landfill gas on adjacent properties as only being an aesthetic problem, in fact, as discussed by Shusterman (7), it is now known that noxious odors can cause illness in people. Odors should be controlled so that they do not trespass across the landfill adjacent property owner's property line.

The only way at present to reliably ensure the protection of adjacent and nearby property owners/users from landfill gas is to provide a sufficient landfill-owner-owned buffer land about the landfill. If an adjacent or nearby property owner/user can smell the landfill, then inadequate buffer land exists between the landfill and adjacent properties, which should make it necessary for the landfill owner/operator to either acquire adjacent buffer land or to use more than the minimum approach for controlling gaseous releases from the landfill. It is also important to control future land use within the landfill area so that releases from the landfill would not be adverse to the land use. For example, agriculture in these areas should be restricted, because releases from the landfill could contaminate some crops. As long as landfill owners are allowed to use adjacent properties for their waste disposal buffer zones, justified NIMBY ("not in my back yard") issues by adjacent property owners will exist.

A common misconception held by landfill applicants and some regulators is that landfill gas production will cease after a comparatively short time after closure of a dry tomb landfill. Estimates of landfill gas production rate and duration are typically based on a model assuming unbagged, homogeneous wastes that are allowed to interact with moisture, which is not the situation that is found in Subtitle D dry tomb MSW landfills. The key to landfill gas production is the presence of sufficient moisture to allow bacteria to metabolize certain of the organic materials in the landfill to methane and CO_2 (landfill gas). Thus, the rate of moisture penetration through the cover and the mixing of that moisture with the waste components control the rate and duration of landfill gas production. Once the landfill is closed, Subtitle D landfills aim to keep moisture out of contact with the buried waste; the dryer the waste is kept, the slower the rate of landfill gas production. Furthermore, because much of the municipal waste that is placed in Subtitle D landfills is contained within plastic bags, and because those plastic bags are only crushed and not shredded, the crushed bags will "hide" fermentable components of the waste. Thus, once moisture does breach the cover and is allowed to contact with the wastes, the period of landfill gas production will be prolonged further, until after the plastic bags decompose and the bagged wastes allowed to interact with the moisture, which can extend gas production many decades, to a hundred or more years.

POSTCLOSURE MONITORING AND MAINTENANCE

The Subtitle D relies on the 30-year postclosure period of monitoring and maintenance to continue the protection of groundwater. The mistaken idea existed that 30 years after closure, the waste in a dry tomb landfill would no longer be a threat. From the characteristics of wastes and their ability to form leachate, as well as the processes than can occur in a landfill, it is clear that 30 years is an infinitesimally small part of the time that waste components in a landfill, especially a dry tomb landfill, would be a threat to cause groundwater pollution through leachate formation. A critical review of the processes that can take place in a MSW landfill that can generate leachate shows that the containment system of a dry tomb landfill, for which there is at least an initial effort to reduce the moisture entering the wastes, will eventually fail to prevent groundwater pollution for as long as the wastes are a threat. The municipal solid wastes in a classic sanitary landfill where no attempt to prevent moisture from entering the wastes exists have been found to generate leachate for thousands of years. Dry tomb landfilling delays and then prolongs leachate generation.

Subtitle D regulations also require that a small amount of assured funding be available for 30 years of postclosure monitoring and maintenance. Some regulatory agencies will allow landfill companies to be self-insured or insured through an insurance company that is backed by a landfill company. Such approaches should not be allowed, because landfill companies are amassing large liabilities for the ultimate failure of the landfill liner systems and the groundwater pollution that will occur as a result of those failures. It is well understood that, ultimately, private landfill companies will not likely be able to comply with Subtitle D regulations for funding of remediation. The amount of postclosure monitoring and maintenance funding that is currently required is grossly inadequate compared with the funding levels that could be necessary during the 30-year mandatory postclosure period, much less the extended period over which the wastes in the landfill will be a threat. Although Congress, through Subtitle D, required that the regulations include provisions to potentially require additional funding at the expiration of the 30-year postclosure care period, the likelihood of obtaining this funding from private landfill companies, even if they still exist 30 years after a landfill has been closed, or from a public agency that developed or owns landfills, is remote.

Lee (8) discussed the importance of solid waste management regulatory agencies requiring that landfill owners, whether public or private, prepare for the inevitable failure of the landfill containment system and provide for funding to address this failure. Designation of a 30-year postclosure assured funding period in RCRA, which is implemented not as a minimum but rather as a definitive period, leaves the public to pay the significant balance of the cost of landfilling; the public is left to deal with the long-term impacts of MSW landfills on public health and the environment, and eventual remediation of the landfill. This significant deficiency in Subtitle D regulations is recognized not only in the technical community but also by various other groups and individuals who have reviewed this issue. For example, in the executive summary of its report *Funding of Postclosure Liabilities Remains Uncertain,* in a section labeled, “Funding Mechanisms Questionable,” the U.S. Congress General Accounting Office (GAO) (9) concluded,

> Owners/operators are liable for any postclosure costs that may occur. However, few funding assurances exist for postclosure liabilities. EPA only requires funding assurances for maintenance and monitoring costs for 30 years after closure and corrective action costs once a problem is identified. No financial assurances exist for potential but unknown corrective actions, off-site damages, or other liabilities that may occur after the established postclosure period.

Further, the U.S. EPA Inspector General (10), in a report entitled “RCRA Financial Assurance for Closure and Postclosure,” came to similar conclusions:

> There is insufficient assurance that funds will be available in all cases to cover the full period of landfill postclosure monitoring and maintenance. Regulations require postclosure activities and financial assurance for 30 years after landfill closure, and a state agency may require additional years of care if needed. We were told by several state officials that many landfills may need more than 30 years of postclosure care. However, most of the state agencies in our sample had not developed a policy and process to determine whether postclosure care should be extended beyond 30 years, and there is no EPA guidance on determining the appropriate length of postclosure care. Some facilities have submitted cost estimates that were too low, and state officials have expressed concerns that the cost estimates are difficult to review.

LANDFILL SITING ISSUES

In the development of Subtitle D landfill regulations, the U.S. EPA failed to address one of the most important issues that should be addressed in developing a minimum Subtitle D landfill, namely, the need to site landfills at geologically suitable sites for a landfill of this type. Although the EPA does require that minimum Subtitle D landfills not be sited too close to airports, where major bird problems could exist for aircraft, too near an earthquake fault, or within a flood plain, the EPA does not address the issue of siting minimum Subtitle D landfills where the underlying geological strata do not provide natural protection of the groundwaters from pollution by landfill leachate when the landfill liner systems eventually fail. In accordance with current regulations, minimum Subtitle D landfills can be sited over highly important aquifers that serve as domestic water supply sources. They can also be sited in fractured rock and cavernous limestone areas, where it is impossible to reliably monitor for the pollution of groundwaters by landfill leachate using vertical monitoring wells.

Subtitle D landfill regulations also fail to address one of the most important causes for people to object to landfills; the deposition of wastes is allowed very near the landfill property owner’s property line. Under these conditions, the landfill gases, blowing paper, birds, rodents, vermin, and so on associated with the landfill can impinge on adjacent properties. For example, it is well established that landfill gas can readily travel a mile or more from a landfill, and thereby be adverse to the adjacent property owners’ use of their properties. It is recommended that at least a mile, and preferably two miles, of landfill-owned buffer lands exist between the area where wastes are deposited and adjacent property owners’ property lines, which would provide for dissipation of releases from the landfill on the landfill owner’s property. Such an approach would greatly reduce the trespass of waste-derived materials from the landfill onto adjacent properties.

ROLE OF 3 Rs IN MSW LANDFILLING

Considerable efforts are being made in many parts of the country to increase reuse, recycling, and reduction (the “3Rs”) of MSW as part of conserving natural resources and landfill space. As discussed by Lee and Jones-Lee (11), the 3 Rs should be applied to the maximum extent practicable to reduce the number of new and expanded Subtitle D landfills that will eventually pollute groundwaters.

JUSTIFIED NIMBY

NIMBY is an acronym for “not in my backyard,” a commonly dismissed plea presumed to be made by those who, without justification, simply oppose having a landfill nearby. However, Lee and Jones-Lee (12) and Lee et al. (13) discussed many of the technical issues that, in fact, justify a NIMBY position for Subtitle D landfills. Table 1 presents typical, real, adverse impacts of landfills on nearby property owners/users.

IMPROVING LANDFILLING

The degree of protection of public health and the environment from adverse impacts of MSW disposed of in dry tomb landfills can be improved to address some of the deficiencies of the approaches and specifications currently commonly accepted.

Siting

Landfills should be sited so that they provide, to the maximum extent possible, natural protection of groundwaters when the liner systems fail. Siting landfills above geological strata that have groundwater whose flow

Table 1. Adverse Impacts of Dry Tomb Landfills on Adjacent/Nearby Property Owners/Users[a]

- Public health, economic and aesthetic impacts on groundwater and surface water quality
- Methane and VOC migration—public health hazards, explosions, and toxicity to plants
- Illegal roadside dumping and litter near landfill
- Truck traffic
- Noise
- Dust and wind-blown litter
- Odors
- Vectors, insects, rodents, birds
- Condemnation of adjacent property for future land uses
- Decrease in property values
- Impaired view

Source: Lee et al. (13).

paths are not readily amenable to monitoring for leachate-polluted groundwaters should be avoided. Of particular concern are fractured rock and cavernous limestone areas, as well as areas with sandy lenses.

Design

MSW landfills should incorporate double-composite liners with a leak detection system between the two liners.

Closure

MSW landfills should incorporate leak-detectable covers that will indicate when the low-permeability layer of the landfill cover first fails to prevent moisture from entering the landfill.

Monitoring

The primary monitoring of liner leakage should be associated with the leak detection system between the two composite liners. If vertical monitoring wells are used, the spacing between the vertical monitoring wells at the point of compliance should be such that a leak in the HDPE liner caused by a 2-ft-wide rip, tear, or point of deterioration at any location in the landfill would be detected based on the plume that is generated at the point of compliance with a 95% reliability.

Landfill Gas Collection

For those landfills that contain wastes that can produce landfill gas, a landfill gas collection system should be designed, installed, and maintained for as long as the wastes in the dry tomb landfill have the potential to generate landfill gas, giving proper consideration to how and for how long gas will be generated in the system. The landfill gas collection system should be designed to have at least a 95% probability of collecting all landfill gas generated at the landfill.

Maintenance

The maintenance of the landfill cover, monitoring system, gas collection system, and so on. should be conducted for as long as the wastes in the landfill will be a threat, with a high degree of certainty of detecting landfill containment system and monitoring system failure, which will extend well beyond the 30-year period typically established, especially with improved provisions for excluding moisture.

Funding

The funding for closure, postclosure monitoring, maintenance, and groundwater remediation should be established at the time the landfill is established, in a dedicated trust fund of sufficient magnitude to address plausible worst-case scenario failures for as long as the wastes in the landfill will be a threat. Unless appropriately demonstrated otherwise, it should be assumed that the period of time for which postclosure care funding will be needed will be infinite.

Buffer Land

At least several miles of landfill-owner-owned buffer lands should exist between where wastes are deposited and adjacent properties.

Adoption of these approaches (or as many of them as possible) will improve the protection of groundwater quality, public health, and environmental quality from adverse impacts of the dry tomb landfilling of MSW.

Further information on the topics discussed is provided by Jones-Lee and Lee (14), Lee and Jones-Lee (6,12,15,16,18), and Lee (17).

LAND USE EFFECTS ON WATER QUALITY

Ross A. Steenson
Geomatrix
Oakland, California

Factors that determine water quality at a site include climate, geology, biology, and land use (anthropogenic practices). Water quality varies naturally as the result of differing natural environments, but anthropogenic practices can override these natural variations. During the last several decades, research and regulatory efforts in the United States have largely focused on understanding and limiting water quality effects from specific or localized anthropogenic sources, which are termed point sources.

Point sources include farms; industrial facilities where chemicals are manufactured, used, or stored; landfills; sewage treatment plants; hazardous waste sites; mines; and construction sites.

There are numerous routes through which sources can affect water quality (e.g., downward migration of source chemicals, wet weather runoff, and direct discharge). The water quality effects observed from sources include increased concentrations of dissolved chemicals (e.g., fertilizers/nutrients, pesticides/herbicides, industrial chemicals, trace elements, and minerals), loss of dissolved gases (e.g., oxygen, carbon dioxide), and change in physical characteristics (e.g., sediment load, temperature). Waters potentially susceptible to these effects include nearby surface waterbodies (e.g., streams and rivers) and underlying shallow groundwater or groundwater that is connected hydraulically to affected surface waterbodies.

More recently, studies and regulatory efforts have shifted beyond water quality effects at specific sites to understanding the broader effects. These efforts at understanding the broader water quality effects of land use have included studies of larger geographic regions and studies of the effects of increased human populations. Regional studies have combined available water quality data with measures of local land use and/or census information and identified general correlations between areal water quality, land use, and population density (1). As a result of the broadened view of water quality effects, the concept of nonpoint sources has evolved. Nonpoint sources can include multiple point sources or more areal sources (or practices).

Nonpoint sources include agricultural activities and agricultural and urban runoff. These diffuse sources have a greater potential to affect water quality and are much harder to address than point sources. An example of a common contaminant that is largely the result of nonpoint sources is nitrate, which is considered the most widespread contaminant in groundwater, particularly in agricultural areas (2). Runoff from urban areas is a potential source of many chemicals (e.g., spilled oils), debris, and sediment that can be rapidly discharged to surface waterbodies following wet weather. Thus, urbanization of watersheds has been viewed increasingly as ever more significantly affecting water quality (3).

In the last decade, concern has increased regarding the indirect effects on water quality from human populations and the pharmaceuticals and personal care products used by individuals. The number of these products is rapidly increasing, and it is believed that many of these chemicals find their way primarily into surface waterbodies, but also into groundwater, through incomplete treatment at sewage treatment plants or disposal in landfills (4).

MONITORING LIPOPHILIC CONTAMINANTS IN THE AQUATIC ENVIRONMENT USING THE SPMD-TOX PARADIGM

B. Thomas Johnson
USGS—Columbia
Environmental Research Center
Columbia, Missouri

SPMD-TOX PARADIGM

SPMD-TOX (Fig. 1) is a monitoring tool that uses microscale techniques to assess the environmental impact of civilization on an aquatic resource. To determine a relevant profile, the sample must reflect the chemical contaminant's effect, not just its presence. To collect and concentrate bioavailable lipophilic contaminants, a semipermeable membrane device is used instead of live animals. To make risk assessments that are both effective and efficient, microscale toxicity tests (TOX) are employed. (Use of specific products by USGS and its laboratories does not constitute an endorsement.)

AQUATIC ENVIRONMENTAL SAMPLING

Water by its very physical and chemical nature is a natural repository and carrier of domestic, industrial, and agricultural products. In the last 50 years, analytical chemists have made significant strides in collecting, separating, and identifying these environmental waterborne contaminants (1). However, to determine the effect of these contaminants on an aquatic ecosystem, additional questions must be answered: Is the contaminant simply a chemical out of place, or is it a pollutant, a chemical toxin injurious to the health of the ecosystem? Where is the contaminant? Does the contaminant move? Is the contaminant a pollutant that is bioavailable and toxic to the ecosystem?

Bioavailability

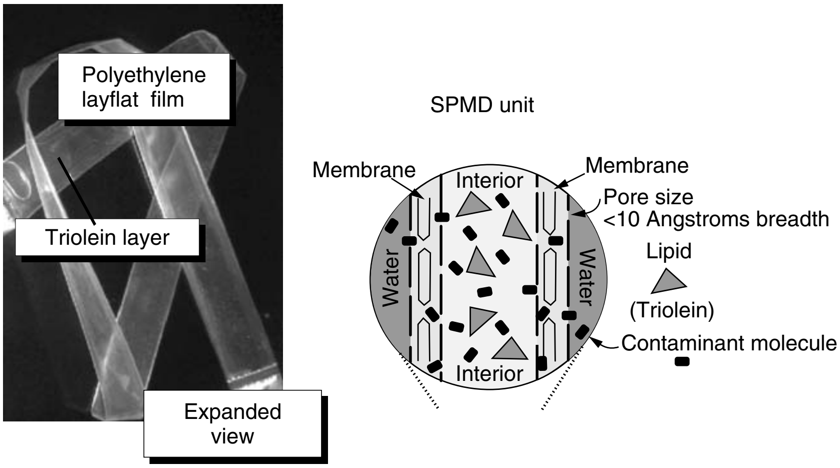
Bioavailability is a critical concept in ecotoxicology because a harmful effect occurs only when biota are exposed to bioavailable pollutants (2). In an aquatic ecosystem, a chemical tends to exist in one of three forms: (1) dissolved in water, (2) passively sorbed directly into the sediment and on biotic or abiotic components suspended in the water column, or (3) actively integrated in some biota and bioaccumulated through respiratory or food ingestion pathways. It is evident that water-soluble contaminants are dissolved and bioavailable to all biota in the water column, but lipophilic contaminants are fat-soluble and, as a result, present a different challenge to identify their toxic effects on biota.

Samples

Samples from an aquatic environment come with some general knowledge. A site may be industrial, rural, urban, recreational, or commercial. The area of concern may be a result of stormwater, a chemical spill, a fish kill, a careless citizen, or a business error. Based on the Paracelsus adage, toxicologists know that all things are toxic and the dosage makes the "toxicant." Paracelsus (1493–1541) is often considered the father of modern toxicology. He brought empirical evidence into toxicology with his writings *"What is there that is not a poison? All things are poison and nothing without poison. Solely the dose determines that a thing is not a poison."* In this context, a toxicant must be defined both qualitatively (identified) and quantitatively (how much); toxicity is clearly dose-responsive. Simply stated, a waterborne chemical in the environment may be a contaminant at one concentration and a toxicant at another concentration; dosage makes the difference. Thus, the modern-day toxicity bioassay is predicated on the dose–response experimental design.

SPMDs

To collect and concentrate a lipophilic sample, a semipermeable membrane device (SPMD) that mimics the bioaccumulation of waterborne organic contaminants by fish is



Dimensions: 2.5 cm × 15 cm

Figure 1. SPMD unit.

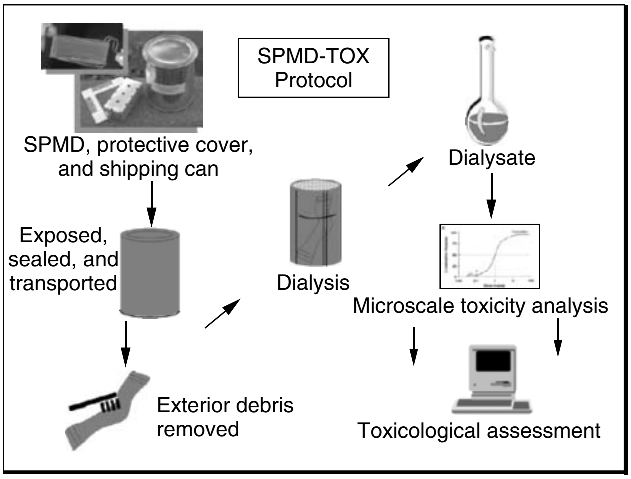


Figure 2. SPMD-TOX protocol.

used (SPMDs are sold exclusively by Environmental Sampling Technology in St. Joseph, MO); the SPMD permits estimates of tissue residues from the exposure site. The SPMD is a small low-density polyethylene lay-flat tube that contains neutral lipid triolein with a membrane surface area to lipid ratio of about $400\ \mathrm{cm}^2/\mathrm{mL}$ (Fig. 2). The SPMD is mounted in a protective stainless steel container and submerged generally 2 to 4 feet below the surface for about 30 days. Waterborne organic molecules diffuse through transitory openings (so called transport corridors) in the polyethylene membrane and sorb to the triolean, thus simulating the passive diffusion of a chemical across a fish gill's membrane. The SPMD monitors the lipophilic contaminant's bioavailability by a log K_{ow} value of less than one, a molecular weight of 600 daltons or less, and a size less than 10 Å. The entire unit is returned to the laboratory and the SPMD is chemically dialyzed using an organic solvent to recover sequestered chemicals.

The SPMDs as environmental contaminant-concentrating tools have many advantages. (1) They are abiotic, which means SPMDs do not metabolize sequestered products but provide a true reflection of bioavailable contaminants. (2) They are time integrative samplers, which means SPMDs will collect all lipophilic materials introduced into the water column during the exposure period, even if the introductions are episodic. (3) SPMDs can survive in heavily polluted, toxic environments where living organisms may not survive. (4) They are not temperature specific; SPMDs can be used in both cold and warm water. (5) SPMDs are easily transported to sites of interest for sampling and to laboratories for processing. (6) SPMD dialysates are analyzed by traditional GC/MS to identify the sequestered contaminants; algorithms and sampling rates are used to back-calculate concentrations in the water column. (7) SPMDs are cost-effective and, as a result, can be used in large monitoring programs.

TOXICITY ASSAYS

Microtox (3) determines the acute toxicity of SPMD dialysates by measuring the changes in light produced when samples are exposed to bioluminescent bacteria under standard conditions. Microtox bacteria *Vibrio fischeri* are clonal cultures, which diminish possible genetic differences and ensure quality control of the tester strain with greater assay sensitivity and precision. The freeze-dried bacteria are available on demand and all test media and glassware are prepackaged, standardized, and disposable. The test requires minimal laboratory space and limited dedicated equipment. The test is well defined, computer assisted, and user friendly.

Microtox is microscale. Dialysates are prepared in the basic dose–response design and placed in an SDI Model 500 Analyzer for incubation. [Columbia Environmental Research Center (CERC) uses Microtox materials and equipment sold by Strategic Diagnostics Inc. (SDI) in Newark, DE, to preserve the Microtox protocol. SDI provides comprehensive instructive guides, manuals and computer software to operate the Microtox test at their Web site (www.azurenv.com). The Microtox protocol described here is a standard USGS SOP.] The amount of light remaining in the sample is used to determine the sample's relative toxicity, which can then be compared to the standard reference's toxicity. As the toxicant's concentration increases, bacterial light emissions decrease in a dose-dependent manner. Supporting computer software is used to determine a 50% loss of light in the test bacteria, that is, the effective concentration (EC_{50}) value. Tests are completed and data are available in <30 min. The lower the EC_{50} value, the greater the acute toxicity of the sample.

Mutatox (4) determines the DNA-damaging substances in SPMD dialysates by measuring the increase in light produced when samples are exposed to dark mutant stains of *V. fischeri*. (Mutatox is prepared and sold exclusively by SDI. The Mutatox protocol described here is a standard USGS SOP.) Similar to Microtox, the test bacteria are stored freeze-dried under vacuum and require no preculturing; aseptic techniques are minimal; all test media and glassware are prepackaged, standardized, and disposable. The test requires minimal laboratory space and limited dedicated equipment. Because most bacterial cells such as these dark mutant strains fail to duplicate vertebrate biotransformation of progenotoxins into active genotoxins (DNA-damaging substances), a vertebrate activation system, typically rat or fish hepatic enzymes, is incorporated into the test.

Mutatox is microscale; all tests are conducted in microvolumes with microcuvettes. A single reaction cuvette contains the dark mutant bacteria, the diluent, the dialysate, a metabolic activation system, and a carrier solvent such as DMSO. Test samples are serially prepared over a 100-fold dose range, preincubated at 37 °C (metabolic activation) for 15 to 30 min, and then grown in the dark at 27 °C for 18 to 24 h. Benzopyrene, a commonly found PAH, is used as a positive control. A genotoxic response is defined as an increased light value of at least three times the light intensity of the solvent control blank. Mutatox is a qualitative test that provides a yes-no assessment of potentially DNA-damaging substances.

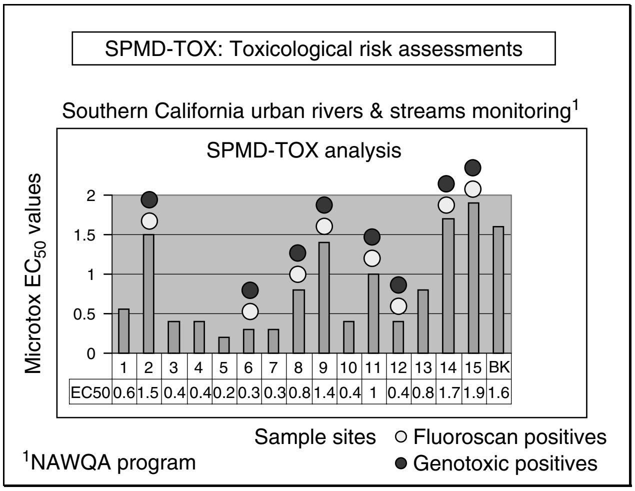

Figure 3. Risk assessment of Southern California urban streams with SPMD-TOX.

Case Study: A Simulated Oil Spill (5)

SPMD-TOX monitored a simulated oil spill during an 8-week period along the St. Lawrence River in Canada. An SPMD was placed weekly in each of the 20 oiled plots and removed 1 week later. The dialysates from the first 2 weeks fluoresced, indicating the presence of PAHs, and Mutatox analyses confirmed these findings with a yes response. Microtox analyses initially showed evidence of acute toxicity followed by a rapid decline and by week 4 no detectable acute toxicity. Samples from weeks 3 through 8 showed no evidence of the oil spill in the water column. SPMD-TOX analyses of these samples during the 8-week exposure period presented a clear picture of the occurrence and rapid recovery of the simulated oil spill site.

Case Study: Urban River Sites (6)

During a 30-day exposure period, SPMD-TOX was used to monitor 15 urban sites at rivers and streams in Southern California for the presence of bioavailable waterborne lipophilic ecotoxins. Fluoroscan, Microtox, and Mutatox data suggested the probable presence of PAHs and the initial identity of both acute toxic and genotoxic substances that were bioavailable in the water column (Fig. 3).

SUMMARY

SPMD-TOX is a sensitive, technically simple, and cost-effective assessment tool for monitoring waterways for bioavailable lipophilic chemical contaminants that may adversely affect aquatic communities and water quality. The SPMD-TOX paradigm can rapidly identify chemical incursions that may impact the quality of the water and provide the ecotoxologist and resource manager with valuable risk assessments of areas of concern.

INTRODUCTION

Water quality monitoring tests have expanded over the years to include the use of bioassays for routine testing and screening of water quality in an attempt to overcome several drawbacks of using the physicochemical tests. The identification of chemicals by the sophisticated chemical and instrumental methods are conditioned by the presence of a reference sample. Such methods are unable to estimate possible biological synergistic or antagonistic interactions between chemicals, and their routine use is limited due to their high cost and the requirement for skilled personnel. The routine use of aquatic bioassays has been limited by the time required (usually days) to perform such tests as well as the cost and skill level. In order to overcome these limitations, numerous short-term bioassays have been developed in the past fifteen years, but the most commonly used and thoroughly validated rapid tests are the bioluminescence-based bioassays based on the use of luminescent bacteria. The following sections describe the various approaches and technologies that utilize luminescent bacteria for determination of water quality.

USE OF NATURAL LUMINESCENT BACTERIA FOR ON-SITE DETERMINATION OF WATER QUALITY

The generation of light by luminescent bacteria involves the activity of the enzyme luciferase that simultaneously catalyzes the oxidation of $FMNH_2$ and long chain aldehyde with the aid of molecular oxygen to yield FMN, long chain fatty acids, water, and light. Seven genes (*luxRICDABE*) are involved in the regulation and synthesis of the *Vibrio fischeri lux* proteins. The intricate molecular aspects of the bacterial *lux* system have been reviewed extensively (1–4).

The use of intact luminescent bacteria for analytical purposes has some clear advantages: the light of a single bacterium may reach about 30,000 quanta/s/cell; thus, one can use a simple luminometer to detect light generated by a few hundred cells/mL. Chemophysical and biological factors that affect cell respiration, the rate of protein or lipid synthesis, promptly alter the level of luminescence. In 1979, Bulich first showed that luminescent bacteria used for toxicity testing could be freeze-dried and provided to testing laboratories in a convenient reagent configuration (5). Freeze-dried (lyophilized) luminescent bacteria reagent can be stored for years at −18 °C. Upon hydration, freeze-dried cultures can yield 95–98% of their original viability, as well as their original level of *in vivo* luminescence. Thus, the use of these preparations for analytical purposes is not different, in practice, from other biochemical tests. Numerous studies described the use of natural luminescent bacteria or recombinant *lux*-carrying bacteria for rapid assessment of toxic components in aqueous environments. The next sections describe in more detail the bioluminescent tests for acute and chronic water toxicants.

MICROTOX TEST

The use of the bacterial luminescence system for the rapid assessment of aquatic toxicity was first suggested by Bulich (5) and later commercially marketed as Microtox. The bioassay is based on a preparation of lyophilized cultures of *Vibrio fischeri* (NRRL B11177). The lyophilized culture is hydrated with high purity water from which 10 μL aliquots each containing 10^6 cells are added to serial dilutions of the tested water supplemented with NaCl. Light measurements from the diluted water sample and clean water control are obtained after 5–15 min of incubation at 15 °C. The minimal concentration of tested water that results in 50% inhibition of light relative to the light level of the control is defined as IC_{50} (or EC_{50}) of the said water sample, or of the tested chemical spiked into it. Figure 1 shows typical results and determination of the IC_{50} value for a toxic agent spiked into a clean water sample. The Microtox test has been successfully applied worldwide for quality testing of industrial water, sewage, effluents, and contaminated sediments (6,7) and qualified as a standard for certain types of samples by various standards organizations in the United States and Europe. For many chemicals and toxic water samples, the sensitivity of the tested water in Microtox agreed well with the results obtained with daphnia or fish-based bioassays (8). In order to meet the need for the higher sensitivity required for drinking water analysis, we developed for AZUR Environmental a 22-h chronic test that involves bacterial growth and *de novo* synthesis of the *lux* system in *V. fischeri* (9,10). The test has been successfully used to screen drinking water samples for the presence of unexpected chemical contamination. The Microtox Test System is commercially available from Strategic Diagnostics, Inc.

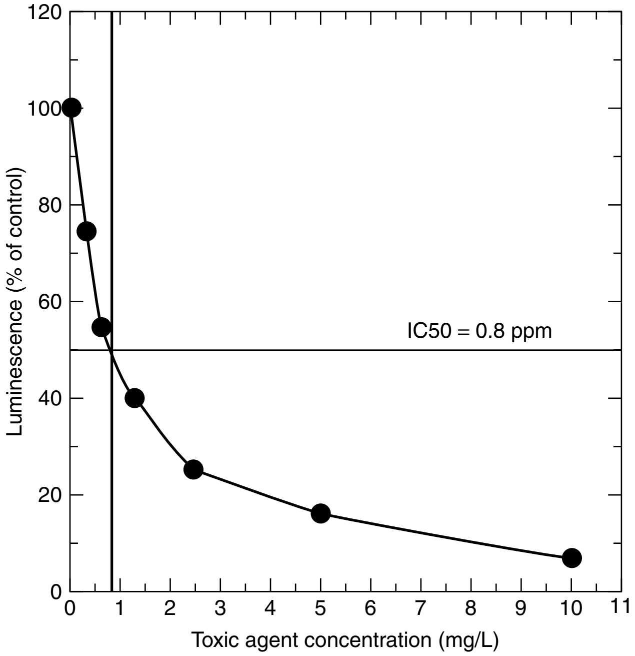

Figure 1. Typical response of luminescent bacteria to a toxic agent (see text for details).

TOXSCREEN TEST

A suitable test for drinking water toxicants should be rapid and sensitive enough to detect very low concentrations of diverse groups of toxic agents. Other requirements from such a test include simple operation, minimal false positive or negative responses, affordability, and the capability to run the test outside the laboratory. A novel bioassay (ToxScreen) that demonstrates those requirements has been developed by CheckLight (11). ToxScreen utilizes a marine luminescent bacterium (*Photobacterium leiognathi*) and applies unique assay buffers that markedly increase the sensitivity of the test and also enable the preliminary discrimination between organic and cationic metal toxicants. Cationic heavy metals can be detected at sub-milligram/liter levels; many of them were detected at 10–50 μg/L range. Similarly, pesticides, PAHs, and chlorinated hydrocarbons were detected in a separate test, all within 20–45 min. For most of the tested toxic agents, ToxScreen was found to be markedly (over 10–100-fold) more sensitive than Microtox (11). A practical feature of the new bioassay is the option of running the test at ambient temperatures (18–35 °C). In addition, the stability of the freeze-dried bacterial reagent preparation precludes the need for refrigeration or freezing during shipment. These features, together with its simple operation procedure, suggest that it has potential applications as a cost-effective prescreening tool to appraise chemical toxicity in various water sources. The higher sensitivity and simplicity of ToxScreen has recently been confirmed by the U.S. EPA's Environmental Technology Verification (ETV) program of rapid toxicity technologies (http://www.epa.gov/etv/verifications/vcenter1-12.html).

USE OF LUMINESCENT BACTERIA FOR ONLINE MONITORING OF WATER TOXICITY

The increasing concern for drinking water quality, together with the growing terrorism awareness, has emphasized the need for real-time monitoring of drinking water quality. Two kinds of bioluminescence-based online monitors for water quality have been developed so far. An online monitor that utilizes lyophilized cultures of luminescent bacteria was first developed by AZUR Environmental and Siemens in the mid-1990s. The device (Microtox-OS) was designed to automate the standard Microtox test and operate on-site, unattended for two weeks. The Microtox-OS Test System was equipped with a statistical process control software to continuously monitor data and was user-configurable to identify test results that were statistically different from preceding values. Due to its high operation cost, however, only a few units were sold.

The TOXcontrol-BioMonitor (now available through Microlan, The Netherlands) is based on freshly cultivated light-emitting *V. fischeri* cells that are continuously mixed with clean water and tested water. Light is detected using an online dual monitoring luminometer as it passes through twin flow cells. Any significant difference in light detected from the reference and monitoring streams results in a number of programmable events: an alarm can be programmed or a valve can be switched to collect samples for further analysis. No information has been published on the sensitivity of this automatic bioluminescent test. In general, luminescent bacteria growing in liquid medium in the presence of nutrients are not expected to show high sensitivity toward toxic agents. The system is mainly used for river biomonitoring and wastewater monitoring in Europe.

The integration of the ToxScreen test with an automatic online monitor was recently introduced by CheckLight Ltd. and Systea Srl and named MicroMac-ToxScreen. MicroMac-ToxScreen is an innovative automated online water quality monitoring system that utilizes the ToxScreen reagents to detect microgram/liter concentrations of toxic organic and inorganic chemical pollutants in surface or groundwater, as well as raw and treated drinking water. Freeze-dried luminescent bacteria are hydrated and kept in the device at 4 °C to maintain a stable luminescent culture. The instrument is resupplied with newly hydrated luminescent bacteria and a fresh inventory of liquid assay every two weeks. Automatic safeguards have been engineered into the system to assure reagent and data quality and appropriate instrument functioning. The instrument is also equipped with autocalibration features to assure reliable instrument performance; microprocessor-based system controls provide for data storage, data downloading, real-time communication with a remote PC, and user adjustable alarm levels.

Cho et al. (12) have recently adapted a 384-multiwell plate monitor for determination of water toxicity. Lyophilized *luxAB* carrying *Janthinobacterium lividum* cells are exposed to the water in question for 15 min followed by luminescence recording after addition of aldehyde. Similar to other terrestrial *lux*-carrying systems, this test is more sensitive to metals than the Microtox test.

LUX REPORTER GENES FOR DETERMINATION OF GENERAL STRESS-INDUCING AGENTS OR SPECIFIC TOXIC CHEMICALS

With the development of recombinant DNA technology, various recombinant bioluminescent bacteria have been engineered by fusing the *lux* gene with a stress-responding inducible promoter or with a specific promoter for a given toxicant (13). Exposing these recombinant cells to active toxic agents resulted in dramatic increase in bacterial luminescence. Such bacteria can be extremely useful for bioremediation studies; they can be utilized to determine the presence and concentrations of specific pollutants such as Hg(II) (14), or detection of linear alkanes (15) and naphthalene (15), or general responses to environmental stress (16,17).

A novel approach for identification of water toxicants by using *Escherichia coli* carrying *lux* genes fused with stress promoters was suggested by Ben Israel et al. (18). Twenty-three out of 25 tested chemicals were identified by a novel testing matrix using a 3-h test procedure. This biological recognition strategy also provides a tool for evaluating the degree of similarity between the modes of action of different toxic agents. Recently, Kim and Gu (19) described a high throughput toxicity monitoring and classification biosensor system using four immobilized bioluminescent *E. coli* strains that have plasmids bearing a fusion of a specific promoter to the *lux*CDABE operon. These strains are immobilized in a single 96-well plate using an LB-agar matrix. The bioluminescence increases when the water sample contains chemicals that cause either oxidative damage, membrane damage, DNA damage, or protein damage.

USE OF LUMINESCENT BACTERIA FOR DETERMINATION OF MUTAGENIC AND CARCINOGENIC AGENTS

Ulitzur et al. (20,21) and Weiser et al. (22) were the first to use luminescent bacteria for determination of mutagenic and genotoxic agents. The first test, later commercialized as Mutatox (23,24), was based on a spontaneous dark variant (M169) of the luminescent bacterium *Photobacterium leiognathi*. Light production was restored when cells were incubated in the presence of subacute concentrations of genotoxic agents, including base substitution, frameshift, DNA synthesis inhibitors, DNA damaging agents, and DNA intercalating agents (25). Mutatox test showed very good correlation with the Ames test (26). The primary genetic lesion of M169 was discovered later to be due to the presence of mutation in the *rpoS* gene (4).

Vitotox® is another example of a bioluminescent test for genotoxic agents (27,28). In this test, two recombinant *Salmonella typhimurium* TA104 strains are used to determine both genotoxicity and cytotoxicity of the tested sample. Under normal growth conditions, the luciferase reporter gene is repressed; in the presence of a DNA damaging agent, the SOS response is stimulated and leads to derepression of the strong promoter controlling the expression of the luciferase gene.

A new mutagenicity assay, in which a series of genetically modified strains of marine bacterium *Vibrio harveyi* was used for detection of mutagenic pollution of marine environments, has recently been described by Czyz et al. (29).

USE OF LUMINESCENT BACTERIA FOR DETERMINATION OF NUTRIENTS IN WATER

AOC (Assimilable Organic Carbon)

Regrowth potential of heterotrophic bacteria in potable water depends mainly on the presence of an assimilable organic carbon source. Many bacteria are capable of dividing in water containing as low as 5–10 μg/L of various carbon sources. Most of the standard or proposed AOC methodologies are hindered by their long duration and require between 5 and 14 days for completion. A bioassay that utilizes a nutrient-deprived culture of autoinducer-requiring mutant of *V. fischeri* has been developed and is commercially available (CheckLight Ltd). Luminescence in this strain is directly proportional to the concentration of utilizable organic material in the water sample. This 2-h test enables the detection of as little as 5 μg/L organic carbon and the test has shown high correlation with the standard 7-d long AOC test.

Haddix et al. (30) have recently described a test system in which *Pseudomonas fluorescens* P-17 and *Spirillum* species strain NOX bacteria were engineered with a *luxCDABE* operon fusion and inducible transposons that were selected on minimal medium. Independent mutants were screened for high luminescence activity and predicted AOC assay sensitivity. All mutants tested were able to grow in tap water under AOC assay conditions. Peak bioluminescence and plate count AOC tests were linearly related. Bioluminescence results that were obtained 2–3 d postinoculation were comparable with the 5-d ATP pool luminescence AOC assay and 8-d plate count assay.

BOD (Biochemical Oxygen Demand)

The biochemical oxygen demand (BOD) test (BOD5) is a crucial environmental index for monitoring organic pollutants in wastewater but is practically limited by the 5-d requirement for completing the test. A rapid BOD test based on an autoinducer-requiring mutant of *V. fischeri* is now commercially available (CheckLight Ltd.). The test procedure requires the water in question to be boiled for 30 min in the presence of 1 N HCl followed by addition of 1 N NaOH to neutralize the sample. This brief hydrolysis step is sufficient to break down proteins and complex carbohydrates into oligomers or monomers that can be assimilated by the bacteria. A good correlation was found between the 2-h bioluminescent test and the 5-d standard BOD test.

A BOD sensing system based on bacterial luminescence using recombinant *E. coli* containing *lux A-E* genes from *V. fischeri* has recently been described by Sakaguchi et al. (31). Frozen cells of luminescent recombinants of *E. coli* were applied to measure and detect organic pollution due to biodegradable substances in various wastewaters. The data from this study showed a similar correlation with that of the conventional method for BOD determination (BOD5).

Other Test Systems

Due to the intense use of synthetic nitrogen fertilizers and livestock manure in current agriculture practices, food (particularly vegetables) and drinking water may contain unacceptable concentrations of nitrate. A plasmid-borne transcriptional fusion between the *E. coli* nitrate reductase (*nar*G) promoter and the *Photorhabdus luminescens lux* operon provided *E. coli* with a highly bioluminescent phenotype when in the presence of nitrate concentrations as low as 5×10^{-3} mol/L (0.3 ppm) (32).

Recently, Gillor et al. (33) have described a reporter system for nitrogen availability. The promoter of the glutamine synthetase-encoding gene, P *gln*A, from *Synechococcus* sp. strain PCC7942 was fused to the *luxAB* luciferase-encoding genes of the bioluminescent bacterium *Vibrio harveyi*. The resulting construct was introduced into a neutral site on the *Synechococcus* chromosome to yield the reporter strain GSL. Light emission by this strain was dependent on ambient nitrogen concentrations. The linear response range of the emitted luminescence was 1 mM to 1 μM for the inorganic nitrogen species tested (ammonium, nitrate, and nitrite) and 10–50-fold lower for glutamine and urea. When water samples collected from a depth profile in Lake Kinneret (Israel) were exposed to the reporter strain, the bioluminescence of the reporter strain mirrored the total dissolved nitrogen concentrations chemically determined for the same samples. This test strain was shown to be a sensitive indicator of bioavailable nitrogen.

CONCLUSIONS

The bioluminescence tests for detecting water toxicants as well as for measuring elementary nutrients have been shown to be simple, rapid, and relatively inexpensive tools for monitoring water quality. Still, the relatively high cost ($3000–25,000) of commercially available luminometers restricts the routine applications of these technologies. The use of the *lux* genes in recombinant microorganisms has not been commercially applied yet mainly due to the restriction on using recombinant DNA in commercial products. Wider application of bioluminescent tests for screening water quality will ensure a better supply of adequate quality and will minimize the danger of water contamination by terrorist acts.

WATER QUALITY MANAGEMENT

Chakresh K. Jain
K.D. Sharma
National Institute of Hydrology
Roorkee, India

INTRODUCTION

Water is one of the basic necessities for the survival of human beings and the prosperity of civilization. The ever increasing growth of population, industrialization, the steady rise in irrigation, urbanization, and the high level of living standards exert tremendous pressure on the available water which is highly uneven in its spatial and temporal distribution in quantity and quality. Water is put to different uses such as irrigation, industry, power generation, drinking, bathing, recreation, fisheries, wild life propagation, and pollution abatement. For each of the uses, water is required in appropriate quantity and quality. Nowadays, there is an increasing awareness of water quality, especially in urban areas. Due to the rapid increase in population and the growth of industrialization in the country, the pollution of natural water by municipal and industrial wastes has increased tremendously.

The term "water quality" is a widely used expression, which has an extremely broad spectrum of meanings. Each individual has vested interests in water for a particular use. The term water quality, therefore, must be considered relative to the proposed use of water. From the user's point of view, the term "water quality" is defined as the physical, chemical, and biological characteristics of water by which the user evaluates the acceptability of water. For example, for the sake of human health, we require a pure, wholesome, and potable water supply.

In recent years, rivers are being used indiscriminately for disposal of municipal, industrial, and agricultural wastes, thereby polluting the river water beyond permissible limits. Due to this, river waters are gradually becoming unfit even for irrigation in some places. Thus it has become essential to evaluate the environmental impacts of water resources to minimize the progressive deterioration in water quality. Therefore, a detailed study of water quality in all vulnerable rivers is imperative for better management and use of water.

WATER QUALITY MONITORING

Water quality problems stem from two factors, the natural hydrology of a river basin and the development and use of land and water resources by human beings. Depending on the interrelation of these two factors, a wide variety of quality problems can result. Each river basin, therefore, is unique, and it must be subjected to individual and intensive water quality assessment to provide a proper basis for judicious management of land and water.

The following points should be considered for proper planning of a water quality monitoring program:

What are the objectives of the program?
From where are samples to be taken?
Which determinants are of interest?
When and how often are samples to be taken?
What is to be done with the results?

These questions will provide a framework for defining measurement programs. The results obtained from such a program should be regularly reviewed to decide if any changes (e.g., determinants or sampling frequency) in the monitoring program are necessary.

Objectives of the Monitoring Program

It is obvious that the objectives of a program should be clearly and precisely formulated by the user. If it is not done, inappropriate analytical data may well be provided, and/or the user is likely to call for needlessly large or unduly small numbers of results. Furthermore, if the objectives are not precisely expressed, it will be difficult or impossible to decide the extent to which they are achieved.

It is suggested that analytical information should be requested regularly only when the user knows beforehand that the results will be used in a precisely known fashion to answer one or more defined questions on quality. Requests for analysis based on the thought that the results may ultimately prove useful should be avoided, particularly when the analytical sampling effort is limited. There is an almost infinite number of analyses that might be useful in most situations, but it is completely impracticable to attempt any such comprehensive coverage. Therefore, selection from all possible objectives and determinants is essential for proper planning of a monitoring program.

As a further means of optimizing measurement programs, users should formulate their information needs as quantitatively as possible. As an extreme and perhaps rather artificial example of a badly defined requirement, consider the statement, "to obtain information on the quality of the river." Such a statement is almost completely useless as a basis for designing a monitoring program for the following reasons:

1. The determinants are not specified, so that the analyses required are not known.
2. The particular river and the locations on the river are not defined, so that inappropriate sampling positions may be chosen.
3. No indication is given of the timescale or sampling frequency, so that too few or too many samples may be collected and analyzed.
4. As a result of all of the above deficiencies, there is no indication of the amount of data that needs to be processed and the nature of the data treatment, so that appropriate data handling techniques cannot be defined.

Therefore, users of analytical results must seek to avoid uncertainties such as those in the preceding example by careful and quantitative definition of every aspect of their requirements. Thus, an objective such as the above would be better expressed by a statement of the form, "to estimate each year the annual average concentration of ammonia ($NH_3 + NH_4^+$) at all river sites used for the production of potable water." Appropriate statements of this type for other determinants of interest then provide a set of quantitative targets essential in optimizing the choice of sampling, analytical, and data handling techniques.

Objectives of GEMS/WATER

The fundamental objectives of the water quality monitoring system within the GEMS/WATER program are to:

1. Assess the impacts of human activities upon the quality of the water and its suitability for required uses.
2. Determine the quality of water, in its natural state, which might be available to meet future needs.

3. Keep under observation the source and pathways of specified hazardous substances.
4. Determine the trend of water quality at representative stations.

The first objective is met by the establishment of impact stations, the second by baseline stations, the third by either impact or baseline stations depending upon whether the hazardous substance is of artificial or natural origin, and the fourth by trend stations.

Baseline stations are located where no direct diffuse or point sources of pollutants are likely to be found. They are used to establish the natural background level of variables, to check if no synthetic compounds are found in remote areas (e.g., DDT), and to assess the long-term trends of surface water quality resulting from global atmospheric pollution. Impact stations are situated in waterbodies where there is at least one major use of the water or which are greatly affected by human activities. Four type of impact stations can be identified according to different uses of water:

1. *Drinking water*: at the raw water intake before treatment for drinking water.
2. *Irrigation*: at the water intake before distribution for irrigation.
3. *Aquatic life*: river and lake stations representative of the general quality of the waterbody.
4. *Multiple impacts*: several water uses at the station and/or of the waterbody.

Trend stations are set up specially to assess the trends in water quality. They must be representative of a large area with various types of human activities. These stations should be more frequently sampled to increase the statistical significance of the average concentrations and to validate the trends.

Sampling Locations and Points

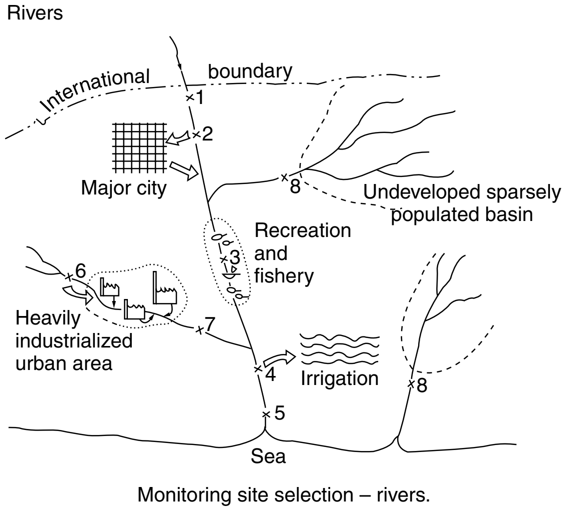
Sampling location and point mean the general position within a waterbody and the exact position at which samples are obtained. The objectives of a program sometimes immediately define the sampling locations. For example, when the concern is to measure the efficiency of a chemical plant for purifying water, sampling locations will be required before and after the plant. Similarly, when the effect of effluent discharge on the water quality of a receiving river is of interest, samples will be required from locations upstream and downstream of the discharge. For larger scale water bodies (e.g., a river basin, a large estuary, a large urban drinking water distribution system), however, the objectives may be defined in terms that do not indicate sampling locations. For example, objectives such as "to measure river quality within a river basin" or "to measure the quality of water in a distribution system" give no indication of which of the large number of possible sampling locations are of interest. Such broadly expressed objectives are completely inadequate for detailed planning of efficient sampling programs and should always be sharpened, so that they do indicate the positions of sampling locations. A commonly useful device for helping in this respect is to consider the intended use of the water because this aids in indicating these positions in a waterbody where quality is of key importance.

Figure 1 illustrates the hypothetical case of a river system along with criteria for choosing different sampling sites. Figures 2 and 3 illustrate the location of sampling sites for lakes and groundwater with corresponding criteria for choosing of different sampling sites.

Determinants of Interest

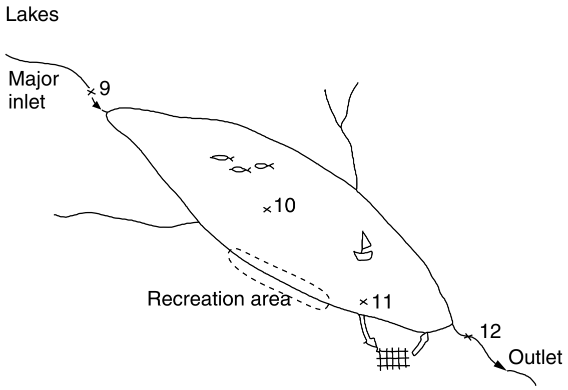
The particular determinants appropriate for a program depend critically on the type of water and the objectives of the study. Depending on the intended use of a receiving water, the parameters listed in Table 1 are significant for water quality characterization. They are guidelines for analysis of wastewater quality for treatment and control. The parameters listed in Table 2 are frequently used to identify various types of pollution from industrial wastewater.

Some of the most important and most frequently used tests for analyzing water are the nonspecific tests listed in Table 3. These tests often measure a property of a group of substances. For example, alkalinity indicates the capacity of water to neutralize hydrogen ions. Many of these tests are used to determine the suitability of natural water for industrial or municipal use and to determine the type and degree of treatment required. Table 4 lists some of the more frequently measured parameters in pollution studies.



Station	Type	Criteria
1	Impact	Immediately downstream of an international (or baseline) boundary
2	Impact	Abstraction for public supply of large town
3	Impact	Important fishing, recreation, and amenity zone
4	Impact	Abstraction for large-scale agricultural area
5	Trend	Freshwater tidal limit of major river
6	Impact	Abstraction for large industrial activity
7	Impact	Downstream of industrial effluent discharge and important tributary influencing main river
8	Baseline	Station where water is in a natural state (no direct or indirect pollution, no water use)

Figure 1. Monitoring site selection—rivers.



Monitoring site selection – lakes.

Station	Type	Criteria
9	Impact (or baseline)	Principal feeder tributary
10	Impact (or baseline)	General water quality of lake
11	Impact	Water supply of major city
12	Impact (or baseline)	Water leaving lake

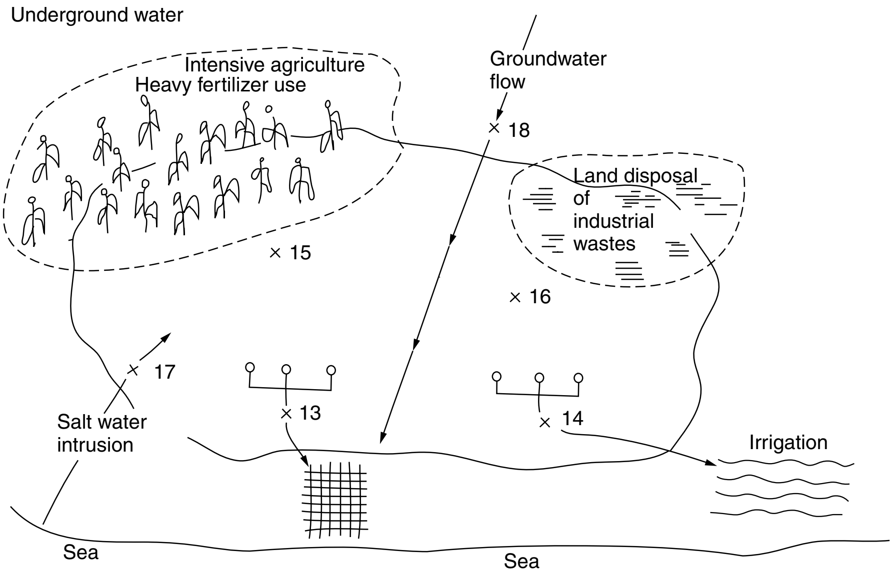
Figure 2. Monitoring site selection—lakes.

Frequency and Time of Sampling

The quality of water in various waterbodies is rarely constant in time. There may be some relationship between the role of change in different variables, but others alter independently. In measuring the mean, maximum, and minimum values of variables over a period of time, the closeness of the monitored values to the true values depend upon the variability of the variables and the number of samples taken. The larger the number of samples from which the mean is derived, the narrower are the limits of the probable difference between the observed and true means. These confidence limits are not directly proportional to the number of samples but to the square of the number. Therefore, to double the reliability of a mean value, the number of samples must be increased fourfold.

Variations in water quality are caused by changes (increase or decrease) in the quantity of any of the inputs to a waterbody. Such changes may be natural or man-made and either cyclic or random. Water quality variation may therefore be similarly cyclic or random.

Variability differs among rivers, lakes, and underground waters. It is most pronounced in rivers, and the ranges are greater, the nearer the sampling point is to the source or sources of variability. As the distance from the source increases, longitudinal mixing smooths out irregularities and fewer samples are needed to meet given confidence limits. However, as the distance between the source of variability and the sampling point increases, there is a reduction in the range of variation, and there is also dilution. Some variables are reduced by self-purification,



Monitoring site selection – underground water

Station	Type	Criteria
13	Impact	Water supply to large town threatened by fertilizer residues and saline intrusion
14	Impact	Water for large-scale irrigation threatened by leachate from waste tips
15 } 16 } 17 }	Impact	Water supply of major city
18	Baseline	No human activities in the groundwater recharge area

Figure 3. Monitoring site selection—underground water.

Table 1. Parameters for Water Quality Characterization

Water Use	Quality Parameters
Domestic water supply	Color, odor, taste
	Organic content: chlorine demand, COD, BOD, TOC, phenols
	Carcinogens and toxic compounds: insecticides, pesticides, detergents
	Turbidity, salinity
	Alkalinity, pH
	Total hardness, Ca, Mg, Fe, Si, etc.
	Pathogenic organisms, total bacterial count (37 °C), *E. coli*, plankton count
Fish, shellfish, wildlife, and recreation	Color, odor
	Toxic compounds
	Turbidity, floating matter, sludge deposits, salinity
	Temperature
	Dissolved oxygen, BOD
	Alkalinity, pH, pathogenic organisms, plankton count, nitrogen, phosphorus (inorganic nutrients that support algal blooms and other undesirable aquatic growth)
Agricultural irrigation	Salinity and Na-Ca content
	Alkalinity, pH
	Pesticides, growth regulators
	Persistent synthetic chemicals (e.g., polyethylene derivatives, asphalt sprays.)
	Pathogenic organisms
Watering livestock	Salinity
	Toxic compounds
	Pathogenic organisms
	Plankton count

Table 2. Significance of Parametric Measurements

Test(s)	Significance
Dissolved solids	Soluble salts may affect aquatic life or future use of water for domestic or agricultural purposes
Ammonia, nitrites	Degree of stabilization (oxidation) or nitrates and total organic nitrogenous matter, organic nitrogen
Metals	Toxic pollution
Cyanide	Toxic pollution
Phenols	Toxic pollution, odor, taste
Sulfides	Toxic pollution, odor
Sulfates	May affect corrosion of concrete, possible biochemical reduction to sulfides
Calcium and magnesium	Hardness
Synthetic detergents	Toxic pollution

deposition, and adsorption. These effects must be considered if a sampling station used for quality control is located some distance from the point of use.

In lakes, the mass of water and good lateral mixing provide inertia against any rapid changes from modifications in input and output. Many lakes exhibit marked seasonal variations due to thermal stratification, overturn, and biological activity. Depending on the type of lake, it may be sampled with a seasonal bias related to the natural cycles of the lake.

Underground water has a lower variability than that of either rivers or lakes. The rate of quality change depends on the depth of sampling, the volume of the aquifer, and hydraulic conductivity. The time elapsing between changes in land use and in surface recharge water and their effect upon the underground water depends on the time of percolation. Variations are often, but not invariably, seasonal with a time lag according to the rate of percolation. Direct injection into boreholes or saline intrusion from subterranean sources may take effect more rapidly.

The time of sampling is also of main concern when the quality of the water shows more or less regular variations, for example, diurnal variations in the concentration of dissolved oxygen in rivers and variations of quality on start-up and shutdown of industrial plants.

It is seldom that the quality of water at only one instant is of interest. Normally, information is required for a period during which quality may vary. The problem arises, therefore, of deciding the time at which to collect samples, so that they will adequately represent the quality during the period of interest.

The best technical solution to this problem is often to use an automatic, on-line instrument that provides continuous analysis of the water of interest. This approach can be of great value in that, in principle, a continuous record of quality is obtained and the problems of selecting particular times for sampling do not arise.

Table 3. Nonspecific Water Quality Parameters

Physical	Chemical	Physiological
Filterable residues	Hardness	Taste
Salinity	Alkalinity and acidity	Odor
Density	BOD	Color
Electrical conductance	COD	Suspended solids
	Total carbon	Turbidity
	Chlorine demand	

Table 4. Tests Used for Measuring the Pollution of Natural Waters

Nutrient Demand	Specific Nutrients	Nuisance	Toxic
DO	Nitrogen	Sulfide	Cyanide
BOD	Ammonia	Sulfite	Heavy metals
COD	Nitrate	Oil and grease	Pesticides
Total carbon	Nitrite	Detergents	
	Organic nitrogen	Phenols	
	Phosphorus		
	Orthophosphate		
	Polyphosphate		
	Organic phosphorus		

MAJOR WATER QUALITY ISSUES

Water Scarcity

Due to uneven distribution of rainfall in time and space and ever-increasing demand of water for agricultural, industrial, and domestic activities, water resources are overexploited. This results in shrinking or even drying up of many waterbodies for a considerable period in a year.

Maintaining targeted water quality in such waterbodies is very difficult. If the objectives of the Water Act of 1974 are to be fulfilled, maintaining a minimum level of water needs to be specified, for example, restrictions on water abstraction from different waterbodies (rivers, lakes, or ground water). The Central Ground Water Authority (CGWA) formed under the Environment (Protection) Act of 1986 has already taken such initiatives. The restrictions need to be extended also to rivers and lakes.

Targets for conservation include reducing demands by optimum use, minimization of waste, efforts to reduce percolation and evaporation losses, conservation efforts in domestic uses, groundwater recharging, rainwater harvesting, afforestation, recycling, and reuse.

There are a number of cases where salinity is increasing in both surface water and groundwater. The increase in groundwater salinity is mainly due to increased irrigation or seawater intrusion in coastal areas. The salinity in surface water is increasing mainly due to discharges of industrial wastewater or agricultural return water. Salinity impairs the fitness of water for drinking or irrigation. It may also affect the ecosystem in surface waters.

Oxygen Depletion

A large portion of wastewater mostly from domestic sources is discharged into watercourses without any treatment. Such wastewater contains high amounts of organic matter. Industries also discharge effluents containing high levels of organic matter, for example, agro industries. When oxidized in water by microbes, this organic matter consumes dissolved oxygen. Water has limited availability of oxygen, and when consumption exceeds the availability, oxygen depletion results. Thus, the survival of aquatic life becomes difficult.

In many waterbodies, a massive input of organic matter sets off a progressive series of chemical and biological events in downstream water. The stretch is characterized by high bacterial population, cloudy appearance, high BOD, and strong disagreeable odor—all indicating general depletion of oxygen. Masses of gaseous sludge rising from the bottom are often noticed floating near the surface of the water. During the monsoon, the sludge deposited in such stretches is flushed and stays in suspension, causing a rise in oxygen uptake downstream. Due to such sudden oxygen depletion, heavy fish mortality occurs every year during the first flushing after the onset of the monsoon.

Pollution Due to Urbanization

Urbanization has encouraged people to migrate from villages to urban areas. This has given rise to a number of environmental problems, such as water supply and wastewater generation, collection, treatment, and disposal. In urban areas, water is tapped for domestic and industrial use from rivers, streams, wells, and lakes. Approximately 80% of the water supplied for domestic use passes out as wastewater. In most cases, wastewater is let out untreated, and either it percolates into the ground and in turn contaminates the groundwater or is discharged into the natural drainage system causing pollution in downstream areas.

Nonpoint Source Pollution

Nonpoint sources of water pollution have been recognized as of greater importance than point sources. This is due in part to the continuing efforts to reduce pollution from point sources over the past few decades, as well as recognition that nonpoint sources, such as stormwater, may contain harmful contaminants. Pesticides and nutrients, particularly, are of major concern because of high toxicity and eutrophication. This has increased the need to identify and quantify major sources of nutrients and pesticides deposited in river systems.

For proper understanding of the nature and the magnitude of diffuse water pollution under different circumstances, it is necessary to consider some source related characteristics, briefly discussed below, for diffuse pollution from some more common sources.

In rural areas, most people use open fields for defecation, a few use pit latrines or septic tanks. Much of the bathing and washing (clothes, utensils, etc.) is in or near the waterbody, reducing abstraction and transport of water but causing *in situ* diffuse pollution.

Eutrophication

The discharge of domestic wastewater, agricultural return water or runoff water, and many industrial effluents contributes nutrients such as phosphates and nitrates. These nutrients promote excess growth of algae in waterbodies. This is not desirable for a balanced aquatic ecosystem.

Salinity

Salinity is increasing in many waterbodies, especially groundwater, due to leaching of salt buildup in agricultural areas under intense irrigation. A number of industrial activities discharge wastewater with high dissolved solids that increase the salinity of water.

Due to the discharge of toxic effluents from many industries and increased use of chemicals in agriculture and their subsequent contribution to waterbodies, many waterbodies in the country are polluted by toxic substances. Toxic substances impair water quality and make it unfit for human consumption, aquatic life, and irrigation.

Natural Contaminants

By far the greatest water quality problem in developing countries is the prevalence of waterborne diseases. Yet, in addition to human induced pollution problems, water supplies also have specific natural quality problems, which are mainly related to local geology. Some of the specific problems of natural origin include fluoride and arsenic.

Pathogenic Pollution

Waterborne diseases are the most important water quality issues in India. This is mainly due to inadequate arrangements for transport and treatment of wastewaters. A major portion of the wastewater generated from human settlements is not properly transported and treated before discharge into natural waters. This results in contamination of both surface water and groundwater. Moreover, the contribution of pathogens from diffuse sources is also quite significant. Thus, most of the surface waterbodies and many groundwater sources are contaminated.

A large population in the country still uses water directly for drinking or contact use without any treatment and thus are exposed to waterborne diseases. This is the single major cause of mortality due to water pollution.

Ecological Health

A large number of areas in our aquatic environment support rare species and are ecologically sensitive. They need special protection. The Water Act of 1974 provides for maintaining and restoring the wholesomeness of aquatic resources, which is directly related to the ecological health of waterbodies, so it is important that the ecological health of waterbodies is given first priority in water quality goals.

GROUNDWATER QUALITY

In recent years, groundwater pollution due to human activity has become an increasing threat. The adverse effects on groundwater quality are the result of human activity on the ground, unintentionally from agriculture, domestic and industrial effluents, and unexpectedly from subsurface or surface disposal of sewage and industrial wastes.

A major problem in urbanized areas is the collection and disposal of domestic wastewater. Because a large volume of sewage is generated in a small area, the waste cannot be adequately disposed of by conventional septic tanks and cesspools. Therefore, special disposal sites may be required to collect and dispose of such wastes in densely populated areas.

The quality of groundwater is of great importance in determining the suitability of a particular groundwater for a certain use (public water supply, irrigation, industrial applications, power generation, etc.). The quality of groundwater is the result of all the processes and reactions that have acted on the water from the moment it condensed in the atmosphere to the time it is discharged by a well. Therefore, the quality of groundwater varies from place to place, with the depth of water table, and from season to season, and is primarily governed by the extent and composition of dissolved solids in it.

The wide range of contamination sources is one of the many factors contributing to the complexity of groundwater assessment. It is important to know the geochemistry of chemical–soil–groundwater interactions to assess the fate and impact of pollutants discharged onto the ground. Pollutants move through several different hydrologic zones as they migrate through the soil to the water table. The serious implications of this problem necessitate an integrated approach to undertake groundwater pollution monitoring and abatement programs.

The supply of groundwater is not unlimited, nor is it always available in good quality. In many cases, the abstraction of excessive quantities of groundwater has resulted in drying up of wells, saltwater intrusion, and drying up of rivers that receive their flows in dry seasons from groundwater. Groundwater quality is increasingly threatened by agricultural, urban, and industrial wastes, which leach or are injected into underlying aquifers. Once pollution has entered the subsurface environment, it may remain concealed for many years, becoming dispersed over wide areas, and rendering groundwater supplies unsuitable for human use.

A vast majority of groundwater quality problems are caused by contamination, overexploitation, or combination of the two. Most groundwater quality problems are difficult to detect and hard to resolve. The solutions are usually very expensive, time-consuming, and not always effective. Groundwater quality is slowly but surely declining everywhere. Groundwater pollution is intrinsically difficult to detect; it may well be concealed below the surface, and monitoring is costly, time-consuming, and somewhat hit-or-miss by nature.

Groundwater in several areas, where sewage is discharged without proper treatment, has been adversely affected by contaminants from sewage. Due to indiscriminate use of fertilizers, very high concentrations of potassium and nitrate have been found in groundwater at several places in the states of Punjab, Haryana, and Uttar Pradesh. Excessive concentrations of nitrate in groundwater that may originate from fertilizers or sewage, or both, have been reported to the extent of several hundred, mg/L in various parts of the country. Groundwater pollution from some industrial sources has reached alarming levels. High levels of hexavelant chromium at Ludhiana and Faridabad, lead near Khetri in Rajasthan, nickel in Coimbatore, and cadmium in Kanpur and parts of Delhi are some of the manifestations of heavy metal pollution. Arsenic concentrations in groundwater have been found in West Bengal in excess of the permissible limit of 0.05 mg/L. The population in these areas is suffering from arsenic dermatosis from drinking arsenic-rich groundwater.

The problem of groundwater pollution in several parts of the country has become so acute that unless urgent steps for detailed identification and abatement are taken, extensive groundwater resources may be damaged. All activities carried out on land have the potential to contaminate groundwater, whether from urban, industrial, or agricultural activities. Large-scale, concentrated sources of pollution, such as industrial discharges, landfills, and subsurface injection of chemicals and hazardous wastes, are obvious sources of groundwater pollution. These concentrated sources can be easily detected and regulated, but the more difficult problem is from diffuse sources of pollution, such as leaching of agrochemicals and animal wastes, subsurface discharges from latrines and septic tanks, and infiltration of polluted urban runoff and sewage where sewerage does not exist or is defunct. Diffuse sources can affect entire aquifers, which are difficult to control and treat. The only solution to diffuse sources of pollution is to integrate land use with water management. Table 5 presents land-use activities and their potential threat to groundwater quality.

Common Groundwater Contaminants

- *Nitrates*: Dissolved nitrate is the most common contaminant in groundwater. High levels can cause blue baby disease (methemoglobinemia) in children, may form carcinogens, and can accelerate eutrophication in surface waters. Sources of nitrates include sewage, fertilizers, air pollution, landfills, and industries.
- *Pathogens*: Bacteria and viruses that cause waterborne diseases such as typhoid, cholera, dysentery, polio, and hepatitis. Sources include sewage, landfills, septic tanks, and livestock.
- *Trace metals*: Include lead, mercury, cadmium, copper, chromium, and nickel. These metals can be toxic and carcinogenic. Sources include industrial and mine discharges and fly ash from thermal power plants due to either fallout or disposal in ash ponds.
- *Organic compounds*: Include volatile and semivolatile organic compounds such as petroleum derivatives, PCBs, and pesticides. Sources include agricultural activities, street drainage, sewage landfills, industrial discharges, spills, and vehicular emission fallout.

Table 5. Land-Use Activities and Their Potential Threat to Groundwater Quality

Land Use	Activities Potential to Groundwater Pollution
Residential	Unsewered sanitation
	Land and stream discharge of sewage
	Sewage oxidation ponds
	Sewer leakage, solid waste disposal, landfill
	Road and urban runoff, aerial fallout
Industrial and commercial	Process water, effluent lagoon
	Land and stream discharge of effluent
	Tank and pipeline leakage and accidental spills
	Well disposal of effluent
	Aerial fallout
	Landfill disposal and solid wastes and hazardous wastes
	Poor housekeeping
	Spillage and leakage during handling of material
Mining	Mine drainage discharge
	Process water, sludge lagoons
	Solid mine tailings
	Oilfield spillage at group gathering stations
Rural	Cultivation with agrochemicals
	Irrigation with wastewater
	Soil salinization
	Livestock rearing
Coastal areas	Saltwater intrusion

LEGAL CONSIDERATIONS

The basic objective of the Water (Prevention and Control Pollution) Act of 1974 is to maintain and restore the wholesomeness of national aquatic resources. Due to the large variation in type, size, shape, quality, and quantity of water available from our aquatic resources, each one has a very specific waste load receiving capacity. This implies the need for prescribing different effluent standards based on the assimilative capacity of recent systems. Notwithstanding its merits, it is difficult to administer compliance with widely varying standards for specific types of effluents. To reduce the administrative difficulties of relating effluent quality to ambient water quality, the concept of Minimum National Standards (MINAS) was developed by the Central Pollution Control Board, whereby minimum effluent limits are prescribed for each category of discharge, regardless of receiving water requirements. Where water quality standards cannot be reached by imposing a standard level of treatment alone, then and only then will the conditions of the receiving waters dictate more stringent controls (State Boards can make the MINAS more stringent). The conventional methods of treatment cannot cope with these specific situations, and the polluters are required to introduce new methods for specific requirements. The number of such situations in our country is gradually rising due to water scarcity in many waterbodies and some times due to the nature of effluents.

APPROACH TO WATER QUALITY MANAGEMENT

The Water (Prevention and Control of Pollution) Act of 1974 reflects the national concern for water quality management. The basic objective of the Act is to maintain and restore the wholesomeness of water through prevention and control of pollution. The Act does not define the level of wholesomeness to be maintained or restored in different waterbodies of the country. To define these levels for different waterbodies, the Central Pollution Control Board (CPCB) had initially taken the use of water as a basis for identifying water quality objectives for different waterbodies. Hence, it has classified the national aquatic resources according to their uses. CPCB has also identified primary water quality criteria for different uses of water as a yardstick for preparing different pollution control programs. The use-based classification system is given in Table 6.

The "designated best use" yardstick, as explained above, is based on a limited number of parameters called primary criteria. While implementing such criteria, there are many practical difficulties, which need scientific support. The criteria should be such that they can support the designated uses and also the ecological sustainability of the waterbody (wholesomeness), which is the prime objective of the Water Act of 1974. Hence, the CPCB, with the help of an expert group, has revised the approach.

Table 6. Use-Based Classification of Surface Waters in India

Designated Best Use	Quality Class	Primary Quality Criteria
Drinking water source without conventional treatment, but with chlorination	A	6.5 to 8.5 (1); 6 or more (2); 2 or less (3); 50.5–200%, and 20–50% (4); NIL (5–8)
Outdoor bathing (organized)	B	6.5 to 8.5 (1); 5 or more (2); 3 or less (3); 500, 5%-2000, and 20%-500 (4); NIL (5–8)
Drinking water source with conventional treatment	C	6.5 to 8.5 (1); 4 or more (2); 3 or less (3); 5000, 5%-20000, and 20%-5000 (4); NIL (5–8)

(4) Total coliform (MPN/100 mL).
(5) Free ammonia, mg/L.
(6) Electrical conductivity, μmho/cm.
(7) Sodium adsorption ratio.
(8) Boron, mg/L.

The Revised Approach

Human interests cannot be ignored or downgraded in importance, but it is now widely accepted that the long-term interests of human beings themselves lie in maintaining the environment and ecosystems in an overall healthy condition. A system totally oriented to the objective of protecting direct beneficial uses by humans and of classifying water quality on that basis may not be adequate. In many cases (such as for small waterbodies or those with no significant current water use), the objective may have to be the protection of basic environmental qualities for sustaining ecosystems. Even where current or potential beneficial uses can be clearly defined and a "designated best-use," the first priority in water quality assessment and management would be maintaining and restoring the desirable level of general environmental quality or "wholesomeness." With this approach, protection of designated best use is not being abandoned, but the overall health of ecology is given its rightful place, ahead of any direct current beneficial uses by humans. Such ecological considerations shall ensure the biological integrity of a waterbody, including structural as well as functional integrity.

For effective management of water quality, it is necessary to involve local administrative bodies at the district, block, municipal, and village panchayat levels, NGOs, and the citizens themselves in conducting at least a crude, rapid, and overall assessment of water quality.

Water quality requirements for specific large-scale organized uses may continue to be prescribed and even strengthened, but the stakeholders could share responsibility for water quality monitoring and management in such cases. It would lead to a two-pronged approach; defining water-quality requirements and classification with the objective of (1) maintaining and restoring wholesomeness of water for the health of ecosystems and the environment in general (basic water quality requirement) and (2) protecting designated organized uses of water by humans and expecting stakeholders to share responsibility in monitoring and managing such quality by associating with them local administrations, NGOs, and citizens in monitoring and managing the desired quality to the extent possible.

All waterbodies whose existing water quality is below acceptable levels should be identified on a priority basis to take remedial measures to restore their quality to acceptable levels within a stipulated period.

For waterbodies whose water is of acceptable quality, but below desirable quality, the limits of the relevant parameters should be identified and a quality restoration program should be implemented within a reasonable period.

WATER QUALITY MANAGEMENT AND NONPOINT SOURCE CONTROL

Harry X. Zhang
Parsons Corporation
Fairfax, Virginia

INTRODUCTION OF NONPOINT SOURCE CONTROL

Nonpoint source (NPS) pollution, unlike pollution from industrial and sewage treatment plants, comes from many diffuse sources. NPS pollution is caused by rainfall or snowmelt moving over and through the ground. As the runoff moves, it picks up and carries away natural and human-made pollutants, finally depositing them into lakes, rivers, wetlands, coastal waters, and even our underground sources of drinking water.

The United States has made tremendous advances in the past 25 years to clean up the aquatic environment by controlling pollution from industries and sewage treatment plants. Despite those successes, approximately 39% of assessed rivers and streams and 39% of assessed lakes are not safe for fish consumption, and 37% of its surveyed estuarine area is not safe for basic uses such as swimming or fishing. The estimates for nonattainment of swimming in surveyed rivers and lakes were 32% and 30%. Today, nonpoint source pollution is the leading remaining cause of water quality problems. It is the main reason that approximately 40% of our surveyed rivers, lakes, and estuaries are not clean enough for basic uses such as fishing or swimming (1,2).

Nonpoint source pollutants include (1) excess fertilizers, herbicides, and insecticides from agricultural lands and residential areas; (2) oil, grease, and toxic chemicals from urban runoff and energy production; (3) sediment from improperly managed construction sites, crop and forest lands, and eroding stream banks; (4) salt from irrigation practices and acid drainage from abandoned mines; (5) bacteria and nutrients from livestock, pet wastes, and faulty septic systems; and (6) atmospheric deposition and hydromodification (3). NPS pollution is widespread because it can occur any time activities disturb the land or water. Agriculture, forestry, grazing, septic systems, recreational boating, urban runoff, construction, physical changes to stream channels, and habitat degradation are potential sources of NPS pollution. Careless or uninformed household management also contributes to NPS pollution problems. The most common NPS pollutants are sediment and nutrients. These wash into waterbodies from agricultural land, small and medium-sized animal feeding operations, construction sites, and other areas of disturbance.

EXISTING REGULATIONS RELATED TO NONPOINT SOURCE CONTROL

During the last 10 years, the United States has made significant progress in addressing NPS pollution. At the federal level, recent NPS control programs include the Nonpoint Source Management Program established under Section 319 of the 1987 Clean Water Act (CWA) Amendments, and the Coastal Nonpoint Pollution Program established by the 1990 Coastal Zone Act Reauthorization Amendments (CZARA).

The most prominent of these was the Nonpoint Source Management Program set up by the 1987 amendments (4). Under this program, states were to identify waterways that would not be expected to meet ambient standards because of nonpoint sources. For these areas, states were to develop NPS programs that identified best management practices for the categories of nonpoint sources involved. Because EPA had little or no authority to regulate many nonpoint sources, it relied upon state and local governments to implement controls. The program provides grants to states, territories, and tribes to implement NPS pollution controls described in approved NPS pollution management programs. In the 1987 amendments to the Clean Water Act, toxic waste and pollution from NPS received more attention than they had previously, and stormwater discharges from urban areas and industrial facilities were included in the NPDES permit program.

Under Section 303(d) of the 1972 Clean Water Act, states, territories, and authorized tribes are required to develop lists of impaired waters. The law requires that these jurisdictions establish priority rankings for waters on the lists and develop total maximum daily loads (TMDLs) for these waters. In 1991, EPA issued the Guidance for Water Quality-Based Decisions: The TMDL Process (5). In 1992, the EPA clarified the goals of the Nonpoint Source Management Program and moved toward a watershed protection approach, which tailors NPS pollution control strategies to fit conditions in particular watersheds and gives state and local governments flexibility. In addition to engineering controls on nonpoint source pollution, management strategies might include outreach and education programs as well as government action to change land use patterns and activities that contribute to NPS pollution.

The 1987 amendments also created the National Estuary Program (NEP), which provides a basis for managing NPS pollution. The NEP relied on existing statutory authority at the state and municipal levels to accomplish program goals. Each National Estuary Program is charged to create and implement a Comprehensive Conservation and Management Plan (CCMP) that addresses all aspects of environmental protection for the estuary, including issues such as water quality, habitat, living resources, and land use.

Another regulation on nonpoint source pollution is the Coastal Zone Act Reauthorization Amendments Section 6217, which addresses coastal NPS pollution problems in coastal waters. This program is administered jointly with the National Oceanic and Atmospheric Administration (NOAA). In its program, a state or territory describes how it will implement nonpoint source pollution controls, known as management measures, that conform with those described in Guidance Specifying Management Measures for Sources of Nonpoint Pollution in Coastal Waters (6). The plans must also specify abatement measures that are “economically achievable” and yet “reflect the greatest degree of pollutant reduction achievable by applying the best available nonpoint source control practices, technologies, processes, siting criteria, operating methods, or other alternatives.

RELATED FEDERAL PROGRAMS FOR NONPOINT SOURCE CONTROL

There are several federal programs available to address nonpoint source control.

U.S. Environmental Protection Agency (EPA)

The EPA administers Section 319 of the Clean Water Act, also known as the Nonpoint Source Management Program. Under Section 319, states, territories, and tribes apply for and receive grants from the EPA to implement NPS pollution controls. The EPA administers other sections of the CWA to help states, territories, and tribes plan for and implement water pollution control programs, which can include measures for NPS control. These include Section 104(b)(3), Water Quality Cooperative Agreements; Section 104(g), Small Community Outreach; Section 106, Grants for Pollution Control Programs; Section 314, Clean Lakes Program; Section 320, National Estuary Program; and Section 604(b), Water Quality Management Planning. Together with the NOAA, EPA helps administer Section 6217 of the 1990 Coastal Zone Act Reauthorization Amendments, a program that tackles nonpoint source pollution affecting coastal waters (7).

National Oceanic and Atmospheric Administration (NOAA)

NOAA administers Section 306 of the Coastal Zone Management Act that provides funds for water pollution control projects, including NPS management activities, in states that have coastal zones. Together with the EPA, NOAA also helps administer Section 6217 of the CZARA.

U.S. Department of Agriculture (USDA)

The USDA administers incentive-based conservation programs through the Consolidated Farm Services Agency, the Natural Resources Conservation Service (NRCS), and the U.S. Forest Service to help control NPS pollution from agriculture and forestry.

U.S. Department of Transportation (DOT)/Federal Highway Administration (FHWA)

Under the Intermodal Surface Transportation Efficiency Act of 1991, the Federal Highway Administration developed erosion control guidelines for federally funded construction projects on roads, highways, and bridges.

U.S. Department of the Interior (DOI)

Within the U.S. Department of the Interior, the Bureau of Reclamation (BLR), the Bureau of Land Management (BLM), and the Fish and Wildlife Service (FWS) administer several programs to help states manage NPS pollution by providing technical assistance and financial support.

NONPOINT SOURCE CONTROL BY SOURCE CATEGORIES

NPS Pollution from Agriculture

The latest National Water Quality Inventory indicates that agriculture is the leading contributor to water quality impairments; it degraded 60% of the impaired river miles and half of the impaired lake acreage surveyed by states, territories, and tribes (1). Agricultural activities that cause NPS pollution include confined animal facilities, grazing, plowing, pesticide spraying, irrigation, fertilizing, planting, and harvesting. The major agricultural NPS pollutants that result from these activities are sediment, nutrients, pathogens, pesticides, and salts. Agricultural activities can also damage habitat and stream channels. Agricultural impacts on surface water and groundwater can be minimized by properly managing activities that can cause NPS pollution.

Managing Sedimentation. Excessive sedimentation clouds water, which reduces the amount of sunlight reaching aquatic plants; covers fish-spawning areas and food supplies; and clogs the gills of fish. In addition, other pollutants such as phosphorus, pathogens, and heavy metals are often attached to soil particles and wind up in the waterbodies with the sediment. Farmers and ranchers can reduce erosion and sedimentation by 20–90% by applying management measures to control the volume and flow rate of runoff water, keep the soil in place, and reduce soil transport.

Managing Nutrients. When nutrients such as phosphorus, nitrogen, and potassium in the form of fertilizers or manure are applied in excess of plant needs, they can wash into aquatic ecosystems where they can cause excessive plant growth, which reduces swimming and boating opportunities, creates a foul taste and odor in drinking water, and kills fish. In drinking water, high concentrations of nitrate can cause methemoglobinemia, a potentially fatal disease in infants also known as blue baby syndrome. Farmers can implement nutrient management plans that help maintain high yields and save money on the use of fertilizers while reducing NPS pollution.

Managing Confined Animal Facilities and Livestock Grazing. Confined animal and livestock areas are major sources of animal waste. Runoff from poorly managed facilities can carry pathogens (bacteria and viruses), nutrients, and oxygen-demanding substances that contaminate shellfishing areas and cause other major water quality problems. Groundwater can also be contaminated by seepage. Discharges can be limited by storing and managing facility wastewater and runoff using an appropriate waste management system.

Overgrazing exposes soils, increases erosion, encourages invasion by undesirable plants, destroys fish habitat, and reduces the filtration of sediment necessary for building streambanks, wet meadows, and floodplains. To reduce the impacts of grazing on water quality, farmers and ranchers can adjust grazing intensity, keep livestock out of sensitive areas, provide alternative sources of water and shade, and revegetate rangeland and pastureland.

Managing Irrigation. Irrigation water is applied to supplement natural precipitation or to protect crops from freezing or wilting. Inefficient irrigation can cause water quality problems. In arid areas, for example, where rainwater does not carry residues deep into the soil, excessive irrigation can concentrate pesticides, nutrients, disease-carrying microorganisms, and salts—all of which impact water quality—in the top layer of soil. Farmers can reduce NPS pollution from irrigation by increasing water use efficiency.

Managing Pesticides. Pesticides, herbicides, and fungicides are used to kill pests and control the growth of weeds and fungus. These chemicals can enter and contaminate water through direct application, runoff, wind transport, and atmospheric deposition. To reduce NPS contamination from pesticides, people can apply integrated pest management (IPM) techniques based on the specific soils, climate, pest history, and crop for a particular field.

NPS Pollution from Urban Runoff

The most recent National Water Quality Inventory reports that runoff from urban areas is the leading source of impairments to surveyed estuaries and the third largest source of water quality impairments to surveyed lakes. Runoff from rapidly growing urban areas will continue to degrade coastal waters.

Increased Runoff. Nonporous urban landscapes such as roads, bridges, parking lots, and buildings do not let runoff slowly percolate into the ground. Receiving waters are often adversely affected by urban runoff due to alterations in hydraulic characteristics of streams receiving runoff such as higher peak flow rates, increased frequency and duration of high flows and possible downstream flooding, and reduced baseflow levels.

Increased Pollutant Loads. Urbanization also increases the variety and amount of pollutants transported to receiving waters. Sediment from development and new construction; oil, grease, and toxic chemicals from automobiles; nutrients and pesticides from turf management and gardening; viruses and bacteria from failing septic systems; road salts; and heavy metals are examples of pollutants generated in urban areas (8). Sediments and solids constitute the largest volume of pollutant loads to receiving waters in urban areas.

Measures to Manage Urban Runoff

To protect surface water and groundwater quality, urban development and household activities must be guided by plans that limit runoff and reduce pollutant loadings.

Managing Urban Runoff from New Development. New developments should attempt to maintain the volume of runoff at predevelopment levels by using structural BMP controls and pollution prevention strategies. Plans for managing runoff, sediment, toxics, and nutrients can establish guidelines to help achieve both goals. Management plans are designed to protect sensitive ecological areas, minimize land disturbances, and retain natural drainage and vegetation.

Managing Urban Runoff from Existing Development. Existing urban areas can target their urban runoff control projects to make them more economical. Runoff management plans for existing areas can first identify priority pollutant reduction opportunities, then protect natural areas that help control runoff, and finally begin ecological restoration and retrofit activities to clean up degraded waterbodies.

Managing Runoff for On-Site Disposal Systems. The control of nutrient and pathogen loadings to surface waters can begin with the proper design, installation, and operation of on-site disposal systems. These septic systems should be situated away from open waters and sensitive resources such as wetlands and floodplains and should also be inspected, pumped out, and repaired at regular time intervals.

NPS Pollution from Forestry

Sources of NPS pollution from forestry activities include removal of streamside vegetation, road construction and use, timber harvesting, and mechanical preparation for planting trees. Road construction and road use are the primary sources of NPS pollution on forested lands; they contribute up to 90% of the total sediment from forestry operations. Harvesting trees in the area beside a stream can affect water quality by reducing the streambank shading that regulates water temperature and by removing vegetation that stabilizes the streambanks. These changes can harm aquatic life by limiting sources of food, shade, and shelter (7).

Establishing Streamside Management Areas. Plans for buffer strips or riparian zones often restrict forestry activities in vegetated areas near streams, thereby establishing special Streamside Management Areas (SMAs). Vegetation in the SMA stabilizes streambanks, reduces runoff and nutrient levels in runoff, and traps sediment generated from upslope activities before it reaches surface waters. SMA vegetation moderates water temperature by shading surface water and provides habitat for aquatic life.

Managing Road Construction and Maintenance. Good road location and design can greatly reduce the transport of sediment to waterbodies. Roads should follow the natural contours of the land and be located away from steep gradients, landslide-prone areas, and areas of poor drainage. Proper road maintenance and closure of unneeded roads can help reduce NPS impacts from erosion over the long term.

Managing Timber Harvesting. Most detrimental effects of harvesting are related to access and movement of vehicles and machinery and dragging and loading trees or logs. These effects include soil disturbance, soil compaction, and direct disturbance of stream channels. Poor harvesting and transport techniques can increase sediment production ten to twenty times and disturb as much as 40% of the soil surface.

Other NPS sources include those induced by hydromodification/habitat alteration, marinas/boating, and roads/highways/bridges, which will not be discussed in detail here.

EMPLOYING BEST MANAGEMENT PRACTICES

Public and private groups have developed and used pollution prevention and pollution reduction initiatives and NPS pollution controls, known as management measures, to clean up our water efficiently. The use of best management practices (BMPs) in addressing runoff problems was frequently identified as a NPS control measure, although additional research and field studies on the performance of BMPs were also needed. A wide variety of BMPs, both structural and nonstructural, are available to address urban storm water runoff and discharges (9–12). In summary, many BMPs are used primarily for water quantity control (i.e., to prevent flooding), although they may provide ancillary water quality benefits. Some BMP types have been analyzed for performance in terms of site-specific pollutant removal, but not extensively enough to allow for generalizations. It is still difficult to develop comparisons of cost-effectiveness for various BMP types. Other BMP types, particularly nonstructural and those that do not have discrete inflow or outflow points, are difficult to monitor. In addition, only limited cost studies have been conducted for stormwater BMPs. Therefore, the pollutant removal performance of certain BMP types is essentially undocumented. The role of chemical pollutant monitoring versus receiving stream biological monitoring in evaluating BMP performance on a watershed scale is not well documented or needs further research.

One particular new design that is becoming popular and is widely used in recent years is low impact development (LID). LID is an innovative stormwater management approach using a basic principle that is modeled after nature; managing rainfall at the source using uniformly distributed decentralized microscale controls. Its goal is to mimic a site's predevelopment hydrology by using design techniques that infiltrate, filter, store, evaporate, and detain runoff close to its source (13). Another important concept in controlling urban NPS pollution is smart growth. Although it recognizes the many benefits of growth, smart growth practice invests time, attention, and resources in restoring community and vitality to existing cities and older suburbs. The purposes of smart growth and low impact development practices are to promote a number of practices that can lessen the environmental impacts of development, to preserve ecosystem functions as well as specific critical areas, and to design developments to maintain predevelopment conditions (14).

WATER QUALITY MANAGEMENT AND TMDL PROGRAMS

Water quality management has become increasingly more complicated. Problems such as toxic contaminants, sediments, nutrients, and habitat alteration result from a variety of point and nonpoint sources. The Water Quality Planning and Management Regulation (40 CFR 130) links a number of Clean Water Act sections, including Section 303(d), to form the water quality approach to protecting and cleaning up the nation's waters. Previous practices for implementing 303(d) have focused primarily on point sources and wasteload allocations (WLA). In recent years, nonpoint source contributions to water quality problems have become better understood, and it is now clear that EPA and state implementation of 303(d) must encompass nonpoint source pollution problems and seek to address problems occurring over large geographic areas (5).

The water quality approach emphasizes the overall quality of water within a waterbody and provides a mechanism through which the amount of pollution entering a waterbody is controlled by the intrinsic conditions of that body of water and the standards set to protect it. Section 303(d) of the Clean Water Act addresses those impaired waters that are not "fishable, swimmable" by requiring states to identify the waters and to develop a total maximum daily load (TMDL). EPA's regulations establish a TMDL as the sum of point source load allocation (WLA) plus nonpoint source allocation (LA) plus a margin of safety (MOS). TMDLs can be expressed in terms of either mass per time, toxicity, or other appropriate measures that relate to a state's water quality standard. If BMPs or other nonpoint source pollution control actions make more stringent load allocations practicable, then WLAs can be made less stringent. Thus, the TMDL process provides for nonpoint source control trade-offs.

The TMDL process is viewed as an effective approach to watershed protection and a water quality management tool for both point and nonpoint source pollution control on a watershed scale. A watershed protection approach is a strategy for effectively protecting and restoring aquatic ecosystems and protecting human health. This strategy has as its premise that many water quality and ecosystem problems are best solved at the watershed level rather than at the individual waterbody or discharger level (15). The current regulations that address water quality problems have tended to focus on particular sources, pollutants, or water uses and have not resulted in an integrated environmental management approach. Consequently, significant gaps exist in our efforts to protect watersheds from the cumulative impacts of a multitude of activities. Existing water pollution prevention and control programs are, however, excellent foundations on which to build a watershed approach. Increasingly, state and tribal water resource professionals are turning to watershed management to achieve greater results from their programs. Major features of a watershed protection approach include targeting priority problems, promoting a high level of stakeholder involvement, integrated solutions that use the expertise and authority of multiple agencies, and measuring success through monitoring and other data gathering.

TMDL IMPLEMENTATION AND NPS CONTROL

NPDES permits are usually sought for point sources, but nonpoint source controls may be established by implementing BMPs, so that surface water quality objectives are met. These controls should be based on load allocations developed by using the TMDL process. When establishing permits for point sources on the watershed scale, the record should show that in the case of any credit for future nonpoint source reductions, there is reasonable assurance that nonpoint source controls will be implemented and maintained or that nonpoint source reductions are demonstrated through an effective monitoring program.

However, it is difficult to ensure, *a priori*, that implementing nonpoint source controls will achieve expected load reductions. Nonpoint source control measures may fail to achieve projected pollution or chemical load reductions due to inadequate selection of BMPs, inadequate design or implementation, or lack of full participation by all contributing sources of nonpoint pollution. States should describe nonpoint source load reductions and establish a procedure for reviewing and revising BMPs in TMDL documentation. The TMDL implementation plan must contain a description of best management practices or other management measures. The implementation plan may deal with sources on a watershed basis, as long as the scale of the implementation plan is consistent with the geographic scale for which the TMDL pollutant load allocations are established. This makes water quality monitoring an important component during TMDL implementation.

The achievement of nonpoint source load reductions is a complex challenge. The variability in nonpoint source loadings due to hydrologic variability can often make it difficult to discern short-term trends. Therefore, achievement of water quality standards is tracked using selected long-term milestones and measures. Tracking the implementation of management actions over time will provide valuable information. The tracking of implementation will assist in determining the success of the load allocation, the adequacy of funding and resources, the potential for water quality improvement, and the need for corrective actions. For areas that have predominantly nonpoint source controls, the use of tracking information can support demonstration of progress in the absence of clear benefit through water quality monitoring (16).

SUMMARY AND CONCLUSION

Today, nonpoint source pollution remains the largest source of water quality problems in the United States. It is the main reason that approximately 40% of our surveyed rivers, lakes, and estuaries are not clean enough for basic uses such as fishing or swimming (1,17). This remaining problem impacting water quality is not easily remedied because NPS pollution comes from pipes and also from diffuse sources such as agricultural and forestry operations, urban areas, and construction sites.

Best management practices or other innovative management measures such as low impact development are frequently identified to address the NPS problem. However, additional research and field studies on the long-term performance of BMPs, especially on the watershed scale, are much needed.

The past decade has seen a shift toward an emphasis from "end-of-pipe" treatment for point source pollution to the watershed approach, which encourages a holistic take on identifying problems and implementing the integrated solutions that are needed to overcome multiple causes of water quality impairment, including NPS. In addition to the watershed approach, the water quality based TMDL program has evolved as an effective tool for addressing more complicated water quality problems (e.g., for waters that remain polluted after the application of technology-based standards). TMDL implementation and NPS control on a watershed basis are two interconnected components for successful water quality management.

WATER QUALITY MANAGEMENT IN AN URBAN LANDSCAPE

Russell N. Clayshulte
Aurora, Colorado

Urban landscape broadly defines a built environment influenced by different combinations of land uses. Residential and commercial development, industrial areas, parks, open space, and roadways are examples of urban land uses. The construction of wastewater, water, and stormwater pipelines, and power lines, generally called utility infrastructure, also change the natural environment and help shape the urban landscape. Land use patterns strongly influence surface water quality and to a lesser extent groundwater. Land use choices are interactive parts of water quality management, restoration, or enhancement programs. Urban land use decisions must consider water quality management strategies and goals. Conversely, water quality must be considered in zoning and plotting processes used by local governments. A goal in shaping urban areas is to produce a sustainable urban landscape that incorporates reasonable and effective water quality strategies to restore, protect, or enhance the urban environment.

Scale affects how water quality is managed and often who is responsible for this management. Water quality management targets overall health and the quality of water and environmental resources. Management also provides direction in fixing specific water quality problems in targeted waterbodies. Consequently, water quality management in urban settings occurs on two basic levels. Macroscale landscapes include all combined urban land uses for a single city or a combination of cities and towns. Water quality management on the macroscale is often linked to watershed restoration or protection efforts. Microscale landscapes can include smaller urban watersheds, drainages, or other limited geographic areas where site-specific water quality management is necessary to control targeted urban-caused pollution. Macroscale watersheds are often measured in square miles (square kilometers); microscale landscapes are identified in acres (hectares).

Water quality management programs in urban landscapes are divided into three general source categories: point sources, nonpoint sources, and stormwater runoff. Point sources are discrete discharges that go from a pipe source (e.g., wastewater treatment plant discharge) back into the environment. Point sources can be permitted to meet very specific discharge limits under local, state, and federal regulations. Nonpoint sources are a type of diffuse pollution without a single point of origin or not introduced into the environment from a single pipe. Common nonpoint sources are agriculture, forestry, urban, mining, construction, hydromodification (e.g., dams, channels, and ditches), land disposal, and saltwater intrusion. Stormwater runoff is a type of nonpoint source runoff usually associated with urban landscapes, which is subject to permitting requirements for medium and large cities. Stormwater and other nonpoint sources in urban landscapes are collectively called urban runoff.

Urban runoff can flow across residential and urban streets, roofs, lawns, open space, hard (impervious) surfaces, and other areas. Urban runoff occurs under both wet and dry weather conditions. Dry-weather runoff from irrigation and leaky pipes contributes various amounts of polluted runoff. Urban runoff carries many different types of chemicals, sediments, debris, and pathogens. An excessive amount of urban pollution impairs water quality in wetlands, streams, rivers, lakes, reservoirs, or groundwater (receiving waters). Construction or other development activities introduce large amounts of sediments and other pollutants into receiving waters. Sediment and solids contribute the largest volume of pollutant load to urban receiving waters. Increased loads can harm fish and wildlife populations, kill native vegetation, reduce or limit recreational uses, and contaminate drinking water.

The terms pollution and pollutants are different. This difference is very important from a regulatory perspective. The 1972 federal Clean Water Act (Public Law 92-500) defines the term "pollution" to mean the "man-made or man-induced alteration of the chemical, physical, biological, and radiological integrity of water." Generally, pollution is the presence of a substance in the environment that because of its chemical composition or quantity prevents the functioning of natural processes and produces undesirable environmental and/or health effects. The act defines the term "pollutant" to mean any substance introduced into the environment that adversely affects the usefulness of a resource or the health of humans, animals, or ecosystems. Common types of pollutants include dredged spoil, solid waste, incinerator residue, sewage, garbage, sewage sludge, munitions, chemical wastes, biological materials, radioactive materials, heat, wrecked or discarded equipment, rock, sand, cellar dirt, and industrial, municipal, and agricultural waste discharged into water. Specific pollutants can be targeted and regulated through a number of local, state, and federal processes. Harmful impacts from pollutants and pollution are often linked to risk studies with measurable impact levels.

Pollution management in urban landscapes is a relatively new requirement for cities and towns. Water quality management, as a national or even global problem, became a higher priority public concern in the late 1940s. The first legislation to control water pollution was the Water Pollution Control Act of 1948 (Public Law 845, 80th Congress). In 1972, the United States Congress enacted the first comprehensive national clean water legislation in response to growing public concern for serious and widespread water pollution. The federal Clean Water Act (Public Law 92-500; as amended in 1977, Public Law 95–217 and as amended in 1987, Public Law 100-4) is the primary federal law in the United States that protects national waters, including wetlands, lakes, rivers, aquifers, and coastal areas. The goal of the federal Clean Water Act is to make waters of the United States "fishable and swimmable, where applicable." Meeting the goals of the act requires an extensive and integrated approach to water pollution abatement.

Federal regulations require all states to maintain, improve, and in some cases restore the quality of their water resources. This federal law significantly altered water resource management in urban settings. Federal regulations provide a clear path to clean water and an effective national water program. In 1972, only a third of U.S. waters were safe for fishing and swimming. Wetlands losses were estimated in excess of 460,000 acres annually with an alarming loss of urban wetlands. The United States Environmental Protection Agency reported almost 100% wetland loss for many larger cities. Agricultural and construction runoff caused erosion of over 2.25 billion tons of soil per year. The deposition of large amounts of phosphorus and nitrogen, referred to as nutrients, into receiving waters was attributed, in a large part, to urban centers. This nutrient enrichment caused many ponds, lakes, and reservoirs to experience excessive algal growth, resulting lost fisheries, and water supply contamination. Sewage treatment plants or point sources served about 85 million people. A large amount of human wastes were flowing into receiving waters with little or no treatment.

Water quality in the United States was characterized in a 1998 report to the American Congress as part of a

Table 1. Leading Sources of Water Quality Impairment Related to Urban Landscapes for Rivers, Lakes, and Estuaries[a]

	Rivers and Streams	Lakes, Ponds, Rivers	Estuaries
Pollutants	Siltation (38%)[b]	Nutrients (44%)	Pathogens (47%)
	Pathogens (36%)	Metals (27%)	Organic enrichment (42%)
	Nutrients (28%)	Siltation (15%)	Metals (27%)
Sources[c]	Hydromodification (20%)	Hydromodification (20%)	Municipal point sources (28%)
	Urban runoff/storm sewers (12%)	Urban runoff/storm sewers (12%)	Atmospheric deposition (23%)
			Urban runoff/storm sewers (23%)

[b] Values in parentheses represent the percentage of surveyed river miles, lake acres, or estuary square miles that are classified as impaired.

[c] Excluding unknown, natural, and "other" sources.

national water quality inventory (1). Table 1 lists leading sources of water quality impairment in urban areas. This report showed that about 40% of receiving waters still did not meet the fishing and swimming goals of the federal Clean Water Act. In fact more than 291,000 miles of assessed rivers and streams did not meet state adopted water quality standards. Sediment and siltation is one of the most common pollutants from urban development and construction. Other major pollutants are pathogens, nutrients, and metals. Runoff from agricultural lands and urban areas is a major source of these pollutants. Across all types of waterbodies, states, territories, tribes, and other jurisdictions have shown that poor water quality affects drinking water, aquatic life, fish consumption, swimming, and other recreational uses.

However, the national water quality picture has improved since the passage of the Clean Water Act. By 2001, two-thirds of the nation's waters were safe for fishing and swimming. The rate of annual wetlands losses is reduced to about 70,000–90,000 acres. The amount of soil lost due to agricultural runoff and urban construction activities has been cut by over 1 billion tons annually. Phosphorus and nitrogen levels in receiving waters are lower. Modern wastewater treatment facilities serve over 173 million people. Aggressive water quality management programs in urban areas have helped make these differences.

States adopt use classifications and numerical water quality standards for receiving waters in urban watersheds. Within urban watersheds, waters are divided into individual stream segments for classification and standard setting. Site-specific water quality classifications are used to protect any existing or intended use of the target water. Typical use classification categories include recreation, agriculture, aquatic life, domestic water supply, or wetlands. These use classification categories are referred to as "beneficial uses." Beneficial use classification types vary from state to state and, in some cases, even within a state. A water quality standard consists of four basic elements: (1) *designated uses* of the water body (e.g., recreation, water supply, aquatic life, agriculture), (2) *water quality criteria* to protect designated uses (numerical pollutant concentrations and narrative requirements), (3) an *antidegradation policy* to maintain and protect existing uses and high quality waters, and (4) *general policies* addressing implementation issues (e.g., low flows, variances, mixing zones).

Regulatory and enforcement programs provide the basic framework for water quality management in an urban environment. These programs generally reside at the state level. Although the federal Clean Water Act and other federal laws provide guidance for regulatory programs, states have the flexibility to establish programs to fit conditions within the state. Often standards and classifications of surface and groundwater drive management options. Urban watershed efforts ensure that waters within an urban landscape meet underlying standards and beneficial uses. Enforcement actions and lawsuits that target the amount of allowable pollutant load discharged into receiving waters (wasteload litigation) have triggered more water quality management programs in urban centers.

An urban watershed protection approach is an integrated, holistic strategy to protect or attain the desired beneficial uses of waters within an urban area. The approach is more effective than isolated efforts under existing programs that do not consider the watershed as a whole. Nonpoint source or stormwater runoff control on a watershed level can have a significant impact on the protection of beneficial uses. A watershed protection approach addresses point source discharges along with nonpoint source and stormwater pollutant loads. An urban watershed approach also considers other human activities that may affect the uses and quality of water resources.

Development patterns change the natural landscape and replace it with hard or impervious surfaces (i.e., concrete, asphalt, or hard-packed dirt), which in turn change the hydrologic or flow patterns from surfaces and into receiving waters. Urbanization causes increased stormwater runoff, which is more intense, has a higher volume, and has less residual runoff than natural runoff conditions. A typical city block characterized by pavement and rooftops generates over nine times more runoff than a woodland area of equal size. Less water gets into underlying groundwater and more water enters receiving waters as runoff flow. Aquifers under urban areas are called "starved" because water recharge is minimized. Natural runoff from an area without any kind of disturbance is called background or sometimes baseflow. Urbanization that alters runoff patterns can decrease baseflow and increase runoff flow. In most urban landscapes, lawn irrigation or other forms of dry-weather discharge can greatly increase runoff flow.

Urban hydrologic changes or major features like roads and parking lots cause many types of water quality problems such as nutrient enrichment, chemical pollutants, turbidity or sedimentation, biological pathogen introduction, toxic conditions, or increased temperature. Transportation systems have the highest pollutant concentrations compared with other urban land uses. Common types of transportation-related pollutants include gasoline, exhaust, motor oil and grease, antifreeze, undercoating, brake linings, rubber, asphalt, concrete, and diesel fuel. Landscaping in urban areas can contribute large amounts of nutrients from fertilizer application and pesticide or herbicide residues. Grass clippings and leaves in stormwater systems are oxygen-demanding substances, which can cause low oxygen conditions in receiving waters and stress aquatic life.

Widespread water quality data from urban areas across the country show that water quality problems are directly caused by increased watershed imperviousness. Ecological stress becomes apparent in an urban watershed when the amount of impervious cover reaches 10–20%. Typically, residential areas have impervious cover ranging from 25% to 60%; commercial areas can reach 100%. Increased pollutant loading is directly linked to the amount of impervious surface. Urban landscapes with greater than 50% impervious surface have highly stressed ecosystems. Low impact development is a new urban management concept designed to reduce the amount of impervious surface and promote more natural runoff patterns and processes.

Changes in flow regimes also cause increased frequency of flooding and peak flow volumes in receiving waters. These floods cause loss of aquatic or riparian habitat and changes in stream physical characteristics (channel width and depth). Stormwater management requires urban areas to develop stormwater drainage systems to avoid flood damage. These systems accumulate runoff from storms and send these flows away from the urban area. Flood control structures and modifications to natural drainage systems decrease natural stormwater purification functions. Runoff quality has not been well addressed in the design criteria of flood control structures. In some cases, stormwater systems are used as a convenient method of waste disposal.

Water quality monitoring for urban runoff facilitates the critical element of relating the physical, chemical, and biological characteristics of receiving waters to land use characteristics. Without current information on water quality and pollutant sources, the effects of land-based activities on water quality cannot be fully assessed, effective management and remediation programs cannot be implemented, and program success cannot be evaluated. Monitoring programs in the past have been the responsibility of state and federal agencies; recent local watershed management has shifted monitoring to the watershed or microscale environment. Some common types of water and environmental quality indicator parameters monitored in urban landscapes are shown in Table 2.

Not all urban runoff is polluted. The severity of the water quality problem in receiving water is directly related to the beneficial uses assigned to the waterbody by the regulating agency. Urban runoff quality is assessed against established standards and classifications. Many stream segments in urban areas have site-specific water quality standards and classifications. Consequently, streams or rivers flowing through urban centers with multiple segments can have differing sets of standards and classifications. Water quality parameters identified as pollutants in one segment may not be pollutants in the next contiguous downstream segment. This factor makes pollutant characterization, management, and control very difficult in urban areas.

There are many implementation methods or tools used in watershed planning and management. The method used for a specific watershed program depends on the problem and available resources. Best management practices (BMPs) are water quality management tools. BMPs used in urban water quality programs fall into two categories: (1) erosion control that prevents discharge

Table 2. Common Indicator Parameters of Urban Runoff and Landscape Alteration

	Common Indicator Parameters
Urban Runoff Pollutants	Nutrients (total phosphorus, *o*-phosphorus, total nitrogen, nitrite, nitrate, ammonia); chemical oxygen demand; total organic carbon; salts (deicer products like sodium chlorides, calcium chlorides); biochemical oxygen demand (caused by grass clippings, animal wastes, leaves, or other carbon compounds); pathogens (total coliform bacteria, fecal coliform bacteria, *E. coli* bacteria, viruses, or protozoa); solids (total suspended solids, total dissolved solids, settleable solids); pH; temperature; aluminum, arsenic, boron, barium, cadmium, chromium, chromium(VI), chlorine, copper, cyanide, iron, lead, manganese, magnesium, mercury, nickel, radium, selenium, silver, sulfate, zinc, uranium; phenols, BTEX (benzene and xylene), organic (oil, gasoline or grease), and inorganic compounds; and herbicides and other pesticides
Urban Hydrologic or Habitat Alteration	Changes in nitrogen and phosphorus concentrations (nutrient enrichment); increased chlorophyll concentrations in urban ponds, lakes, and reservoirs (measure of algal production); bioaccumulation of toxins in plant and animals; changes in species biodiversity; deposition of sediment (sand, soil, or silt); decreases in dissolved oxygen; increased runoff; increased flow velocity; increased or decreased temperatures in riparian corridors; increased sediment and bed-load transport; streambank and coastal erosion and deposition; hydromodification (dams and channels); increased impervious or paved surfaces; and loss of riparian habitat

of pollutants or provides improved water quality in runoff from construction sites or development areas and (2) urban stormwater practices intended to reduce loads in the built urban environment. Similar best management practices are applicable to both stormwater runoff in urban areas and construction site runoff. Many urban watershed programs rely on BMPs to help solve pollution and/or pollutant problems. BMPs include structural and nonstructural methods, measures, or practices that help prevent, reduce, or mitigate adverse water quality problems caused by urbanization.

Structural BMPs are constructed to treat runoff passively before it enters receiving waters. Such BMPs used on a construction or development site can be either temporary or permanent and are designed to reduce sediment load or other runoff waste products for the life of the project. Additionally, these practices should protect aquatic or riparian environments. Nonstructural BMPs include prevention and source control that minimize or eliminate a problem before it occurs. Source control BMPs are sometimes referred to as “good housekeeping” measures because a clean site produces fewer pollutants than a dirty site. Site planning and design of BMPs may, in and of itself, be considered a nonstructural BMP.

Even as treatment facilities have improved, water quality goals have become more difficult and costly to meet. The physical, biological, and ecological characterization of urban water resources intensified after the passage of the 1972 Clean Water Act, and substantial efforts are needed to resolve problems and find workable solutions. A locally defined *balanced ecological community* achievable through water quality protection and water resource management is often not a community goal because of resource limitations. Achieving urban water quality goals requires a balance between the natural environment and designated resource uses. Effective and cost-efficient water quality management and supply require an integrated resource management program.

Maintenance, improvement, and restoration of water resources at a specific, watershed or regional scale are issues of concern to local governments, special districts, state agencies, and federal agencies. Institutional responsibilities vary among these entities in the water quality management system. Many states have approached water quality planning and management through state, regional, or locally linked programs using management and operating agencies. In most states, local management agencies are responsible for implementing state water quality management plans. Local agencies can decide on the need for and specific characteristics of a wastewater treatment process and then implement activities to meet specified state and federal goals.

The protection of surface and groundwater resources from urban growth and development can best be managed by plans that limit runoff and reduce pollutant loads. Local communities can use management plans to address water quality problems on a site-specific (e.g., stream segment or drainage basin) and a larger watershed level. Management planning in the United States and in many places around the world has shifted from a governmental process to a local effort. Consequently, hundreds of new water quality management agencies, particularly in urban areas, have begun grassroots efforts to protect and enhance local water resources.

Local management agencies may be individual municipal governments, watershed associations and authorities, general-purpose governments that hold a state or federal discharge permit, or other special districts responsible for planning and approving permitted facilities. Local governments or affiliated agencies can enter into agreements to form watershed associations or authorities with a single management agency. A municipality can be defined as any regional commission, county, metropolitan district offering sanitation service, sanitation district, water and sanitation district, water conservancy district, metropolitan sewage disposal district, service authority, city and county, city, town, watershed association or authority, Indian tribe or authorized Indian tribal organization, or any two or more of them that act jointly in a domestic wastewater treatment works. Water quality management in urban landscapes is an evolving and dynamic effort of pollution and pollutant abatement involving a growing number of groups, agencies, and governments. Land use decision makers must consider growth and development impacts on urban water resources and identify offsetting mitigative practices.

WATER QUALITY MANAGEMENT IN THE U.S.: HISTORY OF WATER REGULATION

Absar Alum
Arizona State University
Tempe, Arizona

Water is the true lifeline of our planet because of the fundamental role it plays in all kinds of biological activities and its catalytic contribution/functions in major chemical and geologic processes. These fundamental roles make water the single most important factor determining the course of ecological, social, and economic changes on the earth. The sustained growth of any human society is intricately associated with the quality of freshwater resources. The Industrial Revolution in the early years of the last century resulted in much ecological pollution. Biological and chemical contamination of freshwater resources is the greatest threat to sustainability. Water quality management strategies used to prevent progression in water pollution are based on a decision-making process. Mandatory laws have traditionally been proved to be the most effective means to achieve the goals of any society. Historically, human societies have relied on some types of cultural norms, social standards, and ethical, cultural, or religious guidelines to maintain the integrity of water resources.

The Industrial Revolution of the early twentieth century and the environmental pollution quagmire resulting as its aftermath have acted as catalysts of change in water quality management. As a result, mandatory regulations have become a preferred option as opposed to voluntary guidelines to ensure proper water quality.

One of the hallmarks of the last century is increased public awareness of water quality, which has been augmented by plummeting water quality and steadily increasing population. Though water has historically been considered a commodity free for all, in the recent past, water quality and quantity have emerged as the bases of major conflicts on local, regional, national, and international levels. Under the new paradigm, water is perceived as a marketable commodity. Like any marketable commodity, the quality of water is dictated by the type of usage and is valued based on market laws of supply and demand. In the United States, it is estimated that one acre-foot of water used in agriculture and industry would generate revenue of $400 and $400,000, respectively. In the United States, the water quality management program has evolved over several decades. Based on the area of use and type of water, the history of water quality management can be divided into drinking water and wastewater regulations. Early legislation focused on ensuring the appropriate quality of drinking water, whereas the emergence of wastewater management is relatively new. Developing and implementing water quality standards and criteria achieve the appropriate quality of finished drinking water and reclaimed wastewater.

HISTORY OF DRINKING WATER REGULATIONS

The plight of public health during the nineteenth century acted as a driving force to understand waterborne disease outbreaks. By late nineteenth century, scientists established a link between gastroenteritis and drinking water contaminants, which resulted in realization of the need for water quality management. Therefore, the drinking water industry became the first sector with elaborate water quality assurance and management plans; however, there was no regulatory control over this industry. During the early 1900s, most drinking water plants built in the United States were driven by aesthetic need to reduce turbidity that resulted in an incidental reduction in disease causing agents. Slow sand filtration was commonly used by cities (such as Philadelphia) to reduce turbidity. In 1908, Jersey City (New Jersey) had the first water system to use chlorine as primary disinfectant. Other disinfectants (such as ozone) were not employed in the United States until several decades later.

The history of federal regulations for water quality goes back to the late nineteenth century. The River and Harbor Act of 1886 was the first federal regulation to address water quality. In 1893, the Interstate Quarantine Act, enacted by Congress, empowered the United States Public Health Service (PHS) to establish drinking water standards. The objective of the Interstate Quarantine Act of 1893 was "to prevent the introduction, transmission and spread of communicable diseases." The River and Harbor Act of 1886, recodified in 1899, empowered the Corps of Engineers to issue discharge permits.

In 1914, the U.S. Public Health Service (PHS) introduced the first drinking water quality standards. The standards for bacteriological (only contagious) quality of drinking water were applied only to interstate carriers like ships and trains. These standards were revised in 1925. The early 1940s was the beginning of the "Chemical Revolution" with the rapid introduction of synthetic and natural chemicals in the industrial, agricultural, and social sectors. Soon, it was realized that these chemicals were contaminating freshwater sources. Drinking water quality standards were revised again in 1946, and some new chemical standards were introduced.

The Federal Water Pollution Control Act of 1948 (FWPCA) was the first legislation to address the issue comprehensively. Principles of limited federal enforcement and limited federal financial assistance were adopted to develop state and federal cooperative programs. These principles provided the framework for the Federal Water Pollution Control Act of 1956 and the Water Quality Act of 1965. In 1962, the PHS introduced its last revision of drinking water standards. Although the emphasis was on microbial diseases, 28 chemicals were also regulated. These revisions included about 20 standards and, for the first time, recommended the use of qualified personnel. Some of the important recommendations were use of water from protected sources, control of pollution sources, and chlorination of water drawn from unprotected sources. Under the Water Quality Act of 1965, states were required to develop and establish water quality standards; by the early 1970s, all states had developed their standards.

Passage of the Water Quality Act of 1965 (October 2, 1965) also resulted in the creation of the Federal Water Pollution Control Authority (FWPCA) as a separate entity in the Department of Health, Education, and Welfare (HEW); however, FWPCA did not reside there long. In 1966, it was transferred to the Department of the Interior (Reorganization Plan No. 2 of 1966). Under the Water Quality Improvement Act of 1970 (84 Stat. 113, April 3, 1970), FWPCA was abolished and its functions were folded into the new United States Environmental Protection Agency (U.S. EPA).

The sporadic amendments of the FWPCA of 1948 and repeated restructuring and reorganization of the responsible agency resulted in inefficient implementation of these laws and regulations. During the early 1970s, increased awareness of environmental and health issues and emergence of environmental activism along with complacent environmental regulations resulted in an exigent need to overhaul the system and consolidate authority. To resolve these issues, FWPCA was amended in 1972 and Congress passed the Clean Water Act (CWA) of 1972. Under this act (the Clean Water Act of 1972), the U.S. EPA was given the mandate to develop regulations to restore and maintain the chemical, physical, and biological integrity of the nation's water. This act manifests a basic change in strategy, and the focus of enforcement was changed from implementing water quality standards to effluent regulations. The National Pollution Discharge

Elimination System (NPDES) was established under which each point source is required to obtain a discharge permit. Under the Clean Water Act, the U.S. EPA was given a mandate to establish technologically based effluent limitations.

The Clean Water Act of 1972 mandated that all publicly owned sewage treatment works use the "best practical control technology" for industrial wastes and secondary treatment by July 1, 1977, "best available treatment economically achievable" by July 1, 1983, and the elimination of all discharges of pollution by 1985. However, these deadlines were relaxed on the recommendations of the National Commission on Water Quality in 1977, and the zero discharge goals were eliminated. The commission recommended a comprehensive recycling and reuse program using alternative and innovative technologies to achieve the goals of the Clean Water Act.

Over the course of years, the CWA evolved into a multifaceted statute ensuring the achievement of its objectives through the construction of local wastewater treatment plants (construction grant program) and the creation of a major national wastewater discharge permitting system.

Local public agencies were required to submit proposals for each proposed construction project. These projects were funded through the federal grants allocated to the states. During the period 1972–1990, more than $60 billion in federal grant money was invested in municipal sewage treatment works, along with more than $20 billion from state and local governments.

Under the CWA amendments of 1987, the construction grant program was changed, and beginning in 1990, the method of municipal financial assistance was shifted from grants to loans provided by state revolving funds. Since 1990, all the states have created "revolving loan funds," which serve as low-cost financing sources for water quality infrastructural projects.

The Safe Drinking Water Act (SDWA), passed in 1974, established stringent regulatory standards for the quality of drinking water for all public water supply systems except the very smallest. Currently, the Safe Drinking Water Act regulates more than 175,000 public water systems in the United States.

The Surface Water Treatment Rule was passed in 1989. This rule covers all public water supply systems using surface water or groundwater under the direct influence of surface water and intends to protect against exposure to pathogens such as *Giardia*, viruses, and *Legionella*. It requires 4 and 3 log removal of enteric viruses and *Giardia* during water treatment. It also requires a 0.2 mg/L of residual disinfectant at the point of water entry and maintaining a detectable level of residual disinfectant throughout the distribution system. The Interim Enhanced Surface Water Treatment Rule (IESWTR) was promulgated in 1989. It covers all public water supply systems that serve 10,000 people or more and use surface water or groundwater under the direct influence of surface water. It requires 2 log removal of *Cryptosporidium* from filtered water systems.

The Stage I Disinfectants and Disinfection By-products (D-DBP) Rule of 1998 was aimed at providing public health protection to an additional 20 million households by reducing the levels of disinfectants and disinfection by-products in drinking water. This rule established the maximum residual disinfectant level goals (MRDLGs) for chlorine, chloramines, and chlorine dioxide; maximum contaminant level goals (MCLGs) for four trihalomethanes, two haloacetic acids, bromate, and chlorite; and National Primary Drinking Water Regulations (NPDWRs) for three disinfectants (chlorine, chloramines, and chlorine dioxide), two groups of organic disinfection by-products, and two inorganic disinfection by-products (chlorite and bromate). The NPDWRs consist of maximum residual disinfectant levels (MRDLs) or maximum contaminant levels (MCLs) or treatment techniques for these disinfectants and their by-products. The NPDWRs also include monitoring, reporting, and public notification requirements for these compounds.

In 2000, the U.S. EPA proposed a groundwater rule (GWR). It uses a multiple barrier strategy to reduce waterborne health risks. The following five components are the basis of this multiple barrier strategy:

- periodic sanitary survey of groundwater systems
- hydrogeologic assessment to identify wells sensitive to fecal contamination
- source water monitoring for systems drawing from sensitive wells without treatment or with other indications of risk
- correction of significant and fecal contamination
- compliance monitoring to ensure that disinfection treatment is reliably operated

The original Federal Water Pollution Control Act has had six major amendments in the intervening years. The passage of Federal Water Pollution Control Act Amendment of 1972, which is also known as the Clean Water Act (CWA), divides the history of water pollution control (including wastewater treatment) in the United States into two eras: the pre- and post-Clean Water Act periods. Before 1972, states had the regulatory authority for water pollution control, whereas federal involvement was limited to cases involving interstate waters. Due to unique socioeconomic and political circumstances, states have historically shown different levels of motivation and willingness to address water pollution control issues.

The history of water quality management and policy formulation is complicated (Table 1). The three most important lessons learned are institutional reform, improved processes for conflict resolution, and increased use of modern planning and decision-making procedures. All these lessons learned through the evolution of U.S. water quality management policy may serve as a guideline for other countries to avoid repeating mistakes and to ensure efficient use of water resources.

Table 1. Time Line of Water Quality Regulations in the United States

Year	Events	Comments
1890	Harbors and Rivers Act	Prohibited discharge of any refuse in to interstate waters
1893	Interstate Quarantine act	Intended to control spread of communicable diseases from one area to another
1899	Harbors and Rivers Act Amendment	Exempted the “refuse flowing from streets and sewers and passing therefrom in a liquid form”
1912	The Public Health Service Act	First water related regulation that prohibited use of a common cup on interstate carriers
1914	“Treasury Standards” or USPHS standards	First microbial standards applicable to water systems supplying water to interstate carriers. HPC count should be less than 100 per mL and not more than one of the five 10 mL portions of a sample can be positive for *E. coli*
1924	Oil and Pollution Control Act	To control discharge of oil damaging coastal waters
1925	Revised USPHS Standards	1 coliform/100 mL; first physical-chemical standards for Pb, Cu, Zn, and soluble mineral salts
1943	Revised USPHS Standards	Standards revised to include more contaminants
1946	Revised USPHS Standards	Standards revised to include more contaminants
1948	Federal Water Pollution Control Act	Public Law 8-845: first law to address comprehensively the issue based on the principle of limited federal enforcement and limited federal financial assistance
1948	Establishment of Division of Water Supply and Pollution Control (DWSPC),	DWSPC established in PHS, FSA, to administer the Water Pollution Control Act, June 30, 1948
1956	Federal Water Pollution Control Act Amendment	Authorized construction grants for municipal treatment works
1961	Water Pollution Control Act	Congress advocated 85% removal of pollutants using comprehensive programs and plans for water pollution abatement and control
1962	Revised USPHS Standards	Included 28 constituents
1965	Water Quality Act October 2	States are required to have water quality standards to receive grants
1965	Federal Water Pollution Control Administration (FWPCA)	FWPCA was established in the Department of Health, Education, and Welfare (HEW)
1969	Community Water Supply Study (CWSS) initiated	Initiated a survey of 969 public water systems (representing only 5% of nation’s water systems) for compliance with 1962 standards
1970	CWSS report released	41% of public water systems surveyed for compliance with 1962 standards
1970	Water Quality Improvement Act	No new provisions regarding standards. The act continued the authority of states to set water quality standards and the authority of FWPCA to approve such standards. Questioned the Environmental Protection Agency’s authority to require uniform treatment limitation for water discharge
1972	Louisiana (Mississippi River) Water Quality Report Published	36 organic compounds found in drinking water and source waters.
1972	“Clean Water Act” (CWA) or FWPCA amendment of 1972	Set discharge limits and required waste treatment prior to discharge and established National Pollution Discharge Elimination System (NPDES)
1973	GAO report	Out of 446 community water systems investigated, only 60 were found to comply with USPHS standards
1974	Consumer Reports (three part series) published	Organic contaminants in New Orleans
1974	Environmental Defense Fund	Organic contaminants in New Orleans
1974	Trihalomethanes (THMs) identified	A major public health concern
1974	National Organic Reconnaissance Survey	Survey of THM occurrence nationwide
1974	Safe Drinking Water Act (SDWA)	Established stringent regulatory standards for the quality of drinking water for all public water supply systems except the very smallest. Signed on Dec.16, 1974, as Public Law 93-523
1975	National interim primary drinking water regulations (NIPDWRs)	Based on 1962 USPHS standards, interim rules for 18 organic, inorganic, and microbial contaminants
1976	1st NIPDWRs amendment	Standards for four radionuclides
1976	Toxic Substances Control Act (TSCA)	Regulation of all compounds that have or may possess toxic properties
1977	Best practical control technology currently available (BPCTCSA)	Defined best available waste treatment for different industries
1979	2nd NIPDWRs amendment	Total THMs
1980	Comprehensive Environmental Restoration, Compensation, And Liability Act (CERCLA)	“Superfund” bill that established a detailed program to describe priority pollutants and first national database of pollutants
1980	3rd NIPDWRs amendment	Monitoring for corrosion and sodium
1983	4th NIPDWRs amendment	Identifies the best available mean to comply with THMs rule

Table 1. ***(Continued)***

Year	Events	Comments
1986	SDWA amendment	Major revisions introduced in SDWA. Set standards for pollutants in drinking water; authorizes contamination warning and alert system
1987	Volatile organic contaminants standards	Standards for eight contaminants
1988	SDWA amendment	Public Law 100-572: Lead Contamination Control Act
1989	Surface Water Treatment Rule	The Surface Water Treatment Rule regulates public water systems using a lake, stream, or pond water as a source of drinking water. It was intended to ensure the safety of drinking water
1989	Total Coliform Rule (TCR)	Establishes microbiological standards and related monitoring requirements for all community and noncommunity water systems
1991	National Primary Drinking Water Regulation for Radon-222	EPA proposed to regulate radon at 300 pCi/L. Public water supplies (systems serving over 25 individuals or with greater than 15 connections) are required to monitor, report, and notify requirements for radon (July 18, 1991) (56 FR 33050)
1991	Phase II SOCs and IOCs also lead and copper	Standards for 27 new contaminants
1992	Phase V SOCs and IOCs	Standards for 22 new contaminants
1996	SDWA amendment	Public Law 104-182 requires U.S. EPA to publish an MCLG and promulgate NPDWR for contaminants of public health significance
1996	Information Collection Rule	Monitoring only to provide information on the occurrence of disinfection by-products (DBPs) and pathogens, including *Cryptosporidium* (May 14, 1996)
	Analytical Methods for Radionuclides	Approval of additional (66) analytical methods to monitor gross alpha, gross beta, tritium, uranium, radium-226, radium-228, gamma emitters, and radioactive cesium, iodine, and strontium in drinking water (Mar. 5, 1997)
1997	Withdrawal of 1991 proposed rule on radon-222	Withdrawal of drinking water regulations proposed for radon-222 (Aug. 6, 1997)
1997	Small System Compliance Technology List for the Surface Water Treatment Rule	The list of technologies that small systems can use to comply with the Surface Water Treatment Rule (SWTR) (Aug. 6, 1997)
1998	Revisions to State Primacy Requirements	The regulations requiring states to obtain and retain primary enforcement authority (primacy) for the Public Water System Supervision (PWSS) program under Section 1413 of the Safe Drinking Water Act (SDWA) are amended (Apr. 28, 1998)
1998	Drinking Water Contaminant Candidate List	The list of contaminants that are known or anticipated in public water systems and may require regulations under the SDWA (Mar. 2, 1998)
1998	Variances and Exemptions Rule	The rule includes procedures and conditions under which a primacy state/tribe or the EPA Administrator may issue small system variances to public water systems serving less than 10,000 persons (Aug. 14, 1998)
1998	Consumer Confidence Reports	Community water systems are required to prepare annual consumer confidence reports on the quality of the water delivered by the systems and provide these reports to their customers (Aug. 14, 1998)
1998	Stage I D-DBP Rule	Standards for 11 new contaminants (Dec. 16, 1998)
1998	Interim Enhanced Surface Water Treatment Rule	Improve control of microbial pathogens, including specifically the protozoan *Cryptosporidium*, in drinking water; and address risk trade-offs for disinfection by-products (Dec. 16, 1998)
1999	Suspension of Unregulated Contaminant Monitoring Requirements for small public water systems	This rule exempts small and medium public water systems from monitoring unregulated contaminants during 1 year every 5 years, as required under UCMR (Jan. 8, 1999)
1999	Revisions to the Unregulated Contaminant Monitoring Rule.	This final rule includes a list of contaminants to be monitored. The data in the database will be used to identify contaminants on the Drinking Water Contaminant Candidate List (CCL) (Sept. 17, 1999)
1999	Analytical methods for chemical and microbiological contaminants and revisions to laboratory certification requirements	EPA has approved the updated versions of 25 American Society for Testing and Materials (ASTM), 54 Standard Methods for Examination of Water and Wastewater (Standard Methods or SM), and 13 Environmental Protection Agency (EPA) analytical methods for compliance determinations of chemical contaminants in drinking water (Dec. 1, 1999)
1999	Underground Injection Control Regulations for Class V Injection Wells	Class V Underground Injection Control (UIC) regulations are revised and new requirements are added for two categories of endangering Class V wells to ensure protection of underground sources of drinking water (Dec. 7, 1999)
1999	Lead and Copper Rule minor revisions	These minor revisions are intended to streamline requirements, promote consistent national implementation, and, in many cases, reduce the burden for water systems. The LCRMR do not change the action levels or MCLGs for lead and copper, established by the Lead and Copper Rule (Dec. 20, 1999)

(*continued overleaf*)

Table 1. **(*Continued*)**

Year	Events	Comments
2000	Analytical Methods for Perchlorate and acetochlor	This rule specifies the approved analytical methods for measuring of perchlorate and acetochlor in drinking water and also includes minor technical changes to correct or clarify the rule published on Sept. 17, 1999 (Mar. 2, 2000)
2000	Public Notification Rule	Owners and operators of public water systems are required to notify persons served when they fail to comply with the requirements of the National Primary Drinking Water Regulations (NPDWR), have a variance or exemption from the drinking water regulations, or are facing other situations posing a risk to public health (May 4, 2000)
2000	Removal of the MCLG for chloroform	In accordance with the order of the U.S. Court of Appeals for the District of Columbia Circuit, the zero MCLG for chloroform is removed from National Primary Drinking Water Regulations (NPDWRs) (May 30, 2000)
2000	Drinking Water State Revolving Fund Rule	This interim final rule gives each state considerable flexibility to determine the design of its DWSRF program and to direct funding toward its most pressing compliance and public health problem. It also explains the ways to receive a capitalization grant, how to use capitalization grant funds intended for infrastructure projects, and also the roles of both the states and EPA in managing and administering the program
2000	Radionuclides Rule	This rule establishes the MCLGs, MCLs, monitoring, reporting, and public notification requirements for radionuclides. Uranium is added to the list, and the monitoring requirements for combined radium-226 and radium-228, gross alpha particle radioactivity, and beta particle and photon radioactivity have been revised (Dec 7, 2000)
2001	Unregulated Contaminant Monitoring List 2 Rule	The analytical methods for thirteen chemical contaminants on List 2 are approved and also the schedule for *Aeromonas* monitoring is described (Jan. 11, 2001)
2001	Arsenic Rule	A health-based, nonenforceable MCLG for arsenic of zero and an enforceable MCL for arsenic of 0.01 mg/L (10 μg/L) is established for nontransient noncommunity water systems (Jan. 22, 2001)
2001	Filter Backwash Recycling Rule	The purpose of the FBRR is to further protect public health by requiring public water systems (PWSs), where needed, to institute changes to the return of recycle flows to a plant's treatment process that may otherwise compromise microbial control (June 8, 2001)
2002	Long Term 1 Enhanced Surface Water Treatment Rule (Jan. 14, 2002)	The rule requires systems to meet strengthened filtration requirements as well as to calculate levels of microbial inactivation
2002	Unregulated Contaminant Monitoring Regulation for Public Water Systems	Establishment of Reporting Date (Aug. 9, 2002) for water systems (serving more than 10,000 persons) to report all contaminant monitoring results they receive before May 13, 2002 for the Unregulated Contaminant Monitoring Regulation (UCMR) monitoring program; Direct Final Rule (Mar. 12, 2002)
2002	Guidelines establishing test procedures for the analysis of pollutants under the Clean Water Act; National Primary and Secondary Drinking Water Regulations	The test procedures (i.e., analytical methods) for the determination of chemical, radiological, and microbiological pollutants and contaminants in wastewater and drinking water are revised and updated; Final Rule (Oct. 23, 2002)
2002	Unregulated Contaminant Monitoring Regulation: Analytical methods for chemical and microbiological contaminants	Approval of the analytical method and an associated minimum reporting level (MRL) to support Unregulated Contaminant Monitoring Regulation's (UCMR) (for chemical and microbiological contaminants) List 2 *Aeromonas* monitoring; Final Rule (Oct. 29, 2002)
2003	Propose MCLG and National Primary Drinking Water Regulations	Regulations for any contaminant selected from contaminant candidate list (Aug. 2003)
2004	National Primary and Secondary Drinking Water Regulations	Approval of additional method (Colitag™) for detecting coliforms and *E. coli* in drinking water; Final Rule (Feb. 13, 2004)

WATER QUALITY MANAGEMENT IN A FORESTED LANDSCAPE

Thomas M. Williams
Baruch Institute of Coastal
Ecology and Forest Science
Georgetown, South Carolina

In 1955, Trousdell and Hoover published a paper in the *Journal of Forestry* that documented a rise in the water table following clear-cutting of a stand of loblolly pine on poorly drained soil. They warned that this rise may lead to saturated soils that inhibit regeneration and preclude using heavy equipment on the site. In the first century A.D., Pliny the Elder stated, "Often after woods have been cut down, springs on which the trees used to feed, emerge" (cited in Reference 1). Modern scientific methods can document truth that has been observed and debated for millennia. The influence of forests on water is such a subject. During two millennia of observation and nearly a century and a half of scientific investigation, the role of forests in water has been empirically demonstrated, but it is still not understood at a fundamental level.

Forested land produces the highest quality water of any land use (2), and forests have been used to protect drinking water supplies around the world. Forested streams also support food webs essential to the health of fish and other aquatic organisms. Rocky streambeds in forests are essential to aquatic macroinvertebrates that are used by some of our most desirable game fish. Protection of water was one of the objectives of the Organic Act of 1897, which formed the National Forest system, and the Weeks Act of 1911, which added 21 million acres of National Forests in the eastern United States (3).

In addition to protecting water, forests are also used by humans for harvest of timber products, harvest of game and fish, and outdoor recreation. Forests are often managed to enhance their usefulness for these purposes. Humans have used fire to alter ecosystems for hunting for at least 10,000 years, and exploitive logging has been practiced throughout the historical period. Management of forests to produce timber and fiber products has been widely practiced since the late nineteenth century. Much of our knowledge of the influence of forests on water has been gained by our efforts to evaluate the impact of forest management on water.

Modern forest hydrology research began in France in the nineteenth century. Widespread deforestation following the French revolution was blamed for a series of floods and landslides that plagued the country (1). During that debate, proponents of forests argued that reforestation would increase stream flow, regulate floods, and prevent erosion and landslides. Most of these claims were supported by observations of several romantic era writers and references to ancient Greek scholars. To resolve these disputes, the influence of forests became an area of active scientific inquiry. Surell (4) was one of the early researchers to collect numerical data on mountain watersheds and landslides. Observation of stream flow and rainfall began by 1850 and examination of watersheds with different land uses began by 1860. The controversy over the value of forests in regulating streams continued in the United States by the early 1900s. Pinchot (5) lamented that "the writing and talking on this branch of forestry has had little definite fact or trustworthy observation behind it." At that time, the U.S. Forest Service began efforts to collect trustworthy observations.

Studies at Wagon Wheel Gap, Colorado, introduced the most widely used technique in examining water in forested regions (6). The use of paired experimental watersheds (7) has produced statistically valid tests of many ideas that had been debated for centuries. This technique involves measuring the process of interest for several years in two closely matched watersheds, applying a treatment to alter the process in one watershed, and then continuing measures in both watersheds for several years. From a strong correlation between the data from the two watersheds prior to treatment, changes in the treated watershed can be determined with high confidence. Over the last century, paired watersheds have been used to study most aspects of forest management. A solid empirical basis is available for evaluating forest management impacts on water quality. We have a relatively clear understanding how forests produce clean water and which aspects of forest management have the potential to degrade water quality.

Water from undisturbed forests has very little suspended sediment. Estimates of total sediment loss from forested watersheds across the United States are generally less than 0.5 Mg/ha/yr (8). Very low rates of erosion are due to the mechanism of peak flow generation in forested watersheds. Between rains, flow in most streams is derived from groundwater, which has little associated sediment. Sediment is added to streams as rainwater travels across the soil surface and suspends soil particles. Horton (9) explained the generation of surface flow as rain that fell more quickly than water could enter the soil. If water could enter the soil at 3 mm/h and it rained 10 mm/h, then 7 mm of rain must flow across the surface and into streams. However, in temperate forests, measured infiltration rates may approach 1000 mm/h and any incoming rain will enter the soil (10). However, we know that forested streams rise quickly after rain begins. A number of different mechanisms have been found that deliver water quickly to streams in forested watersheds (11). These mechanisms do not include water moving very far along the surface of the ground. In forested areas, most of the sediment found in streams has been eroded from stream banks.

High rates of infiltration on forest soils result from two mechanisms. The tree canopy intercepts raindrops and, once it is wetted, allows drops to fall a short distance to the forest floor, thus protecting the forest floor from high energy impacts during intense rain. Litter covering the soil and organic matter incorporated into the soil create large pores and allow them to stay open throughout the storm. As long as these soil pores remain open, surface water does not erode the soil and add sediment to streams. Protection of the soil pores by litter and organics is the more important mechanism. High infiltration can occur if the litter and organic matter are not disturbed when the canopy is removed.

Disturbance of forest soil by harvest and replanting of trees in commercial forestry is the most likely way that forest management can degrade water quality. Removing forest products from the site requires cutting trees, skidding products to a landing, loading them on a truck, and hauling them to a mill. Each aspect can damage the forest floor. Sediment losses from skid trails and landings may be as high as 7000 Mg/ha and from roads can be as high as 1000 Mg/ha (12). On a watershed basis, sediment losses of 10 Mg/ha/yr have been found following logging and preparation of the watershed for replanting (13,14). This soil loss rate was similar to that considered acceptable to maintain agricultural productivity and occurs only for 3–5 years of a 25-year rotation. Since those studies were concluded, forestry has been challenged to improve water quality associated with harvesting and regeneration. Throughout the United States, foresters have examined techniques to minimize exposure of bare soil and to build roads and landings in a way that maintains a buffer of undisturbed forest soil for infiltration before runoff reaches a stream bank. These techniques, known collectively as best management practices (BMPs), are now being used across the United States (15). A number of studies have shown that BMPs reduce sediments by roughly 90% (16).

Cutting the forest does increase the amount of water that becomes stream flow and will cause an unavoidable increase in sediment in alluvial streams. More water is returned to the atmosphere by evaporation of intercepted rain and transpiration by trees than any other land cover. Examining runoff data from 94 paired watershed experiments, Bosch and Hewlett (17) concluded that there was a generally linear increase in steam flow with increasing percentage of forest removed. They also concluded that cutting conifers resulted in a greater increase than cutting deciduous hardwoods. Sahin and Hall (18) looked at 145 such experiments and estimated that stream flow increased 20–25 mm for each 10% reduction in the cover of conifers and 17–19 mm for each 10% reduction in hardwoods. Increases in stream flow tend to increase the size of alluvial channels, causing an unavoidable increase in suspended sediment. Van Lear et al. (19) found an increase from 0.040 Mg/ha/yr to 0.15 Mg/ha/yr in sediment loss from a watershed where the only source of sediment was a stream channel. However, the stream flow returns to preharvest values as the new forest grows. In some rapidly growing forests, water yield may actually decline below the pretreatment level when the growth rate is at a maximum (20).

An early experiment to determine if forest regeneration was responsible for the decline in stream flow revealed the importance of nitrogen cycling in forest harvesting. At Hubbard Brook, New Hampshire, all trees on a watershed were cut and all vegetation killed for three successive years to examine stream flow (21). Stream flow increased by more than 300 mm during the first year. This increase was maintained as long as herbicide was applied to the watershed and declined when vegetation was allowed to grow. In addition to an increase in flow, the concentration of nitrate, calcium, and magnesium increased greatly. Nitrate concentrations exceeded drinking water standards. The large pool of nitrogen in the vegetation and the forest floor was mineralized. Nitrification of this mineralized nitrogen yielded nitrate and hydrogen ions; nitrate was leached from the system, and hydrogen ions displaced cations, which were then lost.

Due to the concerns raised by the Hubbard Brook experiment, cycling and retention of nitrogen is now better understood than any other biogeochemical process in forested ecosystems. Nitrogen is tightly held in forested ecosystems and export of nitrate to streams is highly limited. Ten separate chemical mechanisms for retention of mineralized organic nitrogen have been identified in forest soils (22,23). The most common are ammonium uptake by bacteria that decompose high C:N material, ammonium or nitrate uptake by plants, and denitrification of nitrate to nitrous oxide or nitrogen gas.

When a forest is harvested, a great deal of organic nitrogen is deposited in the form of logging slash, and moisture and temperature increase in the forest floor. The logging slash is also high in carbon and decomposition bacteria outcompete nitrifiers for mineralized ammonium. As carbon is lost as carbon dioxide, the ratio of carbon to nitrogen declines and decomposition bacteria are less able to compete with nitrifiers. Unless regrowth is inhibited, plants become competitors for ammonium and also can use nitrate produced by nitrifiers. Finally, if nitrate is leached from the forest slope, it moves to the riparian zone where soils are often saturated. In these saturated zones, bacteria deplete oxygen from the soil and then use nitrate as an electron receptor in anaerobic respiration. Nitrate is reduced to nitrous oxide or to neutral nitrogen and lost from the system as a gas. Unless all these mechanisms are limited, normal forest harvesting does not result in nitrate concentrations of more than 1 mg/L. These mechanisms are most effective in moist, warm, temperate forests.

In addition to the original Hubbard Brook experiment, nitrate leaching has been occasionally found in other places, although stream concentrations have generally been found below 10 mg/L. Clear-cutting other watersheds in the mountains of New England also showed elevations of nitrate near 10 mg/L (24). Use of herbicide, especially hexazinone (25), in repeated treatments (26) may increase stream concentrations to the 2–5 mg/L range. In northwestern Europe, nitrogen input from air pollution appears to be increasing stream nitrate concentrations. Nitrate concentrations between 0.5 and 1 mg/L are found in undisturbed forested watersheds in Scandinavia (27). Lepistõ (28) found evidence that a watershed in Finland had become saturated with nitrogen and showed nitrate leaching even during the growing season. This occurred after atmospheric nitrogen input had increased from 2.9 kg/ha/yr in 1969–1979, to 6.2 kg/ha/yr in 1971–1979, to 8.5 kg/ha/yr in 1980–1990.

A number of other anions and cations are found in low concentrations in streams draining forested landscapes. The concentrations of these ions and ratios of one ion to another are related to location and subsurface geology. The ratios of various ions have been used widely to interpret pathways of water within the watershed. Mulholland (29) used ratios of sulfate and calcium to differentiate among vadose zone, shallow groundwater, and deep groundwater sources of stream flow in a watershed dominated by dolomite. In this case, atmospheric input of sulfate resulted in high concentrations in throughfall, but adsorption by iron and aluminum in the soil B horizon resulted in low sulfate in shallow groundwater. Likewise, calcium was very low in throughfall but very high in groundwater that had been in contact with the dolomite bedrock. Eisenbeer and Lack (30) used a similar technique with silica and potassium to examine surface runoff and pipe flow in an Amazonian watershed. Intense weathering of the soil and bedrock resulted in leaching of silica into the water passing through the soil. Intense weathering also isolated potassium into the living biomass; it was leached from leaves in throughfall and surface flow. The ratio of potassium to silica could be used in the same way that sulfate and calcium were used in the other geologic setting.

Hydrogen ions are generally not of great concern in forest streams with pH slightly acid, unless the geology is dominated by calcareous materials. Nitrification produces an H^+ ion for each NO_3^- ion and can be a source of acidification in stream water. Generally, that is not the case because H^+ is held more tightly in the soil cation exchange complex, and potassium, calcium, or magnesium is displaced to be carried to the stream. Afforestation acidified streams in the British Isles on former moorland (31).

As forest management strives to increase the growth of forest products, pesticides and fertilizer have been used on more forest plantations. Although these two activities are not closely related, contamination from both can be avoided in the same way. If rain dissolves fertilizer and pesticide from the soil surface, they will be quickly immobilized within the soil. Contamination from either can be eliminated by avoiding application in streams or near stream areas that may saturate in a large rain. Buffering both perennial and ephemeral streams when fertilizer or pesticide is applied will prevent contamination. Both materials are often aerially applied, so a number of management practices relating to atmospheric conditions are followed in development of best management practices. Most problems with these materials have been caused when aerial sprays are inadvertently applied to surface waters.

Fire is a tool that has been used to manage forest ecosystems since early man first learned to use it. Fire can have a profound impact on water quality. The impact of fire is closely related to the fate of the forest floor. If the forest floor is damp and fire intensity is low, there is little impact on water quality. As fire intensity increases, the impact on water also increases. If trees are killed and the forest floor remains intact, the result is similar to logging with an increase in flow but small changes in sediment or chemistry. However, fire effects can be much larger than those from logging if the forest floor is dry or the fire is intense enough to dry and consume the forest floor. As more bare soil is exposed, infiltration declines and water runs across the surface carrying sediment and cations from the ash. If the fire is highly intense, volatilized organic compounds move from the forest floor into the soil. As these compounds cool, soil particles become hydrophobic and prevent water from entering the soil (32). In this case, all rainwater runs across the surface, there is severe erosion, and streams are filled with sediment. Thus, fire may result in sediment losses from 1–2 Mg/ha to 500 Mg/ha, depending on fire severity and land slopes (33). In areas of high air pollution, severe fire may also result in nitrate concentrations that exceed drinking water standards (34). The goal of fire management is to prevent such intense fires by using prescribed, less intense fires, mechanical fuel reduction, and fire suppression.

Undisturbed forests produce the highest quality water of any land use. However, forested watersheds also lose more water to the atmosphere though evaporation and transpiration than other land uses. Human use of the forest can degrade the quality of water produced if care is not taken to protect the forest floor. Careless logging, especially poorly designed roads, can contribute to stream sedimentation and degrades water for both human use and as fish habitat. Most of these problems can be avoided if best management practices are used. There are few problems with chemical water quality, except for nitrate, which may become a problem if forest regrowth is prevented or in areas with prolonged high atmospheric nitrogen deposition. Such problems have been seen in northwestern Europe and after fire in the Los Angeles basin.

TRACE METAL SPECIATION

Jamie R. Lead
University of Birmingham
Birmingham,
United Kingdom

INTRODUCTION

Trace metals may be defined as those metals whose concentration is low enough so that their presence exerts a negligible influence on the overall chemistry of a water body. They can be contrasted with major ions that are present in sufficient amounts to affect the chemistry of the system. Major metal ions include the alkali and alkaline earth metals (Na, K, Ca, Mg) and perhaps Al, Fe, and Mn. Although there is no strict definition of a “trace metal,” we usually consider the transition metals, certain metalloids, and lanthanides. Radioactive elements are often considered separately. The potential effects on ecological and human health created by a certain number of trace metals mean that these metals are of particular importance and are the subject of intensive study. The effects of these metals may often be deleterious, but many metals are also micronutrients. In no order, some of the most important and most investigated trace metals are chromium (Cr), nickel (Ni), copper (Cu), zinc (Zn), arsenic (As), cadmium (Cd), tin (Sn), mercury (Hg), and lead (Pb).

Trace metals in natural waters can be present at different concentrations but can also be distributed between different physicochemical forms or species. This distribution of a metal between different forms is termed its speciation. Important examples of speciation in the environment are: (1) the oxidation state, for example, Fe(II) and Fe(III); (2) the nature of the ligand in a solution phase metal complex, for example, Cd^{2+} and $CdCl_4{}^{2-}$; and (3) the distribution of metal between dissolved, colloidal, and particulate phases. The exact form in which the trace metal exists substantially mediates the bioavailability and toxicity of the metal and its transport in the environment and has important implications for biomagnification (i.e., increased concentration of pollutant as it passes through the food chain), human and ecological health, and biogeochemical cycling. Speciation is thus intrinsically important and also relevant to understanding wider environmental processes. We can examine the three examples above and discuss some of the possible environmental implications of speciation.

1. *The Oxidation State.* [Fe(II)/Fe(III)]—Fe(II) occurs in reducing (oxygen-deficient) conditions, such as porewaters in sediments and bottom waters of stagnant and/or biologically active lakes, particularly in the summer months. Conversely, Fe(III) occurs in oxidizing (oxygen-rich) conditions, such as surface river, lake, or marine waters. Additionally, Fe(II) tends to be present in the dissolved phase, Fe^{2+} (aq), whereas Fe(III) tends to hydrolyze (react with water) very strongly and form solid colloidal or particulate oxide or hydroxide phases, $Fe(OH)_3$ (s), where the (aq) denotes the aqueous phase and (s) denotes solid. This has important implications for the behavior of Fe, which are discussed below in example 3. In addition, trace metals may bind to the surface of solid Fe(III) particles. Interconversion of Fe(II) and Fe(III) at interfaces between oxidizing and reducing conditions may have an impact on the environmental fate and behavior of any associated metals. See Davison and de Vitre (1) for an in-depth discussion of iron chemistry in aquatic systems.
2. *The Nature of Solution Phase Ligand (Cd^{2+} and $CdCl_4{}^{2-}$).* The salinity of water (the concentration of the chloride ligand) determines the extent to which metals such as cadmium are present as the positively charged hydrated Cd^{2+} or as the negatively charged chloro complex $CdCl_4{}^{2-}$. Intermediate numbers of chloride ions in the complex are also possible. This situation is most commonly encountered in estuarine systems, where freshwater meets seawater and the chloride concentration of the water gradually increases. The change in charge from the positive Cd to the negative $CdCl_4$ affects properties of the metal such as permeability through biological membranes and sorption/desorption to clay, organic, and oxide particles. These changes have implications for metal bioavailability and transport. In addition to chloride, other important ligands exist such as sulfate, amino acids, and EDTA.
3. *Dissolved, Colloidal, and Particulate Distribution.* The distribution of metals between these three phases has long been recognized as essential to the fate and behavior of trace metals. Particular prominence is given to the free (dissolved) metal ion, as it is predicted that the biological response is a function of the dissolved concentration in bulk water (2). The relationship between speciation and bioavailability may, however, be less straightforward; complex and poorly understood physicochemical and biological interactions mediate biological uptake of metal (3,4). Transport through the environment is also affected by the partitioning of metal (5); microbiological activity, aggregation of colloids, and sedimentation of particles are among the dominant processes. Somewhat simplistically, dissolved and colloid-bound metals tend to remain in the water column, and particle-bound metals tend to settle out to the sediments. This geochemical fractionation results in different transportation behavior and alters the ultimate fate of the metal.

Table 1. Approximate Concentrations of Trace Metals in Seawater and Freshwater[a]

Metal	Seawater, molar	Freshwater, molar
Mn	10^{-9}	$10^{-5} - 10^{-9}$
Fe	10^{-9}	$10^{-4} - 10^{-7}$
Cu	$10^{-8} - 10^{-9}$	$10^{-6} - 10^{-9}$
Zn	$10^{-8} - 10^{-10}$	$10^{-5} - 10^{-8}$
Ni	10^{-8}	$10^{-6} - 10^{-10}$
Cd	$<10^{-9}$	$10^{-7} - 10^{-10}$
Pb	$<10^{-10}$	$10^{-6} - 10^{-9}$
Hg	10^{-11}	$10^{-7} - 10^{-10}$

[a] Data from Reference 6.

As indicated briefly in these examples, the question of trace metal speciation is complex. Our understanding of these difficult areas is in part due to the physicochemical and biological complexity of natural waters. Natural waters contain all or almost all elements of the periodic table. Trace metals can be present at extremely low levels, often at or below analytical limits of detection; concentrations are as low as 10^{-12} M in some cases. See Table 1 for illustrative examples of element concentrations, although it must be kept in mind that a wide range of concentrations exists. Additionally, a range of dissolved, colloidal, and particulate organic matter and suspended particles exist that have complex and unknown structures and effects on metal speciation. These include a range of chemistries (silicates, oxides, carbonates, humic substances, etc.) and sizes (1 nm upward). Microorganisms also play an important (and again poorly understood) role in metal speciation, through biochemical processes, sorption to cell walls and membranes, and the production and excretion of complexing ligands into the environment.

Our understanding of speciation is further hindered by the variability of natural waters spatially (e.g., surface waters in lakes may have a higher oxygen content than bottom waters and have significant effects on metal speciation) and temporally (e.g., daily and seasonal cycles in chemistry, often mediated by changes in biological activity) often over very small scales.

CHEMICAL REACTIONS THAT AFFECT METAL SPECIATION

We can distinguish between two broad types of chemical reactions that may affect speciation (7). First is redox reactions where the oxidation state of the atoms is altered. An example of this is the Fe(II)/Fe(III) interconversions in the examples above. Second are reactions where changes in the "coordinative relationships" of participating atoms occur. An example of this is the change from Cd^{2+}, where the coordinative partner is water (i.e., Cd and water are chemically bound to each other) to $CdCl_4{}^{2-}$, where the coordinative partner is the chloride ions (Cd and Cl are chemically bound to each other). Both acid–base, precipitation and complexation reactions fit this category. Reactions occurring in environmental systems are often impossible to separate conceptually because of the system complexity (8). For instance, example 1 in the Introduction

[Fe(II) to Fe(III) interconversions] involves all of these types of reactions. Detailed discussion of these reactions can be found in chemistry textbooks and in relation to environmental systems in Stumm and Morgan (7) and Buffle and Stumm (6). In this review, we concentrate on complexation reactions.

A metal complex is formed by the donation of electrons from a ligand to a metal; this is a stable association of metal and ligand whose characteristics are different from the individual components. The simplest example is that of the hydrated metal, sometimes termed "free" or "dissolved". (Note: It is important to distinguish between the term dissolved in this sense and the operationally used term dissolved, which is used to denote metals passing through a standard membrane during filtration. In the latter definition, a fraction of colloid-bound metals is included.) The hydrated metal ion is often written simply by excluding the coordinated water (as in example 2 above with Cd). Other ligands will always be indicated, as when the Cd is bound to chloride ligands.

Typical ligand groups include

1. oxygen groups: water; various types of organic groups (carboxylic acids, ketones, etc.), which may be in solution or more importantly as part of colloids and surfaces; various types of inorganic groups (silicates, oxides) mostly occurring as solid-phase material;
2. sulfur groups: thiols, thioethers, and other compounds, which may either be simple solution compounds or as part of larger compounds such as humic substances; and
3. nitrogen groups: for instance, amino acids and humic substances.

Solid phases containing ligand groups capable of binding metals in a comparable way to solution phase ligands play a vital role in determining metal speciation. Often this role is dominant as solid material contains a much higher concentration of ligand groups and their associated metal ions compared with the solution phase.

Metal speciation (e.g., the distribution of metal between solid and solution phase) depends on both the solution conditions and the nature of the solid phase. For instance, pH (related to concentration of hydrogen ions, H^+) has a major impact on speciation because it competes directly with metal ions for ligand sites. Generally, as the pH is lowered (higher concentration of hydrogen ions), metal ions tend to occur in the solution rather than in the solid phase. Other factors, which influence metal speciation through complex mechanisms, include ionic strength and the concentration of dissolved organic matter. The role of solid-phase material is also essential in determining the solid: solution distribution; the roles of oxides and organic matter are particularly important.

MEASUREMENT OF METAL SPECIATION

Despite the importance of metal speciation and the major advances in the last few years, speciation measurement remains complicated because of the difficulty of unambiguously interpreting an analytical signal in terms of a chemical species. Ion-selective electrodes can specifically measure the free metal ion activity (concentration) of metals such as copper, but generally they cannot measure the low levels of metal in unpolluted waters (9). Other techniques capable of measuring labile metal complexes include voltammetric methods and various competition methods using ion exchange resins, solid phases or solvent extraction (10). In addition, there are a number of physical separation methods in use such as filtration, centrifugation, and dialysis. When combined with a method for measuring total metal concentration, these give size-based metal speciation data (5). However, the data extracted are, at least to some extent, operational.

MODELING METAL SPECIATION

Similarly to the measurement of metal speciation, modeling has made immense advances during the last 10–15 years. However, the complexity of the systems studied and the difficulties of speciation analysis mean that many fundamental difficulties have not been solved. For instance, speciation modeling assumes that the aquatic system modeled is at chemical equilibrium (11). For many environmental systems, this is not the case. For instance, redox reactions and many sorption reactions of metals to organic surfaces may not be at equilibrium. The difficulties in fully and rigorously modeling these systems can be understood if we consider some of the components present in natural waters. These include

- solution phase inorganic ligands (e.g., chloride, carbonate, sulfate)
- solution phase organic ligands (e.g., amino acids, EDTA)
- inorganic colloids and surfaces (e.g., oxides, silicates, carbonates)
- organic colloids and surfaces (e.g., humic substances, microbial exudates)
- mixtures of ligands and metals
- variety of solution conditions

A number of model types have been used successfully to interpret metal interactions in laboratory systems. Generally, solution phase speciation is relatively well understood. Additionally, much progress has been made in modeling metal interactions to oxide surfaces and humic substances (7,11), and development and validation continue (12). Individual models have been brought together in easy-to-use computer packages called speciation codes. There are now dozens of speciation codes that have been developed from the 1960s onward, often for very different purposes and with their own strengths and weaknesses. Despite this, the use of a valid, predictive speciation model for use in natural waters remains an elusive goal, toward which much effort is focused.

SUMMARY

Trace metal speciation is defined as the distribution of the metal among different physicochemical forms. Speciation has important implications for the bioavailability, toxicity, and environmental transport of metals. For instance, free and colloidal forms of the metal may tend to remain in solution; larger particle-bound metal tends to sediment out and is removed from the water column. This difference in behavior results in geochemical fractionation of different metal forms and results in differences in both the fate and behavior of the metal. Additionally, the size of a metal complex may be an important parameter in understanding metal uptake by organisms, although in more complex ways because of biological processes. However, despite major advances in our understanding, methods of measuring and modeling metal speciation require significant development before they can confidently provide rigorous understanding in this important area.

METAL ION HUMIC COLLOID INTERACTION

Horst Geckeis
Institut für Nukleare
Entsorgung
Karlsruhe, Germany

INTRODUCTION

Humic and fulvic acids in natural water are well known to have significant impact on metal ion bioavailability and mobility in aquifer systems. In natural water, toxic heavy metals, rare earth elements, and radionuclides such as the actinide ions are frequently found to be attached to natural organic matter such as humic and fulvic acids. These complexes are known to be of high kinetic and thermodynamic stability under given geochemical conditions and therefore may control trace metal transfer to bioorganisms and their transport in soil and groundwater systems. For those reasons, the interaction of metal ions with such humic matter is a major issue in a number of research fields such as environmental monitoring, risk assessment of contaminated sites, and nuclear waste disposal. In order to understand and to assess the impact of humic and fulvic acids on the behavior of trace metals, we need to know the interaction mechanisms, complexation kinetics, and finally thermodynamic data that can be implemented into geochemical speciation codes. A large spectrum of experimental methods is used for obtaining (1) insight into the humic acid structure and its properties as a complexing ligand, (2) quantitative information on metal ion speciation in humic containing water, and (3) molecular insight into the metal–humic interaction mechanism.

The ongoing development of understanding and experimental methods still makes the research on humic matter quite a dynamic area. Besides this short overview of the current state of the art in humic–metal ion interaction research, more comprehensive reviews on various aspects of metal–humic interaction are available (e.g., see Reference 1).

BASIC PROPERTIES OF HUMIC ACID

Humic/fulvic acid is a class of organic substances in the natural carbon cycle with a high stability and comparably high residence time (2,3). It is found in different sources, such as dissolved in natural water and as constituent, especially in soil, sediments, and brown coal. Humic acid is used both as a collective term for humic substances with a sufficiently high content of hydrophilic groups that dissolve in pH neutral range and as a specific term for the fraction that is dissolved in pH neutral range and flocculates in the acidic range with the complementary fraction of fulvic acid, soluble also under acidic conditions. In the following, humic acid (HA) is used in the general sense (humic and fulvic acids).

The composition, mass distribution, and functional group content vary within limits, reflecting different origins and histories. Disregarding sulfur and nitrogen (present in varying low concentrations generally on the order of up to around 1% by weight), the atomic composition is dominated by carbon, oxygen, and hydrogen. The contributions of these substances vary around $CO_{0.5}H$; that is, the formal oxidation state of carbon is around zero.

It should be borne in mind that description of the metal ion–humic colloid (or humic acid and fulvic acid as humic colloid constituents) interaction has been hampered in the past by large uncertainty concerning the structure of humic and fulvic acids. For a very long time, the molecular mass was given by number from around 10,000 to 100,000 or higher (2). Recent application of advanced mass spectroscopic methods [matrix assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF), electrospray ionization mass spectrometry (ESI-MS), and TOF–secondary ion mass spectrometry (TOF-SIMS)], Overhauser nuclear magnetic resonance (NMR), and the use of size/diffusion velocity-based methods [size exclusion chromatography (SEC) and flow-field flow fractionation (FFF)] show that the mass distribution maxima are considerably lower, centering at masses below 1000 daltons and ending at around 3000 mass units (4,5). This means that several assumptions made in the past, concerning, for example, assumed pronounced macromolecular polyelectrolyte character, have to be reassessed today. In dissolved form, the molecules are highly hydrated and possibly form associates. Therefore, the size distribution is generally determined to lie within a few nanometers in diameter. The proton exchange capacity can reach up to 14 meq/g (6), where protonation/deprotonation takes place from about pH 10 down into the acidic range (below pH 3 a considerable number of the groups are still ionized). Carboxylic types of groups are normally quantified with about one-third of the total capacity. The rest are mainly ascribed to phenolic-type groups. The carboxylic groups with pK_a values around 4 account for the humic negative charge at even low pH, while the phenolic sites tend to deprotonate in the high pH region only (pK_a around 10).

MODELING APPROACHES

Transformation of species distribution data to complexation constants is not trivial for humic acid. Today there is still no general agreement. Major challenges are the difficulty to take the inherent heterogeneity of humic acid functional group characteristics into account, the appropriate selection of an electrostatic model, and finally the applicability to complex multicomponent real systems with a broad variability in water chemistries. Different model approaches have been developed.

A relatively simple nonelectrostatic approach has been applied to estimate metal ion speciation in a humic-containing groundwater (7). The authors found the accessibility of functional groups for interaction with metal ions to vary with water chemistry (pH, ionic strength) and the origin of the humic acid under consideration. Taking such variability into account by an experimentally determined value for the capacity of metal ion loading under given conditions allowed the determination of complexation constants for a variety of metal ions that are invariant with metal ion concentration, ionic strength, and pH. The hitherto most widely applied humic acid complexation models (8) are the more sophisticated WHAM (Windermere humic aqueous model) (9) and NICA (nonideal competitive adsorption)–Donnan model (10). Both approaches take metal ion interaction with carboxylate and phenolic groups into account. Heterogeneity of functional groups is considered in WHAM by a discrete binding model postulating four different subsites for each functional group type, that is, carboxylic and phenolic sites. In the NICA–Donnan approach, a continuous site distribution is implemented. Both models use Donnan-type expressions for taking electrostatic effects into account. The model assumption of a Donnan gel phase varying with ionic strength is certainly debatable for the very small humic acid molecules but appears to be able to mimic the surrounding diffuse double layer (11). A comprehensive data set on generic values on deprotonation and metal ion complexation constants for a variety of metal ions is available for both codes (12,13) and at least allows for a first estimation of metal ion speciation in complex systems containing humic matter even though parameter adjustment turns out necessary in many specific cases.

Figure 1 shows trends for complexation constants derived from different model approaches for several metal ions. Complexation constants taking an experimentally obtained loading capacity into account are shown in Fig. 1a (14). The bars reflect the uncertainty of the data obtained by applying a multitude of different speciation methods ranging from ultrafiltration to fluorescence spectroscopy. Log ß* values describing the complexation reaction $Me^{z+} + HA(z) \rightleftharpoons MeHA(z)$ increase—as one may expect—more or less with increasing charge of the metal cations and their tendency to hydrolysis in solution. $HA(z)$ corresponds to the accessible site concentration. The fact that the derived complexation constants do not exactly follow the trend in hydrolysis constants suggests the possible influence of steric hindrances. A similar picture can be obtained by plotting generic data obtained from reanalysis of literature data by using the NICA–Donnan approach (Fig. 1b) (12). Those constants K_1 and K_2 represent median affinities of metal ions to HA proton exchanging groups, which are modeled by a continuous site distribution with two maxima.

SPECIATION METHODS

Experimental approaches to differentiate humic-bound metal ions from other species and to characterize the metal–humic compound can be roughly subdivided in two groups:

1. Physical or chemical separation of bound humic from molecular metal ions (invasive speciation).
2. Spectroscopic methods (noninvasive speciation).

Different experimental methods are used for obtaining the different types of information. For the purpose of determining interaction constants, quantification of the noncomplexed and complexed ions is required.

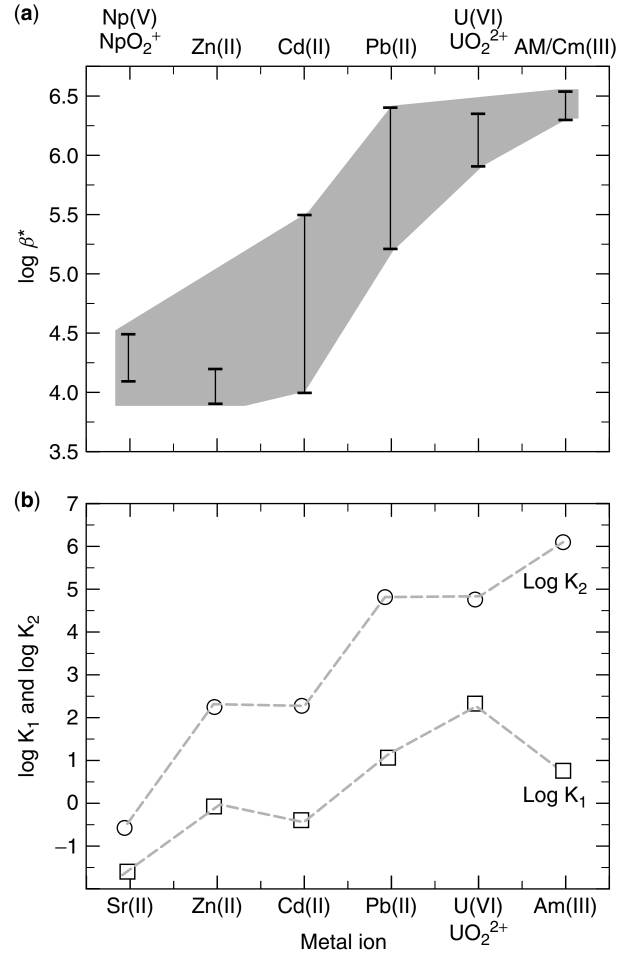

Figure 1. HA complexation constants for various metal ions obtained by using different model approaches. Data in part (**a**) are taken from Reference 14; those in part (**b**) correspond to the NICA–Donnan model approach (12). For explanation see text.

Experimental methods frequently used for determination of the species distribution in the metal ion–humic acid system are given in Table 1. Species distribution can be obtained by separation of the metal ion and the humic acid (complex) by size, density, or charge. Application of such methods is associated with uncertainty with respect to loss of substance, incomplete or uncertain species separation, possible kinetic rearrangements during separation, and problems related to changes in chemical composition. For this reason, methods are preferred where equilibrium is maintained. Frequently applied speciation tools for a number of trace metal ions such as Cu, Cd, Zn, and Pb are the electrochemical methods. Notably, anodic stripping voltammetry (ASV) achieves very low detection limits but intervenes in chemical equilibria and in many cases provides some kind of "operational" speciation. It is possible to differentiate "labile" metal ion species (i.e., free ions and readily dissociating complexed species) from stable or inert complexes.

Spectroscopic methods shown in Table 1 can give the species distribution without disturbing the equilibrium conditions. In general, absorption spectroscopy requires relatively high metal ion concentrations exceeding the ranges relevant to natural conditions. Fluorescence spectroscopy using appropriate fluorescent metal ions as probes [e.g., U(VI), Eu(III), Cm(III)] usually provide higher sensitivity for both excitation and emission. The humic acid itself is also fluorescent. The humic acid fluorescence intensity is quenched by metal ion complexation and thus the degree of fluorescence quenching can be used to study the metal ion–HA interaction and to quantify the complexation reaction. Probing the coordination environment for insight into the structure of the complex is specifically possible by X-ray absorption spectroscopy methods such as EXAFS and XANES as well as multinuclide nuclear magnetic resonance (NMR) spectroscopy. Examples for all these methods are given below.

METAL ION–HA INTERACTION MECHANISMS

Interaction of metal ions with humic/fulvic acids in principle may proceed via different pathways (see Table 2). Those individual mechanisms cannot be differentiated just by physical and/or chemical separation. In many cases spectroscopy can help to identify the binding mode and provide even details of the metal ion coordination environment. The following section is certainly not complete and only aims to give a rough overview into recent investigations on metal binding to humic/fulvic matter.

Complexation to Humic/Fulvic Acid

Various spectroscopic methods have been applied to gain insight into the coordination of the metal–humic/fulvic acid binding. Cu(II) is found to interact with four oxygen or two oxygen and two nitrogen atoms in a tetragonal coordination environment as shown by ESR (27). Later studies combining EXAFS and XANES spectroscopic experiments seem to verify the contribution of N ligands to the Cu(II) coordination (28). Studies on Cd(II) complexation with humic acid by EXAFS resulted in coordination via six oxygen atoms (distances 2.297 Å) (29). It seems to be clear that only carboxylate groups coordinate with Cd(II) as suggested by ^{113}Cd-NMR (30). Similar findings are recorded for the Ni(II) coordination with soil fulvic acid by EXAFS (31). Different to those *d*-transition metal ions, organomercury ions such as $Hg(CH_3)^+$ mainly bind to organic sulfur groups, for example, the thiol or disulfane groups. After saturation of those groups, coordination to oxygen atoms is found by EXAFS (32). Inorganic Hg(II) ions appear to form bidentate complexes with one thiol and one oxygen containing functional group (33). Al(III)–FA interaction studied by ^{27}Al-NMR suggests a coordination by carboxylic acid groups very similar to that observed in the oxalate complex (34). Formation of binary humate and ternary hydroxo and carbonato humate complexes are found for the interaction of trivalent actinides such as Am(III) and Cm(III) by UV/Vis absorption and notably the time-resolved laser fluorescence spectroscopy (TRLFS) (35,36). Such ternary species have rarely been taken into account by most model approaches up to now, but they appear to be even dominant

Table 1. Examples of Experimental Methods Used for Determination of Species Distribution (Complexed and Noncomplexed Metal Ions) in the Metal Ion–Humic Acid System and Methods Providing Analytical Information on the Nature of Such Complexes

Methods	Principle
Invasive	
Ultrafiltration, dialysis, ultracentrifugation, flow-field flow fractionation (FFF), size exclusion chromatography (SEC)	Size- or density-based separation (15–18,48)
Ion exchange, electrophoresis, Donnan membrane	Charge-based separation (19–22)
Ion selective electrodes (potentiometry), anodic stripping voltammetry (ASV)	Separate determination of noncomplexed or “labile” metal ion species (23,24)
Noninvasive (or Minimum Invasive)	
Fluorescence quenching, time-resolved laser fluorescence spectroscopy (TRLFS), UV/Vis, IR absorption	Detection and quantification of the complexation reaction via spectral shifts, emission intensity variations, fluorescence lifetime variations (provides to some extent information on coordination environment) (25,26) (see section below)
X-Ray absorption spectroscopy (EXAFS, XANES)	Absorption spectrum fine structure provides information on coordination environment (see section below)
Nuclear magnetic resonance spectroscopy (NMR)	Chemical shift provides chemical information on coordination environment (see section below)

in the near-neutral range in typical groundwater. It is noteworthy that TRLFS studies can be carried out at metal ion trace concentrations. For Cm(III) concentrations as low as 10^{-8} mol/L are sufficient. Such low metal ion concentrations are not accessible by most other spectroscopic methods. The tetravalent actinide Th(IV) studied by XPS and EXAFS turned out to mainly interact with carboxylic groups and was found to be coordinated by 9–10 oxygens at a distance of 2.43 Å (37), similar to trivalent ions such as Tb(III) (38). The coordination of trivalent metal ions like Eu(III) via carboxylate groups has been unequivocally verified by studying the C1s NEXAFS spectra of the humic acid (39). The $\pi^*_{C=O}$ transition of the carboxylate groups is clearly depressed upon complexation with Eu(III) ions. Hexavalent $UO_2{}^{2+}$ ions are also found to interact only with carboxylate groups as shown by EXAFS study. Phenolic groups appear to be of minor importance as a coordinating ligand (40).

Metal Ion Binding to Inorganic–Humic Agglomerates

Metal ion–HA interaction in natural systems tends to be complicated by the existence of both mineral surfaces and nanosized mineral particles, both partly coated with HA. Simple additive approaches—that is, assuming the metal complexation to be accomplished by interaction with the mineral surface and independently with sorbed and dissolved humic acid—often tend to underestimate the sorbed metal ion fraction (41,42). One possibility for the discrepancy may be the formation of ternary complexes such as ≡S–O–Me–HA (where ≡S–O stands for a deprotonated mineral surface hydroxyl group and Me for the metal ion). A recent study claims, on the evidence of fluorescence spectroscopic experiments, that such ternary complexes indeed exist in the γ-Al_2O_3/HA/Cm(III) system (43).

Formation of Inorganic Colloids Stabilized by Humic/Fulvic Acid

In many cases, redox reactions are involved in the metal ion–humic interaction. Such processes can also be followed by EXAFS and XPS as has been shown for the reactions of Np(V), Pu(VI), and Tc(VII) (44–46). Humic bound Fe(II) and/or quinone groups are thought to act as electron donors. In all those cases it turned out that precipitating oxyhydroxides of the reduced tetravalent species to some extent are kept in solution as colloidal species stabilized by humic acid coatings. The differentiation of Me–HA complexes and colloid–HA agglomerates becomes challenging in such systems because pronounced long-term kinetic effects are involved in such redox reactions. Those studies were performed to investigate the possible behavior of radionuclides tentatively released from a nuclear waste repository. But inorganic colloid–humic aggregates have also been found to dominate the transport of trace elements like iron (47). The binding state of Fe(III) in a river colloidal matter was scrutinized by combined electron paramagnetic resonance (EPR), transmission electron microscopy (TEM), and FFF experiments. It turned out that the total Fe(III) was distributed between humic acid complexes, FeOOH colloids, and structurally

Table 2. Possible Binding Modes of Metal Ion Interaction with Humic Acid (HA)

	Interaction Mechanism	Dissociation Rates^a
	Formation of inner-sphere complexes with functional groups of the HA macromolecules	↑ Increasing
	or	
	Interaction with more than one HA entity. In both cases the formation of ternary complexes with HA and other dissolved ligands are possible.	
	Surface sorption to inorganic colloids (e.g., aquatic clay colloids), which in turn are stabilized by humic/fulvic acid coating.	
	Inclusion of the metal ion into inorganic colloids stabilized by humic/fulvic coating due to formation of oxyhydroxide colloids as a consequence of redox reactions or formation of solid solutions.	

^{a}In a qualitative way, the dissociation rates of metal ions from colloidal species increase from bottom to top

incorporated in clay colloids, the last two agglomerated with humic matter. Similar observations have also been made for trace elements such as the naturally abundant lanthanides, uranium, and thorium in a humic-rich groundwater (48).

It is obvious that the metal ion interaction mode with humic matter is of importance for the assessment of HA influence on the geochemical cycle of trace elements. Notably, the kinetics of the metal ion desorption from the individual HA compounds varies considerably depending on the interaction mechanism (see Table 2). Even though there is still uncertainty concerning the exact coordination environment of HA bound metal ions, the coordination of most metal ions with HA carboxylate groups is now verified by a number of spectroscopic studies.

KINETICS

The metal ion interaction shows a sequence of reaction/exchange velocities. Primary association is rapid, followed by rearrangement to kinetically more stable binding. Dissociation is considerably slower and rates are decreasing with increasing aging time. Dissociation shows different kinetic modes, varying from seconds to weeks (49,50). The metal ion is believed to either migrate to stronger binding sites (51) or move to inner sites of the humic macromolecular structure (52). In view of the now generally accepted relatively small size of the humic acid molecules, the existence of a significant inner space becomes somewhat implausible. It is more likely that intermolecular bridging by polyvalent cations leading to the interaction of metal ions with more than one humic acid entity (see Table 2) become responsible for the observed time-dependent decrease of dissociation rates. The existence of such metal-induced humic agglomeration even at trace metal concentrations has been visualized, for example, by flow-field flow fractionation studies (48) or by using fluorescence probes (53). The metal-induced aggregation of natural organic matter is furthermore well known from studies in the marine environment (54).

Investigating humic matter in a natural groundwater revealed that part of the highly charged metal ion inventory of the humic acid shows a very slow dissociation, basically irreversible for time scales that can be studied under laboratory conditions. These metal ions show a different behavior from that observed for metal ion–humate complexes synthesized under laboratory conditions (48). The exact nature of binding for this inventory is not yet understood. One possibility is association with nanosized inorganic mineral presumably as solid solution. Various support for that assumption is found in analyzing various groundwater humic colloid size fractions: while humic acid is found mainly at sizes <10 nm, a major fraction of natural colloid-borne polyvalent elements such as thorium and rare earth elements are found in larger colloids >30 nm. Since metal ion dissociation from such types of colloids is very slow, their colloid-mediated transport becomes very relevant. Such processes are of interest in areas such as colloid-facilitated radionuclide transport in nuclear waste disposal research. A final conclusion also with regard to the relevance of such mechanisms to the toxic metal transport will require further investigations.

OUTLOOK

Metal ion interaction with humic acid is still a challenging field. A lot of new insight into the metal ion coordination could be obtained by the application of sensitive spectroscopic and other analytical methods. Knowledge about the specific binding state at least allows the estimation of humic-bound metal behavior in a semiquantitative way. There are chemical models available that—with some drawbacks—are able to predict metal ion speciation to some extent in humic-containing media. Open questions still remain concerning the “real” structure of humic/fulvic substances under *in situ* conditions and regarding the “real” configuration of metal ion–humic complexes. Application of newly emerging advanced analytical methods will certainly drive the research field and improve both the insight into the “real” metal–humic interaction mechanisms and the accuracy of model predictions.

HEAVY METAL UPTAKE RATES AMONG SEDIMENT DWELLING ORGANISMS

Jos P.M. Vink
Institute for Inland Water
Management and Waste Water
Treatment–RIZA
Lelystad, The Netherlands

INTRODUCTION

Sediments of rivers, river banks, and floodplains are commonly characterized by elevated levels of heavy metals such as Cd, Cu, Cr, Ni, Pb, Zn, and As (1). Organisms that occur in these sediments are known to accumulate these metals (2,3), which, in turn, are passed on through the foodweb. However, the development of well-defined quality criteria for (aquatic) sediments is seriously hindered mainly because of three reasons:

1. Laboratory exposure tests that are conducted with organisms (bioassays) do not consider the geochemical composition of the sediment *in situ* and do not link temporal changes in chemical speciation with toxicological effects.
2. It is usually unclear which routes of exposure contribute to accumulation in organisms and dictate the adverse effects.
3. There is a general uncertainty about the relative contributions of the various metal species that take part in biological uptake.

The general concept of (bio)availability of metals becomes clear when body concentrations of either aquatic or terrestrial organisms collected from the field are compared with those performed in exposure tests using disturbed, oxygenated, and spiked sediments or waters. In the latter case, concentrations are mostly significantly higher, both in the close environment and in the organism itself. This phenomenon is explained by chemical speciation, which is based on the lability of metal species. The most labile form is the free dissolved ion, followed by dissolved inorganic metal–ion pairs (e.g., M–OH, $M-CO_3$, M–Cl) and organically complexed forms (M–DOM).

This concept of lability, however, has in recent years been more often theorized than actually shown by empirical data. This is mainly due to the fact that only very few techniques have become available to actually measure free ion activities, let alone to measure these periodically during exposure of organisms. The concept of the free ion activity model (FIAM) assumes that free aqueous metal ion concentrations, rather than the total or dissolved concentration, largely determine the toxicological or biological effect that is observed in organisms that are exposed to water or sediment containing heavy metals.

In a critical literature review, Campbell (4) concluded that studies that are suitable for testing the FIAM concept in the presence of natural dissolved organic matter (DOM) are extremely scarce. There are numerous studies that report on the effects of DOM on metal bioavailability, but virtually all of these are qualitative in nature (speciation is underdefined). The few quantitative studies (5–9,11) are, however, not in agreement, and the applicability of FIAM to natural waters (with DOM) remains to be demonstrated. It is concluded that “future progress would be greatly aided by the development of methods capable of measuring the free ion concentration of metals in the presence of DOM.”

Recently, a new technique was introduced aimed at tackling the difficulties described above. This technique was introduced as Sediment Or Fauna Incubation Experiment, SOFIE in short (12). With this technique, it is possible to quantify very labile metal fractions, including free metal ions, in pore water, at low oxygen and reduced conditions, repeatedly, and in a nondestructive manner to the sample. Bioassays are conducted simultaneously in the same setting. Sediment samples are obtained in an undisturbed manner, including the overlying surface water.

Here, we deal with the gradients and speciation of metal species, including free ion activities, over water–sediment interfaces. The effect of metal uptake by sediment dwelling organisms on metal speciation, and vice versa, is discussed.

METHODS

Materials

This study was performed with a novel experimental technique (EU patent 1018200/02077121.8, October 2001, J. Vink, Rijkswaterstaat), which was introduced as Sediment Or Fauna Incubation Experiment, or SOFIE®. The method was described in detail by Vink (12). In short, this “cell” consists of a core, 190 mm radius, 200 mm height, which is used as a sampling device to obtain undisturbed sediment, and the corresponding surface water. After sampling, this water–sediment system becomes part of the cell. Specific pore water probes, constructed from permeable PES polymers, are attached at 5-mm layer increments. Probes are directly connected to preconditioned ion-exchange microcolumns (MIC). A MIC contains a metal chelating polymer (styrene divinylbenzene copolymers, RI-718, containing paired iminodiacetate ions that act as chelating groups), which is highly selective to metals. Retained metals are liberated from the polymer with an acid-extraction procedure. In this setup, ion exchange between pore water and exchange polymer is practically instantaneous and is therefore executed at the reigning geochemical status, including redox potential, of the probed sediment layer.

With these cells, water–sediment interfaces from six different river systems in The Netherlands were sampled (Table 1). Sites were selected for their degree of contamination, physical properties, or their general representativeness for sediments commonly found in the river. Aqueous steady-state conditions were determined by probing the water/sediment on three different occasions. Location MB was probed every 5 mm, but the other locations were probed in intervals that coincided with the layering of the sediment—which could be observed through the transparent cell wall. After the introduction of test organisms, chemical speciation was monitored in time and depth.

Exposure Tests with Benthic Organisms

Species of the oligochaete *Limnodrilus* (family Tubificidae) and the mosquito larvae *Chironomus riparius* were chosen for accumulation test because of their wide abundance in aquatic systems and their importance for the ecological food chain. Both species are sediment dwellers, which means that they live in close contact with the sediment. Populations were bred in the laboratory under contaminant-free conditions. Oligocheate populations consisted mainly of *L. claparedeanus* and *L. hoffmeisteri* in equal amounts. Individuals with corresponding life stages (L2) were introduced in the cell in field-realistic densities (approximately 1250 oligochaetes and 220 chironomids, respectively). For locations MB and SW, only exposure tests with oligochaetes were performed. Body concentrations were measured periodically by sampling individuals from the population on seven occasions at 2–3 day intervals. They were allowed to void their gut for 48 h, which, based on dissection, was an adequate period. The organisms were freeze dried for 48 h and the dry weight was determined. Digestion was done in 500 μL of 14.9 M HNO_3 (Ultrex) at 180 °C. Metal concentrations in the digests were determined using inductively coupled plasma mass spectrometry (ICP-MS, Perkin Elmer Elan 6000). Dolt-2 (certified by the Community Bureau of Reference, BCR, Brussels, Belgium) was used as biological reference material.

Chemical Analysis

Aqueous concentrations of NO_3^-, NO_2^-, SO_4^{2-}, PO_4^{3-}, and Cl^- were measured with segmented ion chromatography (Dionex AS50 chromatography compartment, ED_{50} electrochemical detector). Limits of detection (LOD) ranged from 0.025 $mg{\cdot}L^{-1}$ for NO_2^- to 0.05 $mg{\cdot}L^{-1}$ for PO_4^{3-}. As, Al, Ca, Cd, Co, Cu, Cr, Fe, Mg, Mn, Ni, Pb, and Zn analyses were carried out with ICP-MS (LOD min/max: 0.003 $\mu g{\cdot}L^{-1}$ for Cd to 6.0 $\mu g{\cdot}L^{-1}$ for Zn). NH_4^+ analyses were performed by Skalar segmented flow analyzer SAN+

6250 matrix fotometer (LOD: 0.022 mg·L^{-1}). Dissolved organic carbon was determined with a Shimadzu 5000 TOC analyzer (LOD: 0.45 mg·L^{-1}).

RESULTS AND DISCUSSION

Table 1 shows the solid phase characteristics of the six sites. Steady-state concentrations in pore water and overlying surface water are shown in Fig. 1.

Typically, steep redox gradients occur over the water–sediment interface, more or less pronounced for the various sites. Redox-sensitive compounds follow these gradients: denitrification precedes sulfate reduction, and anaerobic conditions were reached in most cases within 15 mm from the water–sediment interface. The increasing reduction of ferric(III)oxyhydroxides to Fe(II), and manganese(V)oxides to Mn(II) results in increasing concentrations with depth of aqueous Fe^{2+} and Mn^{2+}. Pore water concentrations of Cd, Cu, Ni, Pb, and Zn in most cases tend to decrease with depth and coincide with sulfate reduction patterns. These metals most probably associate with sulfides and therefore become insoluble. Heavy metals, however, compete for binding opportunities between the reactive sulfide phase and relatively large amounts of dissolved organic matter, which keeps them in the aqueous phase. There is a pH range between the sites of almost 2 units.

Time-Varying Exposure Concentrations

Immediately after introduction of the test organisms to the water–sediment system, steady-state concentrations shifted. Oligochaetes and chironomids are sediment dwellers. They live in burrows and irrigate these with oxygen-rich surface water. Consequently, their immediate environment is oxidized, which in turn directly affects the chemical reactivity and bioavailability of metals that remain in the sediment. In Fig. 2, an example is shown of how aqueous concentrations of copper species change with time and depth during the exposure test (site MB).

Dissolved metal concentrations change with time, and so do specific metal species such as M^{2+}. These time-varying changes may follow first-order reaction kinetics:

$$dC/dt = kC$$

so the external concentration, or exposure concentration, at a given time $C(t)$ is written as

$$C(t) = C_i e^{k_0 t} \tag{1}$$

in which C_i is the initial concentration in (pore) water, and k_0 is a rate term that describes the increase or decrease rate of the initial steady-state concentration. In analogy, the free ion activity concentration at a given time, M^{2+} (t), may be written as

$$[M^{2+}](t) = [M_i^{2+}]e^{k_{0,\mathrm{act}} t} \tag{2}$$

The rates at which these concentration shifts occurred proved to highly affect bioaccumulation patterns, which is shown later.

Table 1. Sediment Properties

	Location					
	MB	GA	KV	HD	AS	SW

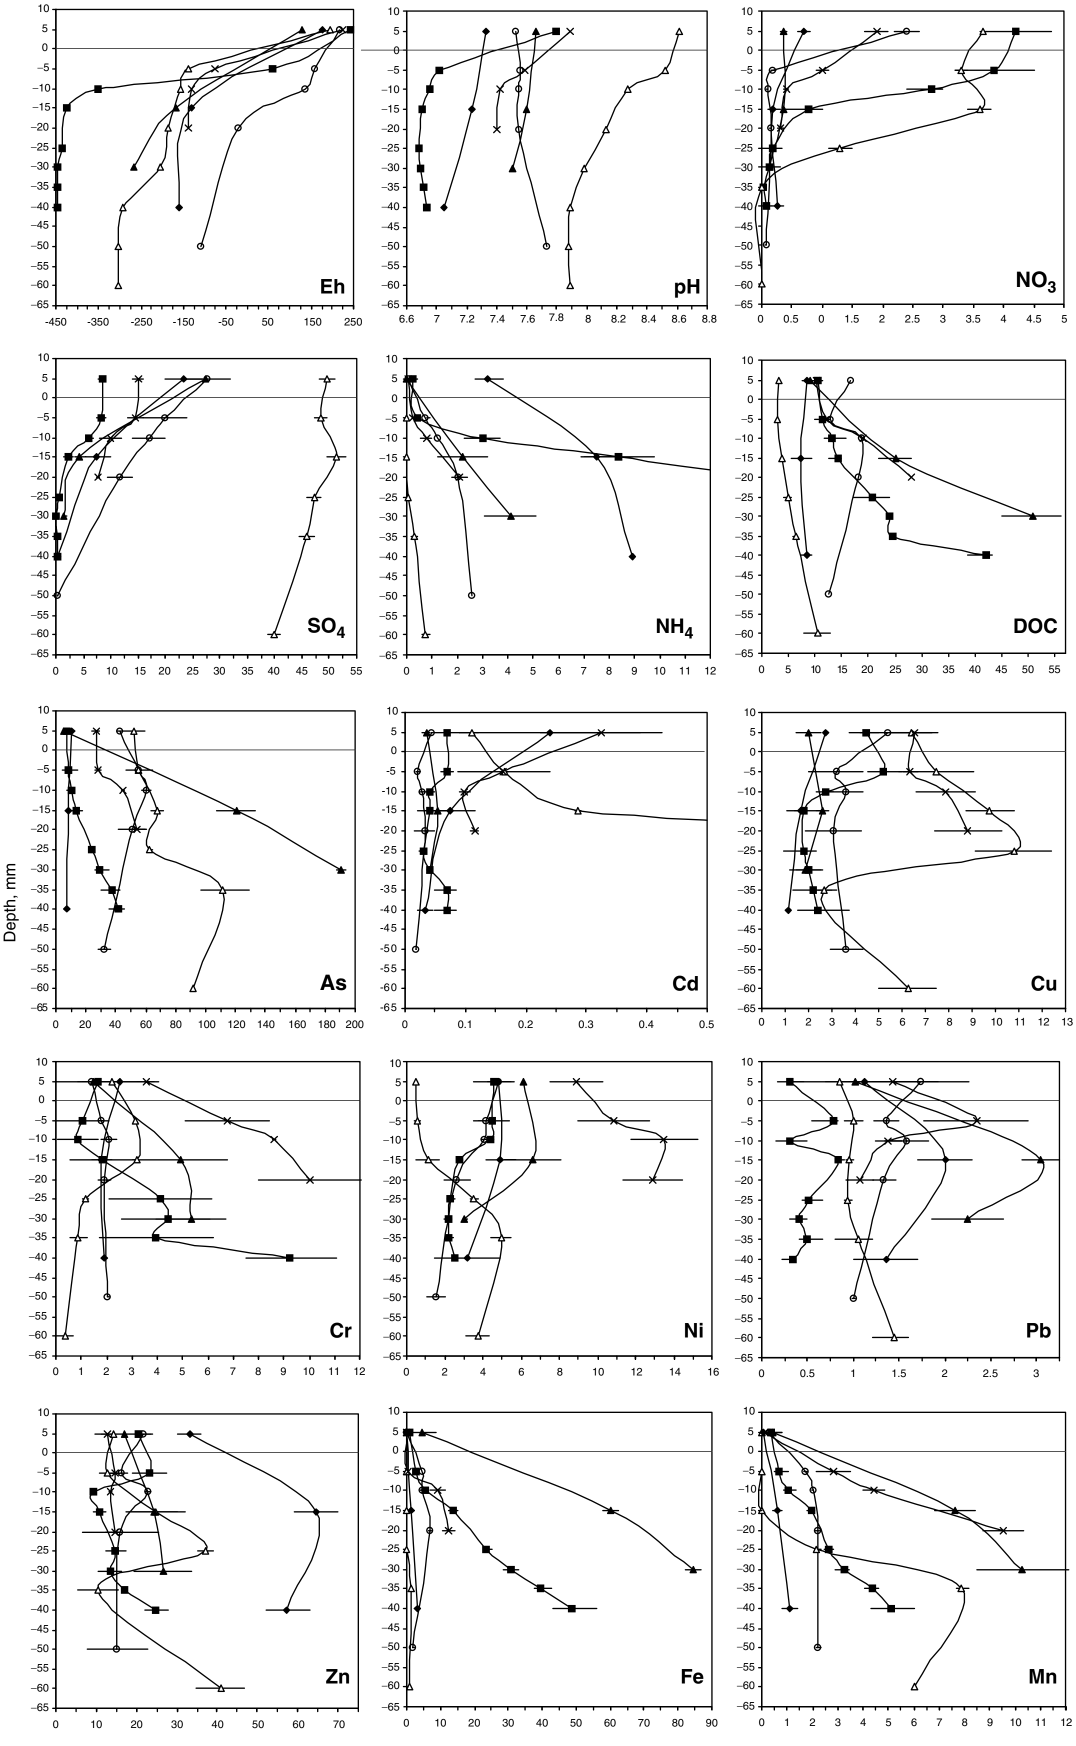

Figure 1. Aqueous steady-state characteristics for the six sites. MB (■); GA (△); KV (×); HD (O); AS (♦); SW (▲). E_h in mV; Fe, Mn, NO_3, SO_4, NH_4, DOC in mg/L; As, Cd, Cu, Cr, Ni, Pb, Zn in μg/L.

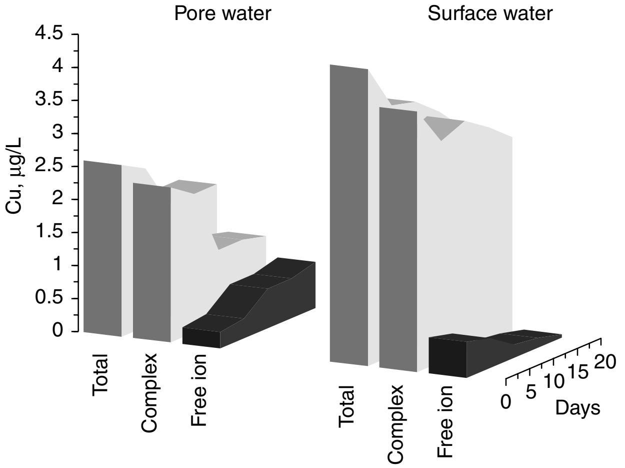

Figure 2. Example of time-dependent speciation shifts in overlying surface water and pore water (20 mm below water–sediment interface) during an exposure test. The free ion concentration in pore water increases, through oxidation, and is exhausted from the overlying water due to uptake by biota.

Uptake and Elimination by *Limnodrilus* and *Chironomus*

Metal uptake and excretion rates were approximated by a time/concentration-dynamic, two-compartment model. It is assumed that body concentrations vary with time and depend on uptake from the water phase with a certain rate. Uptake is at the same time accompanied by elimination (excretion) from the organism's body. Therefore,

$$dQ/dt = k_1 C(t) - k_2 Q(t)$$

with Q being the internal body concentration ($\mu g \cdot g^{-1}$ dw), k_1 and k_2 being uptake and elimination rate constants, respectively (d^{-1}), and t being time. This yields, for $Q(0) = 0$,

$$Q(t) = \frac{k_1 C_0}{k_2 - k_0}(e^{-k_0 t} - e^{-k_2 t}) \tag{3}$$

where C and k_0 are derived from Equations 1 and 2.

In analogy with the free ion activity,

$$Q(t) = \frac{k_1 [M^{2+}]}{k_2 - k_{0,\mathrm{act}}}(e^{-k_{0,\mathrm{act}} t} - e^{-k_2 t}) \tag{4}$$

With the introduction of k_0, time-dependent concentrations determine the overall exposure of organisms, and thus $Q(t)$. Note that elimination may partly be attributed to growth of the organisms during the exposure period. This separate loss term is not considered in the model.

To determine the consequence of *not* considering time-dependent concentrations, a one-compartment model was included for comparison. With this model, a constant uptake rate, a, is assumed, as opposed to concentration-dependent uptake. Body concentrations are then described as

$$dQ/dt = a - kQ$$

which yields

$$Q(t) = C_0 e^{-k \cdot t} + \frac{a}{k}(1 - e^{-k \cdot t}) \tag{5}$$

Figure 3 shows bioaccumulated amounts of some priority elements and heavy metals by oligochaetes and chironomids (site GA). Typically, metals are taken up at a certain rate (k_1), leading to increased body concentrations. After some time, elimination (k_2) exceeds uptake, and concentrations decline to reach a steady state. In general, bioaccumulated amounts can be ranked according to Ca > Fe > Mg > Zn > Al > Mn > Cu > Ti ~ Pb > Cr > As ~ Cd ~ Ni. Of both species, chironomids appear the most sensitive since they tend to take up these elements faster than oligochaetes and accumulate larger amounts (normalized to dry weight).

Examples of accumulation patterns for oligochaetes and chironomids for all locations are shown in Fig. 4. To test whether these sediment dwellers actually show different patterns at different locations (i.e., to determine location specificity), the accumulation data of oligochaetes and chironomids were statistically compared (two-tailed F-test, Mann–Whitney, $p < 0.05$). Results are summarized in Table 2 and show that locations do indeed matter. When distinguishing locations, both test species show the lowest sensitivity for chromium and nickel, which seem nondiscriminating. On the other hand, the combinations cadmium–chironomids and zinc–oligochaetes show a high discriminating potential. The fact that accumulation patterns on various locations are indeed different—also on locations with comparable dissolved concentrations—indicates that there is a difference in the actual bioavailability of metals.

Relation Between Time-Dynamic Speciation and Body Concentrations

To analyze the performance of the uptake and elimination models with varying exposure concentrations and speciation, the overall data set was divided into four subsets: two "environment compartments" (overlying surface water, and sediment pore water), each with two chemical "species" (total dissolved metal concentration, and free ion activities). Performance of the uptake–elimination models (Eqs. 3, 4, and 5) were tested with each subset. Results of measurements and corresponding model parameters C_i and k_0 were subsequently subjected to statistical analyses. As a descriptor for the goodness of prediction for the uptake–elimination model, the standard error of each model parameter was used rather than the correlation coefficient of the model with the measurements. The standard error is a measurement of the variability of a data point Y around the predicted value Y_p. It represents information about the goodness of fit in the same manner as the standard deviation does about the spread around the mean. The standard error is written as

$$sy \cdot x = \sqrt{\frac{\Sigma(Y - Y_p)^2}{n}}$$

By minimizing the sum of squares, values for k_1 and k_2 and corresponding standard errors were derived. Considering only Cu, Cd, Ni, Pb, Zn, and As, the data set consisted of over 1800 chemical and 608 biological measurements.

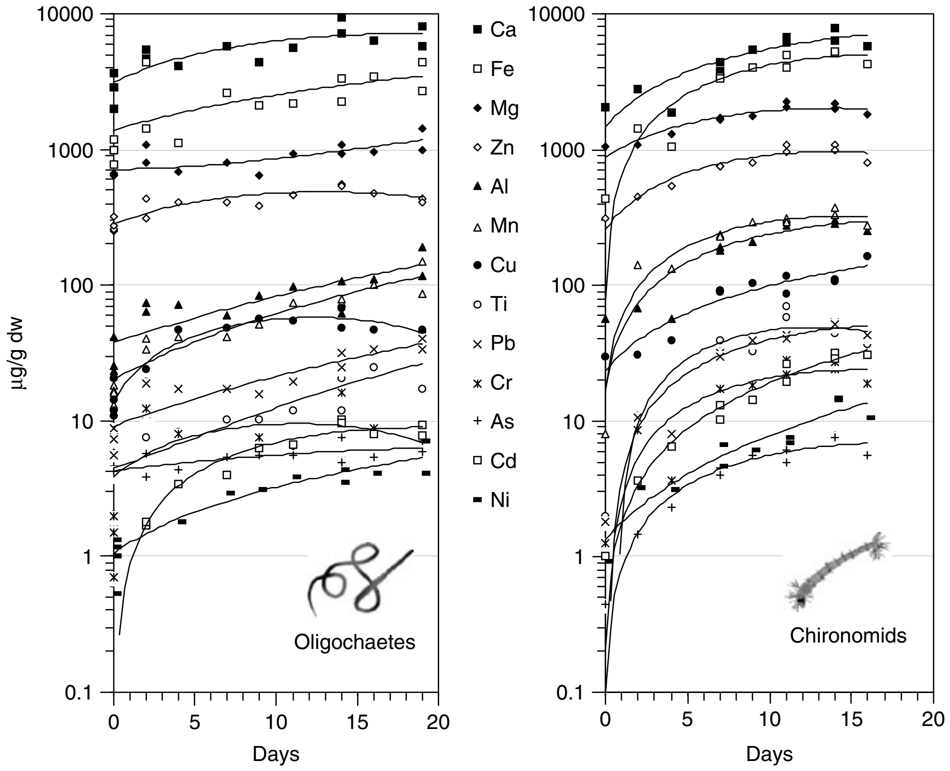

Figure 3. Bioaccumulation patterns of priority elements and heavy metals in two benthic species.

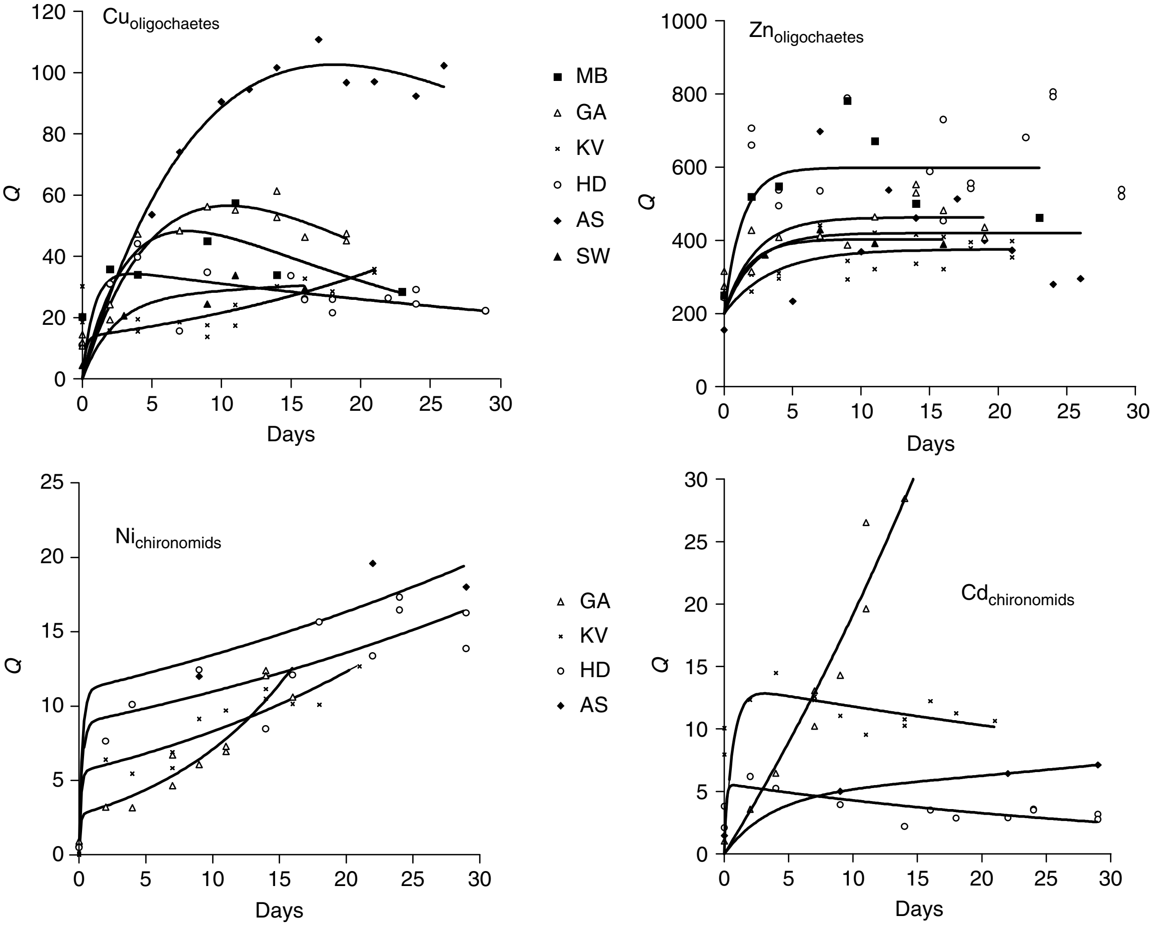

Figure 4. Examples of body concentrations in oligochaetes and chironomids with time. The solid line is the model prediction based on Equation 4 (Cd, Cu, Ni) and Equation 5 (Zn).

[a] Data for oligochaetes shaded gray; D, significantly different; ns, not significantly different.

Only those combinations with standard errors that were of the same magnitude or smaller than the values of k_1 and k_2 themselves were considered significant. This does not mean that other relationships between compartments, chemical species, and accumulation do not exist; this statistical criterion is necessary to identify the best model predictor, and therefore the most significant source of metals to biota.

The outcome of the modeling exercise and the statistical comparisons are summarized in Table 3. Chemical speciation and concentration shifts for the two compartments are shown on the left side. These were used as input for the biotic uptake models, for which results are shown on the right side. Only combinations where the statistical criterion was met ($sy \cdot x < k_1, k_2$) are shown. Obviously, the other combinations are thefore of less significance.

Negative k_0 values indicate a decrease in concentrations, positive values indicate an increase. Combinations of measured C_i and k_0 values were used as initial constants in the iteration procedure. The advantage of this approach is that variables that have a relatively large certainty or reliability do not participate in the iteration process as such. They do not need to be included, since $C(t)$, M^{2+}, and k_0 were actually measured with time. This is a large advantage, since the optimization procedure is now focused on the accurate estimation of the remaining variables k_1 and k_2, that is, the uptake and elimination rates.

The most important conclusion from Table 3 is that both benthic species appear to obtain their metals primarily from the overlying surface water and not from the sediment pore water compartment. Total concentrations in the sediment (mg/kg) are not indicative and do not reflect the magnitude of total body concentrations. Both test species accumulated the largest amounts of cadmium at site GA (chironomids even faced lethal concentrations), although sediment contents are second-lowest. In all cases, and therefore conclusively, the most important source for cadmium and nickel for oligochaetes is the free ion activity in the overlying surface water. In 100% of the cases, the measured C_{act} and k_0 combination for free ions in the surface water compartment yielded the best descriptors for accumulation patterns based on the two-compartment model. For copper, this seems valid in half of the cases. On some occasions, free ion concentrations dropped to a point where the contribution as a relevant source probably becomes negligible (see also Fig. 2). Potential sources of free Cu ions, such as humic complexes, have mostly slow dissociation kinetics that cannot make up for Cu-uptake rates by biota. Chemical dissociation is therefore rate-limiting.

Uptake from the sediment pore water was observed only occasionally, and solely, for lead. The source of Pb appears more variable, which is in agreement with the fact that the physiological mechanisms of Pb uptake are still unclear. It is occasionally suggested that uptake and elimination of Pb obey different mechanisms than in the case of the other heavy metals (i.e., an interaction between the free metal ion and a channel and/or carrier transport system in the external and/or internal epithelium), but this is yet to be demonstrated.

For zinc and arsenic, the performance of the one-compartment model was in 80% of the cases better than the model that used two compartments. External concentrations (i.e., outside the organism) obviously never became rate-limiting for uptake. In river sediments, Zn is mostly present in fair amounts, and the fraction of labile species, among them free ions, is mostly the largest of all metals. Most organisms regulate their Zn body concentrations very efficiently, and steady state is often quickly reached (see also Fig. 4). Dissolved arsenic does not yield significant free ion concentrations, being an oxyanion; the predominant species are arsenate or arsenite, and these are negatively charged.

It is also shown that uptake rates are not "universal constants." The variation of k_1 values over the locations may be significant. Kinetic processes therefore do indeed matter. The fact that the overlying water plays such a significant role in metal uptake should actually not be very surprising. Benthic organisms are often considered to be in close contact with sediment pore water, but species that live in burrows are actually in closer contact with overlying water because (1) the burrow inhibits direct contact between the organism and pore water, and (2) organisms exchange the water in their burrows with overlying water.

These presented findings provide a significant contribution to our understanding of chemical speciation of metals in water–sediment systems and subsequent metal

Table 3. Chemical Speciation in and Uptake from Different Compartments[a]

[a] C, concentration (µg/L); tot, total dissolved; act, free ion activity; k_0, k_1, k_2 are rate constants (d^{-1}); Q_{max}, maximum C in biota (µg/g dw); r^2, correlation coefficient. Values printed in italic are derived with the one-compartment uptake model.

uptake by organisms. It is demonstrated that the presence of benthic organisms in a water–sediment system has a significant effect on chemical speciation, and this has to be considered when performing bioassays and chemical tests. Body concentrations are regulated by temporal variations in metal concentrations and chemical speciation. The measurements illustrate that biological kinetics (uptake) are for most metals faster than chemical kinetics (dissociation of less labile or complexed metals). Exposure can therefore only be estimated and modeled when time-related changes in metal concentrations are taken into account. The construction of generic models that are capable of transferring chemical information to a biological response has undoubtedly a high priority. Knowledge of the free metal ion activity is a significant step forward. Still, it may in cases be insufficient to predict the biological response, since one must also consider potential interactive effects of hydrogen ions (4,10) or effects of other macrochemicals (13). In any case, it is concluded that an integrated cell such as SOFIE provides the necessary experimental tool to support, in a mechanistic way, environmental risk assessments of contaminants. This knowledge may in time be incorporated in the derivation of better-founded quality criteria for sediments.

METHEMOGLOBINEMIA

Daniel Shindler
UMDNJ
New Brunswick, New Jersey

INTRODUCTION

Methemoglobinemia is a disorder of the oxygen-carrying hemoglobin in red blood cells. One cause of methemoglobinemia is contaminated well water. There are also many non-water-related causes. Individuals are particularly susceptible to the development of methemoglobinemia during early infancy and during pregnancy. Exposure to certain foods, drugs, and chemicals may cause methemoglobinemia. Methemoglobinemia can also occur in the absence of environmental exposure as part of several inherited disorders.

BLUE BABY SYNDROME AND WELL WATER

In 1945, Dr. Hunter Comly from Iowa City, Iowa described the blue baby syndrome. Two infants developed a bluish-gray skin discoloration (medically referred to as cyanosis) as a result of being fed infant formula diluted with well water.

The water from these wells was found to have high concentrations of nitrate. Once nitrate contamination was recognized as a cause of methemoglobinemia in infants, an additional 278 cases in 14 different states were reported by Walton in 1951. Yet, despite awareness and well water surveillance for nitrate and nitrite content, cases of methemoglobinemia continue to be reported.

High concentrations of nitrate in drinking water can cause high levels of methemoglobin in the body. Nitrite (converted from the ingested nitrate) oxidizes iron in the hemoglobin of red blood cells to form methemoglobin, which lacks hemoglobin's oxygen-carrying ability. Oxidation occurs when oxygen-carrying ferrous (Fe^{2+}) iron loses an electron and becomes ferric (Fe^{3+}). If unrecognized and untreated, rising levels of methemoglobin progressively decrease the ability of red blood cells to carry oxygen.

SUSCEPTIBLE INDIVIDUALS

Infants are particularly prone to develop methemoglobinemia from nitrate in drinking water until about 6 months of age. In early life, their ratio of fluid intake to body weight is greater than in adults. The stomach bacteria of infants are more capable of changing ingested nitrate to methemoglobin-begetting nitrite. Gastrointestinal problems that frequently occur in infants, such as diarrhea and vomiting, seem to further increase their predisposition to develop clinically significant methemoglobinemia.

Pregnant women also have an increased predisposition to develop methemoglobinemia. Increased methemoglobin levels during pregnancy may cause spontaneous abortion. During March 1993, the LaGrange County (Indiana) Health Department identified three women who reported a total of six spontaneous abortions during 1991–1993 and who resided in proximity to each other; each had obtained drinking water from nitrate-contaminated private wells. A fourth woman from another part of the county had two spontaneous abortions after she had moved into a new home with a nitrate-contaminated private well.

NITRATES IN DRINKING WATER

Nitrate contamination of well water may come from easily identifiable sources such as sewage disposal systems or nearby livestock facilities. Other times the cause of water contamination is less obvious, originating from distant landfills, fertilized cropland, parks, golf courses, lawns, and gardens. Episodes of methemoglobinemia continue to occur in rural farm settings especially with shallow (less than 100 feet deep) domestic wells in a setting where nitrogen-based fertilizers are heavily used. These wells may not be tested frequently enough for fluctuating concentrations of nitrate, which (according to the Environmental Protection Agency) should be no greater than 10 parts per million (ppm) at all times. Runoff of contaminated surface water from cultivated fields into a well may happen after a flood. This mode of well water contamination may be especially common when the well is too shallow, poorly located, or badly constructed.

OTHER WATER-RELATED CAUSES

Contaminated well water is not the only water-related cause of methemoglobinemia. Nor is the danger of undiagnosed methemoglobinemia limited to infants. Nitrite containing boiler fluid additives contaminating the faucet water can be responsible. An outbreak in New Jersey grammar school children in October 1992 was caused by dilution of canned soup with hot tap water. The water boiler had been serviced 5 months earlier with commercial conditioner fluid containing nitrite, and it had not been started until the morning of the incident. In another incident in 1996, six adult office workers developed methemoglobinemia after drinking coffee prepared with water from a hot water faucet connected to a boiler with a defective backflow-prevention valve. The conditioning fluid in this boiler also contained nitrites. Boiling water before using it does not decrease the level of existing nitrate or nitrite in the water. Prolonged boiling may actually increase the concentration of existing nitrate and nitrite in the water.

As water is almost invariably involved in food preparation, it is also important to recognize dietary causes of methemoglobinemia. Although vegetables are washed and cooked in water, nitrates may not be originating from the water used for rinsing, cooking, or serving the vegetables, but rather from the vegetables themselves. Broccoli, carrots, cauliflower, collard greens, onions, and spinach all contain some nitrate. Fortunately, the amount of vegetable nitrate in the normal diet is insufficient to cause significant methemoglobinemia in adults. Yet, ingestion of concentrated vegetables (carrot juice, carrot soup, spinach water) has resulted in methemoglobinemia in susceptible infants. Methemoglobinemia caused by excessive vegetable ingestion is not confined to humans. A herd of cows consumed approximately 20 kg of onions per cow per day for 6 weeks, which caused methemoglobinemia in the cows. Five cows died, and two had spontaneous abortions.

Diaper washing and reuse has also been implicated in methemoglobinemia. Anilines are dyes that are used in laundry ink. Aniline labeled diapers have caused infant methemoglobinemia by direct absorption through the skin and possibly by spreading to other poorly rinsed diapers in the same laundry water. Children's crayons no longer contain methemoglobin-producing dyes, but commercial markers such as red wax crayons may still contain them. Skin contact with dyed blankets and freshly dyed shoes can also potentially cause methemoglobinemia.

NON-WATER-RELATED CAUSES

Nitrates are found in the normal diet, not just in vegetables but also in meat and fish preservatives, and as meat color enhancers. Sodium and potassium nitrate have both caused life-threatening methemoglobinemia when they were mistaken for salt or used inappropriately in meat preparation.

Certain medications contain nitrates. Silver nitrate is used on the skin to treat burns. Nitroglycerin is administered orally, intravenously, under the tongue (sublingual), and on the skin in patients with heart disease. Amyl nitrite is an inhaled medication that is abused as a recreational drug. Amyl nitrite and isobutyl nitrite may be sold as "room deodorizers" to avoid drug laws. Nitrite can also be inhaled accidentally. Firefighters responding to a fire where isobutyl nitrite was stored developed methemoglobinemia because of exposure to the products of combustion.

Many non-nitrate medications have caused methemoglobinemia. Several antibiotics have caused methemoglobinemia during routine administration. Topical anesthetics are common during medical and dental procedures. There are many reports of methemoglobinemia after their routine administration at all ages. They may be given to teething infants and consequently get absorbed into the bloodstream through the mucous membranes of the mouth. Topical anesthetic ointments can also cause methemoglobinemia if they are absorbed through the skin. Anesthetic ointments given for diaper rash should be discontinued if the treated infant develops methemoglobinemia. Infants have also developed methemoglobinemia by accidentally ingesting a small number of tablets of a urinary tract analgesic called phenazopyridine.

Some industrial chemicals can cause methemoglobinemia. They may be ingested accidentally by infants and children when found in the household. Examples include naphthalene in mothballs, nitrobenzene in solvents such as gun cleaners, and copper sulfate in plant fungicides.

HEREDITARY CAUSES

Methemoglobinemia can also occur because of an inherited lack of an enzyme in red blood cells. The enzyme is called NADH diaphorase, or cytochrome b_5 reductase. Several mutations of the enzyme have been identified. The mode of transmission is autosomal recessive, which means that the gene abnormality has to be present in both parents to cause methemoglobinemia. When both parents are carriers of the trait, there is a 25% chance of a child inheriting abnormal genes from both parents, and therefore of developing methemoglobinemia. There is a 50% chance of a child inheriting one abnormal gene and becoming a carrier without actually developing methemoglobinemia. Many reports of such cases describe siblings derived from inbred populations.

Also, rare abnormalities of hemoglobin are inherited in an autosomal dominant fashion—a 50–50 chance of passing the disorder to the children. These inherited abnormal forms of hemoglobin are unstable and, as a result, are more readily transformed to methemoglobin.

DIAGNOSIS

Methemoglobinemia is potentially lethal if it is left undiagnosed. Transient blue or grayish skin discoloration of an infant may be mistakenly dismissed as being caused by changes in temperature. Familiarity with methemoglobinemia and a high index of suspicion by the physician are potentially lifesaving. Untreated infants can become irritable and lethargic. Some may develop seizures. The heart rate may become slow. The blood pressure may drop. They may eventually lapse into a coma and die.

Isolated cases of methemoglobinemia are rare. The diagnosis of this potentially life-threatening disorder can only be made if a physician is familiar with the clinical clues and manifestations. A patient who is visibly cyanotic will initially be suspected to have a primary cardiac or a respiratory problem. Consequently, oxygen is routinely administered to patients with cyanosis. The lack of a response to the oxygen provides a valuable clue to the diagnosis. Patients with methemoglobinemia will remain blue or ashen even after oxygen administration.

Pulse oximetry will be inaccurate and unreliable in these patients. The pulse oximeter is a simple finger-clip device containing a light sensor. It was designed to measure the percentage of oxygen saturation of hemoglobin by measuring the amount of light passing through the finger or earlobe. Methemoglobin absorbs light at wavelengths similar to normal hemoglobin, and as a result, oximetry cannot reliably distinguish the two.

The blood from a patient with methemoglobinemia will be dark red when drawn and remain dark even when exposed to room air. Dark blood drawn from a vein of a patient with heart or lung disease will turn bright red on exposure to the oxygen in room air or after bubbling pure oxygen through the blood.

Methemoglobinemia should also immediately come to mind if multiple cases of cyanosis are discovered. An environmental exposure may then be a likely cause.

As soon as the diagnosis of methemoglobinemia is suspected, a blood methemoglobin level should be measured to confirm the diagnosis. Patients will appear cyanotic when the methemoglobin level is approximately 10% or greater.

TREATMENT

Normal methemoglobin levels in the blood range from 1% to less than 3%. If blood methemoglobin levels are only mildly elevated (less than 20%), patients are observed and given oxygen to saturate the remaining normal hemoglobin.

In more serious cases, where methemoglobin levels are greater than 30%, patients are given intravenous methylene blue. Patients with underlying conditions such as heart problems or severe anemia may get treated with methylene blue even with a lower methemoglobin level.

Although at first glance giving blue dye to a blue patient seems counterintuitive, the treatment is simple and can be life saving. Methylene blue acts as a nonenzymatic electron carrier. It accelerates the rate with which red blood cells convert methemoglobin back to oxygen-carrying hemoglobin. Large doses of methylene blue can indeed cause methemoglobinemia, so if there is no response to the first dose, it is usually only repeated once.

In some patients, however, even a single dose of methylene blue may pose a danger. Patients with a deficient glucose-6-phosphate dehydrogenase enzyme system will not respond to the methylene blue, and their red cells may get destroyed (hemolyzed). In such cases, other more specialized treatments such as hyperbaric oxygen, or packed red blood cell transfusions, may be necessary.

In cases of environmental exposure, such as contaminated well water, it is equally important to identify the excess nitrate source and to prevent repeat exposure to it by the susceptible individual.

MICROBIAL ACTIVITIES MANAGEMENT

Peter D. Franzmann
Luke R. Zappia
CSIRO Land and Water
Floreat, Australia

INTRODUCTION

Microbial activity can be either detrimental or beneficial to the quality of water in water treatment and distribution systems. The growth of microbial community biofilms on the pipe walls in potable water distribution systems, and in water supply reservoirs, can significantly reduce the aesthetic, microbiological, and chemical quality of the water. Microbial processes can also be beneficial in processes such as biofiltration, to prevent reactions that occur in the distribution system that are otherwise detrimental to the water quality.

Normally more than 99.9% of microbial cells in water distribution systems occur in biofilms rather than in the planktonic form. Pipe wall biofilm communities can act as reservoirs of opportunistic pathogenic microorganisms as bacteria embedded in biofilm matrices are protected from water disinfectants (1). Biofilm communities may also impact the chemical and aesthetic quality of distributed waters by concentrating, oxidizing, and releasing metals that can result in "dirty water" problems (2), producing taste and odor compounds (3), enhancing corrosion (4), and reducing disinfectant residuals in chlorinated (5) and chloraminated distribution systems (6).

GENERAL CONTROL OF BIOFILM GROWTH AND ACTIVITY

Many water treatment processes are focused on the management of biofilm growth and activity in distribution systems generally, and more specifically on the control of biofilm processes such as nitrification and manganese oxidation. The parameters that can manage biofilm growth and activity exert their control collectively in management strategies, but their contributions to management of microbial activity are best understood by examination of their individual effects. In a comparative study on the control of microbial activity in four different distribution systems in the United States and France, the authors concluded that it was always difficult to make definitive conclusions from full-scale systems where no operating parameter was truly controlled (7); however they emphasized that maintenance of a disinfectant residual was the strongest controller of bacterial growth in their systems. On the other hand, other studies have suggested that with careful management and appropriate treatments, a disinfectant residual is not required (8).

Control of Biodegradable Organic Carbon in Distributed Water

Control of microbial activity in distribution systems is required so that the water quality meets community health and aesthetic expectations. It can be achieved first by distribution of "biologically stable water," that is, water that will not promote microbial growth and activity in the distribution system, and second by avoiding the use of pipe materials that leach substrates that can support microbial growth (9). Biologically stable water can be produced without the use of a disinfectant by reducing the concentration of biodegradable organic carbon (10) and other growth-promoting compounds such as methane, ammonium, or reduced sulfur compounds, in the water that leaves the treatment plant.

Types of Organic Carbon in Drinking Water. For the distribution of biologically stable water, water treatment plants aim to reduce dissolved organic carbon (DOC), specifically the fractions of the DOC that are consumed by microbes. In practice, two types of DOC bioassay are used at treatment plants to determine if biostable water is being produced, and each assay measures different but related fractions of the bioreactive DOC.

The first of these fractions, the biodegradable dissolved organic carbon (BDOC), is measured by the decrease of DOC over time, usually up to 10 days, after the water has been inoculated with washed biomass from a sand filter (11) or a microbial population that has been grown on glass beads. BDOC is the measure of the change in DOC because of its consumption by a mixed microbial community until that consumption effectively stops. The remaining DOC is considered refractory to biodegradation in reasonable time. Methods for the measurement of BDOC have been detailed by Joret and Lévy (11) and Servais et al. (12), and rapid flow-through methods for the determination of BDOC have been proposed (13).

The other bioreactive fraction of the DOC is the assimilable organic carbon (AOC) and is the fraction used by cells to build biomass. Most water treatment plants measure this parameter by the method developed by van der Kooij (8). In this method, AOC is measured by the increase in viable numbers of two strains of bacteria, *Pseudomonas fluorescens* strain P17 and *Spirillum* sp. strain NOX, over time in water that was pasteurized at 60 °C for 30 min before inoculation. The amount of growth is compared with a standard curve of growth of both strains in AOC-free water to which standard additions of a carbon source, usually acetate, are added. In most water samples, growth reaches the stationary phase in about 10 days. The growth of each strain is taken as the difference between the number of viable cells in the water at completion of growth and the number of cells in the water just after inoculation. AOC is mainly composed of organic matter with a molecular weight of <1000 (14) and is expressed in the units μg (acetate-C equivalents)$\cdot L^{-1}$. Other methods for AOC measurement have been described, using increase in turbidity or ATP as indicators of biomass production (13). As the water industry is increasingly demanding standardized methods so that parameters from different plants can be compared, most AOC determinations now use the van der Kooij method, which is the method detailed in the entry Standard Methods for the Examination of Water and Wastewater.

AOC and BDOC can be measured in chlorine-containing waters only if the chlorine is reduced with thiosulfate by the application of about 2 moles of thiosulfate per mole of chlorine. The ratio of BDOC or AOC to DOC varies in untreated surface and aerated groundwaters, but BDOC usually represents about 10% to 30% of the DOC, and AOC usually accounts for 1% to 3% of the DOC (15). In treated waters, the correlation of AOC or BDOC to DOC concentration is poor (16). van der Kooij (8) showed that distribution of water with an AOC concentration below $10\ \mu g \cdot L^{-1}$ without a disinfectant limited the mean heterotrophic plate count to below 100 colony-forming units$\cdot mL^{-1}$, a guideline value considered by many regulators to indicate water of good microbiological quality. Biologically stable water does not promote growth or activity of microorganisms to a significant extent. Various parameter values have defined biological stability of distributed waters, and some of these are compared in Table 1.

For measures of biostability, Escobar and Randall (19) argued that both AOC and BDOC measures should be used. BDOC has a detection limit of about $100\ \mu g \cdot L^{-1}$, whereas for AOC, the detection limit is about $10\ \mu g \cdot L^{-1}$.

Table 1. Various Parameter Values that Define Biologically Stable Water

Attribute	Value	Comment	Reference
AOC	$10\ \mu g \cdot L^{-1}$	AOC uptake by biofilm limited at $<10\ \mu g \cdot L^{-1}$	9
AOC	$<50\ \mu g \cdot L^{-1}$	For AOC in a system with a chlorine residual	17
BDOC	$200\ \mu g \cdot L^{-1}$	In water with no disinfectant residual	18
BDOC	$500\ \mu g \cdot L^{-1}$	In water <15 °C with no disinfectant residual	18
BDOC	$<500\ \mu g \cdot L^{-1}$	In water with a chlorine residual of 0.1 mgd$\cdot L^{-1}$	18
BDOC	$\leq 150\ \mu g \cdot L^{-1}$	Water without a disinfectant	10

Some treatments like nanofiltration can reduce BDOC almost completely, but considerable AOC can remain in the permeate. Measurement of AOC alone does not give information on the pool of hydrolyzable BDOC than can form AOC in the distribution system; thus, measurement of AOC alone can give an overestimate of the biostability of distributed water (19).

The Effect of Treatment Processes on AOC and BDOC. As the quantity and type of dissolved organic carbon in water is the major factor that promotes bacterial growth (and hence activity) in distribution systems, modern water treatment plants usually investigate the effect of different water treatment methods on the quantity and type of DOC in their treated water. Some treatments, such as the use of oxidants for destruction of pesticides in treatment plant influent, or chlorine for disinfection, can partially oxidize the DOC to form biologically available AOC or BDOC. Other processes, notably those that use methods of biological treatment such as slow sand filtration and biofiltration using a granulated activated carbon support (GAC), can produce water with low AOC and BDOC.

A range of treatments and their effects on AOC and BDOC concentrations are shown in Table 2. The data in Table 2 oversimplify the outcomes of the different treatment options, as combinations of treatment options can have different outcomes, individual treatment options can be modified in many ways, and the success of each treatment type is dependent on the nature of the preceding treatments that were used. For example, in one study, there was 57% less AOC in finished waters from GAC filters than for anthracite sand filters when using polymer as the coagulant, whereas when using ferric ions as the coagulant, that improvement was only 13% [derived from the data of Table 4 of Volk and LeChevallier (20)]. The data in Table 2 provides a list of site-specific examples of the effect of different treatments on AOC and BDOC.

Table 2. Some Examples of the Effects of Water Treatments on DOC, BDOC, and AOC Concentrations. The Examples are Site Specific, as the Outcome from the Use of any Treatment is Dependent on Many Water Parameters, Especially the Nature of the Natural Organic Matter in the Receiving Water, and on the Pretreatment Processes Employed

Treatment	Effect	Reference
Ozonation	↑AOC 560%	23
Enhanced coagulation	↓29% DOC, ↓38% BDOC, no change AOC	24
Ultrafiltration	↓85% DOC, ↓76% to ↑8.7% AOC[a]	24
Alum coagulation	↓16% AOC, ↓49% BDOC	25
Two-stage GAC biofilter	↓51–72% AOC for ozonated water	26
Two-stage GAC biofilter	↓37–70% AOC for non-ozonated water	26
Biofiltration	↓80 to 90% AOC depending on concentration	27
Slow sand filtration	↓48% AOC	21
Chlorination	↑80% AOC	21
MIEX treatment	↓>88% BDOC, ↓24% AOC, ↓> 95% when filtered	Our data

↑= increase, ↓= decrease.

[a] Dependent on water source.

Choice of a treatment option to obtain a desired water quality will require testing by each treatment plant using its receiving water, and its implementation will require some optimization of the process parameters that can be manipulated. For substantial removal of AOC and BDOC, some form of biological treatment is generally required (21), although initial results with a magnetic ion exchange treatment for DOC removal, MIEX (WesTech Engineering, Salt Lake City, Utah), has shown exceptionally good removal of BDOC, and AOC when subsequently filtered (Table 2), in addition to removal of 60–70% of the DOC (22).

AOC concentrations in the distribution system are dependent not only on the water type and treatment system but also on the choice of materials used. Materials in contact with the water can leach considerable amounts of AOC and affect the biofilm growth on pipe surfaces. For example, nonplastic polyvinyl chloride supports an order of magnitude less biofilm than does high-density polyethylene (9).

Although the concentration of the biologically available DOC fraction is arguably the most important determinant of microbial activity in distribution systems, it does not act in isolation, and its effects are modulated by other parameters that control microbial activity in the distribution system, such as disinfectant type and concentration, temperature, residence time, and concentrations of nonorganic oxidizable microbial substrates such as ammonium or manganese. Mathematical models that attempt to explain those interactions have been developed (e.g., Ref. 28), as have relatively simple, descriptive, decision-support criteria (16).

Disinfection to Control Microbial Activity

The maintenance of a disinfectant residual is probably the strongest inhibitor of microbial activity through a distribution system (7). High concentrations of disinfectant, even in the presence of relatively high concentrations of dissolved organic carbon or AOC, can limit microbial activity such as biofilm growth in distribution systems, e.g., $160\ \mu g \cdot L^{-1}$ AOC with a chloramine residual of $>2\ mg \cdot L^{-1}$, or $107\ \mu g \cdot L^{-1}$ AOC with $>0.8\ mg \cdot L^{-1}$ free chlorine [in Pine Hills Distribution System; (7)]. However, as high concentrations of disinfectant are the most common cause of customer taste or odor complaints (29), and as there are increasing concerns about disinfection by-products (30), the goal of water treatment utilities is often to deliver water with a minimal amount of disinfectant residual, often with reduced DOC, to control microbial activity and maintain microbiologically safe water.

As with treatment methods for removal of AOC and BDOC, many different concentrations of disinfectant have been shown to prevent biofilm growth, or specific microbial activities depending on the water quality, temperature, residence time, or type of disinfectant used. As already discussed, if the water quality is high (i.e., biologically stable), in some cases, no disinfectant is required to deliver safe and aesthetically acceptable water to the consumer (9).

Table 3. Disinfectant Residual Concentrations and Their Effects on Microbial Activity in Pilot-Scale and Actual Water Distribution Systems

Treatment: Effect	Reference
Free chlorine 0.05 $mg{\cdot}L^{-1}$: no biofilm growth initiation in pipes	33
Free chlorine > 0.5 $mg{\cdot}L^{-1}$ or chloramine > 1.0 $mg{\cdot}L^{-1}$: required to decrease probability of coliform occurrence	16
Chloramine 2.1 $mg{\cdot}L^{-1}$: inhibited bacterial activity	
Total chlorine 0.3 $mg{\cdot}L^{-1}$: prevents establishment of biofilms	Our data
Total chlorine < 0.02 $mg{\cdot}L^{-1}$: allows establishment of biofilms	Our data
Chlorine 1.0–3.0 $mg{\cdot}L^{-1}$: disrupts established biofilms	34
Free chlorine residual 3 $mg{\cdot}L^{-1}$: no effect on biofilms in iron pipes	17
Chlorine or chloramine 1 $mg{\cdot}L^{-1}$: inactivates bacteria on copper PVC or galvanized pipes	17
Free chlorine 0.2 $mg{\cdot}L^{-1}$: reduced biofilm concentration	35

Although site and water specific, some examples of recommended disinfectant levels to prevent biofilm growth or microbial activity in distribution systems are given in Table 3. In reality, the target level of a disinfectant residual should be decided only after appropriate testing. Once established, biofilms can exert a chlorine demand that increases linearly with the BDOC concentration in the water and with the ratio of the surface area to volume of the biomass, whereas the chlorine demand of detached biomass is related to the amount of biomass (5). The effectiveness of a disinfectant residual in controlling microbial activity is also markedly affected by pipe material, retention time of the water in the distribution system, and water chemistry (17).

Chloramine has been shown to provide better control of microbial activity than has chlorine (31) which may be related to slower decay and greater penetration into biofilms (32).

Temperature and Microbial Activity

Temperature has a marked effect on microbial activity. Generally, microbial growth and microbial processes such as nitrification in distribution systems are limited at temperatures of less than 15 °C, and deterioration of water quality in colder climates can be temperature limited (16).

Control of Nitrification in Distribution Systems

Nitrification, the oxidation of ammonium through nitrite to nitrate, is a microbial activity that is problematic for many water utilities that distribute water with chloramine as the disinfectant. The activity depletes the residual chloramine and can make conditions more conducive to growth of heterotrophic bacteria in the distribution system (36). Ammonium in source waters can lead to biological instability in distribution systems if not treated. For example, ammonium concentrations throughout Illinois averaged 0.62 $mg\ N{\cdot}L^{-1}$, which equates to an oxygen demand of 2.8 $mg\ O_2{\cdot}L^{-1}$ (15).

For distribution systems that do not use chloramine as the disinfectant, ammonium can be removed economically from source waters by nitrifying bacteria. Attached biofilm processes such as GAC-biofiltration, fluidized bed filtration, or rapid sand filtration of nonchlorinated water are generally used because of the slow growth rates of nitrifying bacteria (15). In this way, microbial activity that would otherwise occur in the distribution system is used in a treatment process at the plant to convert ammonium to nitrate. Larger support media (1 mm diameter) should be used in nitrifying biofilters to lessen sheer stresses on slow-growing populations of nitrifying bacteria (15).

In chloraminated systems, nitrification needs to be controlled to prevent the loss of the disinfectant with subsequent increase in biofilm activity. In cooler climates, nitrification may be controlled for much of the year without intervention, as nitrification usually occurs when water temperatures are above 15 °C (6). Active methods of control of nitrification in distribution systems include maintenance of a chloramine residual of 2.5 $mg{\cdot}L^{-1}$ with a chlorine-to-ammonia-nitrogen ratio of 4:1, which limits biofilm development in the distribution system by reduction of the organic carbon of the water, active cleaning of the distribution system by flushing or pigging, reducing the detention time of the water in the system, eliminating “dead ends” in the mains (36), and limiting reactive surfaces on pipes by coating with carbonate or polymer additives (37).

Control of Microbial Activity Involved in “Dirty Water” Formation

“Dirty water” caused by iron and manganese precipitates is a common problem for water supply utilities (38). Dirty water precipitates result from abiotic or biological oxidation of reduced iron or manganese, or organic materials with which they may be complexed. Iron and manganese deposits and sludges can limit the penetration of disinfectants into biofilms. Microbial manganese oxidation in a distribution system has been controlled by maintaining a chlorine residual of $>0.2\ mg{\cdot}L^{-1}$ and reducing manganese concentrations to below 0.02 $mg{\cdot}L^{-1}$ (2).

Removal of manganese and iron before distribution usually involves chemical oxidation to their insoluble forms Fe^{3+} and Mn^{4+} by aeration, chlorine, chlorine dioxide, potassium permanganate, or ozone, with subsequent removal by flocculation, sedimentation or filtration (38), or combined chemical and biological oxidation and removal by biofiltration (15,39). Biofilters are usually slow to develop and generally require the development of $MnO_2(s)$ precipitates to help catalyze the oxidation of soluble Mn^{2+} (15). Biofilters can be used for the simultaneous removal of AOC, BDOC, ammonium, iron, and manganese (40).

CONCLUSIONS

Microbial activity in water distribution systems affects the health compliance and aesthetics of the distributed water. Control of microbial activity in distribution systems is never complete, but it can be sufficiently achieved by limiting microbial energy and food sources (i.e., by removing as much AOC, BDOC, DOC, ammonia, reduced metals, and reduced sulfur compounds as is possible), in most cases by maintaining a reasonable residual disinfectant in the distributed water, and by careful selection and maintenance of distribution infrastructure, so that minimal microbiological growth and chemical reactions can occur on surfaces.

Water utilities have many treatment and disinfection choices for the control of microbial activity in distribution systems, and those choices will be guided by the quality of the waters they receive, their geography, the retention time of water in the system, and the expectations of the community. The most appropriate treatment options for control of microbial activity by any one utility must be guided by analysis of the performance of treatment methods in other treatment plants, and extensive testing and optimization of treatment methods alone, and in combination with the full treatment system.

MICROBIAL DYNAMICS OF BIOFILMS

Pennsylvania State University
Harrisburg, Pennsylvania

BIOFILM FORMATION

The solid–liquid interface between a surface and an aqueous medium (e.g., water, blood) provides an ideal environment for the attachment and growth of microorganisms. Bacteria have a marked tendency to attach to surfaces exposed to an aqueous environment and initiate biofilm formation, characterized as a matrix of cells and cellular products attached to a solid substratum. The biofilm systems that result can be beneficial, as exemplified by fixed-film wastewater treatment processes (e.g., trickling filters and rotating biological contactors). However, this biological matrix can increase operational costs and/or decrease product quality in a variety of industries, including oil and paper production, semiconductor manufacture, and drinking water distribution. In water distribution systems and heat transfer equipment, for example, biofilms can cause substantial energy losses resulting from increased fluid frictional resistance and increased heat transfer resistance. Moreover, the pathogens trapped in microbial biofilm in a water supply pipeline have caused public health concerns.

Microorganisms grow on surfaces enclosed in biofilm and form microcolonies of bacterial cells, which are encased in adhesive polysaccharides excreted by the cells. Biofilm can provide advantages for microorganisms' survival in natural environment, especially under oligotrophic condition, because biofilms trap nutrients for growth of the microbial population and help prevent detachment of cells on surfaces present in flowing systems. In drinking water systems (oligotrophic environment), the percentage (70%) of positive (viable) cells was significantly higher at surface-adhered biofilm cells than that (40%) in the planktonic cells (1). It has been postulated that bacteria attached to surfaces are more active because of enrichment of nutrients at the surface. Therefore, the growth of cells at the surface is predominant over deposition and has advantage over planktonic (free swimming) in an oligotrophic environment.

Biofilms may form on a wide variety of surfaces, including living tissues, indwelling medical devices, industrial or potable water system piping, or natural aquatic systems. The variable nature of biofilms has been observed from an industrial water system and a medical device (Figs. 1 and 2). The water system biofilm is highly complex, containing corrosion products, clay material, freshwater diatoms, and filamentous bacteria. The biofilm on the medical device, on the other hand, seems to be composed of a single, coccoid organism and the associated extracellular polymeric substance (EPS) matrix.

It has been found that microbial motility may play a role in structure formation in biofilms (2). After the initial attachment to the substratum, *Pseudomonas aeruginosa* evidently moves on the substratum by means of twitching motility, which suggests that the initial microcolonies are formed by aggregation of bacteria. Moreover, microcolonies of bacterial cells in biofilms are the basic structural units in sessile communities, different from that of planktonic cells

Figure 1. Scanning electron micrograph of a native biofilm that developed on a mild steel surface in an 8-week period in an industrial water system. Rodney Donlan and Donald Gibbon, authors. Figure 2. Scanning electron micrograph of a staphylococcal biofilm on the inner surface of an indwelling medical device. Bar, 20 μm. Used with permission of Lippincott Williams & Wilkins. Photograph by Janice Carr, CDC (http://www.cdc.gov/ncidod/eid/vol8no9/02-0063.htm).

and there is different gene expression in sessile bacteria. A large fraction of the biofilm bacteria (*P. aeruginosa, Discosoma* sp.) occasionally swim from one microcolony to another. In the initial phase of biofilm formation, bacteria are nonmotile and sessile inside the microcolonies. After several days of biofilm formation, biofilm bacteria start to swim rapidly in circles, the compact microcolonies are dissolved, and loose structures containing bacteria from different microcolonies are formed, along with flow channels. These results suggest that biofilms contain both sessile populations and planktonic populations.

BIOFILM STRUCTURE HETEROGENEITY

Biofilm Physical Structure

It had long been assumed that biofilm had a homogeneous structure, with microorganisms uniformly distributing throughout the entire biofilm at both structure and dynamics levels (3). Recently, biofilm was discovered heterogeneous in structure and function by microelectrode and confocal laser scanning microscope (CLSM). Numerous microbiology and microbial ecology of microbial ecosystem studies revealed that biofilms typically contain many layers with microbial ecology variation in each layer. Biofilms are not composed of bacterial cells randomly distributed in a homogeneous matrix, but they are composed of microcolonies of matrix-enclosed cells with intervening open-water channels. This complex and fascinating organization of biofilm communities was seen in flow-cell biofilms of several *Pseudomonas* species and in mixed-species natural biofilms formed on rock surfaces (4).

Microorganisms tend to accumulate in the bottom layer inside biofilm toward substratum, which leads to higher biomass density in the depth of biofilm. With the higher biomass density, the effective diffusivity distribution in heterogeneous biofilm decreased toward the bottom of a biofilm. It has been measured that the ratio of effective diffusivity in biofilm to the bulk solution diffusivity (Df/D) decreased from 0.68–0.81 in the top layer to 0.38–0.45 in the bottom layer (5). The highest biomass density, 120 g/L, was near the bottom of the biofilm, whereas the lowest density was measured near the top layers of biofilm, 20–30 g/L (6). It is anticipated that in the bottom layer of biofilm, metabolite and other by-products accumulate and have difficulties to diffuse out of biofilm, which lead to high mass.

Besides the mass density and diffusivity, other physiological features also vary along the depth of biofilm, which offer the heterogeneous structure in biofilm property (7). The solid densities (with units of mg-TS (total solid)/cm^3 total biofilm) in the bottom layers were 5–10 times higher than were those in the top layers; the ratio of living cells to total biomass decreased from 72–91% in the top layers to 31–39% in the bottom layers; the porosities of biofilms changed from 89–93% in the top layers to 58–67% in the bottom layers. In contrast, the mean pore radius of biofilms decreased from approximately 1.7–2.7 μm in the top layers to 0.3–0.4 μm in the bottom layers. Thus, bacterial cells living in a dense multilayer matrix face the problem of limited transport of substrate and nutrients into the film inner layers as well as export of waste products out of these deep regions.

Extracellular Polymeric Substances (EPSs)

A biofilm is an assemblage of microbial cells that is irreversibly associated with a surface and enclosed in a matrix of primarily polysaccharide material. The microcolonies in a biofilm are surrounded by large amounts of EPS. It has been found that EPSs play an important role in gene transformation and cell–cell contact in biofilm. Although it is not clear that EPSs have a role in shaping the spatial structure in biofilms, evidence has been provided that EPSs can facilitate storage of nutrients in biofilms for subsequent intake during periods of carbon limitation (8–10). The EPSs play several important roles for the biofilm, including (1) protection from naturally occurring or manmade biocides and antibiotics, (2) stabilization of bacterial adhesion to the substratum and to other cells in the biofilm, and (3) entrapment and concentration of soluble nutrients in proximity to biofilm members.

EPSs may account for 50–90% of the total organic carbon of biofilms (11) and can be considered the primary matrix material of the biofilm. EPSs synthesized by microbial cells may vary greatly in their composition, but the major component is polysaccharide. Some are neutral macromolecules, but most are polyanionic because of the presence of either uronic acids (D-glucuronic acid, D-galacturonic, D-mannuronic acids) or ketal-linked pyruvate. Inorganic residues, such as phosphate or rarely sulfate, may also confer polyanionic status (10). A few EPSs may even be polycationic, as exemplified by the adhesive polymer obtained from strains of *Staphylococcus epidermidis* associated with biofilms (12).

The amount of EPS synthesis within the biofilm is known to depend greatly on the availability of carbon substrates (both inside and outside the cell) and on the balance between carbon and other limiting nutrients (e.g., nitrogen, calcium) (10). Moreover, different organisms produce differing amounts of EPSs, and the amount of EPSs increases with age of the biofilm. Because EPSs are highly hydrated, they prevents desiccation in some natural biofilms. EPSs may also contribute to the antimicrobial resistance properties of biofilms by impeding the mass transport of antibiotics through the biofilm, probably by binding directly to these agents (13). This process can lead to the high antibiotics resistance of pathogens growing in biofilm.

Channel Structures in Biofilm

Biofilms are highly hydrated open structures containing a high fraction of EPSs and large void spaces between microcolonies. Most of the bacteria in the nutrient-sufficient parts of the biosphere grow in distinct microniches in highly structured multispecies communities. Bacterial growth zones form as discrete microcolony structures separated by channel boundaries, and these structures are maintained over time (Fig. 3). Also, open spaces extend from the top of the biofilms to the deep inner regions, which forms a channel-like network. Mushroom-shaped structures, separated by channels and voids, were observed in *P. fluorescens* biofilm (14).

It has been found that when biofilm grew from 20 to 300 μm in thickness, many vertical and horizontal channels permeated the film (15). These channels extended from the surfaces into at least one-half of the depth of the film. Moreover, on anaerobic fixed-bed reactor communities, integrative networks of channel-like structures were found throughout the microbial granules (15), which has been interpreted as playing a role in transport of cooperative substrates, nutrients, and gases (16). This porous architecture of biofilms may represent a more optimal arrangement for the influx of substrate and nutrients and transfer of wastes.

The biofilm heterogeneous structure of microbial clusters of cells and EPSs was also verified by microelectrode measurement (17). The microbial clusters of cells and EPSs were separated by interstitial voids. The cell clusters were 300 μm wide, and the voids were 100 μm wide. Biofilms are not flat homogeneous layers of cells, in which transport is exclusively diffusional. The transport of metabolites involved both convection and diffusion, which offers a relative importance depending on the hydraulic regime. The velocity of the bulk liquid had a strong influence on the oxygen concentration and mass distribution in the biofilm, with high flow velocity increasing oxygen transferring inside biofilm and concentration differences and thus increasing convectional transport.

BIOFILM METABOLIC HETEROGENEITY

Metabolic heterogeneity may account for the phenomenal success of microbial biofilms in nature and in device-related and other chronic bacterial infections, and it may be a major factor in the inherent resistance of medical biofilms to antibiotics.

Heterogeneity within a population (differing activity of single cells associated with increasing depth in a biofilm) might provide useful insight into aspects of substrate and mass transport limitation. The established biofilm population was composed of cells having a variety of growth rates. Such differences might reflect different positions of cells within the biofilm matrix; for example, cells located near the surface of the biofilm may not be as limited by mass transport of, or competition by surrounding cells for, nutrients (18).

Cell ribosome content changes at different growth phases, with higher ribosome content in new cells and lower ribosome content in old cells. The variation in ribosome content can provide a useful tool for evaluating the status of a great variety of microorganism growing at different generation times inside biofilm (19). Quantifying the fluorescent light emitted from *in situ* rRNA hybridized cells indicated that sulfate-reducing bacteria (SRB) in a young multispecies biofilm were more active than were the sulfate-reducing bacteria in an established biofilm (20). When microcolonies of a *P. putida* strain growing in a biofilm reaches a critical size, the light emitted by the cells decreased in the center of the microcolonies and eventually throughout the microcolonies, which indicates that the cells displayed different levels of growth activity correlating with their location in the biofilm and with the biomass of biofilm (18).

MICROBIAL STRUCTURE AND DYNAMIC HETEROGENEITY IN BIOFILM IN WATER/WASTEWATER TREATMENT

The heterogeneity of microbial structure and dynamics is very important in biological wastewater treatment. Trickling filter, which depends on a variety of microorganisms growing in different layers in biofilm, is a major process in nutrient removal. Wastewater biofilms are complex multispecies biofilms, displaying considerable heterogeneity with respect to both the microorganism present and their physicochemical microenvironment. Successive vertical zonations of predominant respiratory processes occurring simultaneously in close proximity have been found in aerobic wastewater biofilms with a typical thickness of only a few millimeters (21). Numerous environmental microbiology and molecular biology studies have revealed the correlation between the microbial structure and dynamic heterogeneity and the availability of oxygen and substrate in two biofilm systems: sulfur-reducing biofilm and nitrification/denitrification biofilm.

Sulfate-Reducing Biofilm

The reduction of sulfate (SO_4^{2-}) or sulfite (SO_3^{2-}) to sulfide (S^{2-}) occurs in an anaerobic zone deeper inside biofilm with organic carbon as the electron donor. It is carried out by anaerobic SRB. The presence of oxygen and nitrate in the deep layer of biofilm has been found to inhibit the anaerobic SRB growth, because oxygen and nitrate compete with sulfate or sulfite to be the electron acceptor in anaerobic biofilm. The correlation of the vertical distribution of SRB with the gradients of oxygen and hydrogen sulfide (the product of the reducing sulfate by SRB) in a trickling filter revealed that hydrogen sulfide was predominant in the anoxic zone of the biofilm, and most of the SRB were found in the anoxic layer as dense clusters of assemblies (22). Oxygen respiration occurred in the upper 0.2–0.4 mm of the biofilm, whereas sulfate reduction occurred in deeper, anoxic parts of the biofilm (below 1.5 mm inside biofilm) (23). Moreover, the presence of sulfate in biofilm significantly affects the stratification of microbial community inside biofilm, because sulfate is the main electron acceptor for SRB in anoxic reaction. Total sulfate reduction rates (μmol S/cm^3/h) increased when the availability of SO_4^{2-} or organic substrate increased as a result of deepening the sulfate reduction zone or an increase in the sulfate reduction intensity.

SRB can even survive in the aerobic zone in biofilm and conduct good sulfur-reducing ability. In one study, SRB (approximately 10^9–10^{10} cell per cm^3 of biofilm) was evenly distributed throughout the biofilm, even in the oxic surface (21). Oxygen penetrated only about 100 μm from the surface in a biofilm approximately 1000 μm thick. Sulfide was produced from SRB in a narrow zone of 150–300 μm below the surface at a maximum specific rate of 21 μmol H_2S /cm^3/h.

Nitrification/Denitrification Biofilm

Nitrogen is removed in biological wastewater treatment by two types of bacteria: aerobic autotrophic nitrifier (oxidize NH_4^+ to NO_3^-) and anoxic heterotrophic denitrifer (reduce NO_3^- to N_2). Two major groups of nitrifiers exist: ammonia oxidizing bacteria (AOB, oxidize NH_4^+ to NO_2^-) and nitrite oxidizing bacteria (NOB, oxidize NO_2^- to NO_3^-). In biofilm, aerobic nitrifier and anoxic denitrifer dominate in the different zones because of the transfusion of oxygen and organic and inorganic substrates. The nitrifying and denitrifying bacterial populations and their activities in biofilms have been investigated by the application of fluorescent *in situ* hybridization (FISH) and microsensor technology. A dense layer of ball-shaped clusters of *Nitrosomonas* cells (ammonium oxidizers) in close physical association with surrounding smaller clusters of *Nitrobacter* cells (nitrite oxidizers) was found in the aerobic zone of a nitrifying biofilm from the trickling filter of an aquaculture (17). The nitrifying zone (measured with microelectrode) was restricted to the outer 100–150 μm of the biofilm, and the nitrifiers were found in this zone as a dense layer of clusters. The central part of the biofilm was found anoxic and inactive for nitrification, and significantly fewer nitrifiers were found there.

The dynamic studies of nitrifers have revealed their stratification and activity inside biofilm. The active ammonia-oxidizing zone was located in the outer part of a biofilm, whereas the active nitrite-oxidizing zone was located just below the ammonia-oxidizing zone (24). The number of nitrite-oxidizing bacteria (NOB) is low compared with the number of ammonia-oxidizing bacteria (AOB). Oxygen penetration depth was about 1200 μm in the wastewater biofilm because of the loose structure and low microbial activity. Nitrification occurred in the top 200 μm, whereas denitrification occurred in the deeper anoxic layers (below a depth of about 1200 μm). The nitrification layer is 150–175 μm, AOB activity is 0.13–0.08 μmol NH_4^+/cm^2/h, and average specific nitrifying rate is 8.7–4.6 μmol NH_4^+/cm^3/h. NOB activity is 0.22–0.3 μmol NO_2^-/cm^2/h, and the specific rate is 14.7–17.1 μmol NO_2^-/cm^3/h. AOB (*Nitrosomonas*) were detected throughout the biofilm, whereas NOB (*Nitrospira*-like bacteria) were found mainly in the inner parts of biofilm and always found in vicinity of AOB clusters, which may have reflected the synthophic association between AOB and NOB (25).

Besides the microbial stratification and activity in biofilm, some parameters were examined to indicate the different microbial processes inside biofilm. The stratification of microbial processes and the associated redox potential (ORP) changes in biofilms were studied by microelectrodes (26). In aerobic/sulfate-reducing biofilm, a clearly stratified structure with depth was observed: aerobic oxidization took place only in a shallow layer near the surface, and sulfate reduction occurred in the deeper anoxic zone. The boundary between these two processes was well defined by redox potential (ORP increased from −100 mV to +100 mV). In the aerobic/nitrifying biofilm, a stratified structure with depth was also observed, but it was less well defined (ORP increased from +300 mV to +330 mV). In this biofilm, aerobic oxidation took place throughout the biofilm depth, and more nitrification occurred in the deeper section of the biofilm.

The competition occurs between anoxic denitrifer and SRB in biofilm (27). In SRB biofilm, oxygen was depleted in the first 0.2 mm of the biofilm (1.5 mm thickness). SRB occurred in the anoxic zones inside biofilm. However, when nitrate is added in the bulking solution, the SRB zone withdrew deeper into the biofilm. Nitrate penetrated into 0.4 mm depth inside biofilm, which indicates that denitrification occurred. Nitrate decreased the sulfide content either by oxidation of produced sulfide or by inhibition of sulfate reduction.

Oxygen Limitation in Biofilm

Growth rate limitation occurs in biofilms presumably as a result of restriction for a particular nutrient (such as oxygen and substrate) that fails to fully penetrate the biofilm. The expression of alkaline phosphatase (APase) could be a physiological indicator. It was found that the band of APase (to indicate enzyme activities) on the *P. aeruginosa* biofilm surface decreased from 46 μm thick with biofilms grown in pure oxygen to 2 μm thick with biofilms grown in pure nitrogen (28). The expression of APase on the biofilm surface revealed marked spatial physiological heterogeneity within biofilms in which active protein synthesis was restricted by oxygen availability inside the biofilm. This heterogeneity has implications for microbial ecology and for understanding the reduced susceptibilities of biofilms to antibiotics agents under limited nutrients in the establishment of physiological gradients.

The direct observation of living biofilms has found many different microniches occupied by individual cells within these complex communities. Cells near the surface of the microcolony would obtain high concentrations of the oxygen delivered by the water in the channels while oxygen is rapidly depleted below the microcolony surface, and the centers of the microcolonies that comprise biofilms growing in air are virtually anaerobic (29). The steep oxygen gradient is paralleled by gradients of differing steepness for every ion and molecule needed or produced by cells in biofilms, and the interaction of these gradients produces a different microniche for every individual cell in the complex heterogeneous community.

BIOFILM DETACHMENT

Biofilm development is a balance between new biofilm growth and old biofilm detachment. Biofilm detachment is the removal of cells from the existing biofilm to the bulk fluid. It is a significant factor that balances cell growth in the biofilm and brings the system to steady state. Biofilm cells may be dispersed either by shedding of daughter cells from actively growing cells, detachment as a result of nutrient levels, or shearing of biofilm aggregates (continuous removal of small portions of the biofilm) because of flow effects.

The mechanisms underlying the process of shedding by actively growing cells in a biofilm are not well understood. It has been recognized that several physical forces are involved in biofilm detachment (30): erosion (continuous removal of small particles of biofilm as a result of shear forces), sloughing (random removal of large portions of biofilm, often occurring in old and thick biofilms or when exposed to dramatic environmental changes), abrasion (removal caused by collisions of solid particles with biofilms particularly in fluidized bed reactors), and predator grazing (consumption of biofilm by larger organisms such as protozoa).

Besides these physical forces, the microbial metabolic dynamic inside biofilm also contributes to biofilm detachment. As biofilm matures, oxygen will be depleted in the upper layer of biofilm and anoxic/anaerobic zones will dominate in the deeper layers of biofilm. The anoxic/anaerobic reactions produce a variety of biogas (N_2, H_2S, CO_2, CH_4, H_2, etc.) and might increase up to 20% in the established biofilm (31). The biogas contributes to the biofilm detachment. Moreover, the amount of EPSs in biofilm also changes during biofilm formation and maturation. The content of EPSs decreased within the biofilm in the course of biofilm maturation. As a consequence, the adhesion strength of biofilm adjacent to substratum becomes more weakened, which leads to biofilm detachment (32).

MICROBIAL ENZYME ASSAYS FOR DETECTING HEAVY METAL TOXICITY

Oladele A. Ogunseitan
University of California
Irvine, California

THE PERSISTENT PROBLEM OF TOXIC METALS IN THE WATER ENVIRONMENT

Throughout the world, industrial development has been associated with increased mining, refining, and use of potentially toxic metals in large-scale manufacturing processes. Industrialization is also tightly linked to increases in the combustion of fossil fuels such as coal and petroleum, which produce considerable amounts of toxic metals such as mercury and lead, respectively (1). Inevitably, many industrial activities generate environmental pollution that changes the natural biogeochemical cycling of elements by modifying the size and flux of metal reservoirs. The primary consequence of metal pollution in natural water systems is toxic effects on aquatic organisms, but ultimately human exposure occurs from consumption of contaminated water, seafood, and plant crops that are cultivated in land irrigated with polluted water.

The United States Environmental Protection Agency (EPA) has established maximum contaminant levels (MCL) for eleven metals that dominate the inorganic contaminants most commonly encountered in drinking water and groundwater sources (Table 1). The symptoms associated with these toxic metals range from skin disease from chromium (MCL = 0.1 mg/L) to more serious conditions such as kidney disease from cadmium (MCL = 0.005 mg/L) and mercury (MCL = 0.002 mg/L). In addition, nonenforceable standards have been established for secondary pollutants such as Al, Cu, Fe, Mn, Ag, and Zn because they are regarded as nuisance contaminants with the assumption of negligible health consequences at the established concentrations permitted in water (Table 2).

Metals are also ranked third among the top 100 contaminant categories most commonly found in violation of established water quality standards such as the total maximum daily load (TMDL; see Table 3). Metals represent the largest proportion (1977 or 20.6%) of the total number of TMDLs approved for contaminant categories in water systems (Table 4). Mercury, copper, and lead are the three metals found most frequently in impaired water systems. These issues make metal pollution one of the most pressing water quality problems. In addition, there is a lot of uncertainty about metal doses that can produce disease because of the variability of individual genetic and behavioral susceptibility factors. Therefore, new techniques are continuously sought to produce consistent and reliable measures of ecological and human health risks from metal exposure. Microorganisms are involved in three of the multifaceted strategies designed to deal with metal contamination of water resources: first, in the control of acid mine drainage; second, in the bioremediation of contaminated water systems; and third, as indicators of metal bioavailability in toxicity testing. This chapter focuses on the third aspect of microbial interactions with metals in water, the use of microbial enzymes to indicate bioavailability and toxicity. A case study of microbial enzyme response to Pb is presented as an example.

MICROBIAL METALLOENZYMES

Several enzymes used by microorganisms to catalyze key reactions of the major biogeochemical cycles are metalloenzymes; to function properly, they require metal ions positioned at or near the active site. At least a third of all proteins in the biosphere are metalloproteins, and several metals are commonly found in physiological systems in small concentrations. For example Ca, K, Na, Fe, Mo, Mn, Mg, Cu, Zn, Co, Ni, W, and Al are commonly

Table 1. Inorganic Chemicals Category of Water Contaminants with Established Maximum Contaminant Levels (MCLs)

Contaminant	MCLG[b], mg/L[c]	MCL or TT[b], mg/L[c]	Potential Health Effects from Ingestion of Water	Sources of Contaminant in Drinking Water
Antimony	0.006	0.006	Increase in blood cholesterol; decrease in blood sugar	Discharge from petroleum refineries; fire retardants; ceramics; electronics; solder
Arsenic	0[d]	0.010 as of 01/23/06	Skin damage or problems with circulatory systems and may have increased risk of cancer	Erosion of natural deposits; runoff from orchards; runoff from glass and electronics production wastes
Asbestos (fiber >10 μm)	7 million fibers per liter	7 million fibers per liter	Increased risk of developing benign intestinal polyps	Decay of asbestos cement in water mains; erosion of natural deposits
Barium	2	2	Increase in blood pressure	Discharge of drilling wastes; discharge from metal refineries; erosion of natural deposits
Beryllium	0.004	0.004	Intestinal lesions	Discharge from metal refineries and coal-burning factories; discharge from electrical, aerospace, and defense industries
Cadmium	0.005	0.005	Kidney damage	Corrosion of galvanized pipes; erosion of natural deposits; discharge from metal refineries; runoff from waste batteries and paints
Chromium (total)	0.1	0.1	Allergic dermatitis	Discharge from steel and pulp mills; erosion of natural deposits
Copper	1.3	TT[e]; action level = 1.3	Short term exposure: gastrointestinal distress Long term exposure: liver or kidney damage People with Wilson's disease should consult their personal doctors if the amount of copper in their water exceeds the action level	Corrosion of household plumbing systems; erosion of natural deposits
Cyanide (as free cyanide)	0.2	0.2	Nerve damage or thyroid problems	Discharge from steel/metal factories; discharge from plastic and fertilizer factories
Fluoride	4.0	4.0	Bone disease (pain and tenderness of the bones); children may get mottled teeth	Water additive that promotes strong teeth; erosion of natural deposits; discharge from fertilizer and aluminum factories
Lead	zero	TT[e]; action level = 0.015	Infants and children: delays in physical or mental development; children could show slight deficits in attention span and learning abilities Adults: kidney problems; high blood pressure	Corrosion of household plumbing systems; erosion of natural deposits
Mercury (inorganic)	0.002	0.002	Kidney damage	Erosion of natural deposits; discharge from refineries and factories; runoff from landfills and croplands
Nitrate (measured as nitrogen)	10	10	Infants below the age of six months who drink water containing nitrate in excess of the MCL could become seriously ill and, if untreated, may die. Symptoms include shortness of breath and blue-baby syndrome.	Runoff from fertilizer use; leaching from septic tanks, sewage; erosion of natural deposits

Table 1. (*Continued*)

Contaminant	MCLG[a], mg/L[b]	MCL or TT[a], mg/L[b]	Potential Health Effects from Ingestion of Water	Sources of Contaminant in Drinking Water
Nitrite (measured as nitrogen)	1	1	Infants below the age of six months who drink water containing nitrite in excess of the MCL could become seriously ill and, if untreated, may die. Symptoms include shortness of breath and blue-baby syndrome.	Runoff from fertilizer use; leaching from septic tanks, sewage; erosion of natural deposits
Selenium	0.05	0.05	Hair or fingernail loss; numbness in fingers or toes; circulatory problems	Discharge from petroleum refineries; erosion of natural deposits; discharge from mines
Thallium	0.0005	0.002	Hair loss; changes in blood; kidney, intestine, or liver problems	Leaching from ore-processing sites; discharge from electronics, glass, and drug factories

[a] Asbestos, cyanide, nitrate, and nitrite are the few nonmetallic chemicals in this category. They are included here for comparison of standards and also because their presence in water may affect the biological availability of metals and the nature of microbial interaction with available metal ions.

[b] Definitions: **Maximum contaminant level (MCL)**: The highest level of a contaminant that is allowed in drinking water. MCLs are set as close to MCLGs as feasible using the best available treatment technology and taking cost into consideration. MCLs are enforceable standards.

Maximum contaminant level goal (MCLG): The level of a contaminant in drinking water below which there is no known or expected risk to health. MCLGs allow for a margin of safety and are nonenforceable public health goals.

Treatment Technique (TT): A required process intended to reduce the level of a contaminant in drinking water.

[c] Units are in milligrams per liter (mg/L) unless otherwise noted. Milligrams per liter are equivalent to parts per million.

[d] MCLGs were not established before the 1986 Amendments to the Safe Drinking Water Act. Therefore, there is no MCLG for this contaminant.

[e] Lead and copper are regulated by a treatment technique that requires systems to control the corrosiveness of their water. If more than 10% of tap water samples exceed the action level, water systems must take additional steps. For copper, the action level is 1.3 mg/L, and for lead it is 0.015 mg/L.

associated with diverse proteins in microorganisms (see Table 5). For each of these “essential” metals, there are at least two other metals that can compete for their interaction with proteins, but these competing “nonessential” metals are likely to be very toxic because the proteins to which they bind do not function properly (2). To survive in environments with fluctuating metal concentrations and parameters of metal bioavailability, many microorganisms have evolved specific uptake systems for essential metals, whereas specific detoxification systems are evolved to resist the detrimental effects of nonessential metals. For example, the uptake of iron is facilitated by the production of pyoverdins in fluorescent *Pseudomonas*, whereas many members of this genus also produce enzymes such as mercuric reductase which has the only known function of mercury detoxification (3). Therefore, measurement of metalloenzyme kinetics in the presence and absence of toxic metal ions can provide a direct assay for the biological availability of metallic contaminants in water systems.

Metal bioavailability is influenced by many factors, including pH, particulate matter that can adsorb metals, and inorganic elements and ions such as sulfur, chloride, and carbonate that can affect metal speciation (4,5). Therefore, monitoring metal concentrations in water based solely on chemical extraction and physical analysis typically generates “total concentration” data, but the biologically available concentration remains unknown. This is the main reason for investigating enzyme bioassays to estimate metal toxicity. When cell-based assays are used, enzyme assays reflect the quantity of metals which must have entered the cell to provoke physiological responses. Ogunseitan (3) and Ogunseitan and colleagues (6,7) have used such responses to monitor the biological availability of Hg and Pb, respectively. The following section describes the use of a microbial enzyme to assess the toxicity of biologically available Pb in water systems.

Table 2. Permissible Concentrations of Six Metals and Some Nonmetal Components[a]

Contaminant	Secondary Standard
Aluminum	0.05 to 0.2 mg/L
Chloride	250 mg/L
Color	15 (color units)
Copper	1.0 mg/L
Corrosivity	Noncorrosive
Fluoride	2.0 mg/L
Foaming agents	0.5 mg/L
Iron	0.3 mg/L
Manganese	0.05 mg/L
Odor	3 threshold odor number
pH	6.5–8.5
Silver	0.10 mg/L
Sulfate	250 mg/L
Total dissolved solids	500 mg/L
Zinc	5 mg/L

[a] The concentrations of the metals are monitored according to National Secondary Drinking Water Regulations (NSDWRs or Secondary Standards), which are nonenforceable guidelines regulating contaminants that may cause cosmetic effects (such as skin or tooth discoloration) or aesthetic effects (such as taste, odor, or color) in drinking water. EPA recommends secondary standards to water systems but does not require systems to comply. However, states may choose to adopt them as enforceable standards. The co-occurrence in water of nonmetallic components of this list may affect the biological availability of metal ions, which is a major factor in toxicity assessments based on microbial enzymes.

Table 3. Metals Are Ranked Third Among the Top 100 Impairments from Water Pollution; Hg, Cu, and Pb are the Most Frequently Cited Pollutants

Impairment	Number of Impairments
Chromium VI	1
Contaminated sediments (zinc)	1
Zinc	351
Contaminated sediments (alum)	1
Contaminated sediments (lead)	2
Molybdenum	1

MICROBIAL AMINOLEVULINATE DEHYDRATASE AS A BIOSENSOR FOR Pb BIOAVAILABILITY

delta-Aminolevulinate dehydratase (ALAD; porphobilinogen synthase; EC: 4.2.1.24) is a 128-kDa metalloenzyme that catalyzes the first common step in the biosynthetic pathway for all tetrapyrroles, including oxygen carriers (e.g., heme), light gathering arrays (e.g., chlorophyll), vitamin B_{12}, and cofactor F430. The enzyme catalyzes the reaction between two molecules of aminolevulinic acid (ALA), which engage in a Knorr-type condensation reaction to produce porphobilinogen, the universal precursor of all pyrroles (Fig. 1) (7). ALAD activity has been demonstrated in all microorganisms that have been investigated across several phylogenetic groups. Microbial ALAD requires either zinc, magnesium, or both for optimum functioning, although these metals can be substituted by heavy metals such as Pb and Hg (Fig. 2).

In the proximity of the enzyme active site is the metal-binding domain, which for zinc consists of three cysteines at positions 133, 135, and 143, and a solvent molecule, presumably a hydroxide ion. Asparagine at positions 135 and 143, it has been postulated, is essential for Mg-dependent ALAD (8). Few microbial ALAD systems have been described, and the metallic component of ALAD differs among species. For example, Zn is required for ALAD activity in yeasts, whereas Mg is required in *Bradyrhizobium japonicum* and *Pseudomonas aeruginosa*, and both Zn and Mg are required by the *Escherichia coli* ALAD, although the requirement for Mg in *E. coli* is not stringent (8). Moreover, the sensitivity of ALAD to toxic metals depends on the identity of the metallic cofactor (8). ALAD activity in aquatic organisms has long been used as a biomarker of lead exposure (9,10), and a polymorphism in the ALAD locus has been described in humans that has implications for susceptibility to lead poisoning (11).

ALAD activity in an environmental strain of *Pseudomonas putida* ATCC 700097 originally isolated from an urban wastewater stream was sensitive to Pb and other toxic metals (12). There is a statistically significant dose–response relationship between ALAD activity in cells of this organism and Pb (Pearson correlation coefficient $= -0.985$; $r^2 = 0.97$; and $p < .001$). The highest level of inhibition of ALAD activity was approximately 74% of the normal level when cells were incubated with $Pb^{2+} > 500\ \mu M$. The relationship between Pb and ALAD activity was statistically described by $\log_{10}$ [Pb] $= 3 : 68 - 1.41$ [ALAD activity]. ALAD activity is measured in μmol of porphobilinogen synthesized per mg protein per minute. The direct exposure of protein extracted from *P. putida* showed a stronger inhibitory effect on ALAD activity, represented by a reduction of up to 85% in response to 500 μM of Pb. A higher concentration of Pb is needed to produce a comparable level of ALAD inhibition in *P. putida* cells seeded into natural freshwater; this suggests that Pb is not completely biologically available in freshwater. Therefore, an immobilized enzyme biosensor can be expected to be an even more sensitive tool for assessing biologically reactive forms of Pb in water, although this measurement precludes the barrier represented by cellular integrity (7).

The reduced bioavailability of Pb in water systems can be attributed to the presence of ligand chemicals, which

Table 5. Examples of Metals Required by Key Enzyme Functions[a]

Metal	Enzyme Examples	Relevant Organisms and/or Ecological Function
Calcium	Collagenase Calpain protease	*Clostridium histolyticum* Pathogenesis
Cobalt	Halomethane methyltransferase	Facultative methylotrophs Chloromethane degradation
Copper	Copper amine oxidases	*Arthrobacter globoformis* Deamination of primary amines to corresponding aldehydes
Iron	Cytochrome P450 Soluble methane Monooxygenase	*Pseudomonas putida*; P450 cam; polyaromatic hydrocarbon biodegradation
Magnesium	Magnesium chelatase	*Rhodobacter sphaeroides* Chlorophyll synthesis
Manganese	Manganese-dependent peroxidases	*Phanerochaete chrysosporium* Carbon cycling–lignin degradation
Molybdenum	Xanthine dehydrogenase Nitrate reductase; nitrogenase	*Pseudomonas putida* *Rhizobium* Purine (caffeine) degradation Nitrogen fixation
Selenium	Selenocysteine (UGA codon) enzymes; glutathione peroxidase; hydrogenases	*Escherichia coli* *Methanococcus voltae* Nitrogen respiration
Tungsten	“True W-enzymes” Aldehyde ferredoxin oxidoreductase	*Thermophilic archaea; Pyrococcus furiosus* Molybdenum antagonist
Zinc	Aminolevulinate dehydratase (inhibited by Pb)	Several bacteria and nearly all Archaea Porphyrin synthesis

[a] The biological availability of metal ions affects enzyme function, potentially constituting the basis for the development of protein-based biosensors.

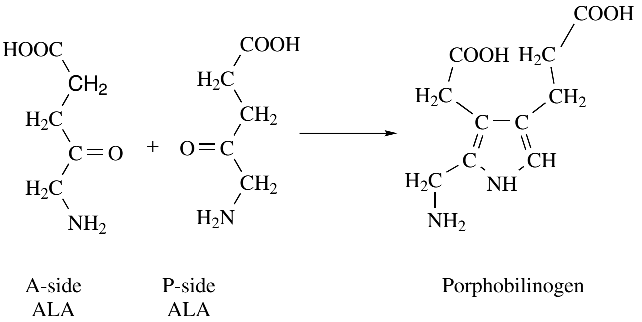

Figure 1. The metalloenzyme, delta-aminolevulinate dehydrate, catalyzes the condensation of two molecules of aminolevulinic acid to produce porphobilinogen, the universal precursor of tetrapyrroles.

are anions or molecules that form coordination compounds or complexes with metals, and commonly occur in natural waters (5). The most important inorganic ligands that form complexes with metals in natural waters are F^-, Cl^-, $SO_4{}^{2-}$, OH^-, $HCO_3{}^-$, $CO_3{}^{2-}$, $HPO_4{}^{2-}$, and NH_3; HS^- and S^{2-} are influential in anoxic waters. The covalent bonding tendency ($\Delta\beta$) and the ionic bonding tendency (Z^2/r) of metals determine the types of ligands that could reduce bioavailability (5). Metals such as Pb are classified as borderline (for Pb, $2 > \Delta\beta > 0$; and $2.5 < Z^2/r < 7.0$). As such, not all of these ligands are relevant to the bioavailability of Pb, but clearly many commonly detected regulated and unregulated inorganic ions in water systems affect Pb bioavailability. This limitation of bioavailability is likely to exist for other toxic heavy metals.

In conclusion, the pervasiveness of metal contamination of water systems indicates a great need to develop sensitive measures of biologically available concentrations of toxic heavy metals in water. The use of microbial enzymes assays for detecting heavy metal toxicity is an emerging technology with abundant resources represented by the physiological diversity inherent in microbial communities. However, further research is required to produce easily interpreted information on enzyme responses to environmental metals in a manner that can supplement the monitoring of other water quality parameters.

MICROBIAL FORMS IN BIOFOULING EVENTS

BIOFOULING FORMATION: NUTRIENT ADSORPTION

The term *biofouling* refers to organic debris as a result of the accumulation of inorganic and organic particulate matter along with the growth of various organisms on a surface. The development of a biofouling layer depends on the initial attachment of bacteria to this surface, their eventual increase in number, and the development of a protective slime layer, or glycocalyx.

Biofouling leads to many undesirable problems in industry, such as decreased heat transfer in cooling towers, regrowth in drinking water distribution systems (Fig. 1), and deterioration of materials. In the medical arena, biofilms are responsible for dental plaque and persistent infections on medical implants. It has long been observed that biofilms are much less susceptible to antimicrobial agents than are their planktonic (free-swimming) counterparts.

Most microorganisms, especially heterotrophic bacteria, can easily access nutrients previously deposited on a surface. The attachment of microorganisms to surfaces has a survival function, because the surface in oligotrophic conditions served as sites of nutrients for microorganisms' growth even though they cannot multiply in the bulk aqueous phase. One possible reason for the rapid bacterial growth at surfaces in aquatic environments was the evolvement of microbially produced extracellular enzymes (1). These enzymes can metabolize the macromolecular or particulate substrates. In the bulk aqueous phase, the contact between enzyme and substrate was rare, and products of enzymatic hydrolysis would diffuse away and be unavailable to the bacterium. At the surface, on the other hand, the enzyme and substrate would be in close contact, and provided the enzyme remained active in the adsorbed state, the bacterium should benefit from the end products of the reaction.

Figure 1. The cut section of a cast-iron pipe shows a severe iron bacteria buildup on the pipe walls.

The adhesion of microorganisms to a solid surface is a strategy for access to nutrients. If the bulk water had very few dissolved organic nutrients in it, the growth and reproduction of bacteria would be a very slow process. However, the attachment to a solid surface can substantially accelerate bacterial growth. The bacterial attachment to surfaces shows a great advantage: attached bacteria, known as *sessile or adherent bacteria,* become exposed to a plentiful supply of fresh water containing fresh nutrients that they can extract continuously. Another advantage that sessile bacteria have is their ability to adsorb dissolved organic molecules (food sources for many bacteria) from the water layer. This attachment or adsorption facilitates the growth of microorganisms, especially in oligotrophic environment.

Because of the easy access to nutrients on the surface, the attached bacteria normally have a bigger size than do free-swimming bacteria. When acetate was a substrate, the attached bacteria were larger (average vol. = $0.271\ \mu m^3$) than were planktonic bacteria (average vol. = $0.118\ \mu m^3$), had a higher frequency of dividing cells, and were responsible for most of the acetate uptake (2). These larger attached cells suggest that many of the planktonic (free-swimming) cells were starving and, hence, remained small, whereas the attached cells were growing on substrate available at the surface (3).

MICROORGANISM FORMS IN BIOFOULING FORMATION

One advantage of attachment to a surface is that microorganisms can easily get access to nutrients on the surface and survive in the adverse environment. Starved cells of the marine *Vibrio* DW1 are more adhesive than are unstarved cells, which leads to the suggestion that adhesion may be a tactic in the survival strategy of these organisms under starvation conditions (4). It has been widely accepted that microorganisms attach to available surfaces and initiate the formation of monolayer covering on surfaces; then they develop into thick layers of extensive biofilms, enveloped within extracellular polymeric matrices (5). Generally, there are five diversities in bacterial growth patterns adhered onto surfaces (Fig. 2). These diversities are as follows:

1. *Mother–Daughter or Shedding Cells*. After bacteria adhere to a surface, the small starved cells ($<0.5\ \mu m$ diameter) grow to normal size ($>1.0\ \mu m$ diameter), presumably with substrate accumulating on the surface. The growing cells (now the mother cell) attach to the surface in a perpendicular orientation, and as each gowing cell begins to divide, the daughter cells exhibit a rapid spinning motion before release into the aqueous phase. The mother cell, which remains on the surface, repeats the processes of cellular growth and reproduction. Many daughter cells return to colonize the surface further to get nutrients, and the extensive secondary colonization of the surface results in nutrient uptake exceeding

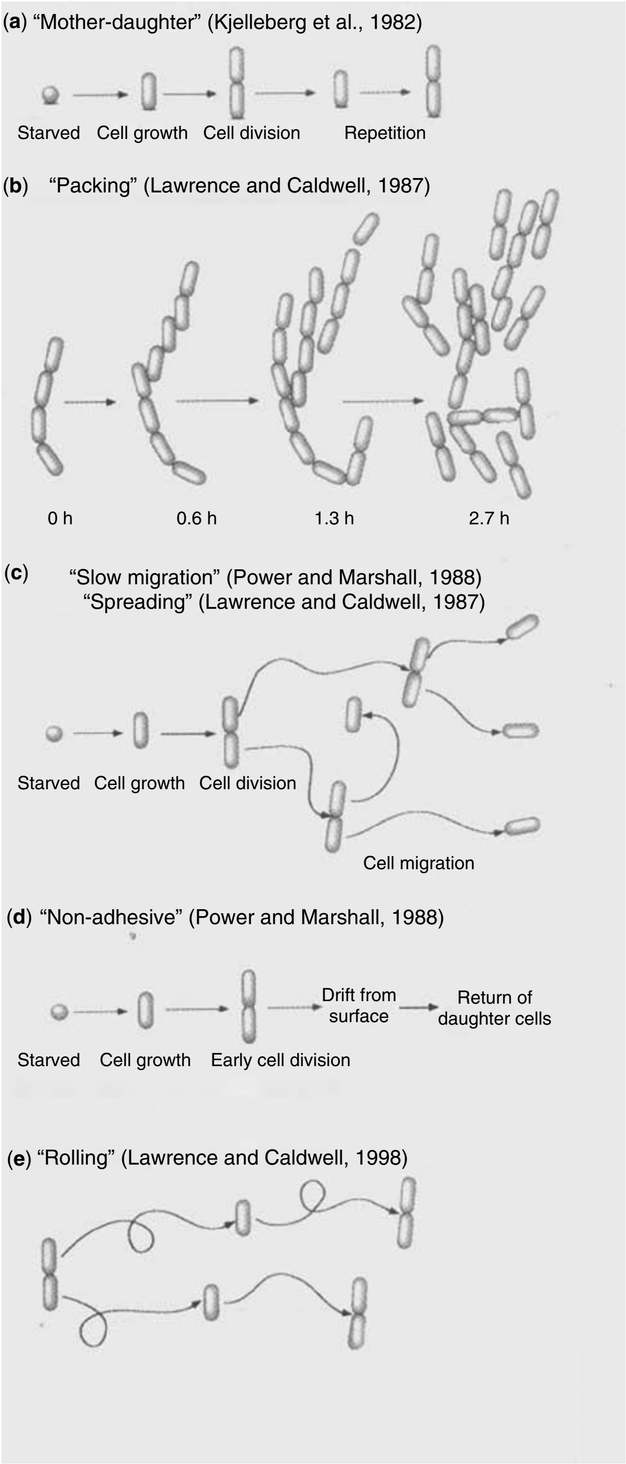

Figure 2. Diversity in growth patterns in bacteria associated with surface. (**a**) Mother–daughter or shedding cells, (**b**) packing cells, (**c**) slow migratory or spreading cells, (**d**) reversibly adhering cells, and (**e**) rolling cells. (Courtesy of Ref. 6.)

nutrient input to the surface, and hence, the cells cease dividing and revert to typical small starvation forms (6).

2. *Packing Cell*. Bacteria divide in a manner that results in the daughter cells aligning adjacent to each other, which eventually leads to the formation of a contiguous monolayer (7).
3. *Slow Migratory or Spreading Cells*. When *Pseudomonas* JD8 cells are in a medium lacking an energy source, the adhering, small, and starved cells grow to normal size and begin to divide, and then the daughter cells migrate very slowly (0.15 μm/min) and at random for variable distances (5–50 times their cell length) across the surface before the next division occurs (8).
4. *Reversibly Adhering or Rolling Cells*. *Vibrio* MH3 is capable of metabolizing surface-bound static acid, the starved cells grow to normal size, and cellular division begins near the surface, but the dividing cells return to the aqueous phase for the final production of daughter cells. That cell division proceeds to completion in the aqueous phase was also described by Lawrence and Caldwell (7) as rolling; that is, cells loosely attached and somersaulting across the surface as they grow and divide similarly may develop as a result of the bacteria reversibly adhering to the surface.
5. *Gliding Cells*. Many cytophage-like gliding bacteria can use complex polysaccharide substrata as an energy substrate. They have a unique form of adhesion that allows them to remain attached to a solid substrate in aqueous condition, and they can glide (translocate) across the surface (9). After the initial attachment to the substratum, *P. aeruginosa* evidently moves on the substratum by means of twitching motility, which suggests that the initial microcolonies are formed by aggregation of bacteria. A large fraction of the biofilm bacteria (*P. aeruginosa, Discosoma* sp.) occasionally swim from one microcolony into another (10). This characteristic certainly makes for efficient use of the solid substrates they metabolize.

THE RELATIONSHIP OF MICROORGANISMS INSIDE BIOFOULING LAYERS

In the biofouling events, different types of microorganisms form either competition or syntrophic correlation. In the mixed biofilms formed by fungi and bacteria, the interactions vary with different microbial species and forms. In the fungal biofouling, *P. aeruginosa* (bacteria) cells readily adhere to *Candida albicans* (a pathogenic fungi) hyphae, but not to the yeast form of *Candida*. Over a 24–48 hour time course, bacteria attach to the *C. albicans* hyphae and form biofilms consisting of densely packed cells surrounded by extracellular matrix (ECM). These findings suggest that the bacteria in biofilm extract nutrients from the underlying *Candida* hyphae, eventually killing the hyphal form of the yeast, and several virulence genes of *P. aeruginosa* that are involved in the killing of *Candida* hyphae in mixed biofilms (11).

Although *P. aeruginosa* is harmful to *Candida* in the biofouling formation, *Streptococcus mutans* can make *C. albicans* strongly adhere to the surface. It was found that *C. albicans* is detached very easily when growing alone, even by a slight movement, when it adheres to plastic rods in a medium containing sucrose (12). However, in mixed cultures of *C. albicans* and *S. mutans, Candida* tend to grow superficially on the surface of a polysaccharide layer formed by the cocci that have colonized the rod surface and are strongly adhered. These findings are confirmed in a subsequent study showing that firm adhesion of *C. albicans* to acrylic resin occurs when the yeasts are incubated simultaneously with *S. mutans* in the presence of glucose. (13). Other studies also found that *S. mutans* grow under and above the yeast and hyphal layers and are clearly adherent to both morphological forms of *C. albicans* (14). This association in the mixed species biofilm makes the biofilm develop very strongly and the fouling is not easy to remove.

Moreover, in a two-species bacterial biofouling event, different metabolic interactions are formed in chemostats (bulk water) and biofouling layers (15). When *P. putida* R1 and *Acinetobacter* C6 strains were grown together in chemostats with limiting concentrations of benzyl alcohol as substrate, they competed for the primary carbon source, which gave *Acinetobacter* C6 a growth advantage. *Acinetobacter* strain C6 outnumbered *P. putida* R1 (cell number ratio: 500:1). However, under similar growth conditions in biofilms, *P. putida* R1 was present in higher numbers than was *Acinetobacter* strain C6 (cell number ratio: 5:1). In addition, these two organisms compete or display commensal interactions depending on their relative physical positioning in the biofilm. In the initial phase of biofilm development, the growth activity of *P. putida* R1 was shown to be higher near microcolonies of *Acinetobacter* strain C6. After a few days, *Acinetobacter* strain C6 colonies were overgrown by *P. putida* R1 cells and new structures developed, in which microcolonies of *Acinetobacter* strain C6 cells were established in the upper layer of the biofilm. In this way, the two organisms developed structural relationships allowing *Acinetobacter* strain C6 to be close to the bulk liquid with high concentrations of benzyl alcohol and allowing *P. putida* R1 to benefit from the benzoate leaking from *Acinetobacter* strain C6.

In sticky biofouling layers, a variety of microorganisms (e.g., hetetrotrophic, autotrophic, aerobic, and anoxic) attach to each other and form a stable and complex microecological community, so the slime layer increases in size and the bacteria become firmly attached to the surface. With the biofilm becoming thicker, oxygen depletion (anaerobiosis) occurs in the lower layers of the biofouling layers, caused by the mass transfer resistance inside the biofilm and the metabolic activity of an aerobic microorganism on the surface layer of the biofilm. Under these conditions, bacteria that require oxygen-free conditions to grow can start to develop. These bacteria include those that can grow in both oxygenated and deoxygenated conditions (known as facultative anaerobic bacteria). Examples are the coliform bacteria, such as *E. coli,* and certain species of *Pseudomonas.* Other bacteria are strictly anaerobic, growing well only in the absence of oxygen. These bacteria include certain species of sulfate reducing bacteria (SRB) and methanogenic bacteria, which are predominant in the deeper layer of biofilm near substratum. The biogas (N_2, H_2S, CO_2, CH_4, etc.) produced by these anoxic and anaerobic bacteria may cause the detachment of the thick biofilm from the surface.

BIOFOULING IN A COOLING TOWER

Biofouling in a cooling tower has been a long-standing problem in industry (Fig. 3). The inorganic and organic contaminants in a cooling tower may precipitate from the flowing water and lead to fouling problems (16). Several major types of microorganisms are involved in cooling tower biofouling, for example, iron bacteria, sulfur reducing/oxidizing bacteria, algae, and fungi.

Major aerobic bacteria that may cause problems in cooling systems are iron-oxidizing bacteria. This group of bacteria are commonly found in well waters that contain soluble iron and large amounts of carbon dioxide. The iron bacteria oxidize the soluble ferrous (Fe^{2+}) to insoluble ferric (Fe^{3+}) as a source of energy, and they use carbon dioxide as a source of carbon for cell growth. They generally produce slimy red-brown flocs of hydrated ferric oxide that can cause plugging of filters and heat exchangers.

Another group of aerobic bacteria in cooling systems is sulfur-oxidizing bacteria, which produce yellow stringy slimes. These bacteria oxidize and reduce sulfur compounds (H_2S) to sulfuric acid ($SO_4{}^{2-}$) in the aerobic environment, which reduces the pH of the water to even lower than 2. The sulfuric acid produced by the sulfur bacteria may cause slime production and corrosion of concrete basins. This group of bacteria is mainly found in refinery cooling towers contaminated with reduced sulfur compounds.

Many types of algae contain the green pigment chlorophyll, which traps the energy from sunlight. Algae synthesize carbon from carbon dioxide from air and require energy from sunlight. Growth of algae primarily occurs in the tower deck area because of ample sunlight. Having been introduced from the atmosphere as spores to water, algae readily become established in areas where plenty of sunlight exists, such as the top of the deck and at the sides of the tower. Algae produce mainly green or blue–green gelatinous slimes, which may be long and filamentous or

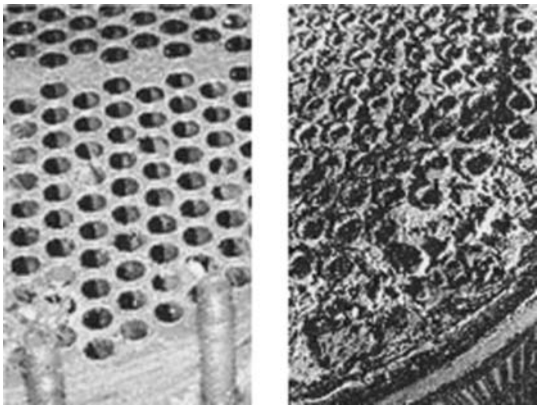

Figure 3. Cooling tower corrosion caused by biofouling. Left: cooling tower wall without biofouling. Right: cooling tower wall with biofouling.

loose and flocculent. The slime species most commonly found is the green algae, the cyanobacteria (originally the blue–green algae) and the diatoms. Prolific algal growth may produce green or blue–green scums in some cooling tower sumps. Algae slimes can plug distribution nozzles and troughs in the cooling tower deck, which causes poor water distribution across the tower and hence reduces cooling efficiency. In the biofouling development, the growth of algae may provide a food source that encourages the growth of other organisms, such as bacteria and fungi.

Fungi are another major group of microorganism that causes problems in the cooling tower. The most insidious problem caused by the growth of fungi is the attack on cooling tower wood, which can go unnoticed for many years. Molds and yeasts can break down the cellulose in the wood, which leads to structural weakening.

BIOFOULING IN MEMBRANE WATER TREATMENT SYSTEM

Biological contamination, known as biofouling, occurs most often during nanofiltration and reverse osmosis in water treatment systems. The attachment of inorganic/organic matters and microorganisms has damaging, often irreversible effects on nanofiltration and reverse osmosis systems (Fig. 4). The major impact of biofouling is the substantial reduction of the flux through the membrane systems, which results in a higher pressure, that causes higher operation cost (18). In some cases, membrane materials are suitable environments for microorganisms to grow, which will cause the membrane to be completely destroyed in a short period of time.

The types of microorganisms, their growth factors, and their concentration in a membrane system greatly depend on critical factors, such as temperature, the presence of sunlight, pH, dissolved oxygen concentrations, and the presence of organic and inorganic nutrients. Both aerobic (oxygen-dependent) and anaerobic (oxygen-independent) bacteria can attach onto the membrane surface and develop biofilm. Aerobic bacteria usually live in an environment of warm, shallow, and sunlit water, with a high dissolved oxygen content, a pH of 6.5 to 8.5, and an abundance of organic and inorganic nutrients. Anaerobic bacteria, on the other hand, are usually present in closed systems with little to no dissolved oxygen and become active when a sufficient amount of nutrients (e.g., organic matter or the debris of dead microorganisms) is present.

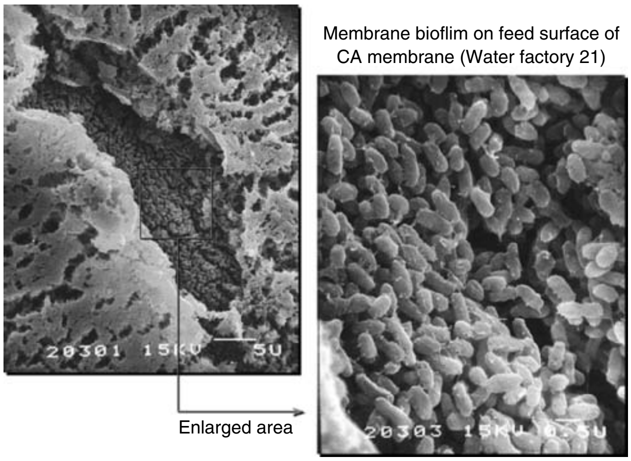

Figure 4. Scanning electron micrographs of mature biofilms formed on cellulose acetate (CA) reverse osmosis (RO) membranes. The RO membranes were fed with a pretreated municipal effluent at Water Factory 21 in Orange County, California. (Courtesy of Ref. 17.)

Another major type of microorganism in membrane biofouling is algae, which can grow on membrane parts exposed to sunlight. The amount of sunlight determines the amount of oxygen that is produced by algae. Aerobic bacteria, which are oxygen-dependent, need the oxygen produced by algae when the dissolved oxygen content in the feed water is insufficient for metabolism. Therefore, the growth of algae boosts the aerobic bacteria growth and further causes biofouling. While the algae die off, they become a food source for bacteria, because they release organic nutrients that bacteria need for growth in a membrane system, especially in an oligotrophic water environment.

METHODS OF BIOFOULING CONTROL

The most efficient approach to solve biofouling is to kill living attached microorganisms by using biocides, or to inhibit the life processes of living organisms without actually killing them by using biostat. It is possible for a chemical to be a biostat to certain organisms at a low concentration and a biocide to the same organisms at a higher concentration. Both biocides and biostats solve the slime problem by affecting various parts of the microbial cell.

Two types of biocides exist: organic biocides, classified as nonoxidizing biocides because they do not oxidize other chemicals or oxidize them only very slightly, and inorganic biocides, classified as oxidizing biocides (e.g., chlorine) because they have a very strong oxidation capacity for many organic and inorganic matters. Nonoxidizing (organic) molecules react with various parts of the microbial cell, generally at a specific site. The most common groups of nonoxidizing biocides are aldehydes, organo-sulfur biocides, chlorinated isocyanurates, organo-nitrogen biocides, amine salts, and heavy metals.

Examples of useful oxidizing biocides are halogens such as chlorine (Cl_2), chlorine dioxide (ClO_2) (19), hydrogen peroxide (H_2O_2), ozone, and chlorine, bromine donors such as chlorinated isocyanurates and hydantoins. The main drawback with the oxidizing biocides is their high level of reactivity to reduce compounds such as iron and H_2S and organic matter during the penetration through biofilm (little residual is left to control microorganisms). So they do not effectively penetrate and disperse microbial slimes. Moreover, some oxidizing biocides (e.g., chlorine) are not effective at solving clogging on the membrane surface. At low chlorine levels, biofilm bacteria can produce extracellular material faster than chlorine can diffuse through biofilm, so they are shielded in slime and make the slime problem worse (20). Therefore, chlorine is usually supplemented by the addition of nonoxidizing biocides in many membrane systems.

MICROBES IN DRINKING WATER

Good drinking water should not be harmful for health or materials of the distribution system. Undesired health effects can be caused by chemicals or biological agents, including viruses, bacteria, fungi, and protozoa (1–7).

Most of bacteria found in drinking water cannot cause disease in the general population (8). Usually waterborne epidemics are caused by accidental contamination of drinking water, for example, by flooding, surface runoff, or leakage of wastewater pipelines (6). Pathogenic fecal microbes like enteric viruses, protozoan parasites, *Campylobacter*, enterohemorragic *Escherichia coli* (EHEC), *Yersinia enterocolitica*, *Microsporidia*, *Helicobacter pylori*, *Salmonella*, and *Shigella* from contaminated raw water sources may also enter the distribution system as a result of inadequate water treatment (2–6,9,10). These microbes probably do not multiply in the drinking water environment, but they may survive there, especially in biofilms (9,11).

The growth of native nonpathogenic microbes in the distribution system can have several undesired effects on the water quality: the microbial growth can complicate bacteriological water quality monitoring, iron bacteria can precipitate iron-producing iron flocs, the growth of actinomycetes and fungi gives an unpleasant taste and odor to the water, and microbes can destroy the piping materials resulting from their biocorrosion (9,12,13). There are some pathogens or opportunistic pathogens like *Legionella, Pseudomonas aeruginosa, Mycobacteria*, and *Aeromonas*, which can grow in drinking water distribution systems (9,10,14,15). Bacteria and fungi also promote the occurrence of protozoa and higher animals by serving as food for them (13,16).

Microbial cells are attached to almost any surface in aquatic environments (17). Bacteria in biofilms represent the most important part of the bacterial biomass in drinking water distribution networks (18,19), and detachment of bacteria from biofilms accounts for most planktonic cells present in water (20). Biofilms promote the survival and growth of pathogenic bacteria and survival of viruses and parasites (4,9,11,21–23), and they increase the disinfection resistance of bacteria (9,21,24,25).

MICROBIAL QUALITY CONTROL

The growth of microbes in a drinking water distribution system is affected by factors like disinfection, availability of nutrients, temperature, and water residence time.

MICROBES IN DRINKING WATER

Good drinking water should not be harmful for health or materials of the distribution system. Undesired health effects can be caused by chemicals or biological agents, including viruses, bacteria, fungi, and protozoa (1–7).

Most of bacteria found in drinking water cannot cause disease in the general population (8). Usually waterborne epidemics are caused by accidental contamination of drinking water, for example, by flooding, surface runoff, or leakage of wastewater pipelines (6). Pathogenic fecal microbes like enteric viruses, protozoan parasites, *Campylobacter*, enterohemorragic *Escherichia coli* (EHEC), *Yersinia enterocolitica*, *Microsporidia*, *Helicobacter pylori*, *Salmonella*, and *Shigella* from contaminated raw water sources may also enter the distribution system as a result of inadequate water treatment (2–6,9,10). These microbes probably do not multiply in the drinking water environment, but they may survive there, especially in biofilms (9,11).

The growth of native nonpathogenic microbes in the distribution system can have several undesired effects on the water quality: the microbial growth can complicate bacteriological water quality monitoring, iron bacteria can precipitate iron-producing iron flocs, the growth of actinomycetes and fungi gives an unpleasant taste and odor to the water, and microbes can destroy the piping materials resulting from their biocorrosion (9,12,13). There are some pathogens or opportunistic pathogens like *Legionella, Pseudomonas aeruginosa, Mycobacteria*, and *Aeromonas*, which can grow in drinking water distribution systems (9,10,14,15). Bacteria and fungi also promote the occurrence of protozoa and higher animals by serving as food for them (13,16).

Microbial cells are attached to almost any surface in aquatic environments (17). Bacteria in biofilms represent the most important part of the bacterial biomass in drinking water distribution networks (18,19), and detachment of bacteria from biofilms accounts for most planktonic cells present in water (20). Biofilms promote the survival and growth of pathogenic bacteria and survival of viruses and parasites (4,9,11,21–23), and they increase the disinfection resistance of bacteria (9,21,24,25).

MICROBIAL QUALITY CONTROL

The growth of microbes in a drinking water distribution system is affected by factors like disinfection, availability of nutrients, temperature, and water residence time.

Waterworks normally disinfect drinking waters by chlorination, ozonation, UV-radiation, or some combination of them. Nutrients, temperature, and residence time are important in microbial growth control when water is distributed without disinfection residuals (ozonation, UV-disinfection) or when disinfection residual is low (chlorine in peripheral parts of distribution system). Also, the pipe material and water hydraulics affect microbial growth in biofilms.

Disinfection

Chlorine is added to water as free chlorine, chlorine dioxide, or chloramines. Free chlorine destroys bacteria by reactions with bacterial enzymes (26), whereas chloramine reacts with nucleic acids, tryptophan, and sulfur-containing amino acids (27). The following factors affect the disinfection efficiency: (1) nature of disinfectant, (2) concentration of disinfectant, (3) length of the contact time, (4) temperature, (5) type and concentration of organisms, and (6) pH (26). One major disadvantage of using chlorine as a disinfectant is the formation of harmful by-products in reactions with organic matter (28,29). Chlorine also degrades organic matter and increases the content of easily available organic carbon for bacteria (AOC) (13,30,31).

There are many advantages to using chloramines instead of free chlorine. Chloramines have a good residual effect and the ability to destroy microbes in biofilms (27). Also, the formation of unwanted chlorinated organic by-products is low with chloramines (32,33). However, the addition of chloramines may enhance growth of ammonia oxidizing bacteria and thus accumulation of nitrite in drinking water (34,35).

Ozonation is a commonly used technique for removing pathogenic microbes, taste, and odor from water (36,37). Ozone is an unstable gas, which has to be generated onsite in the waterworks. The disinfection mechanism is based on the reaction with the double bonds in fatty acids of bacterial cell walls and cell membranes and the protein capsid of viruses (36). In water, ozone is decomposed rapidly back to oxygen and has therefore no residual effects in the distribution system. As a strong oxidant, ozone effectively degrades natural organic matter (30,38). Reactions with natural organic matter increase the content of easily available organic carbon (AOC) and microbially available phosphorus (MAP) in water and thus microbial growth in the distribution network (30,39–41). Ozonation can also produce ozonation by-products; of particular concern is carcinogenic bromate, which is produced when water containing bromide is ozonated (42,43).

UV-radiation ($\lambda = 253.7$ nm) is effective in destroying bacteria and viruses in water (44–47). The destructive effect of UV-radiation is based on DNA and RNA damage such as thymine dimer formation, hydrate formation in the DNA, denaturation of the DNA double strand, and polymerization between nucleic acids and proteins. The absorption maximum of DNA and RNA 255–265 nm is near the wavelengths emitted from mercury low-pressure lamps (253.7 nm). Most microorganisms are inactivated by relatively low UV_{254} dosages—usually in the range of 2–6 mWs/cm^2, although viruses tend to be more resistant to UV_{254} radiation than bacteria (45). There is no evidence on the formation of undesirable by-products or increase in the contents of microbial nutrients like biodegradable organic carbon or microbially available phosphorus by UV-disinfection (45,48,49). Disadvantage of UV-disinfection is similar to ozonation: the lack of residual activity in the distribution system (45).

Biofilms. Some countries use phosphate-based anticorrosion (50–52) chemicals in their distribution systems. The efficiency of phosphates to control biofilm formation is based on neutralization of positively charged corrosion products, such as goethite (α-FeOOH), to negatively charged $FePO_4$, which lowers the adhesion of bacteria to pipe surfaces (50,52). Some studies have shown that these chemicals have not increased microbial growth (50,51,53,54). However, there are geographical regions where use of phosphate against corrosion should be considered carefully because there availability of phosphorus is a limiting factor for microbial growth in drinking waters (see later).

It is difficult to prevent formation of biofilms by chlorine disinfection because residual concentration >1–2 mg/L is needed (20,21,55). Inactivation of fixed bacteria in biofilms needs even a higher concentration of chlorine (>3 mg/L) (25). The inactivation efficiency depends on the composition of the pipe material, the disinfection agent (chloramine vs. chlorine) (27,55), temperature, and water velocity (17).

Microbial Nutrients

Organic Carbon. Except photoautotrophs and chemoautotrophs, organisms need organic compounds for their carbon and energy sources. Organic compounds are partially assimilated into the cell material and partially oxidized to provide energy (56). Bacteria can use a wide range of substrates, but some substrates like amino acids, carboxylic acids, and carbohydrates are more readily usable than others (57).

Aromatic humus substances in drinking water are difficult to use as microbial substrates; usually only a small part of total organic carbon is easily used by microbes (39). There are two commonly used approaches to analyze the microbial usability of aquatic natural organic matter: determination of assimilable organic carbon (AOC) or biodegradable organic carbon (BDOC). AOC is that part of organic matter that can be converted to cell mass. It is expressed as a carbon concentration by means of a conversion factor (39). BDOC is the part of organic carbon that can be mineralized by heterotrophic microbes (58,59).

The first method for AOC assay was published in 1982 by Van der Kooij et al. (39). The test is based on the growth of certain bacterial strains in a water sample, and AOC is calculated using empirical yield values for these bacteria. The bacterial strains used in the test are *Pseudomonas fluorescens* strain P-17 and *Spirillum* strain NOX (60). In regions with high content of organic matter and low amount of phosphorus in water, a modification of the test is required. Miettinen et al. (61) modified the test by adding inorganic nutrients to the water sample to ensure that only organic carbon limits the bacterial growth in the water and suggested the term $\mathrm{AOC}_{\mathrm{potential}}$. They used the term $\mathrm{AOC}_{\mathrm{native}}$ for the assimilable carbon determined without addition of inorganic nutrients.

In the BDOC method, organic carbon is mineralized by the natural microbial community in water, and BDOC is measured as a difference in content of dissolved organic carbon (DOC) before and after (>10 days) incubation of the inoculated water sample (58). There also is a biofilm reactor application for the method. In this application, a water sample is filtered through a column where microbes are attached in biofilm (e.g., glass/sand matrix), and the difference in DOC between inlet and outlet is analyzed (62,63).

Phosphorus. Phosphorus, as a macronutrient, is an essential nutrient for microbes. Bacteria need phosphorus for biosynthesis of nucleic acids, lipopolysaccharides, and phospholipids (56). Phosphate is a vital component of the intracellular energy-transferring ATP system (56). The optimum C:N:P ratio (carbon:nitrogen:phosphorus) for bacterial growth is 100:10:1.

Phosphorus occurs in nature only in the form of chemical compounds, either as inorganic orthophosphate ($\mathrm{HPO_4}^{2-}$, $\mathrm{H_2PO_4}^{-}$) or in organic compounds. In a humus-rich environment, phosphorus is associated with high-molecular-weight humic materials, especially in the presence of iron or manganese (64,65).

Soluble inorganic phosphate is considered to be entirely biologically available (66). All living organisms possess the enzyme, alkaline phosphatase, to convert organic phosphorus to inorganic phosphorus, but only microbes and fungi can excrete the enzyme outside of their cells (exoenzymes) to mineralize and dissolve organic phosphates (66).

Chemical phosphorus analysis has two steps: (1) conversion of phosphorus compounds to dissolved orthophosphate, and (2) colorimetric determination of the dissolved orthophosphate. With these colorimetric standard methods, the detection limit for phosphorus in water is 2–10 μg P/L (60).

Another approach for phosphorus analysis is to measure microbially available phosphorus (MAP) with a bioassay (67). There inorganic nutrients (except phosphorus) and organic carbon are added to the water samples to ensure that inorganic nutrients or organic carbon do not restrict microbial growth. Samples are inoculated with *Pseudomonas fluorescens* bacteria, and the maximum growth of *Pseudomonas fluorescens* is transformed to the amount of microbially available phosphorus with a conversion factor taken from the standardization of the method. The MAP bioassay is very sensitive, and the detection limit is 0.08 μg P/L. MAP represents the part of total phosphorus that is easily available for bacteria. It is important that MAP does not correlate to the content of total phosphorus in water (67).

Nutrient Limitations of Bacterial Growth in Drinking Water. Microbial growth in drinking water is generally limited by AOC or BDOC (39,68–71). In many cases, organic carbon limits microbial growth also in biofilms (18,53–55,72).

The importance of AOC over phosphorus is based on the high ratio of carbon to phosphorus. For example, in an American study, the C:P ratio in drinking water was in the range 100:250 to 100:43, whereas the typical ratio for optimal microbial activity is 100:1 (73). LeChevallier et al. (74) proposed that to limit the growth of coliform bacteria in drinking water, AOC levels should be below 50 μg/L. According to Van der Kooij (13), the AOC concentration should be less than 10 μg/L to limit the microbial aftergrowth. For BDOC, the guideline value of 0.15 mg BDOC/L for biologically stable water has been proposed (69).

In some regions, the correlation between AOC and heterotrophic growth response is weak (73,75) or there is no correlation at all (76,77). Kerneis et al. (78) found no correlation between BDOC and growth of heterotrophic microbes in a drinking water distribution network. It was first found in Finland that microbial growth in drinking water is limited by the availability of phosphorus (79). Subsequently, phosphorus limitation has been reported for drinking waters in Japan (80,81).

In regions where microbial growth in drinking water is limited by phosphorus, a major increase in microbial growth has been achieved with additions of only 1–5 μg/L of $\mathrm{PO_4}$-P (80,82). Sathasivan and Ohgaki (81) reported that phosphorus could become a limiting nutrient at concentrations of 1–3 μg/L. In phosphorus-limited drinking water, the formation of biofilms was also affected by the availability of phosphorus (83).

The reasons for the phosphorus limitation in treated drinking waters are high organic carbon concentration in raw waters and more effective phosphorus removal than that of AOC (31). In fact, in many cases, the AOC content even increases during the drinking water purification process, especially if the waterworks uses ozonation.

WATER QUALITY MODELS FOR DEVELOPING SOIL MANAGEMENT PRACTICES

HARRY X. ZHANG
Parsons Corporation
Fairfax, Virginia

INTRODUCTION

Water quality models are used extensively in water quality planning and pollution control. Models are applied to answer a variety of questions, support watershed planning and analysis, and develop total maximum daily loads (TMDLs). Watershed loading models include techniques designed primarily to predict pollutant movement from the land surface to waterbodies. TMDLs result in allocating the quantity of pollution that can be discharged from point sources (wasteload allocation) and nonpoint sources (load allocation) to ensure that water quality standards are achieved within a specified margin of safety (1). Management measures can be applied to achieve all of the pollution control needed by pollutant sources to achieve the load allocation. Best management practice (BMP) is generally defined as a practice or combination of practices that are the most effective and practicable (including technological, economic, and institutional considerations) means of controlling point and nonpoint pollutants at levels compatible with economic and environmental quality goals (2).

It is important to estimate the collective impacts of all management activities in a watershed to evaluate whether water quality goals will be achieved. In watersheds that have easily characterized problems, it may be easy to project that water quality benefits will be achieved by implementing management measures such as erosion and sediment control and runoff minimization. However, in a watershed that has multiple land uses where agriculture is considered to contribute groups of pollutants, it is more complicated to estimate the combined impacts of a variety of management measures and practices on a fairly large number of diverse farming operations. In this type of situation, computer modeling may be needed. A variety of models exist to help assess the relative benefits of implementing practices at the field and watershed level. Managers can use models to develop goals and objectives for watershed and waterbody use and protection, to develop and to evaluate the effectiveness of various management and mitigation alternatives to improve existing water quality, and to determine the response time of a waterbody after implementing a management alternative. In particular, models can help understanding key “cause-and-effect” processes within the natural environment, developing waste load allocations and TMDL analysis, and evaluating the effectiveness of various contaminant reduction scenarios.

BRIEF OVERVIEW OF NONPOINT SOURCE WATER QUALITY MODELS

Watershed loading models range from simple loading rate assessments in which loads are a function of land use type only, to complex simulation techniques that more explicitly describe the processes of rainfall, runoff, sediment detachment, and transport to receiving waters. Some loading models operate on a watershed scale, integrating all loads within a watershed, and some allow subdividing the watershed into contributing subbasins. Given the complex nature of the processes and interactions that determine the fate and transport of a pollutant or chemical in nature, mathematical models can attempt to represent only the principal components of the environment that influence a given water quality variable. It is virtually impossible to incorporate fully all of the mechanisms and processes that occur in nature. Therefore, there are varying degrees of simplicity or complexity embodied in watershed and water quality modeling.

Many computer models are available to assess soil management practices. Based on their complexity, operation, time step, and simulation technique, watershed-loading models can be grouped into three categories: simple methods, midrange models, and detailed models.

Simple Models

The major advantage of simple methods is that they can provide a rapid means of identifying critical areas with minimal effort and data requirements. Simple methods are typically derived from empirical relationships between physiographic characteristics of the watershed and pollutant export. Simple methods are often used when data limitations and budget and time constraints preclude using complex models. They are used to diagnose nonpoint source pollution problems, when information is relatively limited. They can be used to support an assessment of the relative significance of different sources, guide decisions for management plans, and focus continuing monitoring efforts.

Typically, simple methods rely on a large-scale aggregation of characteristics and neglect features of small patches of land. They rely on generalized sources of information and therefore have low to medium requirements for site-specific data. Default values provided for these methods are derived from empirical relationships that are based on regional or site-specific data. The estimates are usually expressed as mean annual values. Simple methods provide only rough estimates of sediment and pollutant loadings and have limited predictive capability.

In addition, field-scale models, which have traditionally specialized in agricultural systems, are loading models that are designed to operate on a smaller, more localized scale. Field-scale models have often been employed to aid in selecting management measures and practices.

Midrange Models

The advantage of midrange watershed loading models is that they evaluate pollution sources and impacts over broad geographic scales and, therefore, can assist in defining target areas for pollution mitigation programs in a watershed. The midrange model compromises between the empiricism of simple methods and the complexity of detailed mechanistic models (e.g., relating pollutant loading to hydrologic and erosion processes). Mechanistic models usually include detailed input–output features.

Detailed Models

Detailed models best represent the current understanding of watershed processes that affect pollution generation. Detailed models are best able to identify causes of problems rather than describe overall conditions. If properly applied and calibrated, detailed models can provide relatively accurate predictions of variable flows and water quality at any point in a watershed. The additional precision they provide, however, comes at the expense of considerable time and resources for data collection and model application.

Model Comparison

Detailed models incorporate the manner in which watershed processes change over time continuously rather than relying on simplified terms for rates of change. Algorithms in detailed models more closely simulate the physical processes of infiltration, runoff, pollutant accumulation, in-stream effects, and groundwater–surface water interaction. The input and output of detailed models also have greater spatial and temporal resolution. Moreover, the manner in which physical characteristics and processes differ over space is incorporated within the governing equations. However, input data file preparation and calibration of detailed models require professional training and adequate resources. Their added accuracy might not always justify the amount of effort and resources required.

In comparison, simple methods use large simulation time steps to provide longer term averages or annual estimates. Their accuracy may decrease in estimating seasonal or storm loading because they cannot capture the large fluctuations of pollutant loading or concentration usually observed when smaller time steps are employed. Neither the simple nor the midrange models consider degradation and transformation processes, and few incorporate detailed representations of pollutant transport within and from the watershed. Although model applications might be limited to relative comparisons, they can often provide useful information to water quality managers for watershed-level planning decisions. If adequate site-specific data are not available, values can be estimated and assumptions can be made, but these estimates will increase the uncertainty in the model predictions. It will be very difficult to validate whether simple or complex models provide better estimates. Therefore, if data availability does not reach the level that a detailed model requires, it is recommended that a simpler model be employed.

REVIEW OF WATER QUALITY MODELS FOR DEVELOPING SOIL MANAGEMENT PRACTICES

Hydrologic Simulation Program–FORTRAN (HSPF) and WinHSPF (in BASINS 3.0)

Developed and maintained by the EPA (http://www.epa.gov/ost/basins/) and the USGS (http://water.usgs.gov/software/hspf.html), the Hydrological Simulation Program–FORTRAN (HSPF) is one of the most comprehensive modeling systems for simulating watershed hydrology, point and nonpoint loading, and receiving water quality for both conventional pollutants and toxicants. The HSPF model was developed in the early 1960s as the Stanford Watershed Model. In the 1970s, water quality processes were added. The development of a Fortran version incorporating several related models using software engineering design and development concepts was funded by the EPA Research Laboratory (Athens, Ga.) in the late 1970s. In the 1980s, the USGS and EPA jointly developed preprocessing and postprocessing software, algorithm enhancements, and use of the USGS Watershed Data Management (WDM) system.

HSPF simulates hydrologic and water quality processes on land surfaces, streams, and impoundments. HSPF is generally used for a watershed-based analysis of the effects of land use, point and nonpoint source treatment alternatives (e.g., soil management practices), and flow diversions. Time series of the runoff flow rate, sediment yield, and user-specified pollutant concentrations can be generated at any point in the watershed. Compared with many other watershed loading models, HSPF has several advantages. First, HSPF is both a watershed model and a receiving water model; it can simulate both the pollutant loads on land surfaces and in-stream water quality in a complex watershed. Second, HSPF can be run under both continuous and storm situations. Data requirements for HSPF are extensive, and calibration and verification are strongly recommended. Because of its comprehensive nature, the HSPF model requires highly trained personnel. A team effort is recommended to apply it to real case studies.

WinHSPF is a new interface to HSPF Version 12 that is replacing Nonpoint Source Model (NPSM) from Better Assessment Science Integrating Point and Nonpoint Sources (BASINS) Version 2.0. Within BASINS V3.0 system, GenScn is a model postprocessing and scenario analysis tool that is used to analyze output from HSPF and SWAT. WDMUtil is used to manage and create the WDM files that contain the meteorologic data and other time series data used by HSPF. BASINS 3.0 includes several new data and functions including 1° DEM grids, an automatic delineation tool that creates watershed boundaries based on DEM grids, and a new watershed report function for land use, topography, and hydrologic response units.

Applications. HSPF and BASINS are widely used to for develop TMDLs for bacteria and many other wet weather pollutants. HSPF and BASINS produce pollutant concentration time series output that make it easy to determine the frequency and duration of water quality standard exceedances. Control scenario alternatives (e.g., soil management practices) can be evaluated for effectiveness in addressing water quality standard exceedances and the extent to which they would bring excessive costs to a community. The water quality impact of land use changes can also be conveniently evaluated. In addition, HSPF and BASINS can support source water assessments to examine the potential pollution risks to public water supplies.

The latest BASINS V3.0 provides a range of watershed models from which watershed managers can select the one that best meets their needs for an appropriate level of model complexity, control scenario detail, uncertainty, and analysis cost. The three watershed models in BASINS 3.0 are HSPF v12, Soil and Water Assessment Tool (SWAT), and the simple PLOAD model. SWAT and PLOAD models will be further discussed.

Watershed Modeling System (WMS)

The Watershed Modeling System (WMS) (http://www.emrl.byu.edu/wms.htm) is a comprehensive simulation model for hydrologic analysis. It was developed by the Environmental Modeling Research Laboratory of Brigham Young University in cooperation with the U.S. Army Corps of Engineers Waterways Experiment Station (USACE-WES). WMS merges information obtained from terrain models and GIS with industry-standard, lumped-parameter, hydrologic analysis models such as HEC-1, TR-20, and HSPF. WMS V6.1 provides tools for all phases of watershed modeling, including automated watershed and subbasin delineation, geometric parameter computation, hydrologic parameter computation, and result visualization. WMS is a powerful tool for analyzing and visualizing watersheds, which includes interfaces to several industry-standard hydrologic models. Each model can be set up and run within WMS. Model schematics are created and maintained automatically by WMS as you delineate a watershed from Map, Triangulated Irregular Networks (TINs), or Digital Elevation Models (DEMs) data. Terrain models can obtain geometric attributes such as area, slope, and runoff distances. WMS contains several calculators to aid in hydraulic/hydrologic design and analysis. These include an interface to HY-8 for culvert design/analysis, an open channel calculator, a detention basin calculator, a curb and gutter calculator, and a weir calculator. In addition, a calculator for Lag Time and/or Time of Concentration is included in WMS to aid in hydrologic model input. This calculator allows using any basin or flow path equation to compute travel times in the watershed and evaluate the hydrologic impact of management practices.

Soil and Water Assessment Tool (SWAT)

The Soil and Water Assessment Tool (SWAT) (http://www.brc.tamus.edu/swat/) is a watershed-scale model developed by Dr. Jeff Arnold for the USDA Agricultural Research Service (ARS). SWAT simulates the effect of agricultural management practices such as crop rotation, conservation tillage, residue, nutrient, pesticide management, and improved animal waste application methods on water quality. SWAT incorporates features of several ARS models and is a direct outgrowth of the SWRRB model (Simulator for Water Resources in Rural Basins) (3,4). The SWRRB model has been used on several watersheds to assess management practices and to test its validity (5,6). Specific models that contributed significantly to the development of SWAT were CREAMS (Chemicals, Runoff, and Erosion from Agricultural Management Systems) (7), GLEAMS (Groundwater Loading Effects on Agricultural Management Systems) (8), and EPIC (Erosion-Productivity Impact Calculator) (9).

SWAT is a continuous time model, that is, a long-term yield model. The model is not designed to simulate detailed, single flood routing. Instead, SWAT was developed to predict the impact of land management practices on water, sediment, and agricultural chemical yields in large complex watersheds where soils, land use, and management conditions vary over long periods of time. To satisfy this objective, the model is physically based. Rather than incorporating regression equations to describe the relationship between input and output variables, SWAT requires specific information about weather, soil properties, topography, vegetation, and land management practices in the watershed. The physical processes associated with water movement, sediment movement, crop growth, and nutrient cycling, are directly modeled by SWAT using this input data. The benefits of this approach are (1) watersheds without monitoring data (e.g., stream gauge data) can be modeled, (2) the relative impact of alternative input data (e.g., changes in management practices, climate, vegetation) on water quality or other variables of interest can be quantified, and (3) uses readily available inputs. Furthermore, SWAT is computationally efficient. Very large basins or a variety of management strategies can be simulated without excessive investment of time or money. SWAT enables users to study long-term impacts.

A new watershed model, the SWAT 2002 has been added to the EPA BASINS V3.0 system. SWAT is a watershed-scale model developed to predict the impact of land management practices on water, sediment, and agricultural chemical yields in large complex watersheds where soils, land use, and management conditions vary over long periods of time.

Applications. SWAT is ideally suited for simulating agricultural watersheds where fertilizer and pesticide application rates are known and where altering agricultural management practices is viewed as a viable and necessary way to meet water quality standards. SWAT is ideally suited for nitrogen, phosphorous, and pesticide TMDLs due to its use of prepackaged nutrient and pesticide application loads in standard forms (e.g., by type of manure or fertilizer and by the common name of the pesticide) as well as other agriculture specific inputs including tillage practices and crop rotation. SWAT requires a considerable amount of information on agricultural management practices but readily houses and internally processes this information within the interface. Management options are already included, so there is a direct translation to soil conservation practices and BMP-based controls. SWAT can be used to determine the likely reduction in sediment loads from installing small dams in critical areas in watersheds or how employing other land-based best management practices, such as terraces, vegetative buffer strips, or other cropland BMPs, would cut silt runoff/sediment loads to lakes and reservoirs.

CREAMS and GLEAMS

CREAMS, first developed in 1970s by the USDA, is a field-scale model designed to simulate the impact of land management on water, sediment, nutrients, and pesticides leaving the edge of a field. A number of other USDA models such as GLEAMS, SWRRB, AGNPS and EPIC, trace their origins to the CREAMS model.

GLEAMS is a nonpoint source model that focuses on pesticide and nutrient groundwater loadings. GLEAMS (10) simulates the effects of management practices and irrigation options on edge of field surface runoff, sediment, and dissolved and sediment-attached nitrogen, phosphorus, and pesticides. The model considers the effects of crop planting date, irrigation, drainage, crop rotation, tillage, residue, commercial nitrogen and phosphorus applications, animal waste applications, and pesticides on pollutant movement. The model has been used to predict the movement of pesticides (11), nutrients, and sediment from various combinations of land uses and management (12,13).

Erosion–Productivity Impact Calculator (EPIC)

The Erosion–Productivity Impact Calculator (EPIC) (http://www.brc.tamus.edu/epic/index.html) was originally developed to simulate the impact of erosion on crop productivity and has now evolved into a comprehensive agricultural management, field-scale, nonpoint source loading model. In the early 1980s, teams of USDA Agricultural Research Service (ARS), Soil Conservation Service (SCS) (now Natural Resources Conservation Service, or NRCS), and Economic Research Service (ERS) scientists developed EPIC to quantify the costs of soil erosion and the benefits of soil erosion research and control in the United States. Developed in late 1980s, the model uses a daily time step to simulate weather, hydrology, soil temperature, erosion–sedimentation, nutrient cycling, tillage, crop management and growth, pesticide and nutrient movement with water and sediment, and field-scale costs and returns. EPIC (14) simulates the effect of management strategies on edge of field water quality and nitrate nitrogen and pesticide leaching to the bottom of the soil profile. The model considers the effect of crop type, planting date, irrigation, drainage, rotations, tillage, residue, commercial fertilizer, animal waste, and pesticides on surface and shallow groundwater quality. The EPIC model has been used to evaluate various cropland management practices (15,16).

AGNPS

Agricultural Nonpoint Source Pollution Model 2001 (AGNPS 2001) (http://www.sedlab.olemiss.edu/agnps.html) is a joint USDA–ARS and NRCS system of computer models developed to predict nonpoint source pollutant loadings within agricultural watersheds. AGNPS is a midrange model. It contains a continuous simulation, surface runoff model designed to assist in determining BMPs, the setting of TMDLs, and for risk and cost/benefit analyses.

AGNPS 2001 is a tool for evaluating the effect of management decisions that impact a watershed system. The AGNPS 2001 system is a direct update of the AGNPS 98 system of modules containing many enhancements. These enhancements have been included to improve the capability of the program and to automate many of the input data preparation steps needed for use with large watershed systems. The capabilities of RUSLE, used by USDA-NRCS to evaluate the degree of erosion on agricultural fields and to guide development of conservation plans to control erosion, have been incorporated into AnnAGNPS. The AnnAGNPS model has been applied to many field and watershed size areas to estimate pollutant runoff from various land uses and management practices (6,15,17–19).

Revised Universal Soil Loss Equation (RUSLE)

The Revised Universal Soil Loss Equation (RUSLE) (http://www.sedlab.olemiss.edu/rusle/) is an easily and widely used computer program that estimates rates of soil erosion caused by rainfall and associated overland flow. The most current version of RUSLE is Version 1.06b released on January 2001 (20). In the United States, the USDA–NRCS is the principal user of RUSLE and has implemented this approach in most of its local field offices. The NRCS is the major source for data needed to apply RUSLE and is the leading authority on field application of RUSLE. RUSLE is used by numerous government agencies, private organizations, and individuals to assess the degree of erosion, identify situations where erosion is serious, and guide development of conservation plans to control erosion. RUSLE has been applied to cropland, rangeland, disturbed forest lands, landfills, construction sites, mining sites, reclaimed lands, military training lands, parks, land disposal of waste, and other land uses where mineral soil material is exposed to the erosive forces of raindrop impact and overland flow. RUSLE estimates average annual soil loss, expressed as mass per unit area per year, which is defined as the amount of sediment delivered from the slope length assumed in the RUSLE computation.

Water Erosion Prediction Project (WEPP)

The Water Erosion Prediction Project (WEPP) model (http://topsoil.nserl.purdue.edu/nserlweb/weppmain/) is a process-based, distributed parameter and continuous simulation model for erosion prediction. WEPP is expected to become a major component of the “conservation tool kit.” It is a computer program designed to be employed by the same personnel currently using USLE (Universal Soil Loss Equation) or RUSLE. By analyzing how farming and land use affect soil erosion and sediment delivery, WEPP promises better conservation planning, better project planning, and optimum resource inventory and assessment. It will help users select the best erosion control practices, aid in choosing optimum locations for future project sites, and evaluate erosion and sedimentation over specified areas. It is applicable to small watersheds (field-sized) and can simulate small profiles up to large fields. It mimics the natural processes that are important in soil erosion.

WEPP can be applied on the field scale to simulate single hillslope erosion or more complex watershed-scale erosion: Hillslope Applications and Watershed Applications. WEPP (21) simulates water runoff, erosion, and sediment delivery from fields or small watersheds. Management practices, including crop rotation, planting and harvest date, tillage, compaction, strip-cropping, row arrangement, terraces, field borders, and windbreaks, can be simulated. The WEPP model has been applied to various land use and management conditions (22,23).

Nitrate Leaching and Economic Analysis Package (NLEAP)

The Nitrate Leaching and Economic Analysis Package (NLEAP) (http://gpsr.ars.usda.gov/products/nleap/nleap.htm) is a field-scale computer model developed to provide a rapid and efficient method for determining potential nitrate leaching from agricultural practices. It uses basic information concerning on-farm management practices, soils, and climate to project nitrogen budgets and nitrate leaching indexes. NLEAP calculates potential nitrate leaching below the root zone and to groundwater supplies. NLEAP has three levels of analysis to determine leaching potential: an annual screening, a monthly screening, and an event-by-event analysis.

The NLEAP model was designed to answer questions regarding potential leaching of nitrate. The processes modeled include movement of water and nitrate, crop uptake, denitrification, ammonia volatilization, mineralization of soil organic matter, nitrification, and mineralization–immobilization of crop residue, manure, and other organic wastes. The limitations of NLEAP include modeling soil nitrogen processes in organic soils that is not currently available. NLEAP does not predict yield reductions caused by pests or nutrient deficiencies. However, the user should consider the effects of these problems when estimating crop yield. The model should not be used where rapid water infiltration, leaching, denitrification, and ammonium volatilization require time steps smaller than one day. NLEAP (24) evaluates the potential of nitrate nitrogen leaching due to land use and management practices. The NLEAP model has been used to predict the potential for nitrogen leaching under various management options (25,26). Most recently, it has been applied to compare the impact of TMDL allocation scenarios on nitrate leaching (27).

Root Zone Water Quality Model (RZWQM)
