PREFACE

No one really questions that water is the life blood of humankind. We all remain amazed that the existence of water separates our planet from every other we have thus far viewed in our universe. We can arguably do without every naturally occurring molecule on the earth except water. Life was clearly formed within water and exists in one way or another on water.

Few people in the developed world give this simple fact of life much thought. We have an abundance of water for most of our needs, although some agricultural areas, a few municipalities, and some rural families, at times are strapped for the full amount of water they desire. In the developing world, however, in some locations, the collection and distribution of water is a critical part of every day life, with many women devoting the major portion of their day to the provision of water for their family. In other villages, the construction and protection of a single well can be the primary focus of community needs.

In general, the actual delivery of water for a myriad of uses followed by its disposal is taken for granted by all but the individuals charged with carrying out these often amazing tasks. In this volume of the *Water Encyclopedia*, a collaborative effort of hundreds of people from dozens of countries, we have tried to cover every conceivable topic of interest to people in every walk of life, be they students, researchers, professionals, or just plain folks with an intellectual curiosity about our elixir of life.

We are concerned in this volume with the actual delivery of water to the home by the home owner (subjects include disinfection, corrosion control, nitrates, gray water, septic tanks, and windmills), from the municipal supplier (and their challenges, including distribution, filtration, zebra mussels, reverse osmosis, cryptosporidium, arsenic, and public confidence), to industry and its special needs (such as microfiltration, effluent discharge, reuse, energy, nuclear reactor coolants, and even golf course irrigation), and of course the disposal of our used water in a safe and efficient manner (subjects such as air stripping, bioassays, flotation, sludge, bioavailability, and wetlands). We hope that no reader can stump the experts, which means that we have covered every area of interest. However, we know that this goal is not currently possible, but in coming years and in coming editions on paper and on the World Wide Web, we will more closely approach it. Let us know on our website where our information may be incomplete, and we will be sure to follow-up and fill in the gap in the future.

The contributors to this volume have freely offered their expertise to this project. Some have focused their information on those in need of complete and often complex detail of their subject matter. Others have followed a middle road for a wider audience, and still others believed that a very simple approach to conveying information on their subject was best.

The reader may find all approaches on the same subject matter because the editors frequently sought overlapping information presented from different points of view. We are confident that most people will find their needs met.

Through this encyclopedia, which is the most comprehensive effort ever undertaken on behalf of this most important subject, we hope that we will collectively make a contribution that will enhance the distribution and use of our water supplies in ever safer and more efficient ways.

Jay Lehr
Jack Keeley

PREFACE

Cities, towns, states, and nations must manage their water resources wisely from both a quality and a quantitative perspective.

If we do otherwise and manage them with a narrow perspective, the public's needs will not be adequately met. In this volume of the *Water Encyclopedia*, authors from around the world have described a myriad of problems relating to individual water bodies as well as to geographic water resources and their management dilemmas.

Humans and other living creatures contribute to our water quality problems. Neither can be fully controlled. Even the nature of contaminant sources and programs for their elimination can be difficult to design. This volume contains the best and brightest ideas and case studies relating to the areas of water quality and resource management problems.

Quality problems deal with a diverse suite of subjects ranging widely from acid mine drainage to biosorption, colloids, eutrophication, protozoa, and recalcitrant compounds. Resource management features drought studies, flood control, river basin management, perennial overdraft, water banking, and a host of other subjects.

The perspective of scientists from nearly every continent of the world offers a truly catholic view of attitudes and biases harbored in different regions and how they affect scientific and regulatory outcomes.

The editors cannot imagine what has been left out, but we know of course that readers will at times come up short of finding an exact match to a problem they face. We hope they will contact us at our website and allow us the opportunity of adding additional subjects to our encyclopedia. At the same time, the reader will understand that many subjects in the area of water quality may have been addressed in our Surface Water category. It was often difficult to determine where an investigator would be more likely to look for a piece of information. (The complete index of all five volumes appears in the Ground Water volume as well as on our website.)

We trust all users of this encyclopedia will find it detailed, informative, and interesting. Not only are a wide range of subjects treated, but authors choose varying approaches to presenting their data to readers who may be professionals, students, researchers, as well as individuals simply satisfying their intellectual curiosity. We hope we are successfully serving all of these populations in some useful way.

Jay Lehr
Jack Keeley

PREFACE

Surface water and agricultural water are uniquely associated as they provide many of our basic needs, including food and fiber, power, transportation, and recreation. Like other volumes in the *Water Encyclopedia*, we have selected articles as varied in content as they are in technical sophistication. To this end, the reader will also recognize that single topics are occasionally duplicated at varying levels of scientific acumen.

Articles are also provided that demonstrate that surface and agricultural water are associated in yet another way: They must be used efficiently and protected to assure their productiveness far into the future. For example, agricultural water use efficiency is discussed from several viewpoints with respect to irrigation technology. River basin planning is approached in diverse ways, including stream classifications, watershed hydrology, modeling, erosion control, and water conservation.

We have necessarily included articles addressing issues of quality with respect to both surface and agricultural water. In addition to an assessment of pollution outflow from agricultural areas, the quality of reclaimed irrigation is addressed from both chemical and microbial standpoints. Watershed areas are examined according to their contribution and vulnerability to contamination, flooding, sediment transport, and trace elements.

Discourses on surface water would not be complete without articles related to fish. Accordingly, we have included articles on fish growth, fisheries, fishponds, and the use of fish scales in toxicological studies as examples.

Another vital area of study in this volume is perhaps best described as the practical side. These areas are of less esoteric origins, including salt tolerance of plants, irrigation wells, weed control, tile drains, and moisture content in to agriculture. Similar topics in surface water include riparian systems, reservoir design, wetlands, lakes, levees, and the unit hydrograph.

Finally, and *appropriately, this volume of the Water Encyclopedia* contains articles on specific water bodies and the consequences of their being. Included are the Aral Sea, the Ganga River of India, the Great Lakes, and the Yellow River in China, only to name a few. Here, too, the association of surface water and agricultural water are reinforced. This volume presents an important segment of the topic of water. We believe that the reader's educational pursuits will be well met by its contents.

Jay Lehr
Jack Keeley

PREFACE

No natural molecule on the planet is more fascinating than water. It has unique properties ranging from the unusual angles formed between its two hydrogen ions and its single oxygen molecule, to the fact that unlike most substances, it expands when it freezes rather than shrinks and reaches a maximum density as a liquid 4°F above its freezing point. These and many other aspects of the special physics and chemistry are described in this volume, including the impact of a wide variety of chemicals occurring in water, osmosis, diffusion, hydration, isotope exchange, along with the fun physics of the mariotte bottle.

Equally fascinating are the many unusual physical and chemical encounters in both the ocean and the atmosphere. Although oceanography and meteorology are frequently considered separate sciences from hydrology, their limited inclusion in the *Water Encyclopedia* was deemed necessary to tell the complete story. Tidal changes, benthic nutrients, the sea floor, el nino, sea level, and ocean/climate relationships make up but a few of the oceans fascinating stories, whereas water spouts, hurricanes, monsoons, droughts, sublimation, and barometric efficiency just touch the tip of what this volume has in store in the area of meteorology.

But water has a wonderful human face as well. We have reached around the world to describe the history of water and its role in the development of civilizations and the many beliefs held about it. As society developed, the distribution of water needed supervision, which lead to a wide variety of water laws we have attempted to categorize and describe in an interesting and meaningful way.

We are equally proud of our open-minded effort to describe the role that water has played in art and culture. We have attempted not be judgmental, with stories of water forms and water intelligence along with some medical theories and, of course, the wonderful descriptions of early water clocks. This volume is a true intellectual cornucopia of water in the life of humankind on a personal level.

We are confident that in the coming years and editions of the *Water Encyclopedia*, this volume will expand with more participation from individuals working in unusual fields relating to water.

Jay Lehr
Jack Keeley

PREFACE

Throughout history, groundwater has played a major role in providing the resource needs of the world. It accounts for 97% of the world's freshwater and serves as the base flow for all streams, springs, and rivers. In the United States, one half of the population relies on groundwater for its drinking water and is the sole source of supply for 20 of the 100 largest cities. Well over 90% of rural America is totally dependent on groundwater. An inventory of the total groundwater resources in the United States can be visualized as being equal to the flow of the Mississippi River at Vicksburg for a period of 250 years.

One of the first groundwater scientists was a French engineer who was in charge of public drinking water in Dijon. In 1856, Henri Darcy conducted experiments and published mathematical expressions describing the flow of water through sand filters. His work remains one of the cornerstones of today's groundwater hydrologists. At about the same time, a Connecticut court ruled that the influences of groundwater movement are so secret, changeable, and uncontrollable that they could not be subject to regulations of law, nor to a system of rules, as had been done with surface streams.

In this volume of the *Water Encyclopedia*, we have attempted to erase the ignorance that existed in the early years of groundwater science by presenting the most current knowledge on the subject as provided by authors from around the globe. In addition to excellent articles from many American scholars, equally superb writings from such diverse countries as England, Nigeria, India, Iran, Thailand, and Greece are provided.

As the origins of the selected articles are diverse, so are the subjects of discussion. Along with straightforward descriptions of basic groundwater concepts (drawdown around pumping wells, hydraulic head, field capacity, and flow), the reader is introduced to more complex subjects (isotope technologies, aquifer tests, *in situ* remediation, tritium dating, modeling, and geophysical properties). There are also articles for more practical applications (well maintenance, subsurface drainage, nitrate contamination, tracer tests, well yields, and drilling technologies). Of course, for the more fanciful reader, we have selected articles that remind us of the way windmills sounded at night, the ancient use of qanats in Persia to provide sustainable groundwater resources, and the development of Darcy's Law.

In the end, we feel that the information provided will afford an educational home for readers approaching the *Water Encyclopedia* from a variety of needs as well as different levels of scientific acumen. We are also confident that many readers will simply be expanding their knowledge base by these sets of enjoyable reading.

Jay Lehr
Jack Keeley

ACKNOWLEGMENTS

The editors of this encyclopedia wish to acknowledge two special people without whose assistance this enormous undertaking could not have been initiated, administered, or completed.

Bob Esposito, Executive Editor, placed the project before us and convinced us it would be as exciting and rewarding as time has proved.

Jonathan T. Rose, Editorial Program Coordinator, was the true backbone of our team. His warm, accommodating, and skillful management helped us overcome each and every problem. His interaction with contributors and his knowledge of the publishing process offered us the security and comfort required to persevere through the four years required to complete this work. We will forever be in his debt.

Volume 1. Domestic, Municipal, and Industrial Water Supply and Waste Disposal

1.1 Domestic Water Supply 1:1
1.1.1 The Arsenic Drinking Water Crisis in Bangladesh 1:1
1.1.2 Bottled Water 1:3
1.1.3 Corrosion Control in Drinking Water Systems 1:5
1.1.4 Economics of Residential Water Demands 1:12
1.1.5 Gray Water Reuse in Households 1:16
1.1.6 Water and Human Health 1:19
1.1.7 Nitrate Health Effects 1:30
1.1.8 Domestic Water Supply – Public-private Partnership 1:42
1.1.9 Methods of Reducing Radon in Drinking Water 1:51
1.1.10 Water Reuse 1:53
1.1.11 Roof Drainage Hydraulics 1:54
1.1.12 Septic Tank Systems 1:61
1.1.13 Domestic Solar Water Heaters 1:63
1.1.14 Household Drinking Water Treatment and Safe Storage 1:67
1.1.15 Virus Transport in the Subsurface 1:70
1.1.16 Windmills 1:73

1.2 Municipal Water Supply 1:76
1.2.1 Mixing and Agitation in Water Treatment Systems 1:76
1.2.2 Arsenic in Natural Waters 1:81
1.2.3 Evaluation of Microbial Components of Biofouling 1:83
1.2.4 Threat Agents and Water Biosecurity 1:87
1.2.5 Granular Activated Carbon 1:92
1.2.6 Competitive Adsorption of Several Organics and Heavy Metals on Activated Carbon in Water 1:107
1.2.7 A Real-time Hydrological Information System for Cities 1:121
1.2.8 Chlorine and Chlorine Residuals 1:127
1.2.9 Modeling Chlorine Residuals in Urban Water Distribution Systems 1:131
1.2.10 Particulate Matter Removal by Coagulation 1:137
1.2.11 Selective Coagulant Recovery from Water Treatment Plant Residuals Using the Domain Membrane Process 1:139
1.2.12 Physical Water Conditioning 1:141
1.2.13 Consumer Confidence Reports 1:145
1.2.14 Water Conservation Measures 1:146
1.2.15 Preventing Well Contamination 1:149
1.2.16 Corrosion Control 1:152
1.2.17 Cross Connection and Backflow Prevention 1:155
1.2.18 Molecular-based Detection of *Cryptosporidium Parvum* in Water 1:158
1.2.19 Cryptosporidium 1:162
1.2.20 Measuring *Cryptosporidium Parvum* Oocyst Inactivation Following Disinfection with Ultraviolet Light 1:165
1.2.21 Dechlorination 1:169
1.2.22 Desalination 1:170
1.2.23 Diatomaceous Earth Filtration for Drinking Water 1:174
1.2.24 Emerging Waterborne Infectious Diseases 1:177
1.2.25 Improving Waterborne Disease Surveillance 1:183
1.2.26 Disinfectants 1:192
1.2.27 Disinfection 1:196
1.2.28 Water Distribution System Operation 1:200
1.2.29 Water Quality in Distribution Systems 1:204
1.2.30 Design of Water Distribution Systems 1:207
1.2.31 What Is in Our Drinking Water? 1:213
1.2.32 The Economics of Water Resources Allocation 1:215
1.2.33 Answering the Challenge 1:218
1.2.34 Key Causes of Drinking Water Quality Failure in a Rural Small Water Supply of South Africa 1:221
1.2.35 Filtration 1:227

1.2.36 Water Filtration 1:230
1.2.37 Filtration with Granular Media 1:233
1.2.38 Slow Sand Filtration and the Impact of *Schmutzdecke* *1:2*35
1.2.39 Multistage Drinking Water Filtration 1:237
1.2.40 Multistage Filtration: an Innovative Water Treatment Technology 1:238
1.2.41 Particulate Matter Removal by Filtration and Sedimentation 1:243
1.2.42 Filtration Water Treatment 1:245
1.2.43 Synthetic and Natural Organic Removal by Biological Filtration 1:248
1.2.44 Granular Bed and Precoat Filtration 1:249
1.2.45 Flocculation 1:252
1.2.46 Fluoridation 1:254
1.2.47 Giardiasis 1:257
1.2.48 Gravity Separation/Sedimentation 1:259
1.2.49 Water Hammer 1:261
1.2.50 Health Effects of Commonly Occurring Disinfection Byproducts in Municipal Water Supplies 1:264
1.2.51 Health Effects of Microbial Contaminants and Biotoxins in Drinking Water 1:277
1.2.52 Drinking Water and Public Health Protection 1:281
1.2.53 1962 U.S. Public Health Service Standards 1:292
1.2.54 Ion Exchange and Demineralization 1:297
1.2.55 The State of the Water Industry – 2004 .... 1:301
1.2.56 Iron and Manganese Removal 1:312
1.2.57 Extraterritorial Land Use Control to Protect Water Supplies 1:315
1.2.58 Leak Detection and Water Loss Control 1:317
1.2.59 Lime-soda Ash Processes 1:320
1.2.60 Lime Softening 1:322
1.2.61 Ion Exchange – Use of Magnetic Ion Exchange Resin for DOC Removal 1:325
1.2.62 Membrane Filtration 1:331
1.2.63 Water Meters 1:337
1.2.64 Microbiological Concerns of Drinking Water Distribution Systems 1:341
1.2.65 Nitrification of Potable Water Using Trickling Filters 1:346
1.2.66 Organic Removal 1:350
1.2.67 Ozone 1:354
1.2.68 Ozone with Activated Carbon for Drinking Water Treatment 1:357
1.2.69 Ozone-bromide Interactions 1:357
1.2.70 Municipal Water Supply: Ozonation 1:362
1.2.71 Review of Parasite Fate and Transport in Karstic Aquifers 1:365
1.2.72 Particulate Removal 1:370
1.2.73 Pharmaceuticals in Water Systems 1:372
1.2.74 Point-of-use/Point-of-entry Systems (POU/POE) 1:378

1.2.75 Assessing the Bactericidal Efficiency of Polydex for the Disinfection of Drinking Water in Rural Areas of South Africa 1:382
1.2.76 Private Sector Participation, Marketing and Corporate Strategies in Municipal Water Supply and Sewerage 1:387
1.2.77 Pumps 1:391
1.2.78 Radionuclides 1:395
1.2.79 Use of Redox Potentials in Wastewater Treatment 1:399
1.2.80 Repairing Distribution Line Breaks 1:400
1.2.81 Role of Small Water Reservoirs in Environment 1:403
1.2.82 Reservoirs, Towers, and Tanks Drinking Water Storage Facilities 1:408
1.2.83 Water Treatment Plant Residuals Management 1:411
1.2.84 Reverse Osmosis, Process Chemistry 1:414
1.2.85 Reverse Osmosis, Membrane Foulants 1:416
1.2.86 Reverse Osmosis, Membrane Cleaning 1:419
1.2.87 Application of Risk Assessments in Crafting Drinking Water Regulations 1:422
1.2.88 Potential Risks of Waterborne Transmission of *Escherichia Coli* O157:H7 .... 1:429
1.2.89 Slow Sand Filtration 1:431
1.2.90 Approaches for Securing a Water Distribution System 1:434
1.2.91 Water Security: an Emerging Issue 1:437
1.2.92 Guide to Selection of Water Treatment Processes 1:439
1.2.93 Source Water Assessment 1:444
1.2.94 Hydraulic Design of Water Distribution Storage Tanks 1:448
1.2.95 System Control and Data Acquisition (SCADA) 1:449
1.2.96 Settling Tanks 1:452
1.2.97 Treatment for Technologies for Small Drinking Water Systems 1:457
1.2.98 Ultraviolet Disinfection 1:466
1.2.99 Ultraviolet Irradiation 1:469
1.2.100 Water Disinfection Using UV Radiation – a Sri Lankan Experience 1:471
1.2.101 Drinking Water Quality Standards (DWQS) – United States 1:476
1.2.102 Valves 1:482
1.2.103 Removal of Pathogenic Bacteria, Viruses, and Protozoa 1:485
1.2.104 Water Meter 1:489
1.2.105 Municipal Watersheds 1:495
1.2.106 Public Water Supply World 1:500
1.2.107 Ten Key Trends That Will Shape the Future of the World Water Industry 1:508
1.2.108 Zebra Mussel Control without Chemicals 1:510
1.2.109 Package Plants 1:514
1.2.110 Anaerobic Sewage Treatment 1:517
1.2.111 Persistence of Pathogens in Water 1:521
1.2.112 Well Head Protection 1:524

1.2.113 Chemical Drinking Water Standards, Past, Present, and Future 1:529
1.3 Industrial Water 1:534
1.3.1 Magnetic Water Conditioning 1:534
1.3.2 Water Impacts from Construction Sites 1:537
1.3.3 Industrial Cooling Water – Biofouling 1:538
1.3.4 Industrial Cooling Water – Corrosion 1:542
1.3.5 Industrial Cooling Water – Scale Formation 1:545
1.3.6 Economics of Industrial Water Demands 1:549
1.3.7 Electric Generating Plants – Effects of Contaminants 1:553
1.3.8 Energy Dissipation 1:558
1.3.9 Water Use in Energy Production 1:560
1.3.10 Evaluation of Toxic Properties of Industrial Effluents by on-line Respirometry 1:565
1.3.11 Polycyclic Aromatic Hydrocarbons 1:571
1.3.12 Hydrocarbon Treatment Techniques 1:575
1.3.13 Use of Anaerobic-aerobic Treatment Systems for Maize Processing Plants 1:581
1.3.14 Bonding of Toxic Metal Ions 1:586
1.3.15 Application of Microfiltration to Industrial Wastewaters 1:591
1.3.16 Water Treatment in Spent Nuclear Fuel Storage 1:595
1.3.17 Industrial Mine Use: Mine Waste 1:609
1.3.18 Sugarcane Industry Wastewaters Treatment 1:614
1.3.19 Estimated Use of Water in the United States in 1990 Industrial Water Use 1:620
1.4 Waste Water Treatment 1:623
1.4.1 Aeration 1:623
1.4.2 Fine Bubble Diffused Air Aeration Systems 1:626
1.4.3 Air Stripping 1:631
1.4.4 Land Applications of Wastewater in Arid Lands: Theory and Case Studies 1:632
1.4.5 Technologies for Arsenic Removal from Contaminated Water Sources 1:636
1.4.6 Biochemical Oxygen Demand 1:639
1.4.7 Molecular Biology Tools for Monitoring Biodiversity in Wastewater Treatment Plants 1:642
1.4.8 Biosolids 1:646
1.4.9 Integrated Capacity Building Needs for Water Supply and Wastewater Sanitation 1:651
1.4.10 Wastewater Characterization 1:656
1.4.11 Chemically Enhanced Primary Treatment of Wastewater 1:659
1.4.12 Getting Our Clean Water Act Together 1:660
1.4.13 Inadequate Treatment of Wastewater: a Source of Coliform Bacteria in Receiving Surface Water Bodies in Developing Countries – Case Study: Eastern Cape Province of South Africa 1:661

1.4.14 Denitrification in the Activated Sludge Process 1:667
1.4.15 Detergents 1:669
1.4.16 Ecological Wastewater Management 1:675
1.4.17 Waste Treatment in Fish Farms 1:681
1.4.18 Flotation as a Separation Process 1:684
1.4.19 Degradation of Chloro-organics and Hydrocarbons 1:688
1.4.20 Landfill 1:695
1.4.21 Landfill Leachates, Part 1: Origin and Characterization 1:699
1.4.22 Landfill Leachates: Part 2: Treatment 1:702
1.4.23 Macrophytes as Biomonitors of Polychlorinated Biphenyls 1:714
1.4.24 Wastewater Management for Developing Countries 1:718
1.4.25 Mercury Removal from Complex Waste Waters 1:722
1.4.26 Metal Speciation and Mobility as Influenced by Landfill Disposal Practices 1:723
1.4.27 Microbial Foaming in the Activated Sludge Process 1:728
1.4.28 Introduction to Wastewater Modeling and Treatment Plant Design 1:730
1.4.29 Practical Applications of Wastewater Modeling and Treatment Plant Design 1:738
1.4.30 New York City Harbor Survey 1:745
1.4.31 Nitrification in the Activated Sludge Process 1:751
1.4.32 Effluent Limitations and the NPDES Permit 1:755
1.4.33 Odor Abatement in Wastewater Treatment Plants 1:760
1.4.34 Aqueous Reactions of Specific Organic Compounds with Ozone 1:765
1.4.35 The Fate of Persistent Organic Pollutants (POPs) in the Wastewater Treatment Process 1:766
1.4.36 The Role of Organoclay in Water Cleanup 1:771
1.4.37 Combined Sewer Overflow Treatment 1:782
1.4.38 Biological Phosphorus Removal in the Activated Sludge Process 1:788
1.4.39 Photocatalytic Membrane Reactors in Water Purification 1:791
1.4.40 EPA's National Pretreatment Program, 1973–2003: Thirty Years of Protecting the Environment 1:798
1.4.41 Problems Encountered during Pipe Repair and Renewal 1:801
1.4.42 Radioactive Waste 1:802
1.4.43 Reclaimed Water 1:805
1.4.44 Wastewater Treatment and Recycling Technologies 1:808
1.4.45 Wastewater Treatment Processes and Water Reuse 1:814
1.4.46 Wastewater Reclamation and Reuse Research 1:819
1.4.47 Wastewater Reclamation and Reuse 1:825
1.4.48 Wastewater Reclamation and Reuse Treatment Technology 1:826
1.4.49 Sewage 1:828
1.4.50 Domestic Sewage 1:830
1.4.51 Solidification/Stabilization of Hazardous Solid Wastes 1:835

1.4.52 Wastewater Treatment – Small Scale 1:840
1.4.53 Microbial Foaming and Bulking in Activated Sludge Plants 1:844
1.4.54 Aqueous Behavior of Elements in a Flue Gas Desulfurization Sludge Disposal Site 1:848
1.4.55 Sludge Treatment and Disposal 1:853
1.4.56 Wastewater Sludge 1:861
1.4.57 Processing of Sludge 1:864
1.4.58 Municipal Storm Water Management 1:866
1.4.59 What Wastewater Utilities Can Do Now to Guard Against Terrorist and Security Threats 1:870
1.4.60 Wastewater Treatment Techniques – Advanced 1:871
1.4.61 Trenchless Repair and Rehabilitation Techniques 1:876
1.4.62 Basics of Underground Water and Sewer Pipeline Assessment, Repair, and Rehabilitation 1:883
1.4.63 Water Hammer: Quantitative Causes and Effects 1:891
1.4.64 Constructed Wetlands 1:892
1.4.65 Using Ecosystem Processes in a Constructed Wetland to Treat Mine Wastewater in Ireland 1:897
1.4.66 Water and Wastewater Properties and Characteristics 1:900
1.4.67 Anaerobic Wastewater Treatment 1:904
1.4.68 Sewerage Odors – How to Control 1:910
1.4.69 Ultrafiltration – Complexation in Wastewater Treatment 1:916

Volume 2. Water Quality and Resource Development

2.5 Water Quality Control 2:1
2.5.1 Acid Mine Drainage – Extent and Character 2:1
2.5.2 The Control of Algal Populations in Eutrophic Water Bodies 2:2
2.5.3 Arsenic Compounds in Water 2:7
2.5.4 Arsenic Health Effects 2:15
2.5.5 Background Concentration of Pollutants 2:18
2.5.6 Waterborne Bacteria 2:20
2.5.7 Water Assessment and Criteria 2:24
2.5.8 Physiological Biomarkers and the Trondheim Biomonitoring System 2:28
2.5.9 Biomarkers, Bioindicators, and the Trondheim Biomonitoring System 2:29
2.5.10 Active Biomonitoring (ABM) by Translocation of Bivalve Molluscs 2:33
2.5.11 Biochemical Oxygen Demand and Other Organic Pollution Measures 2:37
2.5.12 Biodegradation 2:41
2.5.13 Bioluminescent Biosensors for Toxicity Testing 2:45
2.5.14 Biomanipulation 2:50
2.5.15 Genomic Technologies in Biomonitoring 2:58

2.5.16 Macrophytes as Biomonitors of Trace Metals 2:64
2.5.17 Biosorption of Toxic Metals 2:68
2.5.18 Bromide Influence on Trihalomethane and Haloacetic Acid Formation 2:74
2.5.19 Activated Carbon: Ion Exchange and Adsorption Properties 2:79
2.5.20 Activated Carbon – Powdered 2:86
2.5.21 Chlorination 2:88
2.5.22 Chlorination by-products 2:91
2.5.23 Classification and Environmental Quality Assessment in Aquatic Environments 2:94
2.5.24 Coagulation and Flocculation in Practice 2:98
2.5.25 Colloids and Dissolved Organics: Role in Membrane and Depth Filtration 2:99
2.5.26 Column Experiments in Saturated Porous Media Studying Contaminant Transport 2:103
2.5.27 Cytochrome P450 Monooxygenase as an Indicator of PCB/Dioxin-like Compounds in Fish 2:106
2.5.28 Water Related Diseases 2:111
2.5.29 Dishwashing Water Quality Properties 2:112
2.5.30 Disinfection by-product Precursor Removal from Natural Waters 2:115
2.5.31 Alternative Disinfection Practices and Future Directions for Disinfection by-product Minimization 2:118
2.5.32 Water Quality Aspects of Dredged Sediment Management 2:122
2.5.33 The Economics of Water Quality 2:127
2.5.34 Understanding *Escherichia Coli* O157:H7 and the Need for Rapid Detection in Water 2:136
2.5.35 Eutrophication and Organic Loading 2:142
2.5.36 Trace Element Contamination in Groundwater of District Hardwar, Uttaranchal, India 2:143
2.5.37 Iron Bacteria 2:149
2.5.38 Cartridge Filters for Iron Removal 2:152
2.5.39 Irrigation Water Quality in Areas Adjoining River Yamuna at Delhi, India 2:155
2.5.40 Water Sampling and Laboratory Safety 2:161
2.5.41 Municipal Solid Waste Landfills – Water Quality Issues 2:163
2.5.42 Land Use Effects on Water Quality 2:169
2.5.43 Monitoring Lipophilic Contaminants in the Aquatic Environment Using the SPMD-TOX Paradigm 2:170
2.5.44 Use of Luminescent Bacteria and the *Lux* Genes for Determination of Water Quality 2:172
2.5.45 Water Quality Management 2:176
2.5.46 Water Quality Management and Nonpoint Source Control 2:184
2.5.47 Water Quality Management in an Urban Landscape 2:189

2.5.48 Water Quality Management in the U.S.: History of Water Regulation 2:193
2.5.49 Water Quality Management in a Forested Landscape 2:199
2.5.50 Trace Metal Speciation 2:202
2.5.51 Metal Ion Humic Colloid Interaction 2:205
2.5.52 Heavy Metal Uptake Rates Among Sediment Dwelling Organisms 2:211
2.5.53 Methemoglobinemia 2:219
2.5.54 Microbial Activities Management 2:223
2.5.55 Microbial Dynamics of Biofilms 2:228
2.5.56 Microbial Enzyme Assays for Detecting Heavy Metal Toxicity 2:233
2.5.57 Microbial Forms in Biofouling Events 2:239
2.5.58 Microbiological Quality Control in Distribution Systems 2:243
2.5.59 Water Quality Models for Developing Soil Management Practices 2:248
2.5.60 Water Quality Modeling – Case Studies 2:255
2.5.61 Field Sampling and Monitoring of Contaminants 2:263
2.5.62 Water Quality Models: Chemical Principles 2:269
2.5.63 Water Quality Models: Mathematical Framework 2:273
2.5.64 Environmental Applications with Submitochondrial Particles 2:278
2.5.65 Interest in the Use of an Electronic Nose for Field Monitoring of Odors in the Environment 2:281
2.5.66 Oil-field Brine 2:284
2.5.67 Oil Pollution 2:290
2.5.68 Indicator Organisms 2:292
2.5.69 pH 2:294
2.5.70 Perchloroethylene (PCE) Removal 2:299
2.5.71 A Primer on Water Quality 2:301
2.5.72 Overview of Analytical Methods of Water Analyses with Specific Reference to EPA Methods for Priority Pollutant Analysis 2:304
2.5.73 Source-water Protection 2:311
2.5.74 Protozoa in Water 2:313
2.5.75 Water Quality 2:314
2.5.76 Water Quality 2:316
2.5.77 Emerging and Recalcitrant Compounds in Groundwater 2:316
2.5.78 Road Salt 2:319
2.5.79 Review of River Water Quality Modeling Software Tools 2:325
2.5.80 River Water Quality Calibration 2:331
2.5.81 *Salmonella*: Monitoring and Detection in Drinking Water 2:337
2.5.82 Lysimeter Soil Water Sampling 2:340
2.5.83 Regulatory and Security Requirements for Potable Water 2:343
2.5.84 A Weight of Evidence Approach to Characterize Sediment Quality Using Laboratory and Field Assays: an Example for Spanish Coasts 2:350

2.5.85 Remediation and Bioremediation of Selenium-contaminated Waters 2:355
2.5.86 Shellfish Growing Water Classification 2:360
2.5.87 Sorptive Filtration 2:362
2.5.88 Quality of Water in Storage 2:367
2.5.89 Quality of Water Supplies 2:370
2.5.90 The Submitochondrial Particle Assay as a Biological Monitoring Tool 2:376
2.5.91 Microscale Test Relationships to Responses to Toxicants in Natural Systems 2:379
2.5.92 Toxicity Identification Evaluation 2:380
2.5.93 Whole Effluent Toxicity Controls 2:382
2.5.94 Development and Application of Sediment Toxicity Tests for Regulatory Purposes 2:383
2.5.95 Algal Toxins in Water 2:387
2.5.96 Ground Water Quality in Areas Adjoining River Yamuna at Delhi, India 2:392
2.5.97 Chlorine Residual 2:398
2.5.98 Source Water Quality Management 2:399
2.5.99 Dose-response of Mussels to Chlorine 2:401
2.5.100 Metallothioneins as Indicators of Trace Metal Pollution 2:406
2.5.101 Amphipod Sediment Toxicity Tests 2:408
2.5.102 Ciliated Protists as Test Organisms in Toxicity Assessment 2:413
2.5.103 SOFIE: an Optimized Approach for Exposure Tests and Sediment Assays 2:418
2.5.104 Passive Treatment of Acid Mine Drainage (Wetlands) 2:423
2.5.105 Biomarkers and Bioaccumulation: Two Lines of Evidence to Assess Sediment Quality 2:426
2.5.106 Lead and Its Health Effects 2:432
2.5.107 Microbial Detection of Various Pollutants as an Early Warning System for Monitoring of Water Quality and Ecological Integrity of Natural Resources, in Russia 2:440
2.5.108 Luminescent Bacterial Biosensors for the Rapid Detection of Toxicants 2:453
2.5.109 Development and Application of Sediment Toxicity Test for Regulatory Purposes 2:458
2.5.110 E_h 2:464

DOMESTIC WATER SUPPLY

THE ARSENIC DRINKING WATER CRISIS IN BANGLADESH

Charlie Bryce
Jim Philp
Napier University
Edinburgh, Scotland,
United Kingdom

INTRODUCTION

Although the incidence of arsenic poisoning in groundwater is worldwide and includes Bangladesh and India, Taiwan, Vietnam, Chile, China, North America, and Finland, the area of the highest demand for a resolution of the problem is Bangladesh. The source seems to be geological, for arsenic has been found in tube well water used for drinking and irrigation, although the geochemistry is not completely understood. As many thousands of boreholes have been produced to support modern irrigation systems, the underground aquifers are aerated, which causes transformation of anaerobic conditions to aerobic conditions. The presence of oxygen in this way decomposes arsenopyrite-releasing arsenic acid. At low pH, this arsenic dissolves in water and hence leads to water contamination. The arsenic content of sediments is high relative to crustal concentrations. The biogeochemical cycling of arsenic and iron are coupled in deltaic systems; iron oxyhydroxides act as a carrier for the deposition of arsenic in sediments. From there, it can be mobilized by bicarbonate, which can extract arsenic from sediments under both aerobic and anaerobic conditions.

Arsenic also becomes a pollutant as a result of various industrial uses and activities. Arsenic is a metalloid, and its primary usage has been in agriculture, in formulating herbicides, especially for controlling weeds in cotton fields. Sodium arsenite has been used as an insecticidal ingredient in sheep-dips. In industry, arsenic has found use in glass manufacture and a new role in the semiconductor industry. Copper smelting releases significant amounts into soils.

ARSENIC AND THE GEOGRAPHY OF BANGLADESH

Bangladesh, 85% of which is deltaic and alluvial plain, is situated in the lower end of three large river systems, the Ganges, the Brahmaputra, and the Meghna, whose catchment area is about 600,000 square miles (Fig. 1). The sediments produced in the catchment areas are very high and expose the underlying rocks, including arsenic-bearing rocks.

Arsenic pollution became a live issue in Bangladesh as recently as 1993, following a warning by the World Health Organisation (WHO) that levels of arsenic in groundwater above the permissible limit of 0.05 mg/L had been reported in seven districts of adjoining West Bengal in India. The Department of Public Health Engineering of Bangladesh was invited to test water samples from the adjoining eight Bangladeshi districts that have the same geographical continuity and aquifers as the West Bengal districts; this yielded the result that slightly more than 20% of the samples contained arsenic at levels ranging from 0.01 to 0.4 mg/L. Ten million people populate these areas and hence are at risk of arsenic toxicity.

Figure 1. The geography of Bangladesh.

Since that time, it has been shown that there is groundwater contamination in more than 40 districts that endanger in excess of 50 million people. The problem has been described in *The Lancet* as the world's worst episode of arsenic poisoning; more than 220,000 people reportedly suffer from arsenic-related diseases. In a recent study of 27 districts in Bangladesh, 58% of the water samples were unsuitable for drinking. The worst case was in Nawabganj district, where one well contained 60 times the WHO maximum permissible level.

TOXICITY AND DISEASE

Arsenic occurs principally in the forms of organic arsenic (methyl arsonic acid, dimethyl arsonic acid, arsenobetaine, and arsenocholine) and inorganic arsenic (trivalent and pentavalent arsenic). Of these, the trivalent form is the most toxic to humans (20 times more so than the pentavalent form) and is the most difficult to remove chemically from water.

Arsenic is a suspected carcinogen and has many acute effects on human health. But at the concentrations present in drinking water, it has no immediate side affects. The latency (i.e., the time from first exposure to manifestation of disease) for arsenic-caused skin lesions, in particular keratoses, is typically of the order of 10 years, and so a major increase in the number of cases of arsenic-caused diseases can be projected into the future (Fig. 2).

Figure 2. Common manifestations of long-term, chronic arsenic poisoning.

Exposure to arsenic in this way can lead to latent or manifest clinical symptoms through even low-level exposure over a period of time. This can result in an accumulation of this toxicant in various organs and systems, affecting their normal functioning, including the kidney and nervous system. Arsenic causes skin cancers and internal cancers such as lung and bladder cancer. The most common manifestations in afflicted people in Bangladesh are melanosis (93.5%), keratoses (68.3%), hyperkeratosis (37.6%), and dipigmentation (leucomelanosis) (39.1%). Cancers are found in 0.8% of the afflicted population. Preliminary work indicates that there may be several factors triggering arsenic-related diseases, but experts generally feel that poor nutrition may be a primary cause. Studies in Taiwan have shown that there is an increased occurrence of diabetes in the population exposed to arsenic via drinking water.

Recent studies have shown that arsenic is also a teratogen. Further, at the *5th International Conference on Arsenic* held in Dhaka, 2004, one of the key messages and cause for increased concern is that there is very good evidence that the environmental contaminant is getting into the food chain, thus putting even more lives at risk.

DRINKING WATER STANDARDS

The World Health Organisation has set 10 μg/L as the allowable level for arsenic in drinking water. On January 22, 2001, the U.S. EPA adopted this standard, and public water systems must comply by January 23, 2006.

DETECTING ARSENIC IN DRINKING WATER

In the modern analytical laboratory, arsenic is quantified by soluble arsenic assaying, preferable with GF-AAS (graphite furnace-atomic absorption spectrometry) for detection levels of less than 50 μg/L. However, given the highly dispersed nature of tube wells in Bangladesh, the transport of the many samples to central laboratories is logistically impossible. Field techniques are more important, so that samples can be processed as they are taken. In Bangladesh, this requires inexpensive and completely portable techniques. At present, a chemical test kit is being used (Fig. 3). The disadvantage of this approach is that the sensitivity of the chemistry (poor below 100 μg/L) is not compatible with the levels of contamination that need to be detected (50 μg/L and less). Often, at best, the presence or absence of arsenic can be inferred, but not the level of contamination. In addition, such testing is slow and can take about 6 months to cover some 2000 villages in a district.

Bioavailability Biosensors for Detecting and Quantifying Arsenic

A few strains of bacteria are resistant to arsenate, arsenite, and antimonite through the action of the gene products of the *ars* operon. The *ars* operon consists of five genes that code for three structural and two regulatory proteins. Two structural genes in the *ars* operon, *ars*A and *ars*B, code for proteins that form an efflux pump that transports arsenite and antimonite out of cells.

A means of measuring available arsenicals would be to construct a gene fusion plasmid in which part of the *ars* operon is fused upstream of a reporter gene system, such as the bacterial *lux* operon, which results in the production of light. A transcriptional gene fusion has been done (1) that consists of *E. coli ars*B :: *lux*AB. The detection limit of arsenic is of the order of 10 μg/L. Moreover, bioluminescence may be inducible in a concentration-dependent manner (Fig. 4) by arsenic salts; high concentrations result in higher bioluminescence, so that such biosensors may be able to

- Quantify arsenic within the required range of drinking water in Bangladesh
- Provide a measure of the bioavailability of the arsenic for risk assessment

REMOVAL OF ARSENIC FROM DRINKING WATER

Coprecipitation of arsenate with ferric (Fe^{3+}) ion is currently the most effective and practical method of arsenic removal. Optimum stability of the $FeAsO_4$ precipitate occurs at Fe/As molar ratios of >4; this ratio increases significantly, in practice, depending on water turbidity, slime levels, dissolved solids, and the presence of

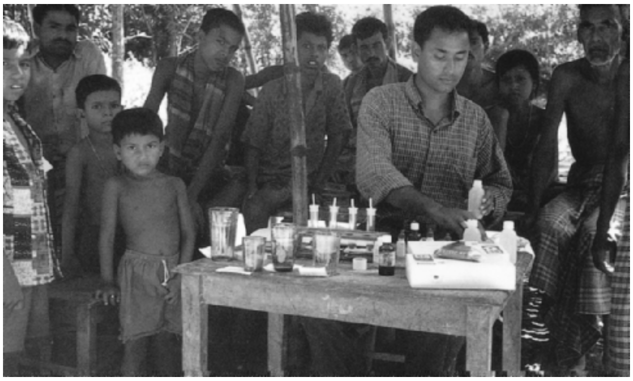

Figure 3. Testing for arsenic in drinking water using test kits at a village.

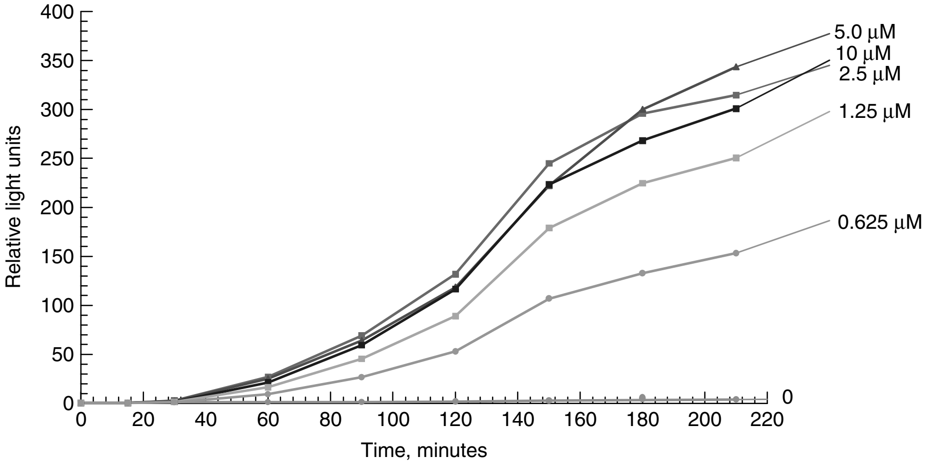

Figure 4. The response of a bacterial whole-cell bioavailability biosensor to increasing concentrations of arsenic.

iron-consuming species. However, Fe^{3+} ion coprecipitation of arsenite ($AsO_3{}^{3-}$) is moderately effective at pH ~7.0. The trivalent As(III) species must be oxidized to As(V) for complete precipitation with Fe^{3+} ion. Oxidation may be achieved through aeration or by adding oxidizers such as hypochlorite, permanganate, peroxide, and ozone. The application of other technologies, including alum and lime precipitation together with activated alumina adsorption, are not fully effective.

In Bangladesh, for geographical and financial reasons, there is likely to be a preference for local treatment rather than large-scale treatment plants. The ideal solution would be to modify each tube well at low cost for arsenic removal by, for example, ion exchange.

BOTTLED WATER

Robert M. Hordon
Rutgers University
Piscataway, New Jersey

INTRODUCTION

Bottled water sales in the United States have increased dramatically during the past decade. Total domestic and imported sales rose 142% from almost 2.5 billion gallons (9.4 billion liters) in 1992 to more than 6 billion gallons (22.8 billion liters) in 2002. Bottled water revenues rose nearly 190% from \$2.66 billion in 1992 to \$7.7 billion in 2002. Using the same 11-year period from 1992 to 2002 (1), per capita consumption in the U.S. increased more than 119% from 9.8 to 21.5 gallons (37.1 to 81.4 liters).

The global water market also shows comparable increases. For example, the world total consumption of bottled water rose nearly 63% from 21.3 billion gallons (80.6 billion liters) in 1997 to 34.7 billion gallons (131.3 billion liters) in 2002. Using the same 6-year period from 1997 to 2002, global per capita consumption increased 107% from 5.7 to 11.8 gallons (21.6 to 44.7 liters). Italy, Mexico, and France were the top three countries in per capita consumption in 2002 at 44.2, 37.7, and 37.1 gallons (167.3, 142.7, and 140.4 liters), respectively. In per capita consumption, the United States rose from a rank of 15 in 1997 to a rank of 11 in 2002 (1).

The rising consumption in the United States is attributed to an increasingly effective advertising campaign that touts bottled water as a safer and better tasting alternative to tap water. Packaging labels that show massive glaciers and springs in alpine settings have also helped.

HISTORICAL USES OF BOTTLED OR MINERAL WATER

The presumed reason for drinking mineral water and more recently bottled water is for the purported therapeutic effects and associated health benefits. Using mineral waters as a form of therapy was discussed by the ancient Egyptians and Greeks. Based on legend, the thermal springs of Bath, England, date to 800 B.C. Hannibal's army (and elephants) was reputed to have refreshed itself in the pools of Vergeze in southern France in 218 B.C. while enroute to attack Rome. Later on, the spring waters at Vergeze became known as the source of Perrier Water. The mineral waters from 12 springs at Vichy, France, date back to Roman times. Spring water from Fiuggi near Rome, Italy, was used by Michaelangelo. Another Italian luminary from the fifteenth century, Leonardo da Vinci, used the mineral waters from the three deep springs (396 m; 1300 ft) at San Pellegrino. Famous spas and watering holes, such as Hot Springs in Arkansas and Saratoga Springs in New York and many others in Europe, developed near mineral springs during the late 1800s and early 1900s (2).

Poland Spring water from Maine began to be distributed during the mid-1800s. Bottled water from Mountain Valley near Hot Springs, Arkansas, goes back to 1871. Commercial bottling of San Pellegrino water from Italy began in 1899, and export of Evian water from France to the United States began in 1905 (2).

TYPES OF BOTTLED WATER

Bottled water can be grouped into the following several categories depending upon the nature of the water and its source.

Nonsparkling Water

This includes spring water, artesian water, mineral water, and purified water. Domestic production of this type of water in the United States made up more than 95% of the bottled water market in 2002 (1).

1. Spring water is ground water. It comes from a water-bearing subsurface geologic formation known as an aquifer from which water flows naturally to the earth's surface. Water of this type can be collected only at the spring or from a well that taps the aquifer that feeds the spring.
2. Artesian water is derived from a well in an aquifer that is under pressure due to overlying confining layers. Artesian or confined well water can be collected with external pumps that supplement the natural underground pressure. The word "artesian" was derived from the first deep wells that were drilled into confined aquifers in the province of Artois in northern France from about 1750 (3).
3. Mineral water naturally contains at least 250 ppm of mineral salts such as calcium, chloride, sulfate, carbonate, and bicarbonate. No minerals can be added artificially, and it cannot come from a municipal source.
4. Purified (or demineralized) water may come from a municipal source and is treated by one or more of the following water treatment processes:
   a) Distillation: heating of water to produce water vapor which is then condensed and collected;
   b) reverse osmosis, where water is filtered by passing it though a membrane;
   c) deionization: a process where minerals are drawn to particles of the opposite electrical charge and then removed.

Sparkling Water

Sparkling water may include any type of naturally carbonated water. In addition, if the water is treated, CO_2 can be added to the product as long as the water has the same amount of CO_2 as it had when it emerged from its source.

Domestic and imported sparkling water made up about 2.6% and 2.1% of the U.S. bottled water market in 2002, respectively (1).

Beverages that contain certain ingredients or additives, such as sugar, fall into a separate category called soft drinks. Thus, tonic water, soda water, and seltzer are not considered bottled waters and are regulated differently.

REGULATORY AGENCIES

Public potable water supplies in the United States are regulated by the Environmental Protection Agency (EPA) under the federal Safe Drinking Water Act (SDWA). This means that all public water systems that operate under either public or private investor-owned companies that serve 25 or more people must be tested regularly for up to 118 chemicals and bacteria that are specified by the SDWA.

In contrast, bottled water in the United States is regulated as a packaged food product by the federal Food and Drug Administration (FDA). By law, the FDA must follow the same water quality standards as outlined in the Safe Drinking Water Act. In addition, bottled water companies are required to comply with FDA's quality standards, labeling rules, and good manufacturing practices. Finally, bottlers that are members of the International Bottled Water Association (IBWA) may opt to receive random, unannounced site inspections annually by a third-party organization. However, not all bottled water companies comply with the standards of the IBWA. To compound the regulatory issues associated with bottled water, the standards of the IBWA are not legally enforceable (4). Also, the results of any water quality tests that are made by the bottled water companies need not be released to the public (5). This stands in sharp contrast with the water quality reports that all United States public water supply purveyors must furnish each year to their customers.

The EPA states that bottled water is not inherently safer than tap water distributed by public water systems (6). Although tap water and bottled water must meet the standards set by their respective regulatory agencies, the FDA requires testing only once a year for bottled water, whereas the EPA requires much more frequent, often daily, testing. Another factor worth noting is that the FDA rules apply only to water sold in interstate commerce. The Natural Resources Defense Council (7) estimates that about 60% of all bottled water is sold in the same state where it is bottled; thus, FDA rules do not apply.

State regulations and industry standards affect bottled water at the state level. Some states abide by the FDA standards; others are even more stringent. For example, the State of New Jersey requires that the labels of all bottled water products must contain an expiration date of 2 years from the date of bottling (8). However, about 20% of the states have either very limited enforcement powers or no regulations at all.

Fluorides

It is well known that fluorides are a key factor in reducing tooth decay, particularly in children. Drinking water that has been adjusted to optimal fluoride levels prevents cavities and thereby improves dental health. The consumption of fluoridated water is more effective than the use of fluoridated toothpastes or mouth rinses as the latter is only on the teeth for a short time, whereas fluoridated water can be delivered to the teeth continuously through the bloodstream and saliva (5). Most bottled water does not have an optimal fluoride level. Although some bottlers provide fluoride information on their labels, they are not required to do so.

Safety of Plastic Bottles

For reasons of convenience and nonbreakability, most bottled waters are sold in plastic containers that contain phthalates. Water is a universal solvent, so phthalates can be leached from a plastic bottle. It is still not known if there are any negative health effects from human exposure to phthalates. However, rodents have experienced adverse effects from the chemical in some studies. It is apparent that additional research is needed on this issue (5).

COST TO THE CONSUMER

One thing is very clear about the differences between bottled water and tap water: the former is orders of magnitude more expensive (240–10,000 times greater). Bottled water packaged in convenient sizes of plastic containers costs about $6.60/gallon ($1.74/liter) compared to average costs of 1/100 of a cent/gallon for municipal tap water.

Is the difference warranted by taste, quality, and convenience in carrying, or does the explosive growth in bottled water sales reflect the success of mass marketing appeals to a more affluent generation that follows current fashion trends in beverage types? Time will tell, but for the forseeable future, bottled water sales continue to increase, even though the EPA states on its website that bottled water is not necessarily safer than regular tap water.

CORROSION CONTROL IN DRINKING WATER SYSTEMS

Christian J. Volk
Indiana-American Water
Richmond, Indiana

CORROSION IN DISTRIBUTION SYSTEM

Corrosion Process and Corrosion Cell

Corrosion can be defined as the wearing away or deterioration of a material because of chemical reaction with its environment. When iron or steel is exposed to water, rust (oxidized iron) forms (1). Water that promotes corrosion is defined as aggressive or corrosive. The corrosion processes consist of a series of electrochemical reactions occurring at the metal surface in contact with water and its constituents. Corrosion is an extremely complex chemical and electrochemical phenomenon. During oxidative reactions, local galvanic couples form on the surface of the metal, in which the metal is oxidized, while the oxidant is reduced. Each couple is a microbattery where the corrosion reaction proceeds with a flow of electric current between anodic and cathodic sites on the metal (Fig. 1). The electrochemical corrosion corresponds to the destruction of a metal by electron transfer reaction. All the components of an electrochemical cell must be present for this type of corrosion to occur. The components include an anode and a cathode (which are sites that have a different electrical potential on the metal), an electrical path between the anode and cathode for electron transport (internal circuit), an electrolyte solution that will conduct ions between the anode and cathode (external circuit), and an oxidizing agent to

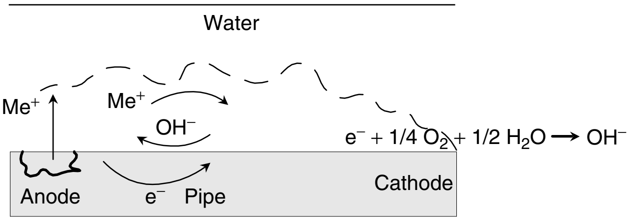

Figure 1. Pipe corrosion in water.

be reduced at the cathode (2). As metallic plumbing materials are not completely homogeneous, anodic and cathodic sites occur on the pipe surface. Oxidation and dissolution of the metal occur at the anode (Fig. 1). Electrons generated at the anode migrate to the cathode, where they are accepted by an electron acceptor, such as oxygen, after chemical reduction. Consequently, the positive ions generated at the anode migrate through the solution to the cathode and negative ions generated at the cathode tend to migrate to the anode. The mechanisms of corrosion are extremely complex and depend on the interactions of physical and chemical factors and the material itself. Table 1 shows different materials, their use in distribution systems, and corrosion-associated problems. Generally, inert and nonmetallic materials like concrete or plastic are more corrosion resistant than metallic pipes.

Scale Formation

The formation of a scale on the pipe surface protects the pipe from corrosion by separating the corrodible metal from the water. Scale is formed when the divalent metallic cations associated with hardness (calcium and magnesium) combine with other minerals contained in water and precipitate to coat the pipe wall. Scale generally includes calcium carbonate ($CaCO_3$), but also magnesium carbonate ($MgCO_3$), calcium sulfate ($CaSO_4$), or magnesium chloride ($MgCl_2$). Water can hold a certain amount of a given chemical in solution. If more is added, it will precipitate instead of dissolve. The point at which no more chemical can be dissolved is the point of saturation. The saturation point depends on water quality, including pH, temperature, and total dissolved solids (TDS) (1).

Types of Corrosion

Different types of corrosion exist, which can be divided into two broad classes: uniform or localized, depending on the material to be corroded, system construction, and water characteristics. Localized corrosion resulting in pitting is produced after galvanic corrosion and concentration cell corrosion. Uniform corrosion takes place in an equal rate over the entire surface (3). The different types of corrosion are summarized in Table 2.

Microbial Corrosion

Bacteria adhere to the pipe surface and form a biofilm (4). Microbes can promote corrosion by creating areas with different concentrations in oxygen, hydrogen ions, minerals, and metals. These concentration differentials promote corrosion. Some microorganisms also catalyze reactions associated with the corrosion process. Iron precipitating bacteria (such as *Gallionella*) can convert Fe (II) to Fe (III) and influence the structure of Fe (III) precipitates (2,5). Organisms involved in the sulfur cycle in water also affect the corrosion process. Sulfate reducers have been found in tubercles under anoxic conditions. Bacteria involved in the nitrogen reaction affect the concentration of oxygen, leading to oxygen concentration cells that produce localized corrosion and pitting. Corrosion also protects bacteria from disinfection. Corrosion products offer a large surface area for microbial attachment. One corrosion product

Table 1. Different Material Types and Corrosion-Associated Problems in the Distribution Network

Material	Sources	Corrosion Problems
Iron and steel	Most common material in water systems	–Buildup of corrosion products on pipe walls and release or iron oxide products
Galvanized pipe	Oldest and most common plumbing material, quality varies	–Better service in hard water –Subject to galvanic corrosion –Leaching of zinc, iron, cadmium, and lead (impurities)
Lead	Lead service lines, lead pipe joints, gaskets	–Corrodes in soft water with pH<8 and hard water with high alkalinity levels –Leaching of lead
Copper	Most commonly used since World War II, excellent characteristics including good corrosion resistance, low cost, and ease of installation	–Subject to uniform corrosion, erosion, and pitting –Attacked by high velocities, soft water, chlorine, oxygen, low pH, and high alkalinity water –Copper leaching
Brass	Alloy of copper and zinc, in meters and plumbing fixtures	–Dezincification (selective removal of zinc) –Good corrosion resistance
Cement/asbestos	Asbestos/cement mains	–Release of asbestos fibers –Calcium can be leached from cement in contact with aggressive water –Increase of pH –Good corrosion resistance
Plastic	PVC pipes	–Resistant to corrosion

Table 2. Different Types of Corrosion

Type of Corrosion	Characteristics
Uniform corrosion	–Corrosion of a single metal –A site is anodic one instant and cathodic the next –Metal loss is uniform over the metal surface
Galvanic corrosion	–Occurs between 2 different types of metals in contact –One metal serves as anode and deteriorates, whereas the other acts as cathode and is protected (Anode: Zinc>aluminum>iron>cast iron>lead>brass>copper: cathode)
Pitting corrosion	–Localized attack, pitting may occur if imperfections in the metal or regions of high stress exist –Imperfection or high-stress area is anodic and surrounded by cathodic area –Corrosion occurs rapidly at point of failure –Chloride is associated with pitting
Tuberculation	–Occurs when pitting corrosion leads to a product buildup at the anode next to a pit
Crevice corrosion	–Form of localized corrosion caused by changes in acidity, decrease in oxygen, or dissolved iron
Erosion corrosion	–Removal of protective films and the pipe metal as well –Results from high flow velocities and turbulence
Cavitation corrosion	–Type of erosion corrosion –Water pressure drops, causing water to form water vapor bubbles that collapse with an explosive effect –Removal of protective coating on metal –Occur in pump impellers, partially closed valves, and reducers
Selective leaching	–Preferential removal of one metal
Stay-current corrosion	–Localized corrosion caused by grounding of home appliances to water pipes
Concentration cell corrosion	Occurs when concentrations of aqueous species (like oxygen) differ between two parts of the metal

(goethite, α–Fe–O–OH) quickly reacts and consumes chlorine. Chlorine is consumed before it can diffuse to the core of corrosion tubercles. The microorganisms within the tubercles are not exposed to lethal concentrations of disinfectant and thus are allowed to grow in the distribution systems. Corrosion products including iron oxides are also capable of adsorbing natural organic matter (NOM) from the bulk fluid (6). NOM accumulates on the surface of corrosion products. It was found that heterotrophic microorganisms found in drinking water supply could readily extract the NOM from the corrosion products for cell growth (7,8). In highly corroded environments, biofilm microorganisms can cause many problems such as bad taste and odor, slime formation, or coliform occurrences.

Consequences of Corrosion

Corrosion is one of the main problems in the drinking water industry. It can affect public health, water aesthetics, and operations. Corrosive water can leach toxic metals from distribution and household plumbing systems. Lead and cadmium may occur in tap water. US EPA promulgated the lead and copper rule in 1991 in order to reduce lead and copper levels in drinking water (9). The methods to reduce lead and copper are the following: removal of these metals from the source water (if present), implementation of a corrosion control program, replacement of lead service lines, and public education. The lead and copper rule defines an action level for the tap concentration of lead and copper higher than 15 ppb and 1.3 ppm, respectively (for the 90th percentile of the samples). Periodic sampling is required to monitor lead and copper concentrations at the customer's tap after leaving the water stagnant in the service lines for 6–8 hours. Moreover, optimal corrosion control water parameters (pH, calcium, alkalinity, temperature, inhibitor level) are defined for the plant effluent and distributed waters. When the lead or copper concentration is above the action level, the water utility has to implement a corrosion control program (9).

Copper in water can cause blue stains and a metallic taste, whereas zinc leads to a metallic taste. Corrosion of cast iron pipes can cause the formation of iron deposits called tubercles in the mains. Red water problems occur when iron is dissolved from cast iron by corrosive water. Iron stains plumbing fixtures, laundry, and makes water appear unappealing for drinking. Responding to customer complaints of colored water or bad taste is expensive in terms of money and public relations. Corrosion-caused problems that add to the cost of water include increased pumping costs after a buildup of corrosion products (tuberculation), uncontrolled scale deposit that can seriously reduce pipeline capacity, and increased resistance to flow. Aggressive water reduces the life of valves and can shorten the service life of plumbing fixtures and hot water heaters. Water leaks lead to loss of water and water pressure (1,3,10).

FACTORS IMPACTING CORROSION

The corrosion rates depend on many site-specific conditions and their interactions, including water characteristics and pipe conditions (2,3,10). The following section describes major factors impacting corrosion. Table 3 shows the effects of some chemicals present in water.

Table 3. Effects of Chemicals on Corrosion

Parameter	Effect on Corrosion
Hardness (measures calcium and magnesium)	Hard water is less corrosive than soft water because of the formation of a film of calcium carbonate ($CaCO_3$) on the pipe wall
Chloride (Cl^-)	Leads to pitting by causing the metal to stay in solution
Sulfate (SO_4^{2-})	Leads to pitting by causing the metal to stay in solution
Hydrogen sulfide (H_2S)	Accelerates corrosion
Ammonia (NH_3)	Increases corrosion rates
Organic Matter	Can increase or decrease corrosion rates

Temperature

Corrosion generally increases with temperature as temperature accelerates chemical reactions. Temperature changes the solubility constants and can favor the precipitation of different substances or transform the identities of corrosion products. These changes result in either more or less protection of the pipe surface, depending on the conditions. Temperature also affects the dissolving of $CaCO_3$. $CaCO_3$ tends to precipitate and form a protective coating more readily at higher temperatures. Temperature can affect the nature of corrosion. Corrosion that can be of pitting type at cold temperatures can become uniform at hot temperatures (2,3,10).

Flow/Velocity

The velocity of water increases or decreases corrosion rates depending on the conditions. When water is corrosive, higher flow velocities bring dissolved oxygen to the corroding surface more rapidly. For water with protective properties or containing corrosion inhibitors, high flow velocities aid in the formation of a protective film. At low velocities, the slow movement does not aid the effective diffusion of protective ingredients to the metal surface. High velocities can lead to the erosion of pipes, especially in copper lines. Stagnant waters in water main and house plumbing have been shown to promote tuberculation accompanied with biological growth (4).

Metal and Manufacturing Process

A metal that easily gives up electrons will corrode easily. When dissimilar metals are connected together, the metal corroding easier becomes an anode, whereas the metal resistant to corrosion becomes a cathode (defined as galvanic corrosion). The anode metal will corrode rapidly, whereas the cathode is protected. Manufacturing process can also impact the durability of the pipe, especially for galvanized piping.

Electrical Current

Corrosion is accelerated when an electrical current is passed through the metal. Improper grounding of household electrical systems or electric railway systems leads to electrical current in water pipes.

Dissolved Oxygen (DO)

Corrosion rate increases with increasing DO concentrations. Oxygen is the molecule accepting the electrons given up by the corroding metal. Oxygen also reacts with soluble ferrous iron ions to form ferric iron, which precipitates and forms a tubercle.

Total Dissolved Solids (TDS)

TDS levels are critical because electrical flow is necessary for corrosion to occur. Corrosion rates increase with increasing concentrations of TDS because water becomes a better conductor.

pH

pH is a measure of hydrogen ions (H^+). H^+ is a substance accepting the electrons given up by the metal. Generally, corrosion rate decreases as pH increases.

Alkalinity and Dissolved Inorganic Carbon (DIC)

Alkalinity measures the ability of water to neutralize acids or bases. The corrosion rates decreases as alkalinity increases.

Chlorine Residual

Gaseous chlorine lowers the pH of water by reacting with water to form hypochlorous acid (HOCl), hydrogen ion, and chloride ion. This reaction makes the water more corrosive. For low alkalinity water, the problem is greater because water has less ability to resist pH changes.

MEASUREMENT OF CORROSION

A comprehensive corrosion control program should include several techniques to monitor corrosion, because no single technique provides all the information on corrosion. The corrosion rates are expressed in mils (1/1000 inch) per year (MPY). Corrosion rates can be determined by weight loss method or electrochemical methods. Physical observations of a pipe exposed to water can be conducted, and corrosion indexes can be determined for given water (2,3,10). Table 4 presents different methods to monitor corrosion.

Coupon Weight Loss Method

A metallic coupon is inserted inside a main. The coupon method determines the average corrosion rate over a period of exposure, which is accomplished by weighing the coupon before and after exposure. The corrosion rate is calculated from the weight loss, initial surface area of the coupon, and time of exposition.

Loop System Weight Loss

This method uses a pipe loop or sections of a pipe for determining the effect of water quality on pipe material. Water flows through the loop under a continuous or intermittent flow to simulate the flow patterns of a

Table 4. Different Methods to Assess Corrosion Levels

Method	Advantages	Disadvantages
Coupon weight loss	–Provides corrosion over a specific period –Economical –Coupons placed in system	–Takes a long time –Does not show variations occurring during test –Analytical error because of weighing –Coupon may not be representative of system material
Loop system weight loss	–Actual pipe sections used –Loops placed in the system –Loop can be used to test different chemicals	–Takes a long time –Does not show variations occurring during test
Electrochemical rate measurements	–Simple and reliable –Instantaneous readings –Continuous monitoring possible –Gives uniform and pitting corrosion	–Relatively expensive –Gives corrosion rates for a particular material
Microscopic techniques	–Examination of particles in water and films on pipes –Determination of the morphology of corrosion products	–Require equipment
X-ray analysis and diffraction	–Identification of the elements or class of compounds present in corrosion products and films with possible quantification depending of the technique	–Require equipment
Corrosion indices	–Various indices available	–Have some limitations, can be misapplied –Useful after the fact but not to predict corrosion problems

household. Pipe sections are removed for weight loss measurement and inspection.

Electrochemical Methods

Several instruments are based on the electrochemical nature of metal corrosion in water. They are based on electrical resistance, linear polarization, or galvanic current. Electrical resistance probes measure the resistance of a thin metal probe; as corrosion causes metal to be removed from the probe, its resistance increases. Linear polarization resistance (LPR) is an electrochemical technique that measures the DC current through the metal/fluid interface, which results from polarization of one or two electrodes of a material after application of a small electrical potential. The corrosion current density, which corresponds to the current flowing in a corrosion cell per unit area, is related to the DC current. The galvanic current method measures corrosion of dissimilar alloys of metals.

Radiography Methods

X-ray emission spectroscopy and X-ray diffraction help characterize the corrosion scales.

Microscopic Methods

The deterioration of pipe surface can be evaluated using optical or scanning electron microscopes.

Chemical Analysis of Water and Corrosion Indexes

Water quality data can be used to calculate stability indexes or indicators of water corosivity (Table 5) (10–14). The Langelier Saturation Index (LSI) indicates whether a given water is likely to form or dissolve a protective film of calcium carbonate (11). The calcium carbonate precipitation potential (CCPP) estimates the quantity of $CaCO_3$ that can be precipitated from oversaturated water and the amount that can be dissolved by unsaturated water (12). Larson and Skold (13) studied the effects of chloride and sulfate ions on iron and proposed two indices. In general, it is very difficult to find a relationship between these indices and potential corrosion problems in the system.

METHODS OF CORROSION CONTROL

The complete elimination of corrosion is almost impossible. However, it is possible to reduce corrosion. As corrosion depends on both water quality and pipe characteristics, optimal corrosion control methods are site specific. Three basic approaches to control corrosion exist: (a) modify water quality so that it is less corrosive to the metal, (b) place a protective barrier between the water and pipe, and (c) use pipe material and design the system so that it is not corroded by water. Methods used to achieve corrosion control involve modifying water quality (changing pH and alkalinity), forming a calcium carbonate coating, using corrosion inhibitors, providing cathodic protection, and using a corrosion-resistant coating (3,10).

pH Adjustment

Adjusting the pH is one of the most common methods of corrosion control. As most metals used in the distribution system tend to dissolve more readily at lower pH (presence of H^+), an increase in pH and alkalinity levels can reduce corrosion by reducing the solubility of metals. The optimum pH is related to water and system characteristics; it is generally above 7.0. Various chemicals can be used in corrosion control treatment (Table 6). For example, lime is commonly used to increase both pH and alkalinity. It is less expensive than the other chemical products. However, lime softening can cause severe scale problems

Table 5. Indexes of Water Corrosion

Index	Formula
Langelier Saturation Index (LSI)	$LSI = pH_{actual} - pH_s$ pH_{actual} : pH of water sample $pH_{s:}$ Theorical pH at which water is saturated with calcium carbonate LSI = 0: stable water, LSI < 0: corrosive water, calcium carbonate dissolves, LSI > 0: calcium carbonate precipitates
Calcium carbonate precipitation potential (CCPP)	$CCPP = 50{,}000\ (Talk_i - Talk_{eq})$ (in mg of $CaCO_3$/L) $Talk_i$: initial total alkalinity $Talk_{eq}$: Total alkalinity at equilibrium
Larson Index	$LI_1 = \dfrac{2[SO_4{}^{2-}] + [Cl^-]}{[HCO_3{}^-]}$ The brackets indicate the concentration in mole/L $LI_2 = \dfrac{[Cl^-]}{[HCO_3{}^-]}$
Ryznar Stability Index (RSI)	RSI = pHs-pH RSI = 6.5–7: water at saturation RSI < 6.5: Scale forming water RSI > 7: Undersaturated water

Table 6. Various Chemicals Used to Adjust pH

Chemical	Effect	Addition Equipment
Lime, $Ca(OH_2)$	Increases pH, alkalinity, and calcium levels	Dry storage, gravimetric or volumetric dry feeders, slurry feed
Caustic soda, NaOH	Raises pH and converts CO_2 to alkalinity species	50% solution, metering pumps
Soda Ash, Na_2CO_3	Increases alkalinity with moderate pH increase	Dry storage with solution feed
Sodium bicarbonate, $NaHCO_3$	Increases alkalinity	Dry storage with solution feed
Sulfuric acid, H_2SO_4	Lowers pH	Metering pumps
Carbon dioxide, CO_2	Lowers pH, converts hydroxyls to bicarbonate and carbonate	Pressurized gas feeder

when it is not stabilized. Stabilization after softening can be accomplished by feeding carbon dioxide or sulfuric acid to decrease pH so that calcium carbonate does not precipitate in the distribution system (1).

Formation of a Calcium Carbonate Coating

Protective coating can be applied by controlling the chemistry of water. A common protective coating technique is to adjust the pH of water to a level just above the saturation of calcium carbonate. This process has to be closely controlled because a pH that is too low may result in corrosion and a pH too high may lead to precipitation and cause plugging of the lines.

Corrosion Inhibitors

Some waters do not contain enough calcium or alkalinity to lead to the formation of a coating. Corrosion inhibitors used in potable water act by forming a protective scale over anodic or cathodic sites. These films are commonly inorganic precipitates containing the ions added as inhibitors. They provide a barrier between the water and the pipe. Chemical inhibitors include phosphates and silicates. The success of an inhibitor in controlling corrosion depends on three requirements. First, when treatment is initiated by adding two to three times the normal concentration of inhibitor to build up a protective film rapidly. Several weeks are required for the film to develop. Second, the inhibitor must be fed continuously at a proper concentration. An interruption in chemical addition can lead to the dissolution of the film. Third, water flow rates must be adequate to transport the inhibitor to all parts of the system, otherwise the protection film will not form (3).

Several types of phosphates are used for corrosion control, including linear and cyclic polyphosphates, orthophosphates, glassy polyphosphates, and bimetallic phosphates. It is also possible to use zinc along with polyphosphates and orthophosphates, or blends of ortho and polyphosphates (15). The choice of a particular phosphate product depends on the water and the distribution system characteristics as well as the utility treatment goals. Some phosphates work better than others for a given system (3). It is recommended to conduct laboratory and pilot testing to evaluate the effectiveness of different products. Phosphate inhibitors need particular pH, alkalinity, and concentrations to be effective; the balance required is poorly understood. Orthophosphates seem to be very effective for a wide range of plumbing materials (15). It can be used alone (phosphoric acid, H_3PO_4) or in combination with zinc. Commercial formulations of orthophosphates exist that contain various levels of zinc. Zinc orthophosphate products are used primary in water where the potential for formation of $CaCO_3$ scale is low (soft and slightly acidic water). When using zinc phosphates, limitations of metal levels in wastewaters can limit the use of products with a high zinc content. Zinc orthophosphate leads to the formation of a zinc phosphate scale (16). When zinc is not available with phosphates, a protective scale still forms, such as ferrous or ferric phosphate scale on iron pipes.

Phosphate is most effective in the absence of prior scale formation because phosphates must be part of the precipitate to be effective. When fed into the system, phosphates soften the previously formed scales, causing red water and bacteriological problems as the scale washes out of the system. Orthophosphates can reduce corrosion rate of iron, lead, zinc, and galvanized pipes; although it is not considered to be very effective in preventing copper corrosion (15,17).

A distinction should be made between orthophosphates and polyphosphates (10). Polyphosphates have been used to control corrosion in cast iron pipes; however, little evidence exists of any beneficial effects of polyphosphates on lead corrosion. Some studies (18,19) showed that lead levels could increase in water after solubilization of protective films on the pipes. Some polyphosphates can be used as sequestering agents to keep in solution scale-forming ions (calcium and magnesium) and iron. These polyphosphate products tie up with iron and prevent red water (3).

Inorganic silicates have also been used to reduce corrositivity; they lead to the formation of a protective film onto various metal surfaces. Silicates inhibit corrosion in asbestos cement pipes, where its effectiveness may be attributed to a surface catalyzed conversion to quartz (20). Soluble silicates are adsorbed onto the metal pipe surface at the anodic area and form a thin film. High dosages (20 mg/L) are required during the first 30–60 days of treatment. Then, doses of 4–8 mg/L are added in the system. Silicates have not been widely used because their effects on corrosion are debatable (21,22).

Cathodic Protection

This process limits corrosion of metallic structures. It is used to prevent internal corrosion in water storage tanks. It consists of using an inert electrode (such as high silicon cast iron or graphite) powered by an external source of current. The current forces the inert electrode to act as an anode, preventing the metal to be protected to become an anode and corrode. Another method involves a magnesium or zinc electrode acting as a galvanic anode. The electrode produces a galvanic action with iron; it is sacrificed and corrodes, whereas the iron is protected from corroding.

Lining, Coating, and Paints

A protective coating can keep corrosive water away from the pipe surface and storage tanks. Some linings include coal tar enamels, epoxy paint, cement mortar, polypropylene, or vinyl. These linings are applied when pipes are manufactured or in the field.

UTILITY EXPERIENCE WITH CORROSION CONTROL

Figure 2 shows corrosion rates as a function of temperature and corrosion inhibitor levels in two pilot systems (23). The first system received a constant dose of phosphate over the entire study (system fed after conventional treatment of the Mississippi water, IL-American Water, E. St. Louis), whereas the second system received changing inhibitor levels (test system to optimize treatment). Corrosion rates were strongly related to water temperature (and/or other seasonal factors). For the plant condition system, corrosion rates could vary up to 7 mpy, even when the plant was feeding a corrosion inhibitor (constant doses of 0.86 mg PO_4/l over the year). Higher phosphate levels in the test reactor resulted in low corrosion rates, especially in the summer. Corrosion rates were maintained below 3 mpy when phosphate dosages were slightly increased (between 1.5 and 2 PO_4/l), especially during warm periods. For this site, a seasonal corrosion control strategy was developed that would require slightly higher corrosion inhibitor concentrations during the summer and possibly lower dosages during winter months, rather than using a constant concentration over the entire year (23).

CONCLUSION

As distribution system pipes are in place for long periods of time ($\gg$50 years), corrosion control is critical to maintain microbial and aesthetic water quality and pipe integrity. Water utilities should set corrosion control goals and monitor corrosion rates on a regular basis to determine seasonal changes in corrosivity and adjust corrosion control programs to prevent excessive corrosion.

ECONOMICS OF RESIDENTIAL WATER DEMANDS

Steven J. Renzetti
Brock University
St. Catharines, Ontario, Canada

This entry examines what is known regarding the economic characteristics of residential water use and how this type of information can be applied in managing water resources. Understanding the economic dimension of household water use is important for several reasons. First and most importantly, all households on the planet share the need for access to potable water supplies. On the other hand, households have very different degrees of access to safe water. For most of North America and Europe, access to clean water is almost taken for granted by many households. In contrast, a great number of households in low-income countries do not have access to reliable supplies of potable water. As the World Bank contends, "The challenge is enormous: one billion people still lack access to safe water, two billion lack safe sanitation. Slow progress is not acceptable, as more than three million children still die every year from avoidable water-related disease" (World Bank Water Supply and Sanitation web-site, September 1, 2001 http://www.worldbank.org/html/fpd/water/). Second, the agricultural sector dominates global water use, but residential and industrial demands have grown much more rapidly during the twentieth century. Third, empirical evidence indicates that the amount of water used by a household is a complex function of a number of influences, including the price of water (both in monetary terms and in time costs), household income, and household characteristics (for example, the number of residents and water-using appliances).

THE ECONOMIC PERSPECTIVE ON RESIDENTIAL WATER DEMANDS

Households use water for personal hygiene, waste removal, cooking, cleaning and a number of outdoor applications (lawn and garden watering, etc.) Table 1, Fig. 1. Except in some arid portions of the United States, the bulk of residential water use occurs indoors and is related to personal hygiene and waste removal (4). In North America, for example, these two applications account for 60% to 70% of the average household's daily indoor water use. Another important feature of residential water use is its cyclical character. On a daily basis, household water use typically displays two peak periods of use: early morning and early evening. On an annual basis, residential water use in summer months is usually substantially higher, than during the rest of the year due to the increase in outdoor water use. Hanemann (5), for example, indicates that for households in the Western states of the United States, total summer water use exceeds total winter water use by 50–60%. The multiplicity of water's uses and the cyclical nature of water use suggest that potentially a number of factors influence a household's water use decisions.

Economic theory provides a useful framework within which the nature of residential water use may be examined. Economists usually assume that a household's demand for any good such as potable water is, in the most general case, a function of all of the prices facing a household as well as its income and demographic characteristics. The household's estimated demand for water may be used to predict household consumption levels and to predict how households will respond to changes in the price of water. This degree of responsiveness is captured by a variable known as "elasticity." This variable is measured as the ratio of the percent change in the demand for a good to the percent change in a price or income. A household's demand is said to be 'inelastic' if the estimated elasticity is less than one. For example, if the price elasticity of demand equals −0.5, then a 10% increase in price, it is predicted, with to induce a 5% decrease in water use. The empirical water demand literature seeks to estimate households' price and income elasticities of water demand as well as those households' valuation of access to potable water supplies.

[a] Ref. 1.

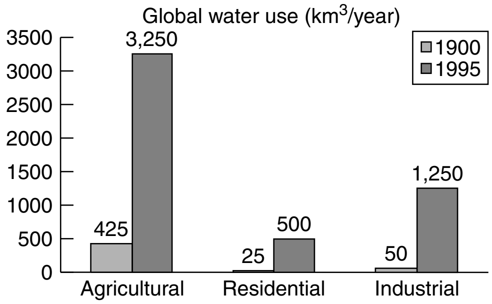

Figure 1. Global water use (1,2).

There are several ways in which the general model of household demand has been altered to reflect conditions that are important in the consumption of water. These include situations when households' choice of water use is constrained by their stock of water-using appliances and the size of the house and property (6), when households must choose not only the quantity of water to consume but also the source of its potable water (7), and when households face water prices that are complex functions of the quantity of water used. The last of these extensions is quite important because of the growing frequency of complex price schedules facing households and because of the implications of this type of price structure for the statistical estimation of residential water demands (5,8).

EMPIRICAL MODELS AND RESULTS

Residential water use has received a substantial amount of attention from economic researchers. There are a number of surveys that summarize the theoretical and empirical research (4,9–11). The main goal of statistical models of water demand is to estimate the relationship between the observed quantity of residential water use and the explanatory variables (such as the price of water) suggested by economic theory. During the evolution of the residential water demand literature, a number of issues have been at the forefront, including the appropriate definition of the price of water, the choice of statistical technique, and the role of other explanatory variables (such as climate and household characteristics).

The modern residential water demand literature begins with the work of Howe and Linaweaver (12). The authors estimate demand models for domestic (indoor) and sprinkling (outdoor) water demands. The demand models are further divided according to climatic zones. The authors assume that the quantity of water demanded by the average household is a function of water and sewage prices, age and value of property, the number of people in the household, and climate conditions. The estimation models indicate that indoor water use is responsive to the price of water to a limited degree (price elasticities ranging from -0.214 to -0.231) and outdoor water use is more responsive to prices (price elasticities ranging from -0.438 to -1.57). Income elasticities follow the same pattern: 0.314 to 0.378 for indoor water use and 0.447 to 1.45 for outdoor.

Since the work of Howe and Linaweaver, statistical models of residential water demand have become more sophisticated, and data on household water use and characteristics have become more detailed and comprehensive. A particularly important issue has been the manner in which the price of water is represented. When prices are set out as complex functions in which prices can increase or decrease with the amount purchased, researchers must take more care in measuring the influence of prices on water use (the variety of statistical methods used to do this is reviewed in Ref. 11).

A number of other factors, it has been found, are influential in determining household water demand. Researchers have found positive relationships between water use and family size, property value, and household income (4). In Hanemann's (5) comprehensive listing of estimated water demand elasticities, the average of the income elasticities reported is 0.52. Another important set of factors that, it has been found, influences residential water demand is related to climate. There is a consensus in the literature that increases in temperature or evaporation rates lead to higher residential water demand, whereas increases in precipitation have the opposite effect. However, indoor residential water use appears to be relatively insensitive to weather conditions, and most of the influence of climate on residential water use works through outdoor water uses.

LOW-INCOME COUNTRIES

Households in many low-income countries face a variety of challenges in their efforts to secure potable water. In large urban centers, water supply systems are often unreliable and fail to provide service to many of the city's poorest residents (13). Residents in rural areas frequently confront even greater risks from contaminated and distant water supplies (14). Households in low-income countries also differ from their high-income counterparts in that they spend a larger share of their income on water. They also may face a different set of circumstances regarding their supply of potable water. For example, it is common for households in low-income countries to have several possible sources of potable water. Mu, Whittington and Briscoe (14) report that the members of a small town in Kenya choose among private pipe, communal wells and pumps, kiosks, and water vendors for their potable water. These sources differ in their relative cost, convenience, reliability, and quality. It is important to note that the cost of each alternative is a combination of the time spent obtaining water, installation charges, continuing connection charges, and prices. Households face the challenge of deciding which supply source(s) to use as well as how much water to obtain from each source, and researchers face the challenge of understanding and modeling these decisions (15).

There have been a number of attempts to model, first, household decision-making regarding its choice of the source of its drinking water and, second, households' valuation of improved access to reliable water supplies in low-income countries. Researchers have conducted surveys that collect information on households' supply–source choices and characteristics. For example, Madanat and Humplick (16) examine the behavior of 900 households in Faisalabad, Pakistan. The authors conclude "the more expensive the in-house pipe connection relative to the other sources, the less likely the household is to connect" (p. 1337). In addition, the connection decision is strongly influenced by household expectations regarding the relative reliability and quality of alternative sources as well as their past experiences with alternative supply sources.

With respect to the value they assign to access to safe water, many households in low-income countries find themselves in what some researchers have termed a "low-level equilibrium trap" (17, p. 1931). By this, the authors mean that the existing water supply system has few connections, low prices, low revenues, low maintenance, poor reliability, and low usage by households. One of the ways to improve this situation is to demonstrate that the value of improved service to households (as expressed in their willingness to pay through higher prices) exceeds the costs of improving service.

The World Bank Water Research Team (15) is the most extensive effort to assess the preferences of households in low-income countries for connection to water supply systems. The authors find that household income is positively linked to the demand for improved services, but the link between the two is not strong. Households with higher levels of education are also willing to pay more for improved access. Gender is often an important factor in explaining willingness to pay, but "the direction of the influence depends on the specific cultural context" (p. 53). In Tanzania and Haiti, female respondents' willingness to pay exceeds that of males, but in Nigeria and India, the reverse is true. As expected, economic variables play an important role, and higher connection charges and monthly prices reduce demand. Finally, households are willing to pay more for private connections and for sources higher expected quality levels and reliability.

RESIDENTIAL WATER DEMAND MANAGEMENT

Historically, the challenge of managing water resources and providing potable water has concentrated on the engineering task of conveying and treating water so that it would be available for household use. However, as the construction and operation of water distribution and treatment systems becomes increasingly expensive (in monetary and environmental terms), attention has turned to the idea of balancing the costs of developing water supplies with the benefits derived from consumption. From this adoption of a more balanced perspective has come a renewed interest in using the information contained in estimated residential water demand to assist in planning and operating water delivery systems.

Estimated residential water demand equations provide information that can be used in a variety of ways to promote water conservation and in the development and operation of water supply systems. First, the structure of residential water demand can provide water utility operators with information regarding the relative efficacy of alternative policy instruments aimed at promoting water conservation. For example, Renwick and Archibald (18) examine the factors influencing Californian households' adoption of water conserving technologies such as low-flow toilets and showerheads. The results of the authors' empirical model suggest that both price and nonprice measures reduce household water use, although their impact varies across households.

Forecasting future water use is a second way in which demand information is used. Dziegielewski (19) provides a brief review of the history of urban water demand forecasting. In the "traditional" method of forecasting that has dominated historically, total future demand is predicted as the product of expected population growth and a fixed per capita water use coefficient. This method was not very accurate as it neglected other influences (such as prices) on water use. The development of the municipal and industrial needs (MAIN) model represents a major change in forecasting methods. The MAIN model disaggregates total water use into a large number (approximately 400) of categories and locations. The factors that influence water demand for each category are determined through statistical analysis. Changes in these explanatory variables (such as income, climate, and energy prices) translate into anticipated changes in water use and, in turn, form the basis for water demand forecasts. A third way in which water demand information is used in assessing the construction and operation of water delivery systems. For example, the costs of improving the reliability of a water supply system can be compared with households' valuation of that increase in reliability (20).

CONCLUSIONS

All households share the need for access to potable water, but actual consumption levels vary significantly due to differences in income, water prices, proximity to reliable water supplies, climate, and a variety of other factors. Economic models of household decision-making regarding water use indicate that households are influenced by these factors and that water prices, income levels, and climate play particularly influential roles. A different line of research highlights the challenges faced by households in low-income countries in their efforts to acquire potable water. One of the facets of this situation that has received attention recently concerns households' decision-making when confronted with more than one source of potable water. As predicted by economic theory, most households consider the relative quality, reliability, and cost of alternative sources when making their choices. The last topic considered here is the use of information regarding the economic features of residential water demand to encourage water conservation. Research indicates that both price and nonprice based conservation programs are effective in curtailing demands.

GRAY WATER REUSE IN HOUSEHOLDS

Fayyaz A. Memon
D. Butler
Imperial College
London, United Kingdom

Gray water is a loosely defined term representing discharges from wash basins, baths, showers, dishwashers and washing machines. This generally excludes wastewater from kitchen sinks and toilets, commonly known as black water. Gray water accounts for about 50% of the total household water consumption activities (Fig. 1).

The quality of gray water depends on factors, including the habits and affluence of the water users, the types of products used for clothes and personal washing, and the nature of the substances disposed of through sinks and other appliances. Substances found in gray water include detergents, shaving foam, toothpaste, soap, hair, body oils, and dried skin residues. Small amounts of fecal material arising from washing of baby diapers and traces of urine are also present in gray water. These pollutants exert oxygen demand and contain some disease causing microorganisms. Typical gray water pollutant concentrations from different sources are shown in Table 1. The average pollutant concentration measured in the effluent from different appliances housed in a residence hall (for example) is shown in Table 2.

Freshly produced gray water usually does not have any objectionable odor. Compared to black water, gray water has a relatively higher temperature and readily degradable pollutants. Therefore, it requires immediate treatment after collection. If stored untreated for long periods, oxygen deficient conditions will develop, and scum will be formed that can float or sink in the collection tank. Experiments have shown that bacterial population also increases with increased storage time (5).

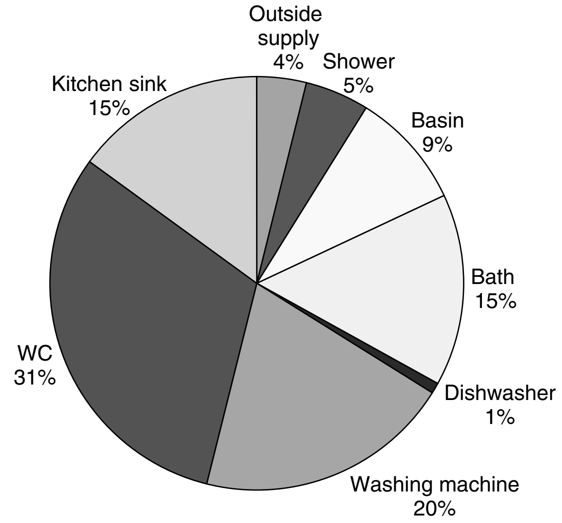

Figure 1. Components of domestic water use (2).

Table 1. Gray Water Quality from Various Sources[a]

	BOD (mg/l)	COD (mg/l)	Turbidity (NTU)	NH_3 (mg/l)	P (mg/l)	Total Coliforms
Single person	110	256	14	–	–	–
Single family	–	–	76.5	0.74	9.3	–
Block of flats	33	40	20	10	0.4	1×10^6
College	80	146	59	10	–	–
Large college	96	168	57	0.8	2.4	5.2×10^6

[a] Ref. 3.

Before gray water is reused, a certain level of treatment is required to minimize aesthetic concerns and the potential for health risk. Table 3 shows a summary of gray water quality criteria for toilet flushing followed in different countries. The level of treatment required depends on the scale and purpose of use. On a small scale (domestic level), a two-stage treatment consisting of filtration of coarse pollutants (hair and suspended impurities) followed by disinfection with chlorine, bromine, or UV is probably sufficient. On larger scales (hotels, commercial buildings), more complex and expensive methods of treatment could be employed.

Domestic gray water recycling systems, normally employed, produce water for toilet flushing. A recycling system (Fig. 2), typically, consists of an underground collection tank and an overhead distribution tank to supply toilet cisterns. The collection tank is designed to prevent groundwater contamination and ingress and is sized to accommodate water volumes intended for reuse. The optimal size of the collection tank has been modeled by Dixon (6), and systems storing 100–200 liters are considered sufficient for a family of five persons (7). Any excess gray water is diverted to the sanitary drain (i.e., the drain going out of the household). Devices are installed to prevent back-flow from the foul drain to the tank. Filtration is typically carried out at the tank inlet. The clogged filters are either replaced or cleaned using water jets. A submersible pump fitted with a float switch

Table 2. Average Pollutant Concentration in Gray Water Measured in a Residence Hall[a]

Parameter	Bath/ Shower	Washbasin	Washing Machine	Laundry and Dishwashing
BOD (mg/L)	216	252	472	110
COD (mg/L)	424	433	725	–
Ammonia as N (mg/L)	1.56	0.53	10.7	–
Phosphate as P (mg/L)	1.63	45.5	101	–

is normally used in the tank to transfer filtered water to the overhead tank. This then contains the disinfectant feeding arrangement and switches to control the water level. When the water volume in the overhead tank drops below a certain level, the pump turns on and stops when the water level in the tank reaches the design level. The overhead tank normally has an inlet to provide a top up supply of mains water when the treated gray water is not sufficient to meet the demand or the recycling system is inoperative. An air gap is typically provided between the inlet pipes of gray water and mains water. The pipework carrying gray water needs to be clearly marked or colored differently to avoid cross connections and contamination of potable water. The underground and overhead tanks will be designed to drain down fully to avoid problems of prolonged gray water storage. There are several packaged recycling systems available on the market. Each offers a different degree of treatment and safety controls. Experience has shown that they are not 'fit and forget' systems but require monitoring to ensure their smooth operation. Therefore, a clear warning mechanism that can show the failure of system components should be installed within the household, and clear maintenance instructions provided.

Gray water recycling is not a problem-free option, and particularly, issues related to health risk must

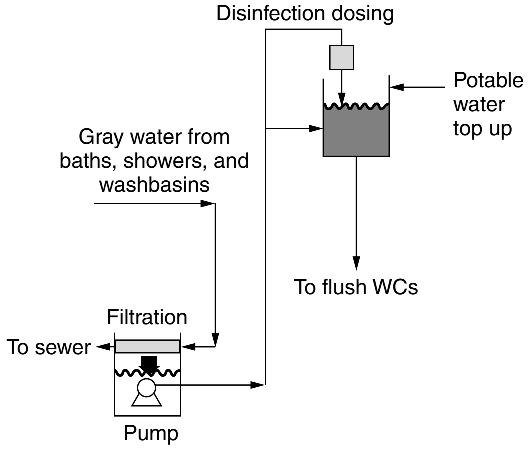

Figure 2. Water flows and components of a typical gray water recycling system.

be addressed. Although most waterborne pathogens are killed by conventional disinfectants, there are certain species (e.g., *Legionella* spp.) that are resistant to normal modes of treatment. *Legionella pneumophila*, a naturally occurring bacterium in domestic hot water supplies, showerheads, cooling waters, and other water services in buildings, has been linked to outbreaks of Legionnaires' disease. Surface fouling, biofilm formation, slow moving or stagnant waters, and increased temperatures are favorable conditions for *Legionella* growth. Therefore, recycling systems could provide an ideal environment for their growth. *Legionella* has an infection route through inhalation, and it is suspected that some bacteria may be inhaled through water vapors during toilet flushing (8). Fortunately, however, research shows that the *Legionella* count in gray water is typically low (3). To avoid in-pipe water stagnation for a prolonged period, the recycling system should be kept free from 'dead legs.' Past case studies on gray water recycling systems suggest that the relative health risk from gray water reuse is not high if it is properly treated and does not come in direct contact with users (8). For additional safety, the use of treated gray water should be discontinued when any of the users living in the household is ill. Spray irrigation with gray water is not advised because it will increase the bacterial exposure potential. There is also concern about the use of chlorine as a disinfectant. It has been found that chlorine can corrode metal switches and fittings in the overhead tank and toilet cistern. Excessive buildup of chlorine gas in the overhead tank (if located in a loft) may produce an unpleasant smell in the household and may be linked to asthma (9). Other disinfectants, such as ultraviolet radiation, are also available. UV lamps are expensive, and their germicidal efficiency reduces with time. They are most effective in waters of low turbidity. Therefore, fine filtration will be needed to achieve improved pathogen removal. The residual effect of UV as a disinfectant is not stable and microbial regrowth is possible, so UV treated waters should not be stored for long periods. Bromine is also used for pathogen removal from gray water. Some forms of bromine disinfectants such as hypobromous acid are considered harmful to plants, and the treated water would not be suitable for irrigation. The health risks from bromine use are yet to be quantified (7).

At present, gray water recycling systems on a single household scale are hardly financially viable. Although there are some savings from reduced consumption of mains water, the capital and operating expenditures incurred for these systems are relatively high, and the pay-back period is 20–25 years (10). The payback period reduces with increase in occupancy.

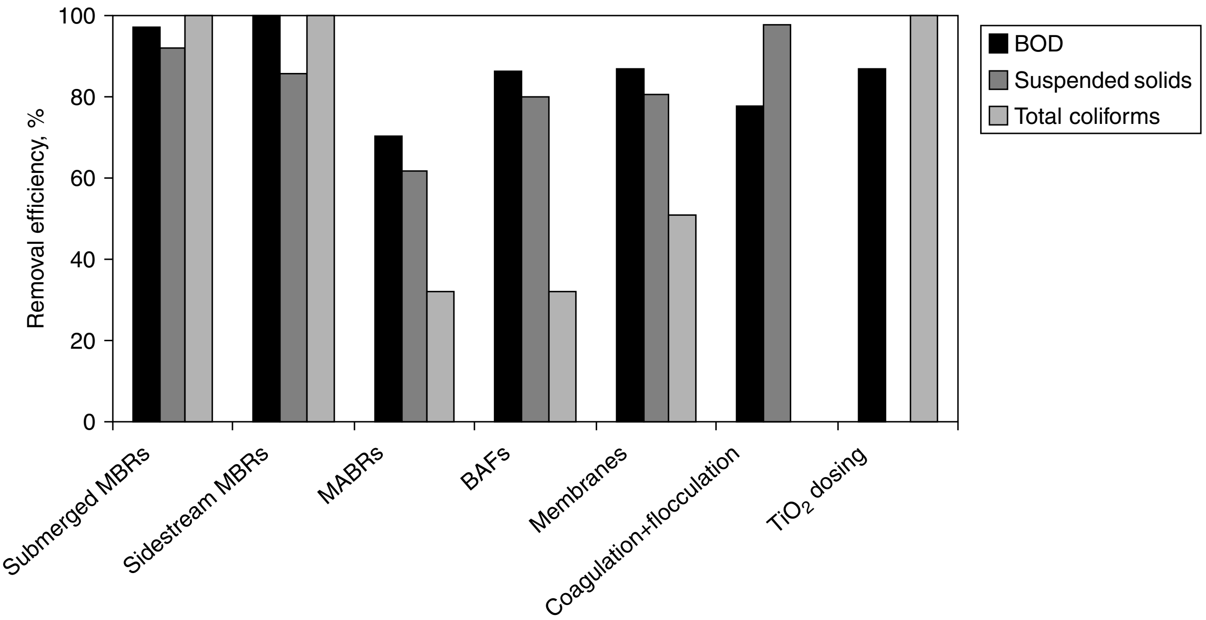

Figure 3. Technological performance in removing pollutants from gray water (3).

Gray water recycling on a medium to large scale (e.g., hotels, blocks of flats, commercial buildings,) may be more viable. A stepwise complex treatment sequence, instead of relying just on simple filtration and disinfection, produces water that has relatively low potential for health risk. A wide selection of gray water treatment technologies is currently available. These include biological aerated filters (BAFs), membranes, sidestream and submerged membrane bioreactors (MBRs), UV treatment, titanium dioxide (TiO_2) dosing, membrane aeration bioreactors (MABRs), and coagulation/flocculation with alum and ferric. Trials with these technologies have shown efficient and reliable removal of pollutants from gray water (3). The comparative efficiency of these technologies in removing BOD, suspended solids, and total coliforms is shown in Fig. 3. Large recycling units perform well, and their use in large buildings in the developed world and particularly in Japan is well established.

The main barrier to wider uptake of gray water recycling systems is lack of adequate consolidated legislation, high capital and maintenance costs, and potential health risks due to technology failure. Studies carried out to gauge public perception have shown that individuals have a positive attitude toward using treated gray water produced within their own households for toilet flushing, as long as safety is guaranteed and it is cost-effective (3).

WATER AND HUMAN HEALTH

S.M.A Adelana
University of Ilorin
Ilorin, Kwara State, Nigeria

INTRODUCTION

Water in the literal sense is the source of life on the earth. Research has shown that the human body is 70% water. Generally, human beings begin to feel thirst after a loss of only 1% of body fluids and risk death if fluid loss exceeds 10%. It has been proved that human beings can survive for only a few days without fresh water. Although it is true that life depends on water, society does not usually act as though water has value equal to life itself. The reason is that the supply of water in many parts of the world far exceeds what is required to sustain life. Estimates revealed that about 9000 cubic meters (9.0×10^6 liters) of water is available for use per person per year. Based on projected population growth, this amount will drop to 5100 cubic meters per person by the year 2025 because another 2 billion people are expected to join the world's population by the year 2025. Despite this sharp drop (by nearly 50% in 35 years), the amount of water available would be sufficient to meet human needs if it were distributed equally among the world's population and less polluted by human activities.

Present estimates give a false picture of freshwater available for human use because the distribution of the world's available freshwater is uneven throughout the seasons and from year to year. According to Falkenmark (1), water is not always where we want it. Sometimes, it is not available in sufficient quantities where we want it or at another time too much water is in the wrong place. Yet, in many parts of the world, people are withdrawing water from surface and ground sources at a rate faster than they can be recharged.

In the last century, world population has tripled, but water withdrawals have increased by more than six times (2,3). For example, since 1940, annual global water withdrawals have increased by an average of 2.5% to 3% a year compared with annual population growth of 1.5% to 2% (4,5). In the past decade, however, water withdrawal has increased from 4% to 8% a year, especially in developing countries (6). If the present consumption patterns continue, by year 2025, about two billion people will be living in areas where it will be difficult or impossible to meet all their needs for fresh water. Half of them will face severe shortages (3,7,8).

Apart from the pressure of population growth on water resources, the supply of freshwater available to humanity is shrinking, in effect, because of increasing pollution. Population growth, urbanization, and industrialization with little regard for the environment are polluting and decreasing the quantity of freshwater available for human consumption (or use). Farming is said to be responsible for a great deal of water pollution in the United States (9). Similarly, in India (where there is heavy dependence on irrigation farming for food supplies), more than 4 million hectares of high-quality land have been abandoned as a result of salinization and waterlogging caused by excessive irrigation (10,11). More than 90% of the rivers in Europe have high nitrate concentrations, mostly from agrochemicals, and 5% of these rivers have concentrations at least 200 times higher than nitrate levels naturally occurring in unpolluted rivers (12–14). Moreover, in the Czech Republic, 70% of all surface waters are heavily polluted mostly with municipal and industrial wastes (15). Havas-Szilagyl (16) reported that 600 out of the 1600 well fields tapping groundwater in Hungary are already contaminated, mostly by agrochemicals.

In developing countries, an average of 90% of all domestic sewage and 75% of industrial wastes are discharged into surface waters without any kind of treatment (17,18). Generally, oil and salts are washed off city streets, and heavy metals are leached from municipal and industrial dump sites. There is also the possibility that pollutants, such as sulfur dioxide and oxygen or nitrogen, combine in the atmosphere to form acid rain which has devastating effects on both surface water and land ecosystems (19) and accompanying health implications (3).

On the whole, both water scarcity and water pollution pose serious health problems. Unclean water is by far the largest environmental killer around the world; it claims millions of lives every year. According to the World Health Organization (WHO), a large percentage of urban population in developing countries do not have access to proper sanitation facilities, and about half lacks a regular supply of potable water (12). In the year 2000, an estimated 1.1 billion people remained without access to improved drinking water (7), and the number of persons drinking water contaminated by human sewage was much higher (21). Obviously, scarce and unclean water supplies are critical public health problems in many parts of the world and are likely to be one of the major factors that will limit economic development in the near future (10,11,13,14).

WATER SCARCITY AND STRESS: IMPLICATIONS FOR HUMAN HEALTH

The world's population of nearly 6 billion is growing by about 80 million people each year (3). This rapid population growth coupled with increasing demands for water for irrigation agriculture, domestic (municipal), and industrial uses puts tremendous pressure on the world's freshwater resources. As population grows, water use per person rises and freshwater withdrawal becomes faster than it can be recharged, resulting in water mining (7,22). If this continues and water needs consistently outpace available supplies, a level will be reached when depletion of surface and groundwater resources results in chronic water shortages (23), as illustrated in Fig. 1.

Investigations have revealed that up to 31 countries, which represent nearly 8% of the world population, face chronic water shortages (3). It has also been estimated that by the year 2025, the number of countries facing water shortages is expected to be near 48, affecting more than 2.8 billion people—35% of the world's projected population (24–27). Figure 2 shows the population in water-scarce and water-stressed countries. It is obvious from this figure that, as population grows, many more countries will face water shortages. Accordingly, a more optimistic outlook predicts that 2.8 billion people in 48 countries will be struggling with water scarcity by the year 2025, whereas worst case scenarios for water shortages

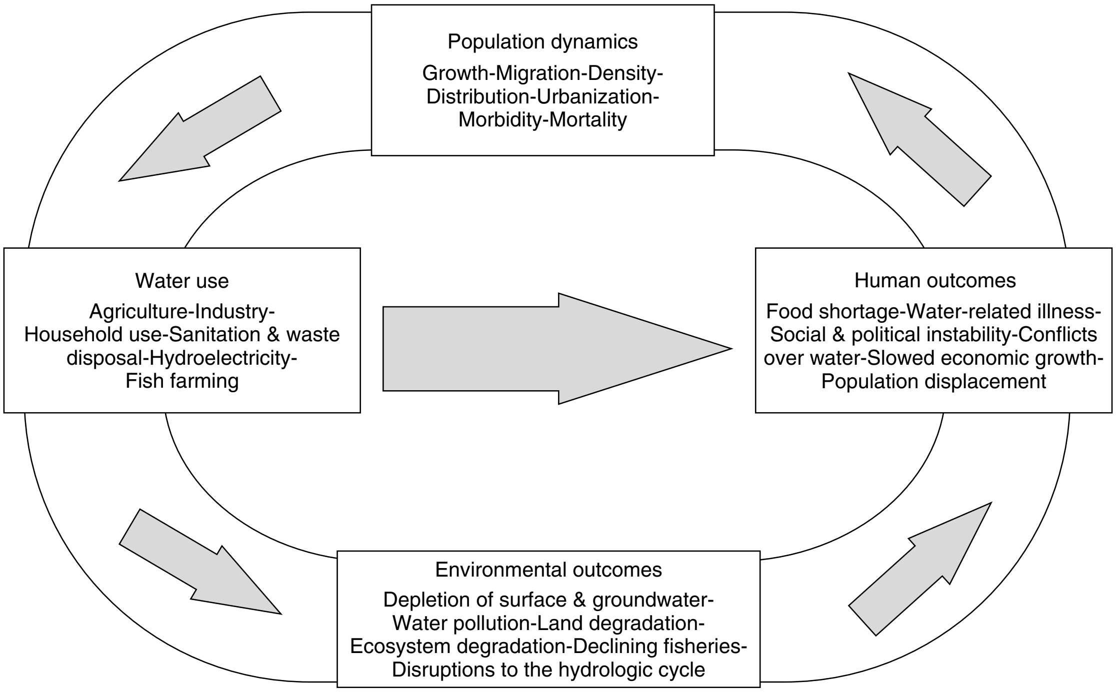

Figure 1. Links between world population and freshwater (3).

foresee 4 billion people in 54 countries facing water shortages in 2050. This critical trend is supported by the water scarcity and population projections of the United Nations (28–30).

From the growing consensus among hydrologists, a country is said to experience water stress when its annual water supply is between 1000 and 1700 cubic meters per person. Such a country can expect to experience temporary or limited water shortages. But when the annual supply of renewable freshwater drops below 1000 cubic meters per person, the country faces water scarcity (1,20,25).

In such cases, chronic and widespread shortages of water that hinder development result, and this could lead to severe health problems. Among countries likely to run short of water in the next 25 years are Ethiopia, Kenya, Nigeria, India, and Peru, whereas most parts of China and Pakistan are already approaching water stress. The list of water-stressed countries and those already suffering from water scarcity has been tabulated in Gardner-Outlaw and Engleman (25) and PR (3) based on the 1995 world population and water per capita and a projection for the year 2025. Gardner-Outlaw and Engelman (25) based their calculations on United Nations Population Division population estimates and growth rate and total fertility rate (TFR) data from the Population Reference Bureau (24), World Population Data Sheet. According to the estimates, it is obvious that in this century, water crises in more and more countries will present obstacles to better living standards and better health and may even bring risks of outright conflict over access to scarce freshwater supplies.

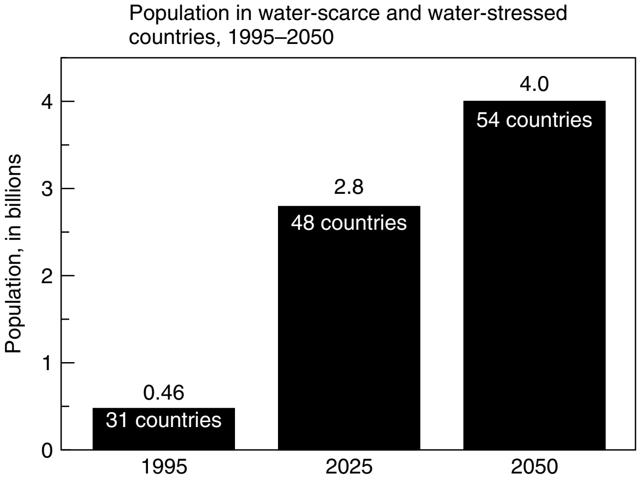

Figure 2. The rising trend in water scarcity and stress, 1995—2025 (3).

Available statistics show that more than half of the world's population suffers from water services that are inferior to those of the ancient Greeks and Romans (8). According to Gleick, this has long been recognized as a serious global water problem that even generated attention at the World Water Conference organized by the United Nations at Mar del Plata in 1977, where strong commitments and resolution were made to finding lasting solutions. Since this initial attempt, considerable efforts have been geared toward providing access to safe drinking water and adequate sanitation services. The United Nations in its Millennium Developmental Goal (during the World Summit on Sustainable Development held in Johannesburg in September 2002) planned to reduce by half, by the year 2015, the proportion of people without sustainable access to safe drinking water and basic sanitation services. Yet, a high percentage of the world's population is still without access to adequate water supply and sanitation (see Fig. 3a, b).

The 1990 world population without access to clean drinking water was estimated at 1300 million, and close to 2600 million people have no access to basic sanitation

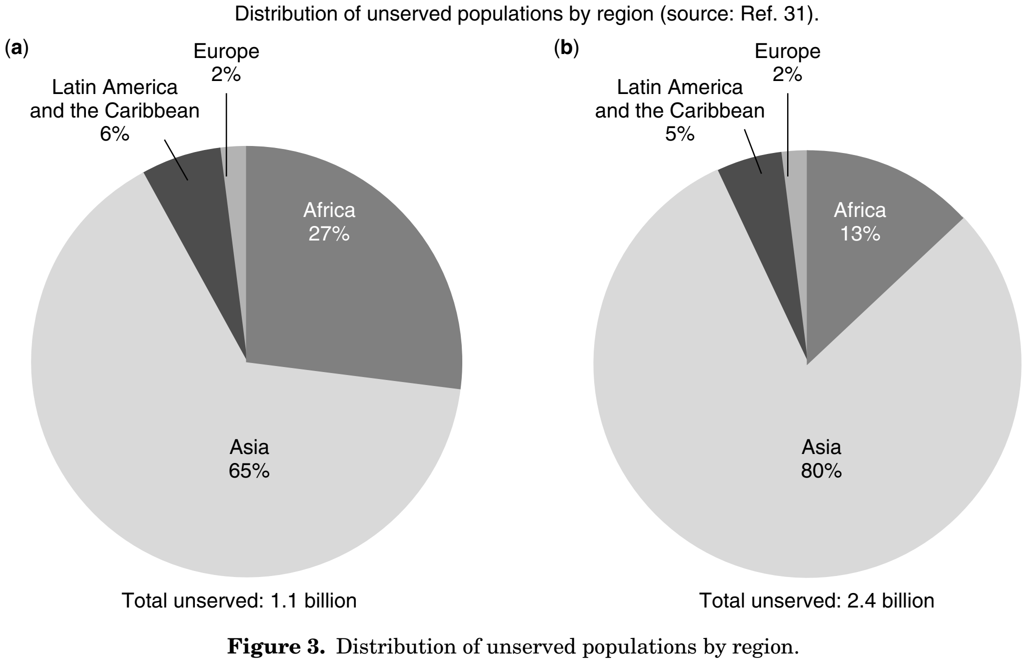

Figure 3. Distribution of unserved populations by region.

services (32). In Africa alone, 54% of the 1994 total estimated population of 707 million have no access to clean drinking water (33). Table 1 shows access to safe drinking water in developing countries by region; the percentage of population that has access to sanitation services is tabulated in Table 2. Illustrative world maps showing estimates of population without access to clean drinking water and adequate sanitation services are included in Gleick (8).

It is important to point out that the failure to provide basic clean water and sanitation services takes a serious toll on human health and results in economic loss in many countries of the world. Reports have shown that water, shortages, polluted water, and unsanitary living conditions claim millions of lives annually (7,20,34). The World Health Organisation reports that 80% of diseases are overtly or covertly waterborne (35) and/or consequent to freshwater shortages. Moreover, in much of the world, polluted water, improper waste disposal, and poor water management cause serious public health problems. For example, diarrheal diseases leave millions of children underweight, mentally as well as physically handicapped, and vulnerable to other diseases.

BASIC WATER, REQUIREMENTS FOR HUMAN HEALTH

Generally, in developing and using water resources, priority has to be given to the satisfaction of basic human needs (35). Therefore, providing water sufficient to meet basic human needs should be an obligation of governments and nongovernmental organizations. The postconference reports on the *International Symposium and Technology Expo* on small drinking water and wastewater systems held at the Hyatt Regency in Phoenix, Arizona (from January 12–15, 2000), demonstrated that the provision of safe drinking water and effective wastewater system managements are key elements that ensure safe and healthful living linked to social and economic development.

The basic water requirements for humans depend on the purpose for which water is used in the different sectors of our society. Among these are drinking (and other domestic use), removing and diluting waste (including disposing of human waste), growing food, producing manufactured goods, producing and using energy, and so on. The water requirement for each of these activities varies with domestic conditions, lifestyle, culture, tradition, diet, technology, and wealth (36).

It has been argued that water requirements for humans should also include any water necessary for disposing of human wastes (33). For example, in regions where absolute water quantity is a major problem, waste disposal options that require no water are available, in most developing nations, preference is given to alternatives that use at least some water (8). However, there are societies that use enormous amounts of fresh water to dispose of wastes. Based on the research carried out so far, a recommendation for a basic water requirement has been made. In 1996, Gleick proposed the overall minimum water required per person per day as 50 liters. This covers

[a] Reference 8.

the minimum standards for drinking, sanitation, domestic (bathing and washing), and cooking. Out of this overall water requirement, 25 liters/person/day is required for basic hygiene (washing, showering, and bathing) and for cooking (33). A minimum of 20 liters/person/day offers the maximum benefits of combining waste disposal and related hygiene, thereby meeting cultural and societal preferences for water-based disposal (8). In other words, the minimum amount of water needed for drinking, cooking, bathing, and sanitation is 50 liters. The average person needs a minimum of 5 liters of water per day to survive in a moderate climate at an average activity level. However, average people in the United States uses between 250 to 300 liters of water per day for drinking, cooking, bathing, and watering their yards, whereas the average person in the Netherlands uses only 104 liters per day for the same tasks (33,37). This amount is slightly above the minimum target of 20–40 liters/person/day set by the United States Agency for International Development, the World Bank, and the World Health Organisation. Many people in the poorest nations survive on far less than the recommended amount. For example, the average person in Somalia uses only 8.9 liters of water per person per day (7,37).

Although different sources use different figures for total water consumption and for water use by sector of the economy (1,25,33,34,37–39), yet from drinking water and sanitation needs, it became obvious that a basic requirement of 25 liters/person/day of clean water must be provided for drinking and sanitation by water agencies, governments, or community organisations. An estimate made in 1990 revealed that about 55 countries whose population was nearly 1 billion people did not meet this standard (33). Yet, it is a desirable goal from a health perspective and from a broader objective of meeting a minimum quality of life. Further information on basic water requirements can be obtained in *The World's Water 1998–1999, The World's Water 2000–2001*, and The World's Water 2002–2003, which are available from Island Press, Washington (http://www.islandpress.com/).

WATER-RELATED, DISEASES

Water-related diseases that affect human health are relatively widespread and abundant, especially in rural communities of developing nations, although there is evidence that they have been reduced to a greater extent as a serious health problem in industrialized countries. The incidence of these diseases depends on local climate, geography, culture, sanitary habits and facilities, and on the quantity and quality of the local water supply as well as the methods of waste disposal (3). Changes in water supply do affect different groups of diseases in different ways. Some may depend on changes in water quality, others on water availability, and yet others on the indirect effects of standing water.

A World Health Organisation (40) estimate of the number of people suffering from water-related diseases is staggering (see Table 3). Generally, in many developing countries, waterborne diseases such as cholera, dysentery,

Table 3. Estimates of Global Morbidity and Mortality from Water-Related Diseases (Early 1990s) Culled from Reference 8[a]

Disease	Morbidity, Episodes/Year or People Infected	Mortality, Deaths/Year
Diarrheal diseases	1,000,000,000	3,300,000

Bancroftian filariasis	72,800,000 (people infected)	—
Onchocerciasis	17,700,000 (people infected; 270,000 blind)	40,000 (mortality caused by blindness)

[a] Original *Source*: Reference 33.

typhoid, malaria, and schistosomiasis are increasing and harm or kill millions of people every year. The Pacific Institute's recent research indicates that lack of clean drinking water leads to nearly 250 million cases of water-related disease each year and roughly five to ten million result in deaths (7). Earlier estimates have shown much higher numbers of people in the world suffering from diseases that are linked with water (5,41) and resultant death (8,15). The true extent of these water-related diseases is unknown, and even the WHO data (40) suggest there may be many more cases of the diseases and resultant death.

However, about 60% of all infant mortality is linked to infectious and parasitic diseases; most are water-related (42), and a large percentage of these diseases is attributable to inadequate water supply and sanitation.

Research has shown that, at any one time, there are probably millions of people who have trachoma, elephantiasis, bilharzias (snail fever), malaria, diarrhea, dracunculiasis (guinea worm disease), and onchocerciasis (river blindness). For example, according to Edungbola (43), at least 15 million Africans suffered from guinea-worm infection; of these, nearly 75,000 people are permanently disabled every year, and about 3 million individuals were irreversibly crippled in Africa. His estimates have further shown that subsistence farmers in Africa lost at least 80 million man-days each year to guinea worm disease.

Water-related diseases are generally classed into four categories: waterborne, water-washed, water-based and water-related insect vectors (8,44,45). Waterborne diseases include those caused by both fecal—oral organisms and those caused by toxic substances; water-washed (also referred to as water-scarce) consists of diseases that develop where clean fresh water is scarce (44). Aquatic organisms that spend part of their life cycles in water and other part as parasites of animals cause water-based diseases. Insects that transmit infections, such as mosquitoes and tsetse flies, cause water-related vector diseases. A full description of each class of water-related disease together with their causative agents and routes of transmission as well as the geographical extent and number of reported cases has been compiled in Population Reports (3).

According to Population Reports, diarrheal disease (which belongs to the class of waterborne disease) is prevalent in many countries where sewage treatment is inadequate or where human wastes are disposed of in open latrines, ditches, canals, and watercourses or are spread indiscriminately on farmland. In the mid-1990s, a large number of people drank water contaminated with human sewage (28), and the World Health Organisation reported that drinking contaminated water contributes directly to diarrhea-related deaths (46). An estimated 4 billion cases of diarrheal diseases are reported annually that cause 3–4 million deaths, mainly among children (34,47–49). In Nigeria alone, more than 300,000 children less than 5 years of age die annually from diarrheal diseases (50). For example, in 1996, a large outbreak of severe diarrhea (which was later confirmed as cholera from tests conducted at the Institut Pasteur, Paris, France) struck the commercial city of Kano in northern Nigeria. According to Hutin et al. (51), a total of 5600 cases and 340 deaths (attack rate = 86.3 per 100, 000 inhabitants) were reported to the Kano State Ministry of Health within 5 months of the incident. This incidence was highest among children less than 5-years-old and was linked to drinking street-vended water and failure to wash hands with soap before meals (51).

Earlier, the consumption of street-vended water was reportedly associated with a cholera outbreak in Latin America (52–54). A similar cause of a cholera outbreak was also reported in India (55,56) and in Peru (57). Recent research has also shown that childhood mortality from diarrhea in Latin America remains high (58).

Gleick (8), using available data on the prevalence of different water-related diseases, presented and discussed two of these diseases extensively—dracunculiasis (guinea worm) and cholera—as case studies. He traced the history and reported the total global cases of these diseases by region and the recurrent deaths as a result of the epidemic from 1990 to 1997 with an update on the complete eradication programs. Reported guinea worm cases, globally, have fallen from an estimated 3.5 million in 1986 to 150, 000 in 1996 (59,60). This is approximately a 97% reduction, and there are hopes that it may have been completely eradicated in accordance with the “New Millennium Plan.”

On the other hand, little has been achieved in the effort to control the transmission of other parasitic infections such as schistosomiasis, intestinal helminthiasis, and malaria which are related to water supply and sanitation, especially in the developing world and particularly in Africa. For further information and statistics on other water-related diseases, readers are referred to (5,12,14,24,34,47–49,59–68).

The issue of water quality or maximum permissible limits of certain elements that can constitute health risks in drinking water should be included here as another source of waterborne disease. For example, increased nitrate concentrations in drinking water add to the variety of water-related health risks. Health problems from nitrate in water sources are generating serious concern in almost all countries of the world, particularly in urban and rural communities where agricultural practises are intensive (69–73). There is increasing evidence that nitrate levels in many aquifers are rising and that the problem of increased exposure of the world population to high nitrate inputs will become more pressing, as speculated earlier by the WHO (74).

Agricultural activities such as fertilizer and pesticides applications are frequent sources of contamination in surface and groundwaters. An estimate from Population Reports has shown that in more than 150 countries, nitrate from the application of fertilizers has seeped into water wells and polluted drinking water (75). Increased concentrations of nitrate often cause blood disorders (76). High levels of nitrate and phosphates in drinking water also encourage the growth of blue-green algae, resulting in deoxygenation (eutrophication) and subsequent reduction in metabolic activities of the organisms that purify fecal-polluted water in the human system. Details of nitrate health hazards are discussed in Adelna (in this volume).

Other sources of water pollution include animal wastes, excess nutrients, salinity, pathogens, and sediments that often render water unusable for drinking, unless it is purified (77–81). Even when any of these substances or chemicals occurs in low concentrations, they can accumulate in humans over time to cause serious health problems such as cancer if the water is used for drinking. For maximum permissible and acceptable levels of ions/elements in water, refer to the standards of the World Health Organisation (62) and of most national authorities, which are consistent with standards for the composition of drinking water (82).

The average contribution of drinking water to the daily intake of mineral nutrients is important in health considerations. Of note here are those for fluoride (F^-) and arsenic (As). Generally, excessive concentrations of these elements often limit the use of groundwater for drinking. Too high an intake of fluoride is often the general cause of painful skeleton deformations called fluorosis, which is a common disease in East Africa, especially in Kenya and Ethiopia. The occurrence of fluoride in groundwater for human consumption has also been reported in Argentina (83). High concentrations of arsenic in groundwater used for drinking are reported in many countries such as India, Bangladesh, China, Thailand, Vietnam, Taiwan, Hungary, Mexico, and Finland (84–88). Nearly 50 million people are at risk of cancer and other arsenic-related diseases due to consumption of high arsenic groundwater in India and Bangladesh (64,89). About 44% of the population of West Bengal (India) is suffering from arsenic-related diseases such as conjunctivitis, melanosis, hyperkeratosis, and hyperpigmentation (90). In certain areas, gangrene in the limb, malignant neoplasm, and even skin cancer have also been observed. High arsenic concentrations lead to black-foot disease. This is sometimes visible in a blackening of the fingers and toe tops and induces general lethargy in the patient. Arsenic toxicity affects almost all organs of the human body. Ingestion of large doses of arsenic usually results in symptoms within 30 to 60 minutes but may be delayed when taken with food (90). High arsenic concentrations have also been reported in Southeast Asia (91), the United States (92), Argentina, and Chile (93–97); all have consequent health implications.

THE IMPACT OF IMPROVED WATER SUPPLY AND SANITATION

The direct consequence of water scarcity and failure to meet basic water requirements is the prevalence of most water-related diseases. In the past, this has caused serious economic and social loss to both governments and communities. Estimates in the late 1970s have shown that water-related diseases cost more than $125 billion per year, excluding social costs, the loss of education and other opportunities, lost economic productivity of sick workers, and other hidden costs (8,98). For example, in sub-Saharan Africa, malaria costs an estimated $1.7 billion US annually in treatment and lost productivity (48). A study in Pakistan (within its capital city, Karachi) has shown that people living in areas without proper sanitation or hygiene education spent six times more on medical care than residents in areas with access to sanitation and basic hygiene (63). In Peru, an economic loss of more than $1 billion dollars in seafood exports and tourist revenues has been reported due to a cholera epidemic (99).

However, the huge investments by governments in Asia, Africa, and Latin America in basic water and sanitation services (5,100) have reduced the prevalence of these diseases in the last decade. The World Bank estimates spending for water and sanitation in developing countries at nearly $26 billion per year (101). Not until clean drinking water and improved sanitation services are universally available will millions of people stop dying from preventable water-related illnesses (8). Rogers (101) estimated that completely meeting basic water supply needs up to the year 2020 would require total capital costs of about $24 billion per year. If the additional costs of meeting a higher level of services, such as advanced wastewater treatments, were included, the cost would be up to $50 billion a year.

Several studies have reported the high reduction in water-related morbidity and mortality as a result of improvements in water services and sanitation consequent to these huge financial investments. According to Population Reports, a review in 1991 of more than 100 studies of the effects of clean water and sanitation on human health revealed a medium reduction in deaths from water-related diseases (up to 69%) among residents, who have access to clean drinking water and improved sanitation services, because effective disposal of human wastes controls the spread of infectious agents and interrupts the transmission of water-related diseases. Table 4 shows the impact of improved water infrastructure on reducing water-related diseases.

Another approach that has shown improved water quality and reduced the incidence of waterborne disease (for example, diarrhea) is the Center for Disease Control (CDC) safe water system. This system combines locally produced sodium hypochlorite solution (chlorine bleach), a CDC water storage vessel, and a public health campaign to change the behavior of rural dwellers to basic hygiene (102,103). This system has improved water quality and reduced the incidence of diarrhea by 68% in Uzbekistan (104), by 44% in Bolivia (105), and by 48% in Zambia (106). It further serves as an alternative method of disinfecting drinking water in rural Guatemala and prevents excessive morbidity and mortality from waterborne diseases (103).

Moreover, according to Population Reports (3), some water development schemes have started disease control programs along with construction of water and sanitation facilities. As a result of such a program in the Philippines, for example, the prevalence of water-related diseases fell from 24% in 1979 to 9% in 1985 (67). There are indications of good progress made so far, and, at this point, some water-related diseases are on the verge of complete eradication. A good example is guinea worm (dracunculiasis) eradication. Pakistan, reportedly the first country to have completely eradicated guinea worm during the new global eradication program, recorded zero cases every month since October 1993 (8). In India, guinea worm was completely eliminated from the Tamil Nadu area in 1984, the Gujarat area in 1989, and Maharashtra in 1991; only nine cases were reported for the entire country in 1996 (60). In the Kwara State of Nigeria (where guinea worm once had devastating effects on the rural populace), any reported case of guinea worm now attracts a monetary prize (107).

Globally, only five of the countries that had guinea worm recorded slightly above 100 cases in 1996. The number of cases has generally dropped by nearly 97% during the past decade (8). Although the eradication program has shown impressive progress, guinea worm is still prevalent in nearly 17 developing nations, mostly in Africa as of the end of 1996 (8). In the final analysis, guinea worm has been eradicated most effectively by providing protected clean drinking water in all countries where the disease was prevalent. Successful eradication programs for guinea worm and other water-related diseases are documented in the series of articles in Population Reports, Series M (3), as well as in (5,59,60,100,108–110). Therefore, an improved water supply and sanitation system will consequently generate tremendous improvements in the health, social welfare, and economic development of any nation, especially a developing one. For details of this and several other studies related to reduction in waterborne morbidity and mortality as a result of improvements in sanitation and water supplies, refer to Esrey et al. (111), Alam (112), Aung and Thein (113), Baltazar (114), Cairncross and Cliff (115), Young and Briscoe (110), Esrey and Habicht (116), Henry (117), Rahman (118), Haines and Avery (119), Khan (120), Torun (121), Ankar and Knowles (122), Koopman (123), Misra (124), and White et al. (36).

SUMMARY

Water is essential for life and health and has cultural and religious significance. Water plays a vital role in transmitting infectious diseases, and 80% of diseases reported are directly or indirectly water-related. Scarce and unclean water supplies are critical public health problems in many parts of the world and are likely to be one of the major factors that will limit economic development in the near future. It has been reported that

Table 4. Impact of Improved Water Infrastructure on Reducing Water-Related Diseases[a]

Place	Type of Facilities or Improvement	Type of Study	Diseases	Difference in Incidence After Improvement
Teknaf, Bangladesh	Hand pumps and health education	Case-control	Diarrheal diseases	17% difference between groups
Northeast Brazil	Latrines, communal taps, laundry facilities, showers, and hand pumps	Case-control	Schistosomiasis	77% difference between groups
Khuzestan, Iran	Courtyard latrine and public standpipes	Case-control	Ascariasis	16% difference between groups
Uttar Pradesh, India	Piped water	Before and after	Dysentery	76% reduction
Peninsular Malaysia	Toilets and running water	Case-control	Diarrheal diseases	82% difference in infant mortality between groups
Kwara State, Nigeria	Boreholes, hand pumps, and health education	Before and after	Dracunculosis	81% reduction
Cebu, Philippines	Private, sanitary latrines	Before and after	Diarrheal diseases	42% reduction
St. Lucia	Household water and latrines	Case-control	Ascariasis	31% difference between groups
Lusaka, Zambia	Extension of piped water supply	Before and after	Typhoid	37% reduction

[a] *Source*: Selected studies compiled in Reference 3.

water shortages, polluted water, and unsanitary living conditions claim millions of lives annually via various water-related diseases.

Research has shown that, at any one time, there are probably millions of people who have trachoma, elephantiasis, bilharzias (snail fever), malaria, diarrhea, dracunculiasis (guinea worm disease), and onchocerciasis (river blindness). The incidence of these diseases, it has been shown, depends on local climate, geography, culture, sanitary habits and facilities, and on the quantity and quality of the local water supply as well as methods of waste disposal. Effective disposal of human wastes controls the spread of infectious agents and interrupts the transmission of water-related diseases. The role of good quality drinking water and access to adequate sanitation facilities in reducing water-related diseases has been reviewed in this article. The universal provision of treated pipe-borne water is not currently feasible due to economic and political constraints, and this consequently leaves millions of people without access to safe drinking water. Generally, the failure to provide clean drinking water and adequate sanitation services has serious implications for human health and is consequent to severe economic loss in many countries.

Furthermore, the water requirements for each of the basic human activities vary with domestic conditions, lifestyle, culture, tradition, diet, technology, and wealth. In any case, the minimum amount of water needed for drinking, cooking, bathing, and sanitation is set at 50 liters. The average person needs a basic minimum of 5 liters of water per day to survive in a moderate climate at an average activity level. This is the absolute minimum amount of water required to maintain adequate human health, independent of lifestyle and culture.

About 60% of all infant mortality is linked to infectious and parasitic diseases; most are water-related, and a large percentage of these diseases is attributable to inadequate water supply and sanitation. Diarrheal diseases, for example, leave millions of children underweight, mentally as well as physically handicapped, and vulnerable to other diseases. However, the huge financial investments by governments in Asia, Africa, and Latin America (as well as by nongovernmental organizations) in basic water and sanitation services have reduced the prevalence of these diseases in the last decade.

NITRATE HEALTH EFFECTS

SEGUN MICHAEL ADE ADELANA
University of Ilorin
Ilorin, Kwara State, Nigeria

INTRODUCTION

Nitrate is a stable nitrogen (N) species under certain natural conditions and forms highly soluble compounds. These are peculiar features that allow nitrate ion to be transported in some groundwater systems to environments where it can be converted into other nitrogen species that either promote surface water eutrophication or are hazardous to humans, livestock, and the environment. Nitrate test results are usually expressed in milligrams per liter as either nitrogen (NO_3-N, sometimes written as plain N) or as nitrate (NO_3).

The following conversion factors can be useful for nitrate reporting:

1 milligram (mg) of compound expressed as nitrogen (N) is equivalent to 4.43 mg when expressed as nitrate (NO_3^-).

1 milliequivalent (meq) of compound expressed as N is equivalent to 62 mg when expressed as NO_3^-.

Therefore the nitrate reporting expressions (mg NO_3-N/L, mg NO_3/L) are used interchangeably throughout this article without any special preference for one or the other.

Problems of nitrate pollution, particularly in groundwater, are widespread in many countries of the world. In the United States, several illustrations of nitrate pollution in groundwater are available in the literature. For example, more than 30 references dealing with nitrate groundwater pollution studies in 15 of the 50 states in America have been reviewed. Information from all these references have been tabulated and presented in detail in Canter (1). Survey results from a study of 25 pesticides and nitrate in 201 rural wells in eight agricultural areas in Missouri revealed that 22% of the wells exceeded the drinking water standard for nitrate (2). A summary of the nature and geographical extent of nitrate pollution of groundwater in Nebraska is given in Exner and Spalding (3).

A total of 27 references dealing with case studies of nitrate groundwater pollution (outside the United States) have been reviewed. Of these references, 22 addressed groundwater nitrate pollution studies in Europe. One of these references (4) is a conference proceeding with 52 papers addressing nitrogen as a surface and groundwater pollutant; Tessendorff (5) and Kraus (6) provided a general discussion of groundwater nitrate problems in the European community countries (EEC). The countries noted with adequate references on groundwater nitrate problems include Czechoslovakia, Germany, The Netherlands, United Kingdom, Denmark, Israel, and Chile.

Overgaard (7), in a nationwide investigation of nitrate concentrations in groundwater in Denmark, based on analyses of samples from about 11,000 wells and drinking water from 2800 groundwater works, revealed that the overall mean level of nitrate in groundwater had trebled within the last 20–30 years and is increasing at a rate of about 3.3 mg NO_3/L per year. Consequently, the result showed that 8% of the water produced in Danish Waterworks now has a nitrate concentration above the EEC guide limit of 50 mg NO_3/L (6). It has been estimated that 800,000 people in France, 850,000 in the United Kingdom, and 2.5 million in Germany are drinking water whose nitrate concentrations are above the permissible limit of the European Community (1).

A survey conducted in France revealed that 81% of the population had nitrate levels less than 25 mg NO_3/L and 96 to 98% had levels less than 50 mg NO_3/L in their drinking water supplies (8). Out of the 53 million people accounted for in the survey, 280,000 at most had a water supply exceeding 100 mg NO_3/L at least once during a 3-year period. Of 20,000 distribution units surveyed, nearly 1000 had nitrate above 50 mg NO_3/L; however, only 61 units were above 100 mg NO_3/L. Most of the high nitrate levels were found in groundwater supplies.

Custodio (9) reported that agricultural nitrate pollution is a widespread problem in irrigated areas in Spain, where nitrate in groundwater often exceeds 50 mg NO_3/L and sometimes reaches 500 mg NO_3/L. A regional survey of nitrate in the Anglian area of the United Kingdom in 1975 indicated that 50 public supply boreholes, wells, and springs had recorded nitrate levels in excess of 11.3 mg/L (as nitrogen), 50 mg NO_3/L (10). Due to increasing agricultural activity after the 1960s, both shallow and deep-water resources in the Czech Republic, including karstic systems, have been contaminated by infiltrating nitrate. The nitrate content of one of the largest springs (yielding up to 19 L/s during minimum discharge) in the Republic now varies from 50 to 60 mg NO_3/L (11). Others reported nitrate pollution studies in Canada (12,13), India (14,15), Israel (16), Chile (17), Portugal (18), Southern Africa (19,20), Nigeria (21–25), Ghana (26), Burkina Faso (27), and Senegal (28).

Note the pollution of groundwater from industry and waste dumps is a serious problem, particularly in the more developed countries in the European community. This is also the case in the United States, Canada, and Australia. High concentrations of nitrates are the other main cause of groundwater pollution. Concentrations of nitrate that approach or exceed 10 mg/L as N, equivalent to 44.3 mg/L as NO_3, present health hazards. Thus, the international drinking water quality standard is set at 10 mg/L for NO_3-N (or plain nitrogen), and it is approximately 45 mg/L as NO_3 (29). Therefore, it is important to consider the health implications of this common pollutant of groundwater with respect to humans, livestock, and the environment, which is the main focus of this paper.

OCCURRENCE AND EXTENT OF NITRATE IN WATER AND FOODS

The occurrence of nitrate concentrations has been reported in many parts of the world such as Europe, the United States, Australia, Chile, Ghana, South Africa, Nigeria, and Cote d'Ivoire. The World Health Organization (WHO) studied the occurrence of nitrate in water and came to the conclusion that nitrate concentrations in surface waters have increased substantially over the last 30–40 years (29). Many countries, mostly in Western Europe and the United Kingdom, showed a more marked increase in the levels of nitrates in groundwater, especially between 1970 and 1980 (30). The reason for these increases in groundwater nitrate is not unconnected with the vast increase in fertilizer application and other forms of animal manure.

In the United States, the occurrence of high nitrate concentrations in groundwater is widespread, particularly as a result of agricultural usage of fertilizers or land disposal of domestic wastewaters. Much research has been conducted to determine the amounts of nitrates in drinking water wells. "USGS data show that the 20 states with the largest agricultural marketing in 1989 had a notably higher percentage of wells with nitrate concentrations above 10 mg NO_3-N/L than the remaining 30 states, 7.1% compared to 3.0%, respectively" (31). Research conducted by private firms also links high nitrogen content in wells with agricultural activity. A survey of 1430 randomly selected and sampled drinking water wells in agricultural areas of 26 states, conducted in 1988 and 1989 by the Monsanto Agricultural Products Company, found nitrate above 10 mg NO_3-N/L in 4.9% of the wells. For wells on farmsteads only, however, the proportion was 10% (31). Monsanto, however, concluded that the frequency of wells with nitrate exceeding 10 mg NO_3-N/L doubled for wells located on farm property.

Several case histories have indicated the geographical extent and seriousness of high nitrate in groundwater in the United States. For example, the Metropolitan Water District of Southern California has indicated that annually it loses 4% of its drinking water supply primarily to nitrate pollution, compared to less than 1/2% from toxic organic chemicals (1). About 12% of the wells sampled in the service area exceeded the state maximum contaminant level for nitrate.

It was estimated that by the year 2000, the groundwater in most of the water table aquifers in Salinas Valley

Table 1. Summary of Nitrate Data in the United States[a]

State	Counties Tested	Number of Samples	Average Nitrate Concentration, mg/L	Percent Over 10 mg/L
Illinois	8	286	5.76	19.9
Indiana	33	5,685	0.92	3.5
Kentucky	90	4,559	2.50	4.6
Louisiana	23	997	1.19	0.8
New Jersey	5	1,108	2.60	6.8
Ohio	80	18,202	1.32	3.0
Virginia	24	1,054	2.92	7.1
West Virginia	13	1,288	0.83	0.8

[a] Reference 33.

would have exceeded the state's drinking water standard of 45 mg/L for nitrate (32). It is expected that the rising trend in groundwater nitrate will continue for many more years, even if nitrate leaching from soils is reduced by changes in agricultural practices. A summary of nitrate data by state is presented in Table 1. This was the result of the multistate groundwater quality testing undertaken for several years at Heidelberg College in Tiffin, Ohio and reported by Swanson (33). The data indicate higher nitrate occurrence in the sampled groundwater from Illinois, Virginia, New Jersey, and Kentucky.

The extent of nitrate and nitrite as (both anthropogenic and natural) water pollutants has been widely reported and published in the hydrogeologic and biochemical/pharmacological literature, especially, in developed nations (1,13,34–43). Such information is scanty in developing countries until recently (19–27,39,44–48). It has been reported that nitrate health hazards are also posed greatly by solid foods from agricultural and diary products and preservatives (24,44,49), yet the greatest threats come from polluted water; fluids and foods cooked and washed are contaminated directly or indirectly with such waters. The occurrence of nitrate is known in foods, especially in African foods. Okonkwo et al. (49) researched and reported high concentrations (in parts per million) for various African foods (Table 2).

Most of these foods are heavily consumed in West Africa and are now largely exported to Europe, America, Canada, and Australia. If the rate and volume at which these foods are consumed continues, nitrate could become potentially hazardous. A high percentage of the world population, as projected by the WHO (29), would ingest increased nitrates in the near future. Nitrates are easily converted to nitrite (the more poisonous form of nitrogen) by various mechanisms. It has been observed that drying tends to change the nitrite content of food items (Table 3). Drying is a common method of food preservation in the tropics, particularly in developing countries. Drying reduces the ascorbate level in food thereby inhibiting its antagonism to the carcinogenic action of nitrites (50). Thus, dried foods especially vegetables, have high nitrite concentrations and consequently increase the hazard. Ezeonu (51) reported high nitrate concentration in some Nigerian beers with frightening statistics. All ten brands of beer selected for study whose production locations are in different parts of the country showed high nitrate content. Yet large volumes of beer are consumed daily in Nigeria. Most breweries in Nigeria do not treat their water sources (i.e., boreholes) for nitrate, yet anthropogenic nitrate is widespread in the country (21).

Table 2. Nitrate Levels in Typical African Foods[a]

Beverages	Range, ppm	Mean, ppm
Palm Wine	0.1–1.4	1.2
Tap water (pooled urban supply)	0.1–0.3	0.2
Cereals		
Guinea Corn & Rice	2.0–4.9	3.0
Proteins (Animal Source)		
Crayfish	18.2–30.8	28.7
Fish	7.9–10.4	8.6
Meat	0.4–1.7	0.7
Proteins (Plant Source)		
Beans (black)	3.2–6.6	4.9
Bean (white)	3.1–6.5	4.9
Ground nuts	4.4–9.7	6.1
Melon	9.0–11.6	10.3
Pigeon pea	1.9–2.7	2.4
Vegetables and Fruits		
Bitter leaf	8.0–9.8	8.9
Flutted pumpkin leaf	0.8–1.2	1.1
Garden egg leaf	0.7–1.2	1.0
Green amaranth leaf	0.5–0.8	0.7
Okra	2.0–2.2	2.1
Pumpkin lead	5.6–15.0	11.3
Nitrate Not Detected in these Foods		
Beer (premier brand)	Corn	Sida
Native Gin	Cassava (Gari)	Yams

WATER QUALITY CONCERNS RELATED TO NITRATE LEVELS

The issue of water quality related to nitrate concentrations, especially in drinking water, is of concern worldwide in view of the various health implications of ingesting high doses of nitrates. Usually, drinking water contributes <30% of the total dietary nitrate intake (52), but when the drinking water nitrate level exceeds 10 mg/L (as N), the

Table 3. Changes in Nitrite Content of Food Items After Drying[a]

Food Item	Number of Samples Analyzed	Change on Drying, ppm Mean Values
Meat	17	0.7–2.0
Bitter leaf	17	9.4–14.2
Flutted pumpkin leaf	17	1.1–2.8
Garden egg leaf	17	1.0–10.5
Green amaranth leaf	17	2.1–14.7
Pumpkin leaf	17	11.5–21.7

[a] After reference 49.

contribution may become considerably higher and result in health problems. This is why the World Health Organization (WHO) originally set the standard at 10 mg NO_3-N/L for nitrate in drinking water (29), although the first limit was set by the United States Public Health Service in 1962 (53). Therefore, most governmental authorities consider approximately 10 mg/L (as NO_3-N) or 45 mg/L (as NO_3) an acceptable limit for nitrate in drinking water for their countries (Table 4). The United States Environmental Protection Agency (USEPA) standard for nitrate in drinking water is set at 10 mg/L NO_3-N to protect babies under about 3 months of age, the most nitrate sensitive segment of the U.S. population. This level of 10 mg/L NO_3-N has been determined as the No Observable Adverse Effect Level (NOAEL) and is therefore considered the safe drinking water limit for nitrate. This was based on the epidemiological studies carried out mainly in the United States (e.g., References 54,55).

However, on the basis of their epidemiological studies, both Super et al. (56) and Hesseling et al. (57), argued that up to 20 mg NO_3-N/L of nitrate would still be an acceptable limit as it presented a low risk to infants. Nevertheless, the maximum permissible nitrate level (in drinking water) still remains 45 mg/L (as NO_3) and 10 mg/L (as NO_3-N), as set by the World Health Organization (29).

The concentration of nitrates in groundwater is of primary concern due to potential human impacts from its usage. Depending on the use of the groundwater, animals, crops, and industrial processes could also be affected (1). The United States Environmental Protection Agency (58,59) conducted a 5-year National Survey of Nitrates in drinking water wells, the main aim was developing national estimates of the frequency and concentration of nitrates in drinking water wells in the United States in two phases. The drinking water wells include both community water system (CWS) wells and rural domestic wells (RDW). Based on the results from phase I, 52.1% (49,300) of all the CWS wells (94,600), it was estimated, contain detectable nitrate, of which 45% of the pollution was due only to nitrate (1). Out of the 827 RDW wells sampled, it was estimated that 57% had detectable nitrate (60). A total of 1.2% of the CWS wells and 2.4% of the RDW wells, it was projected, have nitrate-nitrogen concentrations above the health-based level of 10 mg/L (60).

The phase I survey report further identified some of the chemical characteristic factors related to detection and concentration of nitrates, and that from the phase II survey included estimates of national population exposure and the resultant health risks due to nitrate for RDW and CWS wells (59). Estimates were provided of the populations corresponding to quartiles of general interest (e.g., 95th and 99th percentiles) and of the number of individuals exposed above health-based levels (1). The information related to CWS wells is summarized in Tables 5 and 6.

SOURCES OF NITRATES IN GROUNDWATER AND FOODS

Agriculture is the primary source of elevated nitrate levels, although in some rare cases certain geologic units can

be the origin of the nitrate. Nitrate sources other than applied fertilizers such as wastes from livestock, dairy, or poultry and accidents or careless precautionary handling of fertilizers near well sites may be involved (31). In the United States, for example, there are locations with high agricultural production in at least 14 states where nitrate contamination has been associated with the application of nitrogen fertilizers (1). In certain categories, organic and inorganic compounds of nitrogen, phosphorus, and potassium that originate from many commercial fertilizers may be released into groundwater. In some cases, it has been demonstrated that the leaching of nitrate is accelerated by irrigation (1,31,61).

Septic tank systems also represent a significant fraction of the nitrogen load to groundwater in the United States (62). About 25% of the population in America is served by individual home sewage disposal systems. Research revealed that effluent from a typical septic tank system has a total nitrogen content of 25 to 60 mg/L (62). In the Netherlands, the reason for the rising nitrate level can be due to the application of nitrogen fertilizer (63,64). Jacks and Sharma (15) reported nitrate levels in excess of 300 mg/L (as N) in wells in Southern India owing to anthropogenic and agricultural influences. In Australia, biological fixation in the soil is considered the principal origin, although point sources such as sewage effluent, animal and industrial waste could be significant locally (65). However, in Nigeria and most parts of West Africa, high nitrate levels in groundwater result mostly from indiscriminate waste disposal (21–25,27) and agricultural activities (26,46,47). Table 7 is a summary of nitrate sources in groundwater.

HEALTH EFFECTS OF NITRATE

Nitrate and the nitrite form of nitrogen constitute a general public health concern, related especially to infant methemoglobinemia (infantile cyanosis) and carcinogenesis (66). The concentrations of nitrate and nitrite in foods that include vegetables, crayfish, meat, etc. and drinking water may indicate serious potentials for pollution and also could result in severe health problems. For example, the nitrate levels in Nigerian foods that include drinking water (from surface and subsurface sources) and beverages are reportedly high and generally perceived to be associated with adverse health effects in humans (24,49,51,67). These have resulted in reported cases of water-related diseases such as diarrhea in children or cancerous diseases that claimed lives yearly (24,68,69). According to Population Reports (70), diarrheal disease is a class of waterborne disease, which is prevalent in many countries where sewage treatment is inadequate or where human wastes are disposed of in open latrines, ditches, canals, and watercourses or is spread indiscriminately on farmland. These practices are frequent in developing nations and favor the accumulation of anthropogenic nitrate.

Certain vegetables (e.g., lettuce, spinach, beetroot, and celery) contain relatively high levels of nitrate [>3000 mg/kg for lettuce (Ref. 71)] but the nitrite levels are usually very low. Nitrates and nitrites are also added as preservatives in some foods, such as cured meats, consequently exposing consumers to higher health risks. The World Health Organization (29) estimated daily dietary intake of nitrate and nitrite in different countries.

In most European countries, the mean nitrate intake is about 10–30 mg/day. Vegetarians usually have a two to fourfold higher intake of nitrates than nonvegetarians. In India, it has been estimated that 20–50% of the wells in areas of high population density produce water whose nitrate level is above 50 mg/L, thus causing severe health hazards (72,73). Terblanche (74) reviewed the health hazards of nitrate in drinking water in many developed countries, including South Africa. Of an estimated 219 million people using public drinking water

Table 7. Examples of the Various Sources of Nitrate in Groundwater[a]

Natural Sources
Geologic nitrogen which can be mobilized and leached to groundwater via irrigation practices
Unmanaged (natural) climax forests that are normally nitrogen conserving; however, nitrogen losses to groundwater can occur from human-initiated clear cutting and other forest disturbances
Waste Materials
Animal manures, which may be concentrated in large commercial poultry, dairy, hog, and beef operations
Land application of municipal or industrial sludge or liquid effluent on croplands, forests, parks, golf courses, etc.
Disposal of household wastes or small business wastes into septic tank systems (septic tank plus soil absorption field)
Leachates from sanitary or industrial landfills or upland dredged material disposal sites
Row Crop Agriculture[b]
Nitrogen losses to the subsurface environment can occur as a result of excessive fertilizer application, inefficient uptake of nitrogen by crops, and mineralization of soil nitrogen
Nitrogen losses to the subsurface environment can occur as a function of fertilizer application rates, seasonal rainfall and temperature patterns, and tillage practices
Irrigated Agriculture
Enhanced leaching of nitrogen from excessive fertilizer application rates and inefficient irrigation rates
Associated leaching of nitrogen from soils periodically subjected to leaching to remove salts so that the soils do not become saline and unproductive

[b] Refers to annual crops.

supplies in the United States, approximately 1.7 million are exposed to nitrate levels above 10 mg/L. About two-thirds of those exposed, 1.1 million, are served by public water systems using groundwater supply sources. Almost 27,000 infants a year are exposed to tap water with nitrate levels exceeding 10 mg/L (31). The resulting health hazards and associated statistics in the United States are documented in the Federal Register (75). The following section describes the details of the various health effects of nitrate.

Methemoglobinemia

High nitrate levels in water can cause infant methemoglobinemia. Methemoglobinemia is a disease primarily affecting babies and is often described by the lay term "blue baby syndrome." Infants are the primary concern because they are the most vulnerable. The USEPA standard for nitrate in drinking water is set at 10 mg/L to protect babies under about 3 months of age. Such infants are much more sensitive to nitrate toxicity than the rest of the population for many reasons. For example, bacteria that live in the digestive tracts of such infants convert nitrate into toxic nitrite.

Nitrite transforms hemoglobin to methemoglobin, preventing transport of oxygen and producing symptoms of asphyxiation (another term for blue baby syndrome). This methemoglobin is considerably more stable than the oxygen hemoglobin complex that fulfils the oxygen transport function of the blood. Once the concentration of methemoglobin in the blood exceeds 5% the first symptoms of 'cyanosis' are generally noticeable; anoxia (death) results at levels of 50% and higher (74) or if the condition is left untreated (66). After babies reach the age of 3 to 6 months, acid in their stomachs increases, thereby creating an unfavorable environment for the bacteria causing the problem (31). It must be borne in mind that nitrate itself has low primary toxicity, but acute toxicity occurs as nitrate is reduced to nitrite (NO_2), a process that can occur under specific conditions in the stomach and saliva (66). Consequently, the nitrite ion formed becomes an oxidizing agent, transforming hemoglobin in the blood to methemoglobin (29), thereby preventing transport of oxygen and resulting in methemoglobinemia. Most reported cases of infantile methemoglobinemia have been associated with the use of water containing more than 10 mg/L NO_3-N.

The occurrence of infant methemoglobinemia from consumption of water with high nitrate concentrations was first recognized clinically by Comly (72). The infants were both less than 1 month old and had received rural well water containing 90 and 140 mg/L, respectively. Earlier, Comly (72) suggested a recommended limit of 10 mg/L NO_3-N in drinking water and a maximum of 20 mg/L.

Later on, Shuval and Gruener (76) studied 1702 infants living in the Israel coastal plain in areas with medium to high nitrate (11.3 to 20.3 mg NO_3-N/L) and compared them with a control group of 759 infants in Jerusalem where only 1.1 mg/L of nitrate is in the water supply. There were no significant differences found between the methemoglobin levels in the 1702 infants in the study areas compared to the 758 infants in the control area. In most countries, methemoglobinemia is not a notifiable disease, making its true incidence unknown. From 1945 until 1970, some 2000 cases of methemoglobinemia have been reported in the world literature (76) with a case fatality of about 8%. The WHO (29) cites literature indicating that 10 cases of methemoglobinemia have been reported in the United Kingdom since 1950 when the first cases of methemoglobinemia were reported in East Anglia. Only one death was reported during this period. In 1986, a 2-month-old infant in South Dakota

(USA) died of methemoglobinemia (77). The exact nitrate concentration is unknown. In another nonfatal case in Iowa, the water apparently contained 285 mg/L nitrate (as N) but the 5-week-old infant survived (42). Hungary is one of the countries, with exceptions, that possibly has the best statistics on the occurrence of infantile methemoglobinemia. Table 8 shows the occurrence of methemoglobinemia in Hungary between 1976 and 1990 (78).

Methemoglobinemia became a notifiable disease in Hungary in 1968 (29), and in the first 5 years after 1968, 883 cases were reported. Of the recorded cases, 92% had a nitrate level in the drinking water exceeding 22.6 mg/L as N; in the remaining 8%, it was between 9 and 22.6 mg/L. The highest number of cases was reported in 1977, and the measures taken to supply the population with drinking water low in nitrate have resulted in a definite decrease in the number of cases each year. For detailed statistics on infant methemoglobinemia, readers are referred to WHO (29) and Csanady (78).

In a later publication, Shuval and Gruener (79) confirm a direct relationship between the occurrence of methemoglobinemia in infants and high concentrations (>10 mgNO_3-N/L) of nitrate in water. According to Ross and Desforges (80), other factors important in the pathogenesis of the disease are age, the presence of bacteria in sufficient numbers in the gastrointestinal tract, gastric acidity (a pH >4), gastrointestinal disturbances, the types of powdered milk product used as baby food, high fluid intake, and the effect of nutrition because foods rich in nitrate can increase the severity of illness.

The first epidemiological survey in South Africa to assess the effect of well water nitrates on infant health was published (57) after the review of health hazards by Terblanche (74). The survey was undertaken due to the risk of methemoglobinemia in infants in the Rietfontein area as a result of the large number of boreholes where nitrate-nitrogen exceeded 10 mg/L. Unfortunately, no correlation was found between the nitrate content of the groundwater used and the methemoglobin levels in the blood. A clinical health risk assessment was attempted in South Africa due to high ingestion of nitrate water (81). There was an increased risk of methemoglobinemia as a result of increased in bottle-feeding by HIV positive mothers. In South Africa, it has been shown that breastfeeding increases the risk by 12–43% that HIV-positive mothers transmit the virus to their children (82). For this reason, the South African Department of Health advises HIV-positive mothers to bottle-feed infants to reduce the risk of mother to child transmission of the HIV virus via breast milk (81). This assessment attempts to quantify the potential additional total exposed population (PATEP) facing increased risk from nitrates. Table 9 shows the potential additional total exposed population at significant risk of methemoglobinemia as a result of bottle-feeding infants by HIV-positive mothers. The number of infants has been calculated as proportional to the area of the province in which groundwater contains >10 mg/L NO_3-N (81).

TOTAL	**1653**	**26**

[a] Reference 78.

According to Colvin (81), Gauteng has 10% of the PATEP for >10 mg/L NO_3-N groundwater, due mainly to the high infant population density (7.5 per km^2). This province includes over half of the total area underlain by groundwater with >50 mg/L NO_3-N and has 88% of the potential additional population exposed to very high risk (in South Africa), shown in Table 10.

The qualitative banding of degrees of risk following the matrix model developed by Carpenter and Maragos (83) and simplified by Genthe (84) is shown in Fig. 1.

Severity is defined according to the potential for exposure to nitrate in groundwater sources. For example, a risk that combines high severity with frequent probability is rated "high," whereas a risk that combines low severity with occasional or the remote probability of occurrence is rated "acceptable." The highest risk is for infants <3 months old who are bottle-fed using groundwater with >50 mg/L NO_3-N, and confounding factors (such as lack of vitamin C and gastrointestinal infections) are evident (81).

In another epidemiological study on a comparable population group in Namibia (56), a correlation was found between the nitrate level in the groundwater and blood methemoglobin levels. The main difference between the two studies was that the level of nitrate in groundwater in the Namibian study was much higher, up to 56 mg/L of nitrate-nitrogen (52). However, the ingestion of nitrate has no apparent short-term effects on adults such as methemoglobinemia. Research has shown that adults on a farm near Otjiwarongo, Namibia, continued drinking water with 268 mg/L of nitrate with no apparent ill effects, even after stock losses occurred on that farm (85).

Gastric Cancer

Infants are not the only ones at risk; it is possible that high nitrate concentrations can cause cancer in adults. "Nitrate itself is not directly carcinogenic. However, there is recognition of the fact that nitrate could be converted to nitrite in the human body that can react with secondary and tertiary amines to form nitrosamines—which have been identified as potent carcinogens" (31). Several studies have shown that simultaneous ingestion of nitrite (or nitrate with amines) results in cancers of many organ

systems (1). The N-nitroso compounds are presumed to be the ultimate carcinogenic substances (86). The role of nitrite as a precursor to carcinogenic nitrosamines and other N-nitroso compounds has been established (1). Nitrite reacts with amines or amides under several conditions resulting in N-nitroso derivatives, the majority of which are carcinogenic to animals. The expectation that these N-nitroso derivatives are also human carcinogens suggests a mechanism whereby exposure to nitrite might result in carcinogenesis (86).

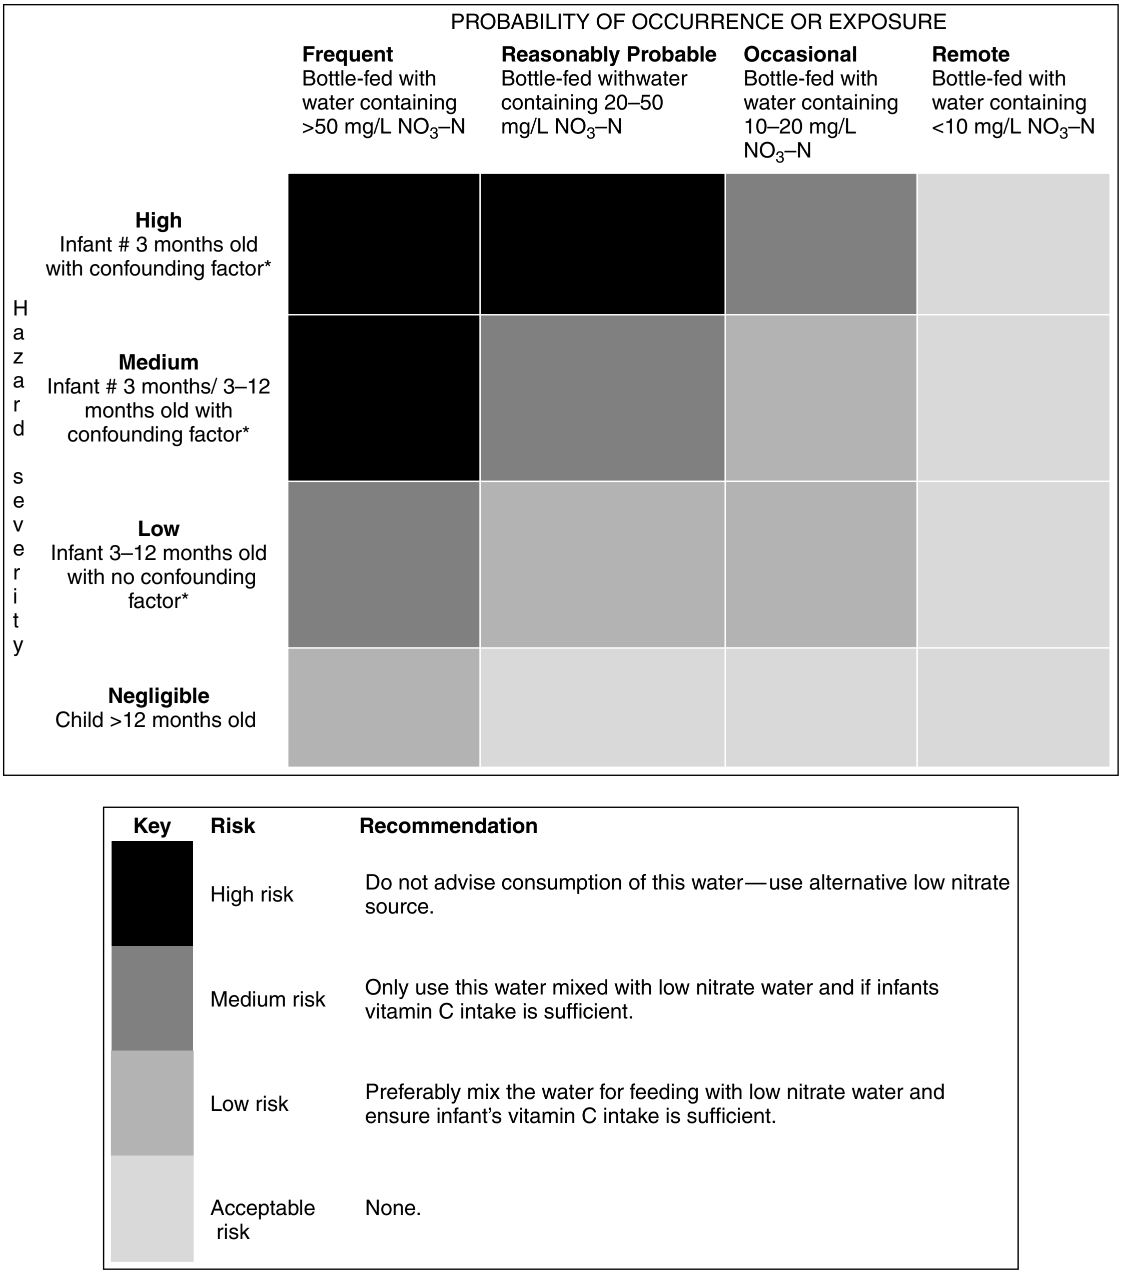
In earlier publications, Wolff and Wasserman (87) reviewed 60 articles on the potential hazard of nitrate, nitrite, and nitrosamines in the environment. Furthermore, Shuval and Gruener (79) refer to the possible carcinogenic, teratogenic, and mutagenic properties of nitrosamines, which can theoretically develop in food or in the human digestive tract if nitrates and nitrites are exposed to secondary and tertiary amines under certain conditions. In both cases, no conclusions were drawn as to the real nature of the potential risks involved. From all available data, the WHO (29) came to the conclusion that no convincing evidence of a relationship between gastric cancer and consumption of drinking-water containing nitrate levels up to 10 mg/L has emerged, yet a link cannot be ruled out; perhaps the inadequacy of the data available would explain this.

However, Hartman (88) in his publication showed a graphical relationship between gastric cancer mortality rates and nitrate ingestion in twelve countries (Fig. 2). Hartman's (88) data on gastric cancer mortality rates are for the years 1974–1975. This graph refers to total nitrate ingestion and does not specifically refer to ingestion via drinking water. Tredoux (52), however, questioned whether the seemingly good correlation is actually related only to nitrate ingestion or possibly also to other dietary factors relating to the various population groups.

Several epidemiological studies have indicated further significant positive correlations between exposure to nitrate and cancer risk. For instance, nitrate in drinking water has been correlated with gastric cancer risk in Colombia and England, and exposure to nitrate-containing fertilizers appeared to be linked to gastric cancer mortality in Chile (1). It should be noted that high risk for gastric cancer correlates with nitrate, and also with several other dietary or environmental factors. These associations, however, cannot be fully traced to the causation of gastric cancer (86,89).

Other Health Effects

The ingestion of nitrate in excess of 10 mg NO_3-N/L is also the possible cause of a number of other adverse effects such as birth defects (congenital malformations), which were studied in South Australia and also in eastern England. Detailed investigation has provided no evidence that these were associated with nitrate levels in water supplies (29). It has also been suggested that



Hazard severity	PROBABILITY OF OCCURRENCE OR EXPOSURE			
	Frequent Bottle-fed with water containing >50 mg/L NO_3–N	**Reasonably Probable** Bottle-fed withwater containing 20–50 mg/L NO_3–N	**Occasional** Bottle-fed with water containing 10–20 mg/L NO_3–N	**Remote** Bottle-fed with water containing <10 mg/L NO_3–N
High Infant # 3 months old with confounding factor*	■	■	▓	░

Key	Risk	Recommendation
■	High risk	Do not advise consumption of this water—use alternative low nitrate source.
▓	Medium risk	Only use this water mixed with low nitrate water and if infants vitamin C intake is sufficient.
▒	Low risk	Preferably mix the water for feeding with low nitrate water and ensure infant's vitamin C intake is sufficient.
░	Acceptable risk	None.

Figure 1. Risk characterization of methemoglobinemia (after References 83 and 84).

chronic exposure to high levels of nitrate in drinking water may have adverse effects on the cardiovascular system. The WHO (29), however, reported that an inverse relationship between cardiovascular mortality and nitrate concentration in water supplies had been demonstrated.

Moreover, excessive nitrates in drinking water have also resulted in problems with ruminants (cud-chewing animals with divided stomachs). Sheep and cattle, in particular, can be seriously affected by nitrates from birth through adulthood (1). Infants of monogastric (single-stomach) animals like horses, pigs, and chickens are also susceptible to problems from nitrate ingestion. However, as chickens and pigs mature, they are much less susceptible to the health effects of nitrate, but horses can be affected through adulthood (90).

Other possible effects of nitrates relate to the thyroid function in animals. Some animal studies indicate that chronic exposure to high levels of nitrates can reduce the intrathyroid iodine pool and thus render the gland more sensitive to goitrogens (29). However, whether or not exposure to nitrate is an etiological factor in human goiter remains unclear (52).

Symptoms of nitrate-nitrite poisoning in livestock include cyanosis in or about the non pigmented areas (mouth and eyes), shortness of breath, rapid heartbeat, staggered gait, frequent urination, and collapse. In severe cases, convulsions, coma, and death may result within a

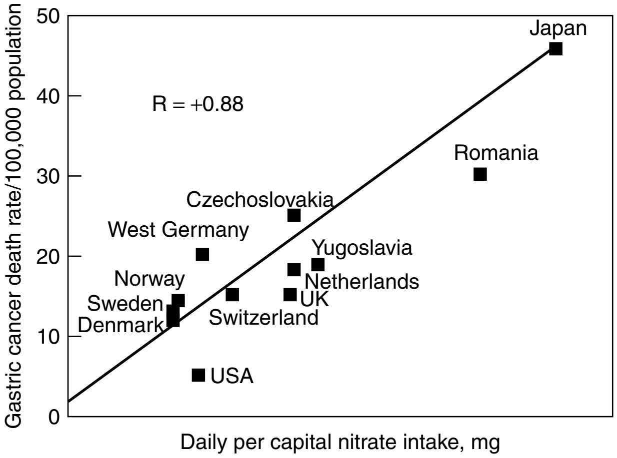

Figure 2. Relationship between gastric cancer mortality rates and nitrate ingestion in 12 countries (after Reference 88).

few hours (1). Loss of milk production in cows and aborted calves are also indicative of nitrate poisoning (90). Stock losses due to nitrate poisoning have been reported in Namibia (91), in the dolomitic area of South Africa (92), and in Bophuthatswana (52).

Exposure to high doses of nitrate is also associated with adverse effects such as the 'hot-dog headache' (52). The 'hot-dog headache' has been described in the literature as related to nitrites used in curing meat to give it a uniform color (93). Nitrites are also vasodilators, so that some people find that soon after eating these meat products, they develop flushing of the face and headache. The 'hot-dog' is the classical example, but other meat products, including bacon, ham, and salami, can also cause these symptoms (52). A farmer in the Springbok Flats regularly complained about hot-dog headaches. The problem was solved when he started using nitrate-free water (94).

Finally, detailed information on the health effects of nitrate and nitrite in humans and animals, the mechanism and quantification of toxicological effects of nitrate and nitrite, as well as other health-related information on nitrates are available in literature (29,43,56,74,76,79, 95–97). Obviously, pollution and contamination problems from NO_3-NO_2 compounds must be causing environmental public health havoc yet to be fully determined and documented. Therefore, nitrate-nitrite pollution control programs must be established to reduce the health effects of these common and widespread contaminants. Excessive chemical fertilizer and animal manure applications must be controlled and curtailed. Exceptionally high NO_3 borehole waters must be abandoned, and unpolluted groundwater exploited. These and possible biodenitrification water treatment (for affected waters before use) could contribute solutions.

SUMMARY

The occurrence of high nitrate concentrations in groundwater is widespread, particularly from agricultural usage of fertilizers and animal manure or land disposal of domestic waste and wastewaters. Much research has been conducted to determine the amounts of nitrates in drinking water wells as well as in foods. Exposure to high doses of nitrate is generally perceived to be associated with adverse health effects in humans and other species. These range from infant methemoglobinemia, cancers, the 'hot dog headache,' and hypertension, to other adverse effects such as birth defects (congenital malformations) and spontaneous abortions. Most reported cases of infantile methemoglobinemia have been associated with the use of water containing more than 10 mg/L NO_3-N.

Pollution and contamination problems from NO_3-NO_2 compounds may be causing environmental public health havoc yet to be fully determined and documented. The evidence as outlined in this article is overwhelming. Therefore, nitrate-nitrite pollution control programs must be established to reduce the health effects of these common and widespread contaminants. Excessive chemical fertilizer and animal manure applications must be controlled and curtailed. Exceptionally high NO_3 borehole waters must be abandoned, and unpolluted groundwater exploited. These and possible biodenitrification water treatment could contribute solutions.

DOMESTIC WATER SUPPLY—PUBLIC–PRIVATE PARTNERSHIP

Muhammad Sohail
Loughborough University
Leicestershire, United Kingdom

INTRODUCTION

> "Food and water are basic rights. But we pay for food. Why should we not pay for water?"
>
> Ismail Serageldin

> "Water should not be privatised, commodified, traded or exported in bulk for commercial purposes."
>
> Maude Barlow

The above two quotes typify the two extremes of the arguments surrounding public–private partnerships (PPPs). Although this ideological debate is intellectually exciting, the more challenging problem can be summarized as follows (1):

- How do you provide access to safe water to around I billion people?
- How do you provide sanitation services to around 2.6 billion people?

Time is ticking by, and the global community must meet the above targets soon. Policymakers and water and sanitation practitioners alike should be prepared to include PPPs as a tool in achieving the above. Before going into detail, a brief summary of the context follows.

Water is essential for life. This is not only in terms of its biological utility, for water also has social, economic, health, technical, financial, and political dimensions. Historically, the availability of a domestic water supply has been a significant factor in the development and sustenance of civilizations.

Water is one of Earth's most important natural resources. If naturally occurring freshwater is polluted as a result animal (including human), plant, or other activities, processes are required to convert the then raw water to a quality fit for a particular use, such as drinking. In most cases, because of high levels of pollution by humans, water must be treated before and after its use.

Various water sources exist, for example, rainwater, groundwater, spring water, surface water, rivers, lakes, ponds, fog, and even glaciers. Water can be supplied from such sources in many different ways, but these can then be divided into either piped or nonpiped options.

The behavior of humans in terms of their consumption of water also has historical, geographical, and cultural dimensions. For example, in some parts of Bolivia people only consume 5 or 6 L per capita each day as compared with the 30 to 250 L consumed each day by a person in developed economies.

Water has various uses, including agricultural, recreational, industrial, and domestic. In terms of its domestic use, water is used for sanitation facilities as well as for drinking. Indeed, a high level of consumption—up to 80%—is caused by piped sanitation wherever such facilities are available. Think about how much water a person flushes as compared with how much he or she drinks! With a limited amount of useable water, there is competition, sometimes tension, among various water users. Both market-oriented and hierarchy-based rules are used to distribute water among its various consumers.

In the supply chain of water—its production, distribution, management, and consumption—private sector organisations are key players. Before moving on to the main discussion of this paper, it is useful to summarize some of the more important concepts.

CONCEPTS

Public and Private Goods

Private goods are those for which consumption (or use) by one person prevents consumption (or use) by another. Public goods are those that can be used by one person without diminishing the opportunity for use by others. There is a seemingly unending debate over whether water should be treated as a public or private good, or both.

Commodification

Commodification is the process of converting a good or service formerly subject to non-market social rules into one that is subject to market rules. Treating water as an economic good implies that the resource will be allocated across competing uses in a way that maximizes its economic value across society. However, it also implies that safety nets will be needed for people who cannot afford to pay. Meanwhile, for some people, considering water to be a commodity at all is sacrilegious!

Governance

Governance refers to the relationship that can be manifested in various types of partnerships and networks. Water governance is the wider context within which water services procurement plays a key role and under which PPP is a niche tool.

What is Partnering?

At the very least, partnering should be viewed as the absence of adversarial behavior.

WHAT ARE PPPS?

The involvement of the private sector in partnership with government has long been advocated as a means of improving the development of sustainable water and sanitation systems. The author uses PPPs in this document as a general term to cover a wide range of agreements or partnerships between private sector (nongovernment) concerns or organizations, public sector utilities, government departments, and consumer groups in relation to the delivery of water and sanitation services. The community has a direct role to play in such arrangements as a beneficiary and in expressing the price people would be willing to pay for an acceptable level of service. It also has an indirect role to play in shaping policy for the urban environment. In a small PPP, the community could take the role of the private partner.

One of the difficulties in determining the scope of discussion concerning private sector involvement in water and sanitation is the sheer diversity of possible partnership arrangements and potential actors. The three main roles are those of the private sector, users (consumers), and the government (often referred to a the client or sponsor; it also may act as regulator). The possible arrangements include complex concession arrangements operated by multinational corporations lasting perhaps 30 years; shorter duration, simpler forms of management or service contract undertaken by medium-sized private enterprises; and service delivery by small-scale independent providers (local entrepreneurs). An outline of formal contracting arrangements is produced in Appendix A.

WHY PPPS FOR DOMESTIC WATER SUPPLY?

The role of the private sector in domestic water supply is not new. Many water supply-related activities in many municipalities in the world have started out as small private water firms or informal organizations of people.

Considering the potential demand for water sanitation, it is obvious that already budget-constrained governments cannot improve services alone. Some estimates indicate huge capital outlays are needed to meet water and sanitation targets; Camdessus and Winpenny (2), for example, estimate US$90 billion per year is needed globally to meet such targets. On the other hand, there is an argument that unless national governments make environmental sustainability a priority, the shortage of water and sanitation services will remain as they are. Other people believe that improved water management and better use of current assets is what is crucial and will reduce the need for more capital infrastructure significantly.

In any case, private finance is only one of the benefits of PPPs. Others include the managerial capacity of the private sector in managing assets for water and sanitation services. The private sector is also more likely to be innovative than the public sector, which leads to more effective and efficient services provision.

Governments are turning to PPP arrangements for the provision of services for a variety of reasons; therefore, these may include the following:

- Lack of capacity of government institutions to deliver a reasonable level of service or to improve service quality.
- Financial weakness of public utilities.
- The inability of public institutions to respond to an increasing growth in demand for services because of, for example, rapid urbanization.
- Problems related to the large numbers of employees in public sector providers.
- The requirement that international financing institutions (IFIs) place on certain indebted countries to reduce domestic spending as part of structural adjustment programmes. Such institutions promote the idea that the private sector is more efficient and effective and delivers a better quality service.

HOW PUBLIC-PRIVATE PARTNERSHIPS GET STARTED

There are various ways in which a partnership can be initiated. In some cases, the initiative comes from the likely partners and in some cases the demand comes from an third party. Public-private partnerships may not always seem to be a desirable solution at first. Most organizations prefer to stay on paths they know well, sharing goals and work practices with other groups that think and act like them—governments working with governments, businesses with businesses, and nonprofit groups with nonprofit groups.

Governments and private firms have long worked together under simple arrangements, such as government purchase of products produced by the private sector. However, both parties often hesitate to enter into more complex relationships. Governments are frequently concerned that private businesses will take advantage of them, whereas businesses often consider government approaches to be burdensome and a waste of time. Therefore, it is useful to allow some time for trust to be established among the key partners.

Three main conditions favor the formation of a partnership: urgency, the involvement of a champion, and some kind of catalyst.

Urgency

Generally, it takes a widely acknowledged urgency—for instance, the lack of particular services or the waste of resources—before key stakeholders start looking for partnerships and partners are open to cooperate to resolve the problem. Although it is hoped that progress can be made in the absence of a crisis, in practice, the inertia that keeps many people on familiar paths is usually broken only by a pressing need for change.

Entrepreneurs/Champion

Sometimes, even in the absence of a urgency, an individual, group, or organization may realize that separate, uncoordinated actions are creating redundancies, missed opportunities, and less-than-optimal use of scarce resources. In reality, even if the crisis is clear and the interest is there, partnership arrangements will not succeed without the drive and commitment of a few individuals. Such “champions” (leaders or pioneers) can be government officials, NGOs, business people, or citizens who—through their personal motivation—make partnerships happen. In other cases, champions are service providers who stand to profit from the partnership.

Catalyst

Frequently, there is a need for some kind of catalyst to bring the partners together. Such a catalyst could be the actions of an external actor, such as one or more international finance institutions or other bodies that are respected and trusted by all partners.

WHAT ARE THE KEY FEATURES OF SUCCESSFUL PARTNERSHIPS?[1]

Characteristics of Successful Partnerships

Compatible Goals. Government , businesses, and community leaders must understand and respect one another’s goals. For instance:

- Government may initially have difficulty accepting the profit motive of private businesses.
- Private companies may be tempted to walk away from the more bureaucratic decision-making processes used in the public sector.
- Local communities may not have the patience needed to address issues affecting other areas of the city.

To resolve these differences, all parties must focus on the broader, complementary goals that are to be achieved. It is important for them to realize that public and private goals do not necessarily need to be the same for partnerships to work—they must be merely compatible.

Enabling Environments. An enabling regulatory, legal, and political environment is the cornerstone of sustainable private sector participation.

Legal Framework. Early on, the public sector must establish an appropriate legal framework for contract procurement and private sector investment. It is important that mechanisms be put into place to minimize the likelihood or appearance of corruption in any procurement processes. Unpredictable and unfair procurement processes reduce both political acceptability and the interest of many private investors.

Regulatory Framework. The government must also establish a clear regulatory framework, and it must implement appropriate tariff regimes and subsidy mechanisms. The creation of a regulatory framework alone, however, does not necessarily guarantee effective regulation. As all local governments are different, the public and private sectors will face a steep learning curve as they try to define and regulate their relationship with one another and their roles in providing services. In particular, the public sector needs to define a clear allocation of responsibilities between the national and municipal governments and a clear statement of its role as a provider and a regulator.

In general, private sector companies prefer that the contract serve as the major regulatory mechanism, and that governments have limited regulatory discretion once the contract is in place. Highly specific contract terms that establish duties, performance targets, rules for changing prices, and dispute resolution procedures allow the private sector to better predict the profitability of the venture and decide whether and what to bid for the contract. Given these preferences, governments will have to make important decisions about the degree of regulatory discretion they are willing to give up, particularly for long-term contracts.

Political Environment. In addition to the regulatory climate, a bad political climate caused by the pressure of election cycles, the potential instability of new democracies, the personal agendas of government officials, and the special status of some services (particularly in terms of access to water, for example) can create barriers to starting or maintaining public–private collaborations. Governments must provide assurances whenever possible to private sector partners that such political factors will not disrupt the contractual partnership.

Acceptance. The government and business leaders cannot build partnerships alone; political and social acceptance of private sector involvement is essential. The population must see private sector participation as beneficial if the partnership is to last over time. Public support of private involvement over the long term will depend on primarily the delivery of promised services and benefits at reasonable costs. Therefore, it is of the utmost importance that mechanisms be developed to ensure that the organization providing the service, whether it is a public or a private sector organization, be accountable to its customers.

Public support will also depend on the ability of the partnership to meet the needs of all stakeholders. For example, public sector workers can be a source of tremendous opposition to increased private involvement in the provision of services. Contracts should ensure the employment or placement of public employees and local residents to the greatest degree possible.

Credibility and Transparency. Effective cooperation between local government, businesses, and the community is always difficult to achieve because of the wide range of participants involved, the low level of trust that often exists between potential partners, and the lack of predictability in the process. The credibility of champions and other leaders involved, as well as transparency in the process, are critical determinants of long-term success. Experience suggests that genuine partnerships must include the principles of equity, transparency of operations, and mutual benefit. Trust and confidence in any project is necessary for successful partnerships.

---

[1] The following section is based on Sohail and Olena (3).

Factors Contributing to the Durable Partnerships

Governments clearly want to establish PPPs that are sustainable over time. Essential ingredients of durable PPPs include those listed below.

Commitment of Resources. All partners to the arrangement should be obliged to commit resources (financial, human, capital) to increase their interest in seeing the partnership succeed, which implies shared risks and rewards.

Capacity Development. Projects requiring substantial institutional change or large capital investments will require capacity development within all groups of stakeholders. For example, development of:

- Consumers, in terms of their knowledge of the service they are to receive and the costs associated with its provision
- Service providers, particularly local organizations, in terms of entrepreneurial skills
- Governments, in terms of their capacity to adopt the frameworks necessary for, and oversee the provision of, the service

Roles and Responsibilities. The delineation of appropriate roles and responsibilities is another element necessary in the development of effective, durable partnerships. It is essential that partnerships be organized in a concerted fashion to make the most effective use of the resources committed by both parties.

Individual responsibilities should be clearly outlined from the beginning so that there is no ambiguity in the tasks that each party is expected to perform. Furthermore, these responsibilities need to be defined realistically with a clear understanding of the strengths and weaknesses of each partner.

Flexibility. All partnerships are context-based and different locally. Partnerships should draw on other experiences but at the same time should be opportunistic about exploiting the comparative advantage of local resources. Over the long term, changes in investment plans, technology choices, and priority actions will be necessary in response to unforeseen circumstances. Including clear procedures for making such changes over the life of the project will reduce the chance that they will have a negative impact on the partnership.

Time. Partnerships take time. The process of understanding the problems to be addressed and the impacts on potential partners, as well as those partners' needs and aspirations, all takes time. Progress can certainly be made along the way, but the process of achieving and maintaining acceptance among users, providers, and regulators is a continuing one; a cooperative dialogue to address shared needs must be maintained throughout the project.

Patience. Projects requiring substantial institutional change or large capital investments require a lot of patience. Careful attention must be paid to the balance between responding rapidly to the most pressing crises and developing integrated solutions that will last. Political cycles and the desire for immediate improvement in a crisis situation often lead to the development of time frames that are too short. Such short-term agendas and limited horizons lead to unrealistic expectations and unsustainable solutions. It is not realistic to expect that private sector involvement will overcome public institutional and operational inefficiencies quickly, nor that it will compensate immediately for a history of insufficient public sector resources and funding.

Social Responsibility. Public services provide public goods—in other words, goods that should be available to everyone. Improving provision of such services is about making people's lives better, especially those of the urban poor. Governments should always make sure that the changes they make promote increased access to, and better quality of, services. An emphasis on social responsibility will also increase political gain, as better services will lead to greater political acceptance by the general population.

What are the Major Obstacles to Forming a Successful Partnership?

A range of possible obstacles or deficiencies in the capacity of both public and private actors could hinder the formation of a successful partnership. Major obstacles in this respect include:

- Reciprocal mistrust and lack of understanding of one another's interests and needs across the public and private sectors
- Absence of locally available information on, and experience with, arranging sustainable partnerships
- Underlying legal, political, and institutional obstacles to forming effective public–private relationships

These obstacles often lead to lengthy negotiations, increased transaction costs, and make smaller projects much less attractive to potential investors. To minimize the harm from such obstacles, PPP arrangements should provide certain safeguards for the public and private sectors and for the community.

The public sector usually expects the private sector to contribute in one or all of the following ways:

- To provide agreed services
- To make agreed investments
- To meet agreed standards/targets
- To not exploit any monopoly situation that might exist

The private sector expects the public sector to contribute in one or all of the following ways:

- To create an enabling environment suitable for the PPP
- To pay agreed fees promptly and in full
- To implement tariff increases as agreed

- To prevent unexpected competition from others during operation (exclusivity)

The community expects the PPP to:

- Provide appropriate levels of services
- Be affordable to the community, either through direct charges or indirectly through general taxation

THE CURRENT SITUATION

Quantitative information in this section is based mainly on the World Bank Private Participation in Infrastructure (PPI) database (4).

- At least 203 water and sanitation projects are taking place in 43 developing countries, with a corresponding commitment of some US $40 billion.
- A few large projects in, for example, Argentina, Chile, and Manila, Philippines can explain peaks in water and sanitation investment during 1991–2000.
- Latin America and the Caribbean are the most active regions in terms of global investment (52%), followed by East Asia and the Pacific (38%) and only then Europe and Central Asia (8%).
- Concession contracts provide the largest proportion of such investment (69%) through the largest number of projects (90).
- Private investment reached a peak in 1999.
- The top five countries by cumulative investment in water and sewerage projects with private participation were Argentina, the Philippines, Malaysia, Chile, and Brazil during 1991–2000.

The above figures relate only to formal PPPs and do not take into account many informal private sector and community-based operations; such operations could be serving many users well.

CHALLENGES[2]

Political Acceptance

Infrastructure services such as water and sanitation are intrinsically political and that fact, along with the politicians' individual agendas, should be acknowledged in policy discussions. For example, PPPs are still seen to be a political risk by many politicians, whose principle objectives include acquiring or retaining power. Quick fixes may be favored to attain popularity rather than making hard decisions for the long-term sustainability of water and sanitation services. Nonetheless, socially sensitive PPPs are more likely to be politically acceptable.

Social Acceptance in Developing Countries

Policy Issue: The Poor are Seldom Mentioned. In many developing countries, private sector involvement in services provision is expected to also fulfill the social role of the public sector. However, where this is the case, it must be negotiated as part of the PPP right from the beginning of the procurement process.

Knowledge and Understanding of Advisers. Terms of Reference mostly appear to be drafted by advisers, who tend to be distant from the sponsor/client's organization. Their expertise will be determined by the requirements specified by the sponsor/client and normally focus on technology and finance. A lack of understanding on the part of those responsible for developing and negotiating the contracts can lead to the omission of important existing informal arrangements among public utility staff, water vendors, and low-income customers. Hence the inclusion of expert staff members that have PPP experience and a workable knowledge of how to improve water and sanitation facilities for low-income (poor) areas and communities is important if PPPs are to become socially sensitive.

The time scale for the sponsor/client's advisers to prepare the necessary bidding information is relatively short, and this inevitably results in workloads being prioritized. Consequently, the complex and little understood issues involved in service provision for the poor are unlikely to receive serious consideration at this stage. The "time factor" may therefore have contributed to the historic underrepresentation of services to low-income communities in many PPP contract documents.

Governance and Relationships with Consumers. Public sector utilities and private companies are experienced in service provision to regular settlements and housing developments occupied by middle and high-income consumers with individual service connections. However, public sector utilities rarely have much experience in dealing with service delivery to the poor, whereas operators from the formal private sector appear to have even less. A key feature of extending coverage to the urban poor therefore involves working out new relationships between a diverse range of actors who have little if any experience of one another.

Direct Links: Partnership does not have to Involve Formal Private Sector. In cases where small local entrepreneurs or civil society groups take on the role of private sector operator, they generally act as an intermediary between the public sector sponsor/client and the consumer. This may, for instance, involve acting as a retailer of water services. In such circumstances, there tends to be more negotiation to address problems and issues at the local level, with local entrepreneurs communicating directly with consumers or their representative groups. Although there is less recourse to legally binding agreements, the key issue remains the same, namely, whether the mechanism works for poor consumers.

User Perceptions

In recent years, consumers have been asked to voice their opinions on the overall process of PPP development involving the formal private sector. Concerns that have

---

[2] This section is based on Sohail (5).

emerged include lack of consultation; concern over lack of public control or safeguards; fear of corruption; high tariffs; unemployment; and the assumption that there will be increased burdens on the "common people," who in turn have no clear idea of the benefits.

Involvement in the processes leading up to change is critical. Although this does not guarantee success, case studies have found that projects in which stakeholder participation was absent or minimal were the least successful in terms of feedback from people on low incomes. In such cases, consumers tended to raise objections to the involvement of private companies in their water supply, especially foreign companies. Commonly, such involvement is precipitated by increases in tariffs, which are perceived to be making profits for private companies at the consumer's expense.

Financial Issues and Tariffs

Payment Problems. Some of the problems faced by households include high arrears, high repayment levels, disconnection of the water supply, and inability to pay reconnection charges. The introduction of higher charges through both metering and increased standing charges creates additional pressure on the household budget. Low-income people are clearly under most pressure to economize, and this results in reduced water consumption and less cash being available for other needs.

Technology

Scope for Innovation. Simple yet innovative technology changes may form part of the implementation of PPP arrangements. Such changes are the result of various factors, including:

- Analysis of settlements and their needs
- Taking community needs and preferences into account
- Knowledge of alternative options, relevant technologies, and proven models—for example, simplified, lower cost designs
- Willingness to experiment to find innovative alternatives to standard technological approaches

Levels of Service and Service Differentiation. There are several cases where PPP has led to the introduction of more appropriate and flexible levels of service. This has involved lowering the conventionally accepted, high levels of service that predominate in wealthier areas.

Information

The Need to Communicate Effectively. The introduction of PPPs normally changes existing roles and responsibilities, and these have to be communicated to consumers. If one of the partners (usually the operator) has no working knowledge of the area, then it is crucial for that partner to find out about consumer needs.

Regulation, Monitoring and Complaints

Formal Regulatory Systems. These should be developed during the preoperational phases of PPP contracts, and they are notably absent during the preparation for many PPPs. No provisions are made to check the operation of a monopoly supplier or to impose penalties for substandard performance. In addition, there may be no defined procedures for routine external monitoring of performance. In particular, lack of capacity for monitoring and reporting is a problem for the relatively small municipalities involved in many PPPs.

Effectiveness of Regulation. International PPP experience has shown there to be situations where regulation does not necessarily safeguard the different interests of the various parties to the arrangement. For instance, poor consumers are often dissatisfied with services and tariffs in formally regulated environments; billing and bill collection by the public partner may be inefficient; and the private operator may perceive lack of control over customer management to be a significant risk.

CREATING TRUST

Communication and information alone are not enough. In many PPPs, consumers are unsure of what to expect from privatization because they have not been involved in the development process. If user groups and other stakeholders had been integrated into the process from the start, then there might not be such widespread opposition.

In conclusion, then:

- There is a pressing need to develop a base of information about low-income groups; this can then be used directly in the development of PPP arrangements. Such action requires a clearer understanding of information needs on the part of both the designers of PPPs and the local institutions and organizations.
- There is also a clear need to provide information for consumers, particularly about proposed roles and responsibilities. Lack of understanding and consensus leads to operational problems and is ultimately disempowering.
- Communication is a vital component of PPPs, and investment in this will pay dividends in operational terms. Lack of information could result in low-income communities refusing to accept or comply with the partnership, and this in turn could lead to the risk of nonpayment.

APPENDIX A: OVERVIEW OF MODELS OF PRIVATE SECTOR PARTICIPATION IN WATER AND SANITATION PROVISION

Full Privatization (Divestiture)

Private company not only takes full responsibility for operation, maintenance, and investment, but ownership of infrastructure is transferred from the public to the private sector at an agreed fee. The government is responsible for regulation.

Partial Private-Sector Responsibilitys

Responsibility for service provision is shared between the private and public sectors, with differing levels of responsibility being delegated to the private partner depending on the contract type.

In all of the following models, ultimate ownership of assets remains with the public sector.

Service Contract

Service contracts are usually short-term agreements whereby specific operations and maintenance activities are contracted to the private sector. The public sector retains overall responsibility for the administration of the service.

Management Contract

A management contract entails private sector responsibility for utility operation and maintenance but without the obligation of investment or commitment of private investment capital.

Lease Contract (Affermage)

Under lease contracts, the private firm operates and maintains the utility at its commercial risk, deriving revenue directly from tariffs, but it does not invest in new infrastructure.

Concession Contract

Under concession contracts, the private company manages the infrastructure facility and operates it at its commercial risk and accepts investment obligations. The role of the government in concession contracts is predominantly regulatory.

Build-Own-[Operate]-[Train]-[Transfer]-Type Contracts (BOO/BOT/BOOT/BOTT)

These are similar to concession contracts, but they are usually used for greenfield projects as the private contractor is also responsible for constructing the infrastructure. At the end of the contract, the assets may either remain with the private company or be transferred back to the government.

Cooperative Model

The cooperative model is a type of government-owned public-limited company (plc) subject to the rules and regulations of other plcs and of which most shares are publicly owned (either by government or citizens/users).

Informal Sector Provision

Provision of water and sanitation services to the poor by "informal" and/or small-scale operators is common in most low- and middle-income countries, especially where the poor lack access to formal service provision. In an increasing number of cases, governments are supporting small-scale private initiatives to increase services provision to the poor.

METHODS OF REDUCING RADON IN DRINKING WATER

Paul D. Robillard
World Water Watch
Cambridge, Massachusetts

William E. Sharpe
Bryan R. Swistock
Pennsylvania State University
University Park, Pennsylvania

Since the late 1980s, radon has become a highly publicized health threat. This naturally occurring radioactive gas is seeping out of the earth's crust and into the basements of thousands of homes across the nation. Until recently, radon concerns have focused primarily on airborne radon; radon in drinking water was not considered a problem. Now, water tests reveal its presence, and many homeowners are asking water treatment dealers, "How can I reduce radon in my water supply?"

WATERBORNE RADON

Waterborne radon usually originates in deep wells that tap radon-contaminated groundwater. Radon increases household air levels during showering, laundering, and dishwashing. The EPA estimates that 2–5% of airborne radon comes from household water. They further estimate that even these small percentages increase the incidence of cancer. If radon is discovered in water, it is likely that radon is entering the house through the basement as well.

Currently, the EPA has not set official standards for either airborne or waterborne radon. EPA suggests that an airborne level of 4 pCi/L is a point at which remedial action should be taken. Recognize that for every 10,000 pCi/L in water, about 1 pCi/L will be released in the air. The EPA's proposed limit for radon in water is 300 pCi/L.

Detection and Testing

Radon and its daughters are radioactive—continually decaying and emitting radioactive particles called alpha and beta rays. Therefore, testing for radon in water requires special sampling and laboratory analytical techniques that measure its presence before it escapes from the sample. Direct water sampling is by far the most accurate testing method.

Treatment

Radon water treatment should remove radon before it becomes airborne.

Methods of Home Aeration

Home Aeration Units. Home aeration exposes the water to enough air so that radon can escape to the air before the water reaches the taps. Using new technological advancements in home aeration, these units can have radon removal efficiencies up to 99.9%. They are also ideal for high waterborne radon levels.

Spray Aeration Unit. A spray aeration unit, as shown in Fig. 1, sprays radon contaminated water into the tank using a spray nozzle. The increased surface area of the sprayed water droplets causes the radon to come out of solution, and the air blower carries the radon contaminated air to a vent outside the home. About 50% of the radon will be removed in the initial spraying. The water must be sprayed several times to increase removal efficiencies. To keep a supply of treated water, at least a 100-gallon holding tank must be used.

Packed Column Aeration Unit. In a packed column system, water moves through a thin film of inert packing material in a column. The air blower forces radon contaminated air back through the column to an outdoor vent. If the column is high enough, removal efficiencies can be between 90 to 95%. For a 6-foot column (shown in Fig. 2), the removal efficiency is around 95%. Packed columns become impractical if the radon level exceeds 20,000 pCi/L.

Shallow Aeration Unit. A final aeration system uses a shallow tray to contact air and water. Water is sprayed into the tray and then flows over the tray as air is sprayed up through tiny holes in the tray bottom (see Fig. 3). The system removes more than 99.9% of the radon and vents

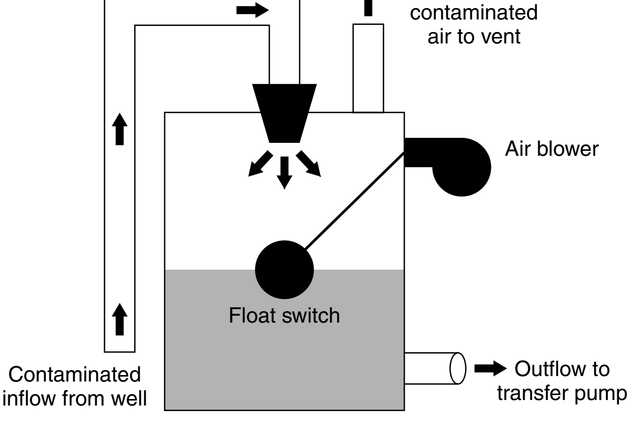

Figure 1. Radon removal using a home spray aeration system.

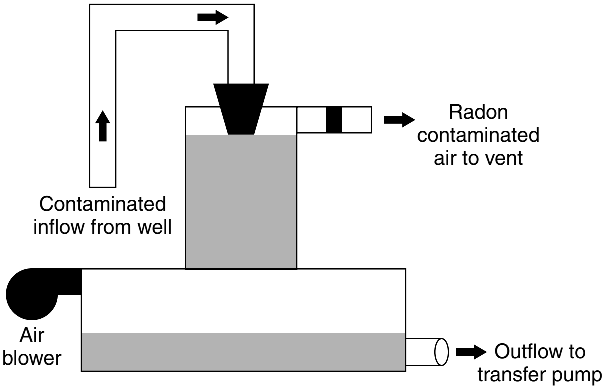

Figure 2. Radon removal using a packed column.

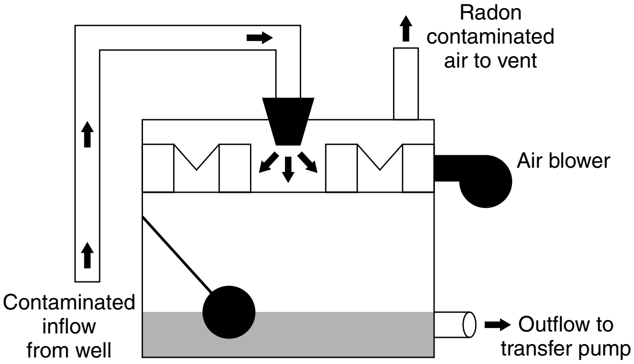

Figure 3. Radon removal by horizontally extended shallow aeration.

it outside the home. The treated water collects in the tank bottom and is pumped to the water pressure tank.

Advantages of this type of aeration include:

- Low pressure air blower
- No fouling problems in tray holes
- Small unit size

However, this unit uses 100 cubic feet per minute of air compared to the others, which can depressurize the basement.

Point-of-Entry Treatment

Another method for removing radon from water is a granular activated carbon (GAC) unit. Figure 4 shows a typical GAC unit.

For radon removal, GACs are constructed of a fiberglass tank containing granular activated carbon—a fine material that traps and holds the radon. Because of the carbon's fine particle size, it easily clogs with sediments or other contaminants in the water.

Important points to consider with GAC units are:

- Some GAC units come with a special backwashing feature for removing sediment, which eventually reduces the effectiveness of the carbon to remove radon.

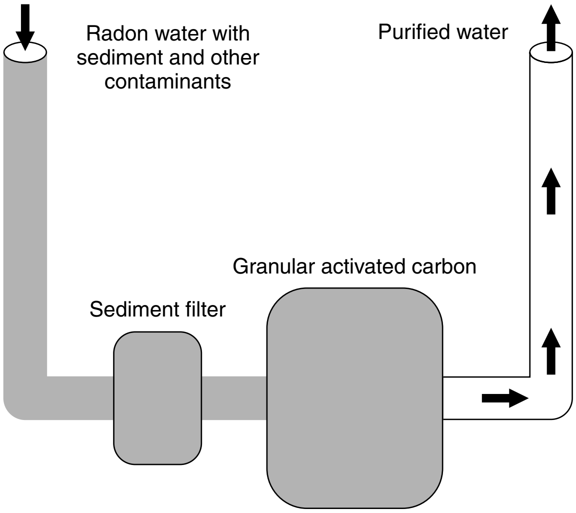

Figure 4. Treatment by activated carbon.

- Elimination of the sediment source or a sediment filter placed ahead of the GAC tank is the best protection against clogging.
- The maximum radon level at which a GAC unit operates effectively is uncertain. Some estimates show that it should not be used if waterborne radon levels exceed 30,000 pCi/L. Other experts say 5,000 pCi/L.
- It is important that the filter size matches the water use and conditions. According to the EPA, a 3-cubic-foot unit can handle as much as 250 gallons of water per day and effectively reduce radon levels. Typical water use in a home ranges from 50 to 100 gallons per person per day.
- GAC filter will remove radon indefinitely providing that sediments or organic pollutants have not clogged the filter.
- A major drawback to using a GAC filter is that if radon is present, the filter becomes radioactive as it picks up the gas. Lead-210 (a radon daughter) builds up on the carbon filter and then gives off its harmful radioactive rays, as it continues to decay.
- A GAC filter may produce a radiation problem when the device is used to remove other contaminants. For example, a GAC unit is installed to remove a pesticide without testing the water for radon. The GAC unit sits under the sink harmlessly removing the problem contaminant. Right? Wrong. Unfortunately, what the homeowner doesn't know is that the water supply has very high radon levels. So, while the GAC traps the pesticide, it also traps radon, thus producing a radioactive filter and a radiation hazard.
- Proper maintenance and handling of the GAC unit can minimize exposure risks. Redevelopment of the well intake or a sediment filter is vital to protecting the fine carbon from fouling and clogging; protected filters won't need to be changed as often. The water should also be periodically retested to insure that radon is still being removed.

WATER REUSE

Peter S. Cartwright, P.E.
Minneapolis, Minnesota

Water reuse is the general term applied to the act of recovering water from a process and reusing it in the same process, or another one, before discharging it. Some experts attach labels to this activity based on the specific use of the water: *Recycle* involves redirecting the recovered water back to the same process. *Reuse* means reusing the recovered water in a different application. *Recovery* generally refers to the technologies used to accomplish this.

Black water is defined as the effluent from toilets and garbage disposers in residences. *Gray water* in the residential environment typically refers to the effluent from bathing, showering, laundry, and dishwashing and other effluents from normal household activities. *Gray water* is distinguished from black water in that it contains much less organic loading and is expected to contain much less fecal coliform bacteria and other pathogenic organisms.

We all are familiar with the admonitions addressing the finite quality of water on this planet: the fact that only 1% is considered “fresh” (nonseawater), but is used for virtually all human activities and, as a result, is rapidly deteriorating in quality. The mindset is there, as are the technologies. The barrier is the commitment to make the economic investment.

From a technical standpoint, there are virtually no barriers to the quality improvement of either black water or gray water, even to the point of drinking water quality! Today it is possible to install a “black box” on the sewer line from residences and drink the treated water coming from it. Presently, the deterrents to this are economics and the “yuck” factor.

Drinking water regulations continue to place new standards for water quality, and industrial and commercial activities are requiring higher quality water in many applications. Due to population growth, water quantity requirements are also steadily increasing. For example, today it is estimated that one-fifth of the world’s population does not have access to safe drinking water; by 2025, the global population is expected to be 8.3 billion people (up from about 6.4 billion in 2004), and the usage of industrial water is expected to double by then. Interestingly, even in cities experiencing severe drinking water shortages, there always seems to be enough water to flush toilets.

Industries, in general, are very poor stewards of water conservation. Most water brought into the plant is used only once, even though that use may have had very little impact on water quality. In most of the industrialized world, we have labored under the misconception that our water supply was inexhaustible as well as inexpensive. This cost aspect has been exacerbated by the fact that, in many areas, the price of water has been partially subsidized by local government.

Undoubtedly, a paradigm shift is taking place with regard to water conservation and reuse. The barriers to reuse activity are

1. the “yuck” factor
2. lack of practical reuse technologies
3. economic factors
4. commitment to reuse

1. The average consumer recoils at the thought of drinking (or even reusing) “sewer water,” not considering the fact that the drinking water for one community is very likely the wastewater discharged from another community on the same river or lake. It is estimated that in major U.S. rivers, water is reused as many as 20 times by the time that river empties into the sea. Most “groundwater recharge” is treated municipal wastewater injected into groundwater supplies to provide sufficient storage capacity or to serve as a barrier to salt water intrusion from the oceans.
2. The key to water reuse is to have an arsenal of technologies available to remove hazardous or undesirable contaminants efficiently from the water supply. There is no single technology that efficiently removes all classes of contaminants; however, for the past century or so, there have been significant developments in treatment technologies that effectively reduce the concentration of virtually any contaminant to acceptable levels for any water use.

   There is little argument that reducing the huge variety of contaminants that may be encountered in typical wastewater, resulting from the combination of sewage, industrial wastewaters, and perhaps even effluent from surface water runoff, requires a stunning array of advanced technologies. The linchpins are the membrane separation technologies of reverse osmosis, nanofiltration, ultrafiltration, and microfiltration. Whereas reverse osmosis has been around for more than 50 years, the others, most notably nanofiltration, are relatively new developments.

   By separating the treatment process into its key components, pretreatment, primary treatment, and posttreatment, it is now possible to create optimum technology trains that can purify the stream from virtually any source and condition it for virtually any reuse.
3. In addition to treatment technology costs, it is also necessary to factor in the fact that raw water costs are steadily increasing and will continue to do so, reflecting the diminishing supply and costs of meeting new regulations.
4. It is estimated that as of the year 2000, there were more than 10,000 water reuse systems installed in the United States, almost all of this recovered water was used to irrigate agricultural fields or residential and commercial landscaping. In California alone, it is estimated that 120 billion gallons per year are reused.

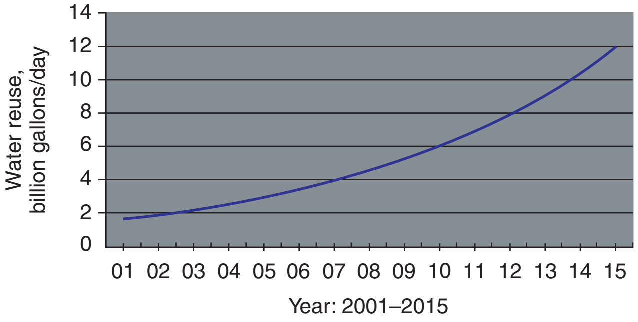

Figure 1. Projected water reuse in 21st century.

The rate of water reuse in the United States is expected to increase markedly over the next decade, as indicated by Fig. 1.

SPECIFIC TECHNOLOGIES

To understand the technologies most applicable to water reuse, it is necessary to understand the contaminants prevalent in water supplies. Contaminants can be categorized by their physical and chemical properties. Table 1 provides this classification.

Suspended Solids

Removing suspended solids from water supplies is probably the oldest water treatment procedure. Throughout history, humankind has used everything from containers of sand to cloth to charcoal to "clarify" water to make it look and taste better. The chronology of water treatment technology development also underscores the improvements to suspended solids removal processes; the latest is microfiltration.

Dissolved Organics

Removing dissolved organic contaminants requires the greatest variety of technologies, reflecting the diversity of dissolved organic chemicals. For most of these contaminants, there are several choices of technologies to effect removal. Some may involve adding chemicals, such as alum, powdered activated carbon, or an acid; other technologies may include physical separation as with a coalescer or ultrafiltration technology.

Dissolved Ionics (salts)

These are contaminants that have ionic charges and are almost all inorganic chemicals. The somewhat limited choice of removal technologies consists of membrane technologies of reverse osmosis, nanofiltration, and electrodialysis; adsorptive resin technology known as ion exchange and the hybrid of electrodialysis and ion exchange known as electrodeionization. Distillation is the oldest technology, mirroring the natural water cycle, but, because of its high energy cost, is now used only in specialized applications.

Table 1. Chemical Properties of Contaminants

Class	Typical Example
Suspended solids	Dirt, clay, colloidal materials
Dissolved organics	Trihalomethanes, synthetic organic chemicals, humic acids, fulvic acids
Dissolved ionics (salts)	Heavy metals, silica, arsenic, nitrate
Microorganisms	Bacteria, viruses, protozoan cysts, fungi, algae
Gases	Hydrogen sulfide, methane, radon

Microorganisms

Microorganism contaminants in most water supplies are from one or more of the following categories:

bacteria
viruses
protozoan cysts
fungi
algae

There are a number of disinfection technologies that inactivate or remove microorganisms. These include chemical (chlorine compounds and ozone). Certain heavy metals in solution inactivate microorganisms. The most common of these are silver for bacteria reduction and copper for algae inactivation. The most prevalent nonchemical technology is ultraviolet irradiation, although heat is still used occasionally in specialized applications, such as preparation of "water for injection" in the pharmaceutical industry. Many disinfectants are effective on only certain classes or types of microorganisms or under very specific conditions.

The most troublesome class of microorganisms is bacteria. Because bacteria are viable and grow under virtually any condition, they are impossible to eliminate completely. In most applications, the goal is to minimize bacterial growth so as not to interfere with the water use.

CONCLUSION

Water reuse is not an abstract concept; it is both a reality and a necessity. For the reasons cited, the requirements and opportunities for water reuse will continue to grow at an increasingly rapid rate.

ROOF DRAINAGE HYDRAULICS

Scott Arthur
Grant Wright
Heriot-Watt University
Edinburgh, Scotland, United Kingdom

INTRODUCTION

Over the past decade, urban drainage systems have moved toward what are now commonly known as "sustainable urban drainage systems" (SUDS) or "best management practice" (BMPs). Fundamental to the implementation of these systems is addressing both runoff quantity and quality at a local level in a manner which may also have the potential to offer benefits to stakeholders. This has led to a change in the way new developments now look and interact within catchments. However, despite the availability of such tools to reduce, attenuate, and treat urban runoff, substantial areas of the urban environment are still 100% impermeable and drain rapidly, namely, roof surfaces. Normally, roof drainage systems do not always receive the attention they deserve in design, construction, and maintenance. Although the cost of a system is usually only a small proportion of a building's total cost, it can be far outweighed by the costs of the damage and disruption resulting from a failure of the system to provide the degree of protection required.

There are basically two different types of roof drainage system; conventional and siphonic (refer to Fig. 1). Conventional systems operate at atmospheric pressure, and the driving head is thus limited to the gutter flow depths. Consequently, conventional roof drainage systems normally require a considerable number of relatively large diameter vertical downpipes, all of which have to connect to some form of underground collection network before discharging to a surface drain. In contrast, siphonic roof drainage systems are designed to run full bore, resulting in subatmospheric pressures, higher driving heads, and higher flow velocities. Turbulent gutter conditions mean that there will always be a small percentage of entrained air within the system (typically 5%). Hence, siphonic systems normally require far fewer downpipes, and the depressurized conditions also mean that much of the collection pipework can be routed at high level, thus reducing the extent of any underground pipework.

Both types of drainage system comprise three basic interacting components:

- the roof surface
- the rainwater collection gutters (including outlets)
- the system pipework

Each of these components can alter the runoff hydrograph substantially as it is routed through the system. This text focuses on the role and performance of each of these components. As the principles of siphonic drainage are generally less well understood and certainly less well documented, particular emphasis placed on the performance of siphonic roof drainage systems.

ROOF SURFACE

The design of the roof surface is usually within the remit of the architect rather than the drainage designer. Notionally, there are three types of roof surfaces:

Flat Roofs

Flat roofs are normally associated with domestic properties in climates with low rainfall and with industrial buildings in developed countries. Such roofs are seldom truly "flat" but simply fall below the minimum gradient associated with sloped roofs in the jurisdiction under consideration; for example, in the United Kingdom, a flat roof is one whose gradient is less than 10° (1). Minimum gradients are usually specified to avoid any unwanted ponding (BS EN 6229:2003 specifies a 1 in 80 minimum gradient) and to help prevent the development of any adverse gradient due to differential settlement (2).

Although flat roofs can be problematic if not maintained properly, they are often preferred; they reduce the amount of dead space within the building and they attenuate flows more than sloped surfaces.

Sloped Roofs

Most residential and many commercial properties have sloped roofs. Such roofs are generally favored because their ability to drain naturally means that there is less risk of leakage. In temperate climates, their specification also means that snow loading is less of an issue. Once a rainfall is underway, the rate at which the runoff flows across a roof is a function of roof slope and roughness. Where rainfall data are available, runoff rates from roof surfaces may be readily assessed using kinematic wave theory (3).

Green/Brown Roofs (Sloped or Flat)

The oldest type of permanent roof is a green roof. These involve planting roof areas to attenuate and/or dissipate rainfall and can take the form of a rooftop garden with trees and shrubs (termed intensive) or a lightweight carpet of growth media and flora (termed extensive). The latter technology is already employed widely (e.g., the Rolls Royce plant at Goodwood; purportedly Europe's largest green roof). Many of these applications tend to focus on the aesthetic benefits such systems offer to high profile developments and are often installed to "green"

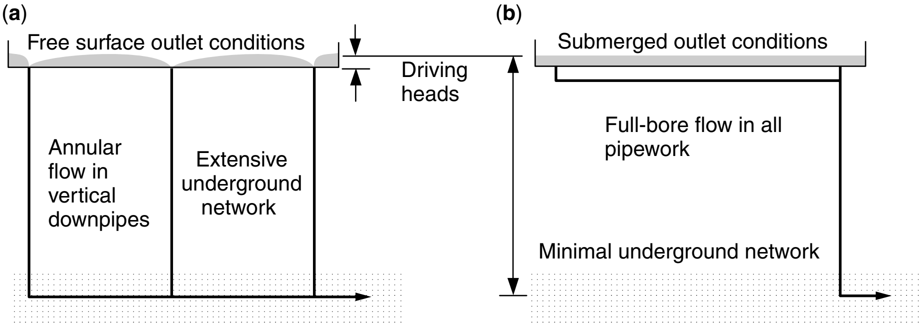

Figure 1. Schematics of a typical conventional (**a**) and (**b**) siphonic roof drainage system (at normal design condition).

a development and thus help secure planning consent in sensitive areas (4). However, as well as being aesthetically pleasing and hydraulically beneficial, green roofs may also offer thermal insulation (5), reduce the heat island effect, the phenomenon whereby absorption of solar radiation by urban surfaces causes a marked increase in ambient air temperature (6), provide acoustic damping, and extend the service life of the roof membrane (7–10).

Green roof systems are used extensively in Germany and to a lesser extent in North America, but again their specification is primarily due to a desire for a reduced aesthetic impact associated with a particular development. Germany probably has the most experience to date, a direct result of their use in the 1800s as a low fire risk alternative to tarred roofs in deprived urban areas (11). Currently, German research is focused predominantly on planting issues, and there is only a limited understanding of how the systems may be used to mitigate the impact of urban runoff. One research project, which ran from 1987–1989 in Neubrandenburg (8), found that an installed green roof with 70 mm of substrate could reduce annual runoff from a roof by 60–80%. Work in Vancouver (Canada), based on an uncalibrated computer model, suggests that for catchments where the roof area comprises 70% of the total surface, installing an extensive system could reduce total runoff to approximately 60% over 12 months (12). The same model was also used to assess specific synthetic rainfall; these results indicated that the catchment experienced increased runoff during longer rainfalls.

Neither of these studies detail how green roofs could be expected to perform during a particular rainfall or where efficiencies may be gained in the design of collection pipework. Limited testing in the United States (13), where green roofs are often irrigated, has indicated that runoff can be reduced by 65% during a single rain. The most authoritative design guidance for green roofs in the United States is produced by The New Jersey Department of Environmental Protection (14). This is focused on lightweight structures and gives guidance on how to ensure "rapid draining" where the rainfall return period exceeds 2 years.

Rainfall return periods are normally set within the context of failure probability and consequence. Conventional systems are usually designed assuming 100% runoff for a 2-minute storm; the 2-minute duration is selected because it is the typical time of concentration for conventional systems. Although advice is given in codes for setting higher runoff rates, there is little guidance on setting runoff rates below 100%. These observations mean that inadequacies are encountered if conventional codes are used to design green roofs:

- Runoff *coefficients* should be expected to be below that used for conventional roofs; 100% is used by BS EN 12056-3:2000 and 98.7% was recorded by Pratt and Parkar (15).
- Peak runoff *rates* are reduced; even where there is no infiltration, the surface roughness has a significant impact.
- Time of concentration is expected to be greater than 2 minutes; particularly relevant when designing collection pipework for large roof areas for public sector, commercial, and industrial properties.
- As with other elements of urban drainage design, it is not efficient for a complex system such as a green roof to be matched to a single rainfall. It is probable that the duration of runoff hydrographs will be orders of magnitude longer compared with conventional systems, and runoff interactions between independent rainfalls are probable; this may make a time-series approach more appropriate.

RAINWATER COLLECTION GUTTERS

The basic requirement for rainwater collection gutters is that they have sufficient flow capacity to accommodate flows from the design storm (16). Although it is common practice to install gutters at a slight gradient to prevent ponding, the nature of the construction industry and the process of settlement means that it is normal to assume that gutters laid at slack gradients are actually flat; for example, BS EN 12056-3:2000 stipulates that gutters at gradients less than 0.3% shall be treated as flat (17). In a level gutter, the water surface profile will slope toward the outlet, and it is the difference in hydrostatic pressure along the gutter that gives the incoming water the required momentum to flow toward the outlet (18).

Gutter Outlet Depths

Key to ensuring whether or not collection gutters have sufficient capacity are the conditions that occur at the gutter outlets. As well as affecting the flow rates entering the drainage system pipework, the outlet depths also affect upstream gutter depths (via the backwater surface profile). Hence, although the depth at a gutter outlet may not cause any particular problems, the greater depths at the upstream end of the gutter may result in overtopping.

Extensive experimental studies in the 1980s determined that the flow conditions in the vicinity of a gutter outlet in a conventional roof drainage system could be categorized as either "weir" type or "orifice" type, depending on the depth of water relative to the size of the outlet (19). At depths below that equivalent to half of the outlet diameter, the flow conditions are "weir" type, and outlet conditions are calculated using an appropriate sharp-edged weir equation (18). At higher flow depths, the flow effectively "chokes," and the flow regime changes to "orifice" type; the outlet conditions are calculated by an appropriate sharp-edged orifice equation (18). Although conventional roof drainage systems are usually designed to ensure free discharge at gutter outlets, design restrictions may mean that the outlets cannot discharge freely; in such circumstances, additional gutter capacity (storage) is normally required to accommodate the resulting higher flow depths.

In siphonic roof drainage systems, the outlets are designed to become submerged to allow full-bore flow to develop and be sustained; if this is the case, the determination of outlet depth is complicated as the gutter conditions depend on downstream conditions (within the connected pipework) as well as gutter inflows. Recent experimental work has also indicated that conventional roof drainage systems incorporating “nonstandard” gutter sections, whose base width and height are significantly greater than the diameter of the outlet, can result in the development of full-bore flow in the vertical downpipe and siphonic action (20); for a given gutter section, the onset and extent of such conditions depend on the diameter of the downpipe. Similar phenomena have also been observed in “standard” gutter sections (semicircular and elliptical); in these cases, limited siphonic action occurs for only a short distance below the outlet (18).

Flow Division within Gutters

In terms of flow division between multiple outlets in a gutter under free discharge, it can be seen from Fig. 2a that the flow splits evenly in any given gutter section (between two outlets or between an end wall and an outlet), whether or not the gutter inflow is uniform or nonuniform. Figure 2b, c indicates the effect of outlet placement within a gutter; evenly spaced outlets require far less gutter capacity than those placed at gutter extremities.

Where outlets are not freely discharging, the flow division between multiple outlets in a gutter may not be as described, as the individual gutter sections may “hydraulically merge” to form one continuous channel and/or downstream system conditions may become significant. For example, the pipework in a siphonic system runs full bore when operating at or near its design point, and the flow division between outlets depends on the relative losses for each branch of the system.

Backwater Profiles

The water surface profile in gutters can only be assessed realistically by applying the momentum equation for channels with lateral input. In many cases, the low velocities associated with gutter flows mean that gutter friction losses are minor and may be ignored (18). If a gutter outlet allows free discharge and frictional effects are neglected, the backwater profile may be determined by applying Equation 1 to determine the horizontal distance (ΔL) between any given upstream depth (h_1) and downstream depth (h_2).

$$\Delta L = \int_{h_1}^{h_2} \left[\frac{\left(1 - \dfrac{Q^2 T}{g A^3}\right)}{\left(S_o - \dfrac{Q^2}{A^2 m C^2}\right)} \right] dh \qquad (1)$$

where Q = flow rate (m^3/s)
T = surface width (m)
g = gravitational constant ($\mathrm{m/s}^2$)
A = flow area (m^2)
S_o = bed slope (-)
m = hydraulic mean depth (m)
C = Chézy coefficient (-)

This equation can be modified if frictional effects are significant (very long gutter lengths or very high flow velocities) or if the gutter outlet is not freely discharging.

Current Design Methods

The foregoing discussion has highlighted the key elements that should be considered when designing a rainwater gutter. However, without recourse to some form of numerical modeling, it is not feasible to calculate backwater surface profiles, and hence gutter capacities, for roof drainage systems; this is particularly the case for large commercial or manufacturing developments which may incorporate many kilometers of different types of guttering. Consequently, current gutter design methods for gutters installed in conventional drainage systems are based primarily on empirical relationships (19) and the assumption of free discharge at the outlet. For example, BS EN 12056-3:2000 specifies that the design capacity of a “short,” level, semicircular gutter located on the eaves of

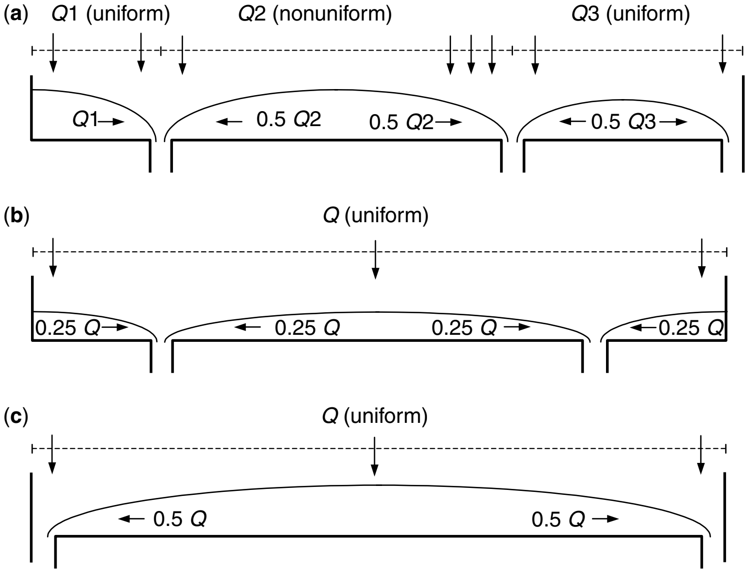

Figure 2. Effect of outlet positioning on flow division in gutters. (**a**) Flow division between multiple outlets in a gutter. (**b**) Flow division between evenly spaced outlets in a gutter. (**c**) Flow division between outlets positioned at gutter extremities.

a building (with outlets capable of allowing free discharge) is given by (17)

$$Q_{\mathrm{L}} = 0.9 \times Q_{\mathrm{N}} = 0.9 \times 2.78 \times 10^{5} \times A_{\mathrm{E}}^{1.25} \qquad (2)$$

where Q_{N} = notional gutter design capacity (L/s)
A_{E} = gutter cross-sectional area (mm^2)

Clearly not all gutters can be designed by application of Equation 2. For example, BS EN 12056-3:2000 (17) contains clauses to account for many eventualities, including

- location of gutter on building that may result in varying consequences of failure; eaves gutter, valley gutter, parapet gutter
- differently shaped gutter sections
- "hydraulically long" gutters (where frictional effects may be significant)
- gutters laid at a significant gradient
- changes in gutter alignment (bends, offsets, etc.)
- additional system elements, such as strainers or rainwater hoppers
- restricted flow at outlets
- gutters installed in siphonic roof drainage systems

In addition to the type of clauses listed above, BS EN 12056-3:2000 also allows designers to use data obtained from experimental testing of a particular arrangement (17).

Numerical Models

Numerical models have been developed that can accurately simulate the flow conditions in any type of gutter as a result of either steady or unsteady roof runoff. An example of this is incorporated into the "ROOFNET" model recently developed as part of an academic research project dealing with the effect of climate change on urban drainage (20). This model enables the user to specify data describing the relevant aspects of a particular installation, including details of the prevailing rainfall conditions, details of the roof surfaces to be drained, and details of the actual gutters. A kinematic wave model is then used to route the rainfall over the roof surfaces and into the gutters. A method of characteristics solution of the fundamental equations of one-dimensional flow in open channels is then used to route the runoff along the gutters to the outlets (21), at which point the flow enters the drainage pipework. The model automatically determines the flow conditions at the gutter outlets and, in addition to dealing with free discharge, can also simulate the effect of restricted flow and submerged outlet scenarios. Output includes depths, velocities, and flow rates along the gutter, as well as the location and severity of any gutter overtopping.

At present, models such as those described before are research tools; they are normally developed and used by universities for specific research projects. However, it is envisaged that such models may soon be used as diagnostic design aids, particularly for national code development.

SYSTEM PIPEWORK

The type and extent of pipework incorporated into a roof drainage system depends primarily on whether the system is conventional or siphonic.

Conventional Rainwater Systems

In conventional roof drainage systems, the aboveground pipework generally consists of vertical downpipes, connecting the gutter outlets to some form of underground drainage network, and offset pipes, used where the gutter overhang is significant. Note that an offset pipe is defined as a pipe with an angle less than 10° to the horizontal. The capacity of the system as a whole usually depends on the capacity of the gutter outlets rather than the capacity of the vertical downpipes.

The flow within vertical downpipes is normally free surface; BS EN 12056-3:2000 (17) specifies that downpipes run no more than 33% full; this effectively installs redundant capacity within the system. If the downpipes are sufficiently long (normally greater than 5 meters), annular flow may occur. Similarly, the flow within offset pipes will also normally be free surface; BS EN 12056-3:2000 (17) specifies that offsets run no more than 70% full, indicating the need to install all offsets at a gradient. The design of the pipework can either be undertaken using the design tables in BS EN 12056-3:2000 or by applying the Wyly–Eaton equation for vertical downpipes (22) and the Colebrook–White equation for offset pipes (23).

Siphonic Roof Drainage Systems

In contrast to conventional systems, siphonic installations depend on purging air from the system (priming) and subsequently establishing full-bore flow within the pipework connecting the outlets in the roof gutters to the downstream surface water sewer network (at ground level).

Current design practice assumes that, for a specified design storm, a siphonic system fills and primes rapidly with 100% water (24). This assumption allows siphonic systems to be designed using steady-state hydraulic theory. The steady flow energy equation is normally employed (25), and the elevation difference between the gutter outlets and the point of discharge is equated to the head losses in the system. Although this approach neglects the small quantities of entrained air that always enter a siphonic roof drainage system, it reportedly yields operational characteristics similar to those observed in laboratory test rigs in the fully primed state (25,26).

However, steady-state design methods are not applicable when a siphonic system is exposed to rainfall below the design criteria or with time-varying rainfall intensity. In the former case, the flow may contain substantial quantities of entrained air and exhibit pulsing or cyclical phases, a result of greatly varying gutter water levels and an indication of truly unsteady, transient flow. Such problems are exacerbated when the system incorporates more than one outlet connected to a single downpipe (multi-outlet system), as the breaking of full-bore conditions at one of the outlets (due to low gutter depths and air entry) is transmitted throughout the system and, irrespective of the gutter depths above the remaining outlet(s), results in cessation of fully siphonic conditions. As subdesign events are the norm, it is clear that current design methods may not be suitable for assessing the day-to-day performance characteristics of siphonic roof drainage systems. This is a major disadvantage, as it is during these events that the majority of operational problems tend to occur, for example, noise and vibration.

Despite any defects that current design methods may have, thousands of systems have been installed worldwide with very few reported failures. Where failures have occurred, they have invariably been the result of one or more of the following:

1. a lack of understanding of operational characteristics
2. poor material specification
3. installation defects
4. a poor maintenance program

In response to these perceived shortcomings, a series of research projects has recently been undertaken to augment the understanding of siphonic roof drainage systems and to develop numerical models for use as diagnostic design aids (27). The remainder of this section will present a selection of the salient points arising from this work.

In contrast to the assumption made in current design methods, the priming of a typical siphonic system actually found was as follows (refer to Fig. 3):

1. Flow conditions throughout the system are initially free surface (Phase 1).
2. Full-bore flow forms at some point within the horizontal pipework (Phase 1).
3. Full-bore flow conditions propagate downstream toward the vertical downpipe and upstream toward the gutter outlets (Phase 1).
4. Full-bore flow conditions reach the vertical downpipe, the downpipe starts to fill, and the system starts to depressurize (Phase 2).
5. Once the conditions throughout the downpipe are full bore, any remaining air pockets are purged from the system (Phase 2).
6. Full siphonic action occurs (Phase 3) and continues until the gutter depth(s) falls below the level at which air can enter the system.

The data shown in Fig. 4a illustrate the type of unsteady flow conditions that occur when a siphonic system is exposed to rainfall below the design point and the gutter flow depths are insufficient to sustain full siphonic action. The data shown in Fig. 4b illustrate the type of unsteady flow conditions that occur when an installed siphonic system is exposed to a “real” rainfall and the rainfall intensity varies with time.

Figure 5 shows an example of the output from one of the numerical models that has recently been developed (SIPHONET). As can be seen, the model can accurately simulate the priming of a siphonic system (0–32 s) as well as steady siphonic conditions (32–62 s). These data also illustrate that the model can simulate complex operating conditions, such as the rise in system pressure when the depth in gutter 1 drops below that necessary for full-bore flow, hence allowing air to enter the system and break the siphon (at approximately 62 s).

CONCLUSION

The text has illustrated how roof drainage systems are a key, but often overlooked, element of urban drainage infrastructure. It has also been shown that their design is a complex process, which relies heavily on gutter outlet performance. The following conclusions may be drawn with respect to the operation of roof drainage systems:

1. Their operation depends on three interacting components: the roof surface, the collection gutter, and the collection pipework.
2. Green or brown roofs provide an opportunity to reduce the flow from roof surfaces, improve urban aesthetics, and increase biodiversity.
3. Outlet conditions are key to understanding how a system performs.

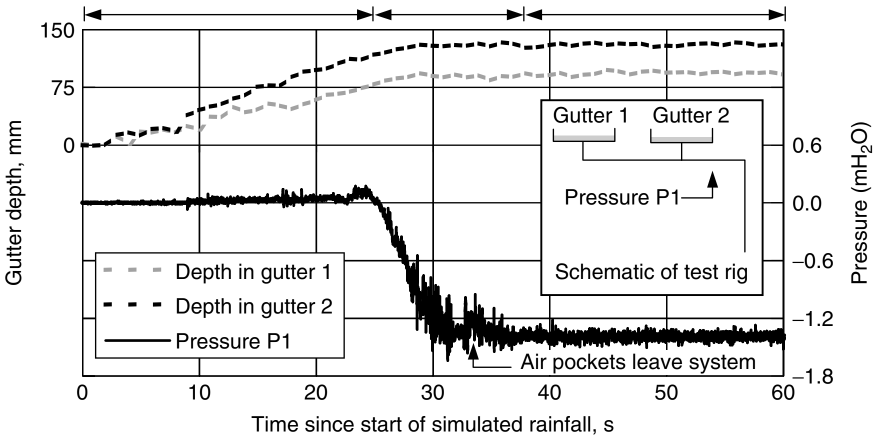

Figure 3. Priming of a laboratory siphonic drainage test rig (28).

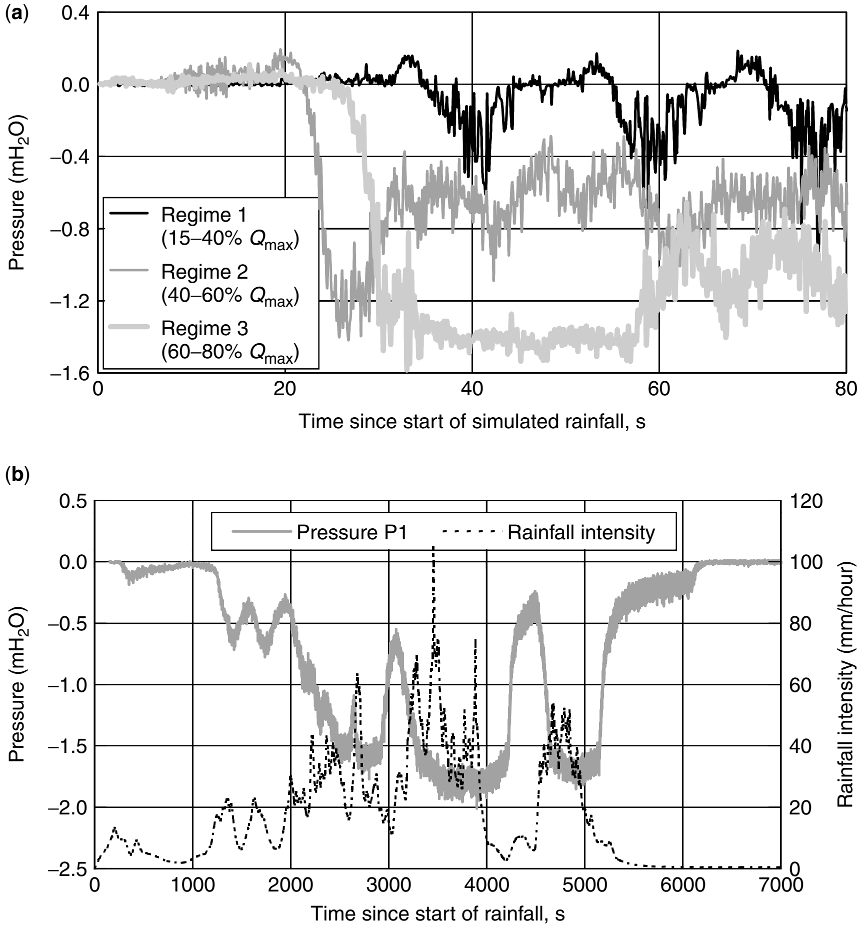

Figure 4. (**a**) Measured system pressures for subdesign rainfall within a laboratory siphonic drainage test rig (28). Note that data refer to the pressure P1, as indicated in Fig. 3. (**b**) Subdesign rainfall within an installed siphonic drainage system (28).

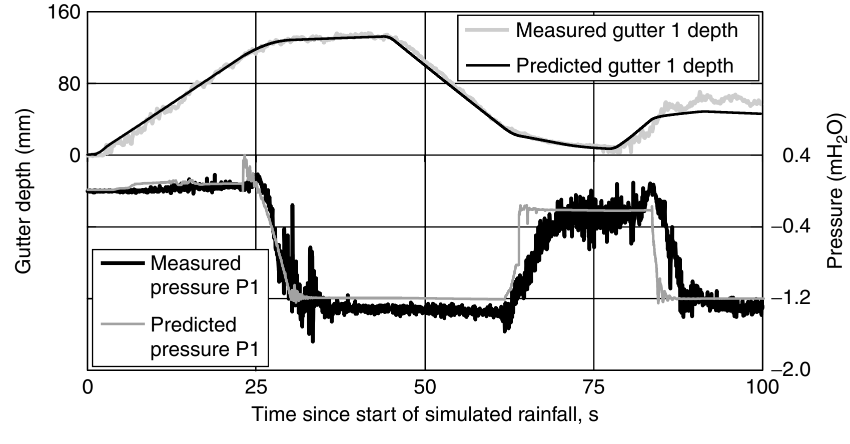

Figure 5. Measured and predicted system conditions within a laboratory siphonic drainage test rig: no inflow into gutter 1 between 62 and 82 s (28). Note that data refer to the system shown in Fig. 3.

4. Siphonic roof drainage systems present a more efficient way to drain large roof surfaces.
5. The design of siphonic roof drainage systems should consider subdesign rainfall and operational problems, such as blocked outlets.

THE FUTURE

Although green roofs are an attractive alternative, it is probable that conventional roof surfaces will continue to dominate domestic installations. However, it is likely that green roofs will experience a step-change in acceptance by the commercial sector once more becomes known about their performance and sustainability. Similarly, the efficiencies offered by siphonic systems means that they will continue to play a significant role in draining large commercial buildings, particularly if numerical models are applied diagnostically to improve performance and reduce costly system failures.

The biggest threat to roof drainage comes from climate change. Existing systems may not simply become more prone to flooding; changes in rainfall patterns may result in long periods of low precipitation, and self-cleansing velocities may be attained less frequently as a result. Furthermore, changes in wind patterns may also increase levels of rooftop debris and hence necessitate enhanced maintenance programs. As concern regarding climate change grows and the sustainability agenda widens, it is possible that harvesting roof runoff may become more widespread. At present, water consumption varies globally between 7 and 300 liters/household/day (L/h/d). In the United Kingdom, average consumption is 145 L/h/d, but only 1–2 liters may actually be consumed by humans, 30% may be used for WC flushing (29). Studies have shown that, when coupled with storage, roof rainwater harvesting has the potential to contribute substantially to domestic water usage in both developing and developed countries (30,31).

SEPTIC TANK SYSTEMS

John E. Moore
Hydrologic Consultant
Denver, Colorado

According to Wilson and Moore (1), a septic tank is an "underground vessel for treating wastewater from a single dwelling or building by a combination of settling and anaerobic digestion. Effluent is usually disposed of by leaching. Settled solids are pumped out periodically and hauled to a treatment facility for disposal." When properly

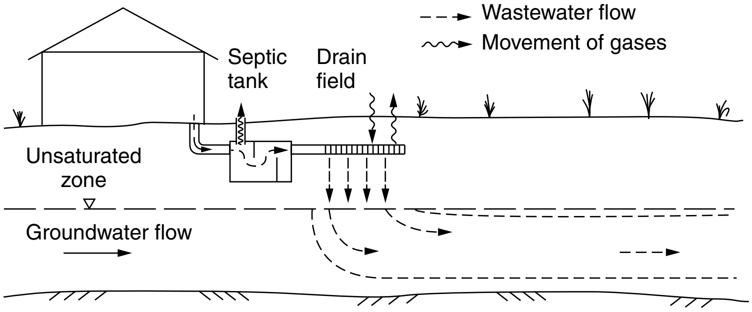

Figure 1. Components of septic tank systems (4).

sited, constructed, and maintained, septic systems can provide a low-cost environmentally responsible method of waste disposal. Improperly sited, constructed, operated, or maintained septic systems can, however, lead to water quality degradation and threats to public health. The basic components of a septic tank system are shown in Figs. 1 and 2. The septic tank is an enclosed receptacle designed to collect wastewater, segregate floatable solids, accumulate, consolidate, and store solids; wastewater treatment is provided by septic tank systems. The tank is the most important component used in these systems (2). The waste enters the tank near the top. There is a pair of baffles in the tank to keep the solids in the tank, preventing them from flowing out of the tank with liquids. Bacteria in the tank break down the solids as much as they can into a liquid form and this with the water leaves the tank on the other side of the baffles. The liquid then flows to a leaching field where the liquid enters the soil and is absorbed. If the bacteria cannot break the solids down, they will build up over time. If these solids are not removed by periodic pumping, the tank will allow solids to be washed out to the leaching field and begin to clog the soil. When the soil is clogged, the system stops working.

Septic systems fail for the following reasons:

1. Faulty design (leaching field that is too small).
2. Faulty installation (plugged lines or uneven grades).
3. Soil conditions (highly permeable soil or relatively impervious soil, less than 6 feet of unsaturated soil cover).
4. High water table less than 6 feet from the land surface.
5. Water overload.
6. Inadequate cleaning of the tank (should be pumped every 2–3 years).
7. Highly permeable soil.

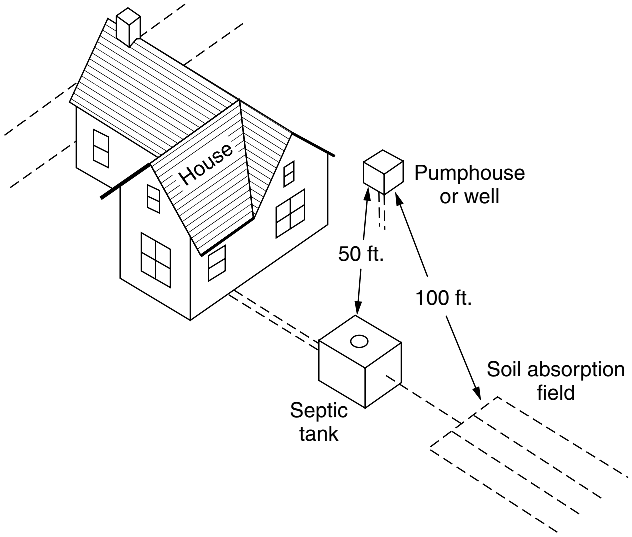

Figure 2. Setback distances (4).

It has been estimated that 25% of the U.S. population uses septic systems for treatment and disposal of their household sewage. Septic system technology is undergoing dramatic changes in efficiency and reduced contamination (2). The American Society of Testing and Material has prepared three standards for the treatment and disposal of on-site waste (D 5879-95, D 5921-96, D5925-96).

Bacterial and viral contamination from septic systems is the most common cause of drinking water contamination in the United States. The liquid effluent from septic systems follows the same path as precipitation moving into an unsaturated zone and aquifer. When the effluent reaches the water table, it moves downgradient to the point of discharge (lake, stream, wetland, and well). The location of the septic system in relation to the slope of the land surface is important because septic tank discharge follows the slope of the land surface. Wells downslope from septic tanks are subject to contamination (3).

The septic tank effluent can contain bacteria and also toxic materials and other contaminants. Some of the contaminants adhere to the soil and aquifer material or travel with the water.

Many septic systems are found in small rural homes sites and are commonly located on small narrow lots along a feeder highway. An increasing number of states are zoning suburban areas to limit the density of houses using septic tanks (4). Community sewer systems are used in some areas to substitute for septic systems.

Some banks require the prospective seller of rural property to provide proof of a bacteria-free water supply. Some sellers chlorinate the water to destroy the bacteria in the well. The bacterial contamination is in the aquifer, so this treatment lasts only a short time (5). The homeowner should have the well water analyzed at least once year for bacteria.

A buyer of rural property should determine the location of the well and the septic system. The buyer should also determine the age, maintenance, distance to the drinking water supply well, and depth to water at the septic system site. A wet area, lush vegetation over the leaching field, or odor of sewage is cause for further investigation. A water sample from the well at a septic system site should be obtained and analyzed for fecal coliform bacteria.

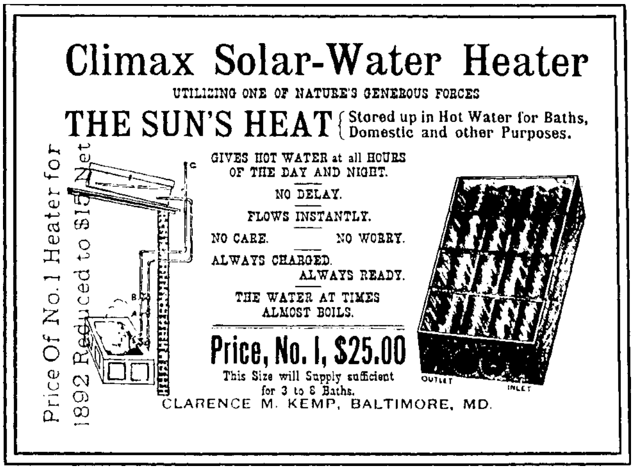
DOMESTIC SOLAR WATER HEATERS

Mervyn Smyth
Centre for Sustainable Technologies
Newtownabbey, United Kingdom

INTRODUCTION

Solar water heating systems convert solar radiation into useable thermal energy in the form of hot water. Domestic solar water heaters can provide households with a large proportion of their hot water needs while reducing the amount of conventional fuel used and hence reducing home energy costs. The amount of hot water produced will depend on the type and size of the system, the climate, and location for solar access. Over the years, a variety of system designs have been developed and tested to meet specific consumer needs and environmental conditions. The following article is a brief description of the many types of system in common use today.

The first solar water heaters consisted of exposed tanks of water left out to warm in the sun. Used on a few farms and ranches in the Southwestern United States in the late 1800s, they were reportedly capable of producing water hot enough for showering by the late afternoon on clear days (1). The first solar water heater, manufactured commercially under the trade name Climax Solar-Water Heater, was patented in 1891 (2). Figure 1 illustrates a reproduction of an advertisement for the Climax Solar-Water Heater. This water heater could be used from April to October in the State of Maryland in the eastern United States. It claimed to produce water hotter than 38 °C on sunny days even during early spring and in late autumn when daytime temperatures sometimes approached freezing.



Climax Solar-Water Heater

UTILIZING ONE OF NATURE'S GENEROUS FORCES

THE SUN'S HEAT { Stored up in Hot Water for Baths, Domestic and other Purposes.

GIVES HOT WATER at all HOURS OF THE DAY AND NIGHT.

NO DELAY.

FLOWS INSTANTLY.

NO CARE. NO WORRY.

ALWAYS CHARGED. ALWAYS READY.

THE WATER AT TIMES ALMOST BOILS.

Price, No. 1, $25.00

This Size will Supply sufficient for 3 to 6 Baths.

Price Of No.1 Heater for 1892 Reduced to $15 Net

Figure 1. Advertisement for the climax solar-water heater, 1892 (1).

Domestic solar water heaters can be categorized as being either active or passive and can be further grouped according to the configuration of the main solar water heating components: integral or distributed. Integrated systems combine the collector and storage functions in a single unit, whereas distributed systems have a separate solar collector and hot water store connected by a piping network. Distributed systems can be either active or passive. In active systems, a pump circulates the transfer fluid between the collector and the store. Integrated systems are almost always passive as they do not require external power.

THE INTEGRATED COLLECTOR/STORAGE SOLAR WATER HEATER

The most basic of solar water heaters is the integrated collector/storage solar water heating (ICSSWH) system or the integral passive solar water heater (IPSWH), commonly referred to as breadbox or batch water heaters. Kemp's early Climax Solar-Water Heater was an integrated system. A simplified diagram of a typical ICS solar water heating installation is shown in Fig. 2.

In its simplest form, the ICSSWH is a water tank painted black to absorb insolation (*in*cident *sol*ar radi*ation*). Variations consist of one or more tanks, painted black or coated with a selective absorbing surface, within a well-insulated box, possibly with reflectors and covered with single, double, or even triple layers of glass, plastic, or a combination of the two. Because of its simplicity, an integrated collector/storage system is easier to construct and install, which reduces maintenance and capital costs. In most climates, the large thermal mass of the store provides inherent resistance to freezing. However, the integrated unit has a significant problem because of its unique mode of operation.

The earliest systems suffered substantially from heat losses to ambient, especially at night and at noncollection periods, which meant no matter how effective the unit was in collecting solar energy, unless the hot water was fully withdrawn at the end of the collection period, losses

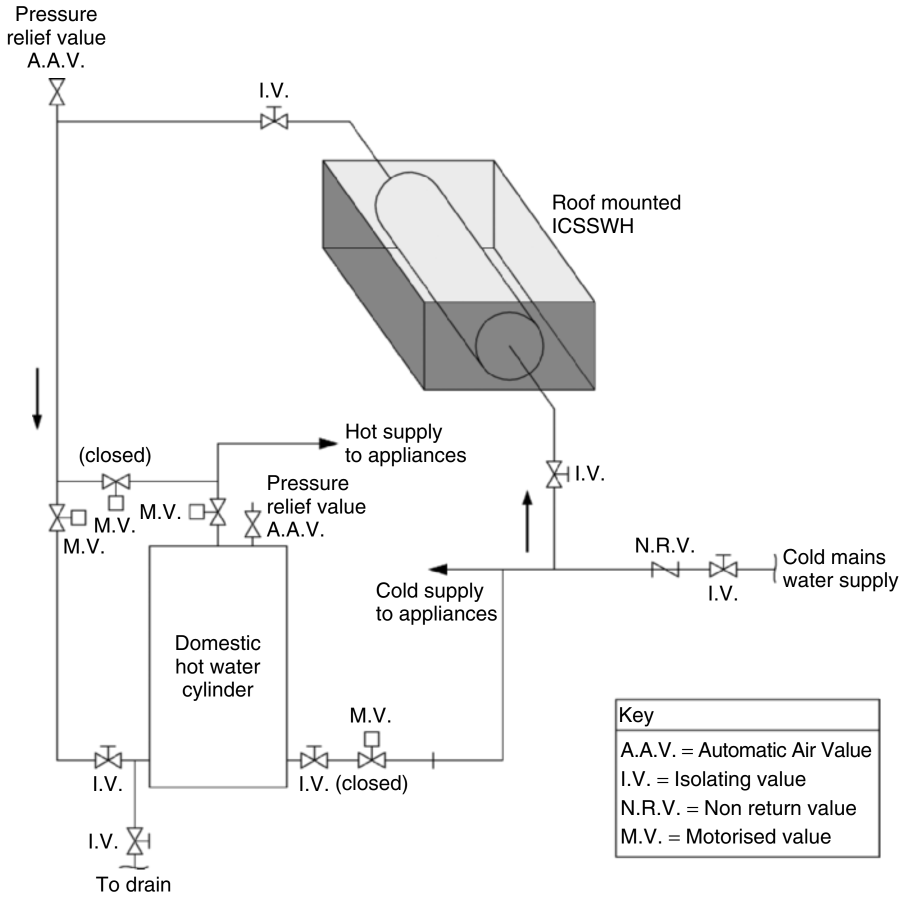

Figure 2. A simplified diagram of a typical roof-mounted ICS solar water heating installation.

to ambient led to only lukewarm water being available early the next day. This process reduced the overall solar fraction, which renders it less viable economically. Indeed this deficiency in the late nineteenth century led to the prominence of thermosyphon solar water heaters with diurnal heat storage to the detriment of the ICSSWH system. To overcome excessive heat loss and be in a position to compete with the more established distributed solar water heater systems, the ICSSWH design has had to evolve and incorporate new and novel methods of improving performance.

DISTRIBUTED SOLAR WATER HEATERS

Distributed systems consist of a separate solar collector and water store, with pipes connecting the collector(s) to and from store(s). As previously mentioned, these systems can be either active or passive, with the active system using an electric pump, and the passive system relying on buoyancy forces in the form of thermosiphonic action. Active systems also require more valves and control systems, which tend to make them more expensive than passive systems but generally more efficient. Figure 3 shows a simplified diagram of a typical roof-mounted distributed (flat-plate) solar water heating installation. Active systems are often easier to retrofit than are passive systems because their storage vessels do not need to be installed above or close to the collectors. In addition, a photovoltaic panel could power the pump, which results in stand-alone, proportional pump operation with reduced running costs.

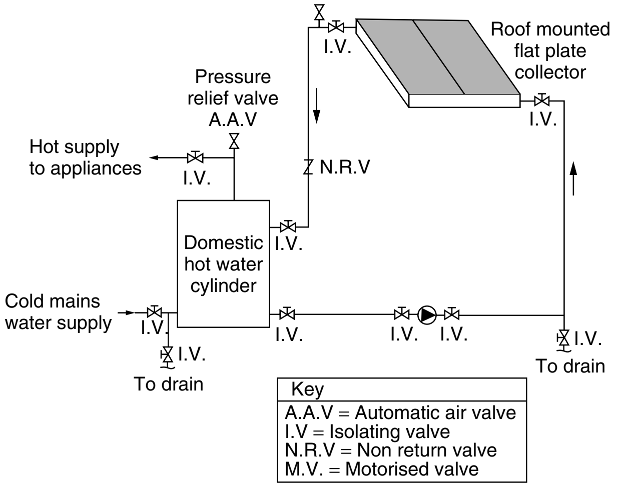

Figure 3. A simplified diagram of a typical roof-mounted distributed (flat-plate) solar water heating installation.

Distributed solar water heaters can also be characterized as being direct (open loop) or indirect (closed loop). A direct system circulates incoming mains water through the collector and into the tank, whereas an indirect system transfers collected thermal energy via a heat exchanger to the domestic water. Indirect systems usually contain an aqueous antifreeze solution that flows through the heat exchanger immersed in the hot water store to provide protection from freezing. This process, however, results in reduced collection efficiencies over the direct system through lower specific heat capacities and losses during the heat exchange process.

Active Direct Systems

Active direct systems use pumps to circulate incoming mains water through the collector and back into the tank. This design is efficient and reduces operating costs but is not appropriate where water is hard or acidic because of scale buildup and corrosion. However, direct active systems are popular in regions that do not experience freezing temperatures (Fig. 4).

Active Indirect Systems

Active indirect systems pump the heat-transfer fluid (usually a glycol-water antifreeze mixture) through the collector and a heat exchanger transfers the heat from the fluid to the water that is stored in the tank. Heat exchangers can be double-walled vessels or have twin coil arrangements. Indirect glycol systems are popular in areas where temperatures regularly fall below zero because they offer good protection from freezing. However, antifreeze systems are more expensive to purchase and install and require regular checking and maintenance.

Indirect drainback systems do not use antifreeze mixtures, but they use pumped water as the heat-transfer fluid in the collector loop. When freezing conditions prevail or the system is not in use, the pump is switched off and the water in the collector is drained out, thus providing protection from freezing. The collector installation and plumbing arrangement must be carefully positioned to allow complete drainage and the pump must have sufficient head pressure to pump the water up to the collector each time the pump starts.

Thermosiphon Systems

A thermosiphon system relies on warm water rising, a phenomenon known as natural convection or buoyancy forces, to circulate water to and from the collector and tank. In this type of installation, the tank must be located above the collector. As water in the collector heats, it becomes less dense and naturally rises into the tank above. Meanwhile, cooler water in the tank flows downward into the collector, thus causing circulation throughout the system. Some forms of thermosiphon solar water heaters can be described as being compact. Compact systems are close-coupled thermosyphon flat-plate or evacuated-tube collector units fabricated and installed as a single item as opposed to a separate collector, store, and pipework. Thermosiphon systems are much cheaper than are active systems as no pump or controller is required and are ideal where a low-cost solar heater is required such as holiday houses and cabins, or countries where low-cost solar heating is required.

SOLAR WATER HEATING COLLECTORS

Basically three types of domestic solar collector are in common use today: flat-plate, evacuated-tube, and concentrating.

Flat-plate Solar Collector

The flat-plate system consists of a "flat" absorber panel through which water or conducting fluid passes. The panel may be of formed channels in a sandwich format or may be pipes connected to expanded absorber plates. Most

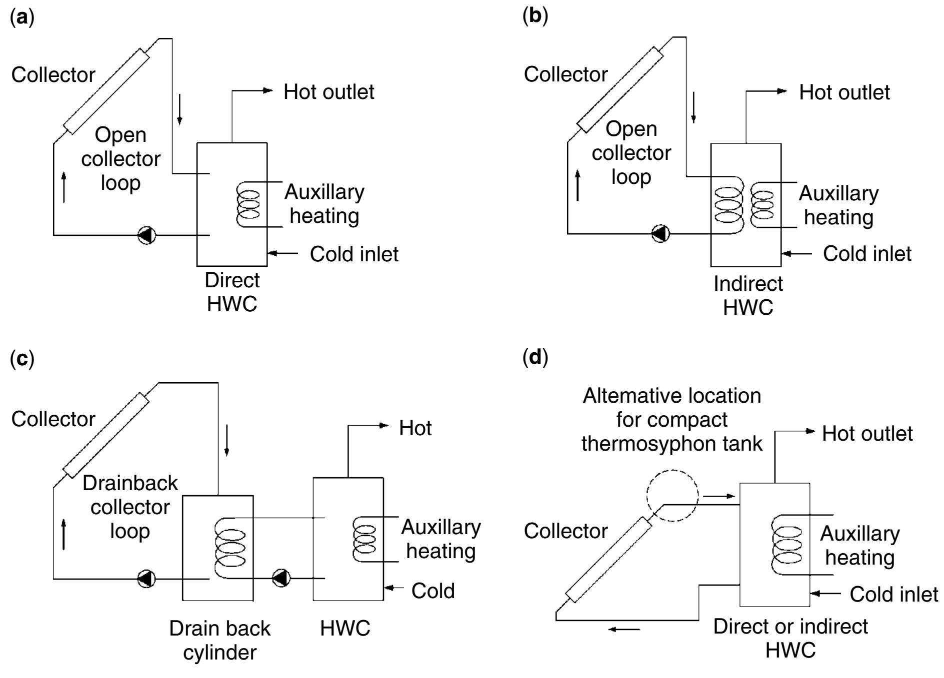

Figure 4. Schematic detail of common distributed solar water heating configurations: (**a**) active direct system, (**b**) active indirect system, (**c**) indirect drainback system, and (**d**) thermosiphon system.

absorbers are covered with a selective coating to improve solar radiation absorption and reduce long-wave radiative heat loss. As the fluid flows adjacent to the heated surface, it is heated. The absorber is mounted in an insulated, weatherproof unit, and the exposed collector aperture is covered with one or more transparent or translucent covers. The make-up of a typical flat-plate solar collector is shown in Fig. 5.

Evacuated-tube Collector

Evacuated-tube collectors are made up of rows of parallel, glass tubes, linked to a common flow (and return) manifold depending on the collector installed. Two types of evacuated-tube collector exist: glass/glass or metal/glass. The glass/glass collector consists of two concentric glass tubes. The inner tube is covered with a selective coating to improve solar radiation absorption and reduce long-wave radiative heat loss. The transparent outer tube forms a space between the two tubes that is evacuated to eliminate conductive and convective heat loss. The metal/glass collector consists of a copper plate attached to a heat pipe or water pipe mounted within a single evacuated glass tube. Again the absorber is coated with a selective coating to improve the collection performance. Figures 6 and 7 illustrate some common evacuated-tube collectors.

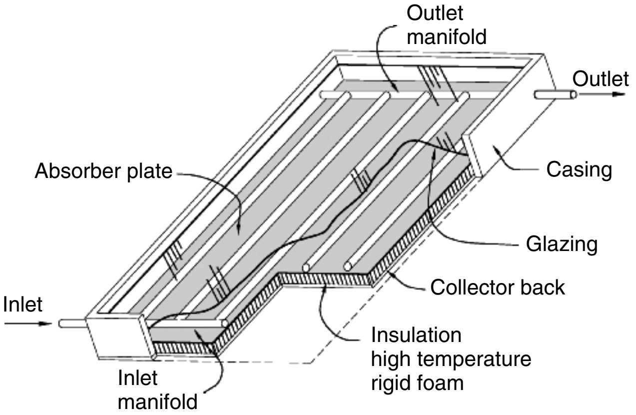

Figure 5. A typical flat-plate solar collector.

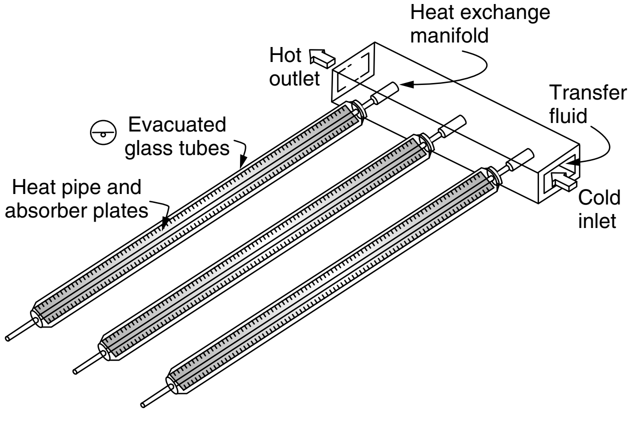

Figure 6. Metal/glass heat pipe evacuated-tube solar collector.

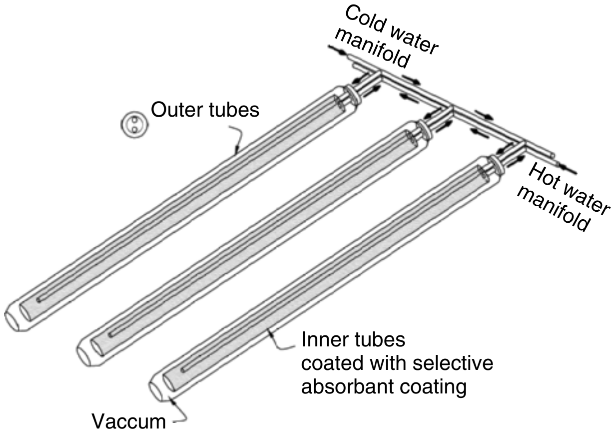

Figure 7. Metal/glass water pipe evacuated-tube solar collector.

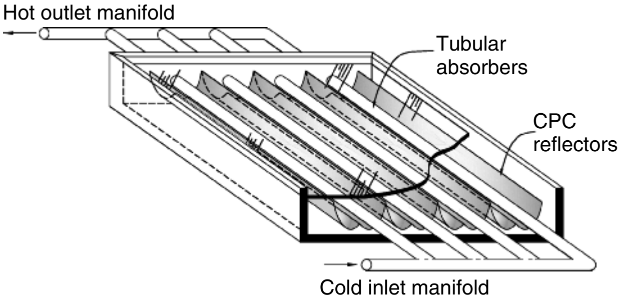

Figure 8. Diagram of a compound parabolic concentrating collector.

Concentrating collector

To increase the insolation on the absorber surface over that incident at the collector aperture, reflectors are employed in solar water heating systems. Concentrating reflectors can obtain higher temperatures on the absorbing surface than can those achievable by a flat absorber, and as the absorbing surface area is reduced relative to that of the aperture, a reduction in the overall heat loss from the system occurs, hence an improved thermal efficiency.

Internal reflectors are contained within the unit enclosure, whereas external reflectors are located outside the sealed casing. Reflecting concentrator designs for low-to-medium concentrations can be flat or curved, line-axis or line-focus (circular, parabolic or compound parabolic) reflectors, symmetrical or asymmetrical. The concentrating collector used for domestic applications usually incorporates a concentrating reflector in the form of parabolic trough or compound parabolic concentrating (CPC) collector, using highly reflective surfaces to concentrate the insolation onto the absorber. Most absorbers are tubular, although not exclusively. Figure 8 illustrates a CPC collector.

HOUSEHOLD DRINKING WATER TREATMENT AND SAFE STORAGE

SUSAN MURCOTT
Massachusetts Institute of Technology
Cambridge, Massachusetts

Household water treatment is the decentralized treatment of drinking water in the home and safe storage is the protection of drinking water in specially designated household storage vessels prior to use. A safe water storage vessel is typically comprised of a container with a narrow mouth to prevent contact with potentially dipped cups or dirty hands, a lid, a spigot to access water and a flat base for easy water extraction. In many cultures and regions, household drinking water treatment and storage has been women's work based on traditional practices stretching back for millennia. For example, an ancient Indian medical text, the *Susruta Samhita*, compiled over several centuries and reaching its present form in about A.D. 300, includes the prescribed water treatment and handling practices as follows:

> Heat contaminated water by boiling on fire, heating in the sun, by dipping hot copper into it seven times, cooling in an earthen vessel and also scenting it with flowers of nagkesara, campaka, utpala, patala, etc. (Book 1, Chapter 45, Verse 12)

Moreover, home storage in various types of containers, including skin bags, ostrich eggs, vessels of wood, ceramic, metal, glass, or stone has been a traditional practice for hundreds or even thousands of years. Thus the twin concepts of household drinking water treatment and safe storage are not new. But there are new developments arising from a global need (Figs. 1–3).

Currently, about 50% of people worldwide are supplied with household connections that provide drinking water on tap in their homes. Sufficient, safe, acceptable, physically accessible, and affordable water for all is a fundamental human right essential to life and dignity. Tapped water for all is the long-term goal, but even among those with tap water today, the drinking water is not always considered safe, in terms of its water quality. In homes with a tapped water supply, household treatment devices typically provide a final "extra" step that begins with a well-protected source and includes a treatment process provided by a centralized water treatment system, administered by a municipal authority or private entity. In these cases, the purpose of the household treatment step is typically to improve the aesthetics of the water (e.g., chlorine odor or taste, hardness) and/or to remove certain harmful contaminants, including possible organic (e.g., benzene, toluene), inorganic (e.g., cadmium, lead), or microbiological (e.g., *Cryptosporidium, Giardia*) substances. These household drinking water

Figure 1. Ceramic filter—Nepal.

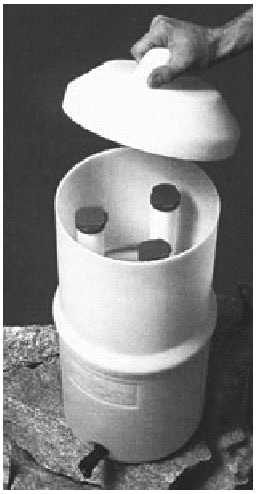

Figure 2. Ceramic candle filter by Katadyne, Switzerland.

Figure 3. Ceramic filter "filtron"—Ghana.

treatment devices take two forms—*point-of-entry* or *point-of-use*—depending on whether the device is installed at the point where the water main enters the home or whether the treatment unit is attached to or placed beside the kitchen faucet (i.e., at the point where drinking water is withdrawn). In such cases, household drinking water treatment in industrialized countries and regions is used to provide an additional barrier of safety to a water supply that has already received treatment upstream or is of known high quality.

Homes lacking a tapped drinking water supply via a household connection or lacking another form of "improved" water supply such as a public standpipe, a borehole, a protected dug well, a protected spring, or rainwater collection are more likely to bear the burden of water-related illnesses:

- 3.4 million deaths are water-related;
- 1.4 million children die annually of diarrhea, making this the third highest cause of illness and the sixth highest cause of mortality globally;
- 1.5–2 billion people are affected by intestinal parasites;
- 1.1 billion people lack access to safe drinking water;
- 2.6 billion people are without access to basic sanitation (1).

These combined conditions can be addressed and an improved quality of life can be realized by applying the same principles that brought about the industrialized world public health miracle of the nineteenth and twentieth centuries—a treated drinking water supply, sanitation, and good hygiene practices—to households globally.

Between 1990 and 2002, 1.1 billion more people worldwide gained access to improved water supplies. Yet that same number—1.1 billion or about one in six people—still lack access to improved water in 2004. Most of these people live in rural areas and urban and peri-urban slums. Their water needs are a focal point of international efforts to provide safe drinking water (2). For these 1.1 billion people, household water treatment and safe storage is not an additional barrier, post-treatment, as it is for those who purchase and use point-of-entry or point-of-use systems, but instead it may be their main barrier in the prevention of water-related illness. And these systems work! "There is now conclusive evidence that simple, acceptable, low-cost interventions at the household and community level are capable of dramatically improving the microbial quality of household stored water and reducing attendant risks of diarrheal disease and death" (3).

Moreover, we know that household drinking water treatment and safe storage, access to sanitation, and hygienic behavior are all interrelated activities. The combination of all these three main interventions will maximize health benefits to all. Household drinking water treatment and safe storage is one essential technology with a special role to play for households lacking a safe water supply. It was with this understanding that the World Health Organization formed the International Network to Promote Household Drinking Water Treatment and Safe Storage, a public–private partnership announced at the Kyoto World Water Forum in March 2003.

While we know that household water treatment and safe storage has been practiced locally and regionally, recognition of the role that household water treatment and safe storage can play globally in securing safe drinking water is a recent development dating to the 1990s. Research and development have been a process of adapting traditional wisdom and best engineering and public health practices, applied in settings that necessitate simple, low maintenance designs, use of local materials, applications under demanding local conditions, social acceptability, and economic sustainability. Research on cost effectiveness indicates that these household water treatment and safe storage practices can avert much of the burden associated with diarrheal disease at low cost(4).

Some of the treatment processes for household drinking water treatment and safe storage currently under investigation and/or in early stages of implementation include (see Figs. 4–6):

Sedimentation
Mechanical and/or biological filtration

Figure 4. Chlorine solution for household disinfection.

Figure 5. Safe water storage container.

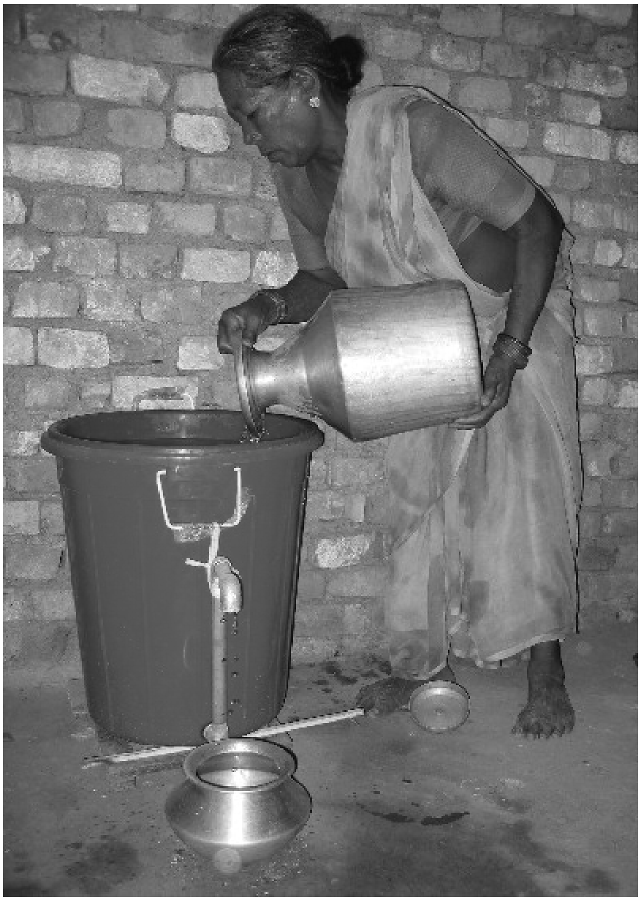

Figure 6. Household arsenic filter (Kanchan arsenic filter—Nepal).

Cloth filters
Ceramic water filters
Intermittent household slow sand filters

Coagulation/flocculation

Metal salts (e.g., alum, ferric chloride, ferric sulfate)
Natural polymers
Mixtures of coagulants/flocculants, weighting agents, calcium hypochlorite

Adsorption

Arsenic remediation household systems
Fluoride remediation household systems

Ion exchange processes
Membrane/reverse osmosis processes
Oxidation processes
Disinfection

Chlorine and the safe water system
Solar UV or UV lamp disinfection
Heat disinfection or pasteurization

Distillation
Combined (multiple barrier) household treatment systems

Sedimentation + solar UV disinfection
Pretreatment filters (strung-wound + granular activated carbon filter + chlorine disinfection)
Pretreatment cloth + sand + ceramic candles with colloidal silver
Coagulation/flocculation + filtration + chlorine disinfection
Other combinations

Beyond inactivation and/or removal of microbiological contamination—which is the major concern for those lacking access to safe drinking water—appropriately designed household drinking water treatment can effectively remove physical substances (e.g., turbidity) and/or toxic chemicals (e.g., arsenic, fluoride, pesticides) as well as microbiological contamination by one or several of the processes listed above.

On every continent, there are promising household drinking water treatment and safe water storage options available. In the decade to come, we will witness new research, innovation, and scale-up of these systems from hundreds to thousands to millions to meet the enormous global need for clean, safe drinking water.

VIRUS TRANSPORT IN THE SUBSURFACE

Ann Azadpour-Keeley
Jack W. Keeley
United States Environmental Protection Agency
Ada, Okaholma

BACKGROUND

The 1986 Safe Drinking Water Act (SDWA) amendments directed the EPA to develop national requirements for drinking water disinfection. The legislation required all public water supply systems to disinfect unless they fulfill criteria ensuring equivalent protection. To provide direction for the regulations associated with "acceptable" health risks to the public (4), the EPA established goals for maximum contaminant levels (MCLGs) of pathogenic microorganisms in drinking water, set or setting a level of zero for viruses (5,6).

On June 29, 1989, a Surface Water Treatment Rule (SWTR) was published addressing microbial contamination of drinking water from surface sources or from groundwater sources directly influenced by surface water, that had strict provisions for filtration and disinfection (5). On January 14, 2002, a SWTR was promulgated with special emphasis on the protozoan *Cryptosporidium* (7).

The development of a corresponding rule for groundwater, Ground Water Disinfection Rule (GWDR, later designated as the Groundwater Rule), to meet SDWA requirements began in 1987 and led to a published discussion piece (8) and a deadline for the GWDR proposal upon completion of the status of public health with respect to the microbial contamination of groundwater by conducting studies to generate a more careful nationwide picture of the problem. On May 10, 2000, "US EPA proposed to require a targeted risk-based regulatory strategy for all groundwater systems addressing risks through a multiple barrier approach that relies on five major components: periodic sanitary surveys of groundwater systems requiring the evaluation of eight elements and the identification of significant deficiencies; hydrogeological assessments to identify wells sensitive to fecal contamination; source water monitoring for systems drawing from sensitive wells without treatment or with other indications of risk; a requirement for correction of significant deficiencies and fecal contamination (by eliminating the source of contamination, correcting the significant deficiency, providing an alternative source water, or providing a treatment which achieves at least 99.99 percent (4-log) inactivation or removal of viruses), and compliance monitoring to insure disinfection treatment is reliably operated where it is used (9). The Ground Water Rule will be issued in 2005.

INTRODUCTION

More than 97% of all freshwater on the earth is groundwater. Of more than 100 million Americans who rely on groundwater as their principal source of potable water, over 88 million are served by community water systems and 20 million by noncommunity water systems (9). Historically, groundwater has been considered a safe source of drinking water which required no treatment. It has long been believed that this valuable resource was protected from surface contamination because the upper soil mantle removed pollutants during percolation. It was also believed that, even if contaminated, groundwater would be purified through adsorption processes and metabolism of indigenous aquifer microflora.

In the United States alone, the estimated annual number of reported illnesses resulting from contact with waterborne pathogens was as low as one million and as high as seven million between 1971 and 1982, and 51% of all waterborne disease outbreaks due to the consumption of contaminated groundwater (1). It is estimated that approximately 20–25% of U.S. groundwater sources are contaminated with microbial pathogens, including more than 100 types of viruses. A literature review by Craun (2) indicated that approximately one-half of the surface water and groundwater sources tested contained enteric viruses. Even 9% of conventionally treated drinking water (coagulation, sedimentation, filtration, postfiltration disinfection using chlorine/ozone) tested positive for enteric viruses.

Although water-transmitted human pathogens include various bacteria, protozoa, helminths, and viruses, agents of major threat to human health are pathogenic protozoa (*Cryptosporidium* and *Giardia*) and enteroviruses. Despite ample information regarding the fate of viruses in the subsurface, research on the persistency of pathogenic protozoa through passage in soil and groundwater is just now emerging. In the past, it was generally believed that pathogenic protozoa are confined to surface water. Contrary to that expectation, recent monitoring results from 463 groundwater samples collected at 199 sites in 23 of the 48 contiguous states suggested that up to 50% of the groundwater sites were positive for *Cryptosporidium, Giardia*, or both, depending on the parasite and the type of groundwater source (vertical wells, springs, infiltration galleries, and horizontal wells) (3).

Viruses are small obligate intracellular parasites that infect and sometimes cause a variety of diseases in animals, plants, bacteria, fungi, and algae. Viruses are colloidal particles, negatively charged at high pH (pH >7), ranging in size from 20 to 350 nm. The smallest unit of a mature virus is composed of a core of nucleic acid (RNA or DNA) surrounded by a protein coat. Due to this unique feature of viral structure and colloidal physicochemical properties, the transport of viruses in soil and ground water can act with a combination of characteristics ranging from those of solutes, colloids, and microorganisms.

Enteroviruses are a particularly endemic class of waterborne microorganisms that cause a number of ubiquitous illnesses, including diarrhea, gastroenteritis, and meningitis, to name only a few. Included in this group are poliovirus, hepatitis type A (HAV), Coxsackie virus A and B, and rotavirus. Although gastroenteritis is the most common disease resulting from these microorganisms, other associated illnesses include hepatitis, typhoid fever, mycobacteriosis, pneumonia, and dermatitis (10).

SOURCES OF VIRUSES

A number of avenues are available for the introduction of viruses to the subsurface, including land disposal of untreated and treated wastewater, land spreading of sludge, septic tanks and sewer lines, and landfill leachates.

Among these, septic systems may pose a significant chemical as well as biological threat to surface and groundwaters. One trillion gallons of septic-tank waste are released into the subsurface annually. Although phosphate and bacteria are ordinarily removed by soil, nitrate and viruses may escape these processes and move through the soil into the groundwater. The presence of viral particles is even more significant in the light of studies that indicate they are not necessarily inactivated in septic tanks and may move into the groundwater where they may survive for long periods of time.

It is a general consensus that the transport of pathogens in the subsurface depends on the extent of their retention on soil particles and their survival. Among the major factors that affect viral transport characteristics in the subsurface are temperature, microbial activity, moisture content, and pH. Among all the factors, temperature appears to be the only well-defined parameter that causes a predictable effect on viral survival. A direct relationship between a rise in temperature and viral inactivation rates ($K = \log$ inactivated/h) among various viruses has been suggested. Badawy et al. (11) stated that during the winter (4–10 °C), viral inactivation rates for coliphage, poliovirus, and rotavirus were 0.17, 0.06, and 0.10 per hour, respectively. Whereas, during the summer (36–41 °C), the inactivation rates for MS-2, poliovirus, and rotavirus were 0.45, 0.37, and 0.20 per hour, respectively. It should be pointed out that this information is based on ambient air. A more direct comparison would be correlation with temperatures in the subsurface. In this regard, the inactivation rates for enteroviruses are 0.06 (10–15 °C), 0.08 (15–20 °C), and 0.19 (20–25 °C). This worker also indicated that viruses may remain viable for 3 to 5 weeks on crops irrigated with sewage effluent, polio and Coxsackie virus up to 4 months on vegetables during commercial and household storage; and up to 30 days on vegetables stored at 4 °C.

Microbial ecology may also play an important role in the inactivation of waterborne viruses. For example, microbial activity could affect viral survival by the action of proteolytic enzymes of some bacteria and protozoa in destroying the viral capsid protein.

As discussed earlier, viral transport through porous media is controlled by sorption and by inactivation. However, adsorption of viruses to soil should not be confused with their inactivation because adsorption is not permanent and can be reversed by the ionic characteristics of percolating water. Viruses can remain infective after a travel distance of 67 meters vertically and 408 meters horizontally (12). The various forces involved in attaching viruses to soil particles include hydrogen bonding, electrostatic attraction and repulsion, van der Wals forces, and covalent ionic interaction.

EFFECT OF HYDROGEOLOGIC SETTINGS ON VIRAL MOVEMENT

The concentration and loading of viruses and the hydrogeologic setting through which they move will control the potential for viral migration to wells to a much greater extent than biological survivability. A hydrogeologic setting often consists of a soil underlain by unconsolidated deposits of sand, silt, and clay mixtures over rock. The setting further incorporates unsaturated and saturated zones.

All other factors being equal, the persistence of viruses at a well or other source of water is most likely where saturated flow transports large concentrations of the particles along short flow paths through media that contribute little to attenuation. Although the interrelated processes that control viral movement and persistence in the subsurface are not completely understood, some of the major hydrogeological factors that can be used to evaluate the potential for viral presence in groundwater wells include

- transport mechanisms (unsaturated versus saturated flow conditions),
- type of media through which the virus will travel (clays versus sands versus fractured media),
- length of the flow path to the extraction point (well), and
- time of travel.

Hydrogeologic settings that have shallow water tables are more susceptible to viral transport. Viruses are attenuated or immobilized by processes such as dessication, microbial activity, and stagnation. Further, viruses commonly bind to soil particles, fine-grained materials, and organic matter. The lower transport velocities associated with unsaturated conditions (e.g., move, stop, move cycle) allow these processes more time to occur. If viruses are introduced directly into the water table (such as from leaching tile fields associated with on-site sewage disposal) or if the volume of contaminants can maintain saturated flow conditions (such as in some artificial recharge situations), the potential for contamination increases. Where the viral concentration is high, the probability of contaminant migration increases regardless of the hydrogeologic setting. Therefore, in hydrogeologic settings that have deeper water tables and where contaminants are not introduced into the aquifer through saturated flow conditions, viruses are much less likely to survive transport to a well.

Hydrogeologic settings that have interconnected fractures or large interconnected void spaces that lack fine-grained materials have a greater potential for viral transport and well contamination. Karst aquifers, fractured bedrock, and gravel aquifers have been identified in the proposed GWDR as sensitive hydrogeologic settings (9).

In these settings, fractures and large void spaces allow rapid transport through the aquifer, thereby reducing the amount of time and particulate contact available for attenuation. Potential interaction with rock walls along fractures is reduced, and contact with fine-grained materials for potential sorption sites is minimal.

Similar to fractured rock aquifers, gravel aquifers that have only a small fine-grained fraction have little potential for viral sorption. However, as the amount of fine-grained material increases, effective grain size decreases, the potential for sorption increases, and travel times decrease. Finer grained aquifers and aquifers where void spaces are less interconnected or smaller are therefore less likely to transport viruses significant distances.

The potential for physical viral removal by filtration also appears to increase as grain size becomes smaller, although the filtration processes are not well understood due to their size. However, filtration of bacteria, which are larger than viruses, it has been shown is an effective removal mechanism.

Hydrogeologic settings, where fractures are not as interconnected or where more tortuous flow paths must be followed to reach a well, also allow greater viral removal. For example, in many rock aquifers, groundwater flow follows bedding planes that may result in an elongated indirect pathway to a well. In other rock aquifers, flow must travel around and through cemented portions of the matrix thereby increasing the flow path. Similarly, sand and gravel aquifers that have fine-grained materials in the matrix will have less direct flow paths as the water flows around the finer grained materials. Generally, it can be stated that tortuosity increases the length of the flow path and decreases the hydraulic conductivity, thus decreasing viral survival. Where finer grained materials are present or fractures are less interconnected, flow paths are also longer, thereby offering some protection to wells in more permeable units.

Hydrogeologic settings where time of travel is short have a greater potential for viral contamination. Where less permeable units (called aquitards) restrict or reduce vertical flow to underlying aquifers, time of travel is increased. Although inactivation rates, it has been shown, are extremely variable, time is a major factor affecting virus viability.

Due to the importance of hydrogeologic settings, the Proposed Ground Water Rule thoroughly addresses this issue to identify wells that are sensitive to fecal contamination. A component of the Proposed Ground Water Rule requires states to perform hydrogeologic assessments for the systems that distribute groundwater that are not disinfected (source waters that are not treated to provide 99.99% removal or inactivation of viruses). The states are required to identify sensitive hydrogeologic settings and to monitor for indicators of fecal contamination from sensitive hydrogeologic settings (see Ref. 9 for the complete proposed strategy).

VIRUS TRANSPORT MODELING

One method of addressing regulations for viral exposure, such as groundwater disinfection, the application of liquid and solid waste to the land, and wellhead protection zones, is using predictive viral transport models. Like most predictive modeling efforts, the results depend on the conceptual basis of the model as well as the quality and availability of input data. Clearly, a thorough understanding of the processes and parameters of viral transport are essential elements in their application.

Some of the more important subsurface viral transport factors include, soil water content and temperature, sorption and desorption, pH, salt content, organic content of the soil and groundwater matrix, virus type and activity, and hydraulic stresses. Berger (14) indicated that the inactivation rate of viruses is probably the single most important parameter governing viral fate and transport in ground water.

Some of the existing models require only a few of these parameters which limit their use to screening level activities, whereas others require input information which is rarely available at field scale and is usually applied in a research setting. One limitation of most models is that they have been developed for use in the saturated zone. It has been shown, however, that the potential for viral removal is greater in the unsaturated zone than in groundwater.

Setback Distances

Traditionally, state and county regulators have established fixed setback distances for all geologic settings in their jurisdictions. For example, the distance between a septic tank and a private well would, in many instances, be as little as 50 feet and would apply for tight clays as well as fractured rock. It would apply to areas where the water table is near the surface as well as at considerable depth. As discussed in this document, the travel time or transport distance of viral particles depends on a number of factors, including moisture content, geologic setting, type and depth of the soil overburden, and source loading, to name only a few.

Frequently, guidelines established as minimum distances became so standard that a well was often positioned precisely 50 feet from the septic tank. In the survey conducted as part of the proposed Ground-Water Treatment Rule, setback distances were quite variable (9). Some of the distances were presumably based on scientific principles, while others were holdovers from past practices.

One approach in determining setback distances for septic tanks in wellhead protection areas and bank filtration sites is to determine travel times using groundwater flow characteristics. This approach has been implemented in the Federal Republic of Germany, for example, where three concentric zones protect each drinking-water well. The zone immediately surrounding the well is faced with the most restrictive regulations which are founded on the belief that 50-day residence time is adequate for inactivation of any pathogen in contaminated water. However, a comprehensive study by Matthess et al. (15), involving the evaluation of the "50-day zone," concluded that the reduction of viruses by 7 log units (current regulations) requires a much longer residence time. Matthess et al. indicated that a reduction of 7 log units occurred in about 270 days (Haltern and

Segeberger Forest) in one study and about 160–170 days (Dornach) would be required, according to another study.

Another approach to this important issue is to consider the vulnerability to viral transport in the subsurface of portions of a state or county or of individual aquifers. Although there are a number of approaches to rank vulnerability, DRASTIC is one assessment methodology that uses hydrogeologic setting descriptions and a numerical ranking system to evaluate groundwater pollution potential (13). DRASTIC assumes that a potential contaminant will be introduced at the ground surface, have the mobility of water, and be flushed toward the aquifer by infiltration. Using existing information on variable scales, the methodology was designed to evaluate areas of 100 acres or larger.

DRASTIC is an acronym representing seven reasonably available factors that are used to develop a numerical score. They are **D**epth to water, net **R**echarge, **A**quifer media, **S**oil, **T**opography (slope), **I**mpact of the vadose zone media, and hydraulic **C**onductivity of the aquifer. DRASTIC uses a weighting system to create a relative pollution potential index that varies between 65 and 223; the higher numbers express greater vulnerability.

Although DRASTIC was not designed specifically to evaluate the movement of viruses in the subsurface, the major transport mechanisms and flow paths for viral transport are considered, and the flexibility of the systems' rating scheme allows many of these factors to be taken into account. For example, depth to water addresses saturated versus unsaturated flow conditions and their importance. Aquifer media, soil, and impact of the vadose zone media all are based on descriptive soil and rock terms that allow variation due to fracturing, grain size, attenuation mechanisms, and overall characteristics that affect flow. Topography addresses the tendency of viruses to be introduced into the subsurface or to be carried away by runoff. Hydraulic conductivity addresses the relative ease of a contaminant to move with the velocity of water through the aquifer.

Clearly, meaningful setback distances can be developed only by using scientific principles that allow the use of available knowledge. The establishment of setback distances from sources of viral contamination to points of extraction (wells) can be established using DRASTIC if both the hydrogeologic setting and sensitivity rankings are considered. For example, high pollution potential index signal the need for greater setback distances. However, the hydrogeologic factors that control viral movement must be evaluated within this context to establish reasonable numbers for setback distances. A matrix that incorporates the important DRASTIC factors can be used to establish setback distances that include the vulnerability concept. Setback distances must incorporate the knowledge of saturated flow, transport pathway length, transport velocities, media interaction, and potential attenuation mechanisms. These setback distances can be used on a regional scale but can be modified if site-specific information is available. The beauty of DRASTIC is that its rationale and sensitivity factors are easily displayed, so that it can be readily modified.

WINDMILLS

Arthur M. Holst
Philadelphia Water Department
Philadelphia, Pennsylvania

Windmills are machines that convert the force of the wind into energy that is applicable to various tasks, like pumping water. Windmills that are used to pump water use the energy generated by these mills to turn the gears that propel the pump. These types of windmills, sometimes referred to as wind pumps, have been used for centuries and continue in use around the world.

A BRIEF HISTORY

The first documented use of windmills was in Persia around 500–900 A.D., however, it is widely accepted that they were invented in China more than 2000 years earlier (1). In these early windmills, vertical-axis systems were used for grinding grain and pumping water. In the vertical-axis system, the wind would have to hit the mill from a specific angle to get the desired effect; therefore, most of the area around the mill had to be shielded. Later, horizontal-axis systems were developed that proved to have greater structural efficiency. By tilting the blade to a certain degree, the system eliminated the dependence on the direction of the wind and harnessed the wind energy lost in the vertical-axis systems by the areas shielded. Horizontal systems were later used throughout Europe.

Windmill technology, it is believed was introduced in Europe in the eleventh century (2). Aiming to their lowlands, the Dutch set out to develop a more efficient windmill and in the process became the driving force behind wind-machine development. Although many innovations were made, one of the fundamental improvements was designing sails that allowed optimum aerodynamic lift. This improvement made the sails rotate faster, greatly increasing their efficiency and speed in completing the task at hand. Wind energy was applied to irrigation, pumping from local wells, and drainage pumping; this in turn made areas habitable and liberated workers from these labor-intensive jobs.

As Europeans sought to expand and colonize, they brought the windmill technology with them. The colonization of the Americas is a prime example. Without this technology, it would have been impossible for immigrants to settle in areas that lacked a constant water supply. Certain areas in Texas, for example, lacked the needed water supply to sustain life and allow cultivating of the land. The drive to expand into these areas helped to stimulate the need to refine the windmill to solve this problem. Daniel Halladay addressed this problem in 1854 by changing the European windmill so it could operate unattended and more efficiently (3). The changes that he made appealed to many companies and small communities without water systems by providing an inexpensive way to get the water they needed (Fig. 1).

Figure 1. Multi-sailed windmill.

By the early twentieth century, windmills were being mass-produced, and millions of them were being used around the world. However, in the 1930s, as other fuel resources such as oil were demanded, wind pumping systems were not as desirable because they were more expensive and not as reliable as these other fuels. This was true until the 1970s when a shortage of oil prompted communities to revisit the idea of wind energy.

Wind pumps are currently being used for crop irrigation, drinking water supply for communities, and even individual household water supply. Between 5,000 to 10,000 wind pumps are being installed worldwide each year, and the market for these is expected to increase as wind technology advances and becomes less expensive (4).

THE WIND PUMP: HOW IT WORKS

The wind pump has four main features the wind turbine, the tower, the actual pumping equipment, and the storage basin. These parts can be found in almost all wind pumps. They vary in design depending on the wind conditions in which they will be used. If the wrong design is used in strong wind conditions, the pump may move too fast and malfunction, and if the wind speed is low, it may not be able to function at all.

The horizontal-axis is the typical system used for wind turbines to pump water. The rotor does not have to follow any specific design but instead should be designed for the wind conditions in which it will be used. However, the pump tends to have more force when there are more blades. The next main part of the wind turbine is its transmission. The transmission of a wind turbine converts each rotation of the rotor into an up and down motion, driving the pump rod in and out of the well. The tail of the wind turbine is a piece that was added during the westward expansion in the United States. It allows the wind turbine to work without constant supervision by changing the direction of the rotor to keep it facing the wind.

A tower holds the wind turbine generally between 10 m and 15 m high (5). It holds up the wind turbine and stabilize its connection with the pumping parts of the machine. The tower has either a square or triangular base, and the pump rod that moves in and out of the well is positioned in the center of the tower. The well that the pump rod enters can either be a shallow hand-dug well or a deep-drilled well. If the latter is the case, the walls of the well should be lined with a water permeable material to prevent them from caving in. A pipe called the rising main lies in the center of the pump rod. Its function is to carry the water pumped up to the surface. The actual pump is at the bottom of the pump rod submerged in the water and is attached to the rising main. The pump fills with water during the downward motion of the pump rod and pushes the water into the rising main and up to the surface as the pump rod moves up.

Finally, all wind pumps should have a storage basin that can hold the excess water that is pumped. When the water moves up into the rising main, it is then redirected into the storage tank. This stored water is also essential to water pumping systems because wind energy cannot always be relied on, and having a surplus at hand is useful.

THE ADVANTAGES OF WIND PUMPS

There are many advantages to using wind energy for pumping water. First, wind pumps are environmentally friendly. As with the atmosphere, wind turbines will not contaminate the land, and in the case of water pumps, there is no chance the water will be contaminated as a result of a malfunctioning wind pump.

Wind turbines generally do not affect the wildlife that inhabits the area. Sheep, cattle, deer, and other wildlife are not bothered by the turbines, and in fact have been known to graze under them. The only argument that has been raised about this issue is the tendency for birds to collide with them. However, several studies suggest that the impact of the wind turbines on birds does not compare to that of other things, such as electrical lines and buildings.

Wind pumps are cost-efficient. After the initial cost of installation, the owner basically has an infinite source of energy for just the cost of maintenance. Whereas using a fossil fuel to work the pump would make the owner subject to its cost.

THE DISADVANTAGES OF WIND PUMPS

There are, however, a few setbacks in using wind energy for pumping water. Because the wind is not reliable, if water is needed on a day where there is little to no wind, obviously the wind pump will not be able to pump water. This problem can be solved by a storage basin, as explained earlier. Many people who inhabit areas around wind turbines complain about the noise that is created by the rotation of the rotor, but this generally applies only to many wind turbines grouped together. As the rotors are improved upon and become more aerodynamic, the noise level will decrease greatly.

MIXING AND AGITATION IN WATER TREATMENT SYSTEMS

Paul Mavros
Aristotle University
Thessaloniki, Greece

Mixing is one of the primary processes involved in water and wastewater treatment. In this article, the state of the art in mixing and impeller design is presented.

INTRODUCTION

Stirring is provided in a wide variety of processes to blend constituents or to disperse one phase into another or several other phases. In a blend-type operation, the purpose is to obtain a homogeneous mixture, whereas in the dispersion process, the goals vary widely, depending also on the nature of the phases involved:

- in gas–liquid dispersions, gas is dispersed into fine bubbles which must be distributed as evenly as possible in the vessel to take part in a subsidiary process, for example, absorption and/or reaction with a dissolved component, as in water and wastewater treatment, or flotation of hydrophobic particles, among others;
- in solid–liquid distributions, it is necessary to provide the appropriate conditions for entraining all solid particles inside the bulk of the liquid, either from the bottom of the vessel or from the free surface of the liquid;
- in liquid–liquid dispersions, fine droplets of one of the liquids have to be dispersed inside the other liquid to produce an emulsion or for a polymerization, among others.

For each of these processes, a particular type of agitator is appropriate. These have evolved from the simple paddles used during the past centuries; modern flow visualization techniques (1) have helped in designing agitator blade shapes optimized for specific processes.

In the following sections, the main types of agitators are presented, according to the processes for which they are intended; this presentation is limited to turbulent flow, which is typical in water and wastewater treatment processes, and does not describe agitators designed for viscous liquids (anchors, gates, etc.).

TYPES OF IMPELLERS

An impeller is a pump; by its rotation, it draws liquid from its neighborhood and then ejects it at a relatively high speed. It is typically mounted on a shaft connected to a motor, and the shaft–impeller structure is inserted in the stirred tank either axisymmetrically or sideways. Close to the impeller blades, the rotation induces a tangential flow. Inside the bulk of the vessel, on the other hand, the action of the impeller induces flow circulation, which follows a pattern typical of the impeller type. Thus, we distinguish mainly radial and axial impellers, depending on the direction of the flow that emerges from the impeller-swept region.

Radial impellers eject a liquid stream radially. In a typical stirred vessel where the impeller is mounted on a shaft, is vertical and is usually centrally located, the ejected liquid flows from the edge of the impeller blades toward the vessel walls. There, it separates into two streams; one flows in the upper part of the vessel and one in the lower part of the vessel, thus forming two flow loops. The liquid from these two streams circulates in the upper and the lower parts of the vessel and eventually is drawn back into the agitator-swept region; two primary circulation loops are established inside the stirred tank.

Figure 1 presents some typical radial impellers. The Rushton turbine (RT; Fig. 1a) is one of the most widely used impellers due to its efficiency in gas–liquid and liquid–liquid mixing. Its construction is simple; usually it has six flat blades mounted on a flat disk. Figures 1b (SCABA 6SRGT turbine or Chemineer CD-6) and 1c (Chemineer BT-6) present two variants of the Rushton turbine, where blades have a parabolic shape, which is even more efficient than the RT, especially in dispersing gas inside a stirred vessel. Finally, the Narcissus (NS) impeller (2) produces an inverse radial flow; liquid is drawn in from its side and pumped out from its upper and lower parts.

Figure 2, which is a 2-D plot of composite radial and axial velocities U_{RZ}—which are obtained from the vector sum of the radial (U_R) and axial (U_Z) components of the local velocity vector—illustrates the typical radial flow patterns of the Rushton turbine—radial flow directed from the impeller toward the vessel walls—and of the Narcissus (NS)—radial flow directed toward the impeller. A similar double-loop circulatory flow pattern is induced by the SCABA turbine (3).

Axial impellers draw liquid mainly from one of their sides, top or bottom, and eject it from the opposite site; when liquid is ejected toward the bottom of the vessel, the impeller is said to work in the "down-pumping" mode, whereas when the liquid is ejected toward the surface of the liquid, this corresponds to the "up-pumping" mode. Often, liquid is also drawn from the side of the rotating impeller. Note that axial impellers are sometimes called "mixed-flow" impellers, too: in some cases, part of the ejected flow is directed sideways; this becomes more pronounced when the viscosity of the liquid increases (4).

Figure 3 presents some typical axial-flow impellers. The marine propeller (Fig. 3a) has been used for the propulsion of boats, and nowadays it is its sole application; far more efficient agitators have been designed for mixing liquids. Figure 3b shows the widely used pitched-blade turbine (PBT); the number of blades and their inclination usually characterizes the PBT more specifically, for example, the PBT in the illustration is referred to as a "4-45-PBT." The Mixel TT has blades, which are wider than those of

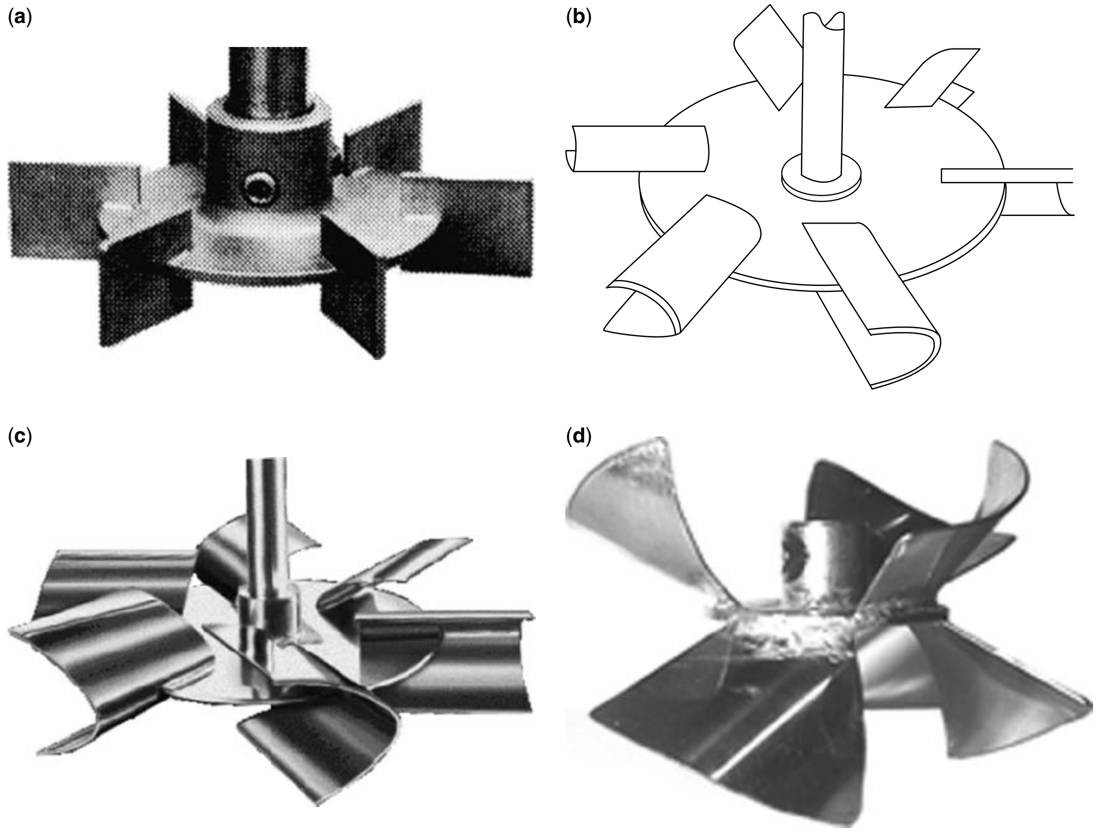

Figure 1. Radial agitators: (**a**) Rushton turbine; (**b**) SCABA 6SRGT (or Chemineer CD-6); (**c**) Chemineer BT-6; (**d**) Narcissus.

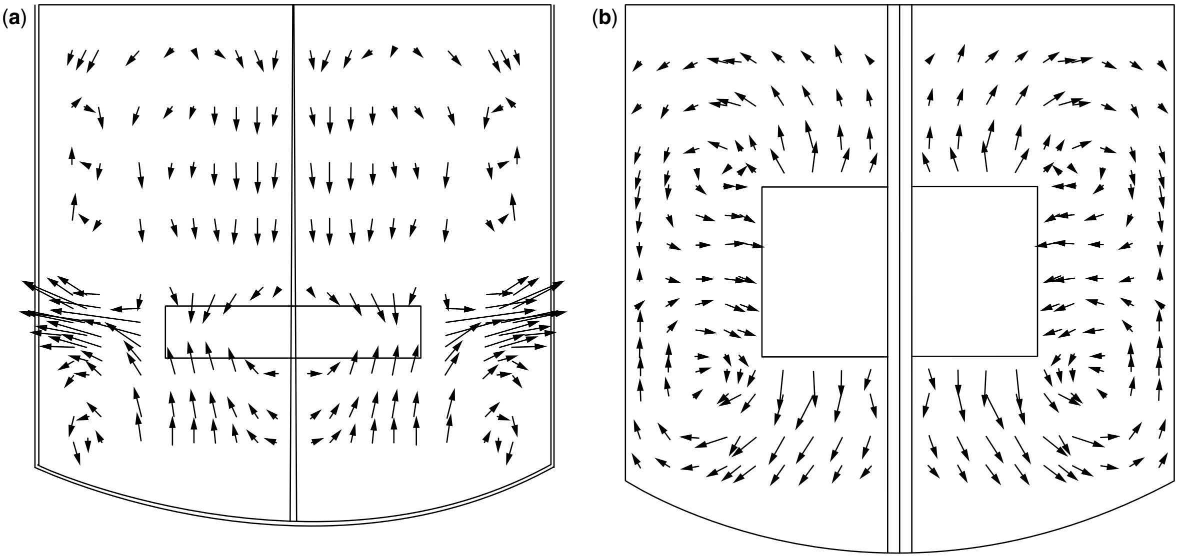

Figure 2. Flow patterns induced by radial impellers in a stirred tank: (**a**) Rushton turbine (4); (**b**) Narcissus (NS) impeller (2).

the PBT and are profiled to be more efficient in energy consumption.

The typical 2-D flow pattern induced by all axial-flow impellers in their usual configuration—“downpumping”—is illustrated in (Fig. 4a). As already stated, liquid is drawn from the upper part and the side of the impeller and is ejected downward. A single circulation loop is established in all cases; liquid flows upward close to the vessel walls and returns toward the impeller. The velocities in the upper part of the vessel are typically rather slow: the U_{RZ} vectors are much shorter than those close to the upper and lower sides of the impeller.

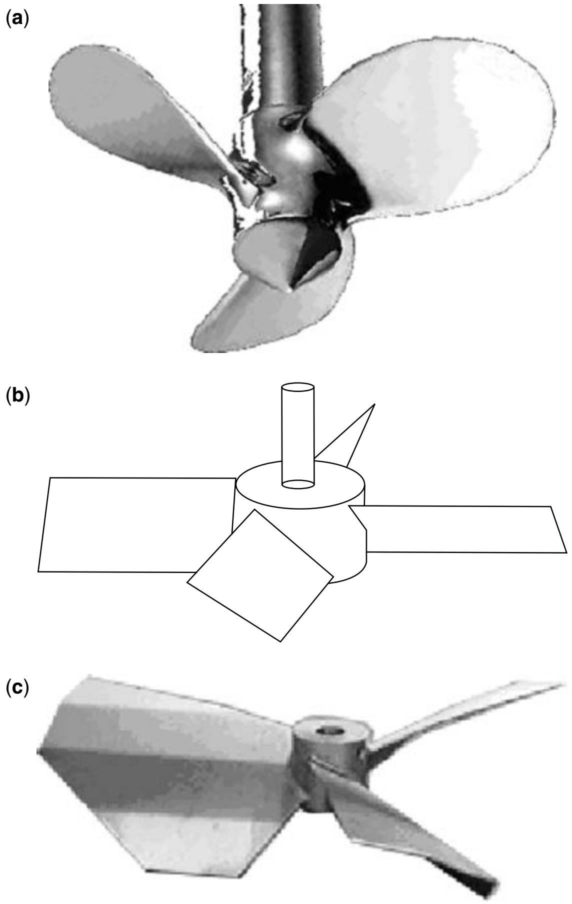

Figure 3. Typical axial-flow impellers; (**a**) marine propeller; (**b**) pitched-blade turbine; (**c**) Mixel TT.

Therefore, the liquid in the stirred tank may be divided into two regions: the first corresponds to the primary circulation loop, which is established around the impeller; liquid flows fast and results in an intensive mixing process. The liquid in the second region, located mainly in the upper part of the vessel, circulates slowly; therefore the mixing process is less intense and effective there; it is often necessary to add a second impeller on the same shaft, to enhance circulation and mixing in the upper part of the vessel.

The inverse configuration—“up-pumping”—again yields a single primary circulation loop, located around the impeller (Fig. 4b). A smaller, secondary circulation loop is established in the upper part of the vessel, achieving better overall circulation and mixing than the “down-pumping” mode.

Several other impellers have been tested and/or marketed, based on extensive hydrodynamic performance measurements, taking into consideration some optimization criterion; some of them are variants of the pitched-blade turbine; others have blade shapes originating from hydrofoils. Figure 5 illustrates some of these impellers.

The size and location of the impeller inside the stirred vessel are dictated by the process needs and affect its performance, for example,

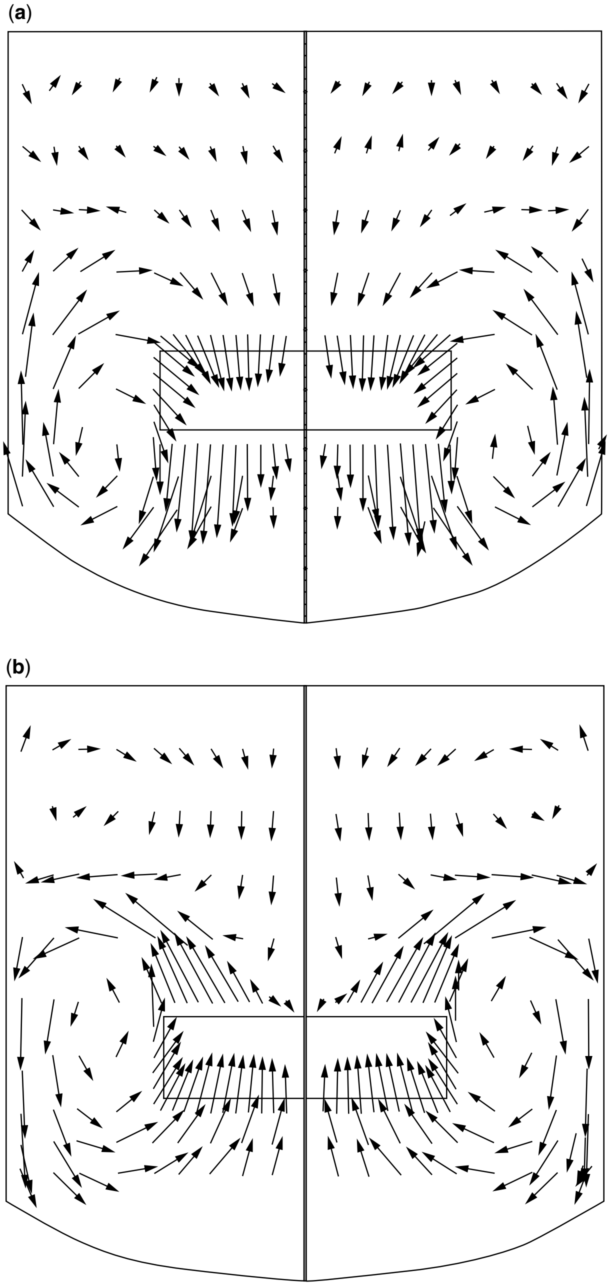

Figure 4. Flow patterns induced by axial impellers in a stirred tank: (**a**) Mixel TT in down-pumping mode [4]; (**b**) Mixel TT in up-pumping mode (5).

- to disperse gas effectively inside a stirred tank, it is necessary to use a radial agitator that has a large impeller diameter (D) to tank diameter (T) ratio, for example, $D/T = 1/2$, and to provide high rotational speed;
- if it is required to provide surface aeration to the stirred tank, the impeller is located close to the free liquid surface;
- if it is necessary to achieve an effective distribution of solid particles, an axial impeller having a reduced size ($D/T = 1/3$) should be used, located closer to the bottom of the vessel, having clearance (C), that is,

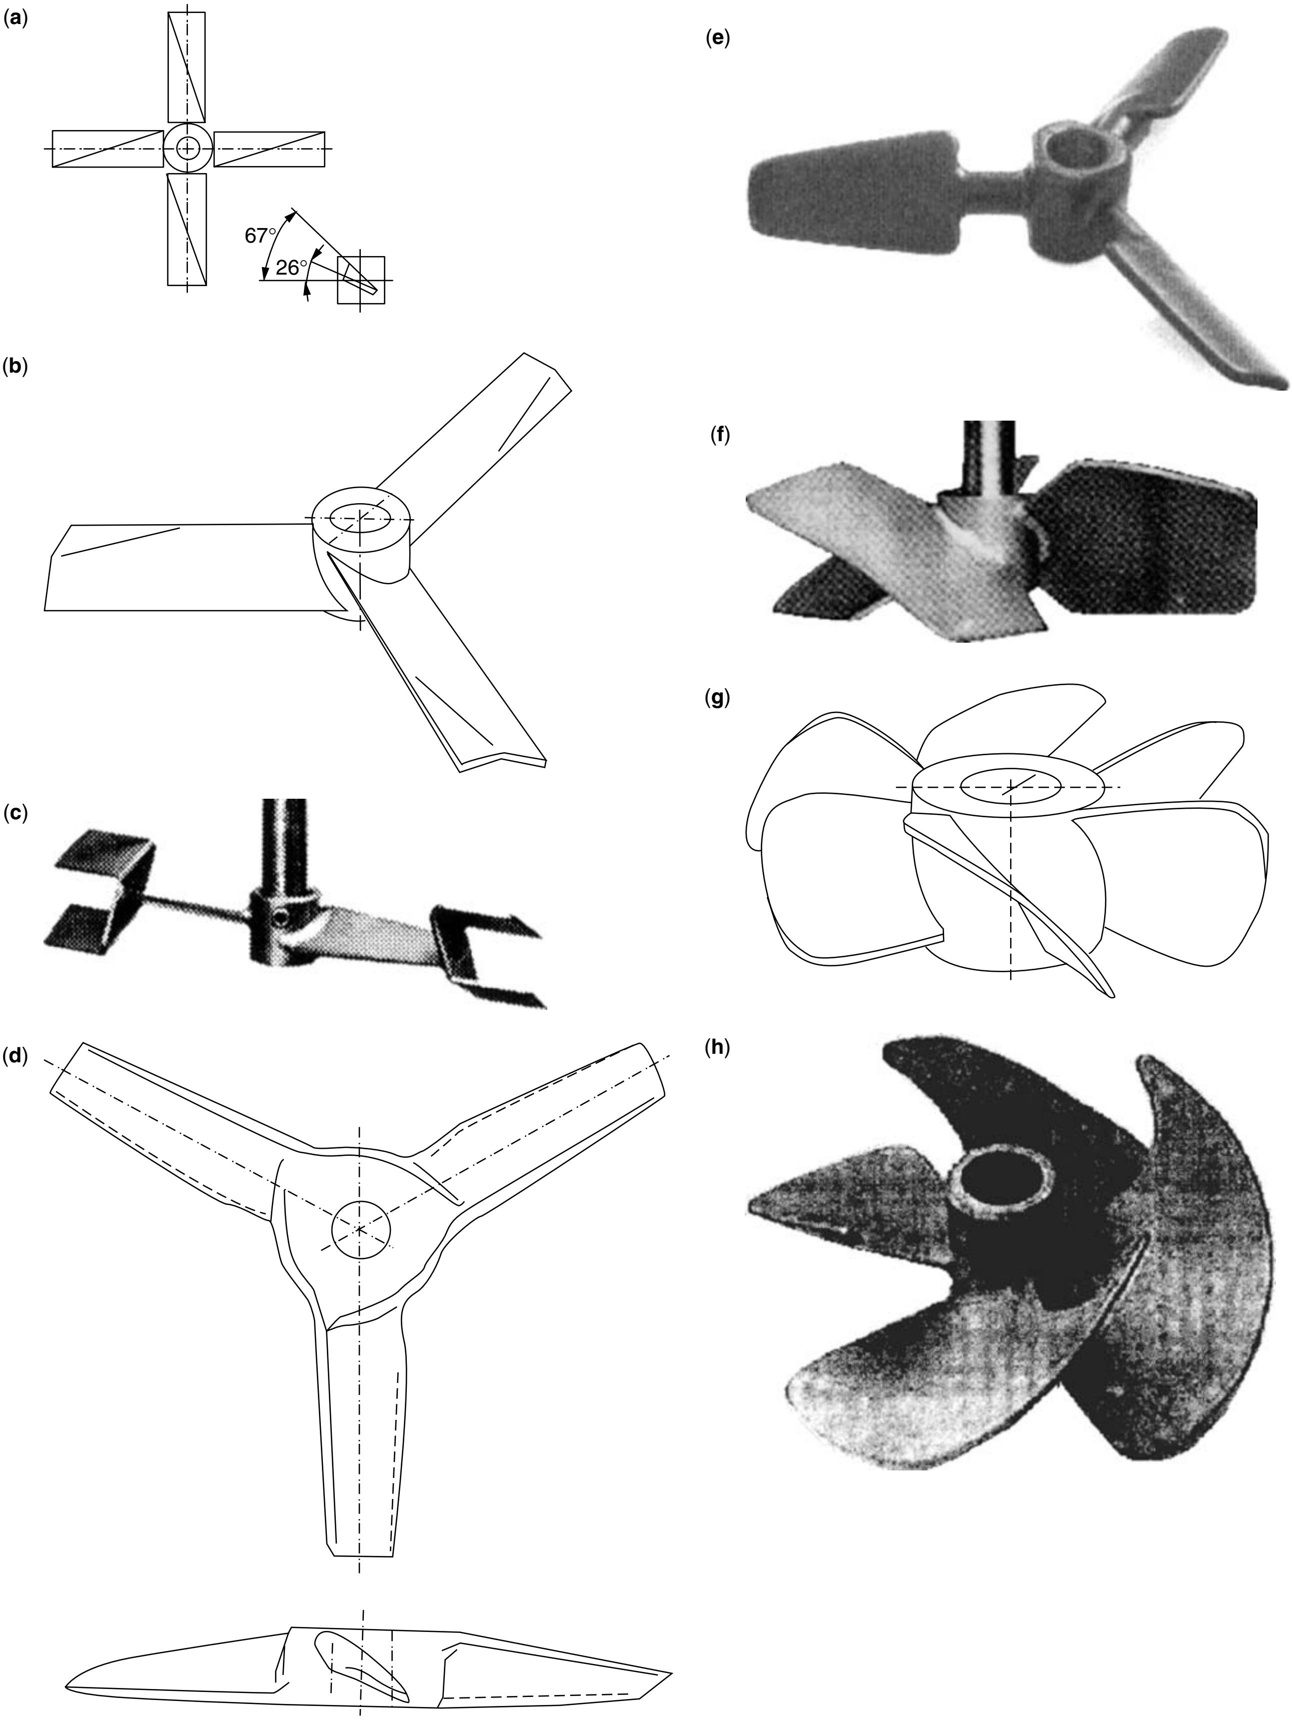

Figure 5. Examples of advanced impellers: (**a**) "Medek" PBT [6,7]; (**b**) Chemineer HE-3 [8]; (**c**) Ekato MIG; (**d**) Lightnin A-310; (**e**) DeDietrich hydrofoil; (**f**) Lightnin A-320; (**g**) Prochem Maxflo; (**h**) APV B2.

the distance from the bottom of the vessel, close to $T/3$ or even $T/4$.

When mixing is applied to rectangular troughs, the axis of the impeller is horizontally located at one end of the trough, and an axial-flow agitator with hydrofoil blades is used to induce longitudinal motion of the liquid in the trough.

PERFORMANCE DATA

The performance of the various impellers is characterized by quantitative criteria; some of these are power consumption, the amount of flow circulation caused by the pumping action of the impeller, the ability of the impeller to cause intense circulation in the stirred tank, and the time necessary to achieve homogeneity of the tank contents, among others.

The power consumption depends upon the impeller type; it has been found that in turbulent conditions, where the dimensionless Reynolds number (Re),

$$Re = \frac{\rho N D^2}{\mu} \tag{1}$$

is larger than about 4000, the dimensionless power number (Po),

$$Po = \frac{P}{\rho N^3 D^5} \tag{2}$$

is approximately constant and characterizes each impeller. Table 1 presents power numbers for a variety of commonly used impellers.

Another feature of impellers is the amount of fluid being "pumped out" of the agitator-swept region; from the flow rate of this stream (Q_p), another dimensionless number, the flow number, (Fl), which also characterizes impellers may be obtained:

$$Fl = \frac{Q_\mathrm{P}}{ND^3} \tag{3}$$

Table 1 presents typical values of flow numbers for the most common types of impellers.

Table 1. Characteristics of Various Impellers

Type	D/T	C/T	Power Number (Po)	Flow Number (Fl)
A310 (Lightnin)	1/2	1/3	0.56	0.62
A315 (Lightnin)	NA[a]	NA[a]	0.75–0.80	0.73
A320 (Lightnin)	0.40	0.39	0.64	0.64
A410 (Lightnin)	0.40	0.40	0.32	0.62
4-45-PBT	1/3	1/3	1.25	0.77
6-45-PBT (down-pumping)	1/3	1/3	1.93	0.75
6-45-PBT (up-pumping)	1/3	1/3	2.58	0.68
6SRGT (SCABA)	1/3	1/3	2.8–3.0	NA[a]
BT-6 (Chemineer)	1/3	1/3	2.1	NA[a]
CD-6 (Chemineer)	1/3	1/3	2.8–3.0	NA[a]
HE-3 (Chemineer)	1/2	1/4	0.31	0.41
Marine propeller	1/3	NA[a]	0.89	0.79
Medek PBT	1/3	1/3	0.41	0.60
Mixel TT (down pumping)	1/2	1/3	0.74	0.67
Mixel TT (up-pumping)	1/2	1/3	0.67	0.61
Narcissus	1/3	1/3	1.14	0.31
MaxFloT (Prochem)	0.35	0.45	1.58	0.82
Rushton turbine	1/3	1/3	4.9–5.2	0.78

[a] NA: not available.

One of the purposes of an impeller is to create circulation inside a stirred vessel, so one quantitative characteristic of its efficiency is the spatial mean velocity achieved in the vessel. This mean velocity, compared to the velocity at the tip of the blades (V_TIP), yields the "agitation efficiency" (I_G) of each particular impeller (9).

Finally, the time to obtain vessel homogeneity is termed "mixing time" (t_MIX); it has been found that for a wide variety of impellers it may be correlated to the power number and to the impeller-to-vessel diameter ratio (10):

$$N\, t_\mathrm{MIX} = 5.3 (Po)^{-1/3} \left(\frac{T}{D}\right)^2 \tag{4}$$

CONCLUSIONS

Mixing is used in a multitude of processes, including water and wastewater treatment, to achieve several goals: to disperse another phase—gas, liquid, or solid—into the bulk of the liquid; to homogenize the stirred tank contents; and to assist and promote a reaction between some of the dissolved and/or dispersed species, among others. This is usually achieved by using rotating impellers, whose blade design has been often optimized for particular processes. Radial impellers, such as the Rushton turbine, are more suitable for homogenization and for dispersing a second phase in liquids; however, they generate high-shear flows. Axial-flow impellers are more suitable for solids dispersion and for cases where shear-sensitive material exists in the liquid, requiring benign mixing conditions.

NOTATION

C: clearance of impeller (from midplane) to vessel bottom (m)
D: impeller diameter (m)
Fl: dimensionless flow number (-)
I_G: dimensionless agitation index (-)
N: impeller rotational frequency (Hz)
Po: dimensionless power number (-)
Re: dimensionless Reynolds number (-)
T: vessel diameter (m)
t_MIX: mixing time (s)
U: liquid velocity (m/s)
V_TIP: liquid velocity at the tip of the impeller blades ($= \pi$ND) (m/s)

GREEK LETTERS

μ: viscosity of liquid (Pa.s)
ρ: density of liquid (kg/m^3)

ARSENIC IN NATURAL WATERS

Robert Y. Ning
King Lee Technologies
San Diego, California

INTRODUCTION

Arsenic is widely distributed in nature in air, water, and soil as a metalloid and as chemical compounds, both inorganic and organic (1). This class of compounds was known to the ancient Greeks and Romans both as therapeutic agents as well as poisons. This dual nature as useful substances as well as toxic matter to be controlled has grown over the centuries. Arsenic and arsenicals have widened use in commerce, but so have the recognition that their presence in drinking water, largely from natural sources, is a major public health problem around the world.

Acute and chronic arsenic exposure via drinking water has been reported in many countries, especially Argentina, Bangladesh, India, Mexico, Mongolia, Thailand, and Taiwan, where ground (well) water is contaminated with a high concentration of arsenic of 100 to more than 2000 μg/liter (ppb) (2). Studies have linked long-term exposure to arsenic in drinking water to cancer of the bladder, lungs, skin, kidney, nasal passages, liver, and prostate. Noncancer effects of ingesting arsenic include cardiovascular, pulmonary, immunological, neurological, and endocrine (e.g., diabetes) disorders (3). Besides its tumorigenic potential, it has been shown that arsenic is genotoxic (4,5). Given the importance of arsenic as a global environmental toxicant, we will summarize the geochemistry, natural distribution, regulation, anthropogenic sources, and removal mechanisms.

GEOCHEMISTRY

Average concentrations of arsenic in the earth's crust reportedly range from 1.5 to 5 mg/kg. Higher concentrations are found in some igneous and sedimentary rocks, particularly in iron and manganese ores. Common minerals containing arsenic are shown in Table 1. Arsenopyrite, realgar, and orpiment are the most important of these minerals, and they are commonly present in the sulfide ores of other metals, including copper, lead, silver, and gold. Arsenic may be released from these ores to the soil, surface water, groundwater, and the atmosphere.

Natural concentrations of arsenic in soil typically range from 0.1 to 40 mg/kg; an average concentration is 5 to 6 mg/kg. Arsenic can be released to ground or surface water by erosion, dissolution, and weathering. Geothermal waters can be sources of arsenic in groundwater.

In Yellowstone National Park, the arsenic concentrations in geysers and hot springs range from 900 to 3,560 ppb. Waters from these sources cause elevated arsenic levels in rivers downstream. Other natural sources include volcanism and forest fires. Volcanic activity appears to be the largest natural source of arsenic emissions to the atmosphere, estimated variously between 2,800 to 44,000 metric tons annually. The relative contributions of volcanic sources, other natural sources (Table 1), and anthropogenic sources to the atmosphere have not been definitively established.

The predominant forms of arsenic in groundwater and surface water are arsenate (V) and arsenite (III). Examples

Table 1. Common Minerals of Arsenic[a]

Arsenopyrite, $FeAsS$	Smalite, $CoAs_2$
Lollingite, $FeAs_2$	Cobaltite, $CoAsS$
Orpiment, As_2S_3	Gersdorffite, $NiAsS$
Realgar, As_4S_4	Tennantite, $4Cu_2SAs_2S_3$
Chloanthite, $NiAs_2$	Proustite, $3Ag_2SAs_2S_3$
Niciolite, $NiAs$	Enargite, $3Cu_2SAs_2S_5$

[a] Reference 3.

of inorganic arsenic compounds found in the environment include oxides (As_2O_3, As_2O_5), and sulfides (As_2S_3, AsS, $HAsS_2$, $HAsS_3^{3-}$). Inorganic arsenic species that are stable in oxygenated waters include arsenic acid [As(V)] species (H_3AsO_4, $H_2AsO_4^-$, $HAsO_4^{2-}$ and AsO_4^{3-}). Arsenous acid [As(III)] is also stable as H_3AsO_3 and $H_2AsO_3^-$ under slightly reducing aqueous conditions. Arsenite is generally associated with anaerobic conditions. Oxidation state, oxidation–reduction potential, pH, iron concentrations, metal sulfide and sulfide concentrations, temperature, salinity, and distribution and composition of biota appear to be the significant factors that determine the fate and transport of arsenic. In surface waters, additional factors include total suspended sediment, seasonal water flow volumes and rates, and time of day.

Sorption of arsenic to suspended sediment may strongly affect the fate and transport of arsenic in surface water systems (6). Where pH and arsenic concentrations are relatively high and total suspended sediment levels are relatively low, sorption processes may be less important. However, where suspended sediment loads are higher, arsenic concentrations are lower, and pH levels are lower, arsenic is more likely to be present in the suspended particulate phase rather than in the dissolved phase. Particulate phase arsenic may settle to bottom sediment in reservoirs and areas of low flow levels. In deeper lakes, remobilization of arsenic from sediment may be minimal, whereas in shallower lakes, arsenic may be remobilized faster from wind-induced wave action and high-flow scouring. Diurnal changes of as much as 21% in arsenic concentrations have been observed in rivers, attributable to pH changes due to sunlight and photosynthesis.

NATURAL DISTRIBUTION

A survey of arsenic concentration in natural waters is of importance relative to the desirable maximum limit of 10 ppb or less for human consumption. An attempt has been made to quantify the global element cycle for arsenic, based on published data (1). Arsenic concentrations in environmental media are presented in Table 2.

Table 2. Arsenic Concentrations in Environmental Media[a]

Environmental Media	Arsenic Concentration Range	Units
Air	1.5–53	ng/m^3
Rain from unpolluted ocean air	0.019	μg/L (ppb)
Rain from terrestrial air	0.46	μg/L
Rivers	0.20–264	μg/L
Lakes	0.38–1,000	μg/L
Ground (well) water	<1.0–>1, 000	μg/L
Seawater	0.15–6.0	μg/L
Soil	0.1–1,000	mg/kg (ppm)
Stream/river sediment	5.0–4,000	mg/kg
Lake sediment	2.0–300	mg/kg
Igneous rock	0.3–113	mg/kg
Metamorphic rock	0.0–143	mg/kg
Sedimentary rock	0.1–490	mg/kg
Biota—green algae	0.5–5.0	mg/kg
Biota—brown algae	30	mg/kg

[a] Reference 7.

In addition to geochemical factors, microbial agents can influence the oxidation state of arsenic in water and can mediate the methylation of inorganic arsenic to form organic arsenic compounds (8). Microorganisms can oxidize arsenite to arsonate and reduce arsenate to arsenite or even to arsine (AsH_3). Bacteria and fungi can reduce arsenate to volatile methylarsines. Marine algae transform arsenate into nonvolatile methylated arsenic compounds such as methylarsonic acid [$CH_3AsO(OH)_2$] and dimethylarsinic acid [$(CH_3)_2AsO(OH)$] in seawater. Freshwater and marine algae and aquatic plants synthesize complex lipid-soluble arsenic compounds (9). Organic arsenical compounds were reportedly detected in surface water more often than in groundwater. Surface water samples reportedly contain low but detectable concentrations of arsenic species, including methylarsonic acid and dimethylarsinic acid. Methylarsenicals reportedly comprise as much as 59% of total arsenic in lake water. In some lakes, dimethylarsinic acid has been reported as the dominant species, and concentrations appear to vary seasonally from biological activity within waters.

REGULATIONS

In the United States, the Safe Drinking Water Act (SDWA) of 1974 called for establishing Maximum Contaminant Levels (MCL) as national drinking water standards and required the Environmental Protection Agency (EPA) to revise the standard periodically. Based on a Public Health Service standard established in 1942, the EPA established a standard of 50 μg/liter (50 ppb) as the maximum arsenic level in drinking water in 1975. In 1984, the World Health Organization (WHO) followed with the same 50 ppb recommendation. Since that time, rapidly accumulated toxicity information prompted a revision of the standard, and a provisional guideline of 10 ppb was recommended by WHO in 1993. In January 2001, EPA published a revised standard that would require public water supplies to reduce arsenic to 10 ppb by 2006. Perceived hardships in implementation and uncertainty in setting the standard at 3, 5, 10, or 20 ppb has led the EPA to announce temporary delays in the effective date for the January 2001 rule to allow for further cost–benefit analysis and public input. The rule is significant because it is the second drinking water regulation for which the EPA has used its discretionary authority under the SDWA to set the MCL higher than the technically feasible level, which is 3 ppb for arsenic, based on the determination that the costs would not justify the benefits at this level.

ANTHROPOGENIC SOURCES

Arsenic is released from a variety of anthropogenic sources, including metal and alloy manufacturing, petroleum refining, pharmaceutical manufacturing, pesticide manufacturing and application, chemical manufacturing, burning of fossil fuels, and waste incineration.

Most agricultural uses of arsenic are banned in the United States. However, sodium salts of methylarsonic acid are used in cotton fields as herbicides. Organic arsenic is also a constituent of feed additives for poultry and swine and appears to concentrate in the resultant animal wastes. About 90% of the arsenic used in the United States is for the production of chromated copper arsenate (CCA), the wood preservative. CCA is used to pressure treat lumber and is classified as a restricted use pesticide by the EPA. A significant industrial use of arsenic is in the production of lead-acid batteries; small amounts of very pure arsenic metal are used to produce gallium arsenide, which is a semiconductor used in computers and other electronic applications. The U.S. Toxics Release Inventory data indicated that 7,947,012 pounds of arsenic and arsenic-containing compounds were released to the environment in 1997; most of that came from metal smelting. The data did not include some potentially significant arsonic sources associated with herbicides, fertilizers, other mining facilities, and electric utilities.

REMOVAL MECHANISMS

At the regulated maximum arsenic level of 10 ppb, the U.S. EPA estimated that 5% of all U.S. community water systems would have to take corrective action to lower the current levels of arsenic in their drinking water. In high arsenic areas of the world, the need for removal from water supplies is even more acute.

Due to their predominance in natural waters, arsenic(V) acid (H_3AsO_4) and arsenous(III) acid ($HAsO_2$) and their salts can serve as the model for these and alkylated species for consideration of removal mechanisms. The pK values of arsenic acid = 2.26, 6.76, 11.29 (10) and arsenious acid = 9.29 (10) or 8.85 (11) are of prime importance in determining the degree of ionization at the pHs of the water from which removal strategies are considered. It is readily apparent that at a natural pH of 7 to 8, arsenic acid is extensively ionized as the divalent ion; arsenious acid remains largely un-ionized.

Due to the ionic charge, arsenate(V) is more easily removed from source waters than arsenite(III). In particular, activated alumina, ion exchange, and reverse osmosis may achieve relatively high arsenate removal rates, but they show lower treatment efficiencies for arsenite. Elevating the pH such as by caustic injection into reverse osmosis system feedwater would be one approach to greater removal of arsenite(III) compounds. Arsenite can also be oxidized to arsenate to improve removal efficiencies. In water that contains no ammonia or total organic carbon, chlorine rapidly (in less than 5 seconds at chlorine concentrations of 1.0 mg/L) oxidizes approximately 95% of arsenite to arsenate. Monochloramine at a concentration of 1.0 mg/L oxidized 45% of arsenite to arsenate. Potassium permanganate performs this oxidation rapidly; oxygen does so slowly unless activated by light and sensitizer.

In contrast to other heavy metals, As^{3+} and As^{5+} are not precipitated as hydroxides, only as sulfides. Alkyl and arylarsonic acids are precipitated by quadrivalent metals such as tin, thorium, titanium, and zirconium. The tendencies of dissolved arsenic species to adsorb on inorganic particle surfaces such as iron, ferric hydroxide, iron oxide, alumina, sulfur, and sulfides allow for removal strategies involving fixed-bed reactors or adsorption/coagulation/filtration schemes. Sulfate, fluoride, and phosphate ions are known to be strong competitors of arsenic adsorption in some systems.

EVALUATION OF MICROBIAL COMPONENTS OF BIOFOULING

STUART A. SMITH
Smith-Comeskey Ground Water
Science LLC
Upper Sandusky, Ohio

Detecting the occurrence of biofouling and assessing its impact involve a range of analytical techniques, including informed observation and inspection of well components, interpretation of hydraulic and water quality testing, and direct analysis of microbial components of biofouling. The latter is the subject of this article.

SYMPTOMS: INDIRECT ANALYSIS

Symptoms can be used as qualitative indicators of biofouling but not specifically of the microbial component. Observable symptoms include the following:

- clogging (both formation/well and pump/discharge systems).

- corrosion
- alteration of water quality in pumped samples
- distinct coating on surfaces visible during inspections, such as borehole television surveys.

Such symptoms are indications of biofouling and should trigger analysis to determine the nature of the biofouling.

DIRECT ANALYSIS OF MICROBIAL BIOFOULING AND COMPONENTS

Standard Methods

Some existing "standard methods" for analyzing aspects of biofouling are described in:

- ASTM Test Method for Iron Bacteria in Water and Water-Formed Deposits (D 932) (1)
- Section 9240—Iron and Sulfur Bacteria, *Standard Methods for the Examination of Water and Wastewater* (APHA-AWWA-WEF, currently 20th ed. Supplement) (2).
- Additional *Standard Methods* (Part 9000) microbiological methods (and others accepted by technical and regulatory bodies) for analysis of heterotrophic bacteria and specific groups of interest such as the total coliform group. All relevant aquatic and public health microbiological methods are applicable in identifying microbiological components of biofouling.
- Microscopic particulate analysis (MPA) ((2), consensus method) can identify biofilm components as part of its larger scope and represents a systematic approach.

Microscopic Examination and Analysis. The presence of filamentous (e.g., *Leptothrix, Thiothrix,* or *Crenothrix*) or stalked (*Gallionella*) iron or sulfur bacterial forms is accepted as a positive indicator of biofouling. Examination by light microscopy has traditionally been the method of choice for confirming and identifying these "iron bacteria" or "sulfur bacteria" (1,2). However, the absence of such visible structures does not necessarily mean the absence of biofouling:

1. Samples may not include enough recognizable materials to provide the basis for a diagnosis of biofouling.
2. Samples examined may not include the filamentous or stalked bacteria normally searched for in such analyses. It is generally understood that the morphologically distinct types are only part of the biofouling present.
3. Analysts vary in their skill and opinions in interpreting what they see.

In addition, the existing standard microscopic tests (1,2) are specified as qualitative. Attempts have been made to quantify degrees of biofouling by microscopy. However, spatial variations and the pulsating, three-dimensional nature of active biofilms make them unreliable (4). An available semiquantitative method using microscopy is described by Barbic et al. (5).

Culturing Methods for Detection. Culturing enriches biofouling microflora that cannot be identified microscopically and helps provide more complete information on the nature of biofilm samples. It can also be used to draw reasonable conclusions about biofouling in the absence of microscopy. *Standard Methods* (2) describes a range of media formulations, and more for other purposes are found in other sections of Part 9000. With regard to Section 9240 formulations, a number of limitations have been identified. These weaknesses have all been recognized by the *Standard Methods* Section 9240 joint technical group:

- No reported effort has been made to standardize these media with reference cultures from well water. Thus the efficiency of recovery of iron-precipitating bacteria from groundwater samples remains unknown at present (4) but is probably very low.
- Except for the modified Wolfe's medium for *Gallionella* enrichment (6), the environmental conditions for growth in these media do not seem to match well with groundwater environmental conditions (7,8).
- Useful Mn-precipitation media have been one area of weakness in common practice (7), although they are being refined (9).
- The available sulfur oxidizer media are still nonisolating, enrichment media.
- Employment of all of these culture methods requires preparation from raw materials (no packaged agar or broth media specific to IRB are available), sterilization, and maintenance in a microbiological laboratory by a skilled person. Thus, they are rarely used in operational practice.

Cultural Media Improvements. An important innovation of the last 20 years in biofouling cultural recovery has been the development of prepackaged cultural media that permit (1) practical use in operational monitoring in addition to more academic analyses and (2) recovery of a range of microflora, resulting in a more complete understanding of the microbial ecology of wells and more refined maintenance and management of water quality (see entry GW-1311 Well Maintenance). Two groups using slightly different approaches developed these methods independently:

MAG Method (MAG Laboratorio Ambiental, La Plata, Argentina). MAG tests for heterotrophic iron-related bacteria (IRB) and sulfate-reducing bacteria (SRB) consist of a prepared liquid medium contained in small septum bottles (10,11). The MAG medium for iron-related heterotrophic bacteria (BPNM-MAG) uses ferric ammonium citrate [like W-R and R2A + FAC (7)] and the SRB medium (BRS-MAG) uses Postgate C medium under a reducing atmosphere, supplemented with iron filings (11). Inoculation of a single bottle provides a presence-absence (P-A) result. Dilution to extinction provides a semiquantitative (MPN) result (11).

BART Method. Currently, the most commonly used cultural approach for routine biofouling monitoring is the Biological Activity Reaction Test (BART^{TM}) Method (Droycon Bioconcepts Inc., Regina, Saskatchewan).

- BART tubes contain dehydrated media formulations and a floating barrier device, which is a ball that floats on the hydrated medium of the sample.
- These devices and their proposed use are described in detail in Cullimore (12). They can be used as an enrichment method to provide a presence-absence (P-A) or semiquantitative (MPN) detection of biofouling factors (7,12–14).

BART tubes are available in a variety of media mixtures. The IRB-BART^{TM} test, for example, is designed to recover microaerophilic heterotrophic Fe- and Mn-precipitating microorganisms and is (like the BPNM-MAG test) derived from the W-R iron bacteria medium (15). This method, which is gaining wide operational acceptance as a means of detecting and characterizing biofouling symptoms, has provided useful qualitative information in well biofouling in various field trials (7) and has proven useful in a range of applications.

These methods have proved to be significant advances in making microbial ecology an important factor in routine operational monitoring as they

1. Reliably provide results to the level of detection needed to make operational decisions.
2. Are relatively easy to use and interpret.
3. Offer a means for precise scientific characterization of the microbial system if properly used and interpreted within their limitations.

At present, neither of these systems is included in *Standard Methods*, although they have become operationally de facto standard methods within the water operational and hydrogeologic communities (16). A definitive comparability test among these and various *Standard Methods* media is yet to be conducted.

Hybrid Methods. A subcategory of cultural methods consists of field-usable enrichment procedures to increase the potential for successful detection by microscopy. For example, Alcalde and co-workers (10,17) describe a simple enrichment and staining technique to enhance the numbers and visibility of filamentous bacteria on glass slides.

Nonculturing Biofouling Analytical Methods. All cultural enrichment methods recover only a fraction (1% is an often cited value) of microflora in environmental samples. Employing a range of cultural media and using media that better approximate ideal growth conditions (and making them easier to use) helps to overcome these problems; however, many microflora types may remain unrecoverable. Nonculturing analytical methods that directly detect interpretable evidence of microflora bypass these limitations.

Phospholipid Fatty Acid (PLFA) or Phospholipid Fatty Acid Methyl Ester (PL-FAME) Analysis. The method described by White and Ringelberg (18,19) and its variations provide a nonculturing method of characterizing the microbial components of environmental samples (solids such as sediment cores as well as fluids). In PLFA or PL-FAME, "signature" lipid biomarkers from the cell membranes and walls of microorganisms are extracted from the sample. Particular types of biomarkers are linked to groups of microorganisms. Amounts of biomarkers can be reliably associated with viable biomass, and compound ratios can be linked to community nutritional status. Once extracted from cells with organic solvents, the lipids are concentrated and fractionated using gas chromatography/mass spectrometry (GC/MS). A profile of the fatty acids and other lipids is then used to determine the characteristics of the microbial community. This "fingerprint" represents the living portion of the microbial community because phospholipids degrade rapidly following cell death (20).

A variation is TC-FAME (total-cell FAME), in which the lipids of whole cells are extracted and characterized from microbial isolates. These fatty acid profiles are compared to libraries of known isolates to identify unknowns in environmental samples or pure cultures.

Adenosine Triphosphate (ATP) and Adenylate Kinase (AK) Detection. ATP is ubiquitous in cellular life and can be detected rapidly using bioluminescence methods. The ATP bioluminescence test (21), detects ATP, which is present only in living cells. The amount of light emitted in the reaction can be correlated with the amount of ATP that can be extracted from a known number of bacteria. The test is rapid (<1 minute) and can be conducted with convenient test kits. Differences in ATP amounts occur by cell type and by growth phase and nutrient availability (22), and 10^5 cells/mL is the lower detection limit, requiring concentration for lower concentrations (*Standard Methods* Section 9211 C). The AK test detects a cellular enzyme (adenylate kinase-catalyzing ATP) that is present at a fairly consistent level in cells of all growth phases except spores, and the process (also rapid) can detect cells at 10 cells/mL (22). These tests are primarily useful in determining the total numbers of cells in a sample. What this means depends on the nature of the sample, but the ATP or AK result can be used for comparisons and in making operational or treatment decisions.

Nucleic Acid Testing. To identify biofouling microbial constituents definitively, genetic testing is used. Nucleic acids extracted are compared to libraries of sequences. Among the most useful procedures in groundwater microbial analysis is 16S rRNA community structure analysis (20). This method permits identifying microbes within complex environmental samples (such as biofilms), typically expressed as percent homology with known groups, but it is possible to identify isolates to the strain level.

Analytical Choice Considerations

All available analytical methods have their limitations. Fortunately, the strengths and weakness of microscopy and cultural enrichment appear to be complementary (7), so they are best used in tandem. The best use of BART or MAG methods is as indications of:

1. early detection or confirmation of probable biofouling and MIC conditions,
2. the presence of viable bacterial types in both liquid and extracted or eluted solids samples, and
3. relative "aggressivity" or activity of biofouling and corrosion-inducing communities.

Standard or heterotrophic plate counts (HPC) have often been used in water analysis for quantitative results. The validity of HPC has been called into question on the viability issue and because agar plates are an osmotically hostile environment. The actual organisms recovered in HPC testing can also vary widely among locations, seasons, and consecutive samples at a single location (23). Also, unamended HPC media tell little about what the recovered bacteria are doing in the environment. For these reasons, cultural methods developed for biofouling analysis are preferred, but HPC can be used if calibrated for specific applications and as a gauge to interpret some BART or MAG results.

PL-FAME provides a nonculturing method that can reliably assay the types of microflora (some of which are nonviable or dormant) in a range of samples, including biofilm samples, and their relative health and vigor. ATP/AK methods provide rapid cells-per-unit counts of living microflora reliable within a margin of error, which can also be conducted under field conditions in certain circumstances.

Where genetic identification is important (as when pathogen presence is suspected or to be ruled out), 16S rRNA analysis identifies all bacterial types. Both PL-FAME and 16S rRNA analyses are relatively expensive, although information-rich.

Sampling Methods

A serious limitation in biofouling monitoring is that recovering "representative" samples of biofouling microflora is difficult. Pumped (grab) sampling is the easiest way to obtain samples for analysis from wells or sample taps in pipelines. However, if pumping fails to detach and suspend biofilm particles, they will not be available for collection and analysis. Thus, a presumption of "probably absent" based on lack of recovery of microscopically visible particles (per Section 9240 or D 932) or cultural recovery may be a false negative. To improve the odds in recovery, it is useful to employ one or more of the following:

1. Filtration or centrifugation as recommended in *Standard Methods* increases the odds of recovering material useful for microscopic identification.
2. Time-series sampling: Cullimore (12) describes a time-series pumped-sampling procedure (similar to familiar procedures for groundwater quality analysis) that attempts to overcome the randomness of grab sampling. The time-series sampling approach, which includes taking replicates of samples at each sampling step, helps to overcome the statistical limitations of random, pumped, grab sampling for culture analysis.
   - This information can be used in assessing the microbial ecology in the well and the aquifer adjacent to the well (12). This procedure can be incorporated into a step-drawdown pumping test procedure.
   - Analysis of samples taken at various points in a groundwater-source system (flow-series instead of time-series) permits developing a profile of the microbial ecology of the system.
3. Collection of a biofilm on immersed surfaces can provide essentially intact biofilms for analysis. These methods are also adaptable for collecting samples of inorganic encrustations.

Several experimental designs for collecting biofilm organisms have been presented in the literature since at least the 1920s. Recent methods and equipment for biofilm coupon collection are summarized in Smith (7).

Sampling methods are closely linked to analytical methods:

- Pumped sampling is used for cultural enrichment (MAG or BART) or noncultural analysis of water (e.g., PL-FAME or ATP/AK).
- Time-series or flow-series sampling permits spatial analysis of results.
- Collection on surfaces is preferred for microscopy samples.
- Collection of solids provides samples that can be examined microscopically or extracted for culturing (qualitative) and nonculturing assay.
- All are practical in the operational setting (7,24).

PRACTICAL ISSUES IN MAINTENANCE MONITORING IMPLEMENTATION AND INTERPRETATION

Successful control of biofouling and associated changes in water quality, such as increased turbidity or alteration of metals content, depends very much on preventive or early warning monitoring (see MW-76, Well Biofouling and GW-1311, Well Maintenance). Among applications of microbiological analysis, biofouling monitoring of groundwater systems is a case study of methods in transition attempting to meet user needs. In contrast to available detection methods for microflora of concern to human health, convenient methods yielding information useful to formulate a response to biofouling have not been readily available to operators of groundwater systems until very recently.

At present, biofouling analytical methods remain at best semiquantitative and offer results that require expert interpretation. Consistency in usage and cross-correlation with other information (e.g., biochemical, physicochemical water quality and mineralogy) are keys to extracting the maximum information from biofouling analysis for a particular situation.

THREAT AGENTS AND WATER BIOSECURITY

JAMES HIGGINS
USDA-ARS
Beltsville, Maryland

THE NATURE OF THE THREAT

This article focuses on biological agents that can be maliciously introduced into potable water supplies and emphasizes those that would most likely be used, what the state of knowledge is on disinfection and/or inactivation protocols, and existing methods for detecting these agents.

The anthrax bioterror event that occurred in the eastern United States in the fall of 2001 provided graphic evidence of the considerable economic and public health impact that deliberate release of a pathogenic agent could engender, even in a technologically advanced nation. The event brought increased awareness of the perils of threat agents to public health and security personnel and led to the implementation of methods to determine when these agents may be present and to ameliorate their effects. The water industry (here used to refer principally to potable water suppliers) has been no exception; as part of the Public Health Security and Bioterrorism and Response Act (H.R. 3448) of 2002, all utilities providing water to 3300 people or more are required to have an emergency response plan in the event of a terror attack on their infrastructure.

In the light of the increased demands these new regulations make on the water industry, it is reasonable to ask, how real is the threat? Undoubtedly, some information on this topic is classified and not available to the general public, but there are indications that militant Islamic groups, such as Al Qaeda, are contemplating the use of threat agents and/or chemicals to compromise potable water supplies in the United States. Accordingly, managers and supervisors of water utilities may find it prudent to have some knowledge of potential threat agents, how they can be detected, and how they may be removed or inactivated when found.

THREAT AGENTS THAT MAY BE INTRODUCED INTO WATER SUPPLIES

Traditional lists of biological threat agents include both viruses and bacteria and the toxins that may be elaborated by some of these organisms. The list of viruses usually includes hemorrhagic fever- and encephalitis-causing viruses such as Venezuelan equine encephalitis (VEE), Ebola virus (EB), and Rift Valley fever virus (RVF). Perhaps the most worrisome virus is smallpox (Variola), enormous quantities of which were created by a clandestine bioweapons program in the former Soviet Union. Most of the world's population lacks immunity to smallpox and would thus be exceptionally vulnerable to infection (1).

Bacterial agents (and their diseases) include *Yersinia pestis* (plague), *Bacillus anthracis* (anthrax), *Francisella tularensis* (tularemia), *Coxiella burnetii* (Q fever), and *Burkholderia pseudomallei* (glanders or melioidosis). The category of toxins includes staphylococcal enterotoxins A and B; the botulinum toxin of *Clostridium botulinum*; ricin; which is produced by the castor bean; and trichothecene mycotoxins, which are extracted from fungi and gained notoriety in the late 1970s as the "yellow rain" used by Soviet-supplied forces in battlefields in Cambodia and Laos (2).

SURVIVAL OF THREAT AGENTS IN WATER

Generally, little is known about the survivability of threat agents in chlorinated or nonchlorinated water, how readily they disperse in water, and whether exposure to water alters their infectivity for the worse (or better, as the case may be). Conducting experiments with virulent strains of threat agents almost always requires use of dedicated Biosafety Level 3/4 laboratory facilities, which places sizeable constraints on the ability to carry out assays to answer these questions. Therefore, it often is necessary to extrapolate data derived from work done with related species, or avirulent strains, of these threat agents.

Some bacterial species that can be used as threat agents are "naturally" encountered in water and have been implicated in small but well-studied disease outbreaks. A waterborne outbreak of tularemia occurred in Chlumcany, Czech Republic, in 2000; 96 people became ill and contaminated water, used for drinking and food preparation, was the vehicle of infection (3). Other documented cases of tularemia linked to contaminated water were observed in Kosovo (4) and Norway (5), and it was hypothesized that an outbreak of oropharyngeal tularemia in Turkey in 2001 was caused by ingestion of nonchlorinated reservoir water (6). Laboratory experiments conducted by Forsman et al. (7) found that cells could be cultured in water devoid of carbon sources and maintained at 8 °C for up to 70 days postinoculation, indicating that *F. tularensis* can survive immersion in an aquatic environment for an appreciable length of time.

Outbreaks of melioidosis have been linked to the ingestion of water contaminated with *Burkholderia pseudomallei*; in Australia in 1997, seven culture-confirmed cases were identified in a small (300 people) rural community served by capped borehole wells 2 km distant (8). Chlorine levels in potable water samples were undetectable prior to the presumed exposure period, reflecting failure to treat water adequately before consumption.

A helpful overview of the ability of conventional water chlorination/disinfection protocols to inactivate threat agents is summarized in Burrows and Renner (9). The ability of some pathogens, such as spores of *B. anthracis*, to remain viable following typical chlorination regimens is a troubling but unavoidable facet of dealing with incidents of bioterorrorism aimed at potable water distribution networks (Fig. 1).

Note that for some agents, exposure to chlorine is bacteriostatic rather than lethal; though log reductions in the numbers of viable bacteria may be achieved, a remnant population may survive and can grow when chlorine concentrations decrease. For example, after 30 minutes of exposure, two strains of *B. pseudomallei* survived exposure to 1000 ppm chlorine; another could survive 300 ppm, but not 500 ppm (10). The utility of alternative methods, for such as chloramines, ozone, peroxides, UV radiation, metal ions, and electrochemistry, water disinfection may offer distinct advantages over chlorine (11). However, the paucity of experiments using actual threat agents requires us to extrapolate results achieved with conventional waterborne pathogens to gain insight as to how well these methods would inactivate species such as *B. anthracis, F. tularensis*, and poxviruses.

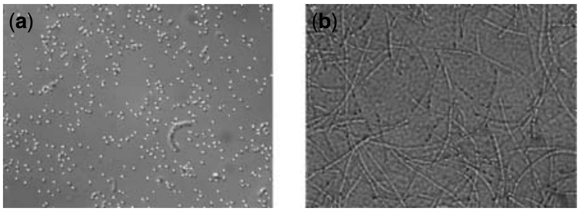

Figure 1. Nomarski interference contrast microscopy images of *Bacillus anthracis* Sterne strain spores: panel A, the comma-shaped organism in the center of the image is a vegetative cell, and vegetative cells (panel B), 1000X magnification (panel A photograph, courtesy of Jeffrey Karns).

MONITORING WATER FOR THREAT AGENTS: RECOVERY FROM SOURCE AND FINISHED WATERS

Successful monitoring of source and finished waters for threat agents is a two-component process: first, the organisms must be removed or isolated from the water samples, usually via filtration or other selective separation protocols. Second, the recovered organisms must be detected and their identity confirmed with a sufficient degree of reliability and accuracy to allow water utility managers to make decisions with confidence.

Approaches to establishing potable water security must deal with three segments of the water delivery system: the source water supply, the water purification/treatment facility, and the distribution network that brings water to individual buildings and homes. The water industry has considerable expertise in detecting select pathogens in source water, such as *Giardia* and *Cryptosporidium*, via protocols such as the U.S. EPA Method 1623, which involves capsule filter-mediated recovery of oocysts from 10 L volumes of water. However, source waters may contain appreciable numbers of naturally occurring flora that can confound detection efforts; they may also contain high concentrations of particulate matter that can impede filtration protocols for pathogen recovery from large volumes of water.

Recovery of viral threat agents presents greater difficulties than for bacterial agents because they are considerably smaller (except for poxviruses, which may approach 0.2–0.3 μm in length) and require culture in living cells to reproduce. As with protozoa, the water industry, private and academic laboratories, and agencies such as the U.S. EPA, have made considerable efforts to develop protocols for isolating enteric viruses from large volumes of water, and these protocols may be useful in dealing with agents such as poxviruses and hemorrhagic fever viruses.

Little is known about the behavior of biological toxins in source waters, particularly when large quantities of the toxins may be deliberately introduced into reservoirs close to intake pipes. The stability of toxins in such an environment is poorly understood. However, larger utilities continuously monitor source water for chemical contaminants (metals, organics, solvents, etc.) and provide some measure of confidence in the industry's ability to adapt preexisting assays for detecting threat toxins. Analytical chemistry protocols, such as gas or liquid chromatography and mass spectrometry, as well as immunoassays and bioassays, can be used in a comprehensive monitoring strategy (12).

Monitoring operations at the second and third segments of the water delivery system—the purification facility and the distribution network—are more difficult targets for bioterror attacks, because they have a more highly supervised structure and offer fewer opportunities for unobserved, deliberate introduction of pathogens. However, deliberate contamination at these segments of the delivery system has far more troubling aspects than for source waters because the infectious dose is comparatively more concentrated in finished water and this water is destined for direct (and indirect) consumption by the public. However, by containing disinfecting agents, "in plant" finished water is less likely to permit survival of infectious agents; by the time it reaches the household tap, potable water may support pathogen viability. For example, in experiments conducted in collaboration with Dr. Kalmia Kniel at the University of Delaware, we have found that raccoonpox virus can survive over two month's exposure in tap water, as measured by its ability to cause lytic infection of Vero cells. These experiments are preliminary, but they indicate a need to learn more about poxvirus survival in finished water (Fig. 2).

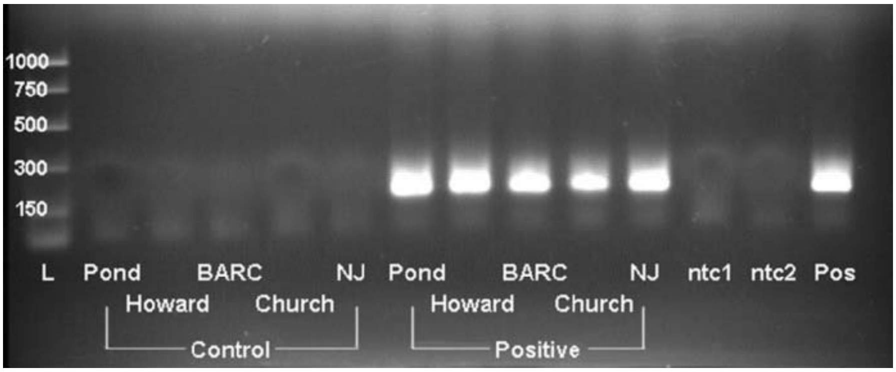

Figure 2. Polymerase chain reaction (PCR) assay conducted on Vero cell supernatant following infection with raccoonpox virus (RPV). RPV ($\sim 1 \times 10^6$ plaque-forming units) was incubated in 2 mL volumes of water from various sources: pond water and water from taps in Howard County, Maryland; the Beltsville Agricultural Research Center (BARC), Maryland; and a home in New Jersey, for 70 days at room temperature. Two hundred μL portions of the water were then mixed with a cell culture medium and applied to Vero cells for 1 hour; after that the medium was replaced and the Vero cells maintained at 37 °C and 5% CO_2. The supernatant (200 μL) was collected after 5 days and subjected to DNA extraction and nested PCR using the hemagglutinin primers of Ropp et al. (13). Control samples represent unspiked tap water samples. Lanes ntc1 and ntc2 represent PCR negative controls and lane Pos is the PCR positive control. Lane L is the DNA ladder, with rung sizes indicated.

MONITORING WATER FOR THREAT AGENTS: IDENTIFYING THREAT AGENTS

Once threat agents have been recovered from source or potable waters, they must be identified. Note Despite significant advances in detection technologies, sponsored in large part by U.S. government Department of Defense research initiatives, there is no single method currently that can reliably and reproducibly detect all potential threat agents in water samples in real time with any appreciable degree of sensitivity and specificity. The lack of such a method obviously presents the water industry with major challenges in monitoring potable water supplies for potentially harmful organisms and/or toxins.

Detection methods can be classified into three broad categories; the first includes traditional detection methods, which offer some advantages: they are often relatively inexpensive to perform, require modest training of the individuals performing the tests, and have standardized methods that have been reproduced by many laboratories over lengthy periods of time. For bacterial pathogens such as anthrax, traditional methods involving culture of vegetative cells on agar, the appearance and morphology of colonies on the agar, and the light microscopy features of the cells comprising the colonies offer a convenient and affordable means to monitor water for this agent (Fig. 3).

The same approach can be used with some degree of success for *Francisella and Burkholderia*, among others. As always, the type of water sampled can influence the sensitivity and specificity of the detection method; when closely related waterborne flora can be mistaken for threat agents, traditional methods must be augmented by other detection protocols to avoid generating false-positive results.

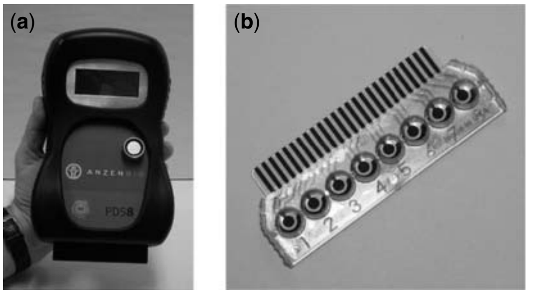

Figure 4. The Anzenbio PDS-8 instrument is a novel platform for field-based detection of toxins and pathogens. The detector (panel A) can be held in one hand and presents data to the end user via the inset LCD screen. The biosensor chip (panel B) is part of a disposable cartridge that is inserted into the detector. Up to six different samples (plus one positive and one negative control) can be analyzed on the chip, using a proprietary antibody-mediated, electrochemical format. The assay can be completed in as few as 2 hours (photo courtesy of Linda Williams, Anzenbio).

The second category of detection approaches involves immunologic methods, which are mediated by antibodies; the formats for such methods can be quite varied and include enzyme-linked immunosorbent assay (ELISA), immunochromatographic lateral flow assay, immunomagnetic separation-electrochemiluminescence (IM-ECL), and time-resolved fluorescence assay (14). Compared to traditional protocols, antibody-based detection methods provide greater specificity and sensitivity, timeliness, and ease of

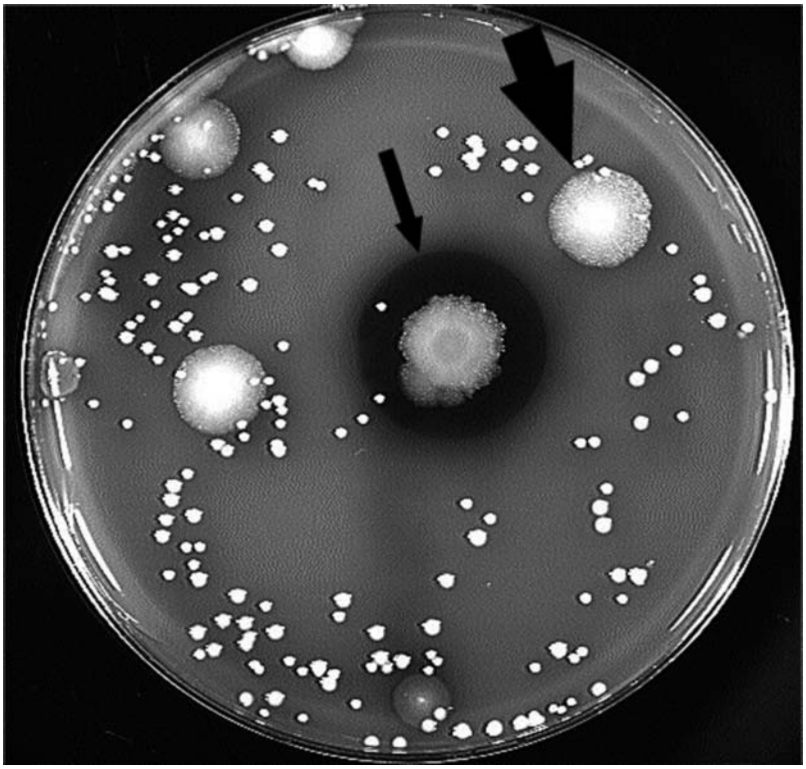

Figure 3. Photograph of bacterial colonies grown from stream water spiked with spores of *B. anthracis* Sterne strain on red blood cell agar plates. The large black arrow indicates a colony of *B. anthracis*; the smaller black arrow indicates a colony of a related *Bacillus* spp. Note the lytic zone surrounding this colony, a feature that can be used to differentiate between colonies of *anthracis* and those of other spore-forming members of waterborne flora.

use. Emerging technologies in this field seek to miniaturize the assay to the point where it can be done in the field or on site; one example of such an emergent technology is provided in Fig. 4.

Immunologic methods for the detecting bacterial, protozoal, and viral pathogens have been reported in the literature; in one of the more recent reports, Tims and Lim (15) detected purified *B. anthracis* spores in less than one hour, using a portable fiber-optic biosensor. Immunologic methods are particularly useful in detecting toxins, which are often proteins and thus not easily amenable to molecular biology-based detection (16).

Immunologic assays do possess some drawbacks. The specificity of the antibodies used to mediate detection is a critical factor; too poor a specificity means that false-positive signals can be generated from organisms that are closely related to the pathogen of interest. And, in general, antibody-based assays may not provide as great a degree of sensitivity as their molecular counterparts.

Molecular biology-based assays, such as PCR, have come into the forefront of pathogen detection technologies. By targeting regions of DNA intrinsic to particular species or strains of microorganisms, molecular methods can provide a high degree of specificity and sensitivity. There is a substantial and ever-increasing body of scientific literature on the use of molecular techniques for detecting and characterizing conventional waterborne pathogens. Many water quality laboratories in the United States, Europe, Australia, and Asia now use these methods routinely and readily adopt new instrumentation and procedures as their testing needs evolve.

Drawbacks of molecular detection techniques include high setup and maintenance costs, which translate into a higher cost per assay than traditional protocols, and the need for more training for laboratory personnel. Nonetheless, the enhanced detection capability of molecular protocols has led to their adoption by U.S. Department of Defense agencies as the first choice for threat agent identification. A detailed recitation of existing threat agent detection protocols is beyond the scope of this article; readers are directed to the paper by Firmani and Broussard (17) for a comprehensive overview of this evolving topic.

FUTURE DIRECTIONS FOR BIOSECURITY OF WATER RESOURCES

As this article is written in early fall 2004, there are encouraging signs that government agencies responsible for regulating water quality are moving to enhance the ability of the industry to respond to threats directed against water resources.

One of these efforts is being mounted by the U.S. EPA, which in July 2004 began testing three competing platforms for the rapid detection of threat agents in water under the aegis of the Environmental Technology Verification (ETV) program. All three platforms, the Idaho Technology, Inc. Ruggedized Advanced Pathogen Identification Device (RAPID), the Applied Biosystems 7000 Sequence Detection System, and the Agilent Bioanalyzer used by Invitrogen Corporation, rely on PCR to mediate amplification and identification of pathogen DNA in real time. These instruments will be tested by the Battelle laboratory's Advanced Monitoring Systems Center using the bacterial threat agents *Bacillus anthracis, Francisella tularensis, Brucella suis, E. coli*, and perhaps *Yersinia pestis*. The platform performing best in sensitivity and specificity may be designated the rapid detection method of choice for utilities and agencies contemplating enhancements of their biosecurity capabilities.

Other U.S. EPA initiatives, such as the Water Quality Protection Center and the Drinking Water Systems Center, are working to provide the industry with up-to-date technologies for providing safe and wholesome water to their customers. Industry organizations such as the International Water Association, the American Water Works Association, the Water Environment Foundation, the European Water Association, and the Australian Water Association are actively funding research and development to provide improved biosecurity resources to their subscribers. All of these developments should assist water quality managers as they deal with the challenge presented by this potential threat to human health.

Activated carbon is the generic term used to describe a family of carbonaceous adsorbents with a highly crystalline form and extensively developed internal pore structure. Activated carbon is distinguished from elemental carbon by the removal of all noncarbon impurities and the oxidation of the carbon surface (1). Activated carbon has the highest volume of adsorbing porosity of any substance known to humans (5 grams of activated carbon can have the surface area of a football field). It can be defined as (2):

> Activated carbon is a crude form of graphite, with a random or amorphous structure, which is highly porous, over a broad range of pore sizes, from visible cracks and crevices, to cracks and crevices of molecular dimensions.

The use of activated carbon is not new. The Egyptians used carbonized wood around 1500 B.C. as an adsorbent for medicinal purposes as well as a purifying agent. The ancient Hindus in India used charcoal for filtration of drinking water. However, the basis for industrial production of active carbons was established in 1900–1901 in order to replace bone char in the sugar refining process (3).

Active carbons can be prepared from a wide range of carbonaceous materials, which include coconut shells, wood char, lignin, petroleum coke, bone char, peat, saw dust, carbon black, rice hulls, sugar, peach pits, fish, fertilizer waste, and waste rubber tire. (Table 1). The range of raw materials is diverse and widespread and greatly influenced by the need to produce low-cost carbon. Among the most commonly used raw materials, precursors for the production of commercially activated carbons are wood (130,000 tons/year), coal (100,000 tons/year), lignite (50,000 tons/year), coconut shell (35,000 tons/year), and peat (35,000 tons/year) (4,5).

TYPES OF ACTIVATED CARBONS

Based on the physical properties, activated carbons can be classified into the following broad categories:

Powdered Activated Carbon (PAC)

These activated carbons are made in the powders or fine granules according to the requirement. Powdered activated carbons have a diameter between 15 and 25 μm. These carbons provide a large internal surface with a small diffusion distance.

Granular Activated Carbon (GAC)

Granular activated carbon (GAC) is commonly used for the purification of liquids and gases. Granular activated carbon adsorbs a vast variety of dissolved organic materials, including many that are nonbiodegradable. GAC removes organic contaminants from water/wastewater by the adsorption process of the attraction and accumulation of one substance on the surface of another. Granular activated carbons typically have surface areas of 500–2000 m^2/g, with some reported as high as 3000 m^2/g. Much of the surface area available for the adsorption in granular activated carbon particles is found in the pores within the granular carbon particles created during

the activation process. GAC have relatively larger particle sixes than powdered activated carbon and therefore provide a smaller external surface. These carbons are preferred for all the sorption of gases and vapors. GAC are also used in water/wastewater treatment, deodorization, decolorization, and separation of components in flow systems.

Spherical Activated Carbon (SAC)

These carbons are prepared from small spherical balls wherein pitch is melted in the presence of naphthalene or tetorlin and converted into spheres. These spheres are then contacted with naptha solution, which extracts naphthalene introduced into the porous structure. These porous spheres are then heated between 100 and 400 °C in the presence of an oxidizing agent. The oxidized spheres are then heated between 150 and 700 °C in the presence of ammonia to introduce nitrogen into spheres followed by activation in steam or CO_2.

Impregnated Activated Carbon (IAC)

In chemical activation, a catalyst may be impregnated into the feedstock. The most commonly used chemical activants include $ZnCl_2$, H_3PO_4, H_2SO_4, KOH, K_2S, and KCNS. In this process, a near-saturated solution of catalyst-impregnated feedstock is dried to influence pyrolysis in such a way that tar formation and volatilization can be kept at a minimum. The resulting product is then carbonized. Silver impregnated activated carbons are used for purification of domestic water.

Polymer Coated Activated Carbons (POAC)

In this process, porous carbon can be coated with biocompatible polymers resulting in a smooth and permeable coat without blocking the pores. It is well documented in literature that activated carbons possess a highly developed porous system. These pores are produced during the activation process of carbonized residue when spaces between elementary crystalline are cleared of carbonaceous compounds and nonorganized carbon.

The precursors used for the production of activated carbons have a large effect on the pore size distribution, surface area, and other physical and chemical properties. Table 2 sums up some of the basic differences between the raw materials used for the production of some important activated carbons, whereas the properties of some commercially available carbons with their sources as collected from literature are presented in Table 3.

METHODS FOR ACTIVATED CARBON DEVELOPMENT

The methods for the development of activated carbons are nearly as widespread as their potential uses and source materials (6). However, the basic steps most commonly used in the preparation of activated carbons are precursor material preparation, palletizing, low-temperature carbonization, followed by chemical or physical activation (Fig. 1). A number of methods were used for the preparation of activated carbons from waste materials from time to time using different activation parameters. Different steps/activation parameters used for the preparation of some of the activated carbons are presented in Table 4. Although the list is not complete, it will provide a general idea of the different methods used for the production of activated carbons.

Raw Materials

The selection of an appropriate raw material (Table 1) for the development of granular activated carbon is the most important aspect. The following points must be considered before selecting any raw material for the production of activated carbons:

1. Industrially inexpensive materials with high carbon and low inorganic content should always be preferred.
2. The impurities in raw materials should be kept at a minimum because after the activation process, many of these may be present in the carbon at higher concentrations than the precursors materials.
3. Importance should be given to the precursors having high density and sufficient volatile content. The volatile results in porous char, whereas high density favors the enhancement of structural strength of the carbon needed to withstand excessive particle crumble during use.
4. The raw material should be available in abundance locally.

The raw materials used for the preparation of activated carbons vary with their applications. A comparison of some of the raw materials is presented in Table 2.

Table 2. Basic Differences in Precursor Materials Used for the Production of Activated Carbons

Raw Materials	Percent Carbon	Percent Volatile Matter	Ash Percent	Density (kg/m3)	Activated Carbon Texture	Applications
Hard wood	40–42	55–60	0.25–1.2	0.50–0.8	Soft with large pore volume	Liquid phase adsorption
Soft wood	40–45	55–60	0.25–1.0	0.40–0.50	Soft with large pore volume	Liquid phase adsorption
Nut shells	40–45	55–60	0.40–0.60	1.4	Hard with large multi pore volume	Vapor phase adsorption
Lignite	50–70	25–40	5–6	1.0–1.40	Hard with small pore volume	Liquid phase adsorption
Soft coal	60–80	25–30	2–12	1.25–1.50	Medium hard with medium micropore volume	Liquid and vapor phase adsorption
Semihard coal	70–75	1–15	5–15	1.45	Hard with large pore volume	Vapor phase adsorption
Hard coal	85–95	5–10	2–15	1.50–2.0	Hard with large pore volume	Vapour phase adsorption

Carbonization

Carbonization, sometimes called charring, converts the organic material into primary carbon, which is a mixture of ash, tars, amorphous carbon, and crystalline carbon.

In carbonization, the material is heated slowly in the absence of air. In this process, most of the noncarbon elements, hydrogen, and oxygen are first removed in gaseous form by pyrolytic decomposition of the starting materials. The important parameters, which determine the quality and quantity of the carbonized product, are (a) rate of heating, (b) final temperature, and (c) soaking time.

Activation

The activation is carried out basically to enlarge the diameters of the pores, which are created during the carbonization process, and to create some new porosity, which results in the formation of a well-defined and readily accessible pore structure with large internal surface area. During the activation process, the spaces between the elementary crystallites become cleared or less organized loosely bound carbonaceous material. The resulting channels through the graphitic regions, the spaces between the elementary crystallites, together with fissures within and parallel to the graphite planes constitute the porous structure, with large internal surface area (24). There are two types of activation, which are used to impart a porous structure within a starting material of relatively low surface area, namely thermal/physical or chemical activation.

Physical or Thermal Activation. Physical or thermal activation occurs after initial treatment and palletizing; it involves carbonization at 500–600 °C to eliminate the bulk of the volatile matter followed by partial gasification using mild oxidizing gas such as CO_2, steam, or fuel gas at 800–1000 °C to develop the porosity and surface area (25). An example includes the gasification of the carbonized material with steam, and carbon dioxide occurs by the following endothermic reactions:

$$C + H_2O \longrightarrow CO + H_2 \text{ (29 kcal)}$$

$$C + CO_2 \longrightarrow 2CO \text{ (39 kcal)}$$

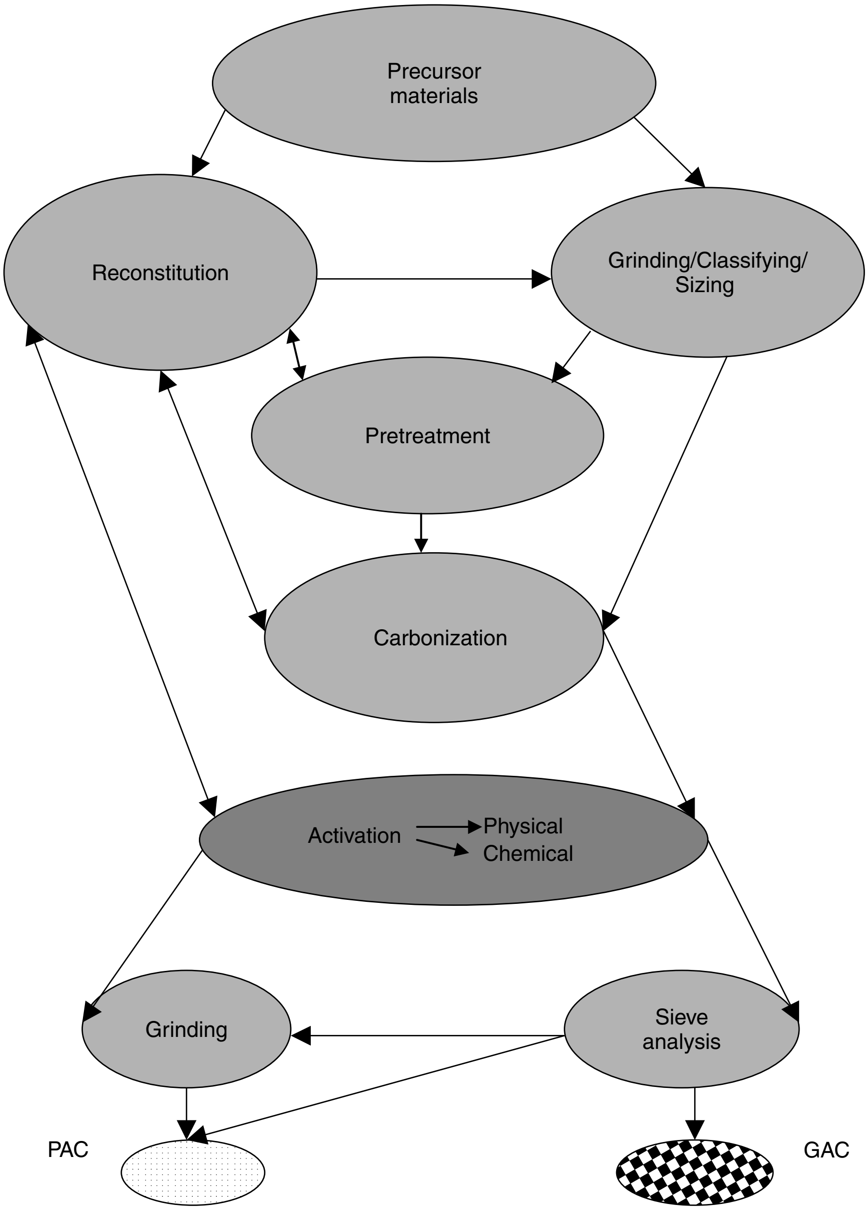

Figure 1. Various steps used in the activated carbon production.

$$CO + H_2O \longrightarrow CO_2 + H_2 \text{ (10 kcal)}$$

The H_2O molecule is smaller than the CO_2 molecule and thus diffuses faster into the pores of the carbon. Consequently, a reaction with steam is faster than that of CO_2. It has been reported in literature that a decrease in the reaction rate with CO_2 activation on carbon-containing wastes is nearly two times less than that of steam. When air or oxygen is used as an activating agent, problems develop because of the exothermic nature of the reactions of carbon with air (oxygen), and thus it is difficult to control. Despite these problems, several researchers have used the same for the activation of their products.

Chemical Activation. The second type of activation involves the incorporation of inorganic additives or metallic chlorides, such as zinc chloride or phosphoric acid, into the precursor before the carbonization (6). It has been reported that carbons with well-developed porous structure, mainly meso and microporous, can be produced by $ZnCl_2$ incorporation. KOH activation has also been shown to successfully increase the surface area and pore volume of active carbons (20,26)

Many other chemicals, such as ammonium salts, borates, calcium oxide, ferric and ferrous compounds, manganese dioxide, nickel salts, hydrochloric acid, nitric acid, and sulfuric acid, have also been used for the activation purpose.

The basic difference between physical and chemical activation is the number of stages required for activation and the temperature at which the activation takes place. Chemical activation is a one-step process, whereas physical activation is a two-step process, including carbonization and activation. The temperature required in physical activation (800–1000 °C) is higher than that of chemical activation (200–800 °C).

Table 4. Some Chemical Activant-Feedstock Couples [Extended Form of (4)]

Feedstock	Activant	Conditions	Reference
Coconut shell	Con. H_2SO_4	1.5 parts by weight H_2SO_4 for 24 hrs at 140–160 °C: steam activation at 1 Kg/m^2 pressure for 30 min.	7
Agricultural by products such as almond shell, olive stones and peach stones	—	Heating in CO_2 at 1123K	8
Coconut shell	Con. H_2SO_4	1.0 parts by weight H_2SO_4 for 24 h at 150 °C	9
Fertilizer slurry	H_2O_2/H_2O, N_2	450 °C, 1 h	10
Palm tree cobs	H_3PO_4/H_2SO_4	730 °C, 6 h	11
Coconut shell	H_3PO_4	450 °C	12
Petroleum coke	KOH/H_2O	700–850 °C, 4 h	3
Raffination earth	$H_2\ SO_4$	10% v/v,350 °C	13
Algerian coal	KOH/NaOH	930 °C	14
Pine saw dust	$Fe(NO_3)_3/CO_2$	850 °C, 1 h; 825 °C, 6 h	15
Almond and pecan shells	H_3PO_4	Chemical activation with H_3PO_4/Physical CO_2	16
Eucalytus woodchars	—	CO_2 activation, 400–800 °C	17
Bituminous coal	$ZnCl_2$	N_2/400–700 °C	18
Coal or coconut shell		Phosgene or chlorine gas at 180 °C	19
Petroleum coke	KOH	Dehydration at 400 °C followed by activation in 500–900 °C	20
Lignite	Na_2MoO_4/ $NaWO_4$/ NH_4VO3/ $(NH_4)_2MoO_4$/ $FeCl_3$/ $Fe(NO_3)_3$	Inert atmosphere/600–800 °C	21
Peanut hulls	H_2SO_4	150 °C, Sodium bicarbonate	22
Coconut shell and cocnut shell fibers	H_2SO_4	600 °C	23

Thus, the activated carbons can be prepared by either physical/chemical activation or a combination of both with well distributed porosity and high surface area.

Characterization of GAC

The effectiveness of activated carbon as a unit process in the treatment of water/wastewater/industrial effluents requires the best selection of an appropriate activated carbon. Following are some of the important properties used for the selection of suitable activated carbon for specific treatment:

Density. The density of carbon can be expressed in several different ways. The two most important among these are apparent and particle densities.

Apparent Density. Apparent density has little role in initial evaluation of an activated carbon, but it has an important role in the regeneration process. It is defined as the mass of carbon per unit volume that can be packed into an empty column. It is expressed in grams per cubic centimeter or pounds per cubic foot.

Particle Density. Particle density is defined as the ratio of the mass of dry and unloaded carbon particles to the total volume of the particles, including pore volume.

Higher density GAC is preferred because of the following reasons:

1. High density GAC has more carbon structure.
2. The high density GAC figured that, for each cubic meter of volume, more GAC could be installed.
3. Bituminous coal-based GAC provides a much denser material than lignite or subbituminous coal.

Moisture. It is important only for shipping and manufacturing purposes. It is defined as the percent by mass of water adsorbed on activated carbon.

Hardness and Attrition. It is an important factor in system design, filter life, and product handling. Large differences exist in the hardness of activated carbons, depending on the raw materials used and activity level (Tables 2 and 3). It is defined as the resistance of a granular activated carbon to the degradation action of steel balls in a Ro–Tap machine. It is calculated by using the mass of granular carbon retained on a particular sieve after the carbon has been with steel balls.

Sieve Analysis. It is very useful in carbon production evaluation. It is also important in the evaluation of purchased carbon to the specifications. The distribution of particle sizes in a given sample is obtained by mechanically shaking a weighed amount of activated carbon through a series of test sieves and determining the quantity retained by or passing given sieves.

Abrasion Number. The abrasion number is important in evaluating the ability of a carbon to withstand attrition. It is defined as a measure of the resistance of the particles to degrade on being mechanically abraded, which is measured by putting a carbon sample with steel balls in a pan on a Ro–Tap machine. In other words, it is defined as the ratio of the final average (mean) particle diameter to the original average (mean) particle diameter times 100.

Ash Percent. The ash percent is very important in the evaluation of the raw materials and the manufacturing process. It is the residue that remains when the carbonaceous portion is burned off. The ash contained mainly has silica, alumina, iron, magnesium, and calcium. Ash in activated carbon is not desirable and is considered to be an impurity. It can be measured by the change in weight by burning the carbon sample to constant weight at 800 °C.

pH. The effect of the carbon on pH of a volume of water is very much dependent on the relative quantities of both activated carbon as well as water. The pH effect can be studied by putting 1.0-gram carbon with 50 ml of de-ionized water and heating to 90 °C followed by cooling to 20 °C and measuring the pH of the supernatant.

Effective Size, Mean Particle Diameter, and Uniformity Coefficient. It is used to establish the hydraulic conditions of an adsorber column. Measurement of the gradation of carbon particles plays an important role in the evaluation of head loss in the flow through granular beds. The mean particle diameter can be calculated as follows:

First the average particle diameter (d) of each sieve used for the particle distribution is calculated by using the following equation:

$$d = w \times n$$

where w is the percent of the total weight retained by a particular sieve and n is the average of the mesh opening of the sieve that contained w and the sieve used immediately above.

By using this d, the mean particle diameter can be calculated as:

$$\text{Mean particle diameter} = \text{sum of all diameters divided by 100}$$

It is very important to note here that the smallest sieve is not considered in calculating the mean particle diameter.

The effective size can thus be calculated by using the cumulative percentage of carbon passing each size and plotting the sieve opening in millimeters (ordinate) versus the cumulative percentage (abscissa) on a semilogarithmic scale. Thus, the effective size is the opening in millimeters, which passes 10% of the total material. The 60% passing sieve size divided by the effective size gives the uniformity coefficient. The 50% passing sieve size is approximately the mean particle diameter. The uniformity coefficient is basically a dimensionless factor, which indicates the degree of uniformity of GAC. A value of one indicates that all parameters are identical in size, whereas greater values relate to a higher degree of variation.

Surface Area. Total surface area is very important to characterize porous solids. Large surface area is generally a requirement for a good adsorbent. However, the total surface area has to possess adequate pore size distribution and surface chemistry to adsorb the targeted species. Surface area determination relies on the accurate knowledge of the average area. It is determined by the sorption of nitrogen gas into the carbon and is expressed in square area per gram of carbon. The most widely accept method is the BET nitrogen adsorption method.

Pore Size Distribution. Activated carbon is a complex network of pores of different sizes and shapes. The shapes include cylinders, rectangular cross sections, and other irregular shapes and constrictions. The identification of different sizes is called the pore size distribution.

The pore size distribution is very much dependent on the source materials and method of activation. According to IUPAC accepted criteria (27), activated carbons have a trimolecular distribution of pore sizes (Fig. 2), as discussed below.

Macropores. These are the pores having diameter greater than 50 nm (Fig. 2). Their pore volume varies from 0.2 to 0.5 cm^3/g and surface area lies between 0.5 and 2 m^2/g. Such low value of surface area renders them of little use in adsorption except for large adsorbate molecules.

Mesopores. These pores have diameter ranging between 2 nm and 50 nm (Fig. 2). The pore volume of these pores varied from 0.02 to 0.01 cm^3/g. The surface area constituted by these pores lies between 10 and 100 m^2/g. The capillary condensation with the formation of a meniscus of adsorbate mainly takes place in these pores.

Micropores. These pores have diameter less than 2 nm (Fig. 2). Their size generally corresponds to that of molecules. The value of these pores ranges from 0.15 to 0.5 cm^3/g and surface area lies between 100 and 1000 m^2/g. They constitute about 95% of the total surface area. These pores are of great significance as far as adsorption studies are concerned.

Besides these, two different types of pores are exist in some of the carbons.

Ultramicropores. These pores have diameter <0.7 nm.

Supermicropores. These pores have diameter between 0.7 and 2 nm.

In practice, total pore volume is calculated by measuring three distinct volumes associated with one gram of the material at a constant temperature. These three distinct volumes are:

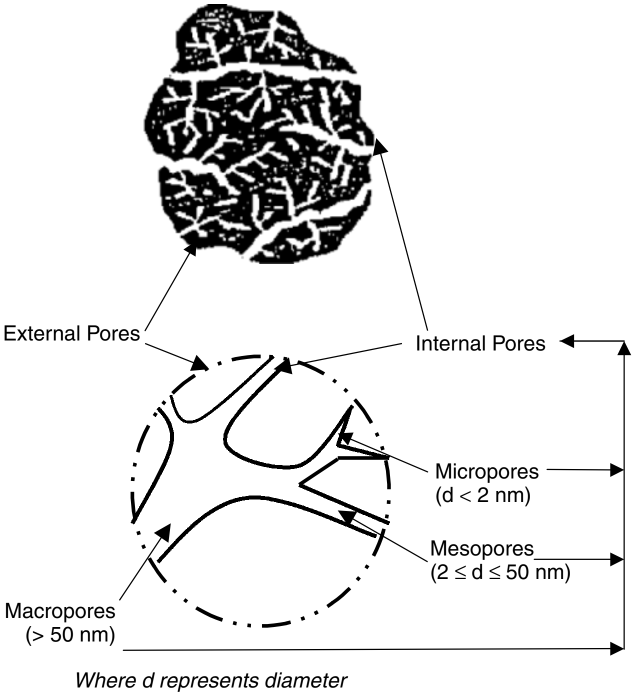

Figure 2. Schematic activated carbon structure.

(a) the volume of its purely solid structure
(b) the external geometrical volume of the solid
(c) the volume of a given fluid that it can displace

Thus, the total pore volume can be given by the difference between (b) and (a).

Iodine Number. It is defined as the number of milligrams of iodine adsorbed by one gram of activated carbon when the iodine concentration of the residual filtrate is 0.02N.

The iodine number provides an indication of the amount of small pores in carbon. It is correlated with the surface area in pores with diameters less than 10 Å. As iodine is a small molecule, it provides an indication of a particular carbon's capacity to adsorb smaller molecules.

Molasses Number. The molasses number represents the amount of large pores in carbon. It is calculated from the ratio of the optical densities of the filtrate of a molasses solution treated with a standard activated carbon and one in question. The molasses number can be correlated with the surface area in pores with diameters greater than 10 Å.

Both the iodine number and the molasses number decrease with time as adsorption occurs.

Methylene Blue Number. It is defined as the number of milligrams of methylene blue adsorbed by one gram of activated carbon in equilibrium with a solution of methylene blue dye having concentration 1.0 mg/L.

Phenol Number. Phenol number has been found to be a less sensitive test as it is very much effected by pH of the actual water used. It is very well documented in literature that at low pH, phenol adsorption is much greater than at neutral or alkali pH.

SURFACE CHEMISTRY OF ACTIVATED CARBON

The type of starting material and the method of activation used in producing activated carbon determines the nature of various surface functional groups. The surface chemistry of carbon has been studied extensively by several investigators from time to time. The nature of the carbon surface basically depends on the conditions and temperatures employed during the activation process. Activated carbon can be divided into two major types, namely acidic (L) and basic (H), according to Steenberg's classification (1) and can be defined as follows:

L Carbons

These carbons are prepared by heating the raw materials at about 200–400 °C in the presence of air. These carbons assume a negative charge (ionized) upon hydration and, thus, yielding acidic pH, are hydrophilic in nature and can neutralize a strong base. These carbons generally develop acidic surface oxides and lower the pH value of neutral or basic solutions. They primarily sorb bases from the solutions and exhibit a negative zeta potential. Wood-based activated carbons are usually L type in nature. The predominant surface functional groups are carboxyl, phenolic hydroxyl, carbonyl (quinone type), carboxylic acid, anhydrides, lactone, and cyclic peroxide (28,29). It has been reported that carboxylic and lactone groups tend to discourage the adsorpion of many aromatic compounds (29). Carbonyl groups in the form of quinone structures, and hydroquinone groups, however, can enhance the adsorption of aromatic compounds by the formation of an electron donor-acceptor complex between the aromatic ring and the surface carbonyl groups (30,31).

H Carbons

The activated carbons are prepared by heating the raw materials at about 800–1000 °C in the absence of air or in the presence of CO_2 followed by exposure to air at room temperature. These carbons assume a positive charge (protonated) upon introduction into water, thus yielding alkaline pH. They are hydrophobic in nature and can neutralize strong acids. These carbons generally develop basic surface oxides and increase the pH value of neutral or acidic solutions. They primarily sorb strong acids from the solutions and exhibit a positive zeta potential. Coconut shell-based and dust coal activated carbons are usually H type in nature. The predominant surface functional groups on the surface of the carbons are lactones, quinones, phenols, and carboxylates. More reports of the chromene (benzpyran) groups on the surface of the carbon exist (32). Boehm and Voll (33) suggested that basic surface oxide may be represented by pyrone-like structures.

It is interesting to note that H-type carbons can be converted into L-type carbons when they are oxides by chemical oxidants or aged in the atmosphere.

The acidic groups on activated carbons are believed to be one of the most important properties of activated carbons for metal ions adsorption (34). The L-type carbon is a stronger solid acid than the H-type carbon, therefore L-type carbon is more efficient for the adsorption of heavy metal ions. Surface area is not a primary factor for adsorption on activated carbon. High surface area does not mean high adsorption capacity, as reported by Perrich, (35), because of the following factors:

(a) In adsorption, only the wetted surface area is effective, which is never equal to the total surface area.
(b) In some adsorption processes, the material to be adsorbed is too large that it cannot enter the small pores where the bulk of the surface area exists.
(c) Data on the surface area, pore volume, and surface nature usually have not been correlated with data on the material to be adsorbed.

The physical and chemical properties of the carbons are very much dependent on the properties of raw materials, method of carbonization, and activation. The properties of some selected carbons developed from different sources are given in Table 3. These properties are collected from various sources including books, literature, and company brochures.

ADSORPTION EQUILIBRIUM

To determine the ultimate adsorption capacity, the solutes are brought in contact with a given amount of activated carbon or any other adsorbent in a closed system. If adsorption is the dominating removal mechanism, then the residual concentration will be reached that will remain unchanged with time, which is also know as equilibrium concentration. This process is known as adsorption equilibrium.

The adsorption process is essentially an attraction of gaseous or liquid adsorbate molecules onto a porous adsorbent surface. In gaseous separations, activated carbon is often used to remove odors and impurities from industrial gases, to recover valuable solvent vapor, and to dehumidify air and other gases. In liquid separations, activated carbon can be applied for removing the taste and odor from water, decolorizing, and treating industrial wastewater containing organics, dyes, and heavy metal ions.

There are two types of adsorption processes.

Physical Adsorption

Physical adsorption is a reversible phenomenon. It results from the action of van der Waals forces, comprised of London dispersion forces and classic electrostatic forces of attraction between molecules of the carbon and the substance adsorbed (adsorbate). Physical adsorption is usually dominant at low temperatures. This type of adsorption is usually multilayered; i.e., each molecular layer forms on top of the previous layer, with the number of layers being proportional to the contaminant concentration.

Chemisorption

It is the result of chemical interaction between the carbon surface and the adsorbed substance. It usually involves strong bonds, and is therefore irreversible.

A number of factors exist that affect adsorption, including chemical properties of adsorbate and activated carbon, pH, and temperature of the adsorbate. Chemical adsorption is usually dominant at high temperatures because chemical reactions proceed more rapidly at elevated temperatures than at low temperatures.

The following factors affect the sorption of organics on activated carbons:

Hydrocarbon Saturation: Double- or triple-carbon bond (unsaturation) organics are adsorbed more easily than single-carbon bond (saturated) organics.
Molecular Structure: Branch-chain organics are adsorbed more easily than straight-chain organics.
Molecular Weight: Larger molecules are generally adsorbed more easily than smaller molecules.
Polarity: Less polar (or weakly ionized) organics are adsorbed more easily than polar (or strongly ionized) organics.
Solubility: Less soluble compounds are adsorbed more easily than more soluble compounds.

ADSORPTION *ISOTHERMS*

An adsorption isotherm is the relationship between the amount of a substance adsorbed on the activated carbon surface and the equilibrium concentration of dissolved adsorbate at a constant temperature and other conditions. An adsorption isotherm is an expression of the principle of microscopic reversibility, although adsorption can be irreversible. The most common method for gathering isotherm data is the bottle point experiment. These equilibrium data are formulated into an adsorption isotherm model. Brunauer et al. (36) pointed out that although the isotherms are different for all sorbents and sorbates, more or less common shapes of isotherms are observed. Six different types of isotherms (37) exist, which are named as type 1, type II, type III, type IV, type V, and type VI. The pictorial representation of the isotherms are given in Fig. 3.

Type 1

This type of isotherm is obtained from carbons having micropores only, which corresponds to monolayer adsorption as postulated by Langmuir. The volume of the gas adsorbed approaches a limiting value, just enough to complete a monomolecular layer even when the gas pressure is rather low. Further increases in pressure hardly produces any further increase in the amount of adsorption. These types of isotherms are typical of a microporous solid where only monolayer adsorption occurs. Examples include the

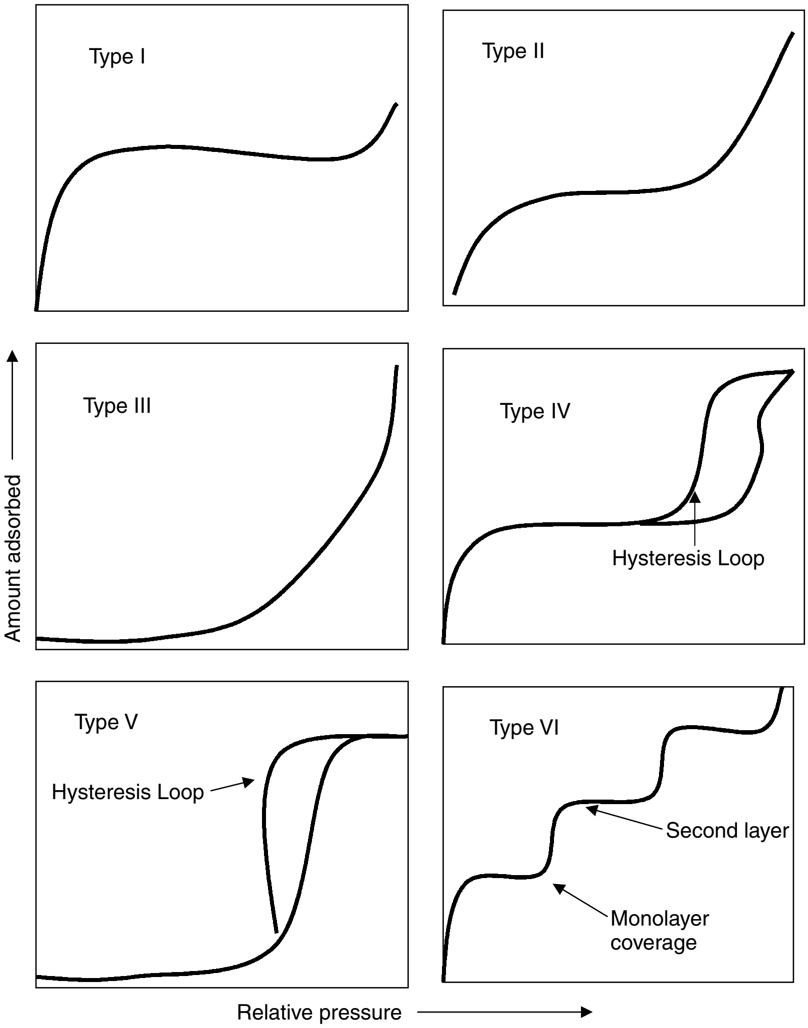

Figure 3. Type of isotherms.

adsorption of nitrogen or hydrogen on microporous carbon at temperatures close to −180 °C.

Type II

This type of isotherm describes the physical adsorption of gases by nonporous solids, and monolayer coverage is succeeded by multilayer adsorption at higher pressure. Examples include the adsorption of nitrogen on iron catalyst at −195 °C.

Type III

This type of isotherm is obtained from carbon having both micropores and mesopores. These types of isotherms show large deviations from the Langmuir model. The amount of adsorption keeps increasing in each case with an increase in pressure, which is attributed to the formation of additional layers of physically adsorbed gas molecules. It is considered that the gas molecules adsorbed in the first layer may hold by van der Waals forces a second layer of gas molecules, which, in turn, may hold a third layer and so on. The examples of type III isotherms include the adsorption of bromine on silica or alumina gel at 80 °C.

Type IV

This type of isotherm is obtained from both nonporous and mesoporous solids.

These are observed in the cases where a possibility of condensation of gases exists within the narrow capillary pores of the adsorbent. This phenomenon is also known as capillary condensation. Examples of type IV include adsorption of benzene on silica gel at 50 °C and that of water vapor on activated carbon at 100 °C.

Type V

This type of isotherm originates from microporous and mesoporous solids. Type V isotherms are basically related to type III isotherms and are very uncommon.

Type VI

This type of isotherm is obtained from uniform nonporous surfaces and represents stepwise multilayer adsorption. The sharpness of the steps depends on the system and the temperature. The step height represents the monolayer capacity for each adsorbed layer, and in the simplest case, it remains nearly constant for two or three adsorbed layers. Examples include the isotherms obtained with argon or krypton on graphitized carbon black at liquid nitrogen temperature.

APPLICATIONS OF ACTIVATED CARBONS

Activated carbons are produced in granular, powdered, and palletized forms and have a wide range of applications. The applications of activated carbon uses can broadly be divided into two categories.

Liquid-Phase Applications

Liquid-phase granular activated carbon adsorption (GACA) is an efficient, easy, and reliable treatment technology. It is very much different from gas-phase carbon as liquid-phase carbons have significantly more pore volume in the macropore range, which permits adsorbates to diffuse more rapidly into the micropores and mesopores. It is considered to be a best available control technology (BACT) by the U.S. Environmental Protection Agency (USEPA) and is a benchmark for other remediation technologies. In order for carbon adsorption to work well, it is important that the final design incorporate both the physical and adsorption process. In liquid-phase granular activated adsorption, activated carbon can be used either in powder, granular, or palletized forms. The average size of powder activated carbon ranges between 15 and 25 μm and are most frequently used in batch applications. On the other hand, the granular activated carbon particle size is normally 0.3–3.0 mm, and these are mostly used in continuous flow systems (fixed and moving bed). In this article, most of the discussion has been restricted to the liquid adsorption only.

Batch Systems. Generally, powdered activated carbons are used in batch systems. Batch system consists of contacting a whole volume of feed solution with a definite quantity of activated carbon in batch stirred vessels. The mixture is stirred or agitated to facilitate mass transfer. The important process design parameters can be calculated from laboratory batch adsorption isotherms, which precisely model the full-scale batch process. The batch adsorption processes are seldom used except in laboratories because they are highly inefficient compared with column adsorption processes and are therefore capital intensive and expensive to operate.

Various theoretical and empirical models have been proposed to describe the different types of adsorption isotherms in batch systems. The most commonly used models include Freundlich (38), Langmuir (39), and BET isotherms.

Freundlich Isotherm. The Freundlich adsorption isotherm model was given by Freundlich (38). This isotherm describes the equilibrium on heterogeneous surfaces and, hence, does not assume monolayer capacity

The Freundlich equation may be written as

$$q_e = K_F {C_e}^{1/n} \qquad \text{(Nonlinear form)}$$

$$\log q_e = \log K_F + \frac{1}{n \log C_e} \qquad \text{(Linear form)}$$

where q_e is the amount of solute adsorbed per unit weight of activated carbon (mg/g), C_e is the equilibrium concentration of solute in the bulk solution (mg/L), K_F is the constant indicative of the relative adsorption capacity of the adsorbent (mg/g), and 1/n is the constant indicative of the intensity of the adsorption.

Langmuir Isotherm. The Langmuir adsorption isotherm describes the surface to be homogeneous. The Langmuir adsorption isotherm assumed that all the adsorption sites have equal affinity for the molecules and that the adsorption at one site does not affect adsorption at an adjacent site (39,40).

The Langmuir equation may be written as

$$q_e = \frac{Q^0 b C_e}{1 + bC_e} \qquad \text{(Nonlinear form)}$$

$$\frac{C_e}{q_e} = \left(\frac{1}{Q^0 b}\right) + \left(\frac{1}{Q^0}\right) \cdot C_e \qquad \text{(Linear form)}$$

where q_e is the amount of solute adsorbed per unit weight of adsorbent (mg/g), C_e is the equilibrium concentration of solute in the bulk solution (mg/L), Q^0 is the monolayer adsorption capacity (mg/g), and b is the constant related to the free energy of adsorption. It is the value reciprocal of concentration at which half the saturation of the adsorbent is reached.

BET Isotherm. The Brunauer, Emmett, Teller (BET) isotherm assumes the pertaining of a compound between liquid and solid compartments or phases. This isotherm assumes the multilayers adsorption of solute on activated carbon (36,40)

$$q_e = \frac{BCQ^0}{(C_s - C)[1 + (B-1)(C/C_s)]} \qquad \text{Nonlinear Form}$$

$$q_e = \frac{C}{(C_s - C)q_e} = \frac{1}{BQ^0} + \frac{B-1}{BQ^0}\frac{C}{C_s} \qquad \text{Liner form}$$

where q_e is the amount of adsorbate adsorbed per unit weight of activated carbon, B is the constant related to the energy of interaction with the surface, C is the equilibrium concentration of adsorbate in solution (mg/L or mol/L), Q^0 is the number of moles of adsorbate per unit weight of carbon to form a complete monolayer, and C_s is the saturation concentration of the adsorbate.

The limitations of the adsorption isotherms are as follows:

1. Isotherms are equilibrium tests, and therefore, the time restrictions are not considered.
2. Isotherms are based on carbon exhaustion—granular systems do not totally exhaust—and the entire bed contents.
3. Long-term chemical and biological effects are not evident.

Thus, batch equilibrium adsorption isotherm tests cannot simulate or predict dynamic performance directly.

Continuous Systems. In continuous systems, mostly granular activated carbons (GAC) are used. The fixed bed adsorber systems are most widely used for conducting adsorption operations where the adsorbate to be treated is passed through a fixed bed. In the fixed bed adsorber operation, a degree of separation and removal is achieved that would require many steps in a batch system. The parameters, which are required to establish a fixed bed reactor, include the type of carbon, physical and chemical characteristics of the carbon, column diameter, water/wastewater/effluents flow rate, pH of the effluent, carbon bed depth, weight of carbon, contact time, concentration of the influent, concentration of the effluent, and desired effluent concentration

When contaminated solute (warer/wastewater/effluents) is passed through a bed of granular activated carbon, a wave front or a mass transfer zone (MTZ) is formed by continuous adsorption of solute in the carbon bed. Figure 4 shows the change in concentration of adsorbed species on the surface of activated carbon with time. The solute is rapidly adsorbed on the top layers of the bed until the amount adsorbed is in equilibrium with influent solute concentration. At this particular time, that portion of the bed is exhausted. Below this zone is a second zone where dynamic adsorption is taking place. The solute is being transferred from the liquid to the adsorbed phase. This zone is known as mass transfer zone, and the depth of the zone is controlled by many fcators depending on the solute concentration being adsorbed, characteristics of activated carbon, and hydraulic factors.

A plot between the concentration of the adsorbate exhibits an S-shaped curve in the adsorption zone with ends asymptotically approaching zero and the influent concentration C_0. This curve is known as a *break through curve*. An ideal break through plot obtained for a fixed bed adsorber is depicted in Fig. 4. The solute or impurity is adsorbed very rapidly by the few initial upper layers of the fresh granular carbon during the initial stages of operation, as shown in Fig. 4. These upper layers are in contact with the sorbate/impurity at its highest concentration level, C_0. The small amounts of solute/impurity that escape adsorption in initial stages are adsorbed in the lower stages, and no solute escapes from the fixed bed adsorber initially ($C_1 = 0$).

FIXED BED ADSORBER

An adsorption process in which liquid being treated is allowed to pass through a carbon column in that carbon becomes exhausted and the unit is removed from service and completely recharged with fresh carbon. The carbon remains fixed in the position during the whole adsorption process.

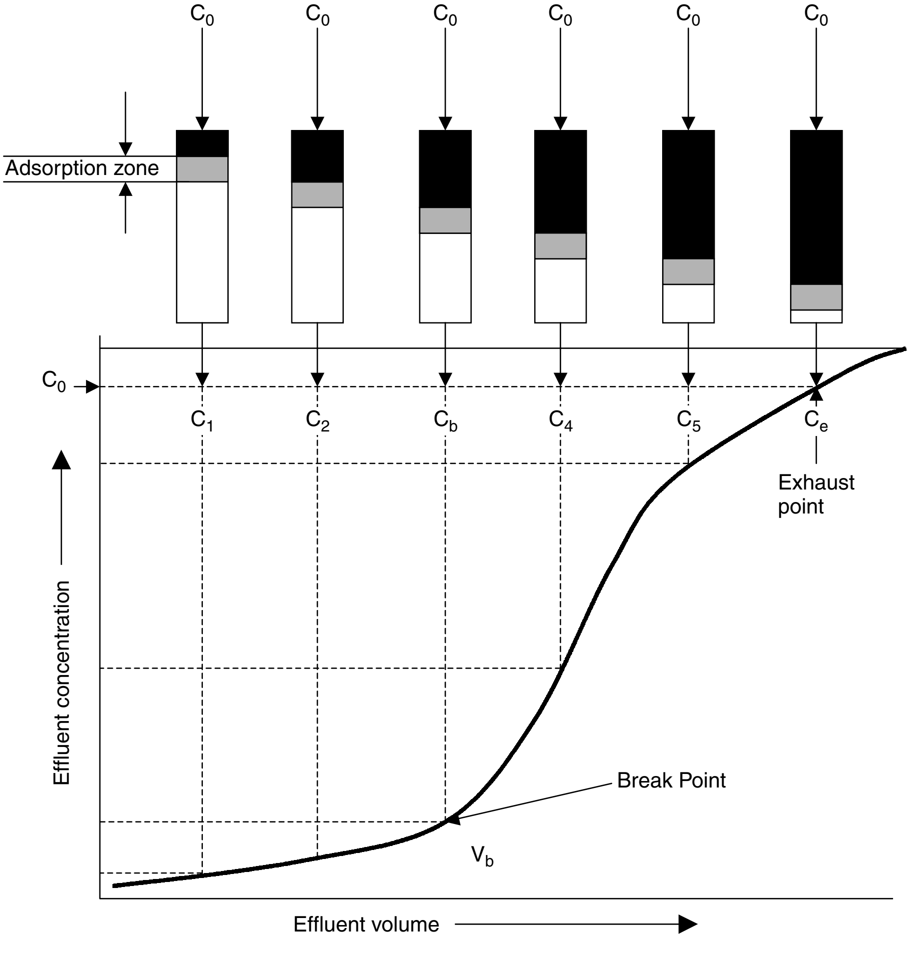

Figure 4. Typical adsorption zone movement in a fixed bed adsorber.

To construct a fixed bed adsorber, the following design parameters are used:

Volumetric Flow Rate (Q)

It is the quantity of solute fed per unit time. Flow rate influences the adsorption capacity of carbon in a dynamic system. If a 1-inch column is to be used, 20.6 ml/min flow rate, which is equal to 1 g/min/ft^2, is to be used.

The following values may further be considered for designing fixed bed reactors:

Column Diameter (cm)	Volumetric Flow Rate (cc/min)
2.56	41.6
5.08	165.2
7.62	374.0
10.16	661.6

Carbon Bed Volume (V_b)

This is the total volume of GAC packed bed, which accounts for both the activated carbon grains and the void volume.

Cross-Sectional Area (A_b)

It is simply the cross-sectional area.

Void Volume (α)

The volume between the carbon particles in a packed bed or column expressed as a percentage of the total bed volume, which corresponds to the part of the fixed bed volume that is not occupied by activated carbon particles

Filter or Linear Velocity (v_F)

It is also know as superficial linear velocity and surface loading rate, which is the velocity in an empty bed with the filter cross-sectional area.

It can be calculated from the following equation:

$$v_F = \frac{Q}{A_b}$$

Effective Contact Time, Resident Time, or Retention Time (t)

It is defined as the time within the GAC bed that is available for the mass transfer of the organic substances from bulk solution to the GAC particle. It is also defined as the theoretical length of time for a liquid to pass through a column assuming all the liquid moves through with the same uniform velocity. It is equal to the volume of liquid in the column divided by the rate of flow. The volume of liquid in a carbon column is simply the total volume of the column times the void fraction. It can be calculated by using the following equation:

$$t = \frac{V_F \alpha}{Q}$$

Empty Bed Contact Time (EBCT)

The time required for the liquid to pass through a carbon column assuming that all the liquid passes through at the same velocity. It is equal to the volume of the empty bed divided by the flow rate. Conventional water treatment plant adsorbers have EBCTs in the range of 7–10 min.

It can be calculated by using the equation

$$\mathrm{EBCT} = \frac{V_b}{Q} = \frac{A_b L}{V_F A_b} = \frac{L}{v_F} = \frac{t}{\alpha}$$

where V_b is the volume of GAC in contactor (m^3); Q is the volumetric flow rate (m^3/h); A_b is the cross-sectional area of GAC, m^2; L is the length of the GAC in contactor (m); V_F is the linear velocity or filter velocity (m/h); t is the retention time (h); and α is the Void volume (m^3).

Filter Operation Time (t_F)

It is the time period that a GAC bed has been in operation.

Throughput Volume (V_L)

It is the volume of solute that has passed through the filter at a time.

It is calculated by using the equation

$$V_L = t_F \times Q$$

Filter Density (ρ_{GAC})

It is calculated using the following equation in g/L:

$$\rho_{\mathrm{GAC}} = \frac{m_{\mathrm{GAC}}}{V_b}$$

where m_{GAC} is the mass of GAC (g) and V_{b} is the volume (L).

Specific Throughput Volume (V_{sp})

As the throughput volume depends on the filter size, it does not allow a direct comparison of different size of plants. If throughput volume is divided by the mass of activated carbon in the bed, the specific throughput volume is obtained. The mass of GAC is determined by multiplying filter density and bed volume.

It is calculated by using the equation

$$V_{sp} = \frac{V_L}{V_b \times \rho_{\mathrm{GAC}}} = \frac{Q \times t}{m_{\mathrm{GAC}}} = \frac{V_b \times t}{\mathrm{EBCT} \times m_{\mathrm{GAC}}} = \frac{V_b \times t}{\mathrm{EBCT} \times (\rho_{\mathrm{GAC}} \times V_b)} = \frac{t}{\mathrm{EBCT} \times \rho_{\mathrm{GAC}}}$$

Throughput Bed Volume (BV)

It is an another parameter used for the comparison of the removal efficiencies regardless of the bed size. It is the ratio of throughput volume and bed volume

$$\mathrm{BV} = \frac{V_L}{V_b} = \frac{t_F}{\mathrm{EBCT}}$$

Carbon Usage Rate (CUR)

It is expressed by the following expression:

$$\mathrm{CUR}, g/m^3 = \frac{m_{\mathrm{GAC}}}{Q \times t}$$

Bed Life

The volume of the water treated for a given EBCT, expressed in liters, and can be calculated as:

$$\text{Volume} = \frac{\text{mass} \cdot \text{of} \cdot \text{GAC} \cdot \text{for} \cdot \text{given} \cdot \text{EBCT}}{\text{GAC} \cdot \text{usage} \cdot \text{rate}}$$

and therefore, the bed life can be calculated as

$$\text{Bed} \cdot \text{Life} = \frac{\begin{array}{c}\text{volume} \cdot \text{of} \cdot \text{water} \cdot \text{treated} \\ \cdot \text{for} \cdot \text{given} \cdot \text{EBCT}\end{array}}{Q}$$

The typical values of the various important parameters as discussed above with their units presented in Table 5.

Carbon Dose

The amount of GAC required to fill each column is calculated by the expression:

$$\text{Weight of carbon} = \text{volume of column} \times \text{A.D} \times 0.85$$

where A.D is the apparent density and 0.85 is the factor to allow backwashed density.

This amount should be degassed and wetted prior to installation in the column. The degassing can be done by boiling the carbon in organic-free water for 2 h or soaking at room temperature for 24 h. The degassed carbon should be charged into the column in small increments as a slurry keeping a layer of organic-free water above the GAC during charging, which is best accomplished by filling the column one-third of organic-free water prior to charging the degassed-free water into the column. It is also noted that all connecting tube and other void space must be filled with liquid in order to avoid the formation of gas pockets in carbon bed.

For designing of fixed bed reactors, a number of theories have been proposed by various researchers. These theories include:

1. Length of unused bed (LUB) approach
2. Bed-depth-service time (BDST) approach
3. Empty bed residence time (EMRT) approach

Table 5

Parameter	Symbol	Units	Typical Values
Volumetric flow rate	Q	m^3/h	50–400
Bed volume	V_b	m^3	10–50
Cross-sectional area	A_b	m^2	5–30
Length	L	m	1.8–4.0
Void fraction	α	m^3/m^3	0.38–0.42
GAC density	ρ	kg/m^3	350–550
Filter velocity	v_F	m/h	5–15
Effective contact time	t	min	2–10
Empty bed contact time	EBCT	min	5–30
Operational time	t_F	days	100–600
Throughput volume	V_L	m3	10^4–10^5
Specific throughput	V_{sp}	m3/kg	50–200
Bed volume	BV	m3/m3	2,000–20,000

PULSED BED

In this type of bed, carbon is removed at intervals from the bottom of the column and replaced at top by fresh adsorbent.

MOVING BED SYSTEM

The most recent development of granular activated carbon has been the use of moving bed. In this system, the direction of the liquid flow is upward, whereas the carbon moves in a downward direction. The basic principle behind this technique is to have one column (or multiple columns running in parallel) packed completely with a carbon bed of sufficient height to have the adsorption–wave front and to provide some operating time with the effluent flow being within specification. As the adsorption wave front moves up the column, it is periodically displaced downward by the removal of a quantity of saturated carbon from the base of the column and the replacement of the same quantity with fresh or regenerated carbon at the top of the column. Although the principle of the moving bed can be applied in smaller units, it is most frequently used in larger units where the lower capital investment is important.

GAS-PHASE APPLICATIONS

Gas-phase applications of activated carbons include separation, gas storage, and catalysis. It is well documented in literature that only 20% of produced activated carbons are used for gas-phase applications. The carbons applied for gas-phase applications are mostly granular in shape.

REGENERATION

Once the granular activated carbons become saturated, it is necessary to change the carbon or to regenerate the fixed bed adsorber. Regeneration is the process of removing adsorbed compounds from the granular activated carbon surface. Here, the carbon surface includes external macropores and micropores.

Carbon regeneration frequently is a major part of total operating cost associated with granular activated carbon (GAC) adsorption systems. Following are the important and potential regeneration methods:

1. Thermal regeneration
2. Biological regeneration
3. Infrared regeneration
4. Supercritical fluids

Spent GAC used in water/wastewater, and other liquid-phase applications, is generally reactivated using a high-temperature thermal process where the GAC is heated to about 815 °C (1500 °F), allowing drying, baking, and gasification to occur. Various types of furnaces used for the regeneration purpose include multiple hearth furnace (MHF) or rotary kilns (RK), electric belt furnaces (EBF), and fluidized bed regenerators (FBR). Details about these furnaces and their operation are well documented in literature (41). The two major criteria involved in the regeneration of the granular activated carbon are (a) characteristic of the spent carbon and (b) choice of the furnace for that particular application. The spent carbon characteristics include the potential for char formation, corrosion, and slagging, whereas the furnace characteristics are assessed by determining the mass transfer efficiency, particle residence time, and temperature control. After reviewing the properties of furnaces and activated carbons, one can select the best possible option.

In thermal regeneration, 5–10% of granular activated carbon is lost as a result of oxidation and attrition, and by the cost of energy in heating, the carbon around 800–850 °C (42). An alternative technique is that of chemical regeneration in which chemical reagents are applied to the exhausted granular activated carbon. The chemical regeneration of exhausted GAC can be achieved by two main categories of substances: inorganic chemical regenerates with oxidizing powers and organic chemical regenerates with solubilizing powers. The efficiency of any regenerate is judged on the extent that it effects the recovery of the adsorptive powers of the granular activated carbons. The regeneration efficiency can be calculated as

$$\text{Regeneration efficiency (RE\%)} = (A_r/A_0) \times 100$$

where A_0 is the original capacity of GAC for a particular adsorbate and A_r is the capacity of regenerated carbon.

APPLICATIONS AND COMMON USES (BOTH LIQUID PHASE AND GAS PHASE)

Activated carbon has wide applications in both liquid and gas/solvent phase systems (43).

Groundwater Remediation

Granular activated carbon is the most common technology employed to pump and treat groundwater remediation systems. It is highly suited to this application and is often used as a single treatment step to remove compounds such as chlorinated hydrocarbons and aromatic compounds, including benzene, toluene, ethylbenzene, and xylene (BTEX). For more highly contaminated groundwater, two or more carbon units may be placed in series or carbon may be used in combination with other treatment technologies such as air stripping or advanced oxidation processes.

Soil Vapor Extraction and Air Sparring

Activated carbon can also be used for the removal of Volatile Organic Compounds (VOCs) from air streams resulting from *in situ* removal techniques such as soil vapor extraction.

Chemical and Pharmaceutical Industries

Chemicals. Activated carbon is suitable for the decolorization and purification of a wide range of organic and inorganic compounds, including amines, hydrochloric and other mineral acids, amino acids, glycols, and hydrocarbons.

Pharmaceuticals. Activated carbon is used to purify a wide range of pharmaceuticals and intermediates.

Granular activated carbon is installed to purify the recirculating amine to remove degradation products and dissolved hydrocarbons.

Military Use

Most of the world's armed forces are using activated carbons to protect against attack by toxic gases such as mustard gas. This is also used in military suiting where combat uniforms are coated by a layer of impregnated carbon under the outer cover.

Nuclear Reactors

Most of the nuclear reactors, especially in the western world, have activated carbon ventilators to protect against radioactive iodine leaks from the core or heat exchanger systems, if any. Special activated carbons impregnated with potassium iodide or potassium tri-iodide are commonly used for this purpose. Another application in nuclear technology is as a filter in emergency ventilation system for the reactor building, which is switched on automatically in case of breakdowns.

Landfill Leachate Treatment

Granular activated carbon in combination with biological pretreatment is the leading technology for the treatment of landfill leachate for the removal of Chemical Oxygen Demand (COD), Adsorbable Organic Halogens (AOX), and other toxic substances. Granular activated carbon is now used at over 50 sites in Europe for this application.

Catalysis

Many chemical reactions require a catalyst to improve efficiency, accordingly; in many cases, activated carbons provide large surface area, thus, further improving the efficiency.

Medicinal Activated Carbon

The activated carbon has been applied in medicine for a long time. The carbons originally used were prepared from waste materials of animal origin, especially blood (animal charcoal-carbo animalis). In *catarrhal* infections of the digestive system, the use of activated carbon serves primarily to remove bacterial toxins, which, being high-molecular-weight substances, are easily adsorbed on active carbon. Activated carbons are also prescribed in large doses in all the cases of acute gastritis and enteritis. It is also a very effective antidote in all the cases of poisoning.

Domestic Use

Activated carbons are used in various home appliances, including fridge deodorizers, air purifiers, and cooker hoods. The activated carbons are used in the removal of caffeine from coffee. Cigarettes are made that, in addition to an antismoke filter, contain finely granulated activated carbon.

Also, activated carbons are used in the coating and printing industries, degreasing and cleaning, solvent recovery, tank venting, ventilation, and air conditioning

The other uses are systems annihilation, condensate de-oiling, and gold recovery.

COMPETITIVE ADSORPTION OF SEVERAL ORGANICS AND HEAVY METALS ON ACTIVATED CARBON IN WATER

Dinesh Mohan
Kunwar P. Singh
Gomti Nagar, Lucknow,
Uttar Pradesh, India

In practice, the water/wastewater/effluents to be treated are multicomponent mixtures. Therefore, other organic or inorganic substances influence the efficacy of activated carbons. In the recent past, most of the research work has been focused on the removal of single solute from its pure solution or a particular solute from a solution having ill-defined chemical character. The other reports available are addressed to the removal of gross organic/inorganic substances, which are measured in terms of BOD or COD from water/wastewater. In actual practice, the treatment of wastewater by activated carbon normally involves a variety of adsorbates competing for adsorption sites on the carbon surface. Thus, a thorough understanding of the competitive effect on various organic/inorganic compounds on carbon adsorption is a must. Unfortunately, very few reports/papers about the competitive adsorption on activated carbon in aqueous solution are available. Thus, a need exists to explore the current status of the competitive adsorption of various organic/inorganic substances from water/wastewater on activated carbons. Multiion systems received less attention than single ion systems.

The adsorption in multicomponent systems is complicated because of the solute–solute competition and the solute-surface interaction involved. Multicomponent interactions take place at the active adsorption sites where the solid-liquid phase equilibrium will emerge showing a different capacity of single solute with a new set of isotherm systems. The interpretation of the multicomponent systems has proved to be complex and may be the function of one or all of the following parameters: ionic radii, electronegativity, system pH, and the availability of the active sites on the adsorbent.

The adsorption capacity or the degree of removal of various organic and inorganic substances from water/wastewater on activated carbon (GAC) very much depends on the multicomponent competitive interactions of organic chemicals that are present in the system. In order to design a cost-effective system, it is necessary to know the adsorption capacity of a solute in the presence of others (1–4). To determine the effects of competing adsorption, mathematical models/equations must be developed to describe the adsorption equilibrium in multicomponent system. Several models are available in literature, but most of them suffer from one limitation or an other. In the paragraphs below, several models are discussed with a view that these are mostly used in multicomponent modeling in aqueous systems. Butler and Ockrent (5), in 1930, developed the first model for binary systems. Since then, a number of models have been developed that are shown to be valid for certain mixtures and conditions by comparing them to the experimental data.

MULTICOMPONENT ADSORPTION MODELS

Prediction of multicomponent adsorption is still a very challenging problem in the adsorption. Many models have been proposed and employed from time to time to obtain the multisolutes isotherms using single-component equilibrium data. However, most of the models are based on either unrealistic assumptions or an empirical equations with no apparent definitions (6,7). Some of the important and widely used models are discussed below to understand the multicomponent sorption of oraganic and inorganic substances on activated carbon.

Butler and Ockrent Model

This model was presented by Butler and Ockrent in 1930 (5). Basically, this model is an extended form of Langmuir model. According to this model, if two solutes are present in an adsorption system, the Langmuir model for the competitive adsorption can be given by Equations 1 and 2 as follows:

$$q_1 = \frac{Q_1^0 b_1 C_1}{1 + b_1 C_1 + b_2 C_2} \tag{1}$$

$$q_2 = \frac{Q_2^0 b_2 C_2}{1 + b_1 C_1 + b_2 C_2} \tag{2}$$

where Q_1^0, b_1 and Q_2^0, b_2 are the Langmuir constants determined from single-solute system with solutes 1 and 2, respectively, and C_1 and C_2 are the equilibrium concentrations of the solutes 1 and 2, respectively, in the mixture.

This model is valid only if the surface area available for adsorption is identical for both the solutes and Q_1^0 and Q_2^0 reflect the size difference for a mono-layer surface coverage of solutes. Further, the free energy change for adsorption is assumed to be independent of surface coverage.

For simultaneous adsorption of N components from a solution, the multicomponent Langmuir equation can be given as

$$q_i = \frac{Q_i^0 b_i C_i}{1 + \sum_{j=1}^{N} b_j C_j} \tag{3}$$

In spite of the limitations, this model was used by various researchers (8,9) to describe their multicomponent sorption on activated carbons.

Jain and Snoeyink Model

The model given by Butler and Ockrent (5) was modified by Jain and Snoeyink (10). Earlier models used for multicomponent systems are not able to explain the fact that in a bi-solute system, a portion of the adsorption often takes place without competition. To overcome this difficulty, Jain and Snoeyink proposed a model for binary systems, which takes into account the noncompetitive adsorption on activated carbon/adsorbent.

Based on this hypothesis, adsorption without competition occurs when $Q_1^0 \neq Q_2^0$ and the number of adsorption sites not being subjected to the competition is equal to the quantity of $(Q_1^0 - Q_2^0)$ where $Q_1^0 > Q_2^0$. Equations 4 and 5 are as follows:

$$q_1 = \frac{({Q_1}^0 - {Q_2}^0)b_1C_1}{1 + b_1C_1} + \frac{Q_2^0 b_1 C_1}{1 + b_1C_1 + b_2C_2} \tag{4}$$

$$q_2 = \frac{Q_2^0 b_2 C_2}{1 + b_1C_1 + b_2C_2} \tag{5}$$

where q_1 and q_2 are the amounts of solute 1 and 2, respectively, adsorbed per unit weight of activated carbon/adsorbent at equilibrium concentrations of C_1 and C_2, respectively. Q_1^0 and Q_2^0 are the maximum value of adsorption for solute 1 and 2, respectively, determined from the respective single-solute systems, whereas b_1 and b_2 are the constants related to the energy of adsorption from solute 1 and 2, respectively, in their pure solution systems.

This model also has some limitations. It is only appropriate to describe the competitive adsorption between the molecules having very different single-solute adsorption capacity. In spite of its limitations, a number of workers have applied this model in their multicomponent adsorption studies. In one of the studies, Huang and Steffens (11) applied this model to determine the competitive adsorption of organic materials by activated carbons. It was concluded that mutual suppression of equilibrium adsorption because of competition between acetic and butyric acids has shown that the observed data are somewhat closer to the values predicted by Jain and Snoeyink's model than by the original Langmuir equation. However, the actual degree of suppression is greater than the prediction for acetic acid and smaller for butyric acid.

Multicomponent Isotherm of Mathews and Weber

Mathew (12) proposed this model in 1975. This model is a modified and extended form of the Redlich–Peterson model (13), which can be given by the expressions below, which is basically three parameter, single-solute adsorption isotherm model

$$q_e = \frac{KC_e}{1 + a_R {C^b}_e} \tag{6}$$

where K, a_R, and b are the Redlich–Peterson constants.

For the N solute mixtures, this equation can be written as

$$q_i = \frac{K_j C_i}{1 + \sum_{j=1}^{N} a_j {C_j}^{b_j}} \tag{7}$$

The parameters K_j, a_j, and C_j can be determined from single-solute isotherm data. A new constant, η_i, has been introduced in this model, which has to be determined from adsorption data in the mixtures. With the addition of this constant, the equation may be written as

$$q_i = \frac{k_j \left[\dfrac{C_i}{\eta_i}\right]}{1 + \sum_{j=1}^{N} a_j \left[\dfrac{C_j}{\eta_i}\right]^{b_j}} \tag{8}$$

where η_I is the interaction parameter, which is constant. In practice, this parameter varies from different equilibrium compositions. Therefore, this model is not very successful in explaining the multicomponent systems.

Fritz and Schlunder Multicomponent Model

This model was given by Fritz and Schlunder in 1974 (14,15). For modeling multicomponent systems comprising species whose single-solute isotherms follow the Freundlich isotherm, a multicomponent Freundlich equation may be used. The first model of this type, as proposed by Fritz and Schlunder (14), can be expressed by Equations 9–12:

$$q_1 = \frac{K_1 {C_1}^{n_1 + \beta_{11}}}{C_1^{\beta_{11}} + \alpha_{12} {C_2}^{\beta_{21}}} \tag{9}$$

$$q_2 = \frac{K_2 {C_2}^{n_2 + \beta_{22}}}{C_2^{\beta_{22}} + \alpha_{21} C_1^{\beta_{21}}} \tag{10}$$

$$\alpha_{1,2} = \frac{\alpha_{1,2}}{\alpha_{1,1}} \tag{11}$$

$$\alpha_{2,1} = \frac{\alpha_{2,1}}{\alpha_{22}} \tag{12}$$

where q_1 and C_1 are the concentrations of solute 1 in the solid and liquid phase, respectively; q_2 and C_2 are the concentrations of the solute 2 in solid and liquid phase, respectively; and K_1, n_1, and K_2, n_2 are the Freundlich constants in single-solute 1 and solute 2 systems.

Equations 9 and 10 consist of ten adjustable variables; however, K_1 and K_2, n_1 and n_2 can be determined from single-solute isotherms using Freundlich model for single-solute systems.

Dastgheib and Rockstraw Model

Very recently Dastgheib and Rockstraw (16) proposed a multicomponent Freundlich equation for binary systems, as given by Equations 13–15:

$$q_1 = \left[\frac{K_1 {C_1}^{n_1}}{K_1 {C_1}^{n_1} + \alpha_{12} K_2 {C_2}^{n_2} + b_{12} {C_2}^{n_{12}}}\right] K_1 {C_1}^{n_1} \tag{13}$$

$$q_2 = \left[\frac{K_2 {C_2}^{n_2}}{K_2 {C_2}^{n_2} + \alpha_{21} K_1 {C_1}^{n_1} + b_{21} {C_1}^{n_{21}}}\right] K_2 {C_2}^{n_2} \tag{14}$$

where q_1 and C_1 are the concentrations of solute 1 in the solid and liquid phase, respectively; q_2 and C_2 are the concentrations of solute 2 in the solid and liquid phase, respectively; K_1, n_1, K_2, and n_2 are the Freundlich constants in single-solute system; and α_{12}, α_{21}, b_{12}, b_{21}, n_{12}, and n_{21} are the interaction constants obtained from a least-squares analysis of the binary data. The term in brackets on the right-hand side represents the overall competition and interaction factor and has a value of less than or equal to unity (where C_2 tends to zero, it is equal to 1). The terms $\alpha_{12}K_2$ and $\alpha_{21}K_1$ can be condensed to single terms and are considered as constants.

For the ith component systems, the general equation model can be written as

$$q_i = \frac{(K_i C_i^{n_i})^2}{K_i C_i^{n_i} + \sum_{j=1}^{N}(\alpha_{ij} K_j C_j^{n_j} + b_{ij} C_j^{n_{ij}})} \tag{15}$$

where q_i and C_1 are the concentrations of solute I in the solid and liquid phase, respectively; C_j is the concentration of other solutes in liquid phase; K_i and n_i, K_j and n_j are the single component Freundlich constants; α_{IJ}, b_{ij}, and n_{ij} are the binary interaction constants obtained from a least-squares analysis of the multicomponent data having $\alpha_{ii} = b_{ii} = 0$; and N is the number of solute. This model is different from the Fritz and Schlunder model in the sense that this demonstrates equal or stronger performance.

Sheindorf et al. Model

This model was given by Sheindorf et al. (17,18) for the multicomponent systems comprised of species whose single-solute isotherm obeys the Freundlich isotherm. This equation was based on the following assumptions:

1. each component in single system obeys the Freundlich model
2. each component in multicomponent system and the adsorption energies of different sites are disturbed exponentially, with the distribution function being identical to that for single-component systems.

The model equations can be given by Equations 16 and 17:

$$q_1 = K_1 C_1 (C_1 + \eta_{12} C_2)^{n_1 - 1} \tag{16}$$

$$q_2 = K_2 C_2 (C_2 + \eta_{21} C_1)^{n_2 - 1} \tag{17}$$

where q_1 and C_1 are the concentrations of solute 1 in the solid and liquid phase, respectively; q_2 and C_2 are the concentrations of solute 2 in the solid and liquid phase, respectively; K_1, n_1, K_2, and n_2 are the Freundlich constants in single-solute system; and η_{12} and η_{21} are the interaction constants.

Ideal Adsorbed Solution Theory (IAST)

The ideal adsorbed solution theory is based on the thermodynamics of adsorption, which is analogous to Roul's law in a liquid-gas system. The only difference is that it is applied to a solid-liqid system. Initially, this model was used to calculate multicomponent adsorption of gaseous mixtures (19) using the parameters calculated from single-solute systems. This model was later modified and applied to calculate various multicomponent adsorption parameters by Radke and Praunitz (20). In the IAST model, the following five basic equations (18–22) are used to predict multicomponent behavior from single-solute adsorption isotherms (21).

The total surface loading can be defined by Equation 18:

$$q_T = \sum_{i=1}^{N} q_i \tag{18}$$

where q_I is the single-solute solid phase concentration for component i, which is evaluated at spreading pressure of the mixture, and N is the number of components.

The mole fraction on the carbon surface for component i can be calculated by Equation 19:

$$Z_i = \frac{q_i}{q_T} \quad \text{and} \quad I = 1 \text{ to } N \tag{19}$$

$$C_i = Z_i C_i^0 \quad \text{and} \quad I = 1 \text{ to } N \tag{20}$$

where C_I is the single-solute liquid phase concentration for component i, which is evaluated at the spreading pressure of the mixture.

The single-solute liquid phase concentration in equilibrium with q_i^0 is

$$\frac{1}{q_T} = \sum_{i=1}^{N} Z_i / q_i^0 \tag{21}$$

$$\frac{\pi_m}{RT} = \int_0^{q_i^0} \frac{d \ln C_i^0}{d \ln q_1^0} dq_1^0 = \frac{\pi_1^0 A}{RT}$$
$$= \int_0^{q_j^0} \frac{d \ln C_j^0}{d \ln q_j^0} dq_j^0 = \frac{\pi_j^0 A}{RT} = \text{for} \cdot j = 2 \cdot \text{to} \cdot N \tag{22}$$

where A is the surface area of carbon per unit mass of adsorbent, R is the gas constant, T is the absolute temperature, π_i is the spreading pressure of the single solute i, and π_m is the spreading pressure of the mixture.

LeVan and Vermeulen Model

LeVan and Vermeulen (22) have modified the competitive Langmuir-like model. IAS theory was considered in modifying the model. This model predicts the equilibrium relationships of solute mixture only from the data derived from single adsorption isotherms. It is the simplest isotherms derived from the IAS model.

Statistical Design for Competitive Adsorption

2^4 factorial experimental design was used to study the competitive adsorption of Fe(II), Mn(II), Ca(II), and Zn(II) on selected activated carbons B3, W2, W3, and lignite by Mohan and Chander (23).

These designs are important for the following reasons:

1. They require relatively few runs per factor studied; and although they are unable to explore fully a

wide region in the factor space, they can indicate major trends and therefore determine a promising direction for further experimentation.

2. When a more thorough local exploration is needed, they can be suitably augmented to form composite designs.
3. These fractional designs are often of great value at an early stage of an investigation, when it is frequently good practice to use the preliminary experimental efforts to look at a large number of factors superficially rather than a small number.
4. These designs and the corresponding fractional designs may be used as building blocks so that the degree of complexity of the family-constructed design can match the sophistication of the problem.
5. The interpretation of the observations produced by the designs can proceed largely by using common sense and elementary arithmetic.

The authors have used a total run of $2^4 = 16$. The variables were the concentration levels of various metal ions, with high level (+) 100 ppm and low level (−) 0 ppm. The experiments were conducted at pH 3.5. The experiments were arranged as the design matrix.

General Factorial Design

To perform a general factorial design, a fixed number of "levels" or (versions) for each of the variables (factors) can be selected, and then experiment is run with all possible combinations. If l_1 levels exist for the first variable, l_2 for the second, ..., and l_k for the kth, the complete arrangement of $l_1 \times l_2 \times l_3 \times \ldots l_k$ experimental runs is called an $l_1 \times l_2 \times l_3 \times \ldots l_k$ factorial design, e.g., a $2 \times 3 \times 5$ factorial design requires $2 \times 3 \times 5 = 30$ runs and a $2 \times 2 \times 2 = 2^3$ factorial design.

COMPETITIVE SORPTION OF INORGANICS ON ACTIVATED CARBON

The adsorption of Pb^{2+}, Cu^{2+}, Zn^{2+}, and Cd^{2+} from aqueous solutions by three activated carbons in single and multicomponent systems were studied by Budinova et al. (24). These three activated carbons were obtained from apricot stones (*A*), coconut shells (*C*), and lignite coal (*L*). The results of the individual metal ions from an aqueous solution containing all four metal ions together in equal concentration are presented in Table 1.

It is clear from Table 1 that the presence of foreign ions diminishes the adsorption of each of the ions. The effect is greatest for the lead ions and smallest for the copper ions. The authors did not mention any mechanism for the multicomponent sorption of these ions. The only reason given was that, apart from the properties of the cations, the chemical nature of the metal ions is of great importance for the adsorption process. They also concluded that a selective adsorption of the metals is observed; the ones preferentially adsorbed do not completely prevent the adsorption of other ions.

Johns et al. (25) reported the sorption of cadmium, copper, lead, nickel, and zinc in single and multicomponent systems on various granular activated carbon developed from agricultural waste materials. A study on the competitive effect of metal ions was carried out from a solution having 2.5 mM of each metal at pH 5.0 and was also unbuffered to reduce solution species complexation. The uptake of various metals from a mixed solution is presented in Table 2.

Bansode et al. (26) evaluated the adsorption effectiveness of pecan shell-based granular activated carbons (GACs) in removing metal ions Cu(II), Pb(II), and Zn(II) commonly found in municipal and industrial wastewater. Pecan shells were activated by phosphoric acid, steam, or carbon dioxide activation methods. Metal ion adsorption

Table 1

	Adsorption from Solution Containing All the Four Ions (mol g^{-1})				Decrease of Ion Adsorption in the Presence of the ion (%)			
Carbon	Cu^{2+}	Pb^{2+}	Zn^{2+}	Cd^{2+}	Cu^{2+}	Pb^{2+}	Zn^{2+}	Cd^{2+}

of shell-based GACs was compared with the metal ion adsorption of a commercial carbon, namely Calgon's Filtrasorb 200. Adsorption experiments were conducted using solutions containing all three metal ions in order to investigate the competitive effects of the metal ions as would occur in contaminated wastewater. The results obtained from this study showed that acid-activated pecan shell carbon adsorbed more lead ion and zinc ion than any of the other carbons, especially at carbon doses of 0.2–1.0%. However, steam-activated pecan shell carbon adsorbed more copper ion than the other carbons, particularly using carbon doses above 0.2%. In general, Filtrasorb 200 and carbon dioxide-activated pecan shell carbons were poor metal ion adsorbents. The results indicate that acid- and steam-activated pecan shell-based GACs are effective metal ion adsorbents and can potentially replace typical coal-based GACs in treatment of metal contaminated wastewater. The surface complex formation model was used successfully to describe the surface change density, as well as the single and multispecies metal adsorption equilibrium by Chen and Lin (27).

Choi and Kim (28) studied the adsorption characteristics of zinc and cadmium ion on granular activated carbon in singular and binary systems. Features of binary adsorption were discussed for several influential parameters, and experimental observations for both ions were correlated with a predicted adsorption isotherm based on a Langmuir multicomponent model.

Yu and Kaewsarn (29) used the multicomponent model on the sorption of heavy metals on low-cost adsorbents. An equilibrium isotherm was predicted by the extended Langmuir model using Langmuir parameters as determined from a single component system. Copper ions were found to have adsorption affinity, and the separation factor $\alpha_{Cu/Cd}$ was determined as 3.05. Trujullo et al. (30) reported the competitive adsorption of six metal ions from a single solution, which led to a model applicable to their batch and semicontinuous packed beds. Binding capacity was highest for copper, independent of the other ions, and copper also exerted the largest competing effect.

Bunzle et al. (31) carried out the studies in the pH range of 3.5–4.5, and the order was found to be $Pb^{2+} > Cu^{2+} > Cd^{2+} \approx Zn^{2+} > Ca^{2+}$, whereas Masslenilov and Kiselva (32) reported the adsorption capacity order as $Cu^{2+} > Zn^{2+} > Fe^{3+} > Ca^{2}$.

Ho et al. (33) reported that competitive effect affected the sorption of three metals in the order $Ni^{2+} > Pb^{2+} > Cu^{2+}$. It was concluded that all the metals are not necessarily adsorbed by exactly similar mechanisms for all the biosorbents, and that each needs to be tested to determine its characteristics. Adsorption of lead is usually greater than of copper, although copper is a more aggressive competitor and the adsorption of nickel is usually weaker than that of others.

The influence of a range of commercially available, water-soluble surfactants on the uptake of heavy metal ions (Cu, Zn, Cd, and Pb) by three types of clay (kaolinite, illite, and a montmorillonite) was reported by Beveridge and Fickering (34). The adsorption of Cu, Pb, Cd, and Zn was significantly reduced in the presence of small amounts of cationic surfactants, particularly with montmorillonite suspensions. The addition of anionic surfactants led to increase metal loss from the solution. Studying multicomponent adsorption system equilibria must commence with an accurate description of each component in its single (or pure) component equilibrium state.

Allen and Brown (35) studied the single component and multicomponent metal sorption onto lignite. A comparison was made between the single component saturation uptake and multicomponent uptakes The multicomponent systems were equimolar binary solutions solutions Cu-Cd, Cu-Zn, and Cd-Zn and a ternary mixture of equimolar Cu-Cd-Zn. In single component systems, the adsorption capacity followed the order Cu > Zn > Cd. These capacities were reported on a molar basis. Despite the competition, the total sorption capacity was found to increase even though the adsorption capacity of a single ion may be less than if it were to present alone. It has been pointed out that a substantial effect of multicomponent mixtures was observed on the capacity of lignite for cadmium and zinc. There appears to be slight increases in capacity in binary Cu-Cd, Cd-Zn, and ternary mixtures and a decrease in the capacity of Cu-Zn mixture compared with single component data. The order of sorption of metals in multicomponent systems is as follows: Cu > Cd > Zn. The preference of the sorbents for metals uptake is related to the electronegativity of the ions. Copper possessing the greatest ionic potential has the strongest attraction to the adsorbent, followed by cadmium then closely by zinc. The sorption capacities for single as well as multicomponent systems as reported by Allen and Brown are presented in Table 3.

Tan et al. (36) reported the uptake of metal ions in single and multicomponent systems by chemically treated human hairs. Various suppressors and promoters were identified and given in Table 4.

Beveridge and Pickering (34) reported the effect of various water-soluble surfactants on the uptake of Cu, Zn, Cd, and Pb ions by three types of clays, kaolinite, illite, and montmorillonite, over the pH range 3–10. Adsorption of Cu(II), Pb(II), Cd(II), and Zn(II) was significantly reduced in the presence of small amounts of cationic surfactants, particularly with montmorillonite suspensions. No multicomponent sorption modeling was reported.

The effect of Cu(II), Hg(II), and Pb(II) on the uptake of Cd(II) by activated carbon was investigated by Krishnan

Table 3

Metal Systems	μmol/gram
Copper alone	440
Cu in Cu-Cd	350
Cu in Cu-Zn	370
Cu in Cu-Cd-Zn	360
Cadmium alone	360
Cadmium in Cu-Cd	90
Cadmium in Cd-Zn	250
Cadmium in Cu-Cd-Zn	85
Zinc alone	375
Zinc in Cu-Zn	50
Zinc in Cd-Zn	130
Zinc in Cu-Cd-Zn	70

Table 4

Metal Ions	Promoters	Suppressor
Hg(II)	Ag(I)>Pb(II)	Cu(II)
Ag(I)	Cd(II)>Cu(II)	Hg(II)
Pb(II)	Cd(II)>Cu(II)	Hg(II)>Cu(II)
Cd(II)	–	Cu(II)>Ag(I)>Ni(II)
Cu(II)	Ni(II)~Cd(II)	Ag(I)>Hg(II)>Cr(VI)>Pb(II)
Cr(VI)	Cu(II)	–
Ni(II)	–	Ch(II)>Cd(II)

and Anirudhan (37). The removal of Cd(II) was reported to be 98.8% in absence of any co-ions. The same decreases to 83.3%, 79.1%, and 72.1%, respectively, when Cu(II), Hg(II), and Pb(II) ions are present in a 1:1 ratio. The results further showed that a 72.2%, 70.5%, and 60.6% reduction in Cd(II) removal was observed when Cu(II), Hg(II), Pb(II) ions were present at a molar ratio of 1:2. The reduction may be because of the competitive ion effect between Cd(II) and co-ions for the adsorption sites available on the carbon surface. Based on these results, it was concluded that Pb(II) ions may be stronger competitive ions than Hg(II) and Cu(II) removal by SA-S-C. The results can also be explained by the selectivity sequence of the most common cations on the adsorbent surface. It was also observed that, among the cations used, interference of Pb(II) ion is highest, followed by Hg(II) and Cu(II). The observed order of interference was the same as that of their increasing ionic radii, i.e., their decreasing hydrated ionic radii. The smaller the hydrated ionic radii, the greater its efficiency to active groups of the adsorbent, which suggests that the energy required in the dehydration of the metal ions, in order that they could occupy a site in the adsorbent, plays an important role in determining the selectivity series for the metal ions.

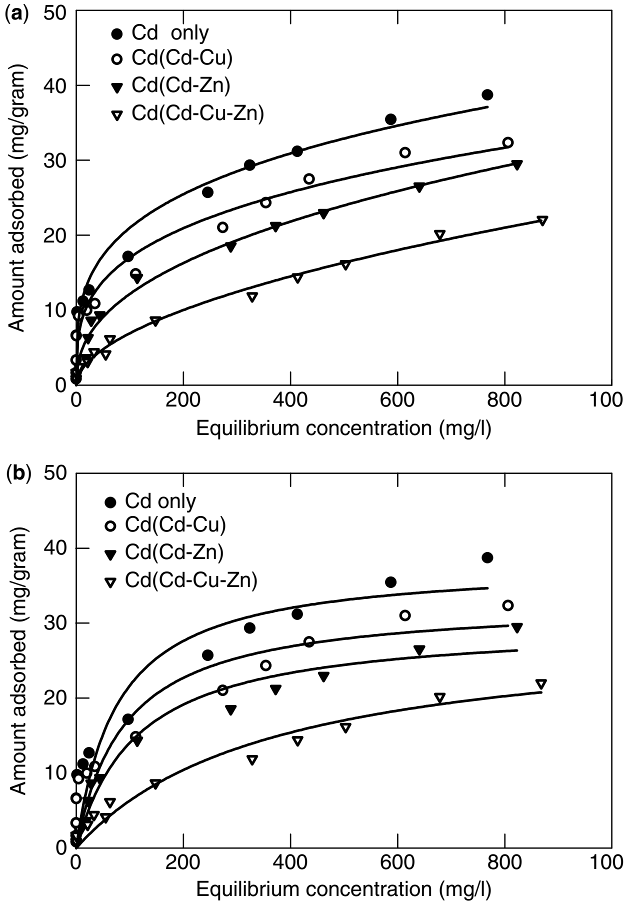

Figure 1. Multicomponent adsorption of Cd(II) on activated carbon developed from bagasse. Solid lines represent the fitting of data by (**a**) Freundlich and (**b**) Langmuir isotherms.

Recently, Mohan and Singh (38) reported the batch sorption isotherm studies to obtain the data required in the design and operation of column reactors for treatment of cadmium- and zinc-bearing wastewater both in single and multicomponent systems. The metals chosen for the investigation in single component studies were Cd (II) and Zn(II). In multicomponent system investigations, four binary systems, Cd(Cd-Cu), Cd(Cd-Zn), Zn(Zn-Cu), and Zn(Zn-Cd), and two ternary systems, Cd(Cd-Cu-Zn) and Zn(Zn-Cu-Cd), were selected. The adsorption isotherms for binary, ternary, and multicomponent systems were obtained at pH 4.5. A 1:1 ratio was used to determine the effect of other metal ions on the adsorption of Cd(II) and Zn(II) on the prepared carbon. The Freundlich and Langmuir adsorption isotherms for Cd(II) and Zn(II) in binary and ternary systems are presented in (Figs. 1 and 2), respectively (38). The results clearly revealed that the presence of other metal ions compete with Cd(II) and Zn(II) ions. It was observed that Cu(II) had the least interfering capacity among Cd(II), Zn(II), and Cu(II) ions in binary systems. Both Langmuir and Freundlich isotherms adequately described the data over the entire range of concentration, and corresponding parameters are presented in Table 5. The effect of ionic interaction (36,39) on the sorption process may also be represented by the ratio of the sorption capacity for one metal ion in the presence of the other metal ions, Q^{mix}, to the sorption capacity for the same metal when it is present alone in the solution, Q^0, such that when:

$$\frac{Q^{\mathrm{mix}}}{Q^0} > 1, \text{ the sorption is promoted by the presence of other metal ions}$$

$$\frac{Q^{\mathrm{mix}}}{Q^0} = 1, \text{ no observable net interaction exists}$$

$$\frac{Q^{\mathrm{mix}}}{Q^0} < 1, \text{ sorption is suppressed by the presence of other metal ions}$$

The values of $\frac{Q^{\mathrm{mix}}}{Q^0}$ were found to be less than 1, as presented in Table 5. The prepared activated carbon followed the same trend, that is, Q^{mix} decreased in the following order for the adsorption of Cd(II) and Zn(II) in multicomponent systems:

$$\mathrm{Cd(II)} < \mathrm{Cd\text{-}Cu} < \mathrm{Cd\text{-}Zn} < \mathrm{Cd\text{-}Cu\text{-}Zn} \qquad \text{for Cd(II)}$$

$$\mathrm{Zn(II)} < \mathrm{Zn\text{-}Cu} < \mathrm{Zn\text{-}Cd} < \mathrm{Cd\text{-}Cu\text{-}Zn} \qquad \text{for Zn(II)}$$

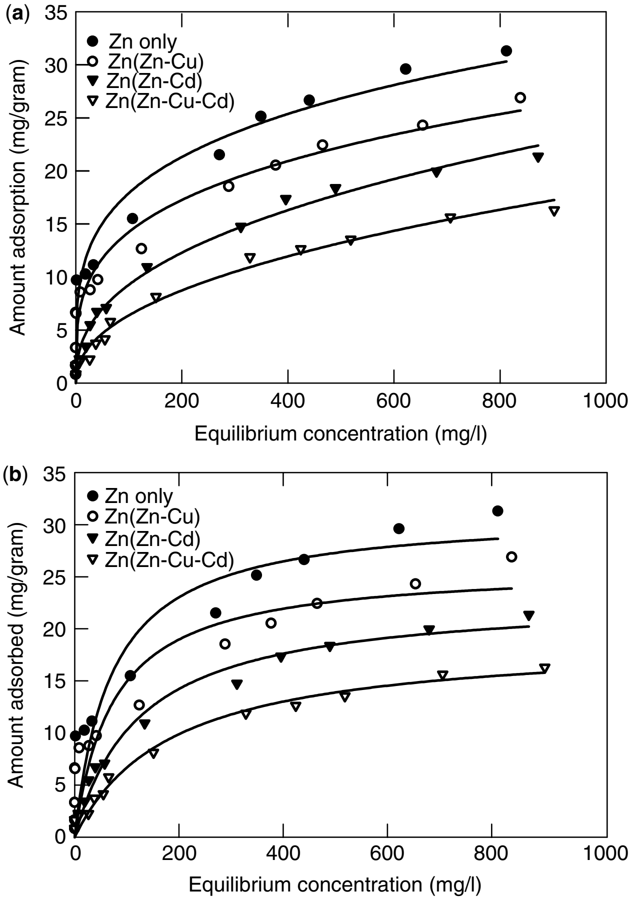

Figure 2. Multicomponent adsorption of Zn(II) on activated carbon developed from bagasse. Solid lines represent the fitting of data by (**a**) Freundlich and (**b**) Langmuir isotherms.

Overall, it was concluded that the adsorption capacity of activated carbon for Cd(II) and Zn(II) decreased more in ternary systems as compared with binary systems.

In acid mine wastewater, some other metal ions are always present besides iron and manganese; therefore, it is desirable to see the effect of other metal ions on the adsorption capacity of different activated carbons. A very important study in this regard was carried out by Mohan and Chander (39) where the adsorption of four metal ions, i.e., Mn(II), Fe(II), Zn(II), and Ca(II), were conducted in binary, ternary, and multicomponent systems on different types of activated carbons. The adsorption isotherms for binary, ternary, and multicomponent systems were obtained at pH 3.5 and 25 °C. The concentration range of 5.0×10^{-5} to 9.0×10^{-3} M was investigated, and a 1:1 ratio was used to determine the effect of Mn(II), Ca(II), and Zn(II) on the adsorption of Fe(II) on carbons. The Freundlich and Langmuir adsorption isotherms for Fe(II) in the absence and presence of interfering metal ions were determined.

Both Langmuir and Freundlich adsorption isotherms were found to adequately describe the data over the entire range of concentration, and the Langmuir and Freundlich isotherm parameters are presented in Tables 6 and 7, respectively. The detailed analysis of the regression coefficients showed that the data was slightly better fitted by Freundlich adsorption isotherm for multicomponent systems. The adsorption isotherms for different carbons revealed that, when Ca(II), Mn(II), and Zn(II) were present in the system with Fe(II), the interference did not change the adsorption of Fe(II) in the low concentration range, whereas a competitive uptake, with Fe(II) being preferentially adsorbed by carbons, took place at the higher concentrations. Carbon B0, which showed abnormal behavior and adsorption, was found to increase in the presence of other metal ions.

It was further concluded that the presence of manganese and/or zinc had limited effect on the capacity of carbons for Fe(II) in comparison with calcium. Thus, overall it was found that Ca(II) had the highest interfering capacity. The adsorption capacity of various activated carbons for Fe(II) in the presence and absence of Mn(II), Zn(II), and Ca(II) are presented in Table 6, whereas the Freundlich constants are presented in Table 7. Thus, when two or more metal ions are present in the solution, they seem to compete for the adsorption sites as the metal ions are adsorbed on the same sides.

The values of $\frac{Q^{\text{mix}}}{Q^0}$ are found to be less than 1, as presented in Table 6, except for carbon B0, thereby confirming the suppression in the adsorption of Fe(II) by the presence of other metal ions. These results are consistent with the adsorption isotherms obtained for Fe(II) in the absence and presence of various metal ions. It is clear from Table 6 that carbons can be divided into two different categories, i.e., wood-based activated

carbons follow the same trend (Fe-Mn<Fe-Zn<Fe-Ca<Fe-Mn-Zn<Fe-Mn-Zn-Ca) whereas the other carbons behave in a similar fashion (Fe-Mn<Fe-Zn< Fe-Mn-Zn<Fe-Ca < Fe-Mn-Zn-Ca). Also, the effect of other interfering metal ions on the adsorption of Fe(II) was found to be less on coconut-based activated carbon followed by coal-based and wood-based activated carbon, respectively. Overall, it was concluded that the adsorption capacity of different carbons decreased more in ternary and quaternary systems as compared with binary systems.

Fixed bed studies were also conducted on solution containing a mixture of several metal ions. For these studies, a bed filled with activated carbon was treated with a solution containing 60 mg/L Fe (II) and 50 mg/L each of Mn (II), Zn (II), and Ca (II). The hydraulic flow rate was 1.7 mL/min. The breakthrough curves are presented in (Figs. 3 and 4). The results are plotted as dimensionless concentration (C_e/C_0) vs. effluent volume. Initially, all the metal ions were adsorbed nonselectively and a metal ion-free effluent was produced. With continued treatment, manganese began to escape the column, followed by zinc and then iron. One can see that manganese and zinc, which initially adsorbed nonselectively, are released with continued passage of iron-bearing solutions. Iron could be adsorbed selectively during the period of testing. Similar results were obtained with other carbons. These results demonstrate that metal ions can be separated and possibly recovered in useful form by treating metal-bearing wastewaters with activated carbons. The studies were also performed in the single column as well as when columns were connected in series. The difference in various parameters obtained are presented in Table 8.

The uptake of Pb(II), Hg(II), and Cr(VI) in a multicomponent system was studied by Srivastava et al. (40) on the activated carbon developed from fertilizer waste material. The sorption efficiency of the adsorbent was found to decrease by 15% and 7%, respectively, for lead and mercury in the presence of each other. No decrease, however, was reported for chromium in the presence of mercury, but the uptake of mercury reduced by 8–10% in the presence of chromium. The reduction in the sorption of metal ions from the mixtures was observed to be almost the same for different levels of interference. Competitive adsorption of various metal ions in the presence of each other is presented (40,41) in Tables 9–12.

COMPETITIVE SORPTION OF ORGANICS

Yen and Singer (42) studied the adsorption of phenols and substituted phenols on activated carbon. Mixtures of phenolic compounds were taken to explore the Ideal Adsorbed Solution (IAS) theory using an improved method of calculation that had been developed to describe the multicomponent adsorption. The IAS model with the

modified calculation method was tested for its performance on ten sets of binary and ternary phenolic mixtures. The Langmuir model was also taken just to compare the results, but the IAS model was found to be successful in precisely describing the competitive adsorption behavior of phenolic mixtures.

The impact of the presence of molecular oxygen on multisolute adsorption of phenols on granular activated carbon was evaluated by Sorial et al. (43). Adsorption equilibrium for binary mixtures of phenol/O-cresol and ternary mixtures of phenol/O-cresol/3-ethylphenol was carried out at 23 °C using three different initial concentration combinations. Adsorption was carried out under oxic and anoxic conditions. The ideal adsorbed solution theory, using Myers equation for correlating the single-solute anoxic isotherms, was found to accurately describe the competitive adsorption behavior of these phenolic mixtures under anoxic conditions. When the Freundlich model was used to describe the single-solute sorption, the deviations were found to increase. It was concluded that poor model predictions for the oxic isotherms were attributed to the presence of molecular oxygen, which promotes the polymerization of solutes on the surface of granular activated carbon. In continuation of this study, the same authors (44) conducted the adsorption of these phenolic compounds in fixed bed GAC adsorbers. The adsorption breakthrough curves were obtained for a single-solute system, i.e., phenol, O-cresol, and 3-ethylphenol, as well as for multisolute systems, i.e., phenol/O-cresol and phenol/O-cresol/3-ethylphenol. The plug through homogenous surface diffusion model was evaluated as a predictor of GAS adsorber, whereas the binary and ternary solute calculations were performed using kinetic parameters determined from a single-solute system. The ideal adsorbed solution theory was implemented. The model for binary and ternary solute systems agrees well with the experimental data collected under anoxic conditions.

The adsorption of 2,4,6-trichlorophenol (TCP) and N-[2-(2,4,6-trichlorophenoxy)propyl] amine(BTS40348) in single and binary systems was carried out on four different activated carbon at pH 4.0 and 9.0 by Garner et al. (45). Competitive adsorption was observed, and at respective pH optima, reduction in adsorption efficiencies were found to be 10% for TCP and 43% for BTS40348.

The interference of catioinc, nonionic, and anionic detergents on the adsorption of phenols was studied as a function of the concentration of detergents (46). As all types of surfactants are found to interact to a varying degree with activated carbons, the effect of anionic detergent (Manoxol 1B), nonionic detergent (triton), and cationic detergent (cetylpyridinium chloride) on the uptake of 2,4,6-trinitrophenol, 4-nitrophenol, 4-chlorophenol, and 1,3-dihydroxybenzene by the activated carbons was studied. The adsorption of 2,4,6-trinitrophenol was found to decreased by 1.3–3.3% in the presence of increasing anionic detergent concentration. A decrease in adsorption efficiency by 3.0–6.0% was observed in the case of 4-nitrophenol. In the case of 4-chlorophemol, the uptake decreased by 5–7%, whereas a 2–5% decrease was observed for 1,3 dihydroxybenzene. In the case of nonionic surfactant, the removal efficiencies of activated carbon was found to decrease by 2–4%, 3–8%, 3.7–7.5%, and 3.3–6.7% for 2,4,6-trinitrophenol, 4-nitro phenol, 4-chloro phenol, and 1,3-dihydroxybenzene, respectively. In the case of cationic detergent, a decrease in the scavenging efficiency of activated carbon by 2.7–6.7% for 2,4,6-trinitrophenol and 4.0–10.0% for 1,3-dihydroxybenzene was observed. Thus, the maximum effect was found with cationic detergent and the minimum with anionic detergent. Nonionic detergent falls in between the two. Authors explained that the decrease in the scavenging efficiency of activated carbon for phenols in the presence of surfactants is consistent with the act that the particles of the carbon surface are negatively charged.

Jossens et al. (47) studied the sorption data at 20 °C for six dilute aqueous bi-solute systems in activated carbon. The six systems were phenol/p-nitrophenol, p-nitrophenol/p-chlorophenol, p-nitrophenol/benzoic acid, p-chlorophenol/phenyl acetic acid, p-nitrophenol/o-phenyl phenol, and 2,4-dichlorophenol/dodecyl-benzol sulfonic acid. A new three-parameter adsorption isotherm was presented that represents the single-solute data very well. For bi-solute systems where dissociation is negligible, the calculated individual adsorption agrees with experimental data within 2%.

The adsorption of acetaldehyde, acetone, 2-butanone, pyridine, and phenol from binary aqueous solutions on activated carbon was reported by Barton (48). The author has applied the Dubbinin–Radushkevich (DR) equation with some slight modifications. The authors explained that the displacement adsorption of 2-butanone and pyridine is driven mainly by the displacement enthalpy. As desorption of water involves an increase in motional entropy, it was therefore concluded that strong adsorbed solutes 2-butanone and pyridine produce a large compensating entropy decrease. On the other hand, more weakly adsorbed substances, such as acetone and acetaldehyde, were not able to compensate for the entropy increase associated with the desorbed water on adsorption. Single and multisolute adsorption isotherms studies of three phenolic compounds, i.e., gallic acid, *p*-hydroxybenzoic acid, and syringic acid, were investigated at 20 °C, 30 °C, and 40 °C using a bituminous coal-based activated carbon (49). The capacity of the activated carbon used to adsorb these compounds follows the order: syringic acid > *p*-hydroxybenzoic acid > gallic acid. In binary and ternary components, experimental data suggested that interactions between adsorbates improve the adsorption capacity of some of the phenolic acid compounds. On the contrary, at high organic concentrations, adsorbed gallic acid was partially removed from the activated carbon surface because of the presence of the other components. A two-component isotherm (phenol/2,6-dichlorophenol) adsorption was also studied by Mameli et al. (50) in order to test activated carbon behavior during competitive adsorption.

Kim and Lordgooei (51,52) reported the adsorption modeling of various volatile organic compounds in single and multicomponent systems. A Dubinin–Astakhov thermal equation of equilibrium adsorption (DA-TEEA) for single component and ideal/real adsorbed solution theories (IAST/RAST) for multicomponent systems were presented successfully. In an another study, Semmens et al. (53,54) studied the influence of pH and coagulation on the removal of organics by granular activated carbon. Okazaki et al. (55,56) reported the multicomponent adsorption of organics from water, whereas Ha et al. (57) developed a predictive isotherm model to evaluate the extent of bioregeneration of granular activated carbon loaded with phenol and 2,4-dichlorophenol (2,4-DCP) in single and bisolute systems. A bisolute system was taken up for assessing the competitive adsorption. The effect of byproducts, which were generated during biodegradation of substrate and measured as COD, on bioregeneration in the bisolute was also investigated. Freundlich adsorption capacity of 2,4-DCP was found to be more as compared with phenol in both single and bisolute systems. Byproducts in the bulk solution brought an adverse effect on adsorption capacity of GAC in all cases. By taking into account the byproduct effect on adsorption, the Freundlich isotherms were used to formulate a predictive model of bioregeneration.

The adsorption of benzoic acid and p-nitrophenol (PNP) at 25 °C was performed by Chern and Chien (58) in a binary system on GAC. The sorption experimental data were fitted to the extended Langmuir isotherm model successfully. The experimental data and the isotherm model parameters showed that the GAC used in this study had a higher affinity to PNP than benzoic acid. Three-column tests were performed to determine the breakthrough curves and effluent solution pH with varying feed compositions. The weakly adsorbed BA exhibited an intermediate zone of effluent concentration higher than its feed one. The authors predicted that the breakthrough curves with varying feed compositions could be predicted by the nonlinear wave propagation theory satisfactorily, only the adsorption isotherm models were required to construct the composition path diagram with which the breakthrough curves could be predicted. In an important study, Bulloch et al. (59) developed a thermodynamic model to predict adsorption equilibrium in the international space station water processor's multifiltration beds. The model was able to predict the multicomponent adsorption equilibrium behavior using single component isotherm parameters and fictitious components representing the background matrix. The fictitious components

Table 13. Competitive Adsorption of Phenols in Presence of Each Other

Adsorbate	Adsorbate Concentration mol/l	Amount Adsorbed mol/g	Amount Adsorbed in Presence of 2,4,6-Trinitrophenol (1×10^{-5} M) mol/g	Amount Adsorbed in Presence of 4-Nitrophenol (1×10^{-5} M) mol/g	Amount Adsorbed in Presence of 4-Chlorophenol (1×10^{-5} M) mol/g	Amount Adsorbed in Presence of 1,3 Dihydroxy Benzene (1×10^{-5} M) mol/g
2,4,6-trinitro phenol	1×10^{-4}	1×10^{-4}	—	—	—	X
2,4,6-trinitro phenol	1×10^{-3}	7.50×10^{-4}	—	—	—	X
4-nitrophenol	1×10^{-4}	0.9×10^{-4}	0.84×10^{-4}	—	—	X
4-nitrophenol	1×10^{-3}	5.00×10^{-4}	4.80×10^{-4}	—	—	X
4-chlorophenol	1×10^{-4}	0.73×10^{-4}	0.65×10^{-4}	0.70×10^{-4}	—	X
4-chlorophenol	1×10^{-3}	4.00×10^{-4}	3.50×10^{-4}	3.80×10^{-4}	—	X
1,3 dihydroxy benzene	1×10^{-4}	0.70×10^{-4}	0.55×10^{-4}	0.65×10^{-4}	0.70×10^{-4}	X
1,3 dihydroxy benzene	1×10^{-3}	3.00×10^{-4}	2.50×10^{-4}	2.75×10^{-4}	2.90×10^{-4}	X

were determined by fitting total organic carbon and tracer isotherms with the ideal adsorbed solution theory. Multicomponent isotherms using a wastewater with high surfactant and organic compound concentrations were used to validate the equilibrium description on a coconut-shell-based granular activated carbon (GAC), coal-based GAC, and a polymeric adsorbent.

The adsorption of three barbiturates—phenobarbital, mephobarbital, and primidone—from simulated intestinal fluid (SIF), without pancreatin, by activated carbon was studied by Wurster et al. (6). The competitive Langmuir-like model, the modified competitive Langmuir-like model, and the LeVan–Vermeulen model were each fit to the data. Excellent agreement was obtained between the experimental and predicted data using the modified competitive Langmuir-like model and the LeVan–Vermeulen model. The agreement obtained from the original competitive Langmuir-like model was less satisfactory. The results of these studies indicate that the adsorbates were found to compete for the same binding sites on the activated carbon surface. The results demonstrated that it is possible to accurately predict multicomponent adsorption isotherms using only single-solute isotherm parameters.

Rozada et al. (60) studied the adsorption of methylene blue and saphranine from single and bisolute systems using the activated carbons developed by chemical activation and pyrolysis of sewage sludges.

The effect of presence of an anionic (Manoxol 1B), nonionic (Triton), and cetyl pyridinium chloride detergent on the uptake of dinitrophenol by activated carbon developed from fertilizer waste slurry was studied by Srivastava et al. (61). The dinitrophenol adsorption showed a decreased (2–8%) w/w with increasing concentrations of anionic, nonionic, and cationic surfactants. The uptake of DNP was also observed in the presence of NaCl, $BaCl_2$, and $AlCl_3$ at a fixed adsorbent concentration. No effect of NaCl was observed on DNP uptake between pH 2 to 4, but at pH 10, adsorption increases by 66% w/w. The presence of $BaCl_2$ and $AlCl_3$ did not affect the uptake of DNP to a significant extent ($2 < 2\%$ w/w). The influence of anions (ClO_4^-, PO_4^{3-}, SO_4^{2-}, and NO_3^-) on the uptake of dinitrophenol was also reported. It was observed that anions have a negligible effect on the sorption of DNP. Various explanations were given for the competitive adsorption, some of which are listed below:

1. Interaction in solution between salts and organics to produce a change in the distribution of the organic species present, thereby influencing the rate or the extent of adsorption.
2. Interactions between salts and the adsorbed organics, resulting in the alteration of the packing, spacing, or alignment of the adsorbed molecules.
3. Interactions between salts and the adsorbate and adsorbent to perhaps create new or particularly favorable adsorption sites.

The enhanced adsorption of DNP in the presence of slats was thus attributed to the interaction between cations and organics in the solution or at a solid surface. Such interaction influences adsorption through the alteration of solubility or the degree of ionization of the organic molecule via the common ion effect, ion pairing, or complexation. The enhance in the uptake of DNP was attributed to ion pair formation

The adsorption of malachite in presence of Manoxol 1B detergent was reported by Gupta et al. (62). The removal was found to decrease by 1.5–2.0%.

Sung-Ryong and Vinitnantharat (63) studied the sorption of phenol and 2,4 dichlorophenol in single and bisolute systems. It was concluded that 2,4 DCP was a stronger adsorbate than phenol in both single and bisolute systems. On desorption of 2,4 DCP, the small fraction of sorbed compounds was reversible, but phenol has comparatively high reversibility.

The competitive adsorption of three cationic polymers, namely JR125, JR400, and JR30M, and a cationic surfactant (cetyl trimethyl ammonium bromide) onto a silica surface from a low ionic strength medium was investigated by Harrison et al. (64). It was reported that competition between polymers showed that smaller molecules were adsorbed, initially preventing the subsequently adsorption on larger polymers. Adsorption from the combined polymer and the smallest polymer (JR 125) was excluded from the surface; the intermediate molecular mass polymer (JR

400) was almost unaffected; the surfactant and the largest molecular mass polymer (JR 30M) were partially excluded from the surface.

Competitive adsorption of substituted phenols by activated carbon developed from fertilizer waste slurry was investigated by Srivastava and Tyagi (65). The uptake of 4-chlorophenol, 4-nitophenol, 2,4,6-trinitrophenol, and 1,3-dihydroxybenzene in the presence of each other provided some interesting data, which is presented in Table 13. Surprisingly, the adsorption of 2,4,6-trinitrophenol did not get at all affected by 4-nitrophenol, 4-chlorophenol, and 1,3-dihydroxybenzene. However, the uptake of 4-nitophenol went down by 6.0% in the presence of 2,4,6-trinitrophenol. No decrease, however, was observed in the presence of 4-chlorophenol and 1,3-dihydroxybenzene. Similarly, the adsorption of 4-chlorophenol was found to reduced by 5.0% and 12.5% in the presence of 4-nitophenol and 2,4,6-trinitrophenol. 4-chlorophenol was not affected by 1,3-dihydroxybenzene. The sorption capacity of 1,3-dihydroxybenzene decresed by 3.3%, 8.3%, and 16.7% in presence of 4-chlorophenol, 4-nitrophenol, and 2,4,6-trinitrophenol, respectively. The electron withdrawing nature of nitro as well as chloro reduced the electron density in the ring in phenols. The effect was highest in 2,4,6-trinitrophenol and lowest in 1,3-dihydroxybenzene. 4-nitophenol and 4-chlorophenol occupy the second and third position if a gradation of all four adsorbates is made vis-a-vis the reduction in electron density of the pi system of the ring, which explained that the removal of 2,4,6-trinitrophenol did not get reduced in the presence of the other three phenols. The observed fact that 1,3-dihydroxybenzene also did not reduce the uptake of other phenols could also be attributed to the above-mentioned reason.

MULTICOMPONENT KINETICS

Similar to equilibrium studies, multicomponent kinetics is also a very important aspect of any adsorption study. It is based on the single component kinetics model. Out of the various kinetic models, the film-solid diffusion model is the best one as far as theoretical background and optimum mathematical conveyance are concerned, and therefore opted by a number of researchers from time to time in multicomponent systems. The details about this model are also very much documented in various articles (12,15,66–68).

The kinetic adsorption of mixtures of phenolic compounds onto a polymeric adsorbent from aqueous solution was studied by Mijangos et al. (69). Van Laar's equation was applied to evaluate the influence of concentration on diffusion. The adsorption kinetics for phenol and p-cresol mixtures at different initial concentration ratios were studied and adjusted to the mentioned kinetic model. They concluded that adsorption from multicomponent aqueous solution is a surface diffusion-controlled process.

The binary soprtion of Cu-Cd, Cd-Zn, and Cu-Zn onto bone char has been studied using an equilibrium and batch agitation system (70). The sorption capacities and selectivity of metal ions follows the order Cu(II)>Cd(II)>Zn(II), which is a reverse order of the hydrated ionic radii. The binary sorption equilibria were predicted by the ideal adsorbed solution theory (IAST) on the basis of single component isotherm data using a Langmuir or Langmuir–Freundlich isotherm. The overall performance of IAST provided a reasonable curve fitting to the experimental data. The single component film-pore diffusion model was extended to the multicomponent systems to correlate the batch kinetic data by incorporating the shrinking core model and IAST. It was found that all the diffusivities in the binary systems are similar to or less than the pore diffusitivites in single component systems.

Table 14

Metal Ions	Single Component D_p (cm^2/s)	Cd-Cu	Cd-Zn	Cu-Zn
Cd	1.14×10^{-6}	1.20×10^{-6}	2.25×10^{-7}	—
Cu	1.59×10^{-6}	1.30×10^{-6}	—	1.50×10^{-6}
Zn	1.21×10^{-6}	—	1.10×10^{-6}	1.00×10^{-6}

The pore diffusivities of the multicomponent systems using the film-pore diffusion model and IAST are given in Table 14. Although the equal molar and unequal molar equilibrium data can generally be predicted by IAST, the results for the mole ratios 3:7 and 7:3 for the Cd-Cu systems cannot be predicted very well.

Hørsholm, Denmark

Nowadays, many organizations collect hydrologic information for various purposes. But still, little information from the huge sources of data is made public in real time, and only a small fraction of the data is applied for real-time decision making. Once the hydrologic data have become "historical" (the data are no longer applicable for real-time decision making), the data are still very valuable for design and for evaluating and understanding the hydrologic environment. But if hydrological data are used only after they have become "history," the value of the data collection is not fully used.

Before starting to disseminate hydrologic information it is important to address the following questions:

1. What kind of real-time information should be shown to the public?
2. How and where should the real-time information be presented to the public?
3. When do hydrologic data change from valuable real-time information to less interesting (from a public point of view) historical hydrologic data?
4. What does it take in knowledge, technology, and hardware to provide real-time hydrologic information?

This article discusses experience gathered from a research project in Bangkok concerning provision of real-time rainfall data to the public through the Internet, handheld computers, and mobile phones. It also provides an outline of the future use of hydrologic information in real time. The potential benefits from the described framework for using the information are

- a public rainfall and flood information service, like the daily weather forecast, and flood warning system
- traffic information about streets that have a potential risk for flooding,
- a decision support system for reducing flooding in the Bangkok area.

INTRODUCTION

Water is a basic necessity for sustaining life and developing society. Proper management, protection and development of water resources are challenges imposed by population growth, increasing pressure on water and land resources by competing usage, and degradation of scarce water resources in many parts of the world.

The cities in Asia are growing rapidly, so it is important to pay attention to the role of cities in integrated water resources management (IWRM). The infrastructure for water in cities consists of water supply networks, sewer systems, and purification and wastewater facilities. Many of the cities are old, and they have developed according to varying historical needs and visions. Hence, the layout and design of the infrastructure has gradually developed into rather complex systems covering large areas, and the systems often have inadequate capacities. The cities are located in the monsoon area, so they have to cope with very high rainfalls every year. Regular flooding during the rainy season is the rule rather than the exception in most areas. For smaller floods, the people seem to have adjusted their daily lives, although there is always a loss of income and property damage. However, when the floods are heavy, the socioeconomic and health impacts on the population are enormous. This requires information and tools that can handle such situations and describe flooding from local rainfall in cities.

An understanding of the physical system and its interaction with the environment is a prerequisite for effective planning and management of urban water resources. It is too expensive to eliminate flooding in urban areas by using only structural measures, such as building new sewers, embankments, and installation of pumps. To manage the existing infrastructure better, nonstructural measures, like real-time rain fall and flood risk information can minimize flooding and the impact of flooding. In addition, provision of flood risk information can help people make more intelligent decisions during floods, and hence reduce the stress and costs of floods.

Today's advances in computer technology can help many cities in the world manage local and minor flooding problems using computer-based solutions. This involves building computer models of the drainage/sewer system. These models are then used to understand the often rather complex interaction between rainfall and local flooding. Computer models provide the opportunity for well-structured analyses of rainfall/runoff/flooding, water availability, water demands, and wastewater disposal, and they offer a sound scientific framework for coordinated management and planning. Once the existing conditions have been analyzed and understood, alleviation schemes can be evaluated and the optimal scheme implemented. In addition to real-time information, modeling increases the value of the hydrologic data tremendously because the combination of models and real-time data provides a full cover of information over a catchment.

BACKGROUND

At present, the Asian Institute of Technology (AIT) is carrying out a research project to apply real-time rainfall information for Bangkok, Thailand. The Greater Bangkok area has a very high level of activity. Millions of people live in the area: On the outskirts of the city, there are a lot of big factories, and many national as well as international offices are situated in the center of town. When heavy rainfall occurs in the Bangkok area, some of the consequences are heavy traffic jams, waterlogging, blackouts, and property damage. If flooding follows, there is often great social impact as well. Many people might lose their jobs for a shorter or longer period due to temporary closing of businesses, and schools have to close because the streets are flooded.

A typical picture of flooding in the city after a minor heavy rain in Bangkok can be seen in Fig. 1. Knowing the condition of rainfall in Bangkok in advance can help in managing and dealing with these problems. Therefore, hydrometeorological forecasts and warnings are effective tools for preventing property damage caused by rainfall and subsequent flooding.

The objectives of the current project are to

1. provide a real-time information system concerning rainfall and flood risk, and

Figure 1. The Nontaburi area in Bangkok after a “minor” heavy rain on the April 27, 2002.

2. explore the possibilities of predicting rainfall and flooding in Bangkok.

The outcome of the project in economic and social impacts depends on the dissemination of the information to the people and the accuracy of the information supplied. The information system is designed to be generic, so that the concepts can be transferred easily and implemented at other Asian locations.

PROVISION OF REAL-TIME HYDROLOGICAL INFORMATION TO THE PUBLIC

Before embarking on a project to provide real-time hydrologic information to the public, it is important to assess which information the public would like to have as individuals and which information local authorities would like to have to manage the assets of the city. For example, a private person driving a car to work may be interested in knowing the approximate duration of the rain and the strength of the rain plus an assessment of the risk of flooding like "Probably small flooding" or "Flooding—Don't drive to zone A, B, etc.," whereas the local authority may want information about an accumulated rainfall of 60 mm during the past 60 minutes (which, by experience, provokes flooding) or other more specific numbers concerning the rainfall. The local authority may then want to process the rainfall information further and pass it to public information sources such as traffic radio and local news broadcasts.

In modern society, much information (maybe too much) surrounds us, and we must choose which information we would like to have. However, one of the basic principles is that information should be available at the time we need it and in a form that fits our demands. Providing rainfall information through a computer requires that we are in front of a computer, which rarely happens when we are walking or driving in the rain. We could stop and visit an Internet café to get the latest rainfall information, but that would be rather unrealistic. You would like rainfall information to be available wherever you are. Mobile phones provide the means of bringing the rainfall information directly to you wherever you are.

Technical Requirements to Transform Hydrologic Data to Real-Time Information

A prerequisite for turning hydrologic data into real-time hydrologic information is the basic infrastructure in terms of rain gauges and stable Internet connections. In addition, the communication between the rain gauges and the Internet service should be available at all times. If these components are available, it is possible to send the hydrologic data to a central place where the data can be processed into information. There are several ways of setting up such a communication system; it may be tailored depending on individual need and available hardware. Figure 2 shows the configuration of the real-time application that is under development at AIT.

Data from rain gauge stations and radar stations were sent to the center by radio and the Internet. After generating the data, Bangkok Metropolitan Administration (BMA) and Thai Meteorological Department (TMD) center sent data packages to AIT by the Internet. The server at AIT was set up to carry out all the main tasks: receiving, generating, and storing online data; creating applications based on data; and answering requests from users. The data are updated using a real-time Internet database (DIMS^{TM}). In DIMS^{TM}, macros have been developed to create the images and other information automatically for the web sites and then upload the results to the web sites, including WAP sites available to the public (Fig. 4). The forecasts of rainfall and flooding are at present based on 53 on-line rain gauges across Bangkok (Fig. 3) and a weather radar located in downtown Bangkok.

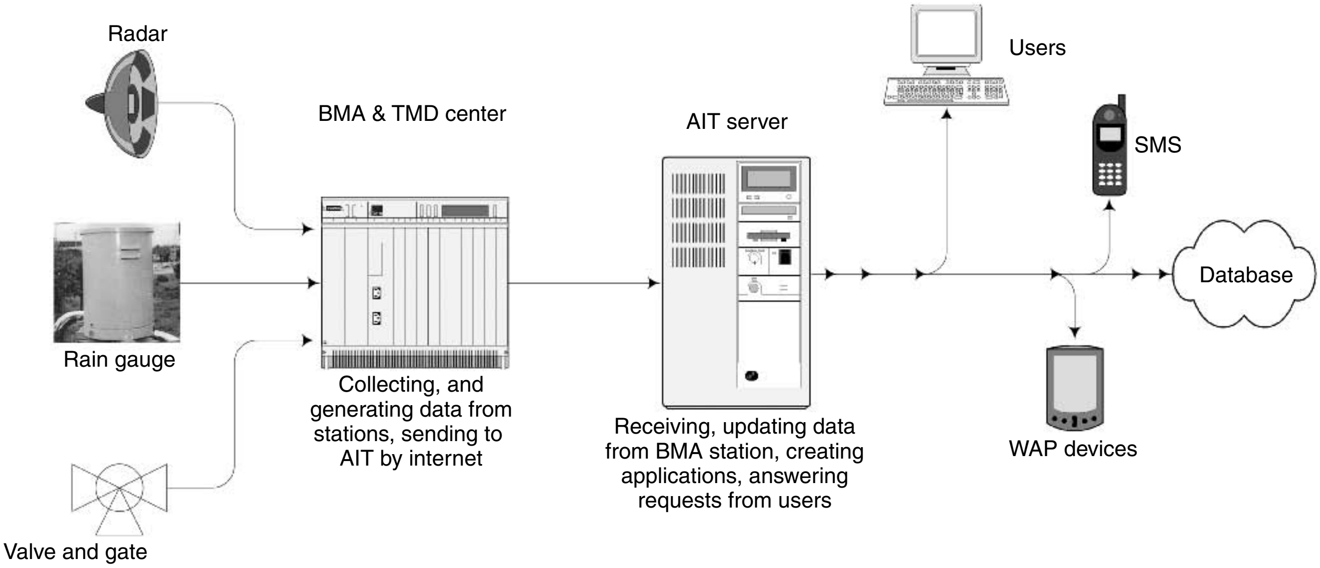

Figure 2. The layout of the real-time rainfall information application at AIT.

How Close to Real Time must Hydrologic Information be to Consider It Valuable Real-Time Information?

This is a question, which is extremely difficult to answer. So far, this article has used the term "real time" to describe the measurements, which were made, sent to the AIT computers, processed, and presented to the public. But the information presented to the public will always have a time delay because of the time it takes for measurements, data transmission, and processing. These time delays are discussed in detail below:

1. The rain gauges run by Bangkok Metropolitan Administration (BMA) measure the rainfall at 15 minute intervals. Thus, it may only rain the first 5 minutes of the sampling interval and the rainfall intensities from the first 5 minutes will be averaged over a period of 15 minutes. Hence, the sample over 15 minutes produces a significantly lower peak intensity, which according to the measurement, lasts 10 minutes longer than the actual rain.
2. The data transmission from the rain gauges to BMA and further to AIT is rather swift and takes only 1 to 2 minutes. But the AIT rain data server looks only for new data from BMA every 5 min, which on average means a time delay of 2.5 minutes.
3. The data processing at AIT and the transmission to the Internet, mobile phones, etc. takes only another minute, but then the hydrologic information stays on the Internet until new information has been measured, transmitted and processed through the loop described before.

The "real-time" information available to the public is updated only after the repetition of a new measurement cycle, as described above. Hence, the information presented as real-time information may in the worst case be around 20–30 minutes old!!! Is this acceptable? This is a question that is difficult to answer and depends on may local conditions such as the speed of the rain front, the uniformity of the rain; the density and number of rain gauges, and the use of the real-time hydrologic rainfall information. For example, if a rain cloud moves at 5 m/s, then it will travel 6 km in 20 minutes. This means that details within an area of travel distance will be difficult to describe accurately. Means to achieve a higher level of accuracy are to reduce the sampling interval from 15 minutes to 5 minutes or even to 1 minute to be able to present information to the public closer to real time. Alternatively, more rain gauges can be installed. One can imagine that the public will not gain faith in an information system, which tells them it is still raining where they are 20 min. after they have felt the last raindrop.

APPLICATION OF REAL-TIME HYDROLOGIC INFORMATION IN CONJUNCTION WITH URBAN DRAINAGE MODELS

Applying a model in conjunction with real-time rain data provides means for improving information about the current status of the hydrologic system. In general, the rain gauges provide information only at specific locations. The application of a model provides the possibility for gap-filling of information between rain gauges. The simplest kind of modeling is an inverse-distance-based interpolation between the rainfall measurements in real time. At present, that is the method applied at AIT for generating hyetographs. In the near future, more interpolative methods will be evaluated and compared.

In addition to interpolation of the rain intensity between the spatial network of rain gauges, surface runoff and urban drainage models can easily be added to the hydrologic information system. The models are automatically executed when the rainfall at specified locations exceeds preset threshold values. Based on a forecast by the hydrologic model or the urban drainage model, the level of information about the hydrologic system can be extended into the future. The general approach behind the level of information about the hydrologic system as a function of the availability of rain gauges, models, and a forecast is shown in Fig. 5. The figure shows how the information level increases and extends in time when more rain gauges and a model are applied.

The present status of the research project in Bangkok, is that rain gauges reporting in real time together with a simple model predict the spatial variation of the rainfall. In addition, forecast tests in real time have been carried out on a small scale. First, the procedures were tested with a small urban drainage model covering AIT only where all the real-time information is measured directly at AIT. Second, the urban flood model for Bangkok was set up and made operational based on real-time data from BMA and TMD. The forecast has shown promising results and will be made operational during November–December 2003.

The ongoing work on flood forecasting for specific areas of Bangkok is based on real-time rainfall data and a deterministic hydrodynamic urban flood model. The urban flood model has already been established during 2001–2002 as part of the AIT research in modeling urban flooding (1,2). The urban flood model builds on a 1-D hydrodynamic urban drainage modelling package, MOUSE (3) from DHI—Water & Environment. Based on input in terms of time series of rainfall, the MOUSE model for Bangkok produces flood inundation maps, showing flooded areas and depths for the Sukhumvit business area in Bangkok. Layout of the system is shown in Fig. 6. The model has been successfully set up and applied to off-line studies of flooding in Bangkok.

WARNING SYSTEMS FOR FLOODING, FLASH FLOODS, AND LANDSLIDES

Real-time hydrologic information makes it possible to detect potential hazards shortly before they happen, for example, heavy rainfall recorded in certain parts of the catchment may indicate potential flooding, a potential flash flood, or a landslide in hilly areas. However, the level of data and information from a real-time hydrologic system is overwhelming, and it is not really suitable for decision support until targeted data processing has taken place. By keeping the rainfall information in a database, it is easy to write scripts, which automatically keeps track of

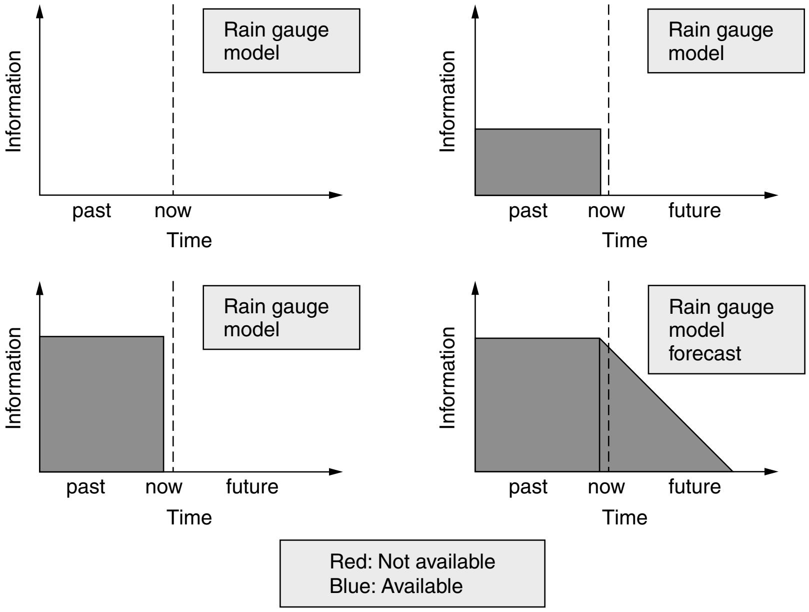

Figure 5. The level of information as a function of the application of (1) no rain gauges and no model available; (2) only rain gauges available; (3) rain gauges and a model available; and (4) rain gauges, a model, and a forecast available.

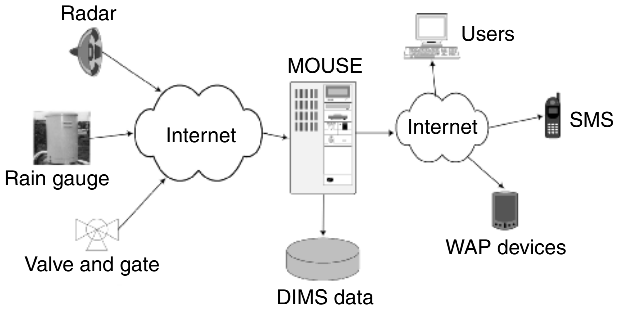

Figure 6. The layout of the real-time data transmission and real-time model.

the accumulated rainfall within the last hour. In Bangkok, experience says that if the accumulated rain within 1 hour is more than 60 mm, then flooding occurs. This criterion has been implemented in the rainfall information system, and warnings are automatically sent to BMA officers, whenever this criterion is exceeded. The warning system is built so that it both sends information about the rain and a personalized message in an e-mail and a SMS message to mobile phones when the criterion is exceeded. Whoever the BMA officer on duty is, he will be alerted about the rainfall conditions either by his email system or by a ringing phone. It is possible to let the information system automatically control gates, weirs, pumps, or other devices in the drainage system, but that is not considered for the moment.

APPLICATION OF WEATHER RADAR FOR HYDROLOGIC REAL-TIME INFORMATION

During the last decade, the use of weather radar has emerged as a tool for rainfall forecasting and at present, research on the use of weather radar for estimating rainfall is carried out at several locations (4–6). A weather radar measures the reflectivity from raindrops in the sky. It does not measure the actual rainfall, and a calibration between the reflectivity and the rainfall is always required for each individual weather radar. A radar provides the potential for getting the spatial variation of rainfall over a large catchment area. For example, the weather radar location in Bang Na, Bangkok, has a range of 60 km, and radar pictures from the Bang Na radar are presently updated every 15 minutes. However, weather radars are still a rather new topic for research in forecasting rainfall. Until now, it has not really been possible systematically to forecast rainfall dynamics (convective effects) with notable success, and operational application of weather radar is rare. However, even though the radar information at present is not highly accurate, radar can still be part of a warning system, where a human is automatically alerted (through the e-mail and SMS warning system described above) when very high rainfall intensities are measured by the weather radar. It will then be up to the duty officer to assess the flood/flash flood risk based on local data, guidelines, and experience. At present, a number of weather radars are already available in Thailand, so there is a good basis for making a warning system that covers the country.

FUTURE PERSPECTIVES FOR HYDROLOGIC DATA IN REAL TIME

At present, hydrologists working in urban areas are facing many new challenges imposed by the ever changing hydrologic environment in cities. Emphasis should be put on managing the urban systems as well as possible by applying currently available information and technology, for example, by implementing real-time hydrologic information systems, like that outlined above. Apart from managing urban hydrology in real time, many other challenges have to be addressed in the near future. An example is Dhaka city, which relies heavily (up to 97%) on groundwater for its water supply (7). During the last 25 years, the groundwater table has dropped by about 25 m. If this drop in the water table continues, it may generate problems for the city's water supply, and surface waters may be needed as additional resources. This is complicated by the growth of Dhaka city. Areas that used to be permeable are being transformed into hard, impermeable surfaces. Such impermeable surfaces prevent replenishing groundwater storage and further aggravate groundwater problems. In turn, the runoff from the new impermeable surfaces generates additional surface runoff, which again increases the flooding in Dhaka city. If the water supply pipes are under low pressure during a period of flooding, polluted floodwater may enter the water supply network. This poses an additional health risk to the population on top of the diseases spread by the floodwater. In addition, there are considerable losses from the water supply network, so quite a large amount of drinking water is lost. This means that being an urban hydrologist does not only involve one problem, but a group of strongly interrelated problems, that have major impacts on the people living in the cities.

The application of real-time hydrologic information is not the solution to all problems mentioned above, but it may mitigate flood problems and in this way reduce the economic losses and health problems the public faces from urban flooding. Finally, the information generated by a real-time hydrologic information system can be applied by using the historical data for design and maintenance analyses to achieve better functionality of the urban hydrologic system before the next heavy rain arrives.

SUMMARY

Making hydrological information publicly available on the Internet and mobile phone is at present a feasible task, which makes data collection more valuable and the work of hydrologists more highly appreciated by the public. In this project, the essential backbone for forecasting rain and urban flooding is established, and it can easily be extended to achieve more accurate forecasts, by adding online rain gauges to the system or by changing the sampling time for the rain gauges to a shorter period. In addition, the hydrologic information can be applied in conjunction with real-time hydrologic and urban drainage models providing decision support and warning systems to deal with urban flooding and flash floods. The authors believe that hydrologic information systems like that described in this article, in the future, may be part of the infrastructure of any major city around the world.

Acknowledgments
The authors sincerely thank the Danish International Development Assistance (DANIDA) for financial support of the current study at the Asian Institute of Technology and the Bangkok Metropolitan Administration and Thai Meteorological Department for providing data.

INTRODUCTION

Chlorine, being a powerful oxidant, is capable of destroying biological molecules (1). It is universally used as a disinfectant for drinking water treatment and as a biocide for cooling water treatment (2). However, the very oxidizing nature of chlorine involves it in a number of side reactions with organic and inorganic substances present in water. A certain fraction of the chlorine actually dosed into water may therefore disappear and not be available for estimation by the normal methods employed. These methods actually estimate chlorine concentration by measuring the amount of oxidants present. The fraction of chlorine that is used in such side reactions is called chlorine demand. Chlorine residual refers to the amount of chlorine (as well as its reaction products, which retain some oxidation potential) that remains after such side reactions.

Chlorine, when dissolved in natural waters, gives rise to various oxidizing compounds depending on the reaction of hydrolysis and oxidation of ammonia, which leads to the production of free chlorine (as hypochlorous acid or its dissociated form) as well as various chloramines, all of which retain oxidant property. The oxidants also react with organic matter to produce halogenated organics. Therefore, chemistry of water chlorination is complex and involves many molecular and ionic species, with often confusing terminology. In literature, chlorine dissolved in water may be described as “free,” “active,” “available,” “combined,” or “residual”—or a combination of the above. A brief explanation of the nomenclature associated with water chlorination is given below.

Free Chlorine/Free Available Chlorine (FC/FAC)

This refers to the amount of hypochlorous acid present in water in its dissociated or undissociated form:

$$Cl_2 + H_2O \longrightarrow HOCl + HCl \tag{1}$$

$$HOCl \rightleftharpoons H^+ + OCl^- \tag{2}$$

In seawater (which contains about 65 mg/L bromide), the following reactions will also take place:

$$HOCl + Br^- \longrightarrow HOBr + Cl^- \tag{3}$$

Therefore, in seawater chlorination, HOBr (as well as hypobromite ion, OBr^-) is also categorized into FC/FAC.

Combined Chlorine/Combined Available Chlorine

Combined chlorine refers to chloramines, which result from the reaction of free chlorine with ammonia (or other nitrogenous compounds with an N-C link) present in water:

$$HOCl + NH_3 \longrightarrow NH_2Cl + H_2O \tag{4}$$

$$NH_2Cl + HOCl \longrightarrow NHCl_2 + H_2O \tag{5}$$

Additionally, the following reactions are also possible in seawater environments:

$$NH_3 + HOBr \longrightarrow NH_2Br + H_2O \tag{6}$$

$$NH_2Br + HOBr \longrightarrow NHBr_2 + H_2O \tag{7}$$

$$2NH_2Cl + Br^- \longrightarrow NHBrCl + NH_3 + Cl^- \tag{8}$$

Chloramines are much less reactive (that is, less effective as biocides) when compared with bromamines. Combined forms of chlorine are, in general, less efficient biocides than free chlorine, but are more persistent than it. Hence, they are very important from the environmental point of view.

Total Available Chlorine (TAC)

This refers to the sum of the two terms just defined and represents a major part of the biocidal capacity of the chlorinated water.

Residual Chlorine

This term is analogous to TAC and is often used to represent the oxydisinfectant capacity of water (consisting of free and combined oxidants) at that point in time (Fig. 1). It must be kept in mind that this capacity goes on reducing as a function of time because of what is known as chlorine decay. The dosed chlorine continuously engages in a series of reactions with substances present in water, which in due time will result in complete disappearance of all measurable chlorine.

Chlorine Demand (CD)

It is defined as the difference between the amount of chlorine added and the useful residual chlorine that remains at the end of a specified contact time. It refers to the amount of chlorine “lost” in side reactions referred to earlier. As the CD of a given sample of water varies with the chlorine dose applied and the contact time (that is, the interval between chlorine dosing and chlorine measurement), it is always denoted with reference to the dose and the contact time. For example, for a chlorine dose of 1 mg/L, a sample of water may return a CD value of 0.6 mg/L after a contact time of 30 minutes. In natural sea or fresh water, chlorine demand also varies as a function of season (Fig. 2) because of the seasonal changes in the concentration of oxidizable substances present in natural waters. The dosed chlorine continuously engages in a series of reactions with substances present in water, which in due time will result in complete disappearance of all measurable chlorine.

Total Residual Chlorine/Total Residual Oxidant (TRC/TRO)

Chlorine estimation in water is carried out indirectly by measuring the oxidant capacity via the stoichiometric iodide/iodine. As the method determines all oxidants produced in Equations 1–7, it is appropriate to use the term total residual oxidants (TRO) rather than total residual chlorine (TRC) in the case of seawater chlorination (Fig. 1). Although different in nomenclature, TRO numerically equals TRC.

Chlorine Produced Oxidants (CPO)

This term is used to distinguish oxidants produced in water after addition of chlorine from those naturally present in a given parcel of water. The latter appear as “background” in blank determination, but because their normal concentrations are very low, they can be generally ignored.

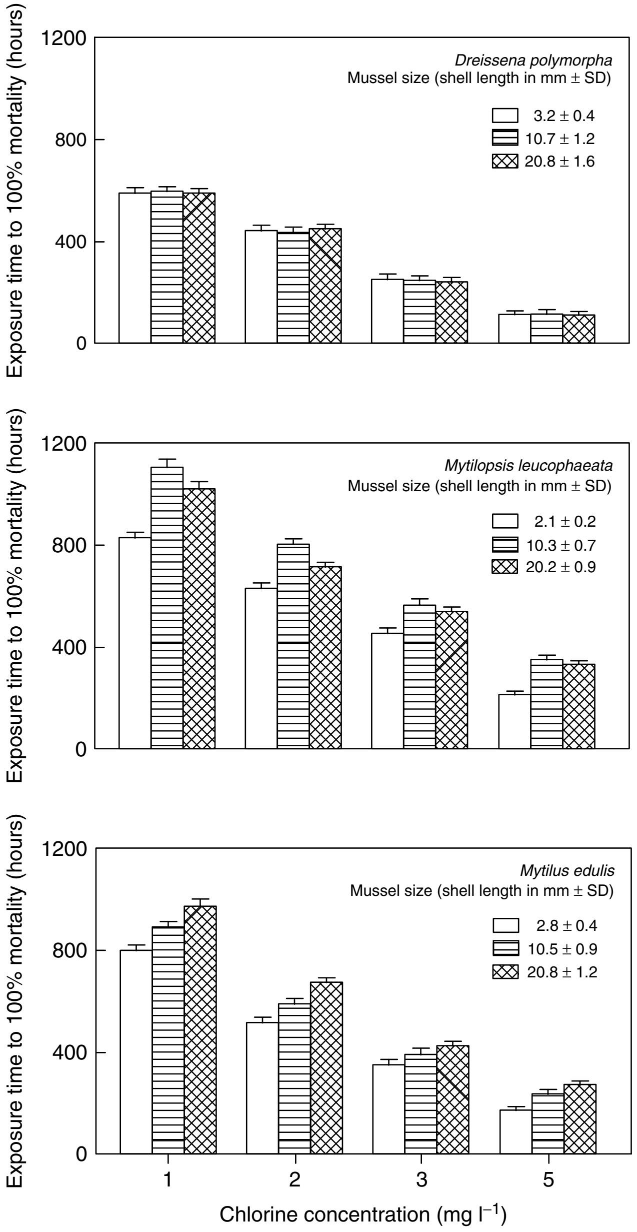

Figure 1. (**a**) Example of a chlorination curve in freshwater containing ammonia [modified after (2)]; (**b**) Experimental chlorination of seawater from intake canals of Gravelines power station. N ammonia = 0.21 mg/L; Contact time = 20 min [modified after (2,3)].

Nonoxidizing Chlorine Byproducts (CBP)

These are byproducts of chlorination that result from the reaction of chlorine with organic matter present (especially humic substances) in water. Several of these compounds exist, but the majority of them come under the category organohalogens called trihalomethanes (THM) (Fig. 3).

From the above discussion, it is clear that the most important term that one comes across in the context of chlorination for disinfection/biofouling control is “chlorine residual,” which denotes the biocidal capacity of water in terms of its oxidizing nature. Both HOCl and OCl$^-$ (hypochlorite ion), produced in Reactions 1 and 2 above, are oxidants and constitute free residuals. However, HOCl is more effective than its ionized form, because being neutrally charged, it can penetrate cells more easily than OCl$^-$ (Fig. 4). The dissociation of HOCl is a pH- and temperature-dependent reaction, higher pH and temperature favoring ionization of the acid. The ionization also increases with increasing total

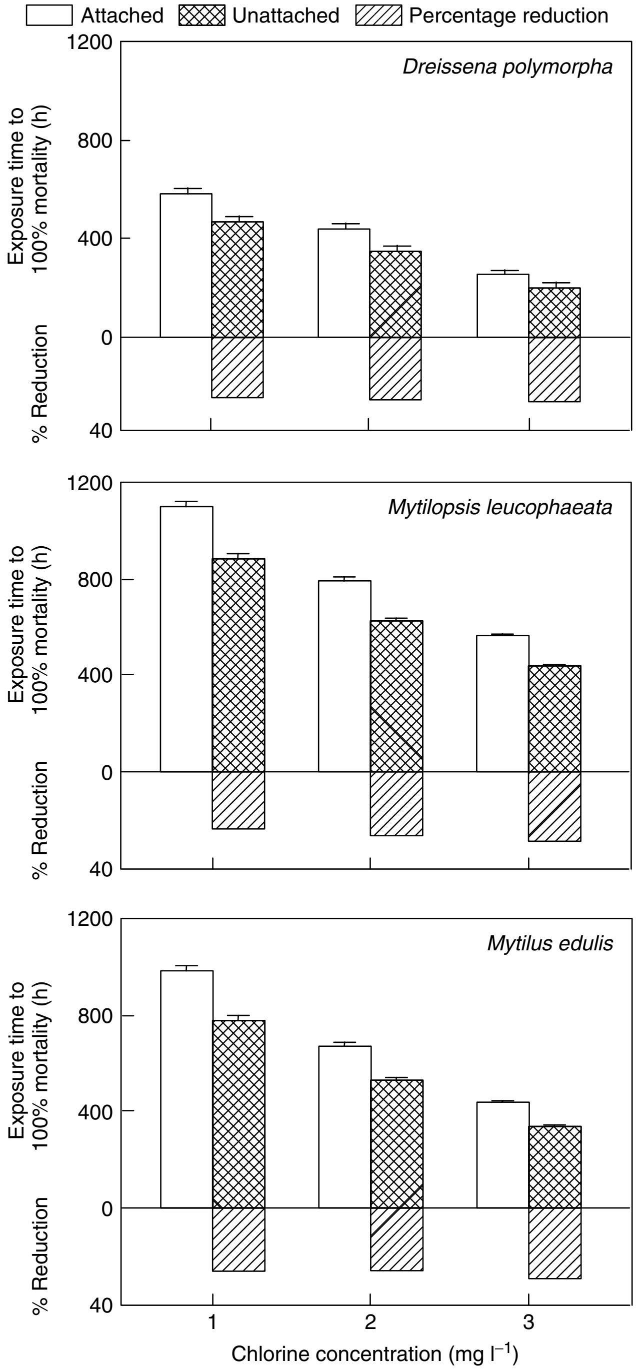

Figure 2. Seasonal variations of chlorine demand at three different chlorine doses in Kalpakkam coastal waters, east-coast of India from February 1989 to January 1990 [modified after (4)]. Total chlorine residuals were measured after 5 min for calculation of the chlorine demand.

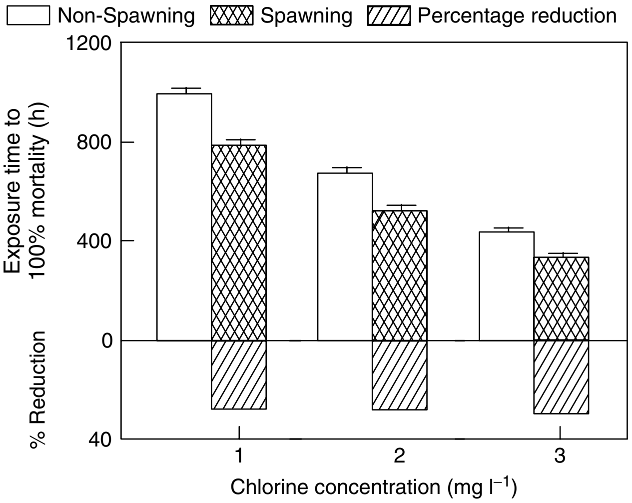

Figure 3. Average distribution of organohalogens measured by gas chromatography in seawater (chlorine dose = 0.8 mg/L) at the Gravelines power station [modified after (2,3)].

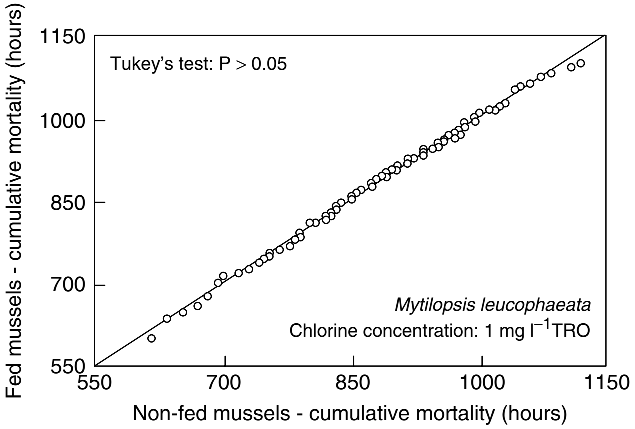

Figure 4. Comparison of the dissociation of hypochlorous acid and hypobromous acid with changing pH at a temperature of 20 °C [modified after (2)].

dissolved salts (TDS) or salinity, in the case of estuarine brackish water.

MEASUREMENT OF CHLORINE RESIDUALS

Several techniques are available for the measurement of chlorine residuals in water. Amperometric titration, potentiometric titration, or colorimetric titration using FAS-DPD (ferrous ammonium sulphate/N,N-diethyl-p-phenylene diamine) can be used. Simple colorimetry (using DPD) can also be used, especially under field sampling conditions, which has the ability to differentiate between free and combined forms of chlorine. Additionally, it allows rapid analysis after sample collection, reducing the chances of chorine loss through decay reactions. The required reagents are currently available commercially as portable kits, ready for field use. Although this method can theoretically detect a chlorine concentration of 0.01 mg/L, threshold detection level in practice is about 0.02 mg/L (2). Details of the various methods are available in APHA-AWWA-WPCF (5). Accurate and reliable instruments for continuous monitoring of residual chlorine levels in water are currently not available.

ENVIRONMENTAL DISCHARGE LIMITS

Several reports are available on the effects of residual chlorine in aquatic systems (6–9). Therefore, environmental release of chlorine residuals (for instance, in cooling water discharge from electric power plants) is tightly controlled in many countries through legislation. However, the permitted levels vary from country to country. For example, in the Netherlands, the permitted limit of chlorine residuals (0.2 mg/L for 2 h per day) is much less than that in India (0.5 mg/L).

INTRODUCTION

The water to be supplied to a community should be adequate in quantity to satisfy their demands and potable in quality to safeguard their health. It is not enough to treat water in the treatment works for safeguarding the health of consumers without trying to take adequate steps in preventing deterioration of the water quality in a distribution system. Treatment can be adequate to provide an excellent product for the consumer at the plant outlet, but it is inadequate to overcome inferior protective measures in the distribution system (1). There are various causes for which the potable water may turn to an obnoxious liquid in the distribution system and become unfit for drinking as could be found after quality assessment. The various causes of deterioration of water quality are pipe materials, constituents of water, intermittent supply, cross connections, dead-end pipes, service reservoirs, commissioning of new distribution system without disinfection, and breakages (2). The significant constituents of water generally include residual chlorine, natural organic matter, nutrient concentrations, temperature, and pH of water. The distribution system plays an important role in assuring a good quality of water to the consumer.

It is well known that the quality of drinking water can change within a distribution system. The movement or lack of movement of water within the distribution system may have deleterious effects on a once acceptable supply. These quality changes may be associated with complex physical, chemical, and biological activities that take place during the transport process. Such activities can occur either in the bulk water column, the hydraulic infrastructure, or both, and they may be internally or externally generated (3). An ability to understand these reactions and model their impact throughout a distribution system will assist water suppliers in selecting operational strategies and capital investments to ensure delivery of high-quality drinking water (4). Water quality modeling provides an engineering insight into the distribution system activities.

The water quality in a distribution system can be represented in the form of a constituent, water age and source trace (in case of multiple sources) analysis. For constituent concentration, the residual chlorine is considered to be important to represent the overall quality of water. Chlorination is a form of disinfection that reduces the risk of infection to an acceptable level by controlling the number of bacteria. The alternative disinfection options available are ozonation and ultraviolet radiation. But these two have no residual action to protect the water during distribution and are expensive. Although the chlorine is not as powerful as ozone, it has a lasting residual effect, is relatively easy to use, and is cost effective. Hence, chlorine happens to be the most predominant water treatment disinfectant. Because of chlorine's oxidizing potential, minimum levels of chlorine residual must be maintained in the distribution system to preserve both chemical and microbial quality of treated water (5). It is well known that as chlorine travels through the distribution system, it reacts with different materials inside the pipe. Free chlorine is consumed on the one hand by water (oxidation of dissolved organic compounds) and on the other hand by the internal walls of pipes (6). For the age-old distribution systems made up of unlined cast iron pipes, the wall component of reaction plays an important role in chlorine reaction kinetics.

CHLORINE REACTION KINETICS

The chlorine disappearance in a drinking water distribution system is governed by both the quality of water (bulk decay) and the chlorine demand of the pipe (wall decay). The chlorine demand exerted in the bulk flow and at the pipe wall is caused by the reaction of chlorine with organic content and materials associated with the pipe wall, respectively. The reactions in bulk flow occur within the fluid volume and are a function of constituent concentration, reaction rate and order, and concentration of the formation products. The various reaction kinetic models that represent bulk decay of chlorine include first-order, second-order with respect to chlorine only, parallel first-order, nth order, limited first-order (7), and two component second-order (8). The variability of bulk reactions with the temperature and organic matter concentration was studied by Kiéné et al. (9). An empirical kinetic model predicted the bulk reaction parameter by taking into account the TOC and temperature. To summarize, the kinetic models are either a single-parameter or a multiple-parameter decay equation. The multiple-parameter decay equations are shown to have an edge over the single-parameter models in describing the chlorine decay in bulk water.

The applicable reaction kinetics for chlorine in the aqueous (bulk) phase can be determined experimentally by conducting the bottle tests, which consist of placing a sample of water in a series of nonreacting glass bottles and analyzing the contents of each bottle at different points in time. The results of these bottle tests are then used for selecting an appropriate kinetic model, and thereby the bulk reaction parameter(s) involved in the model are estimated.

The chlorine decay at the pipe wall is controlled by the mass transfer mechanism from bulk to the pipe wall. The mass transfer expressions are based on either a two-dimensional radial diffusion (10) or a lumped-mass transfer (4) approach. The radial diffusion model can produce more accurate results than those using a lumped-mass transfer coefficient, but it is less suitable for inclusion in network models applied to large systems (11). After the lumped-mass transfer approach, the wall reaction kinetics for chlorine with the materials associated with the pipe wall can be modeled by assuming an active reaction zone located on the wall or in an adjacent molecular layer. The transport of chlorine to the wall is represented by a film resistance model of mass transfer using a mass transfer coefficient suitable to the flow regime in the pipe (4). The reaction at the pipe wall can be modeled according to either first-order or zero-order kinetics. The reactivity of the pipe wall is a function of pipe radius, hydrodynamic conditions, nature of pipe materials, and amount and nature of deposits (12). The first-order wall model may best represent a process in which chlorine is the limiting reactant, as might be the case with reactions involving complex organic compounds that are found in the exocellular enzymes and metabolic products produced by the biofilm on the pipe wall. The zero-order model would better represent the case in which chlorine immediately oxidizes some reductant (such as ferrous compound), and the rate is dependent on how fast the reductant is produced by the pipe. This mechanism would more likely apply to corrosion-induced reactions. These two wall reaction models are further simplified by relating the wall reaction constant inversely with the pipe roughness and thereby converting the equations into a single unknown parameter (5).

MODELING CHLORINE RESIDUALS WITHIN A WATER DISTRIBUTION SYSTEM

The hydraulic analysis of the system is a prerequisite for attempting to model water quality in a distribution system. Steady-state network hydraulic analysis determines the operating behavior of the system under unchanging conditions. Dynamic-state network hydraulic analysis is usually carried out by an extended period simulation that determines the effects on the system over time and is more significant as possible flow reversals in the pipes may affect the quality of water drastically. Steady- or dynamic-state chlorine residual modeling is a direct extension of the corresponding hydraulic network modeling. Basically, the chlorine residual modeling is done in two environments, namely, steady and dynamic. In steady-state modeling, the external conditions of a distribution network are constant in time and the nodal concentrations of the constituents that will occur if the system is allowed to reach equilibrium are determined. The steady-state models determine the ultimate spatial distributions of chlorine concentrations throughout the network. These models (13–18) are based on the law of mass conservation. Dynamic modeling, on the other hand, represents both spatially and temporally varied chlorine concentrations in a distribution system. In dynamic models, the external conditions are temporally varied and the time-varying nodal concentrations of the constituents are determined. Dynamic models rely on a system-simulation approach to determine the movement and fate of chlorine under time-varying demand, supply, and hydraulic conditions. The dynamic-state algorithms developed include (3,9,19–26) models. Because water distribution systems and the processes within them are usually categorized as continuous systems, dynamic modeling provides a more accurate and realistic portrayal of the actual operation of the system.

Flow rates in pipes and the flow paths that define the movement of water through the network can determine mixing, residence times, and other hydraulic characteristics that affect the chlorine transport and reactions. The residence time of water within the system also has its impact on the chlorine concentration. In the chlorine transport models, the physical processes like transport and mixing, and chemical reactions like chlorine decay, are typically represented. The transport of chlorine in water along the length of a pipe takes place by advection and dispersion aided by the reactions involved. Although dispersion of chlorine in water supply pipes with very low flows has been shown to be important (25,27,28), the flows in the water distribution pipes are generally considered to be advection dominated and the dispersion term is negligibly small in most models. Hence, the water quality modeling is generally based on one-dimensional advective–reactive transport through a pipe. A water distribution system, typically represented as a network model, consists of links (pipes, pumps and control valves) interconnected by nodes (junctions, storage tanks and reservoirs) in some particular branched or looped configuration.

STEADY-STATE MODELING

The principle of mass conservation along with the suitable bulk and wall chlorine reaction kinetics are used in formulating the chlorine residual model. The basic governing equation required to determine the steady-state concentration of chlorine at any node j can be formulated as

$$C_j = \frac{\sum_{i=1}^{Ninp_j} C_{nu_i} Rec_i Q_i}{\sum_{i=1}^{Ninp_j} Q_i}; \quad j = 1, \ldots Njn \tag{1}$$

where C_j = chlorine concentration at node j (mg/L); C_{nu_i} = chlorine concentration at node nu_i (mg/L); $Ninp_j$ = number of incoming pipes at node j; nu_i = upstream node of incoming pipe i; Q_i = flow in pipe i (m^3/s); Njn = number of nodes in the network; and Rec_i = reaction coefficient for pipe i. The expression for the reaction coefficient depends on the kinetics used for bulk and wall reactions. For first-order bulk and wall reactions, it is given by

$$Rec_i = Exp - \left[k_{bi} + \frac{k_{wi} k_{f_i}}{r_{h_i}(k_{wi} + k_{f_i})}\right] ptt_i \tag{2}$$

where ptt_i = travel time in pipe i (s); r_{hi} = hydraulic radius of pipe i (m); k_{wi} = first-order wall reaction parameter of pipe i (m/s); k_{bi} = first-order bulk reaction parameter of pipe i (s^{-1}); k_{fi} = mass transfer coefficient of pipe i(m/s) = $(D/d_i)S_{hi}$, where, d_i = diameter of pipe i (m); D = molecular diffusivity of chlorine (m^2/s); and S_{hi} = Sherwood number of pipe i and is given by Rossman (29), for $R_{ei} \leq 2300$ (Laminar flow);

$$S_{hi} = 3.65 + \frac{0.0668\left(\frac{d_i}{L_i}\right)R_{ei}S_c}{1 + 0.04\left[\left(\frac{d_i}{L_i}\right)R_{ei}S_c\right]^{2/3}} \tag{3}$$

for $R_{ei} > 2300$;

$S_{hi} = 0.0149{R_{ei}}^{0.88}{S_c}^{1/3}$;

$S_c =$ Schmidt number $= \nu/D$; and $\nu =$ kinematic viscosity (m^2/s); $L_i =$ length of pipe i.

The reaction coefficients for other combinations of bulk and wall reactions are given in Ref. 25.

If Nsn is the number of source nodes, then Equation 1 with appropriate reaction kinetics results in $(Njn - Nsn)$ number of linear equations. An iterative procedure based on the Gauss–Siedel algorithm can be adopted to solve the equations. The converged solution gives steady-state chlorine concentrations at all nodes for given source chlorine concentrations.

DYNAMIC-STATE MODELING

The unsteady advection–reaction process for the transport of chlorine in a pipe flowing full is given by the following classic equation:

$$\frac{\partial C_i(x,t)}{\partial t} = -v_i\frac{\partial C_i(x,t)}{\partial x} - R[C_i(x,t)] \tag{4}$$

where $C_i(x,t) =$ chlorine concentration in pipe i (mg/L) as a function of distance x and time t; $v_i =$ mean flow velocity in pipe i (m/s); and $R[C_i(x,t)] =$ reaction rate expression. For the first-order bulk and wall chlorine reaction kinetics, it is given by the following equation:

$$R[C_i(x,t)] = k_{bi}C_i(x,t) + \frac{k_{wi}k_{f_i}}{r_{h_i}(k_{wi}+k_{f_i})}C_i(x,t) \tag{5}$$

k_{fi} can be calculated using expressions as described earlier.

Instantaneous and complete mixing of chlorine at the node j and time t is given by the following expression:

$$Cnc_{j,t} = \frac{\sum_{i=1}^{Ninp_j} Q_iC_i(L_i,t) + Q_EC_E}{\sum_{i=1}^{Ninp_j} Q_i + Q_E}; \quad j = 1,\cdots Njn \tag{6}$$

where $Q_i =$ flow in the pipe i (m^3/s); $Q_E =$ external source flow in to node j (m^3/s); $C_E =$ external source chlorine concentration into node j (mg/L); and $Njn =$ total number of nodes in the network.

The numerical approaches adopted to solve the above-formulated problem can be classified spatially as either Eulerian or Lagrangian and temporally as time driven or event driven (30). Eulerian models divide the pipe into a series of fixed, interconnected control volumes and record changes at the boundaries or within these volumes as water flows through them. Lagrangian models track changes in a series of discrete parcels of water as they travel through the pipe network. Event-driven simulation updates the state of the system only at times when a change actually occurs, such as when a new parcel of water reaches the end of a pipe and mixes with water from other connecting pipes, and at the output reporting time (30). The Eulerian methods include the finite difference method (FDM) (30) and the discrete volume element method (DVEM) (21), and the Lagrangian methods are the time-driven method (TDM) (19) and the event-driven method (EDM) (22). The Lagrangian methods are more efficient for simulating the chemical transport in a water distribution system (30).

The input to the dynamic simulation model essentially consists of the system demands, source chlorine concentrations, and reaction parameters (bulk and wall) of the network. The outputs of this model are the spatially and temporally varying nodal chlorine concentrations.

APPLICATION OF THE CHLORINE TRANSPORT MODEL

The Brushy plains zone of the South Central Connecticut Regional Water Authority is chosen to illustrate the application and is shown in Fig. 1. The pipe and node data of the network are taken from EPANET [distributed by USEPA, (29)] example networks. The first-order bulk

and wall reaction parameters used are 0.55 d^{-1} and 0.15 m/d, respectively. The system has been hydraulically well calibrated, with most pipes having been assigned roughness coefficients (HWC) of 100. The chlorine input at node 1 (Fig. 1) to the network has a constant value of 1.15 mg/L. The chlorine transport model is run using the time-driven method for a hydraulic time step of 1 hr and a water quality step of 3 min. The results are obtained for a simulation period of 55 hr. The chlorine concentrations at a few network nodes are represented in Fig. 2.

CHLORINE REACTION PARAMETER ESTIMATION

The chlorine transport model described earlier predicts the constituent concentrations throughout the distribution system under steady or dynamic state. The reliability of these predicted concentrations when compared with the field observations depends on the assigned parameter values involved in the type of reaction kinetics used in the model. The parameters that control the chlorine reaction kinetics within the system can be broadly classified into the bulk and wall reaction parameters. Bulk reaction parameters (first- or non-first-order) are associated with individual pipes and storage tanks, assigned to groups of pipes in an area, which is contributed more by a particular source, or applied globally. Wall reaction parameters (first- or zero-order) are associated with individual pipes, applied globally, or assigned to a group of pipes with similar material/age/roughness factors. The wall reaction parameter can also be related inversely to the Hazen–Williams roughness coefficient and represented in the wall reaction pipe-roughness parameter. The advantage of using this sort of representation is that it requires only a single parameter to allow wall reaction parameters to vary throughout the network in a physically meaningful way (5).

The parameters involved in the single-parameter or multiple-parameter bulk reaction expressions can be determined with the data sets observed by conducting the bottle tests on the water samples. By performing measurements in the distribution system, the researchers have calculated the decay rate constant (overall first-order) for site-specific tests (such as fixed pipe diameter, pipe material, or water source). This process may yield reasonable results; however, a wide range of values for this constant is obtained, thus severely limiting its use as a predictive tool (31). The determination of an overall reaction parameter (which represents the combined effect of bulk and wall reactions) and a wall reaction parameter is much more difficult than is establishing a bulk reaction parameter. Hence, these reaction parameters are more a product of calibration. Calibration is a process of adjusting a model so that the simulation reasonably predicts system behavior. The objective of water quality calibration is to capture the steady/transient dynamic behavior of the network. Wall reaction parameters are similar to pipe roughness coefficients in that they can and do vary from pipe to pipe. Unfortunately, unlike the head loss test for pipe roughness values, direct measurements of wall reaction parameters are extremely difficult to make (32). Because these parameter values are difficult to measure, they need to be estimated with the field measurements. The various techniques adopted to estimate these parameters include the trial-error (33), gradient-descent-based search technique (34), method of Lagrange multiplier (35), Gauss–Newton sensitivity analysis technique (36), and stochastic-based genetic algorithm (GA) technique (37). Gradient-based methods are generally faster, but they are more difficult to formulate because either an analytical expression must be derived or the gradient must be approximated. Stochastic search methods are more robust and simpler to formulate and use, but they are generally slower (32).

The parameter estimation can be formulated as an optimization problem so that the difference between the observed and computed chlorine concentrations at the monitoring nodes are minimized in the least-squares sense. Thus, the objective function is given by

$$Minimize\ E = \sum_{j=1}^{M}\sum_{k=1}^{N(j)}[Cno_{j,t_k} - Cnc_{j,t_k}]^2 \tag{7}$$

where M = number of monitoring nodes; $N(j)$ = number of monitoring times at node j; Cno_{j,t_k} = computed chlorine concentration at node j at time t_k (mg/L); and Cno_{j,t_k} = measured chlorine concentration at node j at time t_k (mg/L).

The simulation-optimization inverse modeling technique, which uses the field measurements and simulated chlorine concentrations at monitoring nodes, can be adopted to solve this unconstrained optimization problem. The flow diagram in Fig. 3 illustrates the simulation-optimization procedure if GA is used in its optimization module.

The various unknown reaction parameters constitute a set of decision variables to be evaluated by GA, and this can work by evaluating the fitness of each potential solution that consists of values for the set of unknown reaction parameters. Fitness is determined by comparing how well the simulated chlorine concentrations that result from the candidate solution match the measured values collected in the field. The computationally intensive step involved in the GA technique is the determination of fitness that is somehow related to the objective function value. The GA continues to spawn generations of potential solutions until comparison of solutions from successive generations no longer produces a significant improvement. In addition, the GA process eliminates most routine and tedious aspects of the calibration process. GA will generally achieve better fits to the available data if the correct set of variables is included in the solution and it can establish the correct range of possible solutions.

APPLICATION OF THE INVERSE MODEL FOR PARAMETER ESTIMATION

The network used earlier is chosen for applying the inverse model. The time-varying chlorine concentrations were observed for this network at the nodes 3, 6, 10, 11, 19, 25, 28, and 34 for a period of 55 hr (10). These measurements become input observed data to the inverse model, and the unknown global wall reaction parameter for the first-order reaction kinetics, which is assumed to be applicable for the system, is estimated. The inverse model is run with a zero concentration tolerance, quality time step of 3 min, and hydraulic step of 1 hr. The estimated value of the global first-order wall reaction parameter is found to be 0.3654 m/d, which results in the lowest possible RMS

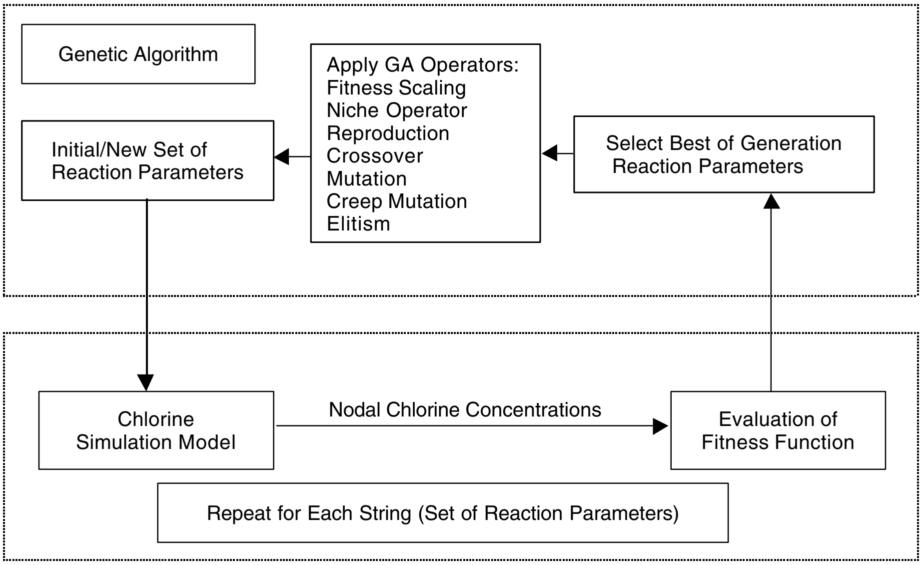

Figure 3. GA implementation.

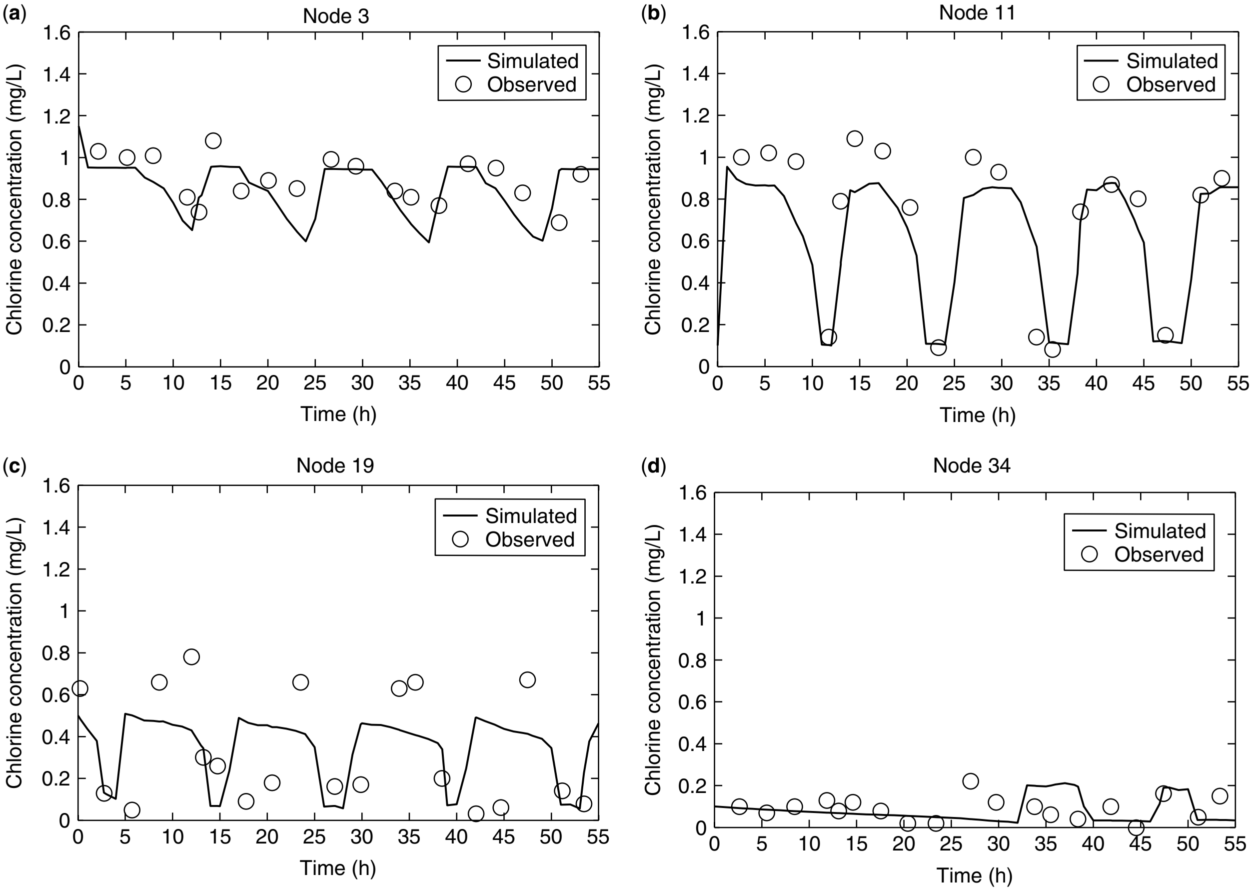

Figure 4. Simulated and observed chlorine concentration at nodes (**a**) 3, (**b**) 11, (**c**) 19, and (**d**) 34.

residual error of 0.172 mg/L without any tedious trial-and-error computations. The comparison of observed and simulated chlorine concentrations for this parameter estimated at node 3, 11, 19, and 34 are represented in Fig. 4.

CLOSURE

The maintenance of chlorine residual is needed at all points in the distribution system supplied with chlorine as a disinfectant. Chlorine is subjected to bulk flow and pipe wall reactions as it propagates through the pipes of the distribution system. The bulk flow reaction term depends on the organic content of the water, whereas the wall reaction term is related to the material and age of the distribution pipe. Because of these reactions, the loss of chlorine is significant between the outlet of the treatment plant and the consumer end. Thus, the study of spatial and temporal distribution of chlorine forms an important aspect of modeling. The chlorine simulation model forms the base for the reaction parameter estimation. The application of the inverse model is more relevant as any combination of bulk and wall reaction kinetics is possible for best fit with field chlorine observations. The inverse model is significant in deciding the operational strategy for real life systems. The chlorine simulation together with the inverse model provides the water supply agencies a tool for better management of their systems.

PARTICULATE MATTER REMOVAL BY COAGULATION

RASHEED AHMAD
Khafra Engineering
Consultants
Atlanta, Georgia

Particulate matter in natural water varies in size, concentration, and surface chemistry. The particle size may range from a few tens of nanometers to a few hundred micrometers. Discrete particles less than one micron in size are called colloidal. Colloidal particles have significantly higher external surface area per unit area and move in a random diffusional motion known as Brownian motion. In colloidal suspension, surface phenomena dominate over mass phenomena. The most important surface property is the accumulation of electrical charges at the particle surface. Loss of atoms due to abrasion, molecular arrangement within the crystal, and imperfections within the molecular structure may result in surfaces being charged. The colloidal particles in most surface water are negatively charged. Because of hydration and/or electrostatic surface charges, colloidal particles repel other material and thereby remain suspended. Surface waters that are turbid due to colloidal particles cannot be clarified without special treatment.

Coagulation is a process for enhancing the tendency of particulate matter in aqueous suspension to attach to one another and/or to attach to collector surfaces. Coagulation promotes destabilization of surface charges on colloidal particles. Destabilization and aggregation of particulate matter and precipitation or adsorption of NOM in subsequent solid–liquid separation processes are the primary functions of the coagulation process. The coagulation process involves two steps: (1) the addition of chemical coagulants to destabilize particulate matter and react with NOM and (2) the physical transport of collisions among particulate matter, resulting in aggregation or floc formation. In the water treatment literature, coagulation refers to all reactions and mechanisms that result in aggregation, and the physical transport step of producing interparticle aggregation is called flocculation. In a water treatment plant, coagulation is achieved by rapid or flash mixing of coagulants followed by flocculation.

The two most common types of coagulants are metallic salts and polymers; the most common metallic salt coagulants are aluminum sulfate (alum) and ferric chloride. The selection of a particular coagulant depends on the required level of effectiveness. A standard jar test is a recommended method for determining the relative effectiveness of coagulants for a particular raw water supply. The factors that are considered normally in selecting a coagulant include cost, availability, overall safety, ease of storage, handling, and application.

Alum is the most widely used coagulant because of its availability, low cost, ease of use, and ease of storage. Ferric chloride, other metallic salts, and polymers are less widely used. Alum's performance, however, is greatly affected by the pH of the influent. The commonly used dosage of alum ranges from 5 to 150 mg/L, but the problem of sludge disposal increases at higher alum dosages. Due to special raw water characteristics and because of health concerns about aluminum, some water utilities use ferric chloride. Although ferric chloride is not always as effective as alum in reducing trihalomethane formation potential (THMFP) and total organic carbon (TOC), it is more effective than alum for water that has high dissolved color, low turbidity, and a moderate pH.

Polymers are effective coagulants, coagulant aids, and filter aids. They consist of monomers and are classified according to their charge or lack of charge. A polymer that has a charge is an ionized polymer, or a polyelectrolyte. Polymers can be cationic, anionic, or nonionic. In applications where polymers are effective, dosages are generally lower than alum dosages for the same effect. Typical polymer dosages range from 1.5 to 10 mg/L. Consequently, polymer coagulants produce less residual sludge than alum.

Coagulant aids are added to the influent after or simultaneously with the primary coagulants to improve particle capture efficiency during flocculation, sedimentation, and filtration. Nonionic and anionic polymers are commonly used as coagulant aids. The ratio of alum to coagulant aid dosages ranges from 100:1 to 50:1. Standard jar tests are required to determine precise coagulant aid dosages.

There are four coagulation mechanisms that, it is thought, occur in destabilizing colloidal particles: double layer compression, surface charge neutralization, sweep coagulation, adsorption and interparticle bridging.

The double layer model is used to understand the ionic environment near a charged colloid particle. The surface charge on the colloid attracts ions of opposite charge and forms a dense layer adjacent to the particle known as the Stern layer. Excess positive ions are still attracted by the negatively charged colloids but are repelled by the Stern layer. This dynamic equilibrium results in creating a diffuse layer of counterions. The Stern and the diffuse layer in the interfacial region around colloidal particles are referred to collectively as the double layer. The electrical potential at the junction of the Stern layer and the diffuse layer, called the zeta potential, can be measured experimentally. It correlates with colloid particle stability. Highly stable colloidal systems are characterized by a high zeta potential, whereas lower zeta potentials reflect less stable systems. The DLVO theory (named after Derjaguin, Landau, Verwey, and Overbeek) governs the net interactive force between colloidal particles by combining the van der Waals attractive force and the electrostatic repulsion force. The double layer can be compressed by adding a coagulant that has a positive charge (to counteract negatively charged colloids). In water treatment practice, destabilization by double layer compression is not a dominant mechanism because it requires an extremely high salt concentration. This is an important destabilization mechanism in natural systems, for instance, delta formation in estuaries.

Destabilization by surface charge neutralization involves reducing the net charge of colloidal particles in the suspension. The net surface charge can be reduced by adjusting the solution chemistry. In other cases, colloidal particles can be destabilized by neutralizing using counterions of coagulants. In water treatment practice, a similar type of surface charge destabilization occurs that is called heterocoagulation. The distribution of charges on a colloidal surface is not uniform. Large particles that have high negative surface charges may come in contact with smaller particles that bear relatively low positive charges. These particles may be destabilized by simple electrostatic interaction.

Sweep coagulation or sweep-floc coagulation is also known as enmeshment in a precipitate. At higher coagulant doses, excess metal salts hydrolyze into metallic hydroxides. These hydroxides are extremely insoluble in water, amorphous, heavier than water, and gelatinous. As the hydroxide precipitate forms and accumulates, the colloidal particles are enmeshed or entrapped in the hydroxide floc. This destabilization mechanism is called sweep coagulation.

Interparticle bridging destabilization occurs when high-molecular-weight polymers are used as coagulants or coagulant aids. These polymers are highly surface-active, and their surface structure may be linear or branched. The polymers destabilize particles by first adsorbing at one or more sites on the colloidal particle surface and then extending the chain length into solution and attaching to other particles. This results in forming an interparticle bridge. Sometimes an excessive dosage of polymer may cause restabilization due to surface saturation or sterical stabilization.

SELECTIVE COAGULANT RECOVERY FROM WATER TREATMENT PLANT RESIDUALS USING THE DOMAIN MEMBRANE PROCESS

Prakhar Prakash
Pennsylvania State University
University Park, Pennsylvania

Arup K. SenGupta
Lehigh University
Bethlehem, Pennsylvania

BACKGROUND

During the last two decades, pressure-driven membrane processes, namely, reverse osmosis (RO), nanofiltration (NF), and ultrafiltration (UF), have found increased applications in water utilities and chemical industries. Unlike RO, NF, and UF, Donnan membrane process (DMP) or Donnan dialysis is driven by an electrochemical potential gradient across an ion exchange membrane. Theoretically, the Donnan membrane process is not susceptible to fouling because particulate matter or large organic molecules do not concentrate on the membrane surface, as commonly observed with pressure-driven membrane processes. Although information on several applications of DMP is available in the open literature (1,2), no work is reported on the use of DMP to treat a sludge or slurry with a high concentration of suspended solids or large organic molecules. It was conceived that a single-step Donnan membrane process could selectively recover coagulant alum ($Al_2(SO_4)_3 \cdot 14H_2O$) (3,4) from water treatment plant sludge or water treatment plant residuals (WTR), which are the endproduct of coagulation. WTR contain insoluble aluminum hydroxide (50–75%) along with suspended inorganic particles, natural organic matter (NOM), and trace amounts of heavy metal precipitates (5).

Several efforts were made to recover alum from WTR. The acid digestion process is the most commonly tried process at the laboratory, pilot-scale, and plant level (6). In this process, WTR are sufficiently acidified with sulfuric acid, dissolving insoluble aluminum hydroxide in the form of alum up to aluminum concentration levels of 360–3700 mg/L. However, the process is nonselective; with the dissolution of aluminum hydroxide, NOM-like humates and fulvates get dissolved too, and the resulting dissolved organic carbon (DOC) concentration ranges from 326 to 1800 mg/L (7). This recovered alum, if reused as a coagulant, may impart a high trihalomethane formation potential (THMFP) during the chlorination stage of water treatment. The trihalomethanes are suspected carcinogens regulated by the USEPA (8). As an alternative to the acid digestion process; the amphoteric nature of aluminum oxide also permits alum recovery from the WTR under alkaline conditions. However, the alkali digestion process suffers from the same limitation as the acid digestion process; i.e., NOM concentration is very high in the recovered solution. Figure 1 shows both DOC and aluminum concentrations of the Allentown Water Treatment Plant (AWTP) in WTR at different pH levels. The Donnan membrane process is uniquely capable of recovering alum from WTR in a single-step process using sulfuric acid and a cation-exchange membrane.

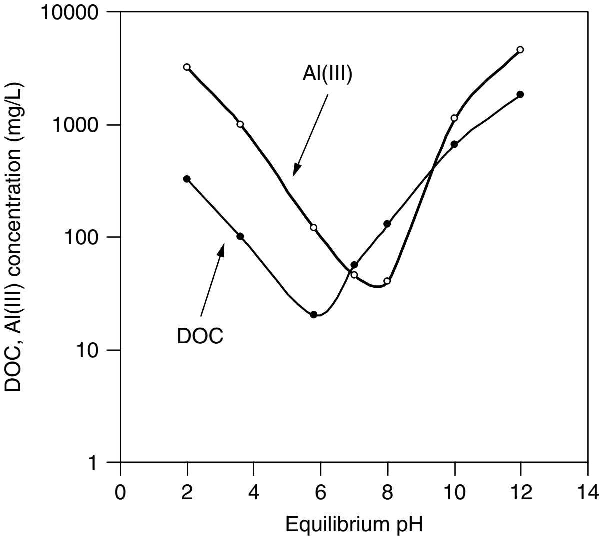

Figure 1. Variation of dissolved organic carbon (DOC) and aluminum concentration with pH for water treatment residuals (WTR) from Allentown Water Treatment Plant (AWTP).

THEORY

Let us consider solutions of aluminum sulfate (feed) and sulfuric acid (recovery) in a Donnan membrane cell divided into two chambers by a cation-exchange membrane that allows only cations to migrate from one side to the other but rejects any passage of anions according to Donnan's co-ion exclusion principle (9). At equilibrium, the electrochemical potential of aluminum ion Al^{3+} ion ($\overline{\mu}$) in the feed solution will be the same as that in the recovery solution for both aluminum and hydrogen ions, which corresponds to the following Donnan equilibrium condition:

$$\left(\frac{C_{Al}^{R}}{C_{Al}^{L}}\right) = \left(\frac{C_{H}^{R}}{C_{H}^{L}}\right)^{3}$$

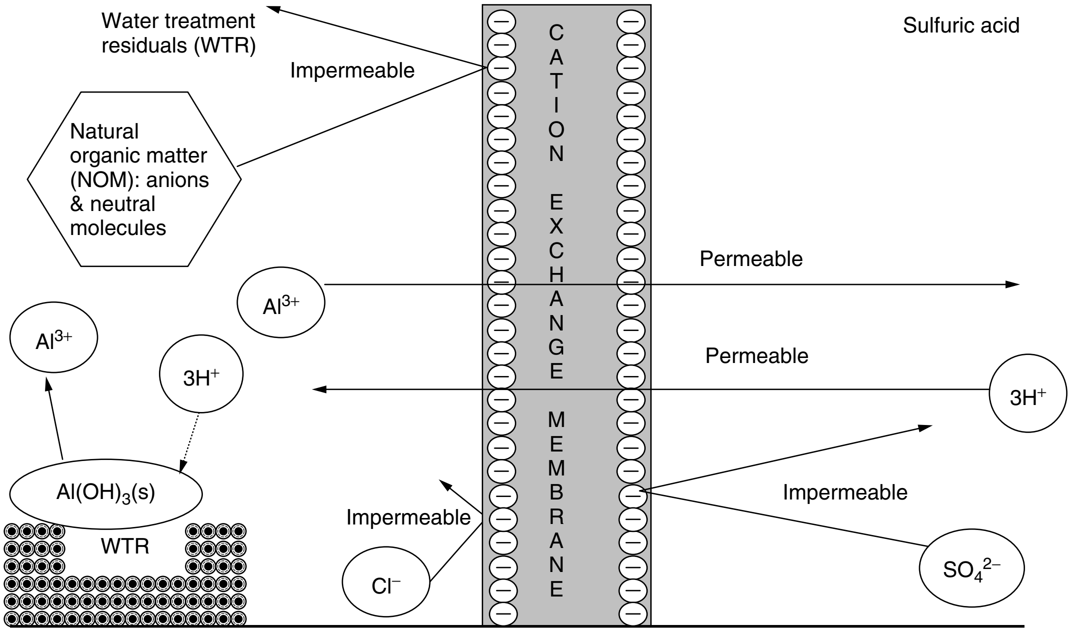

Figure 2. A schematic of Donnan membrane process illustrating selective alum recovery from WTR.

If the ratio $\frac{C_H^R}{C_H^L}$ is 10, it means C_{Al}^R is 1000 times greater than C_{Al}^L. Thus, by maintaining high hydrogen ion concentration in the recovery solution, aluminum ions can be driven from the feed to the recovery side even against a positive concentration gradient, i.e., from a lower concentration region to a higher concentration one. Figure 2 depicts the conceptualized selective alum recovery from WTR, highlighting the following.

KEY FINDINGS

In the Donnan membrane cell, the feed side of the membrane contained 6 L of the decanted and slightly acidified WTR collected from the AWTP, whereas the recovery side contained 1.5 L of 10% sulfuric acid solution, separated by a cation-exchange membrane Nafion 117. At the start, pH of the WTR side was between 3.0 and 3.5. With the progress of the run, aluminum ions from the WTR side moved to the recovery side through the cation-exchange membrane, whereas an equivalent amount of hydrogen ions permeated to the WTR side, thus further reducing the pH. Under the experimental conditions of the Donnan run, free aluminum ions, Al^{3+}, was the predominant aluminum species. Figure 3 shows the results of the process for a period of 24 hours; the percentage aluminum recovery and the concentration of aluminum in the two chambers were plotted against time. It can be seen that over 70% recovery (72%) was attained in 24 hours. The noteworthy observation is that the

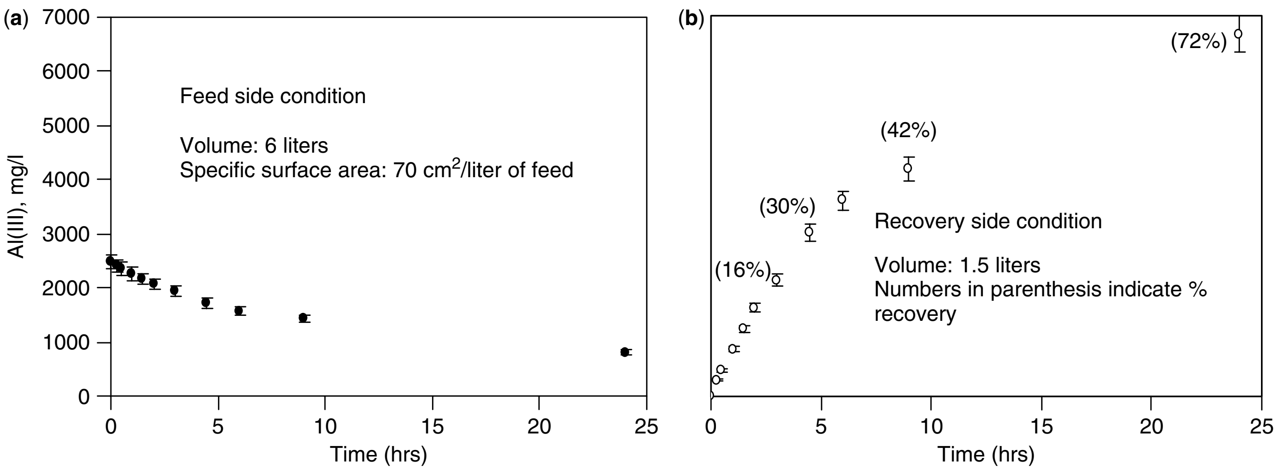

Figure 3. Aluminum recovery from AWTP residuals during Donnan membrane process: (**a**) decrease in Al concentration in feed; (**b**) percentage recovery and increase in Al concentration in recovery solution.

recovered aluminum concentration was 6,650 mg/L as Al, and it was significantly greater than the total aluminum concentration (2400 mg/L) present in the parent sludge. It was also noted that the recovery was selective with respect to trace heavy metal ions. The recovered alum did not contain any suspended solids, whereas NOM expressed as DOC was consistently less than 5 mg/L. The ratio of individual contaminants to aluminum in the recovered alum was comparable, and in some cases lower, than in the commercial alum currently being used in AWTP. Similar results were obtained with WTR received from the Baxter Plant (Philadelphia, PA), which used $FeCl_3$ as a coagulant, where over 75% recovery was made in 24 hours.

Figure 4(a,b) show the visual comparison of recovered coagulants, both alum and ferric sulfate, between the traditional acid digestion process and the Donnan membrane process. Higher transparency of the coagulants from AWTP and the Baxter Plant, recovered by Donnan membrane process, is readily noticeable because of the absence of turbidity and NOM.

CONCLUSIONS

In this work, it was worthy to note that (a) aluminum (ferric) hydroxide precipitates could be dissolved and coagulant ions concentrated in the recovery solution; (b) negatively charged NOM, sulfate, and chloride could not permeate the membrane because of Donnan exclusion; and (c) the recovered alum was sufficiently pure and reuseable in water treatment plants.

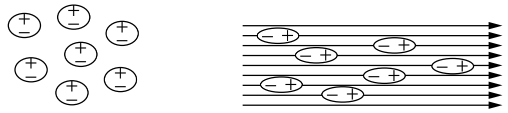
PHYSICAL WATER CONDITIONING

Charles H. Sanderson
Magnatech Corporation
Fort Wayne, Indiana

Magnetic water treatment technology that was used two centuries ago to control hard water scale is now being used in hundreds of different kinds of beneficial applications throughout the world. Permanent magnetic water conditioning (PMWC) does not change the chemistry of the water; only a *physical* change takes place. It is therefore referred to as physical water conditioning (Fig. 1) (1).

Physical water conditioning (PWC) has been highly controversial for many years; however, due to numerous successful installations on boilers, cooling towers, and other HVAC equipment, the technology has gained credibility throughout the industry in recent years. The ASHRAE Handbook (considered the "bible" of the industry) states, "Equipment based on magnetic, electromagnetic, or electrostatic technology has been used for scale control in boiler water, cooling water, and other process applications."

Several laboratory tests have been conducted to evaluate the results of magnetically treated water for scale and corrosion control in heat transfer equipment. The purpose of one such test was to determine the physical or chemical differences between treated and untreated residues. Emission spectrographic analyses of



Arrangement of nonpolar molecules in the absence of a magnetic field

Arrangement of polar molecules in the absence of a magnetic field

Arrangement of polar molecules under the influence of a magnetic field

Figure 1. The effect of a magnetic field.

the two water residues, it was found, have the same chemical constituents; however, a distinctive difference was observed in the crystalline structure. The residue from the magnetically conditioned water was a soft powder (when dry), whereas the untreated water deposit was typical boiler scale (2).

Disassociated dissolved molecules of $CaCO_3$ in water have a tendency to recombine by forming scale that adheres to the inner walls of the piping system, containers, steam vessels, etc. When water flows through a magnetic field of relatively low intensity, the formation of scale in the treated water is prevented in many instances. Instead, aragonite is formed within the flowing bulk water (aragonite forms a dilute slurry in the water, and the sediment can be easily removed by blowdown or bleed-off). The magnetochemical reaction is only one of the many cross effect reactions that enable the transformation of calcite to aragonite. Other reactions include thermochemical and mechanochemical reactions (Fig. 2).

One of the benefits of PWC is energy savings from keeping the heat transfer area clean and free of scale, which prevents efficient transfer from the energy side to the water (see Fig. 3).

Billions of dollars are lost in the United States every year due to corrosion. Laboratory tests and field installations, using corrosion coupons, as a comparison, have proven that magnetic water treatment reduces corrosion rates in HVAC equipment. This is accomplished by eliminating the aggressive chemicals used to control scale, and aragonite talc, a by-product of calcium, which puts a microscopic film on all wetted parts and provides protection against oxygen pitting. The $CaCO_3$ with the PMWC does not build upon itself; however, a thin transparent coating deposits on the metal water side and dries as a fine white or gray powder.

The National Aeronautics and Space Administration (NASA), using their Dynamic Corrosion Test System in an evaluation study, compared magnetically conditioned water to chemical treatment. Corrosion coupon #42 in the magnetically conditioned water loop had a corrosion rate of 0.0 mils per year; #41 and #43, treated with chemical corrosion inhibitors in the loop, had 5 and 6 mils loss per year respectively (Fig. 4) (3).

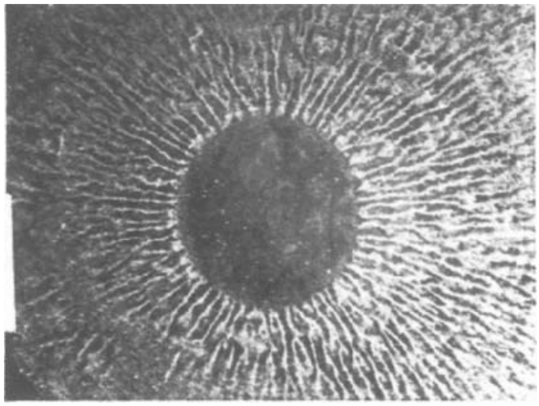
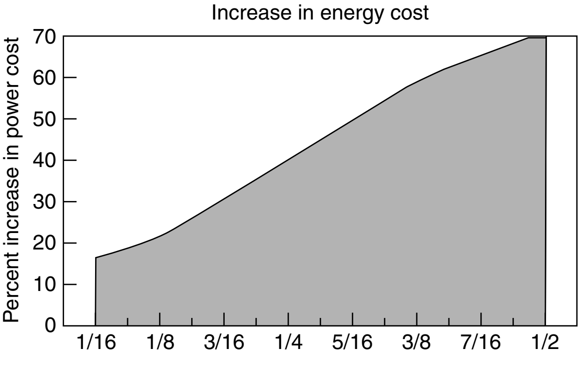
(b)



Magnetically treated water

Figure 2. Partially evaporated water droplets magnified to the 40th power.



(Above data from the University of Illinois and the Bureau of Standards)

Figure 3. Additional fuel consumed with scale accumulation.

An independent laboratory used a test rig consisting of two 48 inch glass cylinders filled with steel wool and tapered at one end to evaluate the effect of magnetically treated water on corrosion. The flow rate of the water entering the top of each cylinder (one treated and one untreated) was adjusted to make the water head in the cylinders about 10 inches. After 72 hours, water in the untreated system overflowed the glass cylinder. The flow rate was then determined (4).

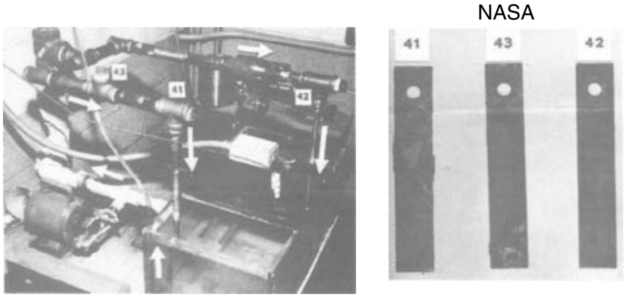


Figure 4. NASA dynamic corrosion test stand and # C-75-1495 photos of coupons.

	Untreated Tap Water	Treated Tap Water
Flow Rate	25 mL per 58.0 s	25 mL per 7.5 s
Water height	46 inches	20 inches

A PMWC system was installed on a 4-year-old, 1500-ton cooling tower and chillers that had moderate scale buildup in the tower and condenser tubes. There was also a considerable amount of corrosion and pitting on the inside of the chiller end caps. The chemical company that treated the system during the first four years of operation suggested that they monitor the results of the PMWC system.

Six months after the installation, the chillers were opened for inspection. The end caps did not require wire brushing to remove the hard brittle scale as previously found, and the small accumulation of mud in the tubes was easily flushed out of the system by a garden hose.

Prior to the PMWC installation, the average corrosion rate of the copper coupon ID # 10008 16-S was 0.01 MPY. After the PMWC installation, the copper coupon ID # 10007 A0882 corrosion rate was also 0.01 MPY; however, the loss was even and general and had an average penetration of 0.15 mils versus 0.50 mils penetration using the previous chemical treatment.

The prior steel coupon ID #10008 48 V had a corrosion rate of 0.36 MPY and an average pit depth of 0.500 mils. The PMWC steel coupon ID # 10007 A3379 had a corrosion rate of 0.22 MPY and an even and general average penetration of 0.150 mils. A 100% return on investment took only 27 months in chemical cost alone (Fig. 5)

In recent years, *pollution prevention* has taken on a new meaning. The transfer of polluted material from one place to another was, at one time, considered "prevention" if the contaminated water was prevented from entering our freshwater streams. However, true prevention is now understood as *eliminating the generation* of toxic waste. The 200-year-old technology is now being used to replace chemicals previously used for water treatment. Research has been spurred recently due to public awareness and concern for the environment. Several different types of applications have been discovered since the turn of the century. The science laid dormant for many years; however, it is now considered "state of the art technology" and is gaining momentum in numerous industrialized countries.

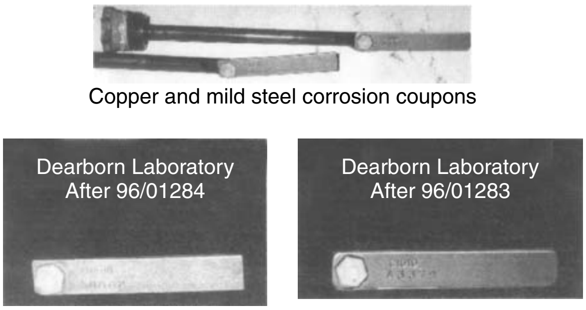

Figure 5. Nissan/Dearborn corrosion coupons.

The arrangement of the magnetic fields is a very important factor to provide adequate and effective treatment for most applications. To a multiple reversing polarity field that has a N–SS–NN–S arrangement is the most successful in controlling hard water scale deposition (Fig. 6) (5).

In addition to the multiple reversing fields, research has shown that scale can be best controlled when the water containing the minerals cuts through the magnetic lines of force at right angles. A steel pipe (magnetic material) surrounding the magnet pulls the magnetic lines of force at right angles through the water passageway. The pipe directs the water flow perpendicular to the magnetic fields (Figs. 7 and 8) (6).

Since the turn of the century, there have been dozens of new beneficial applications for magnetically treated water found through new research discoveries and hundreds more in the field. There are numerous case histories of PMWC installations on various types of equipment that have been documented by third parties as successful applications (7). Most convincing are the original equipment manufacturers (OEM) who install magnetic water conditioners on their equipment to extend the period of time between maintenance service calls.

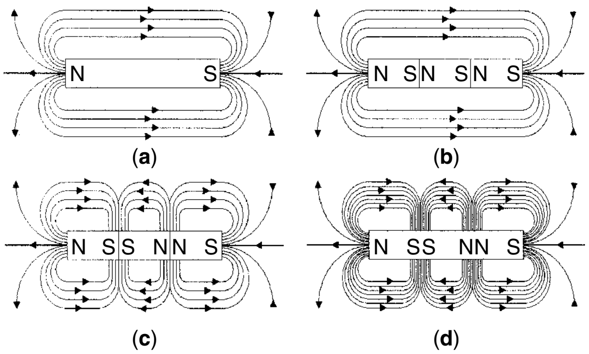

Figure 6. (**a**) One 2 pole, single field; (**b**) Three 2 pole, single field; (**c**) Three 2 pole, three separate fields; (**d**) One 6 pole, three dense fields.

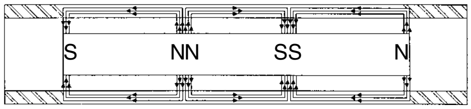

Figure 7. One 6 pole, three dense fields, with steel shield.

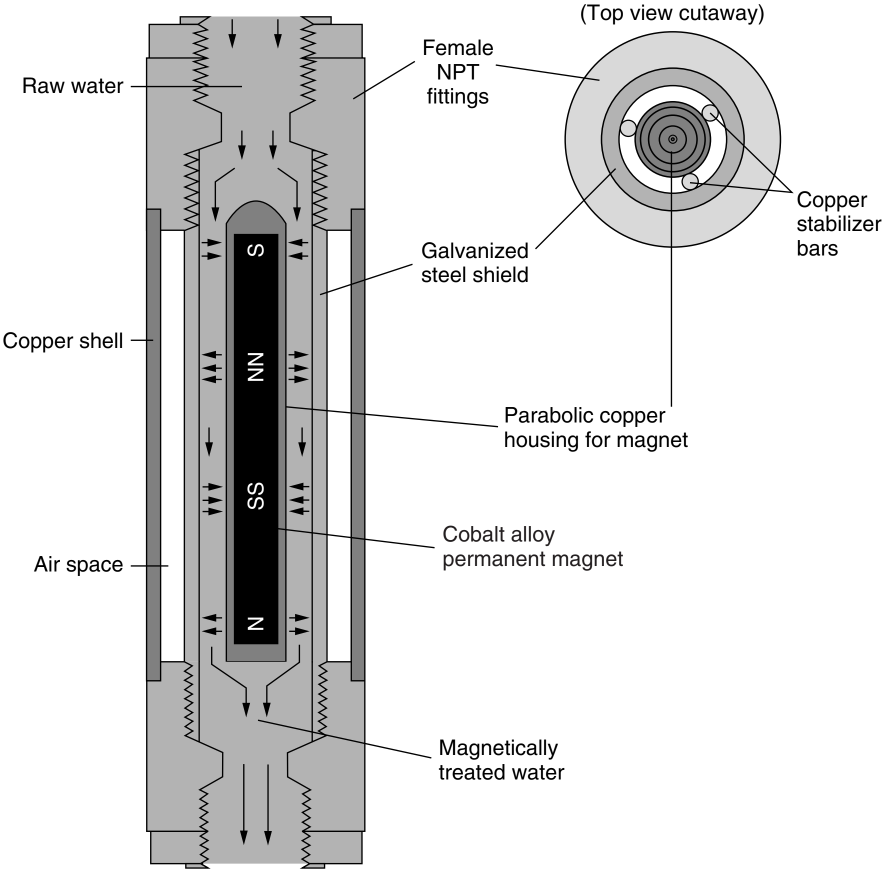

Figure 8. Cutaway view of a PMWC unit showing the water path perpendicular to the magnetic fields.

Water softeners that weighed over 100 pounds, plus bags of salt that were carried in carpet cleaning vans, are being replaced by small magnetic water conditioners (only $1\frac{1}{4}$ inches in diameter and 12 inches long), weighing less than 2 lb. Thousands of these small specially designed units for truck-mounted applications have been installed to prevent scale in steam boilers and related equipment by the manufacturer of a turnkey carpet steam cleaning equipment package.

Hard water is one of the most common causes of truck-mounted heating system failure. Untreated hard water causes loss of performance in heat exchangers and, many times, permanent damage to components (8). Several manufacturers of carpet cleaning systems throughout the United States have installed thousands of PMWC units on their truck-mounted systems during the last 5 years and reported excellent scale control and corrosion protection. Several manufacturers of the truck-mounts now encourage the use of PMWC by their customers who purchased their equipment with water softeners prior to the changeover.

Magnetic water conditioning is believed to be the wave of the future by many proponents, especially environmental groups. It is nonpolluting, does not require energy for continued operation, and needs very little, if any, maintenance. The total value of the overall benefits of PMWC is still not known. There are hundreds of different types of successful applications now in use, and there are dozens more evaluations of laboratory studies and field installation presently underway. The PMWC system has the ability to enhance our environment by reducing chemical use (true pollution prevention) and also helps save energy. The technology is cost-effective and plays a big role in water conservation. (9).

The steel industry is reportedly the single largest consumer of PMWC technology in *total gallons treated per day* due to the high demand for water needed to cool its furnaces. Units are presently available in sizes up to 50,000 gallon per minute with 72 inch flanges.

Economics is also one of the deciding factors in reducing chemical usage; the cost of preventing contaminated process wastewater from entering our freshwater rivers, lakes, and underground aquifers is very high. Transportation to another location can be as much as three times the cost of the chemical, depending on how hazardous the discharge water is.

The food service industry is the largest user of the PMWC in *total number of units*; installations are on ice machines, coffee makers, dish washers, proofers, steamers, and drink dispensers. Sizes usually range from 1 gpm up to 15 gpm (10). Original equipment manufacturers that supply the food service industry have found that adding a small specially designed unit to their water using product eliminates the majority of service calls and replacement of parts under warranty that are prone to scaling or corrosion (11).

As a result of millions of successful installations reported (many documented by qualified professionals), **the question of whether or not magnetic water**

conditioners work has been put to rest. However, the issue of how they work is still being debated. ASHRAE funded a comprehensive research study in 2000, titled *"Efficiency of Physical Water Treatment for the Control of Scale"* This report, published in 2003, confirms the results of several PMWC units performing under very rigid conditions and identifies the most effective velocity through each unit to control scale on heat transfer surfaces (12).

CONSUMER CONFIDENCE REPORTS

Susan L. Franklin
Tetra Tech MPS
Ann Arbor, Michigan

On August 19, 1998, the U.S. Environmental Protection Agency (USEPA) promulgated a final rule (40 CFR Parts 141 and 142) requiring community water systems to prepare and provide annual water quality reports to their customers. Mandated by the 1996 amendments to the Safe Drinking Water Act, these "Consumer Confidence Reports" (CCRs) provide the missing link for consumers to have easy access to valuable water quality information. Just as food products have labeling requirements, CCRs are the public's "right-to-know" resource.

The federal rule outlines a number of required elements, including information on the source(s) of drinking water and any source water assessment that has been completed, plainly worded definitions of industry terminology, information on all regulated contaminants detected in the water, health effects language, notice for non-English-speaking residents, and specific language on vulnerable subpopulations and the reasonably expected presence of some contaminants. The CCR also gives the public direct access to their water system professionals by requiring the inclusion of information on public participation opportunities, local contacts, and additional water-related resources, such as USEPA's toll-free Safe Drinking Water Hotline. In addition to the federal requirements, some states mandate supplementary guidelines.

The first CCRs, due to customers on October 19, 1999, covered test results from January 1, 1998—December 31, 1998. Subsequent annual reports are due to consumers by July 1 each year and include data from the prior calendar year. Detections of contaminants that are tested for less frequently should also be included; however, no data more than 5 years old are permitted.

All community water systems that have at least 15 service connections serving residents year-round must prepare a CCR. Water wholesalers must provide monitoring data and other required information to their retail customers by April 1 of each year. The retail system is responsible for ensuring that its customers receive a CCR containing all required content, whether they produce the report themselves or contract with their wholesaler to provide the report. After completing the CCR, each utility must certify to the state that they have complied with the CCR rule; each state determines the method for certification. A copy of the CCR is shared with the local health department, and the utility must keep the report on file for 5 years.

CCR mailing and distribution requirements are based on the size of the water utility as outlined in the federal guidelines or as modified by the state. The governor of the state has the option to waive the mailing requirements for systems that serve fewer than 10,000 people; however, these systems must still prepare a CCR, inform customers that the report is available upon request, and publish the report in a local newspaper each year. Systems that receive the waiver and serve fewer than 500 customers are not required to publish the report in the newspaper. Systems that serve more than 10,000 people must mail one copy of the report to each customer must and make a "good faith effort" (mailing to all postal patrons in the service area, posting the CCR in public places, delivering multiple copies to apartment buildings or to large employers for distribution) to get reports to non-bill-paying customers. Systems that serve 100,000 or more people must also post their CCR on the Internet.

CCRs are promoted by industry organizations, such as the American Water Works Association (AWWA), as "a timely opportunity for utilities to deliver straight talk to the consumer on quality and other issues affecting drinking water" (1). The AWWA offered training on how to prepare a CCR when the rule was issued, and it commissioned a series of six qualitative focus groups in 1997 to assess public perception and reaction to prototype CCRs in anticipation of the final rule. Their findings suggested that CCRs be called "Water Quality Reports" to let customers decide for themselves whether or not they are confident in the water system; to keep the report basic, simple, and honest; to avoid self-serving or alarming statements; and to gear the materials toward the needs of the system's customers.

According to the USEPA (2), there are more than 54,000 community water systems in the United States. Most Americans (263 million) get their drinking water from one of these community water systems and use about 370 billion gallons of water daily. Approximately $22 billion is spent annually to make tap water fit to drink. CCRs are the first nationwide commitment to educate the public about these important drinking water quality issues.

WATER CONSERVATION MEASURES

National Drinking Water
Clearinghouse

Water is a finite resource, and in many areas, future water supplies are uncertain. Individuals are usually aware when there is a drought; however, because water is inexpensive, there are often few incentives to reduce water loss. Water has no viable substitutes, and its depletion bodes profound economic and social impacts. Citizens and utilities need to consider water conservation programs.

This fact sheet considers the role of water conservation as an integral part of long-term resource planning. It might be more appropriate to use the term "water demand management." Traditional water supply management seeks to provide all the water the public wants, which, in some sections of the country, translates to a constant search for untapped sources.

WHAT METHODS CONSERVE WATER?

The water demand management methods described in this fact sheet incorporate the methods the August 1998 U.S. Environmental Protection Agency (EPA) *Water Conservation Plan Guidelines* recommend for water systems serving 10,000 or fewer people. EPA's Basic guidelines suggest (1) metering, (2) water accounting and loss control, (3) pricing and costing, and (4) education or information.

EPA's Guidelines are not regulations, but recommendations that suggest 11 different conservation methods. How appropriate and desirable any given method is must, in the end, be accepted by the individual community and utility. Pricing may be the primary way to encourage conservation, however, utilities should not automatically rely on any single method.

METER ALL WATER

Metering is a most important part of water demand management. In fact, unless a utility is 100 percent metered, it is difficult to enforce any conservation program. According to a U.S. Housing and Urban Development document, metered customers use an average of 13–45 percent less water than unmetered customers because they know they must pay for any misuse or negligence. A U.S. General Accounting Office report states that metering also assists in managing the overall water system, since it can help to:

- locate leaks in a utility's distribution system by identifying unaccounted-for blocks of water,
- identify high use customers, who can be given literature on opportunities for conserving, and
- identify areas where use is increasing, which is helpful in planning additions to the distribution system.

Once water meters are installed, equipment begins to deteriorate. Eventually meters will fail to measure flows accurately. The question of how long to leave a meter in service has long troubled the waterworks industry. According to a *Journal of the American Water Works Association* (AWWA) article by Tao and a Community Consultants report, average losses of accuracy, for periods greater than 10 years, range from 0.03–0.9 percent per year. To be fair to both customers and the utility, meters must be maintained at regular intervals.

ACCOUNT FOR WATER, REPAIR LEAKS

The EPA Guidelines recommend that all water systems—even smaller systems—implement a basic system of water accounting. The cost of water leakage can be measured in terms of the operating costs associated with water supply, treatment, and delivery. Water lost produces no revenues for the utility. Repairing larger leaks can be costly, but it also can produce substantial savings in water and expenditures over the long run.

Water accounting is less accurate and useful when a system lacks source and connection metering. Although the system should plan to meter sources, unmetered source water can be estimated by multiplying the pumping rate by the time of operation based on electric meter readings.

A utility may want to consider charging for water previously given away for public use or stepping up efforts to reduce illegal connections and other forms of theft.

Drinking water systems worldwide have begun to implement programs to address the problem of water loss. Utilities can no longer tolerate inefficiencies in water distribution systems and the resulting loss of revenue associated with underground leakage, water theft, and under registration. As pumping, treatment, and operational costs increase, these losses become more and more expensive.

If a utility does what it can to conserve water, customers will tend to be more cooperative in other water conservation programs, many of which require individual efforts. In *Economics of Leak Detection*, Moyer states that of the many options available for conserving water, leak detection is a logical first step. A highly visible leak detection program that identifies and locates water system leakage encourages people to think about water conservation before they are asked to take action to reduce their own water use. When leaks are repaired, water savings result in reduced power costs to deliver water, reduced chemicals to treat water, and reduced costs of wholesale supplies.

According to Le Moigne's technical paper *Using Water Efficiently: Technologies Options*, old and poorly constructed pipelines, inadequate corrosion protection, poorly maintained valves and mechanical damage are major factors contributing to leaks. In addition to loss of water, water leaks reduce pressure in the supply system. Raising pressure to compensate for such losses increases energy consumption and can make leaking worse, as well as causing adverse environmental impacts.

A World Bank technical paper by Okun and Ernst shows that, in general, it is normal to be unable to account for 10–20 percent of water. However a loss of more than 20 percent should raise a red flag. It should be noted that percentages are great for guidelines, but volume of water lost is probably more meaningful. According to AWWA's *Leak Detection and Water Loss Reduction*, once a utility knows the volume of water lost, it can determine revenue losses and decide the best way to correct the problem.

EPA's Guidelines recommend that each system institute a comprehensive leak detection and repair strategy. This strategy may include regular onsite testing using computer-assisted leak detection equipment, a sonic leak-detection survey, or another acceptable method for detecting leaks along water distribution mains, valves, services, and meters. Divers can inspect and clean storage tank interiors.

Increasingly, water systems are using remote sensor and telemetry technologies for ongoing monitoring and analysis of source, transmission, and distribution facilities. Remote sensors and monitoring software can alert operators to leaks, fluctuations in pressure, problems with equipment integrity, and other concerns.

Each system should institute a loss-prevention program, which may include pipe inspection, cleaning, lining, and other maintenance efforts to improve the distribution system and prevent leaks and ruptures. Whenever possible, utilities might also consider methods for minimizing water used in routine water system maintenance procedures.

COSTING AND PRICING

In a Journal of the *American Water Works Association* article "Long-Term Options for Municipal Water Conservation," Grisham and Fleming stress that water rates should reflect the real cost of water. Most water rates are based only on a portion of what it costs to obtain, develop, transport, treat, and deliver water to the consumer. Experts recommend that rates include not only current costs but those necessary for future water supply development. Only when rates include all costs can water users understand the real cost of water service and consequently, the need to conserve.

When utilities raise water rates, among other factors, they need to consider what members of the community can afford. According to Schiffler, the ability to pay for water depends on a number of variables, including its intended use. In households, the assumption is that if the share of water costs does not exceed 5 percent of total household revenue it can be considered as socially acceptable. This rule of thumb has no specific foundation, but is widely used.

Many utility managers argue, correctly, that an effective water conservation program will necessitate rate increases. In *Water Conservation*, Maddaus states that a reduction in water use by customers in response to a water conservation program can decrease a water utility's revenues, and the utility may need to re-examine the water rate structure needs and possibly raise rates to compensate for this effect.

Water charges have typically been looked at as a way of financing the operation and maintenance (O&M) costs of a water agency, rather than as a demand management measure to encourage water-use efficiency. As a World Bank document states, political objections and constraints to increasing water charges are often seen as insurmountable. However, low water charges encourage consumption and waste and can put pressure on O&M budgets, leading to poor water treatment and deterioration in water quality.

In *Water Strategies for the Next Century*, Rogers et al. advocate a positive price for water that is less than the cost of desalination, but not zero. Desalination presently costs about $2 a cubic meter. The ideal is to charge a reasonable amount that sends the message to the users.

EPA suggests that systems consider whether their current rate structures promote water usage over conservation. Nonpromotional rates should be implemented whenever possible.

Systems that want to encourage conservation through their rates should consider various issues, such as the allocation between fixed and variable charges, usage blocks and breakpoints, minimum bills and whether water is provided in the minimum bill, seasonal pricing options, and pricing by customer class.

Numerous sources recommend tying sewer prices to water prices. Billing for wastewater is not included in this analysis; however, it is expected to become a more significant motivation for reducing water use over the next 15 years.

INFORMATION AND EDUCATION

According to Maddaus, water conservation initiatives are more likely to succeed if they are socially acceptable. Measuring social acceptability, an exercise in anticipating public response to a potential water conservation measure, may be measured with a two-part survey technique. First, conduct interviews with community leaders to assess the political and social atmosphere. Second, assess the response to selected specific measures via a questionnaire mailed to a random sample of water customers.

The public tends to accept lawn watering restrictions, education, home water-saver kits, low-flush toilet rebates, and a low-flow fixtures ordinance for new construction. Overall acceptance of conservation is strongly related to attitudes about the importance of water conservation, as well as to age, income, and type of residence.

Howe and Dixon note that, “Public participation is now widely understood to be a necessary input for both efficiency and equity.” Public participation should be part of any long-term public education program, as well as an element of plan development. A plan responsive to public needs usually receives continuing support.

The EPA Guidelines state that water systems should be prepared to provide information pamphlets to customers on request. Consumers are often willing to participate in sound water management practices if provided with accurate information. An information and education program should explain to water users all of the costs involved in supplying drinking water and demonstrate how water conservation practices will provide water users with long term savings.

An informative water bill goes beyond the basic information used to calculate the bill based on usage and rates. Comparisons to previous bills and tips on water conservation can help consumers make informed choices about water use. Systems can include inserts in their customers’ water bills that provide information on water use and costs or tips for home water conservation.

School programs can be a great way to get information out. Systems can provide information on water conservation and encourage the use of water conservation practices through a variety of school programs. Contacts through schools can help socialize young people about the value of water and conservation techniques, as well as help systems communicate with parents.

Workshops and seminars can be used to solicit input, and water equipment manufacturers can be invited to these sessions to exhibit their equipment. Maddaus suggests that a number of groups may have a role in water conservation planning:

- Elected officials from all jurisdictions immediately affected by the process;
- Staff persons from private water companies, key personnel from local government agencies, and state agency people;
- Representatives of major local economic interest groups—major industries, chambers of commerce, builders’ associations, farm bureaus, boards of realtors, and landscape contractors;
- Representatives of major community forces, such as federated civic associations, neighborhood associations, school boards, local unions, churches, and local press and media owners;
- Representatives of local government interest groups;
- Local professionals, such as economists and engineers; and
- Representatives of major water users, for example, food processing plants and homeowners’ associations.

PREVENTING WELL CONTAMINATION

VIPIN BHARDWAJ
NDWC Engineering Scientist

Nearly 80% of communities rely on groundwater as their primary drinking water source. Wells extract groundwater for use in homes and businesses. In addition, about 42 million Americans use private wells for drinking water. In light of this information, preventing groundwater contamination is of utmost importance, especially since a number of factors can contribute to groundwater contamination. To prevent well contamination, one of the first steps is to construct it properly. This Tech Brief presents tips about how to site a well and includes information about design issues; material selection and location, such as screens and filter pack; appropriate well sealing methods; and the use of pitless adaptors to prevent contamination

INTRODUCTION

To prevent well contamination, one of the first steps is to construct it properly. This tech brief presents tips on siting a well, its design, choosing proper materials, proper location of screens, filter pack and appropriate method of sealing a well and use of pitless adaptors to prevent contamination.

SITE SELECTION

To prevent groundwater contamination, the first step is to locate the well so that surface water and contaminants cannot flow into it. Site engineers try to install the well uphill from any potential contamination source. This means avoiding potential pollution sources, such as industrial plants, home septic systems, landfills, and underground storage tanks. Hiring a qualified hydrogeologist to investigate potential contaminant sources and likely subsurface conditions makes locating a well easier.

For most private wells, the primary contaminant source is the owner’s septic system. The best protection practice is to locate the well above the area where contaminants can enter it, usually about 50 to 100 feet away. In addition, install a surface seal into a fine-grained layer or non-fractured zone above the aquifer.

To prevent water from collecting near the casing, the ground surrounding the well should slope away from the wellhead on all sides. In addition, most states regulate how far a well must be located from potential contamination sources. For instance, most states require that wells be a minimum of 50 feet away from a septic system.

WELL DESIGN

Proper selection of well casings, seals, screens, filter packs, and pump chamber casings are important factors that determine the efficiency of the well and prevent contamination. Figure 1 shows the components of a well that prevent pollutants from entering the well. Most states have well construction standards and permitting processes that must be followed. The American Water Works Association has a standard A100-90 that deals with construction design.

CASING

A casing is a pipe that is usually made of steel or plastic. It lines the borehole dug in the earth and keeps the well from caving in and prevents runoff and other material from getting into the well.

When contactors select casing, they must take into account the forces that are exerted while installing. In addition, the surrounding materials, such as soil and rocks, tend to collapse into the hole. If possible, the driller should

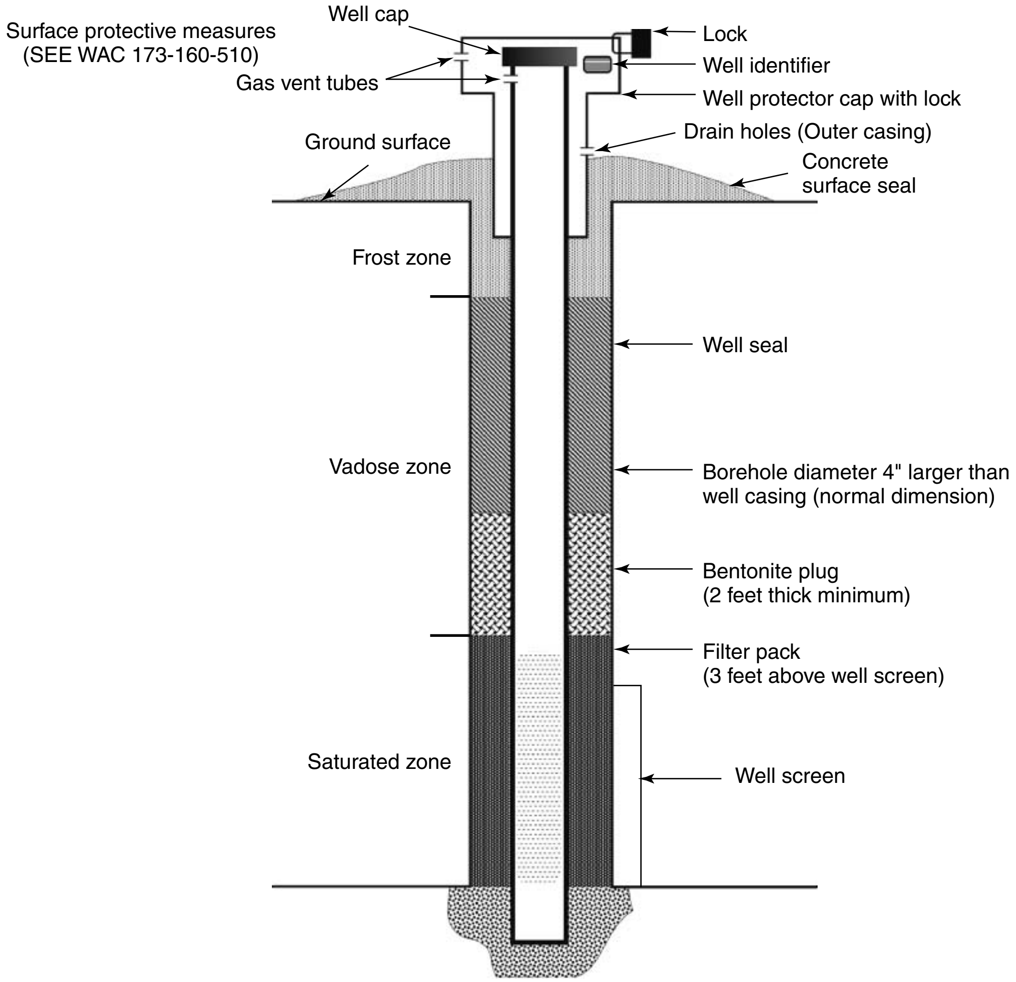

Figure 1. General resource protection well—cross section

Definitions

Well Seal: A seal is a cylindrical layer of material, usually cement, bentonite, or clay, that surrounds the casing up to a certain depth in the well. It prevents runoff or other contaminants from entering the well, and serves to further protect the casing.

Well Screen: Well screen is a cylindrical sieve-like structure that serves as the intake portion of the well. It is a metallic pipe that has holes or perforated sections or slotted sections that is placed on the water- carrying zones of the aquifer.

Filter Pack: A filter pack is made up of sand or gravel that is smooth, uniform, clean, well-rounded, and siliceous. It is placed in the annulus of the well between the bore-hole wall and the well screen to prevent formation material from entering the screen.

Vadose Zone: This is the zone that contains water under pressure less than that of the atmospheric pressure. It is the layer of soil between the water table and the ground surface.

Potentiometric Surface: This is an imaginary surface representing the total head of groundwater in a confined aquifer that is defined by a level to which water will rise in the well.

use a temporary casing for the borehole. The temporary casing diameter must be at least four inches larger than the permanent casing to provide sufficient space for a good well seal.

The American Society for Testing and Materials, the American Petroleum Institute, and the American Iron and Steel Institute have specifications for casings. Most state standards require steel casing of a specified wall thickness for wells, whether for a community or private individual.

The diameter of the casing must leave enough room to install the submersible pump and still have space for maintenance. The size of the pump depends upon the desired well yield.

Casing depth also helps prevent well contamination. Logs of any other nearby wells and the local geology can help determine how deep the casing should go. The casing should extend at least 12 inches above the ground for sanitary protection. Reducing the casing's diameter requires a minimum of eight feet of casing overlap. A watertight well cap should be placed on top of the casing. The Water Systems Council (WSC) has standards for well caps and other well components.

WELL SCREEN

A well screen is a cylindrical sieve-like structure that serves as the intake portion of the well. It is a metallic pipe that has holes or perforated sections or slotted sections that is placed on the water carrying zones of the aquifer. Proper selection, design, placement, and development of the screened section are very important and determine the well's efficiency and yield.

Since certain sections of the ground are more porous than others and, hence, carry more water, placing the screens in these sections will yield higher flow rates. By looking at the data collected during drilling, a good well driller can locate and place the screen in the proper zones.

To better understand conditions at the site, use borehole geophysical logs to grasp the subsurface conditions. In addition, visual inspection of the cuttings or samples can show if the layers of earth are sandy, coarse, or clayey. And to help determine well yield, use sieve analysis and hydraulic conductivity tests.

FILTER PACK

A filter pack is typically made up of sand or gravel that is smooth, uniform, clean, well rounded. It is placed in the area between the borehole wall and the well screen to prevent formation material from entering the screen.

To enhance the permeability of the zone surrounding the screen, place a filter pack around it. A good filter pack keeps sediment out and decreases friction losses around the screen and is especially important if the aquifer consists of uniform fine sand. A filter pack allows for larger openings in the screen and improves well yield. To install a filter pack, start from the bottom of the screen, filling in to at least three feet above the top of the screen. Domestic wells do not require a filter pack.

WELL SEALS

The most important components that prevent contaminants from entering the well are well seals. A seal is a cylindrical layer of material, usually cement, bentonite, or clay, that surrounds the casing up to a certain well depth. It prevents runoff or other contaminants from entering the well and serves to further protect the casing. The drilled hole must be four inches larger in diameter than the outer diameter of the casing so that the seal can be placed in the space between casing and the hole.

Well construction standards specify the material that well installers must use to seal the well, as well as the depth to which the well is grouted. Typically, public water supply wells are grouted to a depth of 50 feet. A cement slurry is pumped in the ring-shaped space between casing and hole and the well is sealed from the bottom up. Grout is placed using a small diameter pipe called a tremie. A layer of bentonite two feet thick should be placed on top of the filter pack.

PITLESS ADAPTORS

Pitless adapters and pitless units are devices that attach to the well casing below the frost line and provide sanitary connections. They prevent entry of contaminants into the well near the surface. These devices provide access to the well for servicing. The adapter connects the casing with a horizontal line that supplies water through a removable seal joint. This connection allows the drop pipe and pumping equipment in the well to be easily removed for repair or maintenance work without digging the ground around the well.

WSC has performance standards for pitless adapters, pitless units, and watertight well caps. A list of manufacturers that meet those standards can be obtained from the WSC.

DISINFECTION PROCEDURES

Well installers must disinfect all equipment and tools using a chlorine solution before any drilling operation to prevent bacterial contamination. The well must be disinfected after it's completed. Some types of bacteria, such as *E. coli*, are found in soils and can contaminate the well. By dissolving calcium hypochlorite or sodium hypochlorite, installers can make a chlorinated water solution. The strength of the solution can range from 50–200 milligrams per liter of available chlorine.

CORROSION CONTROL

National Drinking Water
Clearinghouse

Corrosion occurs because metals tend to oxidize when they come in contact with water, resulting in the formation of stable solids. Corrosion in water distribution systems can impact consumers' health, water treatment costs, and the aesthetics of finished water.

Various methods can be used to diagnose, evaluate, and control corrosion problems. Techniques for controlling it include distribution and plumbing system design considerations, water quality modifications, corrosion inhibitors, cathodic protection, and coatings and linings.

CORROSION CAN CAUSE SYSTEM PROBLEMS

What Problems Does Corrosion Cause?

Corrosion can cause higher costs for a water system due to problems with:

- decreased pumping capacity, caused by narrowed pipe diameters resulting from corrosion deposits;
- decreased water production, caused by corrosion holes in the system, which reduce water pressure and increase the amount of finished water required to deliver a gallon of water to the point of consumption;
- water damage to the system, caused by corrosion-related leaks;
- high replacement frequency of water heaters, radiators, valves, pipes, and meters because of corrosion damage; and
- customer complaints of water color, staining, and taste problems.

How is Corrosion Diagnosed and Evaluated?

The following events and measurements can indicate potential corrosion problems in a water system:

Consumer Complaints: Many times a consumer complaint about the taste or odor of water is the first indication of a corrosion problem. Investigators need to examine the construction materials used in the water distribution system and in the plumbing of the complainants' areas (See Table 1).

Corrosion Indices: Corrosion caused by a lack of calcium carbonate deposition in the system can be estimated using

Table 1. Typical Water Quality Complaints That Might Be Due to Corrosion

Customer Complaint	Possible Cause
Red water or reddish-brown staining of fixtures and laundry	Corrosion of iron pipes or presence of natural iron in raw water
Bluish stains on fixtures	Corrosion of copper lines
Black water	Sulfide corrosion of copper or iron lines or precipitations of natural manganese
Foul taste and/or odors	Byproducts from microbial activity
Loss of pressure	Excessive scaling, tubercle (buildup from pitting corrosion), leak in system from pitting or other type of corrosion
Lack of hot water	Buildup of mineral deposits in hot water system (can be reduced by setting thermostats to under 60 degrees C [140 degrees F])
Short service life of household plumbing	Rapid deterioration of pipes from pitting or other types of corrosion

Source: U.S. Environmental Protection Agency indices derived from common water quality measures. The Langelier Saturation Index (LSI) is the most commonly used measure and is equal to the water pH minus the saturation pH (LSI = pH water − pH saturation). The saturation pH refers to the pH at the water's calcium carbonate saturation point (i.e., the point where calcium carbonate is neither deposited nor dissolved). The saturation pH is dependent upon several factors, such as the water's calcium ion concentration, alkalinity, temperature, pH, and presence of other dissolved solids, such as chlorides and sulfates. A negative LSI value indicates potential corrosion problems.

Sampling and Chemical Analysis: The potential for corrosion can also be assessed by conducting a chemical sampling program. Water with a low pH (less than 6.0) tends to be more corrosive. Higher water temperature and total dissolved solids also can indicate corrosivity.

Pipe Examination: The presence of protective pipe scale (coating) and the condition of pipes' inner surfaces can be assessed by simple observation. Chemical examinations can determine the composition of pipe scale, such as the proportion of calcium carbonate, which shields pipes from dissolved oxygen and thus reduces corrosion.

Can System Design Affect the Potential for Corrosion?

In many cases, corrosion can be reduced by properly selecting distribution and plumbing system materials and by having a good engineering design. For example, water distribution systems designed to operate with lower flow rates will have reduced turbulence and, therefore, decreased erosion of protective layers. In addition, some piping materials are more resistant to corrosion in a specific environment than others. Finally, compatible piping materials should be used throughout the system to avoid electrolytic corrosion.

Other measures that help minimize system corrosion include:

- using only lead-free pipes, fittings, and components;
- selecting an appropriate system shape and geometry to avoid dead ends and stagnant areas;
- avoiding sharp turns and elbows in the distribution and plumbing systems;
- providing adequate drainage (flushing) of the system;
- selecting the appropriate metal thickness of piping, based on system flow and design parameters;
- avoiding the use of site welding without replacing the pipe lining;
- reducing mechanical stresses, such as flexing of pipes and "water hammer" (hydraulic pressure surges);
- avoiding uneven heat distribution in the system by providing adequate coating and insulation of pipes;
- providing easy access for inspection, maintenance, and replacement of system parts; and
- eliminating the grounding of electrical circuits to the system, which increases the potential for corrosion.

How Can System Corrosion be Reduced?

Corrosion in a system can be reduced by changing the water's characteristics, such as adjusting pH and alkalinity; softening the water with lime; and changing the level of dissolved oxygen (although this is not a common method of control). Any corrosion adjustment program should include monitoring. This allows for dosage modification, as water characteristics change over time.

pH Adjustment: Operators can promote the formation of a protective calcium carbonate coating (scale) on the metal surface of plumbing by adjusting pH, alkalinity, and calcium levels. Calcium carbonate scaling occurs when water is oversaturated with calcium carbonate. (Below the saturation point, calcium carbonate will redissolve: at the saturation point, calcium carbonate is neither precipitated nor dissolved. See the section on "corrosion indices,".) The saturation point of any particular water source depends on the concentration of calcium ions, alkalinity, temperature, and pH, and the presence of other dissolved materials, such as phosphates, sulfates, and some trace metals.

It is important to note that pH levels well suited for corrosion control may not be optimal for other water treatment processes, such as coagulation and disinfection. To avoid this conflict, the pH level should be adjusted for corrosion control immediately prior to water distribution, and after the other water treatment requirements have been satisfied.

Lime Softening: Lime softening (which, when soda ash is required in addition to lime, is sometimes known as lime-soda softening) affects lead's solubility by changing the water's pH and carbonate levels. Hydroxide ions are then present, and they decrease metal solubility by promoting the formation of solid basic carbonates that "passivate," or protect, the surface of the pipe.

Using lime softening to adjust pH and alkalinity is an effective method for controlling lead corrosion. However, optimum water quality for corrosion control may not coincide with optimum reduction of water hardness. Therefore, to achieve sound, comprehensive water treatment, an operator must balance water hardness, carbonate levels, pH and alkalinity, as well as the potential for corrosion.

Dissolved Oxygen Levels: The presence of excessive dissolved oxygen increases water's corrosive activity. The optimal level of dissolved oxygen for corrosion control is 0.5 to 2.0 parts per million. However, removing oxygen from water is not practical because of the expense. Therefore, the most reasonable strategy to minimize the presence of oxygen is to:

- exclude the aeration process in the treatment of groundwater,
- increase lime softening,
- extend the detention periods for treated water in reservoirs, and
- use the correct size water pumps in the treatment plant to minimize the introduction of air during pumping.

What About the Use of Corrosion Inhibitors?

Corrosion inhibitors cause protective coatings to form on pipes. Although they reduce corrosion, they may not totally arrest it. Therefore, the success of any corrosion inhibitor hinges upon the water operator's ability to:

- apply double and triple the design doses of inhibitor during initial applications to build a protective base coat that will prevent pitting; (Note that initial coatings typically take several weeks to form.)
- maintain continuous and sufficiently high inhibitor doses to prevent redissolving of the protective layer; and
- attain a steady water flow over the system's metal surfaces to allow a continuous application of the inhibitor.

There are several commercially available corrosion inhibitors that can be applied with normal chemical feed systems. Among the most commonly used for potable water supplies are inorganic phosphates, sodium silicates, and mixtures of phosphates and silicates.

Inorganic Phosphates: Inorganic phosphate corrosion inhibitors include polyphosphates, orthophosphates, glassy phosphates, and bimetallic phosphates. Zinc, added in conjunction with polyphosphates, orthophosphates, or glassy phosphates, may help to inhibit corrosion in some cases.

Silicates: The effectiveness of sodium silicates depends on both pH and carbonate concentrations. Sodium silicates are particularly effective for systems with high water velocities, low hardness, low alkalinity, and pH of less than 8.4. Typical coating maintenance doses of sodium silicate range from 2 to 12 milligrams per liter. They offer advantages in hot-water systems because of their chemical stability, unlike many phosphates.

Before installing any technology for delivering corrosion inhibitors, several methods or agents first should be tested in a laboratory environment to determine the best inhibitor and concentration for each water system.

Is Cathodic Protection an Option?

Cathodic protection is an electrical method for preventing corrosion of metallic structures. However, this expensive corrosion control method is not practical or effective for protecting entire water systems. It is used primarily to protect water storage tanks. A limitation of cathodic protection is that it is almost impossible for cathodic protection to reach down into holes, crevices, or internal corners.

Metallic corrosion occurs when contact between a metal and an electrically conductive solution produces a flow of electrons (or current) from the metal to the solution. The electrons given up by the metal cause the metal to corrode rather than remain in its pure metallic form. Cathodic protection stops this current by overpowering it with a stronger, external power source. The electrons provided by the external power source prevent the metal from losing electrons, forcing it to be a "cathode," which will then resist corrosion, as opposed to an "anode," which will not.

There are two basic methods of applying cathodic protection. One method uses inert electrodes, such as high-silicon cast iron or graphite, which are powered by an external source of direct current. The current impressed on the inert electrodes forces them to act as anodes, thus minimizing the possibility that the metal surface being protected will likewise become an anode and corrode. The second method uses a sacrificial anode. Magnesium or zinc anodes produce a galvanic action with iron, so that the anodes are sacrificed (or suffer corrosion), while the iron structure they are connected to is protected.

Are Commercial Pipe Coatings and Linings Effective?

The nearly universal method of reducing pipe corrosion involves lining the pipe walls with a protective coating. These linings are usually mechanically applied, either when the pipe is manufactured or in the field before it is installed. Some linings can be applied even after the pipe is in service, but this method is much more expensive.

Mechanically applied coatings and linings differ for pipes and water storage tanks. The most common types of pipe linings include coal-tar enamels, epoxy paints, cement mortar, and polyethylene.

Water storage tanks are most commonly lined to protect the inner tank walls from corrosion. The most common types of water storage tank coatings and linings include coal-tar paints and enamels, vinyls, and epoxy.

Where Can I Find More Information?

Information for this fact sheet was obtained from three primary sources: *Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities, EPA/625/4-89/023; Corrosion Manual for Internal Corrosion of Water Distribution Systems, EPA/570/9-84/001; and Corrosion in Potable Water Supplies*, EPA/570/9-83/013. All of these documents are free and may be ordered from the U.S. Environmental Protection Agency (EPA) Office of Research and Development by calling (513) 569-7562.

If these publications are no longer available from the EPA, call the National Drinking Water Clearinghouse (NDWC) at (800) 624-8301. A photocopied version of the 209-page document Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities, item #DWBKDM04, costs $30.05. There is no charge for the other two documents listed above; however, postage charges apply to all orders.

Also, the NDWC's Registry of Equipment Suppliers of Treatment Technologies for Small Systems (RESULTS), version 2.0, is a public reference database that contains information about technologies—including those related to corrosion—in use at small water systems around the country. For further information about accessing or ordering RESULTS, call the NDWC at (800) 624-8301 or (304) 293-4191. You may also obtain more information from the NDWC's World Wide Web site at www.ndwc.wvu.edu.

For additional copies of "Tech Brief: Corrosion Control," item #DWBRPE52, or for a copy of the previously published "Tech Brief: Filtration," item #DWBRPE50, or "Tech Brief: Disinfection," item #DWBRPE47, call the NDWC at the number printed above.

CROSS CONNECTION AND BACKFLOW PREVENTION

Vipin Bhardwaj
NDWC Engineering Scientist

Bethany Reed
NESC Graphic Designer

When drinking water is transported to a consumer, it is possible for contaminants to be introduced in the distribution system. This situation may occur due to connections between potable water lines and non-potable water sources or by a water flow reversal, resulting in contaminated water. This Tech Brief, discusses cross connections and backflow, and explores ways to prevent these situations.

WHAT IS A CROSS CONNECTION?

A cross connection is a link or structural arrangement where potable water in a distribution system can be exposed to unwanted contaminants. It is the point at which it is possible for a non-potable substance to come in contact with the drinking water system. Cross connections are generally unintentional and can happen anywhere pipes supply water.

WHAT IS A BACKFLOW?

Backflow is the reverse flow of undesirable materials and contaminants into the water mains. Backflow can happen because of two conditions: backpressure and backsiphonage.

Backpressure occurs when pressure in a pipe connected to a main pipe in the distribution system becomes greater than the pressure in the main pipe itself. When this happens, a net force acts on the volume of liquid in the connecting pipe, allowing unwanted material to enter the main pipe.

Backsiphonage refers to a situation where the pressure in a service pipe is less than the atmospheric pressure. If water in a supply line is turned off, such as when a pump fails, backsiphonage can cause contamination to be sucked into the system due to a vacuum in the service line.

If a cross connection exists in a system, it does not mean that there will be a backflow every time. But, where cross connections exist, there is always the possibility.

BACKFLOW CONTROL METHODS AND DEVICES

If possible, cross connections must first be eliminated before installing any backflow prevention devices. The device chosen depends on the degree of hazard involved, accessibility to the location of the device, and whether the backflow is due to backpressure or backsiphonage. Basic types of backflow prevention devices are:

- air gaps,
- reduced pressure principle devices,
- double check valves,
- vacuum breakers, and
- barometric loops

Air Gap

Air gaps are one of the most effective ways to prevent backflow and backsiphonage. An air gap is a vertical separation between a water outlet and the highest level of a potential fluid contamination source. However, because of air gaps, flow of water is interrupted and loss of pressure occurs. Because of this, air gaps are used at the end of a pipe. Air gaps should be twice the size of the supply pipe diameter or at least one inch in length, whichever is greater (see Fig. 1).

Reduced Pressure Principle Backflow Preventer

The reduced pressure zone backflow-preventing (RPBP) device has two spring check valves with a pressure-relief valve located between them that can be vented to the atmosphere.

During normal flow of water through this arrangement, the water flows through the two valves (see Fig. 2). The spring action of the first valve opposes the pressure of water as the water flows from left to right and enters the central chamber. Pressure in the central chamber is maintained lower than that in the incoming line by the operation of the relief valve.

The second check valve to the right is designed to open with a pressure drop of one pound per square inch (psi) in the direction of flow and is independent of the pressure required to open the relief valve. If the pressure downstream from the device increases for some reason (backpressure), the second check valve will close because of the spring action. Reverse flow of water or backflow is thus prevented. In case the pressure in the supply line on the left decreases abruptly or if there is a vacuum in the supply line (backsiphonage), the check valves close because of spring action, and backflow is prevented.

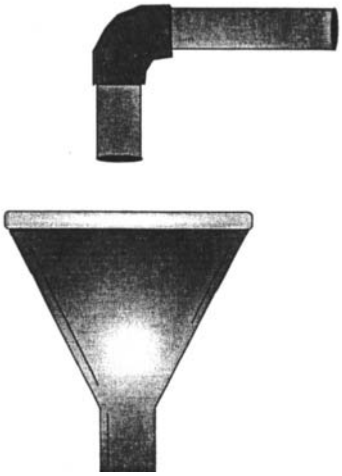

Figure 1. Air gap.

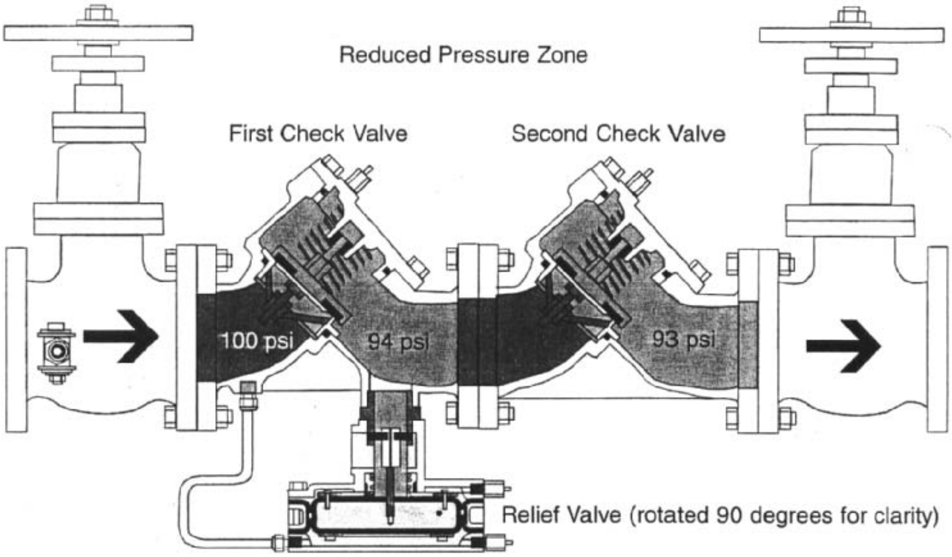

Figure 2. Reduced pressure principle backflow preventer. *Source*: U.S. Environmental Protection Agency. 2003. *Cross-Connection Control Manual*, Washington DC: EPA.

In case the valve leaks and the second check valve on the right does not close fully, water will leak back into the central chamber and increase the pressure in the chamber. The relief valve then opens and discharges water to the atmosphere. Keep in mind, if you see water coming from the relief valve on an RPBP, don't panic. It's actually working as designed. The valve assembly should be checked by a certified tester.

This type of device is usually installed on high hazard locations, such as hospitals, plating plants, and car washes.

Double Check Valve

The double check valve has two single check valves coupled within one body, and has test cocks (to determine if there's any leakage) and two closing gate valves (to isolate each section). It is essentially the same reduced pressure zone backflow-preventing (RPBP) device but without the relief valve (see Fig. 3).

The absence of the relief valve reduces the effectiveness of the device. Double check valves are used in low- to medium-level hazard installations. The check valves are spring-loaded and require one pound of pressure to open.

Vacuum Breakers

Vacuum breakers provide protection against back-siphonage. When the pressure in a service pipe is less than the atmospheric pressure, a vacuum can form in the pipe and cause contamination to be sucked into the system. Vacuum breakers have an element, such as a check valve, that glides on a supporting shaft and seals in the

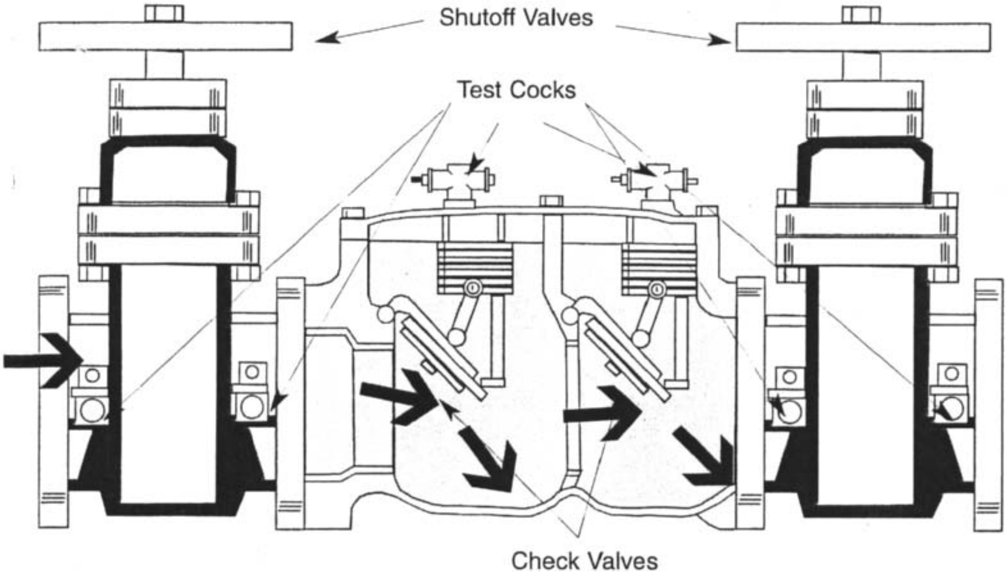

Figure 3. Double check valve. *Source*: AWWA, *Water Transmission and Distribution*, Second Edition.

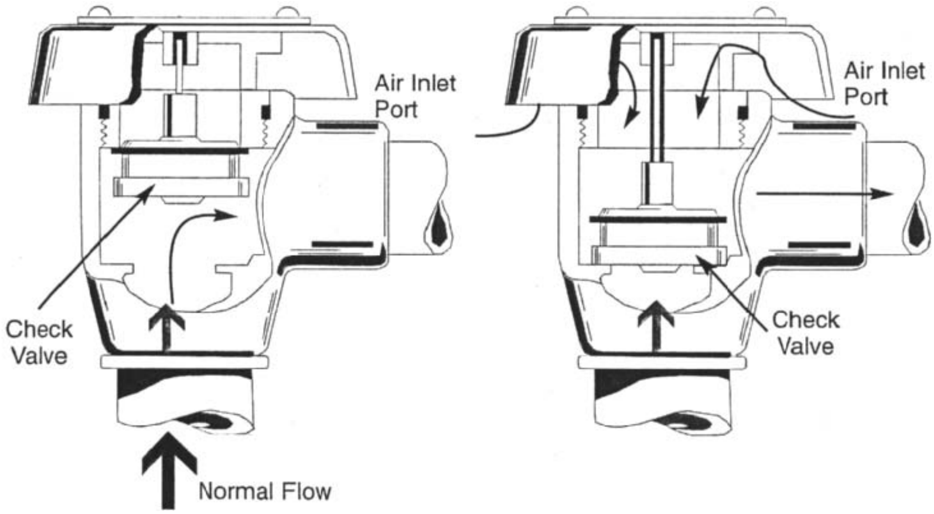

Figure 4. Vacuum breakers. *Source*: AWWA, *Water Transmission and Distribution*, Second Edition.

uppermost position from the push of water pressure (see Fig. 4).

If the flow in the pipe is stopped, the valve drops down, closes the water supply entry, and opens an air vent. This opens up the downstream piping to atmospheric pressure and prevents backsiphonage. Vacuum breakers do not protect against backpressure.

Barometric Loop

A barometric loop is formed by having a section of the pipe in the shape of an inverted "U" upstream of a cross connection (see Fig. 5). Based on a physics principle, the height of a water column open to the atmosphere at the bottom will not be greater than 33.9 feet at sea level pressure.

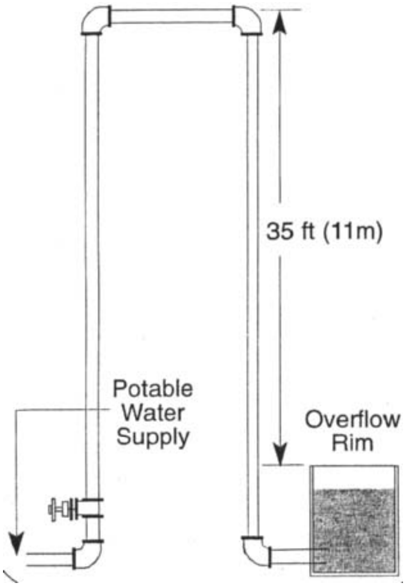

Figure 5. Barometric loop. *Source*: AWWA, *Water Transmission and Distribution*, Second Edition.

If the loop is greater than that height, backsiphonage cannot occur through it. However, the barometric loop is not effective against backpressure.

"YELLOW GUSHY STUFF" FROM FAUCETS

A small town in Maryland provides a dramatic example of what can happen because of a cross connection. One fateful day, yellow gushy stuff poured from some faucets there and the state warned residents from using the water for cooking, drinking, or bathing. The incident drew widespread attention and was a big story in the local media.

An investigation revealed that water pressure in the town mains was reduced temporarily due to a water pump failure in the distribution system. A gate valve between a herbicide chemical holding tank and the town water supply mains had been left open. A lethal cross connection was created that allowed the herbicide to flow into the water supply. When the normal water supply pressure returned, water containing the herbicide was pumped into many faucets.

Door to door public notification, extensive flushing, sampling, and other measures were taken to get the situation under control. Fortunately, no one was seriously injured in this incident.

CROSS CONNECTION CONTROL PROGRAMS

Numerous, well-documented cases about illnesses and other hazards posed by cross connections have been documented. (See the sidebar above.) More information about the health risks cross connections may present and methods to prevent them is needed. Water utility personnel (managers, operators, local officials), plumbers, public health officials, and consumers need to be aware of the risks and understand prevention methods.

As mandated by the Safe Drinking Water Act, water suppliers are responsible for ensuring that the water they supply meets federal primary drinking water regulations and is delivered to consumers without compromising water quality due to its distribution system. Water utilities may want to implement a cross connection program to stave off any problems that could occur. Such a program would include informing consumers, conducting inspections of the distribution system, analyzing and recognizing potential cross connections, and installing backflow prevention devices where needed.

WHAT ABOUT TERRORISM AND WATER SECURITY?

Concern that U.S. water supplies could be vulnerable to terrorist attacks has increased in the post-9/11 era. Because they are a place where lethal substances could be introduced into the water distribution system, cross connections should be identified and corrected.

The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (Section 1433) requires systems that serve more than 3,300 people to assess their vulnerability to a terrorist attack. (See the article "Security and Emergency Planning: Community-Wide Efforts Require Preparation" in the Winter 2003 *On Tap*.)

The act states that the vulnerability assessment shall include but not be limited to "a review of pipes and constructed conveyances, water collection, pretreatment, storage and distribution facilities, electronic, computer or other automated systems."

MOLECULAR-BASED DETECTION OF *CRYPTOSPORIDIUM PARVUM* IN WATER

Nicholas J. Pokorny
Christine M. Carey
Jeanine L. Boulter-Bitzer
Hung Lee
Jack T. Trevors
University of Guelph
Guelph, Ontario, Canada

INTRODUCTION

Cryptosporidium is an apicomplexan protozoan parasite that is becoming increasingly recognized as an important infectious pathogen in water. The parasite is transmitted by the fecal–oral route, usually by ingestion of oocyst-contaminated water or food (1–3). A *C. parvum* oocyst is small, averaging 5 μm × 4.5 μm, and its coat is bilayered and highly proteinaceous, allowing it to resist chlorine-based disinfection in water treatment facilities (4). Within the oocyst are four motile sporozoites (Fig. 1), which are the infectious forms of *Cryptosporidium*. After passing through the stomach, the oocyst releases the infectious sporozoites, which attach to epithelial cells of the small intestine. Asexual and sexual reproduction of *Cryptosporidium* within the infected host results in autoinfection and self-perpetuation of the disease. Sexual reproduction also results in the production of infectious oocysts that are excreted along with fecal matter into the environment.

Cryptosporidiosis, the globally occurring disease caused by *Cryptosporidium* infection, can result in gastrointestinal distress with copious amounts of diarrhea, abdominal cramping, and fever. In healthy individuals, infection is an acute but self-limiting illness that generally lasts 1 to 2 weeks. However, in immunocompromised individuals, symptoms are more severe, and the illness may become chronic and can result in death. It has been recognized that two distinct *C. parvum* genotypes, referred to as the human genotype (genotype I or genotype H) and the cattle genotype (genotype II or genotype C), are responsible for human cryptosporidiosis. Morgan-Ryan et al. (5) proposed a new species, *Cryptosporidium hominis*, to denote the human genotype. *Cryptosporidium hominis* infects humans primarily, whereas *C. parvum* infects both humans and numerous other mammalian hosts such as mice, dogs, cattle, sheep, goats, and pigs. There is no cure therapy currently available for *Cryptosporidium* infection, so prevention is the key to containing and managing this disease. Prevention requires accurate monitoring and detection of the parasites in water and food samples.

As intestinal parasites, *C. parvum* cannot be cultured *in vitro*. Therefore, traditional culture methods used in routine microbiology labs are not suitable to detect and enumerate *C. parvum* oocysts. Classical methods to detect *Cryptosporidium* are based on microscopy of clinical samples that can be combined with different stains for improved visualization. However, microscopy requires training and is subject to human error in both sample preparation and viewing. The use of fluorogenic dyes can make detection easier, but microscopy cannot indicate oocyst viability or infectivity. Rather than relying on the results of clinical samples to identify a *Cryptosporidium* outbreak, recent research has focused on analyzing water samples for oocysts. The U.S. EPA has developed a method that is recommended for detecting *Cryptosporidium* in raw and treated waters. This method requires the concentration of a water sample, immunomagnetic separation (IMS) of the oocysts from the concentrated debris, and determination of oocyst concentrations by immunofluorescence assay (IFA). Potential oocysts are further stained with vital dyes such as DAPI and propidium iodide, followed by differential interference contrast microscopy.

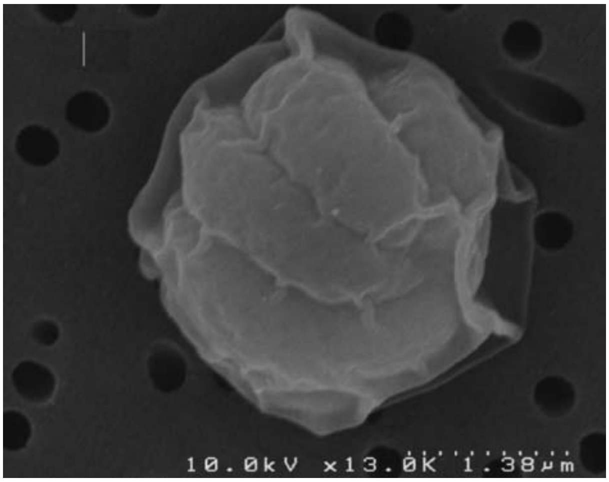

Figure 1. A scanning electron micrograph of a *C. parvum* oocyst. The four crescent-shaped sporozoites are visible within the oocyst. The deflated appearance of the oocyst is the result of dehydration required for sample preparation.

The number of oocysts within water sources is generally low and variable, so large volumes of water need to be concentrated for quantitative analysis. This can be accomplished by filtration, flocculation, or centrifugation. Oocysts are then purified from background detrital material by flotation, immunomagnetic separation, or flow cytometry. The concentrated water samples can be screened by molecular techniques to determine the presence of oocysts. A desired detection method should differentiate between dead or nonviable oocysts, which pose no threat to public health, and those oocysts that are viable and infective. Because only a few oocysts are needed to cause disease, efficient detection methods should be sensitive and amenable to quantification. Additionally, the detection method should differentiate between the *Cryptosporidium* species because not all species are harmful to humans. Molecular detection techniques have the advantage of being more specific, sensitive, reproducible, and often more rapid.

DETECTION OF *CRYPTOSPORIDIUM* INFECTIVITY

Although human infectivity assays are true representations of the disease, they are not practical for routine evaluations of oocyst infectivity. The most direct method for assessing oocyst viability and infectivity is to administer the oocysts experimentally to an animal (typically a neonatal mouse). Following a period of incubation, the intestine is sectioned longitudinally and the cells are examined for histological evidence of infection. Commonly used animal surrogates are neonatal or immunosuppressed rodents, typically CD-1 or BALB/c strains. In addition to ethical concerns, animal infectivity experiments are time-consuming, expensive, and not amenable to routine environmental testing.

Alternatively, *in vitro* infectivity involves exposing oocysts to excystation stimuli followed by inoculating them into a cultured adherent mammalian intestinal cell line, which supports infection and asexual development. Following a suitable infection period, samples are examined by fluorogenically labeled antibodies or nucleic acid sequences specific to *Cryptosporidium*. Based on the presence or absence of infection, the number of infective oocysts can be statistically determined according to a standardized most-probable number (MPN) table or MPN calculator (6).

The success of an *in vitro* cell culture assay depends on the type of cell line, the use of oocysts or sporozoites, preincubation excystation treatment, and centrifugation of the sample. Although cell culture requires intensive labor to grow and maintain the cell monolayer and a prolonged incubation period, the technique remains a good substitute for animal infectivity models. A number of cell lines can support the asexual development of *C. parvum*, but human ileocecal adenocarcinoma (HCT-8) cells that have been found superior in their ability to support parasite growth and represent a practical and accurate alternative to animal infectivity models, yield results similar to those with CD-1 mice in assessing *C. parvum* infectivity (7).

ANTIBODY TECHNOLOGY

Antibodies are produced by immune systems that bind to foreign antigens within the host organism. Strong target affinity, specificity, and sensitivity of antibodies make them ideal for targeting and identifying *Cryptosporidium*. Various types of antibodies can be used for molecular diagnostic methods: monoclonal antibodies (mAbs), polyclonal antibodies (pAbs), and recombinant antibodies (rAbs).

Monoclonal antibodies are identical because they were produced by one type of immune cell, all clones of a single parent cell. In contrast, pAbs are produced by different immune cells and differ from one another. Recombinant antibodies are constructed within a laboratory and are based on the artificial random recombination of antibody genes. This may yield antibodies that may not occur naturally.

Conjugation of antibodies to fluorophores or enzymes allow for the production of a visual signal. Many immunologic methods are available for detecting *C. parvum*, including flow cytometry, immunofluorescence assays (IFA), and enzyme-linked immunosorbent assays (ELISA).

Immunofluorescence Assay (IFA)

Routine detection of *Cryptosporidium* in environmental samples is most commonly performed using the IFA. In detecting the parasite, the characteristics used for identification include size, shape, and fluorescence. The cells become fluorescent via antibody staining, which is carried out either in suspension, on a microscope slide, or on a membrane prior to microscopic examination. Both fluorophore-conjugated pAbs and mAbs are used to identify purified oocysts. Nonspecific fluorescence is a problem with IFAs, along with background fluorescence of detritus, algae, and some freshwater diatoms and cyanobacteria.

Foci Detection Method (FDM)

An *in vitro* cell culture infectivity assay involves exposing oocysts to excystation stimuli followed by inoculating them into a cultured mammalian cell line, which supports infection and asexual development. An infectious focus is the site of infection of at least one sporozoite in the cell culture. After 24–48 h, samples are examined for the presence of infection. Foci are labeled with fluorophore-conjugated antibodies specific to the various life stages of *Cryptosporidium* and are visualized by epifluoresence microscopy.

Enzyme-Linked Immunosorbent Assay (ELISA)

ELISA has been developed to detect and evaluate the growth of *C. parvum* in culture systems using antibodies developed against its various life-cycle stages. ELISA can be used to test multiple samples simultaneously and does not require a high level of technical skill compared with that for identifying parasites based on morphological and staining characteristics by microscopic examination. Tests commonly use 96-well microtitration plates coated by antibodies specific for *Cryptosporidium*. Tests samples are then added to the plate. After washing away nonbinding materials, a second enzyme-conjugated antibody specific to *Cryptosporidium* is added to the sample wells. Addition of the enzyme substrate results in a color reaction to indicate the presence of the parasite. There may be problems of cross-reactivity with algae and turbidity interfering with results, but this can be overcome by the development and use of more specific antibodies.

Flow Cytometry

A flow cytometer analyzes particles in a suspension as they pass by a laser beam. The light scattering pattern is analyzed and correlated to size and internal complexity along with the fluorescent light emitted by each particle. Flow cytometer cell sorters can also sort particles of interest from unwanted particles by using the binding of a fluorescein-conjugated antibody to antigens present on *Cryptosporidium* oocysts. Particles within the sample that do not match the criteria for *Cryptosporidium* are filtered out.

POLYMERASE CHAIN REACTION (PCR) DETECTION METHODS

PCR involves using oligonucleotide primers to amplify a DNA fragment specific to the target organism. The desired fragment is identified by gel electrophoresis and can be subsequently sequenced. PCR is reproducible, cost-effective, sensitive and amenable to quantitation, and capable of differentiating among *Cryptosporidium* species that infect humans. Common gene targets for PCR detection include 18S ribosomal DNA, heat-shock proteins (i.e., *hsp*70), and oocyst wall proteins.

Real-Time PCR

Real-time PCR involves virtual real-time visualization of fluorescence emitted by a fluorogenic probe accumulated during PCR. Quantification of amplified DNA during the exponential phase of the reaction, when reagents are not limiting, allows precise determination of the initial quantity of the target sequences. Real-time PCR offers higher throughput, reduced turnaround time, and minimal amplicon contamination due to a closed-vessel system. The quantification range of real-time PCR methods is greater (5–6 log units) than conventional PCR (2–3 log units).

Cryptosporidium species and genotypes can be differentiated through melt curve analysis, which is based on melting temperature differences of PCR-probe complexes, and reflects the extent of complementation of the probes to the amplified PCR fragments. Real-time PCR investigations for environmental detection have demonstrated that the method is rapid, sensitive, and specific.

Reverse Transcription-PCR (RT-PCR)

Only viable organisms can produce messenger RNA (mRNA), so RT-PCR selectively detects viable organisms. In this method, a specific fragment of the complementary DNA (cDNA), which is produced from an mRNA template by reverse transcriptase, is amplified by PCR. Reverse transcriptase is extremely sensitive to chemical contamination, so the RT step is the source of greatest variability. Common gene targets for RT-PCR analysis of *C. parvum* viability include *hsp70*, amyloglucosidase, and *B*-tubulin.

Cell Culture-PCR (CC-PCR)

Comparable with FDM in detecting oocyst infectivity, a CC-PCR assay involves the extraction of genomic DNA from an infected cell culture and amplification of specific DNA fragments by PCR. A cell culture infectivity assay, coupled with either real-time PCR or an MPN assay, can be used to quantify infective oocysts. Alternatively, mRNA can be extracted from the infected cell culture and subjected to RT-PCR to detect infectious oocysts.

Most Probable Number-PCR (MPN-PCR)

In a standard MPN assay, replicate samples are serially diluted and evaluated by PCR for the presence of *Cryptosporidium*-specific nucleic acid sequences. Used in conjunction with a cell culture infectivity assay, MPN-PCR could provide a good alternative to using FDM alone for enumerating infective oocysts. Because MPN assays are costly, labor-intensive, and require a large volume of samples with multiple preparation steps, alternative detection strategies may be more suitable for quantitative analyses.

NUCLEIC ACID PROBES

Small nucleotide chains (oligonucleotides) can be constructed to a desired DNA sequence. The binding nature of DNA is such that complementary single-stranded DNA (ssDNA) fragments strongly bind to one another, whereas a single nucleotide mismatch drastically reduces the binding strength of the two fragments.

Fluorescent *In Situ* Hybridization (FISH)

FISH uses fluorescently labeled oligonucleotide probes targeted to *C. parvum*-specific sequences, such as ribosomal RNA (rRNA). Ribosomal RNA is used as a target because it should be present in high quantities in viable and potentially infective oocysts, but due to its short half-life, it would be degraded in nonviable oocysts. Oocysts are collected and made permeable to the labeled probes by the addition of organic solvents. Species-specific probes hybridize with target rRNA within the permeabilized oocysts and are detected by epifluorescence microscopy or flow cytometry.

Microarray (DNA Chip)

Microarray technology combines PCR with hybridization of oligonucleotide probes. An array of oligonucleotide probes is synthesized and fixed to a chip. Oocyst genomic DNA is extracted and highly specific, and conserved target genes, such as rRNA and *hsp70*, are amplified by PCR and then fluorescently labeled. For

Table 1. Summary of the Molecular Detection Methods That Can Be Used for Detecting *Cryptosporidium parvum* in Environmental Samples

Detection Method	Differentiate Among *Cryptosporidium* Species	Determine Infectivity	Quantifiable	Detection Limit[a]	Reference

[a] Detection limits are not directly comparable as the conditions used by different researchers may not be similar.

identification at the species level, highly variable or species-specific genes are used. PCR products hybridize with their complementary probe sequences, and the presence or absence of *Cryptosporidium* can be determined by computerized detection of fluorescent emissions. The high throughout capability of microarrays can allow simultaneous detection of numerous different genera of pathogens or species within a genus.

A complete list of the methods described is presented in Table 1. The table indicates whether each method can distinguish among *Cryptosporidium* species, detect oocyst infectivity, quantify detected oocysts, and has a limitation on detection. A reference for each of the methods is also included in the table. A recent review article by Carey et al. (22) provides a more detailed description of *Cryptosporidium* detection methods.

CRYPTOSPORIDIUM

Jacqueline Brabants
University of New Hampshire
Durham, New Hampshire

Cryptosporidia are small, spherical, obligate, intracellular sporozoan parasites that infect the intestinal tract of a wide range of mammals, including humans. *Cryptosporidium* oocysts range in size from 2 to 8 μm, depending on the species and the stage of the life cycle. Oocysts are commonly found in many of the lakes and rivers that supply public drinking water as a result of runoff from sewage and animal wastes applied to nearby fields and pastures or from areas of wildlife or livestock activity (4,7,10). Infection, resulting from ingesting oocysts, manifests as cryptosporidiosis. Although *Cryptosporidium* was first described in 1907, human infection was not reported until 1976. Today, *Cryptosporidium parvum* is well recognized as the cause of the disease cryptosporidiosis in humans and cattle and is one of the more opportunistic agents seen in patients with AIDS that occurs primarily in individuals with compromised immune systems. Currently, there is no totally effective therapy for cryptosporidiosis (3,8,11,12).

LIFE CYCLE AND MORPHOLOGY

Cryptosporidia undergo alternating life cycles of sexual and asexual reproduction that are completed within the gastrointestinal tract of a single host. The developmental stages of the life cycle occur intracellularly and extracytoplasmically and include schizogony, gametogony, fertilization, and sporogony (1). The developmental stages of the organism are contained within a host cell parasitophorous vacuole, located at the microvillous surface of the host cell. The cycle begins when infectious oocysts containing four sporozoites are discharged in the feces of a parasitized animal. These thick-walled oocysts remain viable for months unless exposed to extremes of temperature, desiccation, or concentrated disinfectants (1). Following ingestion by another animal, most likely from food or water that has become fecally contaminated, the oocyst excysts and releases sporozoites that attach to the microvilli of the small bowel epithelial cells, where they develop into trophozoites (2). Trophozoites divide asexually (schizogony) to form schizonts that contain eight daughter cells known as type I merozoites. Upon release from the schizont, these cells attach to another epithelial cell, and the schizogony cycle is repeated to produce schizonts that contain four type II merozoites. Type II merozoites develop into male (microgametocyte) and female (macrogametocyte) sexual forms. Fertilization results in a zygote (oocyte) that develops into an oocyst, which is ultimately shed into the lumen of the bowel. The oocysts undergo sporulation to the infective stage within the brush border of the enterocytes and are excreted as infectious oocysts in the stool (3–5).

The majority of oocysts generated possess a thick, protective cell wall that ensures their intact passage in the feces and survival in the environment; however, approximately 20% of the oocysts generated fail to develop the thick wall, and following release from a host cell, the thin cell membrane on these oocysts ruptures and releases four infectious sporozoites. These sporozoites penetrate the intestinal lumen and initiate a new autoinfective cycle within the original host. The presence of this thin-walled, autoinfective oocyst can lead to an overwhelming infection that creates a persistent, life-threatening infection in an immunocompromised individual (4).

CLINICAL DISEASE

The pathogenesis of *Cryptosporidia* is not completely understood; age and immune status at the time of primary exposure do not appear to influence susceptibility to infection. However, once the primary infection has been established, the immune status of the host plays an extremely important role in determining the length and severity of the illness (4).

Cryptosporidia undergo their life cycle in the enteric epithelial cells and also in the gallbladder, respiratory, and renal epithelium, especially in immunocompromised hosts (1). The symptom found in all reported cases is acute diarrhea (2). Clinical symptoms found in immunocompetent individuals include nausea; low-grade fever; abdominal cramps; anorexia; and profuse watery, frothy bowel movements that may be followed by constipation. Other individuals may be asymptomatic, particularly later in the course of the infection. In patients who have the typical watery diarrhea, the stool specimen will contain very little fecal material, consisting mainly of water and mucus flecks, and the organisms are trapped in the mucus. In most cases, a patient who has a normal immune system will have a self-limited infection lasting 1 to 2 weeks, whereas a patient who is immunocompromised may have a chronic infection with symptoms ranging from asymptomatic to severe (2,4). Studies to examine susceptibility and serologic responses to reinfection have demonstrated that previous exposure of immunocompetent adults to *Cryptosporidium* is not entirely protective but may decrease the severity of disease and the number of oocysts shed (6).

Cryptosporidium can generate life-threatening infections in immunocompromised individuals, particularly in human AIDS patients (1). In these individuals, the duration and severity of diarrheal illness will depend on the immune status of the patient. It is believed that cryptosporidiosis in AIDS patients causes malabsorption and intestinal injury in proportion to the number of organisms that infect the intestine. Most severely immunocompromised patients cannot overcome the infection; the illness becomes progressively worse with time and leads to death. The disease is prolonged; profuse, watery diarrhea persists from several weeks to months or years, as a result of the autoinfective nature of the organism, reportedly resulting in fluid losses as high as 25 L/day (7). In such patients, infections in areas other than the gastrointestinal tract may cause additional symptoms such as respiratory problems, cholecystitis, hepatitis, and pancreatitis (4).

Diagnosis

Oocysts recovered in clinical specimens usually represent the 80% that are thick-walled. The oocysts are difficult to visualize because of their small, colorless, transparent appearance, and may be confused with yeast cells. In the past, cryptosporidiosis has been diagnosed following examination of small or large bowel biopsy material, under both light and electron microscopy; however, in *Cryptosporidium* infections, the entire mucosa may not be infected uniformly; therefore, biopsy specimens may miss the infected area. As a result, cases have recently been diagnosed by recovering the oocysts from fecal material using flotation or fecal concentration techniques. Diagnosis is achieved by demonstrating the oocysts in feces, sputum, or possibly respiratory secretions (3). Special staining techniques such as the modified acid-fast, Kinyoun's, and Giemsa methods may be employed to enhance visualization, along with the direct fluorescent-antibody (FA) or enzyme-linked immunosorbent assay (ELISA) techniques that incorporate monoclonal antibody reagents (4).

Recently, the issues of water quality and water testing have become more important and controversial. Today, most water utilities have developed their own water quality testing laboratories or contracted with commercial water laboratories for the recovery and identification of *Cryptosporidium*. Currently, the most common methods for capturing and recovering oocysts from water employ polypropylene cartridge filters or membrane filtration. The oocysts are subsequently eluted and may be concentrated on a percoll-sucrose gradient by flotation or by immunomagnetic separation (IMS) and visualized with commercially available immunofluorescence assay kits. Oocysts are often present in small numbers in environmental samples; therefore, molecular techniques involving the polymerase chain reaction (PCR) may also be used to detect oocysts in water samples (2,8). Integrated cell culture-PCR infectivity assays address the drawbacks of alternative methods such as vital dye staining by allowing for both detection of organisms and the determination of viability and infectivity (9). Considering that, under favorable conditions of moisture and moderate temperature, oocysts can remain viable and infectious for a relatively long time and have been reported viable after storage for 12 months, a great need still exists for simple, efficient, and reliable procedures for capturing and recovering *Cryptosporidium* oocysts from water (10) (Fig. 1).

Treatment

There is no effective specific treatment for *Cryptosporidium* infection, despite testing of hundreds of compounds (1,6). Cryptosporidiosis tends to be self-limiting in patients who have an intact immune system; the clinical course of infection varies, depending on the immune status of the host. Treatment with antidiarrheal drugs along with rehydration therapy may reduce the severity of acute cryptosporidiosis but is less effective for chronic cryptosporidiosis that involves the colon and extraintestinal tissues (4). The antibiotic paromomycin, it has been shown, slightly reduces parasite numbers and stool frequency and may be combined with azithromycin as a course of treatment (6,11). The establishment of a parasitophorous vacuole within the host cell may somehow protect the parasite from antimicrobial drugs (6).

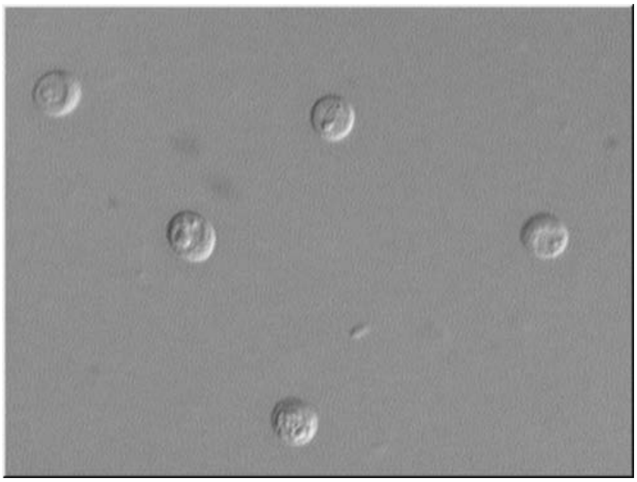

Figure 1. *Cryptosporidium parvum* oocysts viewed at 1000× magnification by Nomarski differential interference contrast (DIC) magnification.

Epidemiology and Prevention

Cryptosporidium is transmitted by oocysts that are usually fully sporulated and infective when they are passed in stool. The principal transmission route is direct fecal–oral spread and transmission by contaminated water. Calves and other animals such as livestock, dogs, cats, and wild mammals are potential sources of human infections, and contact with these animals or their feces may be an unrecognized cause of gastroenteritis in humans (1). Generally, young children tend to have higher infection rates, and there is a high prevalence of cryptosporidiosis in children in areas where sanitation and nutrition are poor (10). Direct person-to-person transmission is likely and may occur through direct or indirect contact with stool material. Outbreaks of human disease in day-care centers, hospitals, and urban family groups indicate that most human infections result from person-to-person contact (5). Indirect transmission may occur from exposure to positive specimens in a laboratory, from contaminated surfaces, or from consuming contaminated food or water. In healthy adults who have no serologic evidence of past infection by *Cryptosporidium parvum*, as few as thirty *Cryptosporidium parvum* oocysts is sufficient to cause infection, and in some cases, infection has occurred from just one oocyst (11). In the United States, the parasite has been identified in 15% of patients who have AIDS and diarrhea (5).

The potential contamination of water supplies by *Cryptosporidium* oocysts is a considerable issue for the drinking water industry. Oocysts can penetrate physical barriers and withstand the conventional disinfection processes used for drinking water treatment. Waterborne outbreaks of *Cryptosporidium* are an increasing public health problem and have resulted from untreated surface water, filtered public water supplies, and contaminated well water (3,12). Large-scale outbreaks of cryptosporidiosis in industrialized countries have been associated with contamination of community drinking water (9). Disease transmission through the waterborne route is especially important because of the capacity for affecting large communities of susceptible individuals. A massive waterborne outbreak was reported in Milwaukee, Wisconsin, where contamination of the public water supply during March and April of 1993 resulted in more than 400,000 infections and about 50 deaths (12,13). Additional outbreaks involving public swimming pools and wading pools demonstrate the ability of *Cryptosporidium* to cause infection even when ingested in small amounts of fully chlorinated water (11).

The increase in the number of reported waterborne disease outbreaks associated with the *Cryptosporidium* species can be attributed to improved techniques for oocyst recovery and identification resulting in the demonstration of oocysts in surface and drinking water and in sewage effluents. It is very likely that cryptosporidiosis is underdiagnosed, especially in immunocompetent adults and children, as analysis for the oocysts is not normally included in a routine stool analysis (6). The importance of agricultural wastewater and runoff, particularly from lambs and calves, is also now recognized as a potential source of infective *Cryptosporidium* oocysts (4).

Prevention involves taking proper steps to reduce the likelihood of waterborne contamination. Properly drilled and maintained wells that tap into groundwater are unlikely to contain pathogens because of the natural filtration that takes place as water passes through the soil; however, contamination may still occur if surface water can move through coarse soils or fractured bedrock into groundwater aquifers. Shallow or poorly constructed wells and springs are at risk of contamination from surface water runoff; therefore, wells should be protected from surface contamination by an intact well casing, proper seals, and a cap above ground (14). Human and animal waste contamination are minimized by protecting the watershed, controlling land use, creating and enforcing septic system regulations, and best management practices in an effort to control runoff (14).

Cryptosporidium oocysts are susceptible to ammonia, 10% formalin in saline, freeze-drying, exposure to temperatures below freezing or above 65 °C for 30 minutes, and 50% commercial bleach (4). For individuals who wish to take extra measures to avoid waterborne cryptosporidiosis in their drinking water, according to the EPA and the CDC, boiling the water is the most effective way of killing the organism (15). In addition to boiling water, oocysts can be removed by certain types of filters to ensure that drinking water is safe (14).

MEASURING *CRYPTOSPORIDIUM PARVUM* OOCYST INACTIVATION FOLLOWING DISINFECTION WITH ULTRAVIOLET LIGHT

Zia Bukhari
American Water
Voorhees, New Jersey

Historically, ultraviolet light inactivation of *Cryptosporidium parvum* oocysts was considered ineffective; however, recently it was demonstrated that the methods for measuring oocyst inactivation can yield erroneous results and that neonatal mouse infectivity assays, which indicated that very low UV doses are highly effective for oocyst inactivation, are needed for determining inactivation of UV-treated oocysts. The moral, ethical, and financial constraints of using mouse infectivity has generated the need for more user-friendly alternative methods for measuring oocyst inactivation. Cell culture infectivity assays are considered promising alternatives, and this article discusses a cell culture-immunofluorescence (IFA) procedure, which following optimization, yielded results similar to those expected from mouse infectivity assays. This cell culture-IFA procedure will be an invaluable analytical tool for control or bench scale studies using *C. parvum* oocysts and the same water matrices as those intended for use in UV reactor validation studies.

HISTORICAL PERSPECTIVE

A number of investigators have examined the effect of low-pressure UV light on viruses and bacteria (1,2) and found that MS2 bacteriophage requires approximately 70 mJ/cm^2 of UV light to render 4-log inactivation and that hepatitis A virus requires fourfold lower UV doses to yield similar levels of inactivation. From the studies of Wilson et al. (1), MS2 bacteriophage was approximately two times more resistant than viruses and three to ten times more resistant than bacteria. Protozoan parasites, which display greater resistance than bacteria or viruses to chemical disinfectants, were examined for their susceptibility to UV light by Karanis et al. (3). Reportedly delivery of 400 mJ/cm^2 yielded 3-log inactivation of *Trichomonas vaginalis*, and *Giardia lamblia* required 180 mJ/cm^2 to yield 2-log inactivation. In 1993, Lorenzo-Lorenzo et al. (4) examined the impact of UV light on *Cryptosporidium* oocysts; however, due to an inadequate description of their disinfection experiments, the effectiveness of UV light for *Cryptosporidium* oocyst inactivation was not recognized. Two years later, a unit known as the *Cryptosporidium* inactivation device (CID), which delivered a total UV dose of 8748 mJ/cm^2 from low-pressure lamps, was examined and 2- to 3-log inactivation of oocysts was reported using the fluorogenic vital dye assay (4′-6′-diamidino-2-phenylindole and propidium iodide) and *in vitro* excystation (5). Following this, Clancy et al. (6) confirmed the findings of Campbell et al. (5); however, the apparent requirement for high UV doses for significant oocyst inactivation continued to present an obstacle to the regulatory and water industry in supporting implementation of this technology.

From 1998 to 1999, comparative bench scale and demonstration scale (215 gpm) *Cryptosporidium* oocyst inactivation studies were performed that used medium-pressure UV lamps and examined oocyst inactivation using *in vitro* viability assays (DAPI/PI and *in vitro* excystation) as well as mouse infectivity assays (7). These studies conclusively demonstrated the effectiveness of low UV doses for inactivating *Cryptosporidium* in finished water. These data rapidly gained attention from both regulatory agencies and the water industry and instigated the revolution in the U.S. water industry for UV disinfection to inactivate *Cryptosporidium* oocysts effectively. In addition to demonstrating the effectiveness of low levels of UV light for oocyst inactivation, Bukhari et al. (7) also found that *in vitro* viability assays underestimated oocyst inactivation following their exposure to either UV light or ozonation (8) and that mouse infectivity assays, albeit cumbersome, needed to be the methods of choice for future studies of this nature. Following these initial studies, a number of investigators confirmed the effectiveness of UV light for inactivating *Cryptosporidium* oocysts as well as *Giardia* cysts (9) and Microsporidia spores (10).

MEASURING *C. PARVUM* OOCYST INACTIVATION FOLLOWING EXPOSURE TO UV LIGHT

In vitro assays for determining the viability of *C. parvum* oocysts offer several advantages over the traditional animal infectivity assays in that results can be generated in a short time. Although these assays are relatively simple to use and relatively inexpensive, recently it was shown that they do not accurately demonstrate whether oocysts are capable of infectivity in neonatal mice. For example, using fluorogenic vital dyes (i.e., DAPI/PI, SYTO-9, and SYTO-59) or *in vitro* excystation, the viability information for oocysts subjected to ultraviolet light (7) or ozone (8) disinfection was grossly overestimated compared with infectivity data using neonatal mice. Unfortunately the "gold" standard mouse infectivity assays have various limitations, which in addition to the moral, ethical, and financial constraints of animal experimentation, include the high degree of variability of using outbred strains of neonatal mice. As a result, the water industry has been seeking alternative, more user-friendly procedures for measuring oocyst viability/infectivity.

In vitro infectivity assays for determining *C. parvum* oocyst inactivation have the potential to fill this void. One such *in vitro* infectivity assay uses human ileocecal adenocarcinoma (HCT-8) cells in conjunction with quantitative polymerase chain reaction (q-PCR) and has been used previously to determine the infectivity of environmentally derived oocysts (11). This assay has the advantage of providing a direct indication of the amount of amplifiable DNA with a specific set of primers. Furthermore, this assay also can help avoid the high variability of using the most probable number format of mouse infectivity assays. Using this assay to measure inactivation of bench-scale, UV-treated *C. parvum* oocysts indicated log inactivation values of 1.16, 1.24, and 1.84 logs for 10, 20, and 40 mJ/cm^2, respectively. These inactivation values for *C. parvum* oocysts were considerably lower than those reported in previous studies using mouse infectivity assays (7,12). Previous research has indicated that oocysts exposed to UV doses ranging between 10 and 40 mJ/cm^2 continue to respond to excystation stimuli and release their sporozoites. This suggests that UV-treated oocysts inoculated onto cell monolayers could potentially excyst, and then released sporozoites could invade cell monolayers. Examination of HCT-8 monolayers confirmed the presence of pinpoints of invasion, which probably originated from invasive sporozoites (Fig. 1). A number of different oocyst pretreatment steps were used to promote differentiation between UV affected and unaffected sporozoites; however, these pretreatments did not nullify the background signal detected by the quantitative PCR procedures.

Figure 1. UV-treated oocysts yielding pinpoints of invasion.

CELL CULTURE-IFA FOR MEASURING INACTIVATION OF UV-TREATED *C. PARVUM* OOCYSTS

Bukhari and LeChevallier (13) used an infectivity-enhancing oocyst pretreatment step consisting of preacidification and 0.05% bile treatment followed by inoculation onto HCT-8 monolayers, incubation at 37 °C for 72 h, and quantitative detection of infection by immunofluorescence microscopy. The rationale behind this assay was that UV-treated oocysts would undergo excystation and subsequently invade HCT-8 cells, leading to discrete pinpoints of invasion. In contrast, untreated organisms would invade the HCT-8 cells but would continue to differentiate further to generate clusters of secondary infection (Fig. 2).

Enumerating secondary clusters of infection for various inocula of oocysts (i.e., 10,100, and 1000 oocysts) has enabled development of a dose response curve (Fig. 3). This curve, which was generated from multiple trials ($n = 75$ to 115) using predetermined oocyst inocula, was analyzed by linear regression to derive an equation for calculating the number of infectious organisms present in an inoculum of UV-treated oocysts after the number of clusters had been determined by immunofluorescence microscopy.

UV disinfection experiments using the Iowa isolate of *C. parvum* oocysts were conducted, and following cell culture infectivity, the infectious clusters were extrapolated from the dose response curve generated for the untreated oocysts to calculate levels of inactivation (Fig. 4). A UV dose of 1 mJ/cm^2 rendered 0.44 log inactivation of oocysts, and UV doses between 1 and 4 mJ/cm^2 yielded a linear decline in oocyst inactivation; 3 mJ/cm^2 rendered 2.79–2.84 log inactivation, and 4-log inactivation occurred at 4 mJ/cm^2. Between 4 and 20 mJ/cm^2, measurements by the cell culture procedure continued to indicate oocyst inactivation levels of 4 logs. It is highly probable that the actual levels of oocyst inactivation after UV doses between 4 and 20 mJ/cm^2 were in excess of 4 logs; however, as the determinable oocyst inactivation by the cell culture procedure is a factor of the highest original inoculum of UV-treated oocysts applied onto the monolayers (i.e., 1×10^5 oocysts), the maximum measurable levels of inactivation by this cell culture procedure were limited to 4 logs or lower in these experiments. Although theoretically it would be possible to use higher oocyst inocula (i.e., 1×10^6–1×10^8 oocysts per monolayer) to accurately determine the levels of oocyst inactivation at individual UV doses between 4 and 20 mJ/cm^2, this would be of little empirical value from the perspective of the disinfection needs of the water industry or the logistics of conducting experiments with adequate quantities of infectious oocysts.

As a result of the investigations by Bukhari and LeChevallier (13), it has been demonstrated that UV-treated *C. parvum* oocysts can undergo excystation and that the sporozoites from these inactivated oocysts can invade monolayers of HCT-8 cells to generate pinpoints of invasion. Optimization of excystation triggers and cell culture incubation periods led to development of a cell culture-IFA procedure that enabled detecting as few as 10 infectious oocysts. Using this cell culture-IFA allowed discriminating pinpoints (generated from noninfectious but invasive sporozoites) from secondary structures (generated from infectious sporozoites). This phenomenon is the primary reason that the cell culture quantitative PCR procedure described by DiGiovanni et al. (11) cannot be used to measure inactivation of UV-treated oocystes because the assay cannot discriminate between DNA originating from invasive sporozoites and that from infectious sporozoites.

Using the optimized cell culture-IFA procedure, it was confirmed that low UV doses (i.e., 2–5 mJ/cm^2) can be very effective for inactivating *C. parvum* oocysts. Comparison of data from this current study with previously published reports, using either tissue culture infectivity or mouse

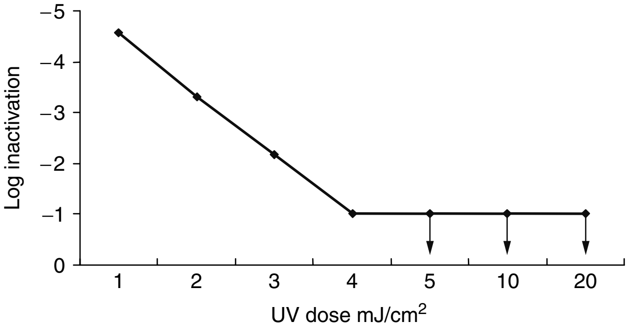

Figure 4. Inactivation of *C. parvum* oocysts by UV light, as determined by the cell culture-IFA procedure.

infectivity assays, also demonstrates excellent agreement. Numerous studies (9,12,14,15) have assessed levels of oocyst inactivation from UV doses ranging between 1 and <40 mJ/cm^2. Not surprisingly, there is wide variability in the data generated from these various studies, which may result from differences in oocyst preparation, disinfection conditions, and methods for infectivity measurements. Nonetheless, using UV doses between 1 and 3 mJ/cm^2, the oocyst inactivation data generated in our current study were within the range of inactivation data generated in the studies cited (Fig. 5).

Data from the previous disinfection studies have also been used in the USEPA's Ultraviolet Disinfection Guidance Manual, to predict the probable levels of oocyst inactivation for a given UV dose. According to these probability tables, the UV dose required for 0.5-log inactivation of oocysts ranged from 0.7 to 3.0 mJ/cm^2, whereas in our current study, 0.44-log inactivation of *C. parvum* oocysts was noted at delivery of 1 mJ/cm^2. The probability tables also predicted 50% likelihood that a UV dose of 2.9 mJ/cm^2 would lead to 2.5-log oocyst inactivation, whereas in our study, delivery of 3 mJ/cm^2 led to approximately 2.8-log inactivation. Although our data indicated 3- and 4-log oocyst inactivation from UV doses as low as 4 mJ/cm^2 and consistently >4-log inactivation of oocysts from UV doses ranging between 5 and 20 mJ/cm^2, >4-log oocyst inactivation was noted only when UV doses exceeded 10 mJ/cm^2 in the previous studies cited. At 5 mJ/cm^2, although our data indicated >4-log inactivation, the previous studies indicated >1-log and approximately 3-log inactivation of oocysts. These differences need to be interpreted with caution and do not necessarily imply differences in susceptibility between the isolates of *C. parvum* used. As an example, it is known that the oocyst inactivation levels can be censored as a result of the original oocyst inoculum administered in the infectivity assay, which in turn influences the outcome of the calculated levels of oocyst inactivation. In (Fig. 5), examining the inactivation data at 5 mJ/cm^2 suggests that a single oocyst inactivation value (>1 log) may be an outlier. Perhaps this inactivation level was derived from administering a lower inoculum of oocysts (i.e., 1×10^3 oocysts) than the inoculum size (i.e., 1×10^5 oocysts) used in our study. Should this be the case, then it would argue that our data provide a more robust indication of the levels of oocyst inactivation than those generated from censored data. Furthermore, examining the general oocyst inactivation patterns for increasing UV doses in (Fig. 5) adds further credibility to the previous discussion, as data accrued during the course of our study both overlap and extend the general trend in oocyst inactivation provided by previous UV disinfection studies. This would further support the finding that oocyst inactivation levels at 5 mJ/cm^2 are more likely to be greater than 3 or 4 logs.

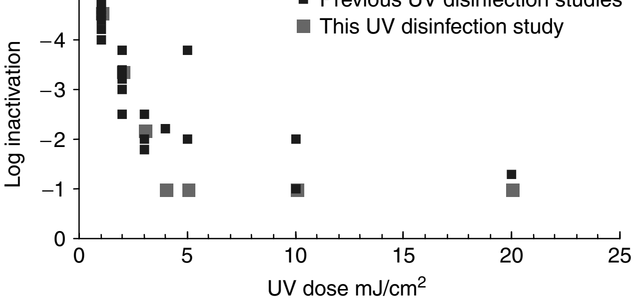

Figure 5. *Cryptosporidium parvum* oocyst inactivation in various UV disinfection studies.

In conclusion, UV disinfection is a promising technology for rapid and effective inactivation of waterborne *C. parvum* oocysts. Numerous manufacturers can supply equipment using medium-pressure, low-pressure, or low-pressure, high-output lamps within their UV reactors. For water utilities to select the appropriate UV reactors for their disinfection requirements, it is imperative that reactors are validated on-site or off-site using the matrices intended for disinfection. Although the validation studies are likely to be conducted using surrogate organisms such as the MS2 bacteriophage, it is imperative to do control- or bench-scale studies also using the same matrix and *C. parvum* oocysts. For the latter, the cell culture-IFA procedure described in this article is an invaluable analytical tool.

DECHLORINATION

Rasheed Ahmad
Khafra Engineering Consultants
Lilburn, Georgia

Dechlorination is the practice of removing all or a specified fraction of total residual chlorine. In potable water practice, dechlorination is used to reduce the residual chlorine to a specified level at a point where the water enters the distribution system. Dechlorination has been beneficial for waters that are burdened with high concentrations of ammonia nitrogen and organic nitrogen. In some cases where taste and odor control is a severe problem, control is achieved by complete dechlorination, followed by rechlorination. This removes the taste-producing nuisance residuals and prevents the formation of nitrogen trichloride (NCl_3) in the distribution systems. Dechlorination of wastewater and power plant cooling water is required to eliminate residual chlorine toxicity, which is harmful to the aquatic life in the receiving waters. Other special applications requiring dechlorination are ahead of demineralizers, boiler makeup water, certain food plant operations, bottled water, and the beverage industry. In these cases, the dechlorination process is arranged to remove all residual chlorine.

The most practical method of dechlorination is by sulfur dioxide and/or aqueous solutions of sulfite compounds. Among sulfur/sulfite compounds, sulfur dioxide (SO_2) is the most widely used chemical for dechlorination. Other compounds such as sodium bisulfite ($NaHSO_3$) and sodium metabisulfite ($Na_2S_2O_5$) can be used as practical alternatives to sulfur dioxide. Sodium thiosulfate ($Na_2S_2O_3$) is another chemical that is used entirely as a laboratory dechlorinating chemical. Other methods used for dechlorination are granular-activated carbon and aeration.

Free and combined residual chlorine can be effectively reduced by sulfur dioxide and sulfite salts. Free chlorine is the amount of chlorine available as dissolved chlorine gas (Cl_2), hypochlorous acid (HOCl), and hypochlorite ion (OCl^-) that is not combined with ammonia (NH_3) or any other compounds in water. Combined chlorine is the sum of species composed of free chlorine and ammonia, including monochloramine (NH_2Cl), dichloramine ($NHCl_2$), and trichloramine or nitrogen trichloride (NCl_3). The sulfite ion is the active agent when sulfur dioxide or sulfite salts are dissolved in water. Their dechlorination reactions are identical. Sulfite reacts instantaneously with free and combined chlorine. Reactions yield small amounts of acidity, which is neutralized by the alkalinity of water (2.8 milligrams of alkalinity as calcium carbonate is consumed per milligram of chlorine reduced). Most potable waters and wastewaters have sufficient alkalinity buffering power that there is no cause for concern about lowering the pH by sulfur dioxide addition. The amount of sulfur dioxide required per part of chlorine is 0.9, but in actual practice, this ratio can be as high as 1.05. Owing to the low vapor pressure of sulfur dioxide, special precaution must be taken when using ton containers to prevent reliquefication. Unlike chlorination, dechlorination with sulfur dioxide does not require any contact chamber as the reaction occurs in a matter of seconds, probably 15–20 s at the most. There has been some apprehension about the possibility that excess sulfur dioxide might consume a significant amount of dissolved oxygen in the receiving waters downstream from a dechlorinated water discharge. In properly controlled systems, this reaction does not have sufficient time for completion. Hence, little effect on dissolved oxygen concentration has been reported.

Granular and powdered carbon may be used to dechlorinate free, and some combined, chlorine residuals. The carbon requirements for dechlorination are typically determined by on-site pilot testing. The parameters of significance include mean particle diameter of carbon (pressure drop within the carbon contactor) and influent quality (pH, organics, and colloids). Carbon doses in the range of 30 to 40 mg/L have been reported. Granular-activated carbon (GAC) has proved effective and reliable as a dechlorination agent in potable water treatment. In addition, carbon provides filtration that removes other undesirable materials. In wastewater treatment, however, GAC has not been successful as a dechlorinating agent, possibly, because GAC is poor at removing organochloramines that form when significant concentrations of organic nitrogen are present. Because of the higher cost of carbon systems, their use is typically limited to specific sites or effluent with special discharge limitations. An aeration process can be used for dechlorination. Chlorine, hypochlorous acid, chlorine dioxide, and nitrogen trichloride are sufficiently volatile to be removed by aeration.

DESALINATION

NIKOLAY VOUTCHKOV
Poseidon Resources Corporation
Stamford, Connecticut

INTRODUCTION

Desalination is the production of fresh, low-salinity potable water from a saline water source (seawater or brackish water) via membrane separation or evaporation. The mineral/salt content of the water is usually measured by the water quality parameter, total dissolved solids (TDS), in milligrams per liter (mg/L) or parts per thousand (ppt). The World Health Organization and the United Sates Environmental Protection Agency (EPA), under the Safe Drinking Water Act, have established a maximum TDS concentration of 500 mg/L as a potable water standard. This TDS level can be used as a classification limit to define potable (fresh) water. Typically, water of TDS concentration higher than 500 mg/L and lower or equal to 15,000 mg/L is classified as brackish. Natural water sources such as sea, bay, and ocean waters that usually have TDS concentrations higher than 15,000 mg/L are generally classified as seawater. For example, Pacific Ocean seawater along the U.S. West Coast has a TDS concentration of 35,000 mg/L, of which approximately 75% is sodium chloride. Approximately 97.5% of the water on our planet is located in the oceans and therefore is classified as seawater. Of the 2.5% of the planet's fresh water, approximately 70% is polar ice and snow, and 30% is groundwater, river and lake water, and air moisture. So even though the volume of the earth's water is vast, less than 10 million of the 1400 million cubic meters of water on the planet are of low salinity and are suitable for use after using only conventional water treatment. Desalination provides a means for tapping the world's main water resource—the ocean.

During the past 30 years, desalination technology has made great strides in many arid regions of the world such as the Middle East and the Mediterranean. Today, desalination plants operate in more than 120 countries worldwide, and some desert states, such as Saudi Arabia and the United Arab Emirates, rely on desalinated water for more than 70% of their water supply. According to the 2003 desalination plant inventory report prepared by the International Desalination Association (1), by the end of 2001, worldwide there were 15,233 desalination plants whose total installed treatment capacity is 32.4 million cubic meters per day (8560 MGD).

Seawater or brackish waters are typically desalinated using two general types of water treatment technologies—thermal evaporation (distillation) and membrane separation. Currently, approximately 43.5% of the world's desalination systems use thermal evaporation technologies. This percentage has been decreasing steadily during the past 10 years due to the increasing popularity of membrane desalination, which is driven by remarkable advances in membrane separation and energy recovery technologies and associated reduction of overall water production costs.

THERMAL DESALINATION

All thermal desalination technologies use distillation (heating of source water) to produce water vapor that is then condensed into low-salinity potable water. Thermal desalination is most popular in the Middle East, where seawater desalination is typically combined with power generation, which provides low-cost steam for distillation. Thermal desalination requires a large quantity of steam. The ratio of the mass of potable water produced to the mass of heating steam used to produce this water is commonly referred to as a gain output ratio (GOR) or performance ratio. Depending on the thermal desalination technology used, site-specific conditions, and the source water quality, the GOR varies between 2 and 24. The thermal desalination technologies most widely used today are multistage flash distillation (MSF), multiple effect distillation (MED), and vapor compression (VC).

Multistage Flash Distillation

In the MSF evaporator vessels (flash stages or effects), high-salinity source water is heated, whereas the vessel pressure is reduced to a level at which the water vapor "flashes" into steam. Each flash stage (effect) has a condenser to turn the steam into distillate. The condenser is equipped with heat exchanger tubes that are cooled by the source water fed to the condensers. An entrainment separator removes high-salinity mist from the low-salinity rising steam. This steam condenses into pure water (distillate) on the heat exchanger tubes and is collected in distillate trays from where it is conveyed to a product water tank. Historically, MSF is the first commercially available thermal desalination technology used to produce potable water on a large scale, which explains its popularity. More than 80% of the thermally desalinated water today is produced in MSF plants. The GOR for the MSF systems is typically between 2 and 8. The pumping power required to operate MSF systems is 2.0 to 3.5 kWh per cubic meter of product water.

Multiple Effect Distillation

In the MED process, the source water passes through a number of evaporators (effects or chambers) connected in series and operating at progressively lower pressures. In MED systems, the steam vapor from one evaporator (effect) is used to evaporate water from the next effect. MED desalination systems typically operate at lower temperatures than MSF plants (maximum brine concentrate temperature of 75 °C vs. 115 °C) and yield higher GORs. The newest MED technologies, which include vertically positioned effects (vertical tube evaporators or VTEs), may yield GORs up to 24 kilograms of potable water per kilogram of steam. The pumping power required to operate MED systems is also lower than that typically needed for MSF plants (0.8 to 1.4 kWh per cubic meter of product water). Therefore, MED is now increasingly gaining ground over MSF desalination, especially in the Middle East where thermal desalination is still the predominant method for potable water production from seawater.

Vacuum Compression

The heat source for VC systems is compressed vapor produced by a mechanical compressor or a steam jet ejector rather than a direct exchange of heat from steam. In these systems, the source water is evaporated and the vapor is conveyed to a compressor. The vapor is then compressed to increase its temperature to a point adequate to evaporate source water sprayed over a tube bundle through which the vapor is conveyed. As the compressed vapor exchanges its heat with the new source water that is being evaporated, it condenses into pure water. VC desalination has been used mostly for small municipal and resort water supply systems and industrial applications. The power required to operate mechanical VC systems is typically between 10 and 20 kWh per cubic meter of product water. Further discussion of the applicability of the thermal desalination technologies described is presented elsewhere (2,3).

MEMBRANE DESALINATION

Membrane desalination is a process of separating minerals from source water using semipermeable membranes. Two general types of technologies are currently used for membrane desalination—reverse osmosis (RO) and electrodialysis (ED). In reverse osmosis, the product water (permeate) is separated from the salts in the source water by pressure-driven transport through a membrane. By the RO process, desalinated water is transported under pressure through the membrane while the minerals of the source water are concentrated and retained by the membrane. Applying high pressure for desalination is mainly needed to overcome the naturally occurring process of osmosis, which drives the desalinated water back through the membrane into the water of more concentrated mineral content. Nanofiltration (NF) is a process similar to RO, where membranes whose order-of-magnitude larger pore size is used to remove high-molecular-weight compounds that make water hard (i.e., calcium and magnesium).

Desalination by Electrodialysis

In ED-based treatment systems, the mineral–product water separation is achieved by applying electrical direct current (DC) to the source water, which drives the mineral ions in the source water through membranes to a pair of electrodes of opposite charge. A commonly used desalination technology that applies the ED principle is electrodialysis reversal (EDR). In EDR systems, the polarity of the electrodes is reversed periodically during the treatment process.

The energy for ED desalination is proportional to the amount of salt removed from the source water. TDS concentration and source water quality determine to a great extent which of the two membrane separation technologies (RO or ED) is more suitable and cost-effective for a given application. Typically, ED membrane separation is cost-competitive for source waters whose TDS concentration is lower than 2000 mg/L. The TDS removal efficiency of ED desalination systems is not affected by nonionized compounds or objects of weak ion charge (i.e., solids particles, organics, and microorganisms). Therefore, the ED membrane desalination process can treat source waters of higher turbidity, biofouling, and scaling potential than RO systems. However, the TDS removal efficiency of ED systems is typically lower than that of RO systems (15 to 90% vs. 99.0% to 99.8%), which is one key reason why they are used mainly for brackish water desalination.

Reverse Osmosis Desalination

Reverse osmosis desalination is the most widely used membrane separation process today. Currently, there are more than 2000 RO membrane seawater desalination plants worldwide whose total production capacity is in excess of 3 million cubic meters per day (800 MGD). For comparison, the number of ED plants in operation is less than 300, and their total production capacity is approximately 0.15 million cubic meters per day (40 MGD).

RO membrane desalination plants include the following key components: a source water intake system, pretreatment facilities, high-pressure feed pumps, RO membrane trains, and a desalinated water conditioning system. The source water intake system could be an open surface water intake or a series of seawater beach wells or brackish groundwater wells. Depending on the source water quality, the pretreatment system may include one or more of the following processes: screening, chemical conditioning, sedimentation, and filtration. Figure 1 shows a typical configuration of a seawater RO membrane system. The filtered water produced by the plant's pretreatment system is conveyed by transfer pumps from a filtrate water storage tank through cartridge filters and into the suction pipe of the high-pressure RO feed pumps. The cartridge filters are designed to retain particles of 1 to 20 microns that have remained in the source water after pretreatment. The main purpose of the cartridge filters is to protect the RO membranes from damage. The high-pressure feed pumps are designed to deliver the source water to the RO membranes at a pressure required for membrane separation of the freshwater from the salts, typically 15 to 35 bars (200 to 500 psi) for brackish source water and 55 to 70 bars (800 to 1,000 psi) for seawater. The feed pressure required is site-specific and is mainly determined by the source water salinity and the configuration of the RO system.

The "engine" of every desalination plant that turns seawater into fresh potable water is the RO membrane element (Fig. 2). The most widely used RO membrane element consists of two membrane sheets glued together

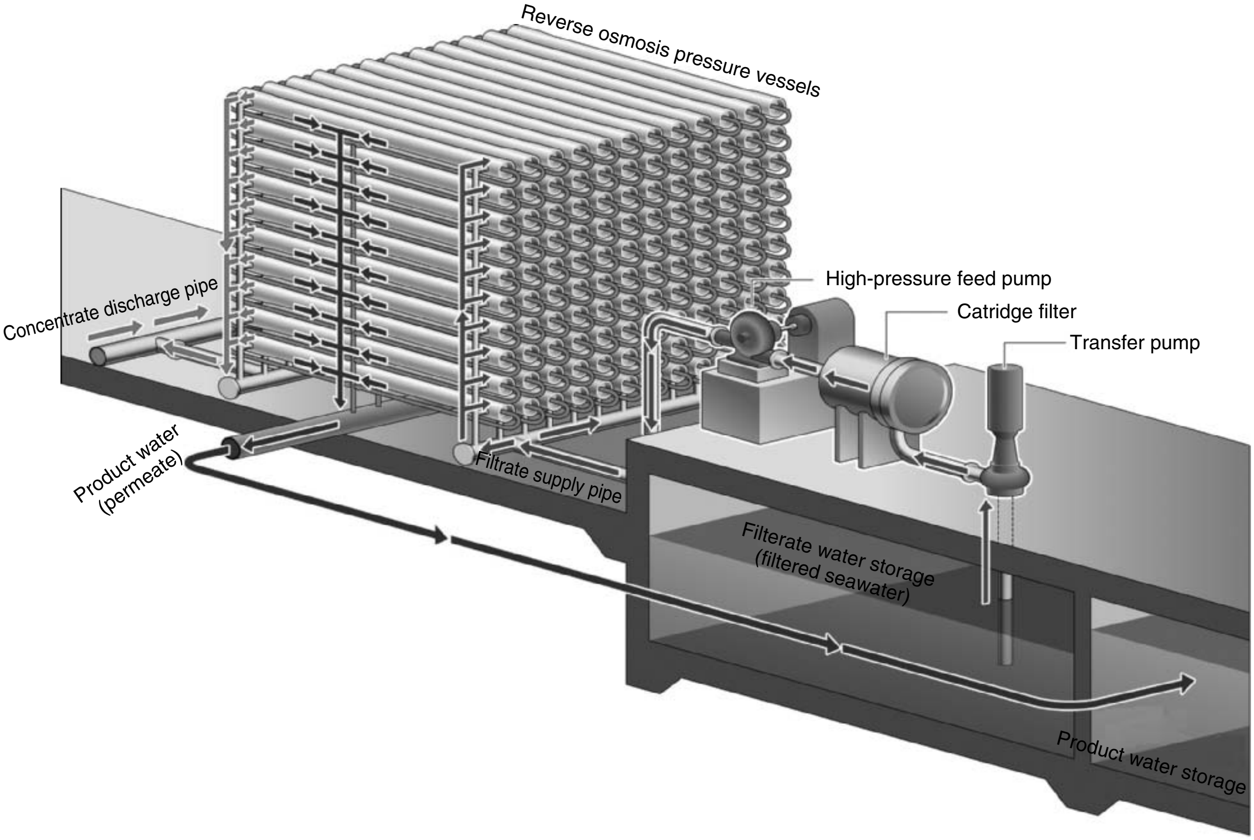

Figure 1. RO membrane train.

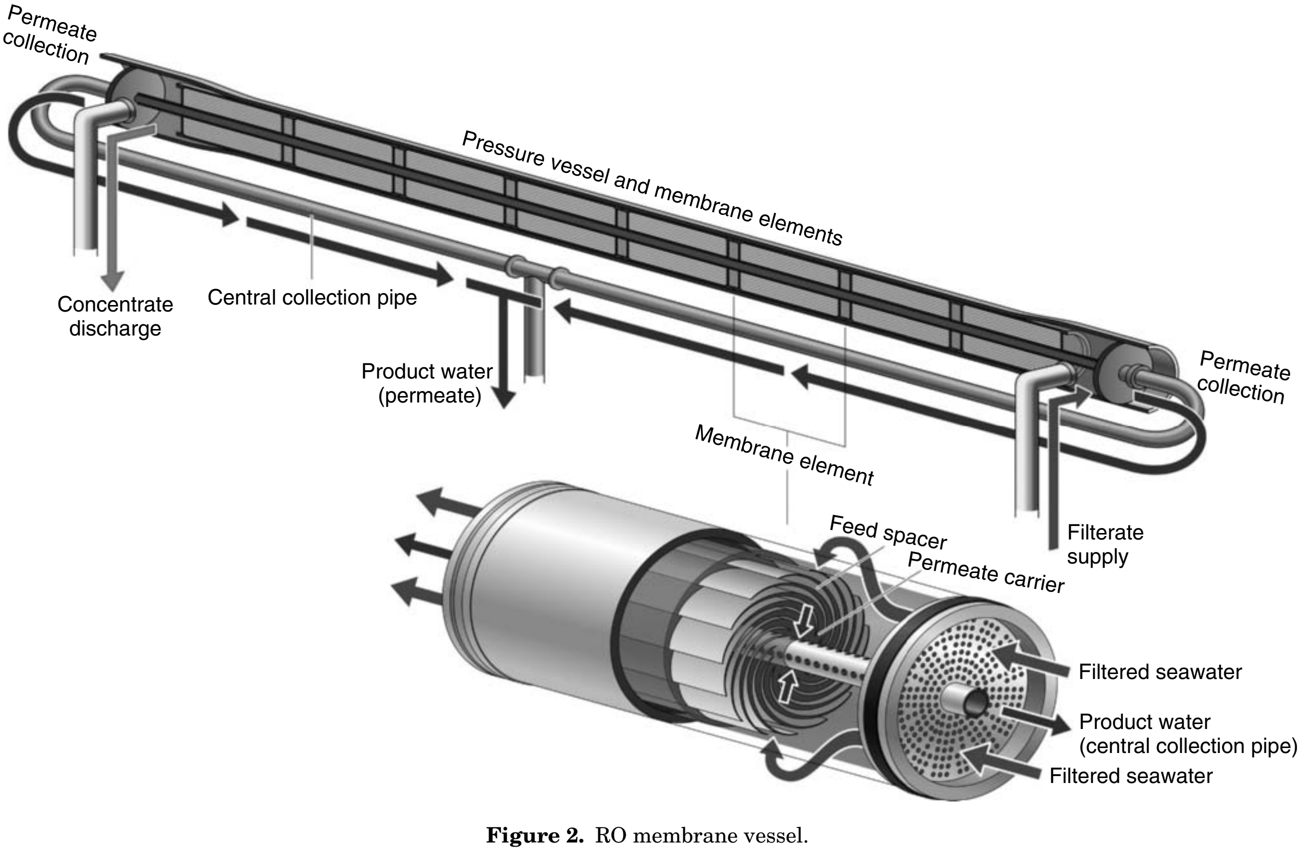

Figure 2. RO membrane vessel.

and spirally wound around a perforated central tube through which the desalinated water exits the membrane element. The first membrane sheet, which actually retains the source water minerals on one side of the membrane surface, is typically made of thin-film composite polyamide and has microscopic pores that can retain compounds smaller than 200 daltons. This sheet, however, is usually less than 0.2 microns thick, and to withstand the high pressure required for salt separation, it is supported by a second thicker membrane sheet, which is typically made of higher porosity polysulfone that has several orders-of-magnitude larger pore openings. The commercially available membrane RO elements today are of standardized diameter, length, and salt rejection efficiency. For example, the RO membrane elements most commonly used for potable water production in large-scale plants are 8 in. in diameter, 40 in. long, and can reject 99.5% or more of the TDS in the source water. Standard membrane elements have limitations with respect to a number of performance parameters such as feed water temperature (45 °C), pH (minimum of 2 and maximum of 10), silt density index (less than 4), chlorine content (not tolerant to chlorine in measurable amounts), and feed water pressure [maximum of 80 to 100 bars (1100 to 1400 psi)].

During reverse osmosis, the water molecules move through the RO membranes at a rate commonly referred to as flux. Membrane flux is expressed in cubic meters per second per square meter (m^3/sm^2) or gallons per day per square foot (gfd) of active membrane surface area. For example, a typical seawater membrane RO element is operated at 8 to 10 gfd.

Membrane performance tends to deteriorate over time due to a combination of wear and tear and irreversible fouling of the membrane elements. Typically, membrane elements have to be replaced every 3 to 5 years to maintain their performance in water quality and power demand for salt separation. Improvements in membrane element polymer chemistry and production processes have made the membranes more durable and have extended their useful life. Elaborate conventional media pretreatment technologies and ultra- and microfiltration membrane pretreatment systems prior to RO desalination are expected to extend membrane useful life to 7 years and beyond, thereby reducing the costs for their replacement and the overall cost of water.

RO membrane elements are installed in pressure vessels that usually house six to eight elements per vessel (see Fig. 2). Multiple pressure vessels are arranged on support structures (racks) that form RO trains. Each RO train is typically designed to produce between 10% and 20% of the total amount of the membrane desalination product water flow. Figure 1 depicts one RO train.

After the RO salt/water separation is complete, a great portion of the feed water energy applied through the high-pressure RO pumps stays with the more concentrated seawater and can be recovered and reused to minimize the overall energy cost of seawater desalination. Dramatic improvements in membrane elements and energy recovery equipment during the last 20 years coupled with enhancements in the efficiency of RO feed pumps and reduction of the pressure losses through the membrane elements have allowed reducing the power to desalinate seawater to less than 3.5 kWh/m^3 (13.5 kWh/1000 gallons) of freshwater produced today. Considering that the cost of power is typically 20% to 30% of the total cost of desalinated water, these technological innovations have contributed greatly to reducing the overall cost of seawater desalination. Novel energy recovery systems working on the pressure exchange principle (pressure exchangers) are currently available in the market, and use of these systems is expected to reduce further desalination power costs by approximately 10% to 15%. The pressure exchangers transfer the high pressure of the concentrated seawater directly into the RO feed water at an efficiency exceeding 95%. Future lower energy RO membrane elements are expected to operate at even lower pressures and to continue to yield further reduction in the cost of desalinated water.

The ratio between the volume of the product water produced by the membrane desalination system and the volume of the source water used for its production is commonly called recovery and is presented as a percentage of the plant RO system feed water volume. The maximum recovery that can be achieved by a given pressure-driven membrane desalination system depends mainly on the source water salinity and is limited by the magnitude of the osmotic pressure to be overcome by the RO system high-pressure feed pumps and by the scaling potential of the source water. Scaling occurs when the minerals left behind on the rejection side of the RO membrane are concentrated to a level at which they begin to form precipitates (crystalline compounds), which in turn plug the membrane pores and interfere with fresh water transport through the membrane. Typically, desalination plants using brackish source water can achieve 65% to 85% recovery. Seawater desalination plants can turn only 40% to 60% of source water into potable water because seawater typically has an order of magnitude higher salinity than brackish water. Detailed guidelines for designing membrane desalination plants are provided elsewhere (4,5).

DESALINATED WATER QUALITY

When membrane desalination is used to produce potable water, the product water quality depends mainly on the concentration of salts in the source water, the salt-rejection capability of the RO membranes, and the applied membrane feed pressure. In thermal desalination, the product water quality depends mostly on the heating system and temperature, the pressure applied, and the type of distillation technology. The product water quality of thermal desalination systems is significantly less dependent on source water salinity than that produced by a membrane system. This makes thermal distillation processes an attractive alternative for parts of the world, such as the Middle East, where source water TDS is very high (40,000 to 46,000 mg/L) and low-cost steam is readily available.

Typically, thermal desalination processes produce water of very low TDS concentration (1 to 60 mg/L). A single-stage, reverse osmosis system for seawater

Next Page

desalination produces permeate of 250 to 350 mg/L. More elaborate RO systems can produce water of quality matching that of a thermal desalination plant. Usually, the temperature of thermally desalinated water is 2 °C to 5 °C higher than the temperature of water produced by membrane separation.

Desalinated water (permeate) produced by both thermal and membrane desalination is highly corrosive and has to be chemically conditioned (typically by lime addition) to increase product water alkalinity and to adjust pH (usually by addition of chlorine dioxide and/or acid to the lime conditioned permeate) to meet potable water quality regulations.

CONCENTRATE MANAGEMENT

The two main streams produced by every desalination plant are low-salinity freshwater and high-salinity concentrate. The results of a recent study completed by the U.S. Bureau of Reclamation (6) on the concentrate disposal methods most widely used in the United States (in order of decreasing frequency) are shown in Table 1.

Sanitary sewer and surface water discharge are the two most popular and cost-effective methods for concentrate disposal. Depending on the site-specific conditions, deep well injection, evaporation ponds, and spray irrigation can also be competitive concentrate disposal alternatives. The zero liquid discharge system typically has the highest construction and operating costs. However, under specific circumstances, such as cold climate, low evaporation and soil uptake rates, high land costs, and low power costs, the zero liquid discharge system can be cost-competitive with evaporation pond and spray irrigation disposal.

Table 1. Concentrate Disposal Methods and Their Frequency of Use in the United States

Concentrate Disposal Method	Frequency of Use, % of Plants Surveyed
Surface water discharge	45
Sanitary sewer discharge	42
Deep well injection	9
Evaporation ponds	2
Spray irrigation	2
Zero liquid discharge	0

COST OF DESALINATED WATER

Desalination water costs depend on many factors, including the type of treatment technology; the source water quality; the target product water quality; the size of the desalination plant; and the costs of energy, chemicals, labor, and membranes. The all-inclusive cost of potable water produced using a brackish water source treated by membrane separation usually varies between US$0.25 and $0.65/m^3 (US$1.0 to $2.5/1000 gallons) of product water. Seawater desalination cost is estimated at US$0.65 to $1.20/m^3 (US$2.5 to $4.5/1000 gallons). For very small plants located in isolated areas, this cost could be significantly higher. For comparison, the cost of water produced from fresh natural water sources (i.e., low-salinity groundwater, lake, and river water) is typically between US$0.15 and $0.40/m^3 ($0.6 and $1.5/1000 gallons). This cost is driven mainly by the source water quality, the type of treatment technologies used, and the size of the water treatment plant. Developments in seawater desalination technology during the past two decades combined with the transition to construction of large capacity plants, colocation with power plant generation facilities, and enhanced competition by using the build-own-operate-transfer (BOOT) method of project delivery have resulted in a dramatic decrease in the cost of desalinated water (7). These factors are expected to continue to play a key role in further reducing the production cost of desalinated water.

DIATOMACEOUS EARTH FILTRATION FOR DRINKING WATER

Vipin Bhardwaj
NDWC Engineering Scientist

Mel J. Mirliss
International Diatomite
Producers Association

Diatomaceous Earth (DE) filtration is a process that uses diatoms or diatomaceous earth—the skeletal remains of small, single-celled organisms—as the filter media. DE filtration relies upon a layer of diatomaceous earth placed on a filter element or septum and is frequently referred to as pre-coat filtration. DE filters are simple to operate and are effective in removing cysts, algae, and asbestos from water. DE has been employed in many food and beverage applications for more than 70 years and was used specifically to filter potable water during WWII. Since then, it has been used to produce high-quality, low-cost drinking water. DE filtration is currently one of the

Previous Page

desalination produces permeate of 250 to 350 mg/L. More elaborate RO systems can produce water of quality matching that of a thermal desalination plant. Usually, the temperature of thermally desalinated water is 2 °C to 5 °C higher than the temperature of water produced by membrane separation.

Desalinated water (permeate) produced by both thermal and membrane desalination is highly corrosive and has to be chemically conditioned (typically by lime addition) to increase product water alkalinity and to adjust pH (usually by addition of chlorine dioxide and/or acid to the lime conditioned permeate) to meet potable water quality regulations.

CONCENTRATE MANAGEMENT

The two main streams produced by every desalination plant are low-salinity freshwater and high-salinity concentrate. The results of a recent study completed by the U.S. Bureau of Reclamation (6) on the concentrate disposal methods most widely used in the United States (in order of decreasing frequency) are shown in Table 1.

Sanitary sewer and surface water discharge are the two most popular and cost-effective methods for concentrate disposal. Depending on the site-specific conditions, deep well injection, evaporation ponds, and spray irrigation can also be competitive concentrate disposal alternatives. The zero liquid discharge system typically has the highest construction and operating costs. However, under specific circumstances, such as cold climate, low evaporation and soil uptake rates, high land costs, and low power costs, the zero liquid discharge system can be cost-competitive with evaporation pond and spray irrigation disposal.

Table 1. Concentrate Disposal Methods and Their Frequency of Use in the United States

Concentrate Disposal Method	Frequency of Use, % of Plants Surveyed
Surface water discharge	45
Sanitary sewer discharge	42
Deep well injection	9
Evaporation ponds	2
Spray irrigation	2
Zero liquid discharge	0

COST OF DESALINATED WATER

Desalination water costs depend on many factors, including the type of treatment technology; the source water quality; the target product water quality; the size of the desalination plant; and the costs of energy, chemicals, labor, and membranes. The all-inclusive cost of potable water produced using a brackish water source treated by membrane separation usually varies between US\$0.25 and \$0.65/m^3 (US\$1.0 to \$2.5/1000 gallons) of product water. Seawater desalination cost is estimated at US\$0.65 to \$1.20/m^3 (US\$2.5 to \$4.5/1000 gallons). For very small plants located in isolated areas, this cost could be significantly higher. For comparison, the cost of water produced from fresh natural water sources (i.e., low-salinity groundwater, lake, and river water) is typically between US\$0.15 and \$0.40/m^3 (\$0.6 and \$1.5/1000 gallons). This cost is driven mainly by the source water quality, the type of treatment technologies used, and the size of the water treatment plant. Developments in seawater desalination technology during the past two decades combined with the transition to construction of large capacity plants, colocation with power plant generation facilities, and enhanced competition by using the build-own-operate-transfer (BOOT) method of project delivery have resulted in a dramatic decrease in the cost of desalinated water (7). These factors are expected to continue to play a key role in further reducing the production cost of desalinated water.

DIATOMACEOUS EARTH FILTRATION FOR DRINKING WATER

VIPIN BHARDWAJ
NDWC Engineering Scientist

MEL J. MIRLISS
International Diatomite
Producers Association

Diatomaceous Earth (DE) filtration is a process that uses diatoms or diatomaceous earth—the skeletal remains of small, single-celled organisms—as the filter media. DE filtration relies upon a layer of diatomaceous earth placed on a filter element or septum and is frequently referred to as pre-coat filtration. DE filters are simple to operate and are effective in removing cysts, algae, and asbestos from water. DE has been employed in many food and beverage applications for more than 70 years and was used specifically to filter potable water during WWII. Since then, it has been used to produce high-quality, low-cost drinking water. DE filtration is currently one of the

U.S. Environmental Protection Agency's (EPA) approved technologies for meeting the requirements of the Surface Water Treatment Rule (SWTR) and is most suitable for small communities that need to comply with the rule.

WHAT IS DE FILTRATION?

DE contains fossil-like skeletons of microscopic water plants called diatoms, which are a type of algae. These diatoms range in size from less than 5 micrometers to more than 100 micrometers, and have a unique capability of extracting silica from water to produce their skeletal structure. When diatoms die, their skeletons form a diatomite deposit. In its natural state, diatomite is 85 percent inert silica. The soluble portion of diatomite is extremely low (less than 1 percent). The odorless, tasteless, and chemically inert characteristics make DE safe for filtering water or other liquids intended for human consumption.

APPLICATION AND HISTORICAL BACKGROUND

During WWII, the U.S. Army needed a new type of water filter suitable for rapid, mobile military operations. The U.S. Army Engineer Research and Development Laboratories (ERDL) developed a DE filter unit that was lightweight, easily transported, and able to produce pure drinking water. Later, DE filtration technology was applied to filtering swimming pool water and more gradually to producing drinking water.

The earliest municipal DE filter installation was a 75,000 gallons per day (gpd) system in Campbell Hills, Illinois, that began operating in 1948. By 1977, municipalities had constructed more than 145 plants. Today, nearly 200 DE plants are successfully operating.

HOW DOES DE FILTRATION WORK?

DE filtration strains particulate matter from water, and the process rarely uses coagulant chemicals. First, a cake of DE is placed on filter leaves. A thin protective layer of diatomaceous earth builds up, or accumulates, on a porous filter septum (a permeable cover over interior collection channels) or membrane. Recirculating DE slurry through the filter septum establishes this layer. The septum is most often plastic or metallic cloth mounted on a wire mesh-covered steel frame. The DE process is also called pre-coat filtration because the solids separation at the start of a run takes place on the built-up pre-coat layer of DE.

After the pre-coat forms on the filter leaves (usually 1/8 inch thick) raw water containing a low dose of DE, which is called body feed, is fed through the filter. Particulate solids in the product flow are separated on the pre-coat surface. With such separation, the unwanted particulate matter actually becomes part of the filter media. During a filter run, removing particulate matter from raw water causes head loss to gradually build up in the filter. The accumulation of DE body feed on the filter reduces the rate of head loss. When maximum head loss is reached, the flow of water into the filter is stopped and the filter cake is cleaned.

High-pressure sprays, directed at the accumulated cake, detach the cake and provide dilution for draining the slurry suspension from the filter vessel. When cleaned, the filtration operation is repeated, beginning with the pre-coat cycle (see Fig. 1). Operators typically discard the DE removed from the filter leaves.

APPROPRIATE FEED WATER QUALITY AND PERFORMANCE CAPABILITIES

The use of DE filters is limited to treating source waters with an upper limit of turbidity at 10 NTU. Also, filtration rates range from 0.5 to 2 gallons per minute per square foot (gpm/ft^2). The particle size that DE filtration removes relies upon the size distribution of the DE particles used for the pre-coat and body feed. DE filters are very effective for removing *Giardia* and *Cryptosporidium* cysts. In some cases, studies have reported up to a 6-log reduction of these cysts under routine operating conditions. Because DE filtration usually does not involve coagulation, its potential for removing dissolved constituents, such as color, is low. Therefore, the utility or its engineer must determine raw water quality before considering DE filteration.

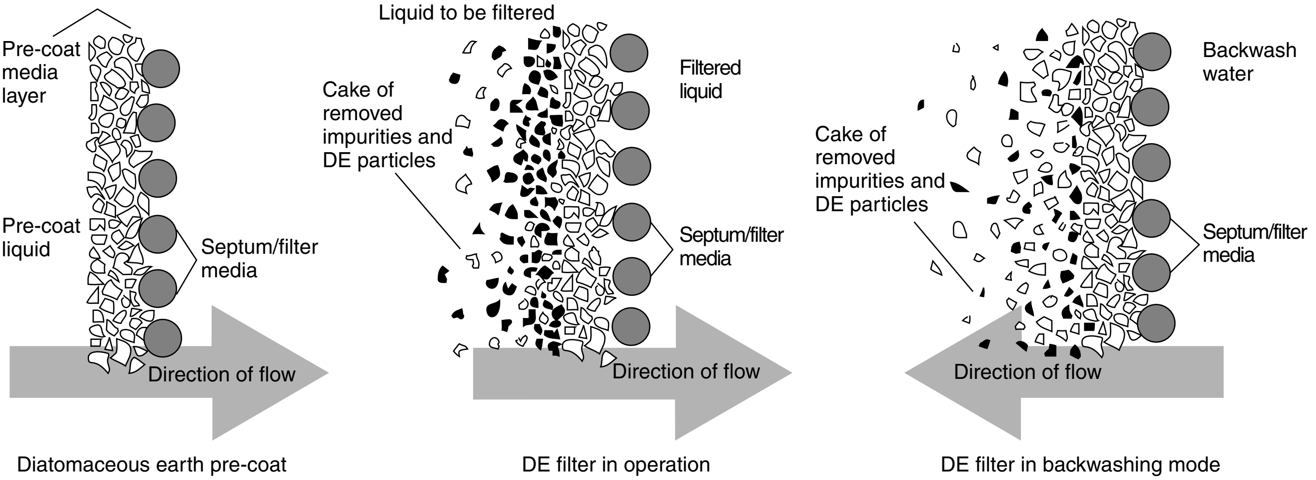

Figure 1. Diatomaceous earth filter. *Source*: Fulton, George P. 2000. *Diatomaceous Earth Filtration for Safe Drinking Water*.

WHAT ARE THE MONITORING AND OPERATING REQUIREMENTS?

Monitoring requirements for DE filtration are simpler than requirements for coagulation and filtration because operators rarely ever use coagulant chemicals for DE filtration. However, operators must continuously monitor raw and filtered water turbidity. Operators also must monitor filter head loss so that they can determine when to backwash the filter.

In general, DE filter plant operators need mechanical skills to operate the body feed pumps, pre-coat pumps, mixers, pipes, and valves. They also must be skilled in preparing the body feed and precoat slurries. Also, keeping DE filter leaves clean is of primary importance. A leaf filter that is not properly cleaned at the end of a filter run can accumulate dirt and slime on the filter cloth, which prevents a uniform pre-coat from forming when the filter is restored to service.

ELEMENTS OF A DE FILTER

Figure 2 shows the common elements in the manufacture of any flat leaf filter used in treating drinking water. The principal elements of a DE filter include the following:

- containment vessel,
- baffled inlet,
- filter leaves mounted on an effluent manifold,
- a method of cleaning the filter leaves at the end of a run,
- a drain to receive the backwash water,
- open top or access mode, and
- DE slurry preparation tank and pump feed.

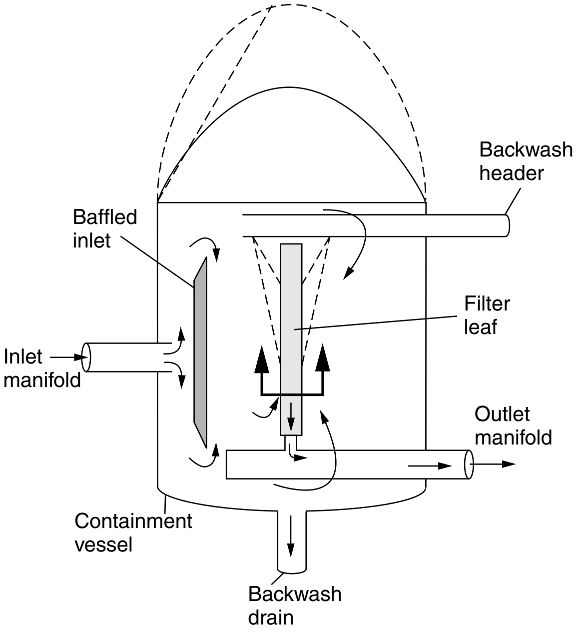

Figure 2. Elements of a flat leaf filter. *Source*: Fulton, George P. 2000. *Diatomaceous Earth Filtration for Safe Drinking Water*.

TYPES OF DE FILTRATION

Two types of DE filters exist: (1) *pressure filters*, which have a pump or high-pressure water source on the influent side and (2) *vacuum filters*, which have a pump on the effluent side. Vacuum filters are open to the atmosphere. Pressure filters are enclosed within pressure vessels.

The two basic groupings of DE filter designs are essentially defined by the hydraulic mode of operation, and are shown in (Fig. 3a and 3b).

The principal advantages of pressure filters over the vacuum filters are related to the significantly higher differential head available.

Table 1. Pressure and Vacuum Filters

Pressure Filters	Vacuum Filters
• Operates at higher flowrates, resulting in smaller, more compact filter units.	• Lower capital fabrication cost.
• Longer filter runs, reducing the use of pre-coat material and backwash water because of less frequent cleaning cycles.	• Lower maintenance costs.
• Less likelihood that gas bubbles will disrupt the media.	• Tanks are open at the top, making access and observation easy.

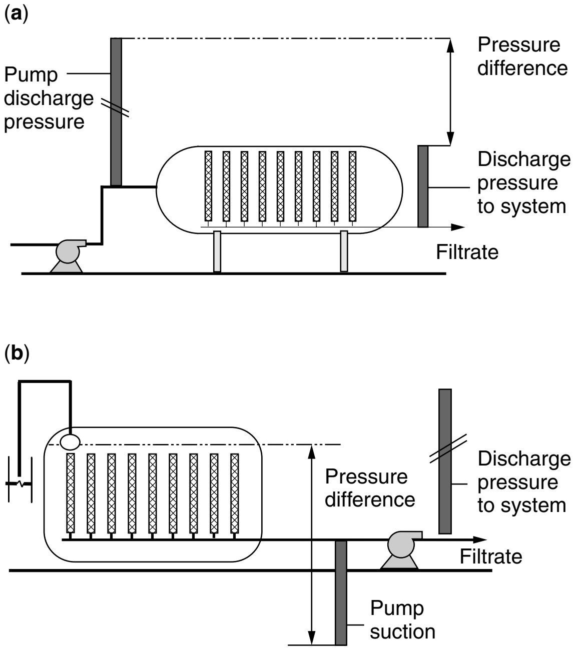

Figure 3. (**a**) Pressure filter. (**b**) Vacuum filter. *Source*: Fulton, George P. 2000. *Diatomaceous Earth Filtration for Safe Drinking Water*.

IS DE SUITABLE FOR SMALL SYSTEMS?

DE filtration is well-suited to small systems, because it does not require chemical coagulation, so operators do not need to learn about this complex aspect of water treatment. In addition, installation costs for DE systems are less than those for other technologies, such as membranes. DE filtration is currently one of the EPA's approved technologies for meeting SWTR requirements.

An ideal, cost-effective DE filtration application is for well water supplies under the influence of surface waters, but that are otherwise acceptable in quality. Superior cyst removal capability makes the DE filter more advantageous than other alternatives. However, there is a potential difficulty in maintaining complete and uniform thickness of DE on the filter septum.

HAVE YOU READ ALL OUR TECH BRIEFS?

Tech Briefs drinking water treatment fact sheets have been a regular feature in the National Drinking Water Clearinghouse (NDWC) newsletter *On Tap* for more than five years.

A package of *Tech Briefs* is now available as a product. A three-ring binder holds all the current *Tech Briefs* in print. New selections can be easily added to the package as they become available. To order this free product, call the NDWC at the numbers listed below and ask for item #DWPKPE71.

Additional copies of fact sheets are also free; however, postal charges may be added.

To order, call the NDWC at (800) 624-8301 or (304) 293-4191. You also may order online at ndwc_order@mail.nesc.wvu.edu *or download fact sheets from our Web site at* www.ndwc.wvu.edu.

Also, the NDWC's Registry of Equipment Suppliers of Treatment Technologies for Small Systems (RESULTS) is a public reference database that contains information about technologies used by small waters systems around the country. For further information about accessing or ordering RESULTS, call NDWC.

Vipin Bhardwaj, technical assistance specialist, has a B.S. in chemical engineering and has recently finished his master's degree in agriculture at West Virginia University. He expects to receive a master's degree in civil engineering this fall.

Mel Mirliss has been associated with the diatomaceous earth industry for the past 28 years. For the past nine years, he has served as the executive director of the International Diatomite Producers Association (IDPA) where he has been a director since the association's founding in 1987. He holds a B.S. in chemistry from the University of California, Berkeley.

EMERGING WATERBORNE INFECTIOUS DISEASES

Louis H. Nel
University of Pretoria
Pretoria, Gauteng, South Africa

Humanity is plagued at present by at least 1709 different infectious diseases. These diseases are caused by pathogens, which are microscopic and parasitic organisms of diverse natures, including infectious proteins (prions), viruses, bacteria, fungi, and protozoa. Compared to diseases like cancer and metabolic diseases that have genotypic roots, including heart disease, diabetes, and the like, progress in the fight against infectious diseases has been rapid during the last half century. Whereas infectious diseases such as smallpox, measles, polio, rabies, plague and numerous other bacterial diseases have once been a global scourge, many of these diseases have now become controllable due to spectacular advances in public health practices, including improvements in the quality of water and sanitation and by immunization, education, early diagnosis, and the use of antibiotics/antimicrobials and other drug therapies. However, globally, 45% of all deaths and 63% of early childhood deaths are still caused by infectious diseases.

INFECTIOUS DISEASES, EMERGING DISEASES, AND ZOONOSES

New, emerging, reemerging, and resurgent infections contribute significantly to the infectious disease problems that the world is experiencing now. At least 156 such diseases have now been identified. Taken from a report by the Institute of Medicine (1), emerging infections may be defined as follows: "emerging infections are those whose incidence in humans has increased within the past two decades or threatens to increase in the near future. Emergence may be due to the spread of a new agent, to the recognition of an infection that has been present in the population but has gone undetected, or to the realization that an established disease has an infectious origin. Emergence may also be used to describe the reappearance (or "reemergence") of a known infection after a decline in incidence." Generally, new diseases are synonymous with emerging diseases and can be regarded as diseases first described in the last 10 to 30 years. Most of these diseases are caused by specific modifications (mutation/evolution, species jump, etc.) of agents that are already in the environment. Reemerging diseases are those that have persisted at a subdued level in the population and recur as a result of antimicrobial drug resistance or other changes that might favor marked increases in disease incidence. Reemerging diseases can also be described as resurgent, pertinently referring to an abrupt increase in incidence or geographic distribution of the particular disease. The emergence and reemergence of diseases are clearly related to changes in the infectious pathogen, the vector or transmission system, and the host population. Such epidemiologically important changes may include drug resistance and mutations resulting in increased virulence, changes in the distribution or activity of vectors, globalization and increased travel, war, population explosions, climatic and ecological changes, geographical displacement of species, movement into previously uninhabited areas, poverty and breakdown of health care systems, and changes in agriculture and industrialization. Six infectious diseases can be identified as current, leading, high mortality rate diseases, and all of them conform to the criteria for emergence described before: AIDS, acute respiratory infection, diarrheal diseases, malaria, measles, and tuberculosis.

A great many infectious diseases are zoonoses: These are diseases that are naturally transmitted between vertebrate animals and man—49% or 832 of all known infectious diseases can be considered zoonoses. A fair number of infectious diseases of man started out as zoonotic events but have since established a much more important human-to-human epidemiological cycle (e.g., HIV-AIDS, dengue hemorrhagic fever). Strikingly, however, 73% of all the emerging diseases considered (114 of 156) are zoonoses. Infectious diseases are typically transmitted through direct contact, insect vectors, sexual contact, respiratory tract (aerosolized microbes), and by contaminated food and water. Here we are concerned with waterborne infection, with pathogen entry through the mouth and alimentary track or, in some instances, through epithelial cells of the respiratory system.

WATERBORNE INFECTIOUS DISEASES: THE SPECTRUM OF PATHOGENS

Human and animal fecal pollution of water sources is the leading cause of waterborne infections. This fecal–oral route of infection contributes to hundreds of millions of cases of diarrhea and millions of deaths (particularly among children) every year. Clearly, improved water sanitation that leads to safe drinking water for all of humanity would be the ultimate solution. Some emerging waterborne infections do not enter through the oral route but through the respiratory route. These infections are attributed to specific pathogens that have been made airborne through water spraying in nurseries, flower and vegetable markets, personal showers, and the like.

Viral Agents

Many waterborne diseases are caused by viruses, which include adenoviruses (types 40 and 41), astroviruses, caliciviruses (including Norwalk and hepatitis E viruses), Enteroviruses (picornaviruses), and reoviruses (including rotaviruses). By far the most common medical condition associated with waterborne viral infection is diarrhea. The medical and economic importance of viral diarrhea should not be underestimated, millions of deaths (particularly, of children) are caused by these infections. At present, only a handful of these viral diseases is considered emerging and the most important of them, astrovirus enteritis, calicivirus enteritis, and hepatitis (E), are specifically discussed here.

Bacterial Agents

Increased resistance to antibiotics is a major factor in the resurgence of common bacterial infectious diseases and epidemic bacterial diarrhea such as those caused by waterborne *Escherichia coli, Shigella*, and *Vibrio*. The use of antimicrobials in agriculture has significantly contributed to this phenomenon, although evolution and adaptation of organisms have also led to converting nonpathogens into pathogens by adding of toxin producing capability. In addition, new bacterial zoonoses emerge, and some human pathogens are newly recognized, thanks to rapidly improving diagnostic techniques. This, as well as the reemergence of pathogens due to immune deficiencies related to HIV/AIDS, applies to the whole spectrum of infectious disease agents.

Protozoal Agents

These parasites typically are contaminants of potable water supplies. Whereas inadequate sanitation and chlorination of water supplies should prevent most of the waterborne bacterial diseases, large outbreaks of protozoan enteritis are usually associated with surface water supplies that are inadequately flocculated and filtered or not treated at all (many of these pathogens are chlorine resistant). In the last decade, enteric protozoa have become the leading cause of waterborne disease outbreaks for which an etiologic agent could be identified. The most common of these infections are caused by *Cryptosporidium* and *Giardia*, *Cyclospora* has also recently emerged as an enteric protozoan.

SPECIFIC EMERGING WATERBORNE INFECTIOUS DISEASES

Aseptic Meningitis and Various Other Syndromes

These diseases are caused by enteroviruses, viruses that—as their name suggests, replicate in the intestinal tract. Enteroviral infection is one of the most common types of viral infections in humans, but they do not often result in serious disease, although some serotypes of enteroviruses may cause serious clinical syndromes. Such syndromes may include acute paralysis, encephalitis, meningitis, myocarditis, hepatitis, and chronic infection (particularly in immunocompromised individuals). Enteroviruses belong to the *Enterovirus* genus of the *Picornaviridae* family and include the polioviruses, group A Coxsackieviruses, group B Coxsackieviruses, echoviruses, and (newer) enteroviruses. There are 3 different polioviruses, 61 nonpolio enteroviruses, 23 Coxsackie A viruses, 6 Coxsackie B viruses, 28 echoviruses, and 4 other enteroviruses. Enteroviruses evolve rapidly and emerge as new strains, but others are of emerging importance due to drug resistance. Some enterovirus serotypes have been responsible for serious, large epidemics throughout the world in recent years. Echovirus infections have been responsible for several large epidemics of aseptic meningitis in Japan, Europe, and the Middle East in the past years. These epidemics involved different highly infectious serotypes of the virus, types 4, 9, and 30, but also of new genetic variants of these viral serotypes. Enterovirus 71 (EV71) has caused major disease outbreaks in North America, Europe, Malaysia, Japan, and Australia since 1995. In 1998, this virus infected at least a million individuals in Taiwan and caused a 20% case fatality among children under 5 years of age.

Astrovirus Enteritis

Today, astroviruses are considered much more prevalent than previously thought (e.g., 75% of 5 to 10-year-old children in Britain demonstrate antibodies against astroviruses). These are small, round viruses that have a starlike appearance under the electron microscope. Following a 1 to 4-day incubation period, the clinical symptoms present as watery diarrhea that lasts 2–3 days. These gastrointestinal disorders are usually not serious, but astroviruses are a leading cause of childhood diarrhea, and dehydration may be especially severe in immunocompromised individuals.

Calicivirus Enteritis

This disease, caused by a group of small cuplike viruses, is very common—serological evidence indicates that most people are infected by age 12. The symptoms are diarrhea with nausea and vomiting. Fever and respiratory infection occur in a small number of cases. It is thought that these viruses emerged from ocean reservoirs, with subsequent zoonotic and interspecies movement. Among the known calicivirus pathogens of humans are the Norwalk and Norwalk-like viruses and the Sapporo and Sapporo-like viruses. Although it is thought that pathogenic caliciviruses are likely to continue emerging from the world's oceans in various forms, only the Norwalk-like viruses are now and from a public health point of view, of emerging importance. Norwalk-like viruses cause sporadic and epidemic gastroenteritis in all age groups of humans, but losses of fluids and electrolytes are particularly serious in the very young and elderly. Transmission is by the fecal–oral route, and shellfish-related outbreaks frequently occur where appropriate standards for proper disposal of human sewage are not applied. Contaminated water, ice, eggs, salad ingredients, and ready-to-eat foods are other sources of infection.

Campylobacteriosis

This diarrheal disease, caused by *Campylobacter jejuni*, occurs worldwide. Infection by *Campylobacter* species has been known in livestock for many decades, but it has also been recognized as an important pathogen in humans since the middle 1970s. The development of selective media contributed to this recognition, and drug resistance and the emergence of toxin producing strains have recently become of considerable importance. Although this disease is usually self-limiting, treatment with antibiotics may reduce bacterial numbers and the duration of the infection and may be of particular value in cases involving immunocompromised individuals or where complications are evident. From this perspective, the emergence of antibiotic resistant strains of *Campylobacter* all over the world is disconcerting. *Campylobacter jejuni* infections, it is thought are more common than infections by other enteric bacteria such as *Shigella, Salmonella* and *Escherichia coli* O157:H7. Whereas other *Campylobacter* species (e.g., *C. laridis, C. hyointestinalis*) may also be involved in disease, *C. jejuni* is responsible for 99% of the cases. The bacterium is gram-negative, has a curved rod-shaped morphology and is motile. It is highly infectious and symptoms are diarrhea, fever, abdominal pain, nausea, headache, and myalgia. Complications are rare, but the infection may progress toward reactive arthritis, hemolytic uremic syndrome, and septicemia. Guillain-Barre syndrome is also recognized as a rare (1 per 1000 infected individuals) complication leading to disease of the peripheral nervous system.

Cholera

Cholera is caused by the gram-negative, motile, rod-shaped bacterium, *Vibrio cholerae*. The disease, essentially an acute and serious infection of the small intestine with diarrhea that can be severe and is accompanied by dehydration and shock, occurs worldwide. The symptoms associated with cholera are caused by the enterotoxins produced by V*ibrio cholerae* during the infection. Accurate records of cholera date back almost a century, but cholera may have been known in India and elsewhere for thousands of years. This disease may be considered emerging due to new pandemics (serotype O1) and the appearance of pathogenic strains that have evolved by genetic recombination (serotype 0139). The emerging serotype O139 appeared in 1992 and has as yet only been reported from Southeast Asia where it causes epidemics in populations that were previously exposed to other serotypes of the same pathogen. In similar evolutionary fashion, *Vibrio cholerae* can become resistant to antibiotics by acquiring a transposon element and/or a plasmid that confers resistance to multiple antibiotics.

Vibrio cholerae O1, however, caused a pandemic spread over six continents during the past 40 years. The bacterium initially (1960s) spread from Indonesia to Eastern Asia, India, the former USSR, Iran, and Iraq.

Thereafter, in 1970, serotype O1 took hold in West Africa and then became endemic in most of the African continent. In 1991, it spread throughout South and Central America, and involved more than a million known cases at a mortality rate of about 1%. Much higher mortality rates (33%) were observed in 1994 in a large epidemic among Rwandan refugees in Zaire (33%). In recent times, Africa continued to host large cholera epidemics. These included a 1997 outbreak in Kenya, Tanzania, and Mozambique, a 1998 outbreak in Congo and Zaire, and in 2000/2001, a large epidemic in South Africa.

Cryptosporidiosis

The etiological agent of this persistent diarrheal disease is the protozoal parasite *Cryptosporidium parvum*. Together with the AIDS epidemic, cryptosporidiosis emerged in the early 1980s as a zoonosis, after having been known as a veterinareal disease for more than a century. Apart from persistent diarrhea, symptoms may include abdominal pain, nausea, and low-grade fever, and significant weight loss. Infectious oocysts may still be excreted long after diarrheal disease has ended (up to 5 weeks). In the growing number of immunocompromised individuals worldwide, this has become a life-threatening and highly infectious enteric disease. Compounding the threat of this disease is the fact that the pathogen is difficult to filter from water resources, is resistant to chlorine, is ubiquitous in many animals, can survive in infected water for long periods of time, and is highly infectious. It is therefore not surprising that *C. parvum* has now become the major protozoan pathogen of humans. A wide spectrum of water supplies has been implicated and these include contaminated and inefficiently treated/flocculated/filtered drinking water such as from water plants and boreholes or from swimming pools, wading pools, hot tubs, jacuzzis, fountains, lakes, rivers, springs, ponds, and streams. A high rate of secondary person-to-person transmissions in households and institutions has also been documented.

Cyclosporiasis

This protracted, relapsing gastroenteritic disease is similar to cryptosporidiosis and is also caused by a coccidian parasite, in this case, *Cyclospora cayetanensis.* This organism is food- and waterborne, and it emerged in the 1990s as a serious and widespread gastrointestinal parasite. In contrast to the zoonotic *C. parvum*, *C. cayetanensis* is specific to human hosts and is not a known pathogen of vertebrate animals. Cyclosporiasis is most common in tropical and subtropical regions and endemic in Central and South America, Southeast Asia, the Caribbean islands, and parts of Eastern Europe, but large outbreaks have recently been reported in the United States and Canada, reports also came from the United Kingdom and various African countries. Apart from fecally contaminated water, various types of fresh produce such as raspberries, basil, field greens, and salad mixes have been indicated as sources of the pathogen. Although *Cyclospora* oocysts, like *Cryptosporidium* oocysts, are resistant to chlorine, they are double the size of *Cryptosporidium* oocysts and may be more easily removed by flocculation and filtration methods used in water plants. Further, due to the noninfectious nature of newly formed oocysts, secondary person-to-person spread of *Cyclospora cayetanensis* is a much less likely route of transmission than that for cryptosporidiosis.

Dermatitis

This is an inflammation of the skin marked by redness, pain, and itching (skin rashes) that is caused by the gram-negative and rod-shaped bacterium, *Pseudomonas aeruginosa*. Until the recent recognition of waterborne dermatitis caused by *Pseudomonas aeruginosa*, this organism was rarely implicated in disease. The bacterium typically survives in biofilms and antibiotic resistant strains are also appearing, but effective control should be possible by proper water treatment.

Gastritis

Helicobacter pylori, a spiral gram-negative bacterium was first recognized in 1982 as a cause of gastritis. It appears that the human stomach is the only recognized reservoir for this bacterium and infection is common in the general population. Although most infected individuals are asymptomatic and are unlikely to develop a serious medical problem from the infection, *H. pylori* causes 90% of duodenal ulcers and up to 80% of gastric ulcers, and infected persons have a twofold to sixfold increased risk of developing gastric cancer. In fact, *H. pylori* is classified as a group I (or definite) carcinogen by the World Health Organization's International Agency for Research on Cancer. It is not known why some patients become symptomatic and others do not. The transmission of *H. pylori* also remains unclear, although the bacteria are most likely to spread from person to person through fecal–oral or oral–oral routes.

Giardiosis

This disease, one of the most common diarheal diseases spread by drinking and recreational water in the United States and probably worldwide, is caused by the intestinal protozoan parasite *Giardia intestinalis*, also known as *G. lamblia* or *G. duodenalis*. This agent also infects domestic and wild animals (e.g., cats, dogs, cattle, deer, and beavers). Emerging as a widespread and common disease during the past two decades, giardiasis has been traced back to contaminated swimming pools, hot tubs, fountains, lakes, rivers, springs, streams and ponds. As for the other parasitic diseases discussed here, the life cycle begins when cysts are ingested through person-to-person transmission or ingestion of fecally contaminated food or water. The ingested cysts release trophozoites in the duodenum where they attach to the surface of the intestinal epithelium. *Giardia* cysts can be excreted in fecal stools intermittently for weeks or months, and infection of a new host can result from ingestion of as few as 10 cysts.

Hemorrhagic Colitis and Complications

Enterohemorrhagic *Escherichia coli* (EHEC) is another bacterial pathogen that has recently emerged as a major waterborne enteric pathogen. After recognition of waterborne infection by this agent in 1985, the disease has been reported worldwide, and case numbers are ever increasing. Whereas *E. coli* bacteria are usually symbiotic as part of the normal intestinal flora of animals and humans, some strains of the organism can cause disease by producing large quantities of Vero toxins. It is a bacterial virus (or bacteriophage) that carries the toxin gene. When infecting the bacteria, the bacteriophage, integrates into the bacterial genome and from there provides the toxin producing capability. Today, a large number of *E. coli* serotypes that can produce Vero toxins are recognized, but the serotype O157:H7 is the predominant pathogen that is most frequently associated with hemorrhagic colitis in humans. The disease is serious, usually characterized by bloody diarrhea, abdominal cramps and nausea, but more severe complications, known as hemolytic uremic syndrome (HUS)—leading to complete renal failure, may follow. Case fatality rates for *E. coli* O157:H7 range from 3–36%, the fate of patients depends on age and immunocompetence.

Waterborne transmissibility through both drinking and recreational waters together with antibiotic and chlorine resistance and an ability to survive in water for long periods of time, are major factors in the widespread emergence of EHEC. In addition, these organisms are highly infectious and are often spread to humans as zoonoses, EHEC has a very wide host range among domestic animals and wildlife. Outbreaks continue to be recognized worldwide in the United States, Japan (1996—6000 cases), United Kingdom, Australia, Europe, Argentina, Chile, and throughout Africa (e.g., South Africa, Swaziland, Kenya, Nigeria, Cote d'Ivoire, Central Africa Republic, and Egypt). In recent years, a number of efficient diagnostic techniques have been developed for accurate detection of isolate *E. coli* O157:H7, which also allows for distinction from other bacterial enteropathogens (e.g., *Shigella*) with which it may easily be confused due to clinical similarities of disease manifestation.

Hepatitis (Hepatitis E-Like Viruses)

Hepatis virus E (HEV) was isolated for the first time in 1988. This virus was then characterized in subsequent years, and it has recently been placed in its own taxonomic group, "hepatitis E-like viruses", within the class IV (+) sense RNA viruses. The disease is found most frequently in the developing world (e.g., South East Asia, India, Middle East, Africa, and Central America) and is transmitted primarily through the fecal–oral route in contaminated drinking water. Person-to-person transmission of HEV may occur during large epidemics, but this route of transmission appears to be uncommon. The incubation period following exposure to HEV is, on average a lengthy 40 days but may range from 15 to 60 days (mean, 40 days). Diarrhea is a less common symptom in this case, malaise, anorexia, abdominal pain, arthralgia, fever, anorexia, hepatomegaly, jaundice, nausea, and vomiting are more common. The disease is most often seen in young to middle-aged adults (15–40 years old) where the fatality rate is relatively low at 0.1–1%. However, pregnant women appear to be exceptionally susceptible to severe disease, and excessive mortality has been reported in this group (up to 30%). Recent genetic and serological evidence suggests frequent transmission of HEV between animals and humans, and zoonoses may explain the mechanism of HEV maintenance in populations during the periods between epidemic outbreaks.

Legionnaires' Disease

Legionnaires' disease, or legionnellosis, is an acute pneumonia caused by the bacterium *Legionnella pneumophila*. This is a flu-like illness, typically occurring 3 days after exposure and followed within a week by high fever, chills, dry cough, muscle aches and headache. The disease is usually self-limited but can lead to higher mortality in the presence of various risk factors such as immunodeficiency, cigarette smoking, chronic lung diseases, lung malignancies, heart disease, and old age. When this disease was first recognized in the late 1970s, the associated etiological agent was hard to isolate, given that *Legionnella* is a particularly fastidious organism that does not grow on typical culture media. The importance of these waterborne gram-negative, rod-shaped bacilli has since become clear, following the development of suitable diagnostic techniques. Of importance is the fact that these bacteria are parasites of protozoa (e.g., *Amoeba* sp.) that are common in rivers, lakes, and streams. Within these hosts, *Legionnella* will proliferate and be protected from environmental hazards, including chlorination. In addition, following intracellular replication in protozoal cells, *L. pneumophila* converts to a virulent form and expresses a number of traits (including enhanced motility) that will assist in extracellular survival and transmission to new cells. This phenomenonant is thought, explains the virulence of *L. pneumophila* for the macrophages in the human lung, given the similarities in cell biology of these cells and protozoal cells. If the virulent form of the bacteria is inhaled, replication may occur within the alveolar macrophages, and disease will ensue. This transmission occurs most easily in the presence of airborne water droplets, so Legionnellosis has become particularly important and common following the various practices leading to aerosolization of water (e.g., showers, spraying of produce in large markets, and air conditioning).

Shigellosis Colitis

Shigella is a highly infectious, gram-negative, rod-shaped bacterium, most species are implicated in waterborne infections. Although not new, it is the virulence and ability to develop drug resistance through plasmids that confers resistance to a large spectrum of antibiotics, which characterize a resurgence of shigellosis colitis. Disease symptoms include abdominal pains, fever, and rectal pain, and complications may include sepsis, seizure, renal failure, and hemolytic uremia syndrome. *Shigella dysenteriae type 1* (Sd1) is the cause of epidemic dysentery that usually originates from water polluted with human feces. This type is a major cause of dysentery in Asia and Central and South America and has only recently arrived in Africa. After major pandemics in southern Africa in the early and middle 1990s, *Shigella dysenteriae type 1* has now become endemic in many countries in Africa. Other species of *Shigella* that are frequently responsible for waterborne infections are *Shigella sonnei* and *Shigella flexneri.*

Toxoplasmosis

This infection, which is symptomless in most cases, is caused by the coccidian protozoan *Toxoplasma gondii*. However, the parasite is considered an important emerging pathogen in the AIDS patient group worldwide, where infection can cause lymphadenopathy, central nervous system disorders, myocarditis, pneumonitis, and cranial lesions. Domestic cats are the definitive host for *Toxoplasma* but, apart from humans, there are numerous additional intermediate hosts in the animal kingdom. Infection takes place by ingesting contaminated food and water or by inhaling airborne *Toxoplasma* oocysts.

Tuberculosis (TB)

Although most individuals infected with *Mycobacterium tuberculosis* are asymptomatic carriers of TB, this should be considered a serious long-term pulmonary disease. In symptomatic cases, listlessness, chest pain, loss of appetite, fever, and weight loss are early symptoms of pulmonary tuberculosis. This may progress into night sweats, bleeding in the lungs, coughing up of sputum with pus, and shortness of breath. Exposure usually occurs through inhalation of infected droplets and thus, similar to legionnellosis, the aerosolization of water contributes to the transmissibility of *Mycobacterium* where water supplies are contaminated with the organism (often in hospitals). Tuberculosis is not a new infection, but multidrug-resistant tuberculosis (MDRTB) has become a major public health problem during the last 10 years, particularly as an opportunistic infection in concert with the AIDS epidemic.

CONCLUDING REMARKS

In considering the reasons for the emergence of the specific waterborne infectious diseases described, it is easy to identify a number of common and very specific causal elements. These include (1) the rising incidence of diseases or other factors that affect immune competence in groups or populations, including HIV/AIDS, malnutrition, and the like; (2) genetic adaptation of pathogens, including the acquisition of resistance plasmids, toxin genes, and other virulent factors; (3) overcrowding combined with poor sanitation and deteriorating or inadequate public health infrastructure; (4) increased exposure to animal reservoirs (as a result of geographical expansion, overpopulation, and competition for dwindling water resources) and continual zoonoses. Based on these factors, the potential for the continued emergence and reemergence of infectious diseases seems inexhaustible. Advances in vaccination, therapeutic intervention, and surveillance are crucial elements in the fight against these diseases, but even so, much may be achieved through education, improved hygiene, and proper water sanitation.

INTRODUCTION

Public health surveillance has played a key role in controlling the spread of communicable disease and identifying the need for specific public health practices, such as the filtration and chlorination of drinking water supplies. However, the characteristics of waterborne outbreaks since the early 1990s have raised questions about whether current water treatment practices can prevent transmission of some enteric pathogens (1–5). In addition, one analysis suggested that a significant fraction of all enteric disease in the United States may be due to drinking water (3). Another study found evidence that consuming surface-derived drinking water which meets current U.S. Environmental Protection Agency (USEPA) drinking water standards may significantly increase the risk of enteric illness (6). These concerns have motivated the U.S. Congress to require USEPA to prepare a report on the magnitude of epidemic and endemic waterborne disease in the United States.

Even as the needs increase for better information about waterborne disease occurrence and causes, some have suggested that our disease surveillance system is in a state of crisis and may possibly collapse (7). Another study revealed that state health departments often cannot dedicate any staff to enteric disease surveillance (8). Current concerns over the preparedness for detecting and controlling bioterrorism attacks have also motivated interest in the adequacy of waterborne disease surveillance. In this chapter, issues relating to disease surveillance and outbreak investigations are presented to assist readers in understanding the strengths and weaknesses of current waterborne disease surveillance and outbreak detection programs and to suggest additional steps to strengthen the system. With limited public health resources available, it is important to carefully consider the goals and approaches to waterborne disease surveillance. In addition to addressing the information needs of governmental disease control programs, it is essential to ensure that the information needs of the drinking water industry, the regulatory agencies, and the public are best served. It may also be essential for drinking water utilities to participate in and, perhaps, help fund these surveillance systems.

BACKGROUND

It is increasingly accepted that additional information is needed about the occurrence and causes of waterborne disease, both epidemic and endemic. The Centers for Disease Control (CDC) funded "emerging pathogen" surveillance projects in selected state health departments, in part to improve surveillance for several important waterborne agents. In New York City (NYC), the Department of the Environment (DEP), responsible for drinking water treatment and delivery, convened a panel of public health experts in 1994 to evaluate current health department disease surveillance programs. The panel recommended specific waterborne disease surveillance activities and epidemiologic studies to determine endemic waterborne disease risks associated with use of unfiltered surface water sources (Table 1) (9). Efforts to improve NYC waterborne disease surveillance are funded by the NYC DEP, the first time this has occurred for a drinking water utility in the United States.

Table 1. New York City Panel Recommendations on Waterborne Disease Surveillance

Designate an individual who is specifically responsible for coordinating waterborne disease surveillance
Conduct special surveillance studies of nursing and retirement home populations
Conduct surveillance in managed care populations
Monitor visits to emergency rooms
Conduct surveillance of high-risk populations
Monitor sales of prescription and nonprescription medications

An option for improving waterborne disease surveillance is to build on the current surveillance programs in place in most state and local health departments. This system is based on voluntary disease reporting by healthcare providers and clinical laboratories. However, a number of limitations of the system have been identified, and other factors may have already significantly reduced the effectiveness of traditional disease surveillance programs. Some pathogens, such as *Cryptosporidium*, are often difficult to diagnose, and other pathogens may exist for which there are no known diagnostic tests or no tests available for routine use. Changes in healthcare access and delivery practices may reduce the number of patients seeking healthcare and, also, the chances that medically attended diseases are confirmed by laboratory tests.

An outbreak resulting in many medically attended illnesses in a large city could be unrecognized, as almost happened in the Milwaukee outbreak. In that outbreak, a large increase in the occurrence of diarrheal illness occurred around March 30–31, 1993. On Thursday, April 1, 1993 a pharmacist noted a dramatic increase in sales of over-the-counter antidiarrheal and anticramping medications. Normally his pharmacy sold $30 a day of such medications. Starting that Thursday, drug sales increased to approximately $500–$600 a day, or 17–20 times the normal sales. The increased sales continued on Friday, as a result of which the pharmacy sold most of its supply of antidiarrheal medications. The pharmacist called the health department to inquire about excessive reports of diarrhea or intestinal illness. The health department was unaware of any outbreak. On Saturday the increased sales continued so the pharmacist contacted the three local television stations to report what he believed to be a major occurrence of diarrheal disease in the city. On Sunday night his report was carried on the evening news for one station and by Wednesday, April, 7, the outbreak was confirmed by the Milwaukee Health Department.

In the case of the Milwaukee outbreak, few of the people sought medical care for their diarrhea. However, even in situations where care was sought, it is possible that no one physician would notice an outbreak. For example, if many different healthcare providers treated the patients, it is possible that no one provider would recognize excess occurrences of illness. In addition, the existence of health effects in a small but extremely susceptible subpopulation might be difficult to detect because of the small number of people at risk.

As some changes have made it more difficult to detect outbreaks, other changes present new disease surveillance opportunities. Computerization of patient records, healthcare and laboratory workloads, prescription and nonprescription pharmaceutical sales, and calls to nurse hotlines are potential new tools for more effective and less costly disease surveillance. Technological advancements, such as detection of antigen or antibodies specific to a pathogen in sera, stools, and other secretions, may improve detection of etiological agents. These may also allow detection of infections in the absence of disease.

To better evaluate the current and alternative surveillance opportunities, five questions have been selected for discussion in this chapter:

1. What are the limitations of our current disease surveillance systems?
2. Should the early detection of outbreaks be the primary goal of a surveillance system and, if so, how can it be best achieved?
3. What is meant by endemic or background rates of disease, can some of this endemic disease be attributable to drinking water, and what should water utilities do to better understand these risks?
4. Can findings from outbreak investigations be used to estimate the unreported burden of enteric disease attributable to drinking water?
5. Since only a fraction of infected persons become ill from most enteric infections, should expanded surveillance programs monitor infection rather than illness?

LIMITATIONS OF THE CURRENT DISEASE SURVEILLANCE SYSTEMS

What are the limitations of our current disease surveillance systems? Detection of waterborne disease outbreaks depends, in part, on a state-federal system of notifiable or reportable diseases. Disease reporting is primarily the responsibility of healthcare providers and diagnostic laboratories. State or local laws require the reporting of certain diseases. Primary responsibility for disease surveillance rests with the state or local public health authorities. Most state surveillance systems are “passive,” in that reports are sent to the state or local health department by cooperative health care providers or laboratories. Providers and laboratories usually receive little encouragement from the health department to report illnesses. Government enforcement of reporting requirements is minimal. An “active” system will routinely contact some or all healthcare providers and laboratories, asking for illness reports (Table 2) (10).

It has long been recognized that both passive and active disease reporting incompletely ascertain the level of disease in the community. The level of completeness varies by disease, by state, and by areas or populations within a state (11). For example, reporting is likely to be more complete for severe diseases such as hemorrhagic *E. coli* than for milder infections, such as Norwalk virus gastroenteritis. Laboratories tend to be much better at reporting their findings than are physicians (10). Even within an area, there can be great variations in reporting, depending on the interest of clinical laboratories and the dedication of diagnosing physicians (11). For example, for pathogens that are new or where there are questions about the mode of transmission, reporting may be more complete than for agents that are common, where the mode of transmission is well known and where public health intervention is less necessary.

Table 2. Surveillance System Definitions

Mandatory reporting	A diagnosed case of disease is required, by law, to be reported; for example, in the case of cryptosporidiosis, all diagnosed cases are to be reported
Passive	Disease reports are submitted by providers and/or laboratories without specific follow-up by the health department
Active	Providers and/or laboratories are contacted to encourage diseases reporting; because of resource requirements, this is usually done as a special project for a limited duration of time
Enhanced	Special additional efforts are made to encourage disease reporting; this might include news releases, posters at strategic locations, presentation to special populations, or health surveys in communities with water quality problems

In addition to incomplete reporting of diagnosed illnesses, only a portion of all infections will ever be medically attended. As illustrated in (Fig. 1), only a fraction of infections will lead to illness. These infected persons may be unaware of their infection. In other cases, such as sometimes occurs as a result of childhood *Giardia* infection, the child fails to thrive but experiences none of the classic symptoms of giardiasis. When symptoms occur, they may be mild and/or may resolve in a short period of time. In this case, the person may not seek medical care or may simply visit a pharmacy to obtain medication to alleviate their symptoms. In the case of Milwaukee, despite the large number of reported cases of cryptosporidiosis, very few people visited their physician and few stool specimens were positive for *Cryptosporidium* oocysts.

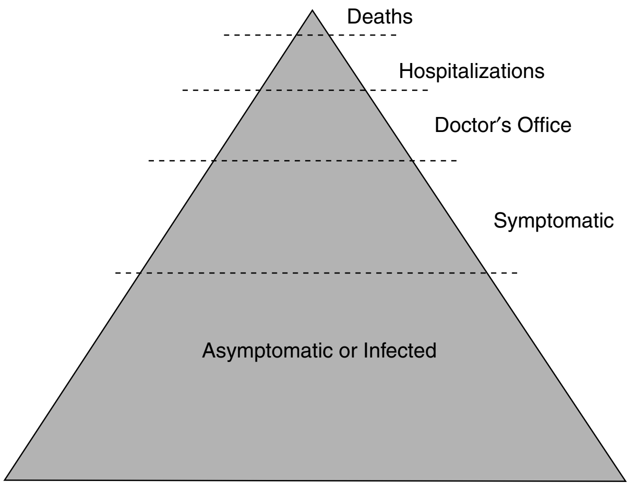

Figure 1. Disease pyramid.

If the person seeks healthcare, the physician may fail to correctly diagnose the infection, since in many cases symptoms are not sufficiently specific to accurately identify the pathogen. If misdiagnosed and the infection resolves itself, the patient may not seek additional healthcare and no report of an infection will be generated. Even when the physician correctly diagnoses the illness and prescribes the appropriate medication, a confirmatory laboratory test may not be ordered. If ordered, the patient may not submit the sample to the laboratory, since many patients are unwilling to submit stool specimens for laboratory analysis. Since laboratories are the primary source of disease reports for surveillance systems, without a laboratory-confirmed diagnosis, a report may never be filed. When a stool or blood sample is submitted for laboratory analysis, it can also test negative because of analytical or specimen collection error, untimely collection or because the material submitted was, by chance, free of the pathogen (12). Laboratory proficiency can vary considerably. This may be more of a problem for laboratories that run only a small number of the ordered test. For persons infected with enteric parasites, single stools may often be free of the parasite or have insufficient numbers of parasites to assure laboratory detection. In some cases, even multiple stools may be pathogen-negative.

If a sufficient number of cases of illness from the same pathogen are reported to the health department at about the same time and if the epidemiologist is alert to an increase in case reports, an outbreak may be identified. Because of the time required to perform the diagnostic tests and to report the results, outbreak recognitions may occur weeks after the onset of the actual outbreak.

Many outbreaks are first detected by an alert clinician. For example, in 1976, a Camas, Washington physician's son had returned from Russia with giardiasis. The physician later recognized that several of his patients had similar symptoms. This lead to the identification of a waterborne giardiasis outbreak (13). As mentioned earlier, in Milwaukee, Wisconsin a pharmacist noted a dramatic increase in sales of antidiarrheal medication. In California and Arizona, diarrheal illnesses reported to health agencies by 65 campers who had visited an Arizona park initiated an investigation that implicated contaminated water as the source of an outbreak that affected 1850 people (14). The fortuitous circumstances surrounding the detection of many outbreaks raises concerns about how many medium to large outbreaks are never detected. Small outbreaks may seldom be detected, especially among travelers who consume water from noncommunity systems or who swim in multiple locations.

Limitations of the current disease surveillance systems prompted a series of studies in the early 1980s to evaluate potential improvements in disease reporting and to evaluate the efficacy of active surveillance programs. A three state study of various approaches to active disease surveillance, funded by USEPA, detected no additional waterborne disease outbreaks in two states (Washington and Vermont) (15). However, in one state (Colorado) a greater than threefold increase in the number of detected waterborne outbreaks occurred (16). The reasons why Colorado was able to identify so many more outbreaks than either Washington State or Vermont are unclear. An intense effort was made to increase disease reporting in all states and dramatic increases in reports of enteric diseases were observed in all three states. It is possible that a combination of poor quality water supplies plus an exposed tourist population, without protective immunity, may have allowed Colorado to identify more outbreaks than the other two states.

In summary, active disease reporting can increase reporting of diagnosed illnesses only from providers and laboratories. All the other barriers to disease identification and reporting will still remain (Fig. 1). If healthcare access declines over time or, to reduce healthcare costs, physicians use fewer laboratory diagnostic services, then the number of diagnosed reportable illnesses will decline. This will occur despite the efforts of health departments to insure that most diagnosed illnesses are reported.

EARLY DETECTION OF OUTBREAKS

Should the early detection of outbreaks be the primary goal of a surveillance system, and, if so, how can it be best achieved? The occurrence of a waterborne disease outbreak is an exciting, newsworthy, and politically important event. Affected populations may experience severe illness and a large number of people may become ill. As a result of the investigation, much is often learned about the cause of major failures in water treatment or distribution. However, when the excitement has subsided, water system deficiencies have been corrected and the outbreak is officially said to be over, has the problem been solved or is disease continuing to occur but at a reduced level, below what is detectable by traditional surveillance activities?

For example, a waterborne disease outbreak investigation detected major problems with the filtration system of an anonymous small community water supply. The system was, at the time of its installation, considered adequate. However, high turbidity levels were observed in treated water at the time of the outbreak, suggesting poor operation of the filtration facility. Optimization of treatment by consulting engineers allowed the plant to dramatically improve pathogen removal. This improvement reduced the number of new cases of disease, and the outbreak officially ended. However, 2 years later a serological survey of the town's residents revealed the continued occurrence of infection by the same etiologic agent responsible for the earlier outbreak. These new data presented both philosophical and technical problems. Should all outbreaks be followed by such a survey? Is evidence of continuing infection sufficient reason for further intervention? If the serological survey were not conducted, there would be no evidence of increase risk of infection. If the plant was already optimized, what are the remaining intervention options without new filtration or disinfection technology?

This scenario assumes that the continued high serological levels resulted from waterborne transmission. In fact, without a follow-up epidemiologic investigation, it is not possible to distinguish waterborne from other routes of transmission. In addition, without improved surveillance activities, we know little about the absence of symptomatic disease. Low levels of disease from exposure to waterborne microbes over a period of many years can result in a much larger health burden for a community than the number of disease cases that might occur during a detected outbreak. However, exposure to some waterborne pathogens at levels that boost the immune response may prevent symptomatic illness. These concerns must all be considered when developing a surveillance system. Without clear goals and a commitment to conduct epidemiologic investigations and take appropriate actions, a better surveillance system will not improve public health.

Failure to detect low levels of disease transmission may provide a false sense of security. For example, why should an outbreak such as occurred in Milwaukee not have been preceded by many smaller outbreaks? Is it possible that in each of the cities experiencing a large waterborne cryptosporidiosis outbreak, prior undetected smaller outbreaks occurred? In fact, is it possible that lower levels of waterborne *Cryptosporidium* infection had occurred years prior to the outbreak? At the time of the detected outbreak, a higher number of oocysts may have passed through the treatment system or a more virulent strain of the pathogen emerged. If so, relying on disease surveillance systems that can only detect large outbreaks will seldom provide public health officials and the industry early warnings of emerging new diseases. This may be equivalent to basing the science of meteorology only on the study of hurricanes.

The detection of an outbreak can also affect future disease reports in an area. For example, it is possible that overreporting of symptoms consistent with the disease of interest could occur. If so, similar outbreaks may be detected in neighboring areas. Given the increased popularity of bottled water use, it is possible that the at-risk population could change following an outbreak if a significant fraction of the population discontinued drinking tapwater. Therefore, decreases in the occurrence of reported waterborne disease may not reflect better control of the contamination but a reduction in the number of exposed individuals.

ENDEMIC DISEASE

What is meant by endemic or background rates of disease and can some of this endemic disease be attributed to drinking water? Endemic level of disease is defined by the CDC as a persistent low to moderate level of disease occurrence. A persistently high level of occurrence is called *hyperendemic* while an irregular pattern of occurrence is called *sporadic* (Fig. 2). For most enteric infections, endemic disease results from a statistical averaging of small to moderate-sized undetected outbreaks or clusters of infection. There is little information to suggest that endemic levels of disease remain constant over time or across geographic areas, nor is there reason to believe the endemic level of disease is unimportant.

Over the past century, the importance of endemic disease has become increasingly recognized. Following World War I, an attempt was made to estimate the prevalence of parasite infections in both the returning British soldiers and the British population who remained at home (17). To the surprise of the researchers, a high prevalence of asymptomatic infection was found among persons who had never left Britain. Later, a survey of Wise County, Virginia in 1930 revealed that half of the population carried *Entamoeba histolytica* and that 38% carried *Giardia lamblia* (18). A study to determine the incidence of *Cryptosporidium* infection among Peace Corp workers to be sent overseas revealed that almost 30% had possibly experienced infection prior to leaving the United States (19). More recent work we conducted suggests that endemic rates of *Cryptosporidium* infection may be very high, but that rates of cryptosporidiosis may be low (20,21).

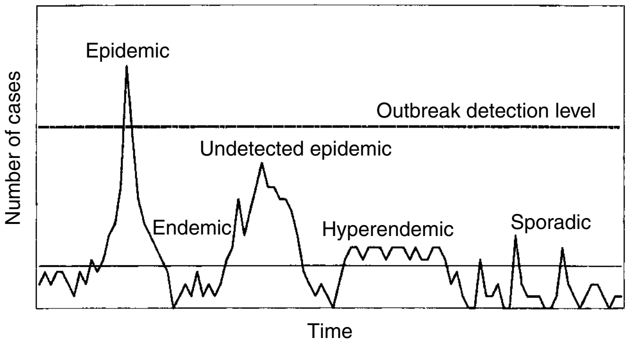

Figure 2. Epidemic versus endemic disease.

Data derived from disease surveillance systems cannot be used to compare endemic disease levels between areas or populations with different water systems. Whether observed differences in disease reports are due to the differences in the completeness of reporting or to differences in the occurrence of the disease or the infection cannot be answered, even with improved surveillance systems. In addition, it has become increasingly recognized that populations can develop protective immunity to infectious agents. If so, rates of infection may remain high while rates of illness remain low (21). The absence of disease in a population may, therefore, not mean that there is an absence of infections. Epidemiologic studies must be specifically designed and conducted to address the association of endemic disease with water system type or quality.

Several epidemiologic studies have reported waterborne disease associated with public water systems in the absence of a reported waterborne outbreak. In New Zealand, the incidence of laboratory-confirmed giardiasis was found to be higher in a part of the city receiving chlorinated, unfiltered surface water compared to the part where surface water was treated by coagulation, flocculation, granular filtration, and chlorination (22). In Vermont, a higher incidence of endemic giardiasis was found in municipalities using unfiltered surface water or wells than in municipalities with filtered surface water (23). A Canadian study attempted to estimate how much endemic enteric illness was due to drinking water (6). The fraction of illness attributable to drinking water was estimated by comparing rates of reports of "highly credible gastrointestinal illnesses" among persons drinking tapwater with rates among people drinking water from reverse osmosis filtration units. Although different rates of illness could have resulted from reporting biases, if the findings are confirmed by future studies, then drinking water may significantly contribute endemic disease in at least one community. Unfortunately, a study using a similar design conducted in Melbourne, Australia, did not provide evidence of endemic waterborne disease (24).

A variety of approaches have been proposed for estimating the burden of endemic diarrheal disease from drinking water sources. In addition to the Australian replication of the Payment design, a small pilot household intervention study in California has recently been completed (25). That study concluded that it was possible to blind families as to the type of treatment device they had, and although the study was not powered to examine illness rates, the families with true home treatment devices reported a lower rate of illness. A larger randomized household intervention study is under way in the United States. The advantage of the randomized household interventions is that the design precludes reporting biases and assignment biases, assuming that people do not know whether they are in the intervention or the control group. A major disadvantage of this approach is that only household drinking water quality is altered. Drinking water from other sources, such as work or at restaurants, is not altered. Another limitation is that long-term healthy residents are usually recruited and these people may have the lowest risk of suffering illness from waterborne infections. Therefore, negative results are difficult to interpret. Household intervention studies are limited in generalizability because they are conducted in single communities, although the study design would be amenable to national randomized trial.

Another proposed approach is to relate variations in the occurrence of health events, such as emergency room visits and hospitalization, with variation in drinking water turbidity levels (26,27). This approach has some merit; however, the results are difficult to interpret since no causal agents are identified. There are also concerns that the optimized statistical modeling cannot be statistically evaluated. Therefore, many of the claimed associations may be spurious.

Another approach uses planned changes in drinking water treatment and then evaluates the occurrence of potentially waterborne disease before and after intervention. The advantage of this approach is that most or all drinking water from an area is changed. This avoids one of the problems with household interventions. One disadvantage of this approach is that the sites receiving new water treatment technologies are not randomly assigned. For example, most unfiltered drinking water systems in the United States use high-quality source water. Adding filtration may not dramatically change the health risks from the drinking water. Another is that the community intervention looks at only one city or one pair of cities, so the sample size is restricted.

APPLICABILITY OF OUTBREAK INVESTIGATIONS

Can findings from outbreak investigations be used to estimate the burden of enteric disease attributable to drinking water? Epidemic disease is defined as an unusual occurrence or clustering of a specific illness. Between 1971 and 1994 there were 737 documented waterborne disease outbreaks (28–30). Almost half of these were due to unknown etiological agents that caused acute gastrointestinal illness. Among these outbreaks, the relative importance of different etiologic agents (viruses, bacteria, protozoa, and chemicals) can be estimated. For example, the etiologic agents most commonly associated with waterborne disease in the United States include, in descending order, undefined gastroenteritis, giardiasis, shigellosis, viral gastroenteritis, and hepatitis A. This ranking is based on outbreaks and may or may not reflect the relative importance of these etiologic agents for all waterborne disease.

For diseases where outbreaks account for the majority of illnesses, the outbreak is of primary interest. However, for many waterborne pathogens, outbreaks account for only a small fraction of all illnesses. For example, in a 1.5-year period during the late 1970s in Washington State, 1347 laboratory confirmed cases of giardiasis were reported to the state health department (31). Extensive follow-up of these cases (Table 3) revealed that clusters or possible small outbreaks accounted for only 16% of all cases of giardiasis reported during this time period. These data suggest that "endemic giardiasis" was overwhelmingly more abundant than "epidemic giardiasis" in Washington State during this time period.

There are a number of problems with extrapolating the characteristics of cases involved in outbreaks to revise all cases of illness, including the following:

1. If there is variation in the virulence of a pathogen, then detected outbreaks may predominantly be caused by the more virulent strains of the pathogen. This may overestimate the severe morbidity or mortality associated with the pathogen.
2. By examining only detected outbreaks, one may overestimate the importance of drinking water as a

Table 3. Case Clusters of Giardiasis in Washington State 1977–1978

Number of Cases	Etiology
10	Untreated streamwater consumption
14	Untreated water consumption at a work camp
11	One small community water system
12	Tourists returning from a resort in Mexico
17	One-daycare center outbreak
8	One-daycare center outbreak
24	Among 10 different daycare centers
73	Multiple cases among 21 families
51	Nonfamily association with another case
220	Total in all clusters

route of transmission. Because of the large number of cases often involved, waterborne outbreaks may be more detectable than outbreaks from other routes of transmission. Even a severe day care outbreak would involve only a few cases. Within family clusters usually involve too few cases to be a detectable outbreak.

3. Outbreak detection is often more difficult for common or endemic diseases than for uncommon diseases. For example, two cases of cholera anywhere in the United States might be considered an outbreak whereas 50 cases of cryptosporidiosis widely dispersed in a large U.S. city during a week might easily be absorbed as expected background cases of diarrhea and not recognized as an outbreak (9).

Outbreaks of short duration of illnesses (e.g., some viruses) are more difficult to detect and study than are outbreaks of long duration illnesses (e.g., giardiasis, shigellosis, hepatitis A). Therefore the importance of acute, self-limited gastrointestinal illness of undetermined etiology and short duration may be underestimated relative to outbreaks of parasitic infections and some bacterial or viral pathogens with a longer duration of symptoms.

Pathogens with long incubation periods are difficult to investigate since the conditions that allowed transmission of the pathogen may have changed between the time of infection and the time when the outbreak was detected. Underascertaining waterborne sources for disease outbreaks caused by these agents is likely.

MONITORING INFECTION VERSUS DISEASE

Only a fraction of infected persons become ill from the most commonly occurring enteric infections. Of the people that become ill, only a fraction of cases will be reposted (Fig. 3). Should expanded surveillance programs attempt to monitor infection rather than disease? The existence of asymptomatic carriers of infections has been known for some time (e.g., Typhoid Mary). However, the number of asymptomatic carriers for many infections has only relatively recently been appreciated. The parasite prevalence surveys in Britain (17) and in Virginia (18) found more asymptomatic infected persons than expected. Even as late as 1952, in New Hope, Tennessee, 10.6% of the general population was infected with *Giardia lamblia* (32). Following a 1966 giardiasis outbreak in Aspen, Colorado, a stool survey found that 5% of the population was infected with *Giardia* (33). A survey of Boulder, Colorado, also conducted following an outbreak, found a prevalence of 5% (34). Most of the individuals participating in these surveys were asymptomatic. A stool survey of one to 3-year-old Washington State children was conducted in 1980 (35). This survey found that 7% of the children were infected with *Giardia lamblia*. All participating children were reported as healthy at the time of the survey. The Seattle Virus Watch program, conducted during the 1960s and early 1970s monitored virus infections among a sample of people in selected U.S. cities. This study found that illness was reported in less than half of all enterovirus infections (36).

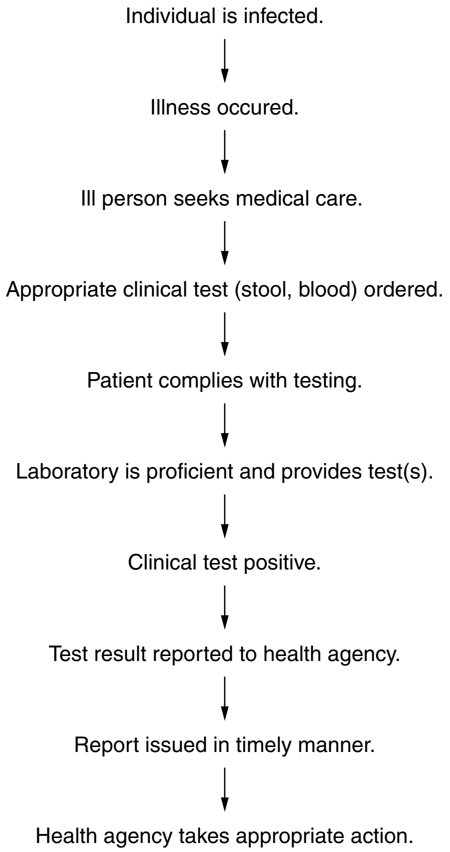

Figure 3. Events in reporting an individual infection.

New serological tools have been developed since the early 1980s to better monitor the prevalence of prior infections among the population. Even though infection may not result in moderate or severe illness, there are several reasons for considering infection rather than disease, including the following:

1. Information on infections can provide a much expanded understanding of the relative importance of various routes of transmission and provide an early warning for risks of outbreaks.
2. Serological epidemiologic studies of infection can better estimate the extent of endemic waterborne disease. These studies are statistically more powerful to detect low risks in moderate-size populations.
3. Just as the occurrence of a coliform test indicates the potential of disease risk for a drinking water source, the waterborne transmission of pathogens, even when infection is predominantly asymptomatic, can provide critical information for evaluating water treatment systems and may help identify correctable problems in water source protection and/or treatment.
4. Widespread, unrecognized transmission of infection in the general population may indicate a devastating outbreak for a susceptible subpopulation.

Another advantage of serological surveillance occurs during an outbreak. An outbreak of cryptosporidiosis was detected in Las Vegas, Nevada in Spring 1994. Although this was clearly a cryptosporidiosis outbreak, the inability to detect problems with the water treatment system and publicity prior to the investigation that suggested the outbreak was waterborne raised questions over whether the outbreak could be classified as waterborne (37–39). Since the majority of the diagnosed cases also suffered from HIV or AIDS, the extent of the outbreak was unclear. Had asymptomatic infected persons been identified serologically, the effects of reporting bias would be reduced since asymptomatic cases would have no motivation to explain an asymptomatic infection.

IMPROVING DISEASE SURVEILLANCE

Several options are available for enhanced waterborne disease surveillance. The option or combination of options selected will depend on the specific goals for disease surveillance. The currently used national system of surveillance, based on diagnosed illness, has a long-established record of both performance and nonperformance for detecting outbreaks (Table 4). Because the current system is both inexpensive to maintain and currently operational, it has considerable appeal among public health practitioners. However, monitoring pharmaceutical sales, nurse hotline calls, or physician visits is a potential enhancement to the traditional disease surveillance programs (Table 5) (39,40).

The goal of our current disease surveillance system is outbreak detection. Unfortunately, there is little rigorous evaluation of its capability to detect outbreaks. Furthermore, the common occurrence of fortuitous situations that lead to the outbreak detection raise questions about the sensitivity of the system. To improve the sensitivity to detect small to medium-size outbreaks or to provide early information on the occurrence of an outbreak, these alternative approaches mentioned have promise. Over-the-counter pharmaceutical sales may be useful, but it has some significant limitations (40). The use of nurse hotline calls to continuously monitor the occurrence of infectious disease has tremendous promise, but no efforts have been made to use this surveillance tool (39). Better linkages with infectious disease specialists in healthcare organizations may also improve disease surveillance.

Table 4. Advantages and Disadvantages of the Current Waterborne Disease Surveillance System

Advantages

In-place and operational across the nation

Extensive health department experience using the system

Inexpensive to maintain

An operational nationwide network, operated by the Centers for Disease Control (CDC), for summarizing and reporting findings

Methodological development of algorithms for detecting excess occurrences of disease

Disadvantages

Inability to detect outbreaks when diagnosed cases are not reported to the health department

Delays in detecting outbreaks due to the time required for laboratory testing and for reporting of findings

Undetected outbreaks where health problems are not medically treated or where infection results in only mild or no illness

Limited opportunities for system improvement

Possible long-term trend in healthcare delivery that may reduce its efficacy

Table 5. Advantages and Disadvantages of New Waterborne Surveillance Systems

Advantages

They may detect outbreaks where few patients seek healthcare or where the illness is of sufficiently short duration that healthcare is unimportant

They are relatively fast in reporting outbreaks since the time delay between the onset of symptoms and the purchase of drugs or calls to nurses is likely to be short

They are relatively inexpensive to maintain, especially if nationwide retail pharmacies are involved or common nurse hotline software is programmed for reporting

Disadvantages

Since only symptoms are ascertained, they will not usually identify an etiologic agent

Although inexpensive to maintain, initial computer programming and establishing data sharing agreements would require some investment

The specificity of the system for outbreak detection (e.g., number of false leads) is untested

None of the traditional or enhanced surveillance tools will provide much useful information on low-level or endemic risk of enteric pathogen infection. However, new serological tests have increased the feasibility of studies to estimate the incidence of new infections or the prevalence of antibody response to pathogens and to relate this information with modes of transmission. In the early 1970s, the Seattle Virus Watch program examined occurrences of viral infections among volunteers in selected communities (33). Similar approaches to monitoring the occurrence of *Giardia* (41) and *Cryptosporidium* (42) infections have been developed since then. More work is needed to evaluate these new tools as well as to develop other tests. We also need to design cost-effective approaches to their widespread implementation. These tools may give us an opportunity to greatly improve our understanding of the importance of various modes of transmission and identify reasons why one population group has a higher endemic level of disease than another. It is likely that as more is known about the modes of transmission, a better understanding will emerge of both drinking water and nondrinking water routes of pathogen transmission.

Healthcare reforms may reduce the use of diagnostic laboratory services, reducing the value of laboratory-based disease surveillance. However, new opportunities for improved disease surveillance, including both individual and community disease reporting and surveillance of endemic infections, may also result. To fully exploit these opportunities, a new public health partnership with distributed responsibilities may be needed between healthcare providers, health maintenance organizations (HMOs), pharmacies, and the traditional public health agencies.

The increasing age of our population has resulted in increases in the number of immunosuppressed persons. Some of this immunosuppression may result from chronic diseases, while some may result from medically induced immunosuppression following treatment for other conditions. For example, many cancer patients have temporary periods of immunosuppression following treatment. These populations may be at especially high risk of adverse consequences of infection. Since diarrheal disease in this population is also relatively common, many infections may not be detected.

Infectious disease surveillance systems are operated by state and local public health agencies with little or no direct contact with healthcare providers. To improve disease surveillance system, it will likely be necessary to better integrate healthcare delivery systems with those disease surveillance programs. This integration can only occur if both the state public health agencies and the healthcare providers recognize benefits from this cooperation and barriers to data sharing are reduced.

Disinfection of drinking water was instituted at a time when waterborne infectious diseases were the primary focus in public health. The use of disinfectants such as chlorine, chloramine, chlorine dioxide, ozone, and ultraviolet radiation has resulted in a reduction in the outbreak of diseases such as cholera and polio in many parts of the world. The choice of disinfectant is dependent on their availability, ease of use, cost, and their efficacy in disinfecting water. Some disinfectants commonly used in water treatment plants are not stable in water for long periods of time, which reduces their disinfection efficacy. Current practices to control pathogens in drinking water include using a combination of disinfectants, coagulation, and filtration. A main disadvantage of using disinfectants in drinking water is their ability to react with organic and inorganic matter in water to form disinfection byproducts that may be of health concern. The disinfectants can also be hazardous at high concentrations, but toxicological studies suggest that their toxicity is likely not relevant at the low concentrations encountered in drinking water.

PURPOSE

Contaminated, untreated, or inadequately treated water is known to transmit disease-causing pathogens such as bacteria, viruses, fungi, and protozoa (1). The size of these pathogens varies from a few hundred microns for bacterial clusters to around 0.01 μm for viruses (2). Although physical water treatment processes such as sedimentation and filtration may remove pathogens that are greater than 10 μm in size, ultra- or nanofiltration may be required to remove disease-causing pathogens (3). Conventional filtration is usually not practical for smaller systems, and, ultrafiltration may not be economically viable to treat large quantities of water; therefore, chemical treatment may have to be employed to treat water. The process of reducing the number of pathogenic microorganisms through the addition of chemicals (i.e., disinfectants) into water is called disinfection.

A variety of disinfectants may be used in water treatment plants, with the choice dependent on the location and size of the plant, the cost effectiveness, the pathogen(s) of concern, the water source, the characteristics of the pretreated water, and the disinfectant characteristics (e.g., solubility, stability, disinfecting and deodorizing ability, corrosiveness, and the time required to disinfect). Other factors that are considered include the effectiveness of the disinfectant in killing a range of microorganisms, the potential to form disinfection byproducts (DBPs) that may cause health effects in humans and animals, and the ability of the disinfecting agents to remain effective in water throughout the water distribution system.

HISTORY

Prior to A.D. 1600, civilizations consumed water based on visual clarity, or after treatments such as exposing the water to sunlight, dipping heated copper or other metals in water, boiling, and filtering water through a cloth (4). Other types of water treatment such as exposure to germicidal metals (e.g., silver and copper), sand filtration, distillation, coagulation, and adsorption with alum, lime, plant extracts, charcoal, clay, or plant materials have been employed since the 1600s. Modern methods of water disinfection were first used in Europe in the mid-to-late 1800s. One of the first known uses of chlorine as a germicide was Ignac Semmelweis' introduction of chlorine water for hand cleansing in the Vienna General Hospital maternity wards in 1846 (5).

Following research advances on the effect of microorganisms on human health in the 1870s, and improvements to physical water treatment technologies such as slow sand filtration in the 1880s, chlorine (as chloride of lime) and ozone were first used as drinking water disinfectants on a plant-scale basis at water treatment facilities in Hamburg, Germany and Oudshoorn, Holland, respectively, in 1893 (5,6). In 1897, Sims Woodhead used bleach to sterilize potable water at Maidstone, England after a typhoid outbreak. In 1903, a water treatment facility in Middlekerke, Belgium was the first to use chlorine gas as a disinfectant (4,7).

In North America, the first use of chemical disinfection at water treatment plants began in 1908 when chlorine was used as a disinfectant in Jersey City, New Jersey (as sodium hypochlorite) and Chicago, Illinois (as chloride of lime). Chloramination was first used in Ottawa, Canada and Denver, Colorado in 1917, whereas ozonation was first used in the United States in the 1940s (4). Today, chemical disinfection of drinking water is widely recognized as a necessity and is widely practiced at city, community, and point-of-use levels throughout the United States.

TYPES OF DISINFECTANTS

Chemical disinfection is considered the most effective treatment to inactivate pathogens in drinking water. A majority of the disinfectants that are in use in water treatment plants today are oxidants such as chloramine, chlorine dioxide, chlorine gas, electrochemically generated oxidant from sodium chloride (NaCl), hypochlorite, ozone, and ultraviolet (UV) light. Additional chemical disinfectants used to treat drinking water, especially in households, include acids and bases such as citric juices, lime, mineral acids and hydroxide salts, metals such as copper or silver, surfactants, and permanganate (8). Since each disinfectant has its own advantages and disadvantages (summarized in CHLORINATION BYPRODUCTS and the ALTERNATIVE DISINFECTANTS), a combination of multiple treatment processes including sedimentation, coagulation, flocculation, filtration, and disinfection is used in the majority of the water treatment plants in the world today. Table 1 provides a summary of the water treatment methods used, their availability, ease of use, cost, and efficacy in neutralizing the disease-causing pathogens.

DISINFECTION EFFICACY

Disinfection kinetics is usually expressed by Chick's law (also known as the CT law), which relates the activity [e.g., 3-log (99.9%) or 5-log (99.999%) reduction] to the product of disinfectant concentration (C) and contact time (T) (12). For example, to provide a given degree of disinfection, a low concentration and high contact time may be maintained or vice versa (13). The CT law may not provide adequate disinfection due to various factors that may affect the efficacy of the disinfectant, such as the type of pathogen; type of disinfectant; chemical factors such as pH, dissolved organic matter, salts, and ions; and particulate matter (14). Among the pathogens, vegetative bacteria are generally the easiest to disinfect followed by viruses, bacterial spores, fungal spores, and protozoan parasites (8). The formation of aggregates with other microorganisms or particulates in water may reduce the disinfectant's efficacy by preventing access to the pathogens. Among the most commonly used disinfectants, ozone's ability to disinfect is generally the highest followed by chlorine dioxide, electrochemically generated chlorine, and chloramine. However, ozone is the least stable disinfectant in water and is hence unable to provide a stable disinfectant residual in treated water that is necessary to prevent regrowth of the disease-causing pathogens (15). The chlorine-based disinfectants on the other hand are relatively stable in water in the absence of pathogens. At neutral pH, the half-life of chlorine dioxide is 30 min and 14 h for a 0.01 M and 0.0001 M solution, respectively (15). At ambient temperatures, the half-life of chloramines is approximately 100 h (16), whereas the half-life of sodium hypochlorite varies between 60 and 1700 d for water containing 18% and 3% available chlorine, respectively (17).

The characteristics of the source water also influence the efficacy of the disinfectants. Certain disinfectants such as hypochlorite are more effective at low pH, whereas chloramines are effective at a higher pH (5,15). The disinfectants may be consumed through reactions with other dissolved constituents in the water such as dissolved

Table 1. Advantages of Different Water Treatment Methods and Their Efficacy

Method	Availability	Difficulty	Cost	Pathogen Efficacy	Comments
Acids and bases	☺☺☺☺	×	$$	⊖⊖	Mostly used for pH control in water treatment plants; some microbial deactivation reported.
Adsorption	☺☺☺	×××	$$$$	Variable	Some bioreactors remove pathogens and organics.
Aeration	☺☺☺	×	$	⊖	Has to be used with other methods to be practical.
Boiling	☺☺☺☺	×	$$	⊖⊖⊖⊖	Used mostly at the point-of-use level.
Chloramines	☺☺☺☺	××	$$$	⊖⊖⊖	Less effective than free chlorine when used as a primary disinfectant; more practical as a secondary disinfectant.
Chlorine gas	☺☺☺☺	×××	$$$	⊖⊖⊖⊖	Widely used disinfectant.
Chlorine generated electrochemically from NaCl	☺☺☺☺	××	$$$	⊖⊖⊖⊖	Can be generated on site.
Chlorine dioxide	☺☺	×××	$$$$	⊖⊖⊖⊖	Highly effective as a primary disinfectant but is a poor secondary disinfectant.

organic matter and other salts to form DBPs, thereby limiting the amount of disinfectant available for pathogen inactivation.

CHEMISTRY OF DISINFECTANTS

The physical and chemical properties of disinfectants can affect their behavior in drinking water as well as their toxicity. Apart from reacting with natural organic matter or other solutes to form DBPs, disinfectants undergo a number of reactions to form products that may be toxic to humans and animals.

Free Chlorine

Chlorine gas (Cl_2) when exposed to water forms hypochlorous acid (HOCl) and hydrochloric acid ($HCl \rightleftharpoons H^+$ and Cl^-).

$$Cl_2 + H_2O \rightleftharpoons HOCl + H^+ + Cl^- \tag{1}$$

At $pH > 7.5$, HOCl will dissociate to form hypochlorite ion (OCl^-) (18). In addition, calcium hypochlorite [$Ca(OCl)_2$] and sodium hypochlorite (NaOCl) also immediately dissociate in water to form OCl^-. HOCl is a better disinfectant than OCl^- due to the relative ease with which it can penetrate cell walls (5). Hence, the pH of the water has to be lowered to improve the disinfection efficacy.

$$Ca(OCl)_2 \rightleftharpoons Ca^{2+} + 2OCl^- \tag{2}$$

$$NaOCl \rightleftharpoons Na^+ + OCl^- \tag{3}$$

$$H^+ + OCl^- \rightleftharpoons HOCl \tag{4}$$

At $pH > 12$, hypochlorite ions can react to form chlorite ($ClO_2{}^-$) and chlorate ($ClO_3{}^-$), which are of major health concern (19,20).

$$OCl^- + OCl^- \rightarrow ClO_2{}^- + Cl^- \tag{5}$$

$$OCl^- + ClO_2{}^- \rightarrow ClO_3{}^- + Cl^- \tag{6}$$

In waters containing bromides, hypochlorite can react with bromide (Br^-) to form hypobromous acid (HOBr), thereby consuming the available free chlorine meant for disinfection (21).

$$HOCl + Br^- \rightarrow HOBr + Cl^- \tag{7}$$

Chlorine Dioxide

Chlorine dioxide (ClO_2) dissolves in water under alkaline conditions to form chlorite ($ClO_2{}^-$) and chlorate

Table 2. Disinfectant Use in the United States

Disinfectant	Medium and Large Systems (>10,000 People)	Small Systems (<10,000 People) Using Groundwater	Small Systems (<10,000 People) Using Surface Water
Chloramines	29%	—	2%
Chlorine dioxide	8%	—	6%
Chlorine gas	84%	61%	82%
Hypochlorite	20%	34%	26%
Ozone	6%	—	—

Source: References 36 and 37.

(ClO_3^-)(22,23). However, unlike free chlorine, hypobromous acid and organohalogen DBPs are not produced.

$$2ClO_2 + 2OH^- \rightleftharpoons ClO_2^- + ClO_3^- + H_2O \quad (8)$$

The half-life of aqueous ClO_2 decreases substantially with increasing ClO_2 molar concentration and with pH values above 9 (22,24). Even at neutral pH values and low ClO_2 concentrations, the half-life of ClO_2 is usually less than 24 h. Hence, the storage of stock solutions of ClO_2 for even a few hours is impractical.

Ozone

Dissolved ozone (O_3) either reacts with other dissolved solutes in water to form DBPs or decomposes in water to form highly reactive hydroxyl radicals ($OH^\bullet$) (25). Both ozone and hydroxyl radicals are effective disinfectants. Unlike ozone, hydroxyl radicals are highly nonselective in reactions with organic and inorganic solutes and are easily consumed, thereby limiting the amount available for disinfection.

$$O_3 + H_2O \rightarrow O_2 + OH^\bullet \quad (9)$$

The kinetics of ozone reactions are favorable for disinfection and oxidation of many organic and inorganic contaminants in drinking water. However, for many difficult-to-oxidize organic compounds such as chloroform, some alcohols, and saturated alkyl moieties, the kinetics of ozone oxidation may be very slow (26–28).

Chloramines

When ammonia is added to drinking water containing free chlorine, hypochlorous acid will react with ammonia to form one of three types of chloramines depending on temperature, pH, and reaction time (29). Monochloramine (NH_2Cl) and dichloramine ($NHCl_2$) are formed between pH 4.5 and 8.5 and are commonly found at pH typical of drinking water (pH 6–8.5). Monochloramine is most common when the pH is above 8. When the pH is below 4.5, the most common form of chloramine is trichloroamine (NCl_3), which produces a very foul odor and is sometimes found in swimming pools. Chloramines are effective disinfectants against bacteria but not viruses (30,31).

$$NH_3 + HOCl \rightarrow NH_2Cl + H_2O \quad (10)$$

$$NH_2Cl + 2HOCl \rightarrow NHCl_2 + 2H_2O \quad (11)$$

$$NHCl_2 + 3HOCl \rightarrow NCl_3 + 3H_2O \quad (12)$$

TOXICOLOGY OF DISINFECTANTS

At high concentrations, chlorine gas, chloramine, chlorine dioxide, dichloramine, monochloramine, and ozone have been shown to be strong respiratory irritants in humans (32). Hypochlorite is highly caustic and causes skin and esophagus irritation even at low concentrations (33). When household cleaning agents containing hypochlorite and ammonia are mixed, chloramine gas is formed, which can cause severe lung injury (34). The limited toxicological studies on the above-mentioned disinfectants suggest that their toxicity is likely not relevant at the low concentrations encountered in drinking water (35).

TYPICAL USE IN THE UNITED STATES

Chlorine-based disinfectants are used in more than 95% of the water treatment systems across the United States. Table 2 provides a breakdown of the percentages of water treatment systems that use the various disinfectants. Some water treatment systems use multiple disinfectants due to different primary and secondary disinfection practices. Additional information on the use of various disinfectants in other countries, their advantages and disadvantages, including DBP formation, are available in CHLORINATION BYPRODUCTS and ALTERNATIVE DISINFECTANTS.

DISINFECTION

National Drinking Water
Clearinghouse

Disinfection is an important step in ensuring that water is safe to drink. Water systems add disinfectants to destroy microorganisms that can cause disease in humans. The Surface Water Treatment Rule requires public water systems to disinfect water obtained from surface water supplies or groundwater sources under the influence of surface water.

Primary methods of disinfection are chlorination, chloramines, ozone, and ultraviolet light. Other disinfection methods include chlorine dioxide, potassium permanganate, and nanofiltration. Since certain forms of chlorine react with organic material naturally present in many water sources to form harmful chemical byproducts, the U.S. Environmental Protection Agency has proposed maximum levels for these contaminants.

DISINFECTION KEEPS WATER SAFE

Why Disinfect Drinking Water?

Disinfection kills or inactivates disease-causing organisms in a water supply and must provide a 99.9 percent inactivation of *Giardia lamblia* cysts and enteric viruses to protect health and to comply with the U.S. Environmental Protection Agency (EPA) regulations. There are two kinds of disinfection: primary disinfection achieves the desired level of microorganism kill or inactivation, while secondary disinfection maintains a disinfectant residual in the finished water that prevents the regrowth of microorganisms.

What Regulations Govern It?

The EPA Surface Water Treatment Rule (SWTR) requires systems using public water supplies from either surface water or groundwater under the direct influence of surface water to disinfect.

Also, since some disinfectants produce chemical by-products, the dual objective of disinfection is to provide the required level of organism destruction and remain within the maximum contaminant level (MCL) for the SWTR disinfection set by EPA. At this time, an MCL is set for only Total Trihalomethanes, and proposed for additional disinfection by-products.

How is Disinfection Achieved?

Our natural environment contains numerous microorganisms. Most of these present no concerns. However, some—such as *Giardia lamblia* and various viruses, which can be present in water supplies—are extremely harmful and can cause disease in humans. These disease-causing organisms are known as pathogens.

Because pathogens can be present in drinking water supplies, disinfection is very important—the EPA requires it for surface water and groundwater under the influence of surface water. Disinfection treatment methods include chlorination, chlorine dioxide, chloramines, ozone, and ultraviolet light.

When combined with conventional treatment, such as coagulation, flocculation, sedimentation, and filtration, good results have been obtained. Direct filtration, slow sand filtration, and diatomaceous earth filtration, along with disinfection, have been just as successful.

Groundwater systems that disinfect may have to add filtration if the water contains iron and manganese. In fact, insoluble oxides form when chlorine, chlorine dioxide, or ozone are added to these systems. Both ozonation and chlorination may cause flocculation of dissolved organics, thus increasing turbidity and necessitating filtration. The effectiveness of disinfection is judged by analyzing for an indicator organism (total coliform bacteria). This organism is considered harmless, but its presence indicates that pathogens may also have survived.

COMPARING DISINFECTANTS

Chlorination (Gas)

At normal pressures, elemental chlorine is a toxic, yellow-green gas, and is liquid at high pressures.

Advantages. Chlorine is very effective for removing almost all microbial pathogens and is appropriate as both a primary and secondary disinfectant.

Limitations. Chlorine is a dangerous gas that is lethal at concentrations as low as 0.1 percent air by volume.

Process. Chlorine gas is released from a liquid chlorine cylinder by a pressure reducing and flow control valve operating at a pressure less than atmospheric. The gas is led to an injector in the water supply pipe where highly pressurized water is passed through a venturi orifice creating a vacuum that draws the chlorine into the water stream. Adequate mixing and contact time must be provided after injection to ensure complete disinfection of pathogens. It may be necessary to control the pH of the water.

Equipment. A basic system consists of a chlorine cylinder, a cylinder-mounted chlorine gas vacuum regulator, a chlorine gas injector, and a contact tank or pipe (see Fig. 1). Prudence and/or state regulations would require that a second cylinder and gas regulator be provided with

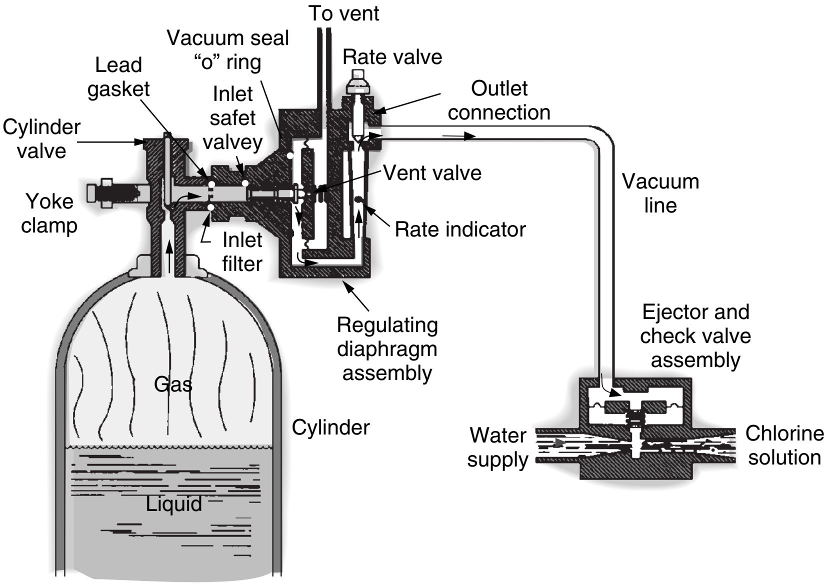

Figure 1. Cylinder-mounted chlorinator. Reprinted with permission from Capital Controls Company, Inc.

a change-over valve to ensure continuity of disinfection. Additional safety and control features may be required.

A gas chlorinator should be installed in a room or chamber with direct emergency access to outside air and fitted with an exhaust fan ventilation system.

Federal and state safety regulations must be observed. If not onsite, self-contained breathing apparatus and a chlorine cylinder repair kit should be available within a reasonable time frame and/or distance.

Chemicals. Chlorine gas is supplied as liquid in high pressure cylinders.

Chlorination (Sodium Hypochlorite Solution)

Sodium hypochlorite is available as a solution in concentrations of 5 to 15 percent chlorine, but is more expensive than chlorine gas (as available chlorine).

Advantages. Sodium hypochlorite is easier to handle than gaseous chlorine or calcium hypochlorite.

Limitations. Sodium hypochlorite is very corrosive and should be stored with care and kept away from equipment that can be damaged by corrosion. Hypochlorite solutions decompose and should not be stored for more than one month. It must be stored in a cool, dark, dry area.

Process. Sodium hypochlorite solution is diluted with water in a mixing/holding tank. The diluted solution is injected by a chemical pump into the water supply pipe at a controlled rate. Adequate mixing and contact time must be provided.

Equipment. A basic liquid chlorination system, or hypochlorinator, includes two metering pumps (one serving as a standby), a solution tank, a diffuser (to inject the solution into the water), and tubing.

Chemicals. Sodium hypochlorite solution is readily available.

Sodium hypochlorite can also be generated onsite by electrolysis of sodium chloride solution in specialized proprietary equipment. The only supplies required are common salt and electricity. Hydrogen is given off as a by-product and must be safely dispersed.

Chlorination (Solid Calcium Hypochlorite)

Calcium hypochlorite is a white solid that contains 65 percent available chlorine and dissolves easily in water.

Advantages. When packaged, calcium hypochlorite is very stable, allowing a year's supply to be bought at one time.

Limitations. Calcium hypochlorite is a corrosive material with a strong odor that requires proper handling. It must be kept away from organic materials such as wood, cloth, and petroleum products. Reactions between calcium hypochlorite and organic material can generate enough heat to cause a fire or explosion. Calcium hypochlorite readily absorbs moisture, forming chlorine gas. Therefore, shipping containers must be emptied completely or carefully resealed.

Process. Calcium hypochlorite may be dissolved in a mixing/holding tank and injected in the same manner as sodium hypochlorite. Alternatively, where the pressure can be lowered to atmospheric, such as at a storage tank, tablets of hypochlorite can be directly dissolved in the free flowing water by a proprietary device that provides flow-proportional chlorination with gravity feed of the tablets.

Equipment. The equipment used to mix the solution and inject it into the water is the same as that for sodium hypochlorite. Solutions of 1 or 2 percent available chlorine can be delivered by a diaphragm-type, chemical feed/metering pump or by tablet chlorinator.

Chemicals. Calcium hypochlorite can be purchased in granular, powdered, or tablet form.

Chloramine

Chloramines are formed when water containing ammonia is chlorinated or when ammonia is added to water containing chlorine (hypochlorite or hypochlorous acid).

Advantages. An effective bactericide that produces fewer disinfection by-products, chloramine is generated onsite. Usually, chloramine-forming reactions are 99 percent complete within a few minutes.

Limitations. Chloramine is a weak disinfectant. It is much less effective against viruses or protozoa than free chlorine. Chloramine is appropriate for use as a secondary disinfectant to prevent bacterial regrowth in a distribution system. Nitrogen trichloride appears to be the only detrimental reaction. It may be harmful to humans and imparts a disagreeable taste and odor to the water. The use of the proper amounts of each chemical reactant will avoid its production.

Process. Chlorine (gaseous solution or sodium hypochlorite) is injected into the supply main followed immediately by injection of ammonia (gaseous solution or as ammonium hydroxide). As before, adequate mixing and contact time must be provided. The mix of products produced when water, chlorine, and ammonia are combined depends on the ratio of chlorine to ammonia and the pH of the water. Chlorine-to-ammonia ratios of 5:1 should not be exceeded. If the pH drops below 5, some nitrogen trichloride may be formed.

Equipment. The generation of chloramines requires the same equipment as chlorination (gaseous or aqueous hypochlorination), plus equipment for adding ammonia (gaseous or aqueous).

All chlorine added to drinking water must meet American National Standards Institute (ANSI), and NSF *International*, formerly the National Sanitation Foundation (NSF) standards. *ANSI/NSF Standard 60: Drinking Water Chemicals—Health Effects* covers water treatment chemicals.

Chemicals. Chemicals used to generate chloramine from ammonia and chlorine gas depend on the ammonia-based chemical used. Anhydrous ammonia is the least expensive, while ammonium sulfate is the most expensive.

Ozonation

Ozone, an allotrope of oxygen having 3 atoms to each molecule, is a powerful oxidizing and disinfecting agent. It is formed by passing dry air through a system of high voltage electrodes.

Advantages. Requiring shorter contact time and dosage than chlorine, ozone is widely used as a primary disinfectant in many parts of the world—but is relatively new to the U.S. Ozone does not directly produce halogenated organic materials unless a bromide ion is present.

Limitations. Ozone gas is unstable and must be generated onsite. A secondary disinfectant, usually chlorine, is required because ozone does not maintain an adequate residual in water.

Process. The five major elements of an ozonation system are:

- air preparation or oxygen feed;
- electrical power supply;
- ozone generation—usually using a corona discharge cell consisting of two electrodes;
- ozone contact chamber; and
- ozone exhaust gas destruction.

Equipment. Ozonation equipment includes air preparation equipment; an ozone generator, contactor, destruction unit; and instrumentation and controls. The capital costs of ozonation systems are relatively high. Operation and maintenance are relatively complex. Electricity represents 26 to 43 percent of total operating and maintenance costs for small systems.

Chemicals. For many applications, pure oxygen is a more attractive ozone feed gas than air because:

- it has a higher production density,
- it requires lower energy consumption,
- it doubles the amount of ozone that can be generated per unit, and
- it requires smaller gas volumes for the same ozone output, thus lowering costs for ancillary equipment.

Ultraviolet Light (UV)

Ultraviolet (UV) radiation is generated by a special lamp. When it penetrates the cell wall of an organism, the cell's genetic material is disrupted and the cell is unable to reproduce.

Advantages. UV radiation effectively destroys bacteria and viruses. As with ozone, a secondary disinfectant must be used to prevent regrowth of micro-organisms. UV radiation can be attractive as a primary disinfectant for small systems because:

- it is readily available,
- it produces no known toxic residuals,
- it requires short contact times, and
- the equipment is easy to operate and maintain.

Limitations. UV radiation may not inactivate *Giardia lamblia* or *Cryptosporidium* cysts, and should be used only by groundwater systems not directly influenced by surface water—where there is virtually no risk of protozoan cyst contamination. UV radiation is unsuitable for water with high levels of suspended solids, turbidity, color, or soluble organic matter. These materials can react with or absorb the UV radiation, reducing the disinfection performance.

Process. The effectiveness of UV radiation disinfection depends on the energy dose absorbed by the organism, measured as the product of the lamp's intensity (the rate at which photons are delivered to the target) and the time of exposure. If the energy dosage is not high enough, the organism's genetic material might only be damaged instead of destroyed. To provide a safety factor, the dosage should be higher than needed to meet disinfection requirements.

Equipment. UV lamps and a reactor (see Fig. 2).

Chemicals. No chemical oxidant required; therefore, microorganisms can be killed without generating byproducts of chemical oxidation or halogenation.

HOW DO YOU CONTROL DISINFECTION BYPRODUCTS?

A number of factors can affect the formation of disinfection byproducts. These include the types and concentrations of organic materials present when chlorine is added, the dosage of chlorine, the temperature and pH of the water, and the reaction time.

To control the formation of halogenated byproducts (compounds formed by the reaction of a disinfectant, such as chlorine with organic material in the water supply) during chlorination, EPA has identified these three strategies:

1. Remove the byproducts after they are formed, which can be difficult and costly.
2. Use alternative disinfectants that do not produce undesirable byproducts, which is often the most cost-effective strategy.
3. Reduce the concentration of organics in the water before oxidation or chlorination to minimize the formation of byproducts. This will provide the highest quality finished water.

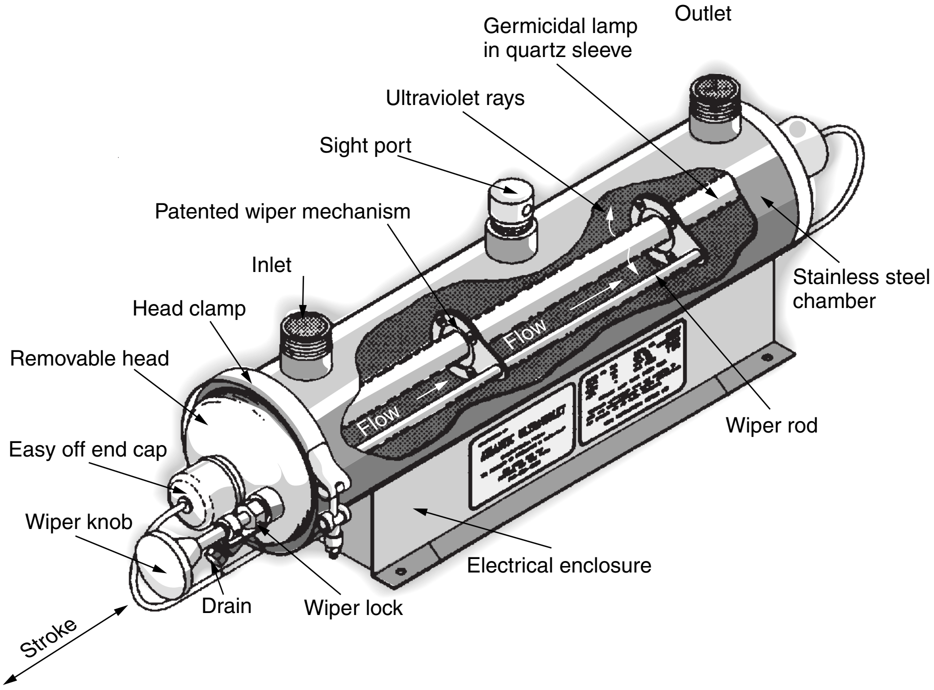

Figure 2. Ultraviolet water purifier. Reprinted with permission from Atlantic Ultraviolet Corporation.

WHERE CAN I FIND MORE INFORMATION

Information on disinfection was primarily obtained from two sources: Environmental Pollution Control Alternatives: Drinking Water Treatment for Small Communities, *EPA/625/5-90/025*; *and* Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities, *EPA/625/4-89/023. Both can be ordered free from the EPA Office of Research and Development at (513) 569-7562.*

These publications also can be ordered from the National Drinking Water Clearinghouse (NDWC); however, copying costs apply. The first book, item #DWBKGN09, an 82-page publication, costs $11.82; and the second, item #DWBKDM04, a 209-page book, costs $30.05. Shipping and handling charges apply.

For further information or to order additional copies of "Tech Brief: Disinfection," item #DWBRPE47, or the above publications call the NDWC at (800) 624-8301.

WATER DISTRIBUTION SYSTEM OPERATION

Mario O. Buenfil-Rodriguez
National University of Mexico &
Mexican Institute of Water
Technology
Cuernavaca, Morelos, Mexico

OPERATION, MAINTENANCE, AND DESIGN OF WATER SERVICES

Contemporary cities and their inhabitants depend on a reliable and generous public water supply system for their functioning and to protect and promote health, productivity, and well-being. The possibility of having piped water and sewerage systems at home explains why cities can support such huge human concentrations. Some major technological and cultural changes to make cities less dependent on such public services are needed but still far in the future. These vast systems, almost invisible to many, as they are underground networks, are complex and delicate arteries that require daily operation and care by professional people devoted exclusively to such tasks.

Various and ample are the duties and responsibilities of any water utility, although there are some variants around the world. Some utilities deal exclusively with clean water distribution; others have broader functions such as extraction from a remote site, conduction, purification, distribution, sewerage, waste treatment, and even tasks such as operation of pipe networks for fire combat, or selling treated wastewater, pluvial drainage, solid waste collection, or energy supply.

The operational tasks for distributing clean water in a city involve monitoring flows, pressures, storage levels, and water quality at different network locations; controlling and moving valves; attending to reports and enquiries from the public; billing and charging for consumption; keeping updated infrastructure maps and consumer records and census; repairing leaks; and replacing or improving pipes, hydrants, pumps, and other water distribution networks components.

There is no clear or definite boundary between operational and maintenance tasks, and their distinction is merely the intensity or frequency of a given job. Sometimes, the same employee team performs operational, preventive, or corrective maintenance tasks. In contrast, other rather specialized tasks can require a contract with a private service provider (*as analyzing water samples to detect a specific and difficult pollutant or controlling and supervising a sophisticated automated pump*).

There is a strong bond between the system's "hydraulic design" and its "operation," and often they can be synonymous. For instance, pressure may be controlled automatically by properly locating storage tanks or automatic valves. Although in some not-so-well-designed systems, frequent manual movements (*operation*) of valves may be needed. The same can be said for filling and emptying water volumes in regulating tanks to meet differences in demand and supply flows. When storage tanks are properly sized to accommodate daily variations of demand, with timing of supply pumps, they will function correctly, but if not, a lot of work is required from "operations personnel" (*usually accompanied by uneasiness and complaints from consumers*).

One practical definition of our topic, although not accepted everywhere (*and not even here*), is this: *Operation* is the organized procedure for causing a piece of equipment, a treatment plant, or other facility or system to perform its intended function, but not including the initial building or installation of the unit. Usually operation and maintenance are referred simultaneously, as *O & M*, meaning the management of a facility involving operating, repair, and replacement.

Another more general definition (*World Bank*) states that *operation* includes the planning and control of the extraction/collection, treatment, conveyance, and delivery of water, and/or the collection, treatment, and disposal of effluent. It also covers the management of client and public relations, legal, personnel, commercial, and accounting functions.

DESIRABLE OPERATING CONDITIONS

Not all cities offer the same service standards of water quality, pressure, and reliability, although most of them guide their performance and duties by a certain set of local goals or regulations. Sometimes, an external autonomous supervisory board exists, sponsored by consumers or by an international agency, to guarantee the provider's accountability in protecting people's health and economy.

Some of these operational goals may be

— Continuity of supply (*24 hours, 365 days per year*).

— Keep low water tariffs (*in balance with expenditures and investments*), and in an increasing block fashion (*the more you consume, the more you pay per water unit to keep the water demand as small as possible and preserve the resource*).

— Promote and advise customers to keep their water consumption low (*demand management*).

— Keep pressure not too weak, nor too strong at each house connection (*around 10 m to 30 m of water column, that is, between 1 to 3 bars*).

— Curb water leaks (*pipes burst*), and when they occur, repair them within a few hours.

— Satisfy daily and seasonal variations in water demand without spillage or damage to infrastructure or inconvenience to consumers.

— Use the least possible energy for pumping and other processes (*low operating costs*).

— Courteous, fair, and undiscriminatory treatment to all consumers.

— Water quality in all points of the network must meet established standards.

— Optimize the use of the system's installed capacity for water storage, pumping, and conduction (*profit from and use the existing infrastructure, keep it in good shape, and avoid the need for building more of it*).

ELEMENTS OF WATER DISTRIBUTION SYSTEM

It is convenient that any water supply system operator be simultaneously involved in, or at least aware of, the sewerage system and the treatment and disposal of wastewater. However, focusing only on the supply side, a water network may depend on the water coming from remote sources, purification plants, aqueducts and pumping stations. All these installations rely on various minor components and devices such as gates, valves, cisterns, and filters. All such items require careful operation and maintenance by the same institution attending to the distribution network in the city. Sometimes, the water sources are within the urban area, as in the case of pumping wells intermingled with the network. In that case, the water quality and pressure can be assured merely by local additions of chlorine or equivalent, and through booster pumps or pressure-breaking valves or tanks.

Some of the elements in a water distribution network are elevated tanks, underground reservoirs or cisterns, booster stations, valves of different types, meters (*for water mains and for customer consumption*), pipes, house connections, various types of fittings and protection cages, fire and public hydrants, local chlorination equipment, monitoring and sampling devices, and telemetry and SCADA systems (*supervisory control and data acquisition*) and all their electronic and electric apparatuses and connections. Besides those previously mentioned "fixed" (*on-site*) elements, there is a wide range of necessary mobile equipment such as vehicles, cranes, winches, mobile laboratories, and maintenance and repair equipment.

Water distribution pipes are normally arranged in grid or loop designs to provide easy flow of water by different routes (*particularly during hours of high demand*) and to avoid lines that dead-end and may cause water quality problems. All distribution systems should contain sufficient valving so that any area can be isolated for repair or for scrutiny in case of contamination risk, and only a minimum number of customers should be affected during the disruption.

PRINCIPAL OPERATIONS

Public water systems are designed to provide and maintain a reliable, high-quality water source (*e.g., groundwater or surface water*). Although one important operation to meet drinking water standards is water treatment, it will not be covered here to concentrate on what happens and is required in the water distribution network. Operations there deal with different cares and purposes, among which is preserving the water quality in the network.

The operation of a water distribution system (*inevitably linked to its maintenance and design*) includes attending to all kinds of requests or complaints from customers; meeting local standards and federal regulations; and the upkeep of pipes, storage tanks, and pumps that convey the water. Some of the activities are

- Hydraulic performance to meet water demands
- Map control and updating
- Modeling and corroboration of system's hydraulic behavior
- Records (*telemetry, samplings*), control, and analysis
- Leak detection and repair
- Cross connection control and backflow prevention
- Gauging flow (*district metering areas, DMA*) and consumption (*meters*)
- Billing consumers and collecting money from them
- Exercising of valves
- Water pipe flushing and internal cleaning
- Water quality monitoring
- Chlorination or dechlorination at local points
- Water main repair/replacement
- Electric and electronic equipment conservation and upgrading
- Inspecting quality of materials (*pipes, joints, chlorine*) and performance of equipment (*water meters, valves, etc.*)
- Storage tank maintenance
- Pump maintenance
- Prevention and training against vandalism, terrorism, and emergencies (*drought, flooding, earthquake, etc.*)

It would take too long to give details of all these operations, so only brief comments for some of them will be given in the following sections:

WATER DELIVERY AND MONITORING

The most important operation of any water distributing system is ensuring that enough and timely water arrives at each house. Therefore, one basic operation is the regulation of flows to adapt them to the hours of peak demand (*e.g., from 6 AM to 8 AM*), and to those of low demand (*e.g., during the night*). Usually, in well-designed and developed countries' systems, these maneuvers are performed "automatically" through "*operational storage*" from regulating tanks around the city. These tanks have float or diaphragm actuated valves that close the inflow when full, preventing spillage, and besides can send a signal to halt a remote pump. This exemplifies how operation depends on design, which in poor or simple systems, or in emergencies, has to be done manually.

Pumps and valves can be preprogrammed to start or stop on given schedules and can be monitored and acted-on through automatic or semiautomatic computerized *supervisory control* systems (*SCADA*) that can check pressure and flow at selected network points. On the other hand, they could simply be controlled manually, according to certain seasonal rules (*e.g., rationing of water in drought times*).

Telemetry and the ability to *communicate* efficiently are important in the successful operation and maintenance of a complex and expanded water supply system. One option is the use of mobile radiotelephones. Telemetry can provide a complete updated picture of the status of all components in the network, such as reservoir contents, water movements and trends, and pump stations. Condition monitoring is part of preventive maintenance and will help to minimize unscheduled shutdowns and improve reliability of service. Sites operating as unmanned installations require that intrusion and hazard *alarms* be reported as soon as possible, so that steps can be taken to limit possible damage. Remote operation of pumps, gates, etc. is required to ensure coordinated operation of tandem plants and to alleviate staff shortages.

One important and routine monitoring task is *reading the house meters* of all consumers. This will not only give data for billing according to consumption, but also gives clues about possible leaks in the system or about clandestine connections, when combined with information of *DMA* (*district metering areas*), which is another important monitoring operation. The purpose of these is to have knowledge about volumes supplied and consumed to detect possible money losses, leaks, bursts and waste, and to correct them as soon as possible.

Water balances (*audits*) and statistics will give information to decide if, instead of a local repair, full pipe replacement is more convenient. Water *leaks* can be visible, but often they are hidden, requiring specialized equipment and personnel to locate them.

Continuous *surveying and sampling* of water quality and hydraulic parameters (*pressure, flow direction, volume supplied*) at different locations is an important task. Those records must be compared to written standards and particular utility goals and performance rules. The purpose of that would be to detect failures and correct them, as well as to find opportunities to improve service quality and efficiency, besides the utility's revenues, through the design of better operating strategies. In this regard, an important tool is *hydraulic modeling* of the distribution system.

Hydraulic transients, or *surges*, occur during rapid flow changes in pressurized water conveying pipelines. Normally, such transients (*water hammer*) are considered a problem as they might damage the pipeline due to strong pressure peaks, subatmospheric pressures, or fatigue. By using simulating models incorporated into hydroinformatic tools, it is possible to assess existing water distribution systems, to suggest more efficient hydraulic performance and propose rehabilitative strategies.

PREVENTION AND SAFETY

Many operational tasks could be classed as related to "prevention and safety." Some of them, such as leak detection and control and water quality sampling, have already been mentioned. Some others are cross connection control, backflow prevention, and protection and vigilance against vandalism or emergencies.

Continuous positive pressure is necessary in all distribution systems to prevent a vacuum in the water-supply main. These vacuums can lead to backsiphonage and possible contamination or even collapse of pipe sections.

Cross connection control and backflow prevention are operational programs that both the utility and its customers must implement to prevent contaminants and nonpotable water (*e.g., wastewater, storm water, process water*) from being drawn into the drinking water system.

Backflow typically occurs when the distribution system's pressure drops, due to a water main break or due to firefighting demands. It has two interpretations: (1) a flow condition, induced by a differential in pressure, which causes the flow of water or other liquid into the distribution pipes of a potable water supply from any source or sources other than its intended source; (2) back up of water through a conduit or channel in the direction opposite to normal flow.

Cross connections are physical piped connections between potable water and an unsafe or polluted water source. They threaten water quality and public health through the backflow of such hazardous substances as antifreeze, boiler water, and sewage. Cross connection control operation, besides building codes and regulations to avoid them, consists of inspection routines and checking backflow prevention devices on particularly high-risk service connections (*e.g., a wastewater treatment plant*).

Numerous recommendations, concerns, and routines can be implemented for *general protection and vigilance* against vandalism or emergencies. Their selection and adoption depend on the risks, the characteristics of the utility and its infrastructure, and even the present or expected climate and political and socioeconomic atmosphere. These are some examples: *Lock all doors and set alarms at offices and main installations. Limit access to facilities, especially to water supply reservoirs. Secure hatches, meter boxes, hydrants, manholes, and other access points to the water distribution system. Control access to computer networks and control systems. Write and periodically review security and emergency plans, and train employees frequently. Assess the vulnerability of water sources, drinking water treatment plants, distribution networks, and other key infrastructure elements. Improve the computer system and remote operational security.*

MAINTENANCE AND REPAIR

It is important to operate all network valves periodically, merely to ensure their proper performance when really needed. A dead-end line must be flushed frequently or the customer on that line will receive poor quality water.

Water pipe flushing is a preventive maintenance task intended to preserve the hydraulic characteristics of the pipe, besides the quality of the water flowing through it. It removes any accumulated sediments or other impurities deposited in the pipe. Flushing is performed by isolating sections of the distribution system and opening flushing valves or, more commonly, fire hydrants to cause a large volume of flow to pass through the isolated pipeline and suspend the settled sediment.

Water *mains* may also be *mechanically cleaned* by using swabs or pigs which are devices that are pulled through a section of line to scrape the accumulated debris off the inside of the pipe. The major environmental concern of water pipe flushing is the discharge of flushed water, which may be high in suspended solids and other contaminants that can harm water bodies. The negative impacts of the discharge may be minimized by discharging the flush water into a sanitary sewer of adequate capacity or by discharging the flush water into a separate storm sewer system, preferably using management measures such as a detention pond, where solids can settle before the water is discharged.

Water *mains* must be *repaired* or *replaced* frequently to correct or substitute broken, corroded, or leaking sections of pipe. Either the broken pipe section is replaced or, as is often the case, a repair sleeve is placed around the outside of the broken pipe section and clamped into place. Following the pipe repair, the line is typically flushed and then disinfected with a chlorine solution. The chlorine solution is usually mixed on site using powdered calcium hypochlorite or sodium hypochlorite. Pipe repair and replacement could affect the environment (*erosion of soil, sediments, high concentrations of chlorine, etc.*), and such impacts should be minimized by control measures.

Storage tanks require frequent inspection and maybe occasional repairs. The most frequent repairs are repainting of walls and replacing screens over vents and other points of access to insects, birds, and rodents. Steel tanks are subject to corrosion, which is prevented by painting them regularly.

Pumps must be maintained to ensure that booster and other distribution pumps stay in working order. Their maintenance involves frequent inspection and tests for excessive vibration or noise, providing grease and lubrication regularly, and checking the pump bearings and packing glands.

PUBLIC RELATIONS AND MANAGEMENT

Operation of a water distribution system has much to do with the management of client and public relations, legal, personnel, commercial, and accounting functions.

To be sustainable, an operation must be *financially viable*. Because of the pressure to expand the area served, viability generally implies recovering the costs of operation and maintenance, as well as capital. Public utilities often have difficulty getting approval for increasing their charges to levels that are financially and economically adequate. Sometimes, this is for political reasons, but often it is also because the requests are poorly prepared and their urgency is not well perceived. Higher charges must be justified not only to the parent entity but also to consumers. Public relations campaigns can be helpful here, but quality service is often crucial to securing consumers' acceptance of increases.

Demand management to keep water needs low and congruent with natural local resources is a vital task. For this purpose, education campaigns directed to the public, installation and reading of water meters, appropriate and fair setting up of water tariffs, proper operation and location of consumer information and attention modules (*telephone, internet, direct presence*) are basic. Employees must be trained and aware of their role in transmitting correct information and messages to the public.

WATER QUALITY IN DISTRIBUTION SYSTEMS

Z. Michael Lahlou
Technical Assistance
Consultant

A drinking water system's water quality may be acceptable when the water leaves a treatment plant. However, a variety of physical, chemical, and biological transformations can happen once the water enters and travels through a distribution system. Water producers need to understand the sources of water quality degradation during the distribution process because, in addition to taste and odor problems that can occur, research also suggests that degraded water quality increases the risk of gastrointestinal illnesses

WATER QUALITY DETERIORATION FACTORS

A distribution system's pipes and storage facilities constitute a complex network of uncontrolled physical, chemical, and biological reactors that can produce significant variations in water quality. The principal factors that affect water degradation during distribution are the system's structure, its operation, and a number of water quality factors.

STRUCTURAL FACTORS

Drinking water distribution systems are typically thought of as the underground network of interconnecting mains or pipes. They also can include storage facilities, valves, fire hydrants, service connections, and pumping stations.

Historically, water system designers tended to create oversized pipelines and storage facilities. While system designers may be considering an area's future drinking water needs, oversized facilities result in long detention times, loss of chlorine residual, taste and odor concerns, and other water quality problems.

Furthermore, some of the materials designers choose to install in distribution systems create suitable environments for microorganism growth. Materials, such as cast or ductile iron, asbestos-cement, or pressurized concrete, can pit and make way for microorganisms to colonize.

In addition, oxidant-resistant microorganisms settle on pipe surfaces and produce a complex microenvironment known as biofilm. Biofilms form when organisms enter the distribution system and become entrapped in slow-flow areas, line obstructions, or dead-end sections. They usually appear as a patchy mass in pipe sections or as a uniform layer along the inner walls of a storage tank.

While not all biofilm is bad, researchers are currently unsure of its exact effect. Coliform bacteria may colonize in it, and biofilm may interfere with coliform detection. It may also cause taste and odor problems.

Designers now theorize that the material manufacturers use in pipes, as well as the condition of pipes, valves, and storage facilities, may exert a high-chlorine demand.

Pipe materials can cause water quality to deteriorate in other ways. Iron pipes can corrode, and lead and copper from pipe walls can dissolve. For example, unlined or exposed ferrous materials in pipelines can corrode and cause red or rusty-colored water. To avoid corrosion problems, systems are turning to plastic materials, such as polyethylene and polyvinyl chloride (PVC).

Finally, contamination via cross-connection, leaky pipe joints, or pipe breaks may influence water quality. Pathogens, such as *Cryptosporidium* and *Giardia lamblia*, may enter the system through contaminated raw water, in-line reservoirs, or breaks in pipelines. System personnel need to carefully and thoroughly perform flushing and disinfection procedures following repairs.

OPERATIONAL FACTORS

From an operations standpoint, network operating conditions—such as slow water velocities, supply sources going on and off-line, and the amount of time that systems store water—greatly affect water quality. Any of these factors can cause chlorine residual to fade, and, thus, allow microbial growth in the network. Further, hydraulic conditions can cause sediment to deposit, accumulate, and serve as both habitat and protection from disinfectants for microbial growth.

What's more, many storage facilities are kept full so that the system can be better prepared for emergency conditions. However, the long detention times result in degraded water quality.

WATER QUALITY FACTORS

Some of the factors that provide optimal conditions for microorganisms to multiply include long water-detention times in tanks and pipes, adequate nutrient levels, and warm temperatures.

In addition, research has shown that the level of biodegradable organic matter in the distribution system strongly affects bacterial re-growth and harbors opportunistic pathogens. An opportunistic pathogen can be any disease-causing organism, bacterium, virus, helminth, or protozoan that slips through the treatment processes or enters the distribution system during pressure loss and finds the opportunity or favorable circumstances to lodge or reproduce in organic material, bacterial slime, or other material that it finds attractive.

A number of other conditions also can affect water quality. For example, disinfectants may react with organic and inorganic compounds and cause taste and odor problems or form disinfection by-products. Also, particulate re-suspension may cause increased turbidity.

CONTAMINATION PREVENTION AND CONTROL

Drinking water systems can improve water quality or prevent its deterioration in the distribution system. They can modify system operations and maintenance alternatives, make changes in treatment practices, and improve water quality monitoring and modeling. Generally, systems need to find an optimal combination of these actions, which can involve trade-offs between cost, water supply needs, and water quality considerations.

MODIFICATIONS TO SYSTEM OPERATION

Systems can use five primary operation procedures to maintain water quality:

1. minimize bulk water detention time,
2. maintain positive pressure,
3. control the direction and velocity of the bulk water (see Fig. 1),
4. maintain a disinfectant residual in the distribution system (Disinfectant residual, usually chlorine, provides a relatively effective barrier to the growth of microorganisms in bulk water and biofilm.), and
5. prevent cross-connections and backflow.

Utilities should minimize bulk water detention time because the interactions between the pipe walls and the bulk water result in water quality deterioration. Furthermore, stored finished water should be turned over frequently because the stored water's age contributes to the overall water age in the distribution system.

To reduce possible pathogen intrusions, drinking water utilities should maintain minimal water pressure in the distribution network, particularly if cross-connections are present. Further, the utilities should maintain a positive pressure throughout the distribution system to minimize the potential for back siphonage or backflow of contaminants to occur. However, excessive water pressure may cause pipe leaks or even breaks.

Utilities should minimize rapid or extreme fluctuations in flow velocities and should minimize the frequency of reversals. Activities that may affect flow velocities include rapidly opening or closing a valve, a power loss, and hydrant flushing. Changes in flow velocity can scour

Distribution Material	Corrosion Resistance	Potential Contaminants
Copper	Resists corrosion well, but is subject to corrosive attack from high velocities, soft water, chlorine, dissolved oxygen, and low pH.	Copper
Lead	Corrodes in soft water with low pH	Lead, arsenic, and cadmium
Mild steel	Subject to uniform corrosion, particularly sensitive to high dissolved oxygen levels	Iron, resulting in turbidity and red-water complaints
Cast or ductile iron	Aggressive waters can cause surface erosion	Iron, resulting in turbidity and red-water complaints
Galvanized iron	Aggressive waters can cause galvanic corrosion of zinc	Zinc and iron
Asbestos-cement	Good corrosion resistance; aggressive waters can leach calcium from cement	Asbestos fibers
Plastic	Resistant to corrosion

sediments, tubercles, and deposits from interior pipe surfaces and degrade water quality.

MAINTENANCE ALTERNATIVES

Distribution system flushing is an important tool to keep the water system clean and free of sediment, remove stagnant water, and remove unwanted contaminants that may have inadvertently entered the system. (See summer 2002 *On Tap* "How to Flush a Distribution System.")

Drinking water systems can use a variety of pipeline cleaning techniques. These techniques include mechanical scraping, pigging, swabbing, chemical cleaning, and flow jetting. Utility maintenance also includes emergency pipe repairs with sanitary precautions in place. Utilities should:

- try to keep contaminated water out of the trench and pipe;
- flush the line in the vicinity of the break;
- apply disinfectant to potentially contaminated components;
- disinfect new mains;
- disinfect storage tanks after construction, inspection, or maintenance; and
- conduct bacteriological testing to confirm the absence of contaminates.

Other maintenance activities that utilities can use to minimize water quality degradation:

- prevent and eliminate cross-connections;
- cover and vent storage tanks;
- maintain an adequate separation from sewers; and
- enforce applicable building plumbing codes.

CHANGES IN TREATMENT PRACTICES

Disinfection means using chemicals to inactivate harmful microorganisms that might be present in water. This practice protects distributed water from pathogen regrowth or recontamination. Water systems treating surface water supplies maintain a level of residual chemical disinfectant throughout the distribution system. They also usually use some kind of booster disinfection or a more stable secondary disinfecting chemical, such as chloramines.

On the other hand, excessive chlorine levels will produce taste and odor problems, may accelerate pipe corrosion, may enhance formation of harmful disinfection by-products, or produce health concerns for the system's customers.

Pipes can and do corrode internally, reacting with the water and deteriorating. Internal corrosion can cause toxic metals, such as lead and copper, to leach into water, impart a metallic taste to water, stain plumbing fixtures, harbor nuisance and pathogenic microorganisms, reduce a pipe's hydraulic carrying capacity, and ultimately result in leaks and clogs.

Numerous physical, chemical, and biological factors can increase corrosion's rate and occurrence. Some individual factors can either promote or inhibit corrosion, depending upon other conditions. The most significant factors include temperature, pH, alkalinity, dissolved oxygen, total dissolved solids, hardness, and bacteria.

THREE APPROACHES TO CONTROL CORROSION

1. Modify the water quality to make the water less corrosive, such as adjusting the pH.
2. Lay down a protective lining between the water and the pipe, such as using chemical inhibitors.
3. Switch to plastic pipe, which is less prone to corrosion.

Attempts to control biofilm in the distribution system have taken several directions. To avoid releases of biofilm, utilities can manipulate their water chemistry, such as adjusting pH, alkalinity, or the Langlier Index (an indicator of corrosiveness). They also can apply corrosion inhibitors not only to protect pipe materials but also to firm up the coating of the sediments that harbor microbial communities.

WATER QUALITY MONITORING AND MODELING

Utilities should develop a sampling plan to address monitoring and modeling issues, such as selecting sampling sites, establishing test parameters and monitoring frequencies, establishing field-monitoring protocols, and addressing laboratory considerations. The most commonly monitored test parameters to determine general distribution system water quality include coliform bacteria, heterotrophic plate count (HPC) bacteria, disinfectant residual, temperature, turbidity, pH, and color.

Utilities may find that it is difficult to use monitoring data alone to understand all the possible interactions among the multiple parameters that affect water quality between the treatment plant and the user's tap. The flow pathways and travel times of water through these systems are highly variable because of the looped layout of the pipe network and the continuous changes in water usage over space and time. In addition, utilities commonly use storage facilities that are not part of the distribution system, making matters even more variable.

For these reasons, water utility managers are turning to hydraulic and water quality models as attractive monitoring supplements. They can use these models to perform a variety of water quality-related studies. Systems can:

- use chemical tracers to calibrate and test hydraulic models of the system,
- locate and size storage facilities,
- modify system operations to reduce the age of the water,
- modify the design and operation of the system to provide a desired blend of waters from different sources,
- find the best combination of pipe replacement, pipe relining, pipe cleaning, reduction in storage holding time, and location and injection rate at booster stations to maintain desired disinfectant levels throughout the system,
- assess and minimize the risk of consumer exposure to disinfectant by-products, and
- assess the system's vulnerability to incidents of external contamination.

Furthermore, as water utilities make more use of such tools as geographic information systems (GIS) and supervisory control and acquisition (SCADA) technologies, they can achieve a degree of data integration that enables more reliable network analysis and management.

HAVE YOU READ ALL OUR TECH BRIEFS?

Tech Briefs, drinking water treatment and supply fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) publication *On Tap* for more than six years.

A package of *Tech Briefs* is available in a three-ring binder that holds all the *Tech Briefs* currently in print. New selections can easily be added to the package as they become available. To order this free product, call the NDWC and ask for item #DWPKPE71.

Additional copies of the *Tech Brief* fact sheets are also free; however, postal charges may be added.

DESIGN OF WATER DISTRIBUTION SYSTEMS

Srinivasa Lingireddy

Lexington, Kentucky

INTRODUCTION

Providing quality service at minimum possible cost is the ultimate goal of drinking water utilities. Quality of service includes delivering adequate and reliable quantities of water at sufficient pressures, meeting drinking water quality standards throughout the distribution system, and providing for adequate fire protection within the service area. Water distribution systems that help achieve this goal are generally designed in three stages: planning, preliminary design, and detailed design. The planning stage should properly identify the service-related constraints (e.g., limits on pressures, flows, and water quality parameters) along with the right set of decision variables (i.e., distribution system components).

The preliminary design should identify the alignment of pipelines, locations for storage and pumping facilities, availability of easement or right-of-way, and so on. Precise quantification of the decision variables takes place in the detailed design phase. The following sections describe various components of water distribution systems, the constraints associated with quality of service, and the steps involved in detailed design.

COMPONENTS OF A WATER DISTRIBUTION SYSTEM

Depending on the size of the population served, a water distribution system (WDS) could be a small network of branching pipes gravity fed by an elevated source to a highly complex web of pipe loops, isolation and control valves, multiple supply sources and associated pumping facilities, elevated/ground/pumped storage tanks, hydrants and blow-off valves, and so on. The following section describes various groups of components and their importance in the design of a WDS.

Pipes and Joints

Pipes and joints constitute the most abundant group of components in a WDS. Pipes owned and maintained by a water utility may generally range from 2 inches (50 mm) to several feet (or meters) in diameter, although for those systems that provide fire protection, a minimum diameter of 6 inches is usually specified (1,2). Pipes for water distribution are available in a variety of material—cast iron, ductile iron, steel, concrete, asbestos cement, polyvinylchloride, polyethylene, and so on. Selection of an appropriate pipe material is an important step in the design of a WDS as it influences initial and maintenance costs, type and number of joints, and hence leakage potential, load bearing capacity, capacity to withstand static and transient (water hammer) pressures, corrosion/tuberculation and consequent loss of capacity, pipe roughness characteristics, and so on. The relative advantages of one material over the other, along with many other relevant data needed for the design, may be obtained from the handbooks prepared by the respective manufacturers associations (3–5). Pipes should be buried to protect them against various natural and other forces, and care must be taken to provide minimum cover based on maximum frost-depth in cold climate regions.

Pumps

Although some water distribution systems rely completely on gravity for supplying water to the consumers, most systems employ pumps in some shape or form. Pumps in a distribution system may appear near clear wells or other sources, at pressure boosting stations, and at pumped storage tanks. Power requirements or the head-flow characteristic curve may define the pump capacity. It is common practice to use system head curves in sizing the pumps. The net positive suction head (NPSH) requirements play a crucial role in locating and sizing the pumps. Variable-speed pumps are becoming more common as they offer a wide range of operating conditions. For detailed description on different types of pumps, their operating characteristics, along with their relative advantages and disadvantages, the readers should refer to ANSI/HI (6) and Sanks et al. (7). Irrespective of the size of the pumps employed, the use of pumps in a WDS adds additional operating costs that should not be overlooked at the design stage. The use of pumps, however, allows for smaller transmission mains, thereby reducing the capital costs. From a design perspective, there will be an optimal tradeoff between the capital cost associated with the pipes and the operating costs associated with the pumps.

Tanks

Tanks in a WDS are used for a variety of reasons. Treated water may be stored in ground storage tanks or clear wells. Elevated storage tanks are generally used as balancing tanks that are filled during slack demand periods so they can feed the distribution system during peak demand periods. Such an operation minimizes frequent cycling (on/off status or pump speed changes) of pumps, thereby permitting efficient operation. Small distribution systems employ hydropneumatic tanks to maintain specified pressure ranges in an effort to minimize or eliminate continuous pump operation. Tank capacities are dictated by the need for emergency storage requirements (e.g., to temporarily offset treatment plant failures), for fire fighting requirements over extended periods, and to cater for peak-hour demands where the treatment plant capacities are limited to maximum-day demands. However, larger tank capacities—beyond the need to cater for peak-hour demands—could lead to water quality problems as water in storage for extended periods tends to lose disinfection potential. As water quality requirements on tank capacities are in direct conflict with other requirements for storage (e.g., fire fighting needs), a careful tradeoff must be arrived at when sizing the tanks. It is not uncommon for most systems to be designed to provide excess storage in the system equivalent to meet an average-day demand.

Valves

Valves in a WDS may be classified into isolation valves and control valves. Isolation valves are needed to isolate portions of WDS during emergency situations such as pipe breaks, or for routine maintenance purposes such as pipe rehabilitation, and flushing operations. Control valves, such as pressure-reducing valves and pressure-sustaining valves, throttle or maintain specified pressures in certain portions of the distribution system. They are also employed to isolate multiple pressure zones within a WDS. Flow control valves may regulate flowrates to certain processes that draw water directly from the WDS. Other types of control valves that are frequently used in a WDS include check valves, pump operational control valves, throttle control valves, and so on. Control of transient pressures might warrant the use of special types of valves such as pressure relief valves and air relief/vacuum valves.

Hydrants

Most water utilities are mandated to provide water for adequate fire protection within the service area. Hydrants connected to the pipes provide easy access for water for fighting fires. Insurance companies in the United States make use of hydrant ratings (hydrant flowrates without dropping the pressures below 20 psi during peak demand conditions) in setting the property insurance premiums. Hydrants are also used for flushing the pipelines as part of routine maintenance.

DESIGN CONSTRAINTS

Efficient design of a WDS must satisfy several constraints. These constraints include water quantity requirements, limits on pressures and velocities, limits on water quality parameters, and fire protection requirements, besides the usual constraints on overall system costs.

Constraints on Water Quantity

A well-designed WDS should supply adequate quantities of water to all consumers, including fire demands. Therefore, estimating the desired quantities of water by various consumers becomes an important task. Normal water consumption originates from three distinct groups of consumers: residential, commercial, and industrial. State and local guidelines on per-capita consumptions would be helpful in estimating the commercial and residential demands (8). Industrial demands should be estimated in consultation with the industries being served. Demands may also be estimated based on land-use and associated consumption data from neighboring systems of similar characteristics (population and commercial activities). Demand calculations for the existing WDS should come from monthly meter records. Peaking factors must be applied to the average daily demands to account for maximum-day demand as well as maximum-hour (peak–hour) demand (9). Most water utilities ensure that the supplies (treatment plant and pumping capacities) are adequate to meet maximum-day demand and rely on the floating storage tank capacities to meet the maximum-hour demand.

Constraints on Pressures and Velocities

It is not only important to deliver adequate quantities of water to the consumers but also to ensure that the water is delivered at adequate pressures. Pressures less than 30 psi under maximum-hour demand conditions are not acceptable for most water systems. Although the upper bound on pressure would depend on the pressure rating of the pipe material or the pipe joints, many water utilities are mandated to maintain pressures well below the rated capacities of pipes (e.g., 70–80 psi) to safeguard the appliances that derive water directly from the distribution network. Limiting the upper bound on pressures would also reduce the leakage losses as well as the pump operating costs (10). Lower and upper bounds on velocities may also be imposed when designing a WDS. Lower bounds on velocity ensure adequate scouring, thereby reducing sedimentation problems. Upper bounds on velocities minimize the transient pressure-related problems.

Constraints on Water Quality

With the new safe drinking water regulations, the utilities are required to ensure delivery of water that meets or exceeds all drinking water standards (limits on physical, chemical, and microbial parameters) right at the consumer connection. In addition, the water supplied should also carry specified minimum levels of residual disinfectant (e.g., chlorine or chloramines). As most disinfectants are nonconservative chemicals (i.e., concentrations drop with time), concentration levels higher than the required minimum values are necessary near the supply sources (11). Very high disinfectant concentration levels may not be acceptable either because of their perceived or real carcinogenicity or simply because of the resulting taste and odor problems. As a last resort, supplemental or chlorine booster stations must sometimes be installed at more remote or isolated sections of the system to ensure residual protection.

Constraints on Fire Demands

Except for certain small systems serving scattered rural communities, most WDS in the United States are expected to provide water for adequate fire protection. Hydrants are expected to provide water at a minimum of 500 gpm without dropping the pressures in the system below 20 psi under maximum-hour conditions. Many hydrants in a WDS are rated and are color coded based on the flowrates they can deliver while maintaining a minimum of 20-psi pressure (12). Hydrants that are capable of supplying 1500 gpm or more are painted light blue-green for 1000–1499-gpm capacity, orange for 500–999-gpm capacity, and red for those that cannot supply 500 gpm. Many utilities are not only mandated to ensure minimum specified instantaneous (or static) hydrant flowrates (e.g., 500 gpm) while maintaining the specified minimum pressures (e.g., 20 psi), but they are also required to ensure adequate hydrant flowrates over extended periods (e.g., 2 hours). The latter requirement would influence the capacity requirements of storage facilities.

DESIGN OF WATER DISTRIBUTION SYSTEMS

The need for designing an entirely new drinking water distribution system develops less frequently in modern times. Most current-day designs involve enhancements to existing systems, such as adding pipelines to serve areas of new development, strengthening the existing pipelines to improve the reliability of service, and/or replacing old and deteriorated pipelines. Current-day designs also include sizing new transmission mains, pumping stations, storage facilities, and so on. Whether a WDS is being designed from the ground-up or a few of its components are being strengthened, the use of mathematical models representing the WDS would greatly simplify the design process. The debate on the use of mathematical models in designing WDS dates back to the days of wood-stove pipes (13). Recent advances in computing power, both in terms of hardware and software, resulted in routine use of mathematical models in designing WDS. In addition, scores of optimization techniques have been proposed in the literature to help with the design process. An optimization technique involves formulating an objective function and the associated constraints as functions of decision variables and solving for the decision variables that optimize the objective function while satisfying all the constraints. Most optimization techniques for WDS design use minimization of annualized total costs as the objective function. Lansey (14) summarizes various methods proposed in literature for optimal design of WDS.

A robust and efficient optimization technique is supposed to provide an optimal set of decision variables that result in a minimal cost design while satisfying all constraints. However, design of water distribution systems involves an extensive and diverse set of decision variables and a complex set of constraints in addition to an elaborate cost function. Although a particular design may not involve all decision variables and constraints outlined in the previous sections, a robust optimization platform should allow the designer to choose any combination of constraints and decision variables besides allowing specification of a desired cost function. In addition, such optimization platforms could also work with existing mathematical models of the water distribution systems. Lack of such robust optimization platforms within the popular WDS modeling software packages prevented the widespread use of seemingly powerful optimization techniques in designing water distribution systems. Most designers continue to work with trial-and-error methods for sizing various components of a WDS with the help of a hydraulic network model representing the WDS being designed. A comprehensive iterative method for the design of a WDS is presented in the following. Although the method presented is meant for the design of new water distribution systems, the method can be easily adapted for designing enhancements to existing systems.

Iterative Method for Designing Water Distribution Systems

- Identify the supply sources: clear wells, natural springs, groundwater wells, and so on. Choose a layout for the distribution network. Start with trunk mains; other mains and laterals may be added later. The points to be connected by trunk mains include supply sources, large consumers, and storage tanks. Use a skeleton layout for preliminary designs and a complete layout for detailed designs. Most systems serving 100,000 populations or more do not model pipes less than 4 inches (100 mm) in diameter to simplify the design process. Most systems exclude all branching pipelines from the design process as well, unless the design is specifically aimed at sizing the branch lines. In addition, the hydraulic modeling software package might limit the number of pipes in the model, which in turn limits the ability to model all pipes in the network.
- Estimate nodal demands, taking future growth into account. Refer to the subsection *Constraints on Water Quantities* for details. If the WDS being designed is for serving a rural community with no mandatory provision for fire flows, special care must be taken in estimating the nodal demands. Refer to the section on *Rural Water Systems* in Appendix A for more details.
- Develop a hydraulic network model for the chosen layout, and provide all known data—supply sources, pump nodes, nodal elevations, demands and pipe lengths, and so on.
- Assign pipe diameters and roughness values for all pipes. Use larger diameters for pipes closer to the supply points and smaller diameters for pipes at the extremities of the system. Estimates of pipe roughness values may be obtained from manufacturer handbooks (3–5).
- If the WDS design involves pump stations, provide an estimated useful power (horsepower or kilowatt units) data for the pumps. Choose an arbitrary pump power that can be adjusted later to satisfy the pressure and flow constraints. If the supply source is a pressure main, collect head-flow data for the location where the distribution system will be connected to the pressure main. Refer to the section on *Pressure Supplies* in Appendix A for more details.
- Identify all constraints on the proposed design. Refer to the section on *Design Constraints* for details.
- Perform hydraulic analysis of the network model, and review the pressures and flowrates throughout the distribution system.
- Adjust pipe and/or pump sizes until pressures and velocities in the distribution system are well within the required range. Make sure the minimum pressures are at least 20% greater than the lower limit and the maximum pressures are at least 20% lesser than the upper limit to allow for eventual variation in pressures with diurnal demand changes.
- Replace the constant power data with suitable head-flow characteristic data obtained from the pump manufacturers. If required, use multiple pumps in parallel and/or series. Satisfactory design should include a standby pump in case of mechanical failure of a duty pump.
- Analyze the network model with maximum-day peak-hour and average-day slack-hour demand conditions, and review the pressures and velocities. Adjust the pipe and/or pump sizes if needed.
- Note the lowest and highest hydraulic gradeline (HGL) values at locations near the elevated storage tanks.
- Update the model to include the elevated storage tanks. Use an overflow elevation slightly below the highest HGL and a tank bowl elevation slightly above the minimum HGL. Choose a tank diameter large enough to hold a predetermined quantity of water (1/4 to 1/2 of the daily average demand or the specified minimum required storage, whichever is greater).
- Run an extended period simulation (EPS) with an appropriate diurnal demand curve. Use an AWWA-recommended diurnal demand curve (9), if no other information on the demand variation is available.
- Adjust the pump/pipe/tank characteristics, and rerun the analysis, if needed.
- Simulate hydrant flows, and verify if the flows to maintain the required residual pressure (e.g., 20 psi) are satisfactory. Revise network data, and rerun the hydrant flow simulation, if needed.
- Perform system reliability studies. Remove (or close) one pipeline at a time from the network model,

and quantify the reduction in service—pressures less than required values (15,16). Provide necessary improvements to the model to enhance the system performance under crippled conditions.

- Run water quality simulations with appropriate bulk and wall reaction rates and supply concentrations. Adjust network characteristics if the residual disinfectant concentrations are not within the specified bounds. Consider booster chlorination stations. Security and easement issues are of biggest concern when designing booster chlorination stations.
- Perform transient analysis on the model with several different operating scenarios to ensure no unwanted low/high pressures are generated. Modify the model characteristics or provide adequate surge protection, if needed. Refer to the section on *Transient Analysis* in Appendix A for more details on the significance of transient modeling studies.

The procedure outlined in this section ensures satisfactory design but not necessarily an optimal design. One could repeat this process by adjusting design variables, each time quantifying the total cost of the system. The readers should refer to the section on *Cost Calculations* in Appendix A for a discussion on various costs associated with WDS design and the use of annualized costs to compare various design alternatives. Figure 1 shows the design procedure in a flowchart format.

SUMMARY

The design of water distribution systems is a complex and tedious process. Several optimization techniques have been reported in literature to automate and reduce the complexity of the design process. However, lack of robust optimization platforms that allow specification of preferred objective functions and desired combinations of constraints and decision variables have seriously limited the use of available optimization technology for water distribution systems design. This article presents a comprehensive iterative method that makes use of a hydraulic network model for design of water distribution systems. Although the procedure presented is for design of new water distribution systems, the method can be easily adapted for sizing enhancements to existing systems.

APPENDIX A

Cost Calculations

Cost is a major factor in designing a water distribution system. Two types of costs influence the decision-making process: capital costs and operating costs. One way of comparing competing designs is to annualize the capital costs and add the annual operating costs to arrive at annualized total costs. If C_P is the total capital cost, i is the annual interest rate for a period of N years and then the annualized capital cost C_A is given by

$$C_A = C_P\left[\frac{i}{(i+1)^N - 1} + i\right]$$

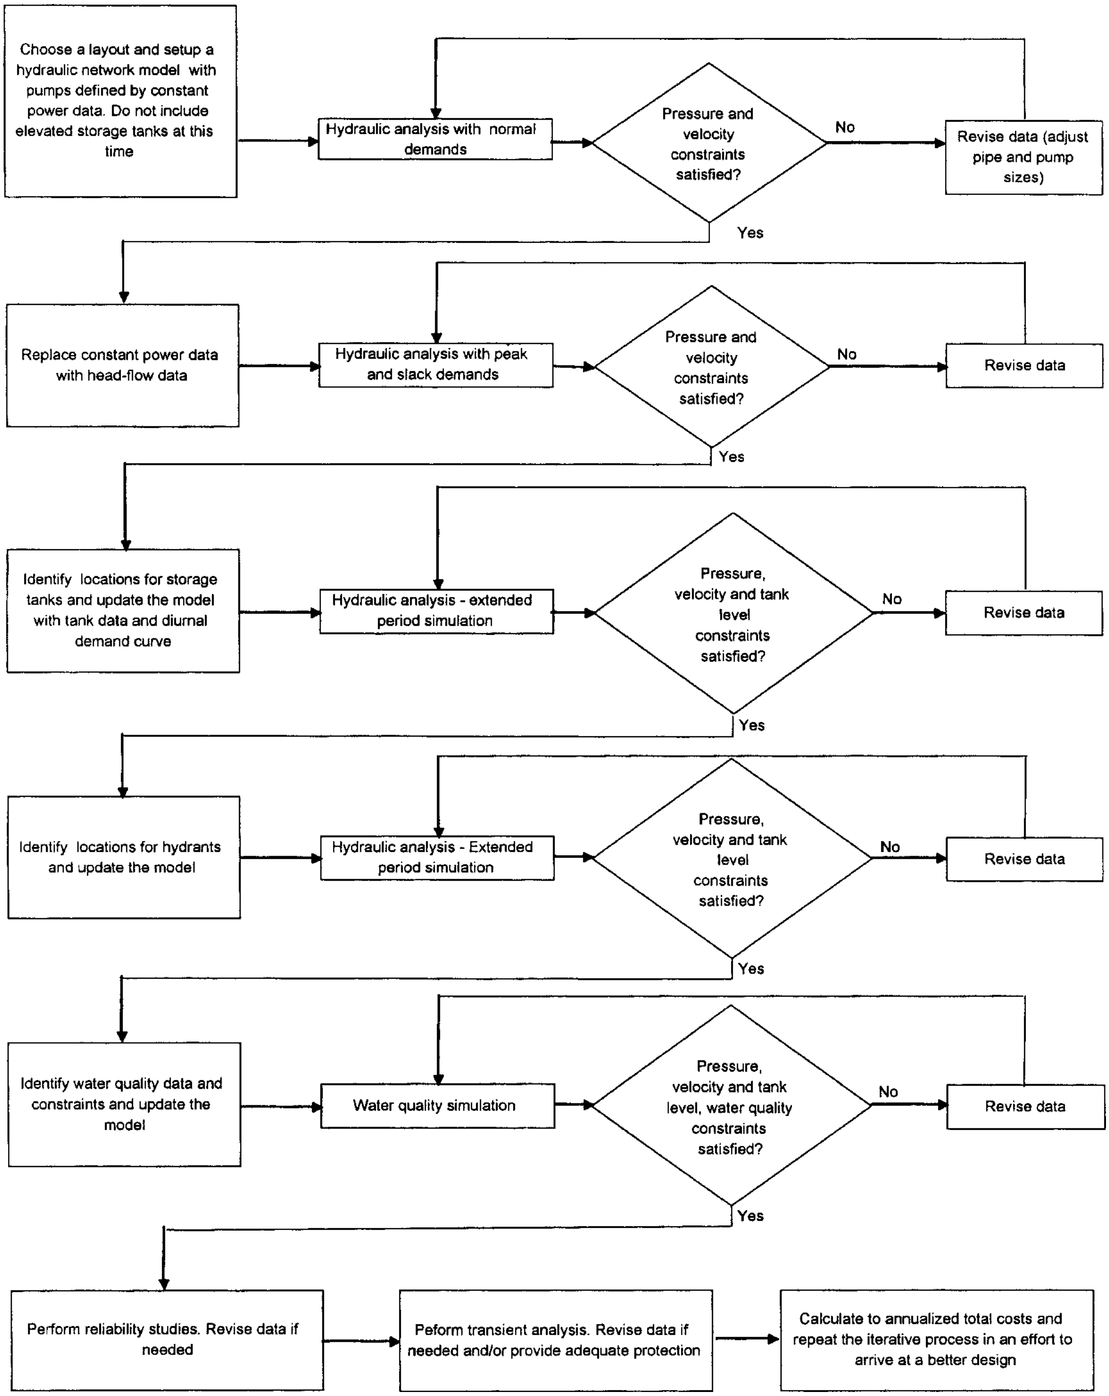

Figure 1. Iterative method for designing water distribution systems.

The total capital costs comprise primarily cost of easement or right-of-way, cost of piping including joints, excavation and backfill costs, cost of pumps and pumping station, cost of storage facilities, and cost of valves. Means' Construction Data Handbooks, in particular, the *Site Work and Landscape Cost Data Handbook* are excellent sources of information on capital costs (17). Operating costs are primarily the energy costs resulting from pumping operation. The energy costs vary inversely and nonlinearly with the piping costs. That is, the pressure constraints in the system could be met by using small-diameter pipes that require large-pump energy requirements or by using large-diameter pipes that require small-pump energy requirements. Figure A1 shows a typical capital and energy costs tradeoff curve.

Pressure Supplies

When designing pipelines serving a new subdivision, there are two ways to approach the problem (1). Append calibrated model of the existing distribution system with

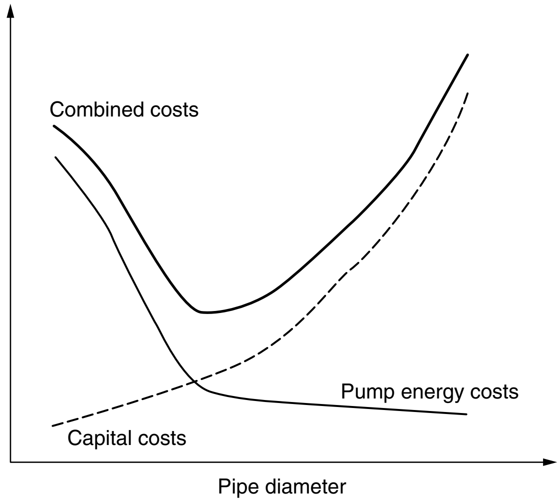

Figure A1. Typical capital and energy costs tradeoff curve.

new pipes and other network elements, and use the complete model in the iterative design process of sizing the new network elements (3). Create and use a network model pertaining to the proposed distribution system only, and use that model in the iterative design process. Although the first approach is more accurate, it requires a well-calibrated model of the existing distribution system along with a right set of demands and other boundary conditions. On the other hand, the use of the second approach requires head-flow characteristics at the location where the new piping will be tapped into the existing system. The head-flow characteristic curve at this location may be obtained by performing a hydrant flow test at or near the location where the new system will be tapped into the main distribution system. The hydrant flow test should record the static pressure as well as two other head-flow values to generate a head-flow characteristic curve. Figure A2 shows a typical head-flow characteristic curve generated from a hydrant flow test. This approach of using a head-flow characteristic curve in lieu of using the entire network model may not work well if a significant diurnal variation in static head is expected at the test location.

Transient Analysis. Rapid flow changes in a WDS can result in unexpectedly high or low pressures that can damage pipes or other components of the distribution system. Rapid flow changes are not uncommon in WDS. Routine pump startup and shutdown and pump trip resulting from power failure situations can result in rapid flow variations. High transient pressures might result in pipe breakages or loosening of pipe joints. Pressures below the vapor pressure of water lead to formation of vapor cavities. Subsequent high pressures can collapse the vapor cavities producing high-pressure spikes. Recent studies have shown that pressures below atmospheric levels can lead to pathogen intrusion problems at certain vulnerable points such as leaky pipe joints (18). Therefore, it would be prudent to perform a transient analysis of potential rapid flow variation scenarios and provide adequate protection to the WDS. The protection methods include use of pressure vessels (surge tanks), relief valves, rupture disks, and air release/vacuum valves (19).

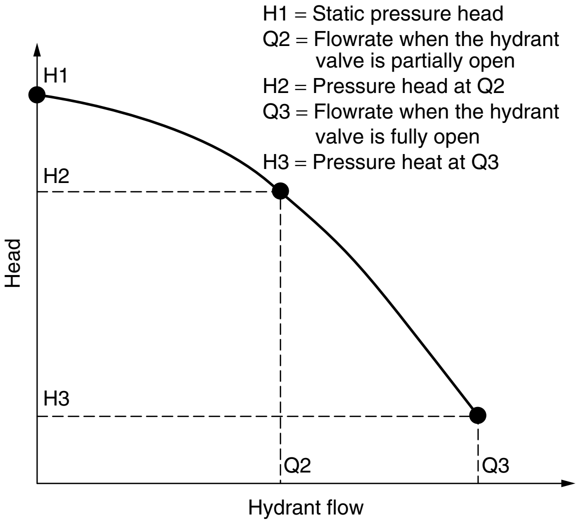

Figure A2. Example head-flow characteristic curve for a pressure supply.

Rural Water Systems

If rural water systems are not designed to provide fire flows, then special handling of long branch-lines serving few customers may be necessary. Requirements for residential water delivered through branched lines depend on the number of residential (domestic) connections served by each branch. These requirements should be based on probability considerations, and the requirement per connection served decreases as the number of connections increase. Relationships called Instantaneous peak demand curves (IPD) are available to calculate these requirements as a function of the number of connections served by each branch line. Additional conventional demands can be added at junctions. Branch line pipes should be sized to accommodate residential requirements calculated in this manner (20).

WHAT IS IN OUR DRINKING WATER?

Susan Richardson
U.S. Environmental Protection Agency

WHAT IS A DBP?

A drinking water disinfection by-product (DBP) is formed when the chemical used for disinfecting the drinking water reacts with natural organic matter in the source water. Popular disinfectants include chlorine, ozone, chlorine dioxide, and chloramine. Source waters include rivers, lakes, streams, groundwater, and sometimes seawater. DBPs have only been known since 1974, when chloroform was identified as a DBP resulting from the chlorination

---

Figure 1. Chloroform and trichloroacetic acid, two common DBPs, in chlorinated tap water.

of tap water. Since then, hundreds of DBPs have been identified in drinking water.

WHY IT'S IMPORTANT

Millions of people in the U.S. are exposed to these drinking water DBPs every day. While it is vitally important to disinfect drinking water, as thousands of people died from waterborne illnesses before we started disinfection practices in the early 1900s, it is also important to minimize the chemical DBPs formed. Several DBPs have been linked to cancer in laboratory animals, and as a result, the U.S. EPA has some of these DBPs regulated (Fig. 1). However, there are many more DBPs that have still not been identified and tested for toxicity or cancer effects. Currently, less than 50% of the total organic halide that is formed in chlorinated drinking water has been identified. Total organic halide is a measure of all of the organic compounds that contain a halogen atom (chlorine, bromine, iodine), and includes DBPs such as chloroform, bromoform, and trichloroacetic acid. There is much less known about DBPs from the newer alternative disinfectants, such as ozone, chlorine dioxide, and chloramine, which are gaining in popularity in the U.S. Are these alternative disinfectants safer than chlorine? Or do they produce more harmful by-products? And, what about the unidentified chlorine DBPs that people are exposed to through their drinking water—both from drinking and showering/bathing? The objective of our research is to find out what these DBPs are—to thoroughly characterize the chemicals formed in drinking water treatment—and to ultimately minimize any harmful ones that are formed.

OUR RESEARCH APPROACH

- Gas chromatography/mass spectrometry (GC/MS), liquid chromatography/mass spectrometry (LC/MS), and gas chromatography/infrared spectroscopy (GC/IR) techniques are used to identify the unknown by-products
- NIST and Wiley mass spectral databases are used first to identify any DBPs that happen to be present in these databases
- Because many DBPs are not in these databases, most of our work involves unconventional MS and IR techniques, as well as a great deal of scientific interpretation of the spectra
  - High resolution MS provides empirical formula information for the unknown chemical (e.g., how many carbons, hydrogens, oxygens, nitrogens, etc. are in the chemical's structure)
  - Chemical ionization MS provides molecular weight information when this is not provided in conventional electron ionization mass spectra
  - IR spectroscopy provides functional group information (e.g., whether the oxygens are due to a carboxylic acid group, a ketone, an alcohol, or an aldehyde)
  - LC/MS is used to identify compounds that cannot be extracted from water (the highly polar, hydrophilic ones). This is a major missing gap in our knowledge about DBPs—so far, most DBPs identified have been those that are easily extracted from water
  - Novel derivatization techniques are also applied to aid in the identification of highly polar DBPs
- Once DBPs are identified, ones that are predicted to have adverse health effects are studied in order to determine how they are formed (so that the treatment can be modified to ultimately minimize their presence in drinking water)

CURRENTLY

We have a major nationwide DBP occurrence study underway, where we are sampling drinking water across the U.S. (disinfected with the different disinfectants and with different water quality, including elevated levels of bromide in the source water).

SOME RESULTS

More than 180 previously unidentified DBPs have been identified for the first time.

Ozone is tending to produce oxygen-containing DBPs, with carboxylic acids, aldehydes, ketones, and di-carbonyl compounds the most prominent.

The presence of natural bromide in the source water is resulting in a tremendous shift from chlorine-containing DBPs to bromine-containing DBPs when chlorine or chloramine is used as a disinfectant (even in combination with ozone).

Chlorine dioxide is producing very few halogenated DBPs by itself, but when chlorine impurities are present, and natural levels of bromide or iodide are present in the source water, many bromo- and iodo-DBPs are formed.

New analytical methods have been developed (and are continuing to be developed) for the analysis of highly polar DBPs.

Collaborations have been forged with health effects researchers to study selected DBPs for potential adverse health effects.

THE ECONOMICS OF WATER RESOURCES ALLOCATION

PATRICK BOND
Kensington, South Africa

No one would doubt "the principle that water is a scarce good with dimensions of economic efficiency, social equity, and environmental sustainability." Yet as articulated in the World Bank's (1) *African Water Resources* document, the principle disguises two polar-opposite positions about pricing water.

On the one hand, *The Economist* magazine's (2; pp. 1–5) survey on water declared the central dilemma: "Throughout history, and especially over the past century, it has been ill-governed and, above all, collossally underpriced." Identifying this problem, naturally begets this solution: "The best way to deal with water is to price it more sensibly," for "although water is special, both its provision and its use will respond to market signals." In rural areas where there is competition among farmers for irrigation water, "The best solution is water trading." As for the problem of allocating and delivering water to the poor, "The best way of solving it is to treat water pretty much as a business like any other." We can call this the "neoliberal" position.

Six months later, on the other hand, an international movement with "progressive" politics, the People's World Water Forum (PWWF), emerged in Delhi, India, to promote the "decommodification" of water, based on feeder social movements from around the world in both cities and rural sites of struggle over water access. The PWWF (3; p. 1) founding statement declared that "Water is a human right; that corporations have no business profiting from peoples' need for water; and that governments are failing in their responsibilities to their citizens and nature."

Because there are many different ways that the pricing of water can be considered in bulk and retail settings, it makes sense first to outline the positions using a simple graph that distinguishes between neoliberal and progressive values. At the extreme where maximizing the production of economic goods is the prime objective, a leaked 1991 World Bank memo by then chief economist Lawrence Summers proposed an environmentally and socially insensitive allocation of resources: "I think the economic logic behind dumping a load of toxic waste in the lowest-wage country is impeccable and we should face up to that" (http://www.whirledbank.org). Rather than "internalize the externalities" of social impact or ecological damage, Summers' solution was simply to displace these to someplace where political power was negligible and the immediate environmental implications were less visible, in the name of overall economic growth.

And yet there are well-established critiques of gross domestic product (GDP), the most common measure of the aggregation of economic goods. Contrary to a more nuanced "economic logic," GDP treats the depletion of natural capital (including water resources) as income instead of depreciation of an asset; ignores the nonmarket economy of household and community, in turn devaluing child care, elder care, other home-based tasks and volunteer work (all of which rely on access to clean water); and considers natural disasters and pollution as economic gain because of associated service sector employment and repair/clean-up/replacement opportunities, not as a debit from social welfare or, with respect to drought and flooding, from ecosystem integrity.

Even as a caricature of neoclassical economics in the memo cited, the promotion of commodifed nature and society struck a chord during the neoliberal epoch of the late twentieth century. Throughout, those lobbying to treat water "much as any other business" grew in strength, and privatization and commercialization of water supplies expanded in many parts of the world. The intense conflict over the economics of water resources allocation was prefigured by the 1992 International Conference on Water and the Environment in Dublin, where water was formally declared an "economic good." Four years later, the formation of the Global Water Partnership and World Water Council advanced the position that commodification of water would lead to both private sector investments and more efficient use. In the same spirit, 1997 witnessed the first World Water Forum in Marrakesh, the founding of the World Commission for Water in the 21st Century, and an emblematic statement by the Swedish International Development Agency (4; pp. 11–13): "As the realisation increases that fresh water of satisfactory quality is a scarce and limited resource, matters related to management of the water resources have become more into focus .... At least four conditions need to be fulfilled to carry through efficient water allocation: (1) well defined user rights; (2) pricing at its marginal cost; (3) information related to availability, value, quality, delivery times; and (4) flexibility in allocation responding to technologic, economic and institutional changes." The United Nations Panel on Water declared in 1998 that "water should be paid for as a commodity rather than be treated as an essential staple to be provided free of cost" (5).

At the same time, the International Monetary Fund (IMF) and World Bank became much more explicit in promoting water commodification through what were once mainly macro-oriented structural adjustment programs, whether the Enhanced Structural Adjustment Facility, Poverty Reduction and Growth Facility, or Poverty Reduction Strategy Programme (6). According to one NGO critique by the Globalization Challenge Initiative (http://www.challengeglobalization.org), "A review of IMF loan policies in 40 random countries reveals that, during 2000, IMF loan agreements in 12 countries included conditions imposing water privatization or full cost recovery. In general, it is African countries, and the smallest, poorest and most debt-ridden countries that are being subjected to IMF conditions on water privatization and full cost recovery." When the World Bank (7, Annex 2) instructed its field staff on how to handle water pricing in even impoverished rural Africa, the mandate was explicit: "Work is still needed with political leaders in some national governments to move away from the concept of free water for all.... Promote increased capital cost recovery from users. An upfront cash contribution based on their willingness-to-pay is required from users to demonstrate demand and develop community capacity to administer funds and tariffs. Ensure 100% recovery of operation and maintenance costs." It was not long before a bureaucratic class emerged within Africa to work on cost recovery, for according to the 2001 Kampala Statement coauthored by the World Bank and the African Utility Partnership (8; p. 4), "The poor performance of a number of public utilities is rooted in a policy of repressed tariffs."

But a debate quickly followed over the merits of full cost recovery of operating and maintenance costs. In most urban systems, the cost of supplying an additional drop of water—the "short-run marginal cost curve" (Line A in Fig. 1)—tends to fall as users increase their consumption, because it is cheaper to provide the next unit to a large consumer than to a small consumer. Reasons for this include the large-volume consumers' economies of scale (i.e., bulk sales), their smaller per unit costs of maintenance, the lower administrative costs of billing one large-volume consumer instead of many small ones, and the ability of larger consumers to buy water at a time when it is not in demand—for example, during the middle of the night—and store it for use during peak demand periods. The premise here is that the pricing of water should correspond directly to the cost of the service all the way along the supply curve. Such a system might then include a profit markup across the board (Line B) that ensures the proper functioning of the market and an incentive for contracting or even full privatization by private suppliers.

The progressive principle of cross subsidization, in contrast, violates the logic of the market. By imposing a block tariff that rises for larger consumers (Line C), the state would consciously distort the relationship of cost to price and hence send economically "inefficient" pricing signals to consumers. In turn, argue neoliberal critics of progressive block tariffs, such distortions of market logic introduce a disincentive to supply low-volume users. For example, in advocating against South Africa's subsequent move toward a free lifeline and rising block tariff, the World Bank advised that water privatization contracts "would be much harder to establish" if poor consumers had the expectation of getting something for nothing. If consumers did not pay, the Bank suggested, South African authorities required a "credible threat of cutting service" (9; pp. 49–53).

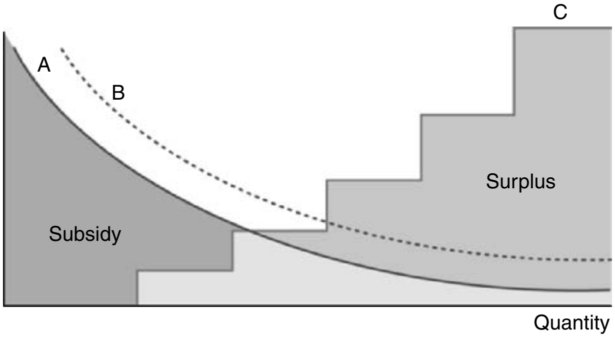

Figure 1. Three ways to price water: marginal cost (A), for-profit (B), and cross-subsidized lifeline plus rising block tariff (C).

The progressive rebuttal is that the difference between Lines A and C allows free universal lifeline services and a cross-subsidy from hedonistic users to low-volume users. There are also two additional benefits of providing free water services to some and extremely expensive services to those who have hedonistic consumption habits:

- Higher prices for high-volume consumption should encourage conservation, which would keep the longer run costs of supply down (i.e., by delaying the construction of new dams or supply-side enhancements).
- Benefits accrue to society from the "merit goods" and "public goods" associated with free provision of services, such as improved public health, gender equity, environmental protection, economic spinoffs, and the possibility of desegregating residential areas by class.

By way of definition, public goods can be observed and measured, for underlying their existence are two characteristics: "nonrival consumption" and "nonexclusion" from consumption. Nonrival consumption means that the consumption of a public good/service by one person need not diminish the quantity consumed by anyone else. A classic example is a national defense system, which is "consumed" by all citizens in a quantity that is not affected by the consumption of defense benefits by fellow citizens. Likewise, the benefits of a clean environment and hygienic public water system—reflecting a strong municipal water system and lifeline access to all—are enjoyed by all municipal consumers, regardless of how much water is consumed by a particular individual, although a minimum consumption level is required for all citizens to prevent the spread of infectious diseases. The principle of nonexclusion simply means that it is impossible to prevent other citizens from enjoying the benefits of public goods, regardless of whether they are paid for. This is important, as a state determines the detailed character of water pricing policy and distinguishes between necessities guaranteed by the state versus luxuries that people must pay for. A simpler way of putting it is that where the net benefits to society outweigh the costs of consumption of a good/service, the result is a "merit good." When the merit good benefits apply universally so that no one can be excluded from their positive effects, the result is a "public good." Markets usually underprovide for public goods, so the "Post-Washington Consensus" style of economics attempts to correct this market imperfection, even if it might mean introducing other market distortions, such as a free lifeline supply of water.

Another progressive critique of private suppliers who require tariffs reflecting marginal cost plus profit is that water infrastructure is a classic natural monopoly. The large investments in pipes, treatment centers, and sewage plants are "lumpy" insofar as they often require extensive financing and a long-term commitment, of which the state is more capable. To the argument that a progressive tariff could still coincide with a private sector supplier through a strong state regulator, progressives mistrust "captive regulatory" relations, given the long history of corruption in the water sector. Rebutting those who argue that Third World states are intrinsically incapable of providing water services, progressives cite more proximate reasons for the recent degeneration of state water sectors: 1980s–1990s structural adjustment programs that decapacitated most states, corrupt state bureaucrats, weak trade unions, and disempowered consumers/communities.

Finally, the progressive argument for making a water subsidy universal—not means-tested for only "indigent" people—is both practical and deeply political. If the service is means-tested, it invariably leads to state coercion and stigmatization of low-income people by bureaucrats. Furthermore, it is an administrative nightmare to sort out who qualifies because so many people depend on informal and erratic sources of income. More philosophically, though, it is a premise of most human rights discourse that socioeconomic rights such as water access are *universally* granted, not judged on the basis of a subjective income cutoff line, especially given the differences in household size for which different low-income people are responsible. This is partly because international experience shows that defense of a social welfare policy requires universality, so that the alliance of poor, working-class and middle-class people that usually win such concessions from the state can be kept intact (10).

As *The Economist* observed in mid-2003, one of the most important sites for considering the economics of water resources allocation is South Africa. One reason is that because of the international drive to commercialize water, even postapartheid South African citizens were subject to neoliberal cost recovery and disconnection regimes. This affected many who simply could not pay their bills. From the late 1990s through 2002, as a result, approximately 10 million people suffered water disconnections. Africa's worst-ever recorded cholera outbreak—affecting more than 150,000 people—can be traced to an August 2000 decision to cut water to people who were not paying a South African regional water board.

After the ruling, the African National Congress promised free basic water supplies in December 2000 during a municipal election campaign; the same bureaucrats responsible for water disconnections began redesigning the water tariffs. In July 2001, revised price schedules provided a very small free lifeline: 6000 liters per household per month, followed by a very steep, convex curve (see Fig. 2). But the next consumption block was unaffordable, leading to even higher rates of water disconnections in poor areas. The 6000 liters represent just two toilet flushes a day per person for a household of eight, for those lucky enough to have flush toilets. It left no additional water to drink, wash with, clean clothes, or for any other household purposes. In contrast, from the progressive point of view, an optimal strategy would provide a larger free lifeline tariff, ideally on a per-person, not a per-household basis, and then rise in a *concave* manner to penalize luxury consumption.

Johannesburg's tariff was set by the council with help from Suez Lyonnaise des Eaux, a Paris-based conglomerate, and began in July 2001 with a high price increase for the second block of consumption. Two years later, the price of that second block was raised 32%, with a 10% overall increase, putting an enormous burden on poor households that used more than 6000 liters each month. The rich got off with relatively small increases and a flat tariff after 40 kiloliters/household/month, which did nothing to encourage water conservation and hence did not mitigate the need for further construction of large dams, which in turn would drive up the long-run marginal cost curve and further penalize low-income Johannesburg townships residents.

This discussion of the economics of water resources allocation shows, simply, that pricing is political, and indeed the pursuit of "impeccable economic logic" in the water sector has generated some of the most intense struggles in the world today, calling into question the

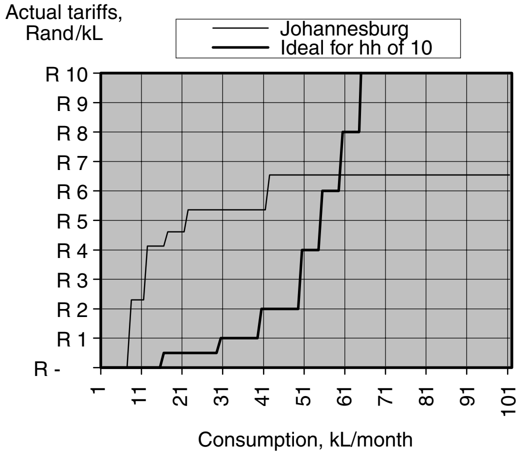

Figure 2. Divergent water pricing strategies—Johannesburg (2001) vs. ideal tariff for large household. *Source*: Johannesburg Water (thin) and own projection (thick).

very tenets of neoliberalism. The economics of privatized or commercialized urban water services have been challenged from Cochabamba, Bolivia—where the U.S. firm Bechtel tried to take ownership of rainwater collected by poor residents in the context of huge price increases—to Accra, Ghana, to most Argentine cities, to Manila and Jakarta, to Atlanta and Johannesburg, and to many other sites in between. Working out the contrasting discourses in political-economic analysis is crucial to any resolution of the problem in public policy.

ANSWERING THE CHALLENGE

EUGENE R. REAHL
Ionics, Inc.
Watertown, Massachusetts

The City of San Diego, California shares a problem in common with many other western cities. The problem is how to meet the water supply demands of a rapidly growing region when new sources are not readily available, at least not without spending huge sums of money.

In the late 1990s, San Diego (Fig. 1) took a major step to help solve this problem by equipping the brand new North City Reclamation Plant with an EDR (electrodialysis reversal) system, from Ionics, Incorporated. The system would desalinate tertiary treated wastewater and provide a new source of high-quality irrigation water, which would then reduce demands on the freshwater supply. Wastewater to be treated had salinity levels up to 1300-ppm TDS during the summer and early fall months.

With desalinated and blended reclaimed water having lower sodium levels (and less than 1000-ppm total TDS), San Diego used an existing 47-mile-long pipeline system to deliver high-quality irrigation water to golf courses, plant nurseries, parks, highway green belts, and homeowner associations. The strategy of selling this water as an attractive alternative to the use of hard-to-replace drinking water supplies caught on quickly.

In 1998, the EDR plant produced 2.2 mgd—with blending, 3.3 mgd was available. After two expansions, the latest of which will be completed in early 2005, EDR will produce 5.5 mgd of approximately 300-ppm TDS water. With blending, up to 12 million gallons per day of irrigation water can be supplied through a recently lengthened 67-mile-long pipeline. Future EDR expansion will increase this blended flow up to 15 mgd.

Originally, the city looked into desalination through the conventional use of microfiltration and reverse osmosis (MF-RO). This approach had already been installed at several locations in the Los Angeles area. Before making a final commitment, the city investigated to see if another alternative was possible (Fig. 2).

They found that electrodialysis reversal (EDR) had been successfully used at a number of wastewater locations to desalinate reclaimed irrigation water.

EDR offered the opportunity to use a less expensive single treatment membrane process, with a higher water recovery to make better use of available wastewater supplies. Overall, MF-RO water recovery would be about

Figure 1. San Diego uses EDR technology to produce low salinity irrigation water from reclaimed municipal wastewater.

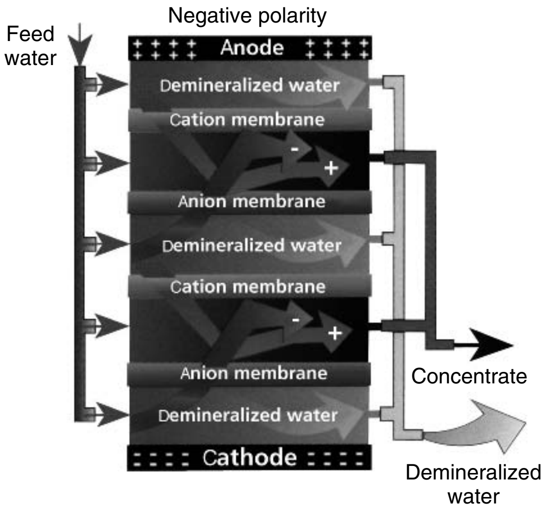

Figure 2. Electrodialysis reversal system.

80%. EDR would operate at 85% recovery. MF-RO required chemical pretreatment to control salt scale buildup on the RO membranes. EDR would operate with no chemical addition to the feedwater. One more major advantage to using EDR was that future capacity could be added by installing fully preassembled EDR systems within 53-foot-long enclosed trailers for up to 1.2 mgd flow per trailer (Fig. 3).

In 1997, city officials elected to use an EDR 2020 system for the North City irrigation water project after receiving bids from several general contractors. When all bids were opened, the least expensive MF-RO option was priced at US $4,775,975. The EDR cost was $3,569,000, or 25% less than MF-RO. This price was for the initial 2.2-mgd capacity EDR system.

With sequential use of MF and RO, water is forced through a membrane under pressure. MF membranes are used to pretreat RO feedwater, removing suspended solids materials, some organics, and other fouling-type materials that will affect the salt-removing RO membranes. With RO, water is pressure-driven through the membrane leaving unwanted salts behind. Chemicals (acid and antiscalants) are added to control scale buildup on the brine side of the membrane from concentrated wastewater constituents such as calcium phosphate, calcium carbonate, calcium sulphate, and others. One problem with today's high-performance RO membranes is that they cannot treat water containing chlorine, an essential ingredient in helping maintain bacterial control with wastewater. Chlorine will destroy RO membranes. It must be removed prior to the RO membranes.

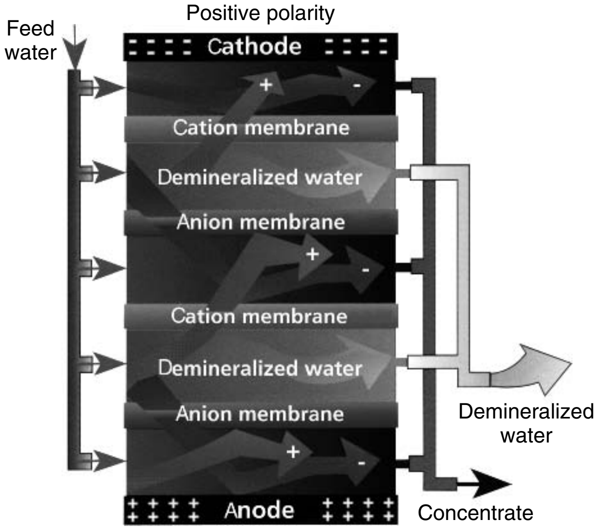

Figure 3. Electrodialysis reversal system.

ED (electrodialysis) was first commercially applied in 1954 for desalting brackish groundwater in a remote area of Saudi Arabia. ED is an electrically driven process in which a DC field generated between electrode plates pulls charged ions making up the water salinity through flat sheet cation and anion membranes. Water is not transported through the membranes—it continues on through the process. The ions (depending on their charge) are attracted to the anode or cathode electrode. Alternating cation and anion membranes generate a segregated product stream and a recirculating concentrated wastewater loop from which waste is eventually bled off. A single "ED stage" will remove up to 50–60% TDS. For still greater salt reduction, membrane and electrode plate stacks are staged in series one after another. Typically, up to 200,000 gpd can be treated in a single line of stacks. For higher flow applications, multiple lines of ED stacks are installed in parallel (Fig. 4).

By automatically switching the membrane stack DC field orientation every 15 to 30 minutes, the EDR system keeps ED membranes free of salt scale buildup without having to add chemicals in the feedwater. Even at 85% water recovery, with highly concentrated levels of salts in the EDR brine, the EDR systems in San Diego operate without chemical feed to control salt scale buildup. By choice, one chemical that is added is a 0.5 ppm of free residual chlorine to keep EDR membrane stacks free from unwanted bacterial growth. Compared with MF-RO, the only pretreatment used with EDR are 10-micron disposable cartridge filters to remove solid particulate matter prior to the membrane stacks.

PAST RESULTS AND TODAY'S LATEST DEVELOPMENTS

When the initial system started operation in 1998, it was supplied as two parallel, land-based 1.1-million gallon per day units located under a sunshade. The systems had a single-stage membrane stack design. Approximately 55% of the salt was removed in this process, and then ED product water was blended up to 3.3 mgd at less than 1000-ppm TDS.

The demand for EDR product flow increased as the city continued to sell more reclaimed irrigation water. In 1999, the EDR system was expanded with the addition of a third land-based unit (a two-stage, 1.1-mgd EDR unit), and with the retrofitting of second-stage membrane stacks to the original EDR equipment. With EDR product flow of 3.3 mgd now having still better quality (less than

Figure 4. San Diego took a major step in the late 1990s by equipping a new high-technology wastewater reclamation plant with EDR (electrodialysis reversal) system from Ionics, Incorporated, to desalinate tertiary treated wastewater.

300 ppm), more non-desalted water is blended with EDR product. The plant is now rated to deliver over 7 mgd of <1000-ppm irrigation water.

To continue development of this alternative irrigation water supply, city officials purchased still more EDR capacity in the fall of 2003. Two options were available. The first used the conventional approach of adding more "land-based" EDR systems. This option required a major rework of the site, with more conventional building of sunshades, concrete pads, and extensive site installation work. The second approach called for the installation of fully preassembled EDR systems within 53-ft-long over-the-road enclosed trailers. On arrival at site, a simpler retrofit using preassembled trailers allows for the quick installation of two additional 1.1-mgd EDR systems (Fig. 5).

Total EDR production will be 5.5 mgd when the latest EDR units go online in January 2005. With blending, up to 12 mgd of irrigation water will be supplied to a now further expanded irrigation water pipeline infrastructure system. This water will go to additional golf courses and new home developments. The latest expansion also includes adding enough concrete pad area and water treatment site pipeline capacity to bring in a third EDR trailer in the future. EDR's ultimate plant will then have 6.6 mgd of EDR capacity and up to 15 mgd + total blended flow. Results at North City have proven very positive for San Diego and for the EDR process

FUTURE OUTLOOK

Based on San Diego's success, other municipal agencies in California are looking at EDR to treat their municipal wastewaters for irrigation reuse. In a recent tertiary-treated wastewater pilot test performed in California, EDR and MF-RO were run side-by-side for 9 months. Based on a present worth analysis of capital cost, installation cost, and 20 years O&M, EDR was rated as 40% less expensive than MF-RO.

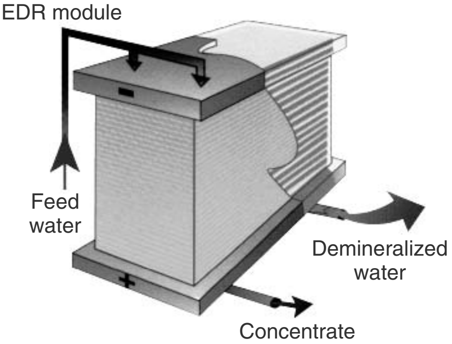

Figure 5. Preassembled EDR module.

In another case, where EDR or MF-RO could be used, highly concentrated brines have to be trucked 15 miles to a sewer line disposal site. Transportation costs are very high. The ability of EDR to operate at over 90% water recovery makes treatment practical. The greater volume of MF-RO treatment does not pencil out for this project.

AUTHOR'S NOTE

Eugene R. Reahl is the Western Regional Sales Manager for municipal systems sales at Ionics, Incorporated, based in Watertown, Massachusetts. Reahl sold the second and third EDR system expansions at North City and has been involved with many municipal EDR and RO systems since 1981. Contact the author at ereahl@ionics.com.

KEY CAUSES OF DRINKING WATER QUALITY FAILURE IN A RURAL SMALL WATER SUPPLY OF SOUTH AFRICA

Alice, South Africa

B.M. Brouckaert
University of Natal
Durban, South Africa

INTRODUCTION

Of the advances made possible through science and technology, the treatment and distribution of safe water use is truly one of the greatest. Abundant, clean water is essential for good public health. It has been increasingly recognized by world leaders that safe drinking water is a critical building block of sustainable development. Disinfection, a chemical process whose objective is to control disease-causing micro-organisms by killing or inactivating them, is critically important in drinking water treatment. However, research has shown that about 1.2 billion people lack access to safe drinking water worldwide (1). As a result, the World Health Organization estimates that 3.4 million people, mostly children, die every year from water-related diseases (2).

The provision of adequate water services was one of the more difficult and pressing challenges inherited by the new South Africa. Prior to the change of government in 1994, an estimated 30–40% of South Africa's population (14–18 million people) were without adequate water supply services and some 21 million people were without adequate sanitation (3). As of 2004, some 10 million additional people have been supplied with drinking water, thereby reducing the backlog in 2003 to some 4 million (4). Provision of access to a basic level of water can be regarded as the first step up the water ladder, and progress achieved to date is indeed impressive. Although great strides have been made in the effort to provide safe and clean water to all South Africans, studies have shown that in small rural towns and small remote villages with adequate water supply services, the drinking water quality is generally poor and often not fit for human consumption at the point of use (5–7). A study aimed at determining the upgrading needs of small and rural surface water treatment plants in South Africa and the subsequent process of drawing up guidelines on how to address these needs also revealed that most small water treatment plants in the country do not produce safe, clean potable water (8).

The study presented here was undertaken in the town of Alice, a small rural town in the Eastern Cape, one of South Africa's poorest provinces. The Alice Water Treatment Plant (AWTP) is one of many small water treatment plants in the Eastern Cape Province that has difficulty providing safe drinking water. Previous studies (6,7,9) on the microbiological quality of Alice drinking water indicated a high number of fecal and total coliforms and heterotrophic bacteria far exceeding the limit allowed for potable water (10). *Aeromonas hydrophila, Escherichia coli, Serratia odorifera, Salmonella arizonae, Pseudomonas aeroginosa, Pseudomonas fluorescens, Serratia liquefaciens*, and *Serratia marcescens* were present in all water samples collected from various sites of the distribution system. The possibility of *Vibrio* species existed in one of these sites (7). This situation, therefore, places the Alice community at risk of disease outbreaks. A crucial need exists for scientifically sound answers to the problems of the inadequate treatment of drinking water in small water treatment plants in the country in general and the Alice Water Treatment Plant (AWTP) in particular.

The present study aimed at assessing the causes of the drinking water quality failure within the Alice Water Treatment Plant from the raw water intake to the finished water in the in-plant reservoir and at identifying the key causes affecting the performance of the plant including the effectiveness of the disinfection process for the removal of indicator bacteria.

METHODOLOGY

Plant Description

The Alice plant is a conventional water treatment plant, which includes coagulation, flocculation, sedimentation, rapid sand filtration, and chlorination. Water drawn from the Binfield Dam on the Tyume River (approximately 12 km from Alice) is fed under gravity to the head of the works. The design capacity of the plant is 7 mL/d; however, it is currently operating between 3 and 4 mL/d. A number of surrounding villages currently without water services are to be connected to the Alice system in the near future.

At the beginning of the investigation (June 2002) until November 2002, lime and alum were used for the pretreatment of the raw water. The coagulants are dosed at the same point, just ahead of a 90° V-notch weir and hydraulic jump. Powdered hydrated lime and granular alum were mixed with domestic water in separate dissolving/slurry tanks and then fed under gravity to the dosing point. Flash mixing of the chemicals with the raw water results from the turbulence generated over the hydraulic jump. Granular alum and hydrated lime were replaced by ultrafloc (a polyaluminium chloride and polyamide mix supplied by Sudchemie) at the beginning of December 2002. At the foot of the jump, the water enters a relatively short hydraulic flocculator before flowing under gravity to a three-way flow splitter via an underground pipe. From the splitter, the water flows through short intermediate channels into each of the three-clarifier inlet channels. From the influent channels, the water flows into the clarifier inlet chambers via pipes passing through the clarifier walls (nine per clarifier). The discharge into the inlet chambers induces gentle hydraulic mixing, which promotes the formation of large settleable floc. The water passes over a vertical baffle wall into the main body of each of the three rectangular horizontal clarifiers. Settled water overflows into a common channel, which feeds into the filter influent pipe. The filter influent is split among three 4.3-m-diameter self-backwashing valveless sand filters. Chlorine gas is added to the combined filtrate just before the onsite reservoir from where it is fed into the bulk distribution system.

Identification of the Problems Affecting the Performance of the AWTP

The following activities were undertaken from June 2002 to January 2003, with the exception of the experimental study on the dissolved organic carbon, biodegradable dissolved organic carbon, the bacterial regrowth, and the growth factor, which was performed from August to October 2003. The chlorine residual was determined during both periods of the study.

- A tour of the plant and a visual inspection of the various unit processes.
- Interviewing of the operators and plant superintendent about operating practices and the monitoring program.
- Measurement of the raw water flow rate using the V-notch weir.
- Determination of the optimum doses of alum and lime using Jar tests.
- Measurement and interpretation of the turbidity at each step in the treatment process.
- Opening and inspecting one of the valveless filters.
- Measurement of the initial chlorine dose and free chlorine residual concentration in the onsite reservoirs.
- Monitoring of the bacterial quality of the finished water.
- Investigation of the removal of dissolved organic carbon and assessment of the impact of the biodegradable dissolved organic carbon on the bacterial regrowth in the finished water. Details of these activities are given below.

Flow Rate Measurement and Control. The plant was equipped with a flow meter; however, this was located in a sump, which was flooded and the meter had not been read for several years. The flow could also be measured at the V-notch weir at the hydraulic jump; however, the plant operating personnel were unaware of this prior to the project team's visit. During the investigation, the flow of the raw water was calculated using the existing 90° V-notch weir according to Kawamura (11).

For a 90° V-notch weir, the total flow rate, Q, is related to the height of the crest over the weir, H, as follows:

$$Q(\mathrm{m}^3/\mathrm{s}) = 1.40\ \mathrm{H}^{2.5}$$

where H (m) is the height of water above the weir crest.

Table 1 shows H values with corresponding flows as calculated using the hydraulic equation given above.

Alum and Lime Consumption and Cost Estimation. The consumption of alum and lime onsite was estimated by collecting and weighing the amount of dry chemical fed to the mixing tanks during a given time interval. Using the flow rate measured on each day, the corresponding dosages in mg/L and the cost were estimated, which were compared with the optimum doses determined from standard jar tests (11). The costs of chemicals corresponding to the various dose estimates were then calculated taking into account the cost of a 50-kg bag of alum, which is R 96 (US$ 14.9), and a 25-kg bag of lime, which is R 30 (US$ 467).

Clarifier and Filter Performance. The turbidity of the clarified and filtered waters was measured for each settling tank and filter using a Microprocessor Turbidity Meter (HACH Co., Model 2100P). The filtrate was allowed to run out of a sampling tap on the filter under the drain until the measured turbidity stabilized. One filter was opened directly after it had backwashed to assess the state of the filter media. The impact of backwashing on filtrate turbidity was investigated by measuring turbidity before, immediately after, and 4 h and 6 h after backwashing.

Disinfection. The chlorine residual and the turbidity of the treated water were measured in the in-plant reservoir using a multiparameter ion-specific meter (Hanna-BDH laboratory supplies) and Microprocessor Turbidity Meter (HACH company, Model 2100P), respectively.

Monitoring of Bacterial Quality of the Finished Water. To assess the performance of the AWTP for the removal of bacterial indicators, the intake raw water and the chlorinated water samples from the in-plant reservoir were collected twice a week. Treated waters for microbiological analysis were collected in sterile 1-L glass bottles, which contained sodium thiosulphate (ca 17.5 mg/L), and placed in an ice bag. Microbiological analyses were conducted within 1 h after the collection of the water samples. Total coliforms (TC), fecal coliforms (FC), presumptive Salmonella (PS) spp., and heterotrophic plate count bacteria (HPC) were used as bacterial indicators. The membrane filtration technique and chromocult coliform agar (Merck) were used for the enumeration of coliforms and PS. Standard spread plate procedure and R2A agar (Oxoid) were used for the

Table 1. Examples of Flow Rate Measurement Considering Height (*H*) of Water

enumeration of HPC bacteria. Water samples were analyzed for the above micro-organisms using internationally accepted techniques and principles (12). Bacterial colonies differing in size, shape, and color were randomly selected from the different plates and further isolated on MacConkey agar (Biolab) by the streak plate technique and incubated at 37 °C for 24 h. These were further purified by the same method at least three times using nutrient agar (Biolab) before Gram staining was done. Oxidase tests were then done on those colonies that were gram negative. The API 20E kit was used for the oxidase-negative colonies, and the strips were incubated at 35 ± 2 °C for 24 h. The strips were then read, and the final identification was done using API LAB PLUS computer software (BioMérieux).

Dissolved Organic Carbon (DOC), BDOC, and Bacterial Regrowth Analyses. Water samples (raw water, water after filtration, and water after chlorination) for the dissolved organic carbon (DOC), biodegradable dissolved organic carbon, bacterial regrowth, and growth factor were collected weekly using sterile glass bottles (brown sterile bottles for raw water and water after filtration). Prior to use, all glassware (except the filter frit) was pretreated according to Servais et al.'s (13) methods, which were modified by Grundlingh et al. (14) to make sure that there were no traces of organic matter left in the glassware, as this might lead to false results. Water samples for DOC analysis were prepared according to Mathieu et al. (15). The DOC concentrations were determined using an AQUADOC™ TOC Analyzer.

The preparation of the inoculums was performed according to Grundlingh et al. (14). A 50-mL raw water sample was filtered through a 2.0-μm nucleopore polycarbonate membrane, 47-mm diameter (Merck, Cat. No. 111111), and was stored in a sealed glass bottle. This water sample was used for the analysis of BDOC and for the growth factor. The BDOC was determined according to the method previously used by Servais et al. (13) modified by Grundlingh et al. (14). Briefly, a water sample was vacuum-filtered through a 0.2-μm nucleopore polycarbonate membrane, 47-mm diameter (Merck, Cat. No. 111106), and 200 mL of this water sample was measured using a glass measuring cylinder into a brown bottle. Two milliliters of the innoculum was added. The water sample was then incubated for 28 days in a dark cupboard to prevent the breakdown of DOC by sunlight. After every 7 days, 20 mL was removed and prepared for the DOC analysis. The concentration of BDOC was calculated as the difference in the DOC concentration before incubation and on the last day of incubation. Bacterial regrowth was then determined using total coliforms (TC), fecal coliforms (FC), and heterotrophic plate count (HPC) as main parameters, which were enumerated as described for the monitoring of the bacterial quality of the finished water using standard methods (12).

Growth Factor. The growth factor was analyzed according to Page et al. (16) to evaluate the potential of the water to support the regrowth of bacteria. Each water sample was allowed to warm to room temperature after collection and was then vacuum-filtered through a 2.0-μm nucleopore polycarbonate membrane, 47-mm diameter (Merck, Cat. No. 111111), and 200 mL of this water sample were measured into a brown bottle, 20 mL of sterile nutrient broth were added to the sample. This water sample was then vacuum-filtered using a 0.2-μm nucleopore polycarbonate membrane, 47-mm diameter (Merck, Cat. No. 111106), and then poured into three sterile turbidity cuvettes. A Microprocessor Turbidity Meter (HACH Co., model 2100P) was zeroed using this sample. The inoculum (bacteria from raw water) was added until the turbidity readings were between 0.2 and 0.4 NTU. The turbidity meter was zeroed again to ensure that only the growth of new bacteria was enumerated. Turbidity readings were taken after every 30 minutes until a plateau was reached. The growth factor was calculated as follows:

$$\frac{\text{Turbidity at the plateau}}{\text{Turbidity at the lag phase}}$$

Results and Discussion

To ensure effective water treatment processes, which will result in the production of safe and clean potable water, trained and skilled personnel remain a prerequisite. However, this is not the case in most small water supplies in rural developing communities. Lack of trained operators at the AWTP resulted in the malfunctioning of the plant.

Coagulant Dosing and Control. Two major operating problems identified during this investigation were the lack of flow rate measurement and chemical dosing control. Raw water flow rates were adjusted based on the level of the in-plant reservoir, but coagulant chemical feed rates were not automatically adjusted in proportion to the raw water flow rate, resulting in large fluctuations in coagulant doses. The operating staff apparently sometimes adjusted the alum and lime doses based on the taste and appearance of the final water and the formation of floc in the clarifiers; however, the coagulant demand was not determined. Table 2 summarizes the raw water flow rates, coagulant feed rates and doses for 4 different days, and an estimate of the annual cost of alum and lime used. Jar tests on the raw water indicated that the optimum alum dose was approximately 15 mg/L, three to five times smaller than the doses used by the plant operators during the study period. With an average flow of 3.27 mL/d obtained during the investigation, the cost of alum per year at a dosage rate of 15 mg/L was calculated at R 33,323 (US$ 5182.43), which represents one quarter of the cost of the dose currently used by the plant. The jar tests conducted also indicated that lime addition was not necessary for coagulation at the time the tests were undertaken and was probably detrimental to the process. Theoretically, lime addition should only be necessary if insufficient alkalinity exists in the raw water to prevent the pH dropping below 6 or the colloidal particles becoming restabilized. If the coagulated water pH is above 6, then the addition of lime increases the solubility of aluminium and the amount of alum required. Lime may have been necessary at other times of the year. Overdosing lime and alum appeared to have a negative impact on plant performance. There was a large amount of floc deposited throughout the plant, including in the in-plant reservoir. Post-precipitation of floc after the filters because of alum overdosing was evident on at least one occasion.

Clarification. The general performance goal of a settling tank preceded by chemical coagulation is that its effluent (settled water) must have turbidity of less than 5 NTU (17). This protects subsequent sand filtration processes against high loads of suspended solids, preventing turbidity breakthrough and/or short filter runs. However, the clarified water turbidities measured in the AWTP during the study period were found to range between 8.5 and 17.9 NTU. During the plant inspections, it was noted that the flow splitter was not being operated correctly: Gate valves downstream of the overflow weirs had been set so that one of the three weirs was submerged. An uneven flow split may have contributed to poor clarifier performance; however, the major problem appeared to be overdosing with lime and alum. Clarifiers were usually manually desludged twice a week. No written procedures or records for desludging existed.

Filtration. For efficient disinfection, WHO guidelines (17) for potable water production state that the filtrate must have turbidity of <1 NTU because high turbidities exert high disinfectant demands, and particles may shield micro-organisms from disinfectants. However, the average filtered water turbidity recorded from October 2002 to January 2003 was greater than 1 NTU (Fig. 1). When alum and lime were used, poor filter performance was sometimes linked to post-precipitation of alum floc. However, switching to Ultra-floc did not have a positive effect on filtrate quality. The small improvement in filtrate turbidity in December and January is not necessarily attributable to the change in coagulant because the raw water turbidity decreased at the same time. Filtration rates of ~ 2–4 m/h were recorded during the evaluation of the AWTP, which are conservative rates for rapid sand filtration and should not have unduly challenged the filter performance if pretreatment had been adequate. Apart from inadequate pretreatment, the most common source of problems in rapid filtration is inadequate backwashing.

Table 2. Estimating Alum and Lime Consumption and Costs According to Onsite Measurements

	Alum		Lime

Valveless filters are designed to backwash automatically when a specific headloss across the filter media is developed. Their chief advantage and the reason they are a popular choice for small treatment plants is that they backwash without any operator intervention. Important disadvantages include the following (18): (a) no auxiliary backwash is used, so cleaning is relatively inefficient; and (b) slow headloss development may result in excessively long run times, which could, in turn, lead to mudballing problems. The recommended maximum run length is 24 hours. No records of filter backwash were kept at the AWTP, but the filters appeared to go for days without backwashing. This may have been attributable to low filtration rates and poor coagulation.

Inspection of a filter bed directly after manual backwash revealed that the filter media was in a fairly good state, except at the edges of the filter, where it had built up against the filter walls and where a number of mudballs were found, which indicates poor flow distribution adjacent to the walls. The media away from the walls appeared to be clean except for a few millimeters of sludge on the top surface of the bed (typical of filters backwashed without auxiliary backwash). An analysis of the filter effluent turbidity immediately after a manual backwashing revealed very high values (27.5–39 NTU); thereafter a gradual decrease in the turbidity was noted within 4 h (2.33–3.44 NTU) and 6 h (1.98–2.02 NTU). These high turbidities indicated that the volume of backwash was insufficient to flush out all of the floc detached during backwashing.

Disinfection. The chlorine dose rate was manually controlled and set using a rotameter housed in the chlorination room. Like the coagulant doses, the chlorine dose was not ratioed to the plant flow rate. Furthermore, no attempt was made to match the dose to the chlorine demand. During the preliminary plant visits, the dosing rate was set at 100 g/h Cl_2, which translated into applied chlorine doses of 0.6 to 1.3 mg/L at plant flow rates of 2.75–3.97 mL/d. Given the poor quality of the filtrate, these doses were insufficient to establish an adequate residual. It was also noted that a substantial amount of floc had settled in the contact chambers, which could also lead to high consumption of the disinfectant. The dosing rate was subsequently increased to 400 g/h without any improvement in dosing control. Water samples collected at the point of treatment (in-plant reservoir) showed that the free chlorine residual values ranged from 0 to 1.14 mg/L for the period of 5 months. Figure 2 shows the average

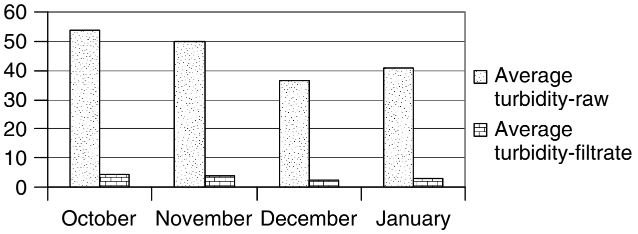

Figure 1. Performance of AWTP for the removal of the turbidity (NTU).

free chlorine residual for each month. It can also be seen that chlorine residual increased as the filtrate turbidity decreased. Alice drinking water at the point of treatment contained less chlorine than the target chlorine residual concentration, i.e., 1 mg/L. The present results confirm those of previous investigators who also observed a low level of chlorine residual in the AWTP's reservoirs (9).

Microbiological quality of drinking water at the point of treatment. The bacterial quality of the finished water as suggested by the indicator organisms used (Figs. 3 and 4) did not meet the standards for potable water. Among 14 species of potential pathogenic bacteria identified from the raw water (*Aeromonas hydrophila, Aeromonas caviae, Aeromonas sobria, Escherichia coli, Serratia odorifera, Serratia liquefaciens, Serratia marcescens, Salmonella arizonae, Pseudomonas aeruginosa, Pseudomonas fluorescens, Vibrio fluvialis, Chryseomonas luteola, Enterobacter aerogenus, Enterobacter sakazakii),* 8 species were still prevalent in the chlorinated water from the reservoirs (*Aeromonas hydrophila, Escherichia coli, Serratia odorifera, Serratia liquefaciens, Serratia marcescens, Salmonella arizonae, Pseudomonas aeruginosa, Pseudomonas fluorescens*). In general, the result suggested that the performance of the AWTP for the removal of indicator bacteria (HPC, TC, FC, and PS) was not adequate. The finished water produced by this plant places the consumers at a serious health risk. These results confirm our recent study, which also showed the failure of the AWTP to provide potable water to its consumers at the point of use (7).

The removal of DOC and the impact of BDOC on bacterial regrowth. Sand filtration processes are performed to decrease the DOC concentration from the raw water to the filtered water. Overall, DOC removal at the AWTP appeared to have been very poor for the entire monitoring period, as indicated in Table 3. The AWTP's filtration system did not decrease the DOC concentration to the level recommended by the water industries, which ranges between 0 and 5 mg/L (10). The DOC concentrations in the filtered water samples were above these limits (Table 3). The highest DOC concentration in raw water was found in October and the removal was at 59.57%, whereas the lowest concentration of the DOC in raw water was recorded in August. No removal of the DOC was noted in August and in September; in contrast, an increase in DOC concentration occurred at rates of 13.64% and 35.34%, respectively. The inefficiency of the filtration process could be attributed to the lack of backwashing of the sand filters in the AWTP. It was noted that the filters went for days without backwashing, which impacted the quality of the filtrate in terms of the DOC removal.

samples at the point of chlorination. Although no free chlorine residual was noted in August and during the first week of September (Table 3), the DOC concentrations increased by 24% and by 46.5%, respectively, during the monitoring period. In October, the free chlorine residual concentrations exceeded the limits recommended for potable water, which are in ranges of 0.3–0.6 mg/L as ideal free chlorine residual concentration and 0.6–0.8 mg/L as good free chlorine residual concentration for insignificant risk of health effects (19). During this month, the DOC concentration decreased by 16.67%. As indicated in Table 3, high concentrations of the DOC in the Alice finished water contributed to the biodegradability of the organic matter in the drinking water, which followed the trend of chlorine residual as it increased each month.

Biologically stable water is free of biologically available substances. In addition, it is well known that the degree of bacterial regrowth is determined by the overall content of biodegradable organic carbon present in the water and is largely determined by the origin of the drinking water produced (20). The results of the present experimental study showed close relationship between the DOC concentrations and both BDOC concentrations and the growth factors (Table 3). The concentration of BDOC and the growth factor revealed that water distributed by the AWTP was biologically unstable. Water with growth factors below 5 is considered biologically stable (16). In the AWTP, the average values of growth factors were found to be high in September (7.72), and October (5.97), exceeding the above limit. The lowest values of the growth factor were found in August (4.37).

Removal of BDOC to the level that limits microbial regrowth provides not only a direct control of bacterial population but also an indirect control of protozoan population through a trophic food web (21). A high BDOC concentration in finished water indicates poor quality and a potential for micro-organisms to multiply in the water (22). It has been reported that treated water containing a BDOC concentration of less than 1 mg/L is not prone to regrowth (23). However, treated water supplied by the AWTP had very high concentrations of BDOC, up to 40 mg/L (Table 3), which resulted in high bacterial regrowth during the study period (Fig. 5). The increase of the bacterial counts was parallel to the increase in the BDOC concentration from August to September, but bacterial regrowth decreased in October contrary to the increase in the BDOC concentration. This decrease in bacterial regrowth could be related to a high concentration of free chlorine residual, which was up to 3.58 mg/L (Table 3). The variation of the free chlorine residual concentration was associated with the fact that the operators in the AWTP have little understanding of the chlorination process in the purification system. Chlorination in the AWTP was done without considering the chlorine demand of the water.

CONCLUSION AND RECOMMENDATIONS

The Alice Water Treatment Plant should be operated to consistently produce a combined filtrate turbidity (measured at the first clear well) of less than 0.5 NTU and a free chlorine residual of at least 0.5 mg/L in the main storage reservoirs for the town and 0.2 mg/L at the end of the distribution system. If the water is to be stored for considerable periods of time at the point of use, then higher residuals may be required.

Coagulation should ideally also be optimized for maximum DOC removal prior to disinfection. The operating staff should aim to meet turbidity removal goals with the minimum amount of coagulants necessary. Jar tests should be used to determine what these optimum doses are, which will result in a reduction of sludge production and disposal problems, lower solids loading, and less risk of post-precipitation in the filters, as well as cost savings for the plant. Filters should backwash at least once a day. If necessary, manual backwash should be initiated to prevent filter run times of greater than 24 to 36 h.

The success of any attempt to optimize the plant operation requires the full cooperation of the operating staff, especially because they will be required to undertake additional duties. All decisions and strategies should be discussed with the operators, and they should be encouraged to take a personal interest and pride in any improvements achieved.

FILTRATION

National Drinking Water
Clearinghouse

Filtration is the process of removing suspended solids from water by passing the water through a permeable fabric or porous bed of materials. Groundwater is naturally filtered as it flows through porous layers of soil. However, surface water and groundwater under the influence of surface water is subject to contamination from many sources. Some contaminants pose a threat to human health, and filtration is one of the oldest and simplest methods of removing them. Federal and state laws require many water systems to filter their water. Filtration methods include slow and rapid sand filtration, diatomaceous earth filtration, direct filtration, packaged filtration, membrane filtration, and cartridge filtration.

FILTRATION KEEPS WATER SAFE

Why Filter Drinking Water?

Natural filtration removes most suspended matter from groundwater as the water passes through porous layers of soil into aquifers. Surface water, however, may be subject to direct animal, human, and industrial contamination that can cause disease or illness in humans, so they must be filtered by a constructed treatment system.

What Regulations Govern Filtration?

The Surface Water Treatment Rule under the 1986 Safe Drinking Water Act (SDWA) Amendments requires that many surface water supply systems and groundwater under the influence of surface water filter their water supplies.

What Processes Precede Filtration?

Conventional filtration processes are normally preceded by coagulation, flocculation, and sedimentation. Direct filtration processes are preceded by coagulation and flocculation only; the floc is removed directly by the filters.

Filtration processes may include one or all of the following pretreatment procedures:

Chemical Feed and Rapid Mix: Chemicals may be added to the water to improve the treatment processes that occur later. These may include pH adjusters and coagulants. A variety of devices, such as baffles, and static mixers can be used to mix the water and distribute the chemicals evenly.

Flocculation: The chemically treated water is sent into a basin where the suspended particles can collide and form heavier particles called floc. Gentle agitation and appropriate detention times facilitate this process.

Sedimentation: The velocity of water is decreased so that suspended material (including flocculated particles) can settle out of the water stream by gravity. Once settled, the particles combine to form a sludge that is later removed from the clarified supernatant (the liquid removed from settled sludge) water.

How is Filtration Achieved?

Filtration is usually a combination of physical and chemical processes. Mechanical straining removes some particles by trapping them between the grains of the filter medium (such as sand). Adhesion is an equally important process by which suspended particles stick to the surface of filter grains or previously deposited material. Biological processes are also important in slow sand filters. These filters form a filter skin containing microorganisms that trap and break down algae, bacteria, and other organic matter before the water reaches the filter medium itself.

COMPARING FILTRATION SYSTEMS

Slow Sand Filtration

The filter consists of a bed of fine sand approximately 3 to 4 feet deep supported by a 1-foot layer of gravel and an underdrain system (Fig. 1).

Advantages. Low cost, simplex2 operation, reliable, and able to achieve greater than 99.9 percent *Giardia* cyst removal. It also does not require extensive active control by an operator.

Limitations. It is not suitable for water with high turbidity. Filter surface requires maintenance. Extensive land is required due to low-flow operation (0.03 to 0.10 gallons per minute per square foot [gal/min/ft^2] of filter bed area).

Process. Filters are operated under continuous, submerged conditions maintained by adjusting a control valve located on the discharge line from the underdrain system. Biological processes and chemical/physical processes common to various types of filters occur at the surface of the filter bed. A biological slime or mat referred to as "schmutzdecke" forms on the surface of the bed, which traps small particles and degrades organic material present in the raw water. Slow sand filters do not require coagulation/flocculation and may not require sedimentation.

Equipment. Small plants are typically designed with cast-in-place concrete structures with wood or concrete structures with wood or concrete slab covers. Piping is either cast iron or polyvinyl chloride (PVC). Flow meters are used to monitor the output for each filter. In climates subject to freezing temperatures, filters usually must be housed, and may require heating, lighting, and ventilation. Unhoused filters in cold climates develop an ice layer that prevents cleaning during winter months.

Chemicals. Water applied to slow sand filters is not prechlorinated because the chlorine can destroy organisms in the schmutzdecke.

Diatomaceous Earth Filtration

Diatomaceous earth filtration, also known as precoat or diatomite filtration, relies on a layer of diatomaceous earth approximately 1/8-inch thick placed on a septum or filter element. Septums may be placed in pressure vessels or operated under a vacuum in open vessels.

Advantages. The filters are simple to operate and effective in removing cysts, algae, and asbestos. They have been chosen for projects with limited initial capital, and for emergency or standby capacity to service large seasonal increases in demand.

Limitations. This filter is most suitable for water with low bacterial counts and low turbidity (less than 10 nephelometric turbidity units [NTU]). Coagulant and filter aids are required for effective virus removal. There is potential difficulty in maintaining complete and uniform thickness of diatomaceous earth on the filter septum.

Process. Operation and maintenance of diatomaceous earth filters require: preparing slurries of filter body feed (diatomaceous earth) and precoat diatomaceous earth; adjusting body feed dosages for effective turbidity removal; periodic backwashing—every 1 to 4 days; disposing of spent filter cake; periodically inspecting the filter septum for cleanliness and damage; and verifying effluent quality.

Equipment. The minimum amount of filter precoat should be 0.2 pounds per square foot (lb/ft^2); and minimum thickness of the precoat should be increased from 1/8 to 1/5 inch to enhance *Giardia* cyst removal. In addition, minimum design criteria outlined in the *Recommended Standards for Water Works* (better known as 10 State Standards) should be met.

Chemicals. Use coagulant to coat the body feed to improve removal rates for viruses, bacteria, and turbidity.

Direct Filtration

Direct filtration systems are similar to conventional systems, but omit sedimentation.

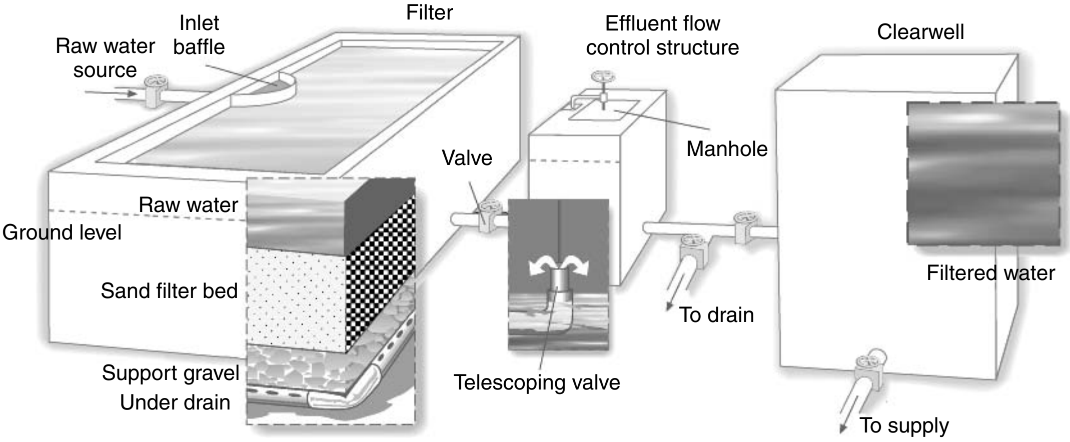

Figure 1. Slow sand filter.

Advantages. Effective direct filtration performance ranges from 90 to 99 percent for virus removal and from 10 to 99.99 percent for *Giardia* removal. The most effective direct filtration configurations for *Giardia* removal must include coagulation. Often used with steel pressure vessels to maintain the pressure in a water line to avoid repumping after filtration.

Limitations. Direct filtration is only applicable for systems with high quality and seasonally consistent influent supplies. The influent generally should have turbidity of less than 5 to 10 NTU and color of less than 20 to 30 units. (Water with 15 or more units of color causes aesthetic problems, such as staining.)

Process. Direct filtration consists of several combinations of treatment processes. It always includes coagulation and filtration, and may require a flocculation tank or a pressure vessel after the coagulation addition.

Equipment. Dual- and mixed-media filters are used to effectively process higher influent turbidities without the use of sedimentation.

Chemicals. Typical coagulant dosages range from less than 1 to 30 milligrams per liter. Cationic polymers often successfully coagulate water supplies and assist direct filtration. Nonionic polymers are sometimes added to the filtration step to increase filter efficiency.

Packaged Filtration

Packaged filtration is simply all of the features of filtration—chemical addition, flocculation, sedimentation, filtration—mounted as a unit on a frame for simple hookup of pipes and services. It is most widely used to treat surface water supplies for removal of turbidity, color, and coliform organisms with filtration processes. Packaged filtration is often used to treat small community water supplies, as well as supplies in recreational areas, state parks, construction sites, ski areas, and military installations, among others.

Advantages. The four major advantages of package plants are their compact size, cost effectiveness, relative ease of operation, and design for unattended operation. (Some states require that an operator be in attendance at all times. Check your state regulations.)

Limitations. When the turbidity of the raw water varies a great deal, these package plants require a high level of operator attention and skill.

Process. Package plants are most appropriate for plant sizes ranging from 0.025 to 6 million gallons per day. The most important factor to consider in selecting a package plant is the influent characteristics, such as temperature, turbidity, and color levels. Pilot tests might be necessary before a final system can be selected.

Equipment. Package plants are assembled in a factory, skid mounted, and transported to the treatment site, or they are transported as component units to the site and then assembled.

Chemicals. Chemical feed controls are especially important for plants without full-time operators or with variable influent characteristics. Even with these automated devices, however, the operator needs to be properly trained and well acquainted with the process and control system.

Membrane Filtration

A membrane is a thin layer of material capable of separating substances when a driving force is applied across the membrane.

Advantages. Membrane filtration can be an attractive option for small systems because of its small size and automated operation. Membrane processes are increasingly employed for removal of bacteria and other microorganisms, particulate material, and natural organic material, which can impart color, tastes, and odors to water.

Limitations. Fouling of the membranes is the major problem preventing widespread application of this technology.

Process. Membrane filtration works by passing water at high pressure through a thin membrane in the form of hollow fiber or spiral-wound composite sheets. Organic and other contaminants are retained on the high-pressure side and frequently must be removed by reversing the flow and flushing the waste. Periodic chemical cleaning may be required to remove persistent contaminants. Membrane assemblies are contained in pressure vessels or cartridges.

Equipment. The membrane technologies are relatively simple to install and for groundwater sources that do not need pretreatment, the systems require little more than a feed pump, a cleaning pump, the membrane modules, and some holding tanks.

Chemicals. Periodic backflushing and occasional chemical cleaning is necessary to maintain the membrane or fibers.

Cartridge Filtration

Cartridge filters are considered an emerging technology suitable for removing microbes and turbidity in small systems (Fig. 2).

Advantages. Cartridge filters are easy to operate and maintain, making them suitable for small systems with low-turbidity influent.

Limitations. Cartridge filtration systems require raw water with low turbidity. Polypropylene cartridges become fouled relatively quickly and must be replaced with new units. Although these filter systems are operationally simple, they are not automated and can require relatively large operating budgets.

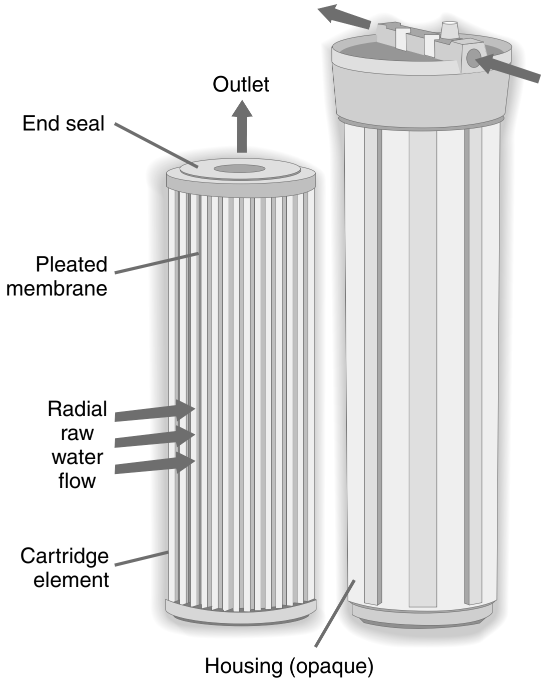

Figure 2. Cartridge filter with replaceable inner package.

Process. Cartridge filtration uses a physical process—straining water through porous media. It can exclude particles 0.2 micrometers (μm) or smaller. The pore sizes that are suitable for producing potable water range from 0.2 to 1.0 μm. Roughing filters, for pretreatment prior to cartridge filtration, are sometimes necessary to remove larger suspended solids and prevent the rapid fouling of the cartridges. Roughing filters can be rapid sand filters, multimedia filters, fine mesh screens, or bag filters.

Equipment. A cartridge consists of ceramic or polypropylene filter elements fitted into pressurized housings.

Chemicals. A disinfectant is recommended to prevent surface-fouling microbial growth on the cartridge filters and to reduce microbial pass-through. Except for a disinfectant, no chemical additions are necessary. However, corrosive chemicals may be required for the periodic membrane cleaning process.

How Does One Select the Appropriate Filtration System?

First, review all raw water quality data to establish the requirements for the alternatives. Once the potential alternatives are selected, determine the necessity of pilot or bench-scale tests. If the desired performance of one or more of the alternatives is in doubt, testing is appropriate. (Testing is always useful if time and budget allow).

Otherwise, literature surveys, bench-scale studies, or pilot-test results can be used to derive each alternative's performance characteristics and design considerations. Following this initial selection, the basic process concerns for the various alternatives should be identified and evaluated, including:

- turbidity removal performance,
- *Giardia* removal performance,
- color removal performance,
- cleaning cycle frequency,
- necessary chemicals/chemical dosages,
- applicable regulatory standards,
- required operational skills, and
- necessary sludge management.

Where Can I Find More Information?

Information in this fact sheet was primarily obtained from two sources: Environmental Pollution Control Alternatives: Drinking Water Treatment for Small Communities, *EPA/625/5-90/025; and* Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities, *EPA/625/4-89/023. Both can be ordered free from the U.S. Environmental Protection Agency Office of Research and Development at (513) 569-7562.*

If these publications are no longer available from the EPA, call the National Drinking Water Clearinghouse (NDWC). Environmental Pollution Control Alternatives: Drinking Water Treatment for Small Communities, *item #DWBKGN09, an 82-page publication, costs $11.82.* Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities, *item #DWBKDM04, a 209-page book, costs $30.05. Shipping and handling charges apply.*

Also, the NDWC's Registry of Equipment Suppliers of Treatment Technologies for Small Systems (RESULTS) is a public reference database that contains information about technologies in use at small water systems around the country. For further information on accessing or ordering RESULTS, call the NDWC at (800) 624-8301.

For additional copies of "Tech Brief: Filtration," item #DWBRPE5O, or a copy of "Tech Brief: Disinfection," item #DWBRPE47, call NDWC at the number above.

WATER FILTRATION

Rasheed Ahmad
Khafra Engineering Consultants
Atlanta, Georgia

Particulates that are removed by a water filtration process include microorganisms (bacteria, viruses, and protozoan cysts), clay and silt particles, colloidal and precipitated humic substances and other organic particulates from natural decay of vegetation, precipitates of an aluminum or iron coagulation process, calcium carbonate and magnesium hydroxide precipitates from lime softening, and iron and manganese precipitates.

Granular medium filtration is a water treatment process that uses a porous medium through which water passes to remove particulates or suspended solids (Fig. 1). There are different types of filters classified by various schemes. Filters can be classified based on the type of medium (single medium, dual medium), hydraulic arrangement (gravity or pressure), rate of filtration (rapid

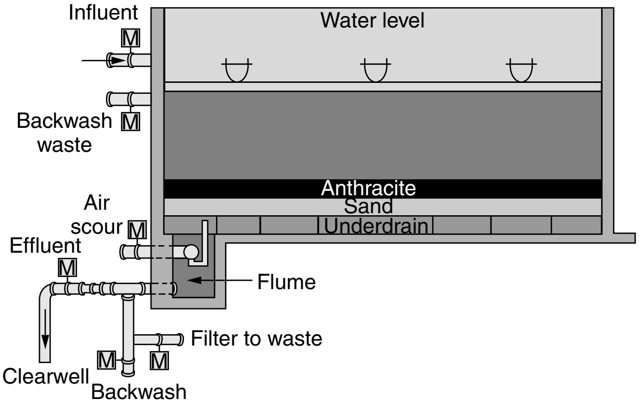

Figure 1. Rapid gravity filter (*Source*: F.B. Leopold Company).

or slow), and depth of solids removal (deep or cake). The most common types of filter media used in granular bed filters are silica sand, anthracite coal, and garnet. These may be used alone or in dual- or triple-media combinations. Granular-activated carbon (GAC), another type of medium, has been used to reduce taste and odor in granular beds that serve for both filtration and adsorption.

Rapid granular bed filtration consists of passing pretreated water through a granular bed at rates ranging from 2 to 10 gpm/sq ft (5 to 25 m/h). Flow is typically downward through the bed. During the filtration cycle, solids are removed from the water and accumulate within the voids and on the top surface of the filter medium. This accumulation results in clogging and a gradual increase in head loss. When the head loss becomes excessive (generally 8–9 ft), the filtrate quality begins to deteriorate, and/or the filter cycle reaches a predetermined time limit (usually 3 or 4 days), then rapid filters need cleaning.

Dirty/clogged filters may be cleaned by scouring the clogged portion or by reversing the flow through the bed. This application of expanding and washing out trapped particles is called backwashing. Backwashing by water fluidization is frequently assisted by a surface wash or an air scour. The most effective backwash is achieved by simultaneous air scour and subfluidization water backwash. Typical backwash rates range from 15 to 23 gpm/sq ft depending on media sizes. The bed expansion varies from 20% to 50%. The backwash usually lasts from 5 to 15 minutes. The air-scour rate varies from 2 to 4 cu ft/min/sq ft (0.6 to 1.2 cu meter/min/sq meter). For effective rapid granular bed filtration, source water must be pretreated.

Chemical destabilization is an essential prerequisite for effective filtration. Chemicals used for particle destabilization are limited primarily to metal salts or cationic polymers as primary coagulants. Pretreatment may also include aeration or introducing an oxidant if water treatment aims to remove iron or manganese. Sometimes, a filter aid polymer is added in the influent to the filter to improve particle capture efficiency.

Granular bed filtration consists of three principal mechanisms: (1) transport, (2) attachment, and (3) detachment. *Transport* mechanisms move a particle into and through a filter pore so that it comes very close to the surface of the filter medium or existing deposits where *attachment* mechanisms retain the suspended particle in contact with the medium's surface or with previously deposited solids. *Detachment* mechanisms result from the hydrodynamic forces of the flow acting so that a certain portion of the previously attached particles, less strongly adhered to others, is detached from the filter medium or previous deposits and carried further, deep into or through the filter. Important transport mechanisms include screening, interception, inertial forces, sedimentation, diffusion, and hydrodynamic forces. Attachment of particles to media surfaces is generally governed by physicochemical and molecular forces. Detachment is caused by the impact of arriving particles on unstable deposits and by hydraulic shear stresses without the influence of arriving particles. A number of properties of a filter medium are important for filtration performance and for characterizing the medium. Important media properties include size, shape, density, and hardness. The efficiency of a filter is more sensitive to changes in the filtration rate rather than in the actual rate. Therefore, filtration process control is critical to successful operation.

In recent years, direct filtration has received considerable attention and application in treating of drinking water. Direct filtration is not preceded by sedimentation. It offers several advantages over conventional treatment of "good-quality" surface water. Because there is no sedimentation process and a lower coagulant dose, the capital and operating costs are lower compared with conventional treatment. Sludge volumes are lower, which results in lower chemical costs for sludge treatment and disposal. Because of the increased interest in ozone application in potable water, biological filtration has received noticeable attention and application in recent years. Granular filters become biologically active when ozone is used as a preoxidant. Ozone reacts with organic compounds in water and forms several ozonation byproducts such as aldehydes, carboxylic acids, and keto acids, which are relatively easy to biodegrade. By operating filters in a biological mode, these ozonation byproducts can be effectively removed and in turn reduce the potential for bacterial regrowth in a distribution system and formation of chlorination byproducts.

A slow sand filter generally consists of a watertight basin containing a layer of sand over a layer of gravel (Fig. 2). It is operated at very low filtration rates without coagulation in pretreatment. A smaller grain size and lower filtration rate result in removing the solids almost entirely in a thin layer on the top of the sand bed. This layer, composed of dirt and living and dead micro- and macro-organisms from the water, is called *schmutzdecke* or dirty skin. Most of the solid removals in a slow sand filter take place in the *schmutzdecke* layer. The dominant removal mechanisms are both physical and biological. A typical filter cycle may vary from 1 to 6 months (or longer) depending on the source water quality and the filtration rate. Filtration rates range from 0.016 to 0.16 gpm/sq ft (0.04 to 0.40 m/h). Effective sand sizes ranged from 0.15 to 0.40 mm, sand uniformity coefficients from 1.5 to 3.6, and initial bed depths from 1.5 to 5.0 ft. The sand is supported on graded gravel 6 to 36 inches deep. Slow sand filters

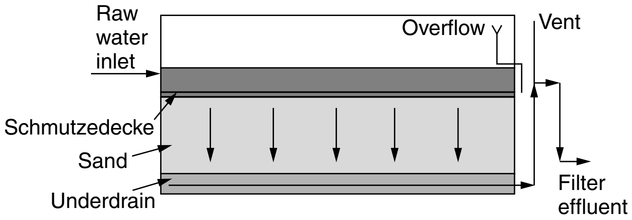

Figure 2. Conventional slow sand filter.

are cleaned by scraping *schmutzdecke* and a small amount of sand depth. Usually scraping is done manually but, in some cases, mechanically. The scraped sand is cleaned hydraulically and stockpiled for later reuse.

Diatomaceous earth filtration, also called precoat or diatomite filtration, uses a layer of diatomaceous earth approximately one-eighth inch thick placed on a septum or filter element as a filter medium. The septum may be placed in a pressure vessel or operated under a vacuum in an open vessel. As the water passes through the filter medium and septum, the suspended particles are captured and deposited. The majority of particles removed by the filters are strained at the surface layer of the filter medium, and some are trapped within the layer. As the filter cycle proceeds, additional filter medium called *body feed* is regularly metered into the influent water in proportion to the solids removed. Ultimately, a gradually increasing pressure drop through the filter system reaches a point where continued filtration is impractical. The forward filtration process is stopped, the filter medium and collected dirt are washed off the septum, a new precoat of filter medium is applied, and the filtration process continues. Diatomaceous earth filters are widely used in industrial filtration applications and in swimming pool filtration. They have also been used in municipal potable water treatment, primarily in direct, in-line filtration of high-quality surface water (turbidity 10 NTU or less and acceptable color), and in filtering iron and manganese from groundwater after appropriate pretreatment to precipitate these contaminants. Precoat filters are simple to operate and are effective in removing cysts, algae, and asbestos.

Membrane filtration represents an important set of processes for drinking water treatment. A membrane is a thin layer of natural or synthetic material that can separate substances when a driving force is applied across the membrane. Membranes used for water treatment are commonly made of a synthetic organic polymer. Membrane processes applicable to potable water treatment are reverse osmosis (RO), nanofiltration (NF), electrodialysis (ED), ultrafiltration (UF), and microfiltration (MF). Reverse osmosis is primarily used to remove salts from brackish water or seawater. Nanofiltration is used to soften freshwaters and remove disinfection byproduct (DBP) precursors. Electrodialysis is used to demineralize brackish water and seawater and to soften freshwater. Ultrafiltration and microfiltration are used to remove turbidity, pathogens, and other particulates from freshwater (Fig. 3).

Membranes are normally classified by solute exclusion size, which is sometimes referred to as *pore size*. Membrane filtration works by passing water at high pressure through a thin membrane in the form of hollow fiber or spiral-wound composite sheets. The contaminants are retained on the high-pressure side and frequently must be cleaned by reversing the flow and flushing the waste. Periodic chemical cleaning may be required to remove persistent contaminants. Membrane assemblies are contained in pressure vessels or cartridges. Low-pressure membranes, in the form of either ultrafiltration (UF) or microfiltration (MF), have become more economical in both capital and operating costs and have received increased attention in drinking water applications. Fouling of the membrane is the major problem preventing widespread use of this technology.

Figure 3. Microfiltration (MF) system (*Source*: U.S. Filter).

Cartridge filters traditionally have been applied to point-of-use systems and for pretreatment prior to membrane treatment systems. Composed of membrane, fabric, or string filter media, the filter material is supported by a filter element and housed in a pressure vessel. The application of cartridge filters using either a cleanable ceramic or disposable polypropylene cartridge seems to be a feasible method for removing modest levels of turbidity, algae, and microbiological contaminants. As water is filtered through a cartridge filter, the pressure drop increases, which necessitates terminating the filter run. When this process is done, the filter is not backwashed, but rather the cartridge is thrown away and replaced by a clean filter.

The desire to reduce costs or to treat some waters more effectively is driving the development of new technologies involving filtration. Several examples of such proprietary filters include low-head continuous backwash filters, two-stage filtration systems, bag filters, moving media filters, and flotation and filtration systems.

FILTRATION WITH GRANULAR MEDIA

Rasheed Ahmad
Khafra Engineering Consultants
Atlanta, Georgia

REGULATORY REQUIREMENTS FOR DRINKING WATER FILTRATION

The U.S. Environmental Protection Agency's (USEPA) Surface Water Treatment Rule (SWTR), promulgated on June 29, 1989 (Federal Register 40 CFR Parts 140 and 141), requires community water systems to disinfect all surface waters and requires filtration for most surface water sources. The 1998 Interim Enhanced Surface Water Treatment Rule (IESWTR) requires that surface water or groundwater systems under the influence of surface waters must produce a turbidity of less than or equal to 0.3 NTU in 95% of measurements taken each month. This rule was later extended to smaller systems as part of the Long Term Enhanced Surface Water Treatment Rule (LTESWTR).

FILTRATION HYDRAULICS

Pressure drop (i.e., head loss) occurs when water flows through a bed of a clean medium. The head loss caused by water flowing through a filter medium can be calculated from well-known equations such as the Kozeny equation. At the velocities commonly employed in granular water filters, flow is normally laminar. Initial head losses in clean filters commonly range from less than 1 to 2.5 ft, depending on the particle size distribution of the medium and the overflow rate (flow/filter surface area). The error in the head loss equation increases at flow rates used for filter backwashing where calculations show that the Reynolds number of particles lies in the transitional range. The most commonly used expression to calculate these head losses is the two-term Ergun equation, which applies to all regimes of flow. The flow through the underdrain system and effluent pipes is frequently turbulent. Negative head (less than atmospheric pressure) can occur in a gravity filter when the summation of head loss from the filter medium surface downward exceeds the pressure available.

PARTICLE REMOVAL MECHANISMS DURING FILTRATION

Filtration consists of three principal mechanisms: (1) transport, (2) attachment, and (3) detachment. *Transport* mechanisms move a particle into and through a filter pore so that it comes very close to the surface of the filter medium or existing deposits where *attachment* mechanisms retain the suspended particle in contact with the medium's surface or with previously deposited solids. *Detachment* mechanisms result from the hydrodynamic forces of the flow acting so that a certain portion of the previously attached particles, less strongly adhered to others, is detached from the filter medium or previous deposits and is carried further, deep into or through the filter. Important transport mechanisms include screening, interception, inertial forces, sedimentation, diffusion, and hydrodynamic forces. Physicochemical and molecular forces generally govern attachment of particles to media surfaces. Detachment is caused by the impact of arriving particles on unstable deposits and by hydraulic shear stresses without the influence of arriving particles.

TYPES OF FILTER MEDIA AND PROPERTIES

The most common types of filter media used in granular bed filters are silica sand, anthracite coal, and garnet. These media may be used alone or in dual- or triple-media combinations. Granular-activated carbon (GAC), another type of medium, has been used in granular beds for both filtration and adsorption to reduce taste and odor. A number of properties of a filter medium are important in filtration performance and in characterizing the medium. Important media properties include size, shape, density, and hardness. The porosity of the granular bed formed by the grains is also an important governing factor in filtration performance. Selection of filter media type and characteristics is based on a number of design decisions concerning source water quality, pretreatment, and desired filtered water quality. Filter media cleaning requirements and underdrain system options depend on the filter configuration and filter medium selected. Pilot plant studies using alternative filter media and filtration rates can determine the most effective and efficient medium for a particular water.

FILTER CLASSIFICATION

Several different types of filters are based on various classification schemes. Filters can be classified by type of media (single media, dual media), hydraulic arrangement (gravity or pressure), rate of filtration (rapid or slow), or depth of solids removal (deep or cake).

Slow Sand Filters

A slow sand filter generally consists of a watertight basin containing a layer of sand over a layer of gravel. It is operated at very low filtration rates without coagulation in pretreatment. Smaller grain size and lower filtration rate remove the solids almost entirely in a thin layer on top of the sand bed. This layer, composed of dirt and living and dead micro- and macro-organisms from the water, is called *schmutzdecke* or dirty skin. Most solid removals in a slow sand filter take place in the *schmutzdecke* layer. The dominant removal mechanisms are both physical and biological. A typical filter cycle may vary from 1 to 6 months (or longer) depending on the source water quality and the filtration rate. Filtration rates range from 0.016 to 0.16 gpm/sq ft (0.04 to 0.40 m/h). Effective sand sizes range from 0.15 to 0.40 mm, sand uniformity coefficients from 1.5 to 3.6, and initial bed depths from 1.5 to 5.0 ft. The sand is supported on graded gravel 6 to 36 inches deep. Slow sand filters are cleaned by scraping *schmutzdecke* and a small amount of sand depth. Usually scraping is done manually but, in some cases, mechanically. The scraped sand is cleaned hydraulically and stockpiled for later reuse.

Rapid Granular Bed Filters

Rapid granular bed filtration consists of passing of pretreated water through a granular bed at rates ranging from 2 to 10 gpm/sq ft (5 to 25 m/h). Flow is typically downward through the bed. During the filtration cycle, solids are removed from the water and accumulate within the voids and on the top surface of the filter medium. This accumulation results in clogging and a gradual increase in head loss. When head loss becomes excessive (generally 8–9 ft), filtrate quality begins to deteriorate, and/or filter cycle reaches a predetermined time limit (usually 3 or 4 days), then rapid filters need cleaning. Dirty/clogged filters may be cleaned by scouring the clogged portion or by reversing the flow through the bed. This application of expanding and washing out trapped particles is called backwashing. Backwashing by water fluidization is frequently assisted by a surface wash or an air scour. The most effective backwash is achieved by simultaneous air scour and subfluidization water backwash. Typical backwash rates range from 15 to 23 gpm/sq ft depending on media sizes. The bed expansion varies from 20% to 50%. The backwash usually lasts from 5 to 15 minutes. The air-scour rate varies from 2 to 4 cu ft/min/sq ft (0.6 to 1.2 cu meter/min/sq meter) (Fig. 1).

Filter Underdrain Systems

Underdrain systems are used to support the filter medium, collect filtered water (in downflow filters), and distribute backwash water (and air, if employed). Four basic types of underdrain systems are commonly used: pipe laterals, blocks, false bottom, and porous bottom. Pipe underdrain systems generally consist of a centrally located pipe to which are attached smaller, equally spaced laterals. The lateral pipes usually have one or two rows of less than one-inch diameter perforations on their bottom sides. The lateral pipes may be fitted with nozzles. The blocks are self-supporting type underdrains. The block underdrain consists of vitrified clay blocks with one-fourth inch diameter dispersion orifices across the top of each block. Support gravel is typically used with this type of underdrain. As a replacement for support gravel, an integral media support (IMS) cap made of plastic beads sintered together may be installed. False-bottom underdrains are made of precast or cast-in-place reinforced concrete supported on concrete sills. This underdrain system consists of uniformly spaced inverted pyramidal depressions. Unglazed porcelain spheres are placed in the depressions to distribute flow. Porous-bottom underdrains constructed of porous aluminum oxide plates have been used in both block and false-bottom configurations. These types of underdrains are constructed of plates mounted on

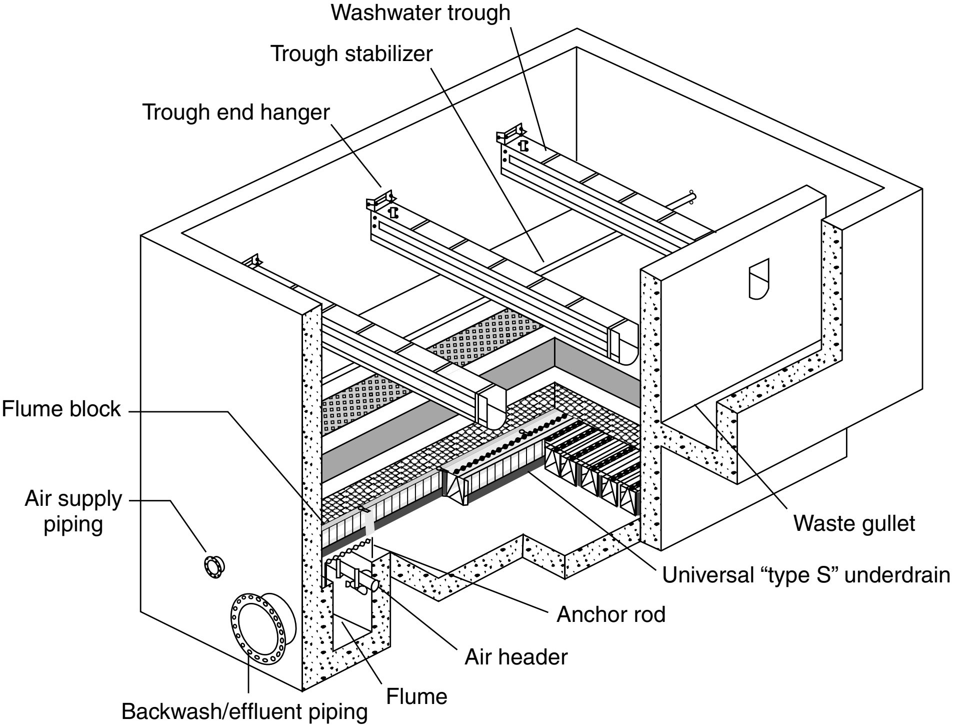

Figure 1. Rapid gravity filter box (*Source*: F.B. Leopold Co.).

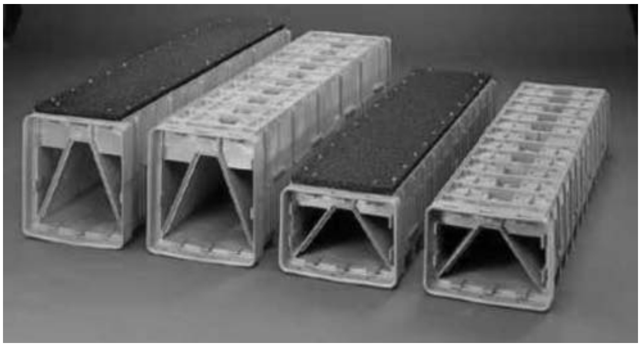

Figure 2. Filter underdrain (*Source*: F. B. Leopold Co.).

concrete or steel piers or on clay tile saddles to form blocks (Fig. 2).

FILTER OPERATION AND CONTROL

The efficiency of a filter is more sensitive to changes in the filtration rate rather than in the actual rate. Therefore, filtration process control is critical to successful operation. Two basic modes of gravity filter control are commonly found: constant rate and declining rate. Constant-rate mode operation of a filter can be achieved in three ways: (1) use of a flow control valve in the filtered water piping; (2) influent flow splitting where the water level over the filter is maintained at a constant level; and (3) influent flow splitting where the water level varies during the filter run. Declining-rate filters, which are most widely designed, are equipped with effluent weirs rather than with rate controllers. Flow is distributed on the basis of the relative conditions of the beds. Common filter problems include inadequate pretreatment or filter washing, gravel bed upset, air binding, restart after shut down, and filter media replacement. These problems lead to operational difficulties like dirty filter media, mudballs, and mineral deposits.

INNOVATIONS IN GRANULAR FILTRATION TECHNOLOGIES

In recent years, direct filtration has received considerable attention and application in treating of drinking water. Direct filtration is not preceded by sedimentation. It offers several advantages over conventional treatment of “good-quality” surface water. Because there is no sedimentation process and a lower coagulant dose, the capital and operating costs are lower compared with those of conventional treatment. Sludge volumes are lower, which results in lower chemical costs for sludge treatment and disposal. Because of increased interest in ozone application in potable water, biological filtration has received noticeable attention and application in recent years. Granular filters become biologically active when ozone is used as a preoxidant. Ozone reacts with organic compounds in water and forms several ozonation byproducts such as aldehydes, carboxylic acids, and keto acids, which are relatively easy to biodegrade. By operating filters in a biological mode, these ozonation byproducts can be effectively removed and in turn reduce the potential for bacterial regrowth in distribution systems and formation of chlorination byproducts. The desire to reduce costs or to treat some waters more effectively is driving the development of new technologies for filtration. Several examples of such proprietary filters include low-head continuous backwash filters, two-stage filtration systems, bag and cartridge filters, moving media filters, and flotation and filtration systems.

SLOW SAND FILTRATION AND THE IMPACT OF *SCHMUTZDECKE*

Aurora, Oregon

INTRODUCTION

The use of sand media to filter drinking water dates to the early nineteenth century; installations in Paisley and Greenock, Scotland are the earliest known successful uses of the technology. The European cholera epidemic of the early 1890s proved conclusively the benefits of filtered water supplies to the health of urban populations (1). Current construction of slow sand filter systems are based on the design refined by Simpson for the London-area Chelsea Water Company in 1829 (2).

Rural areas are the primary benefactors of slow sand technology due to the passive nature of the treatment process and the availability of large tracts of land necessary for filter construction. The lack of a need for constant pumping to maintain the filtration rate through the filter, the ease of operation, and the possibility of using nonmechanical maintenance procedures make slow sand filtration an appropriate technology for small and rural communities (3).

SLOW SAND FILTERS

The source water flows by gravity through the filter column. The supernatant level can be kept constant as the effluent flow rate declines with head loss in the sand media, or the influent may be adjusted for constant flow while the supernatant level rises. The water flows through a layer of sand (0.5–1.0 m), travels through a layer of larger gravel (0.3–0.6 m), and flows out from a perforated pipe or tile underdrain collection grid to the treated water storage and distribution system (Fig. 1).

During slow sand filtration, biomass forms at the sand/water interface (*schmutzdecke*) that provides an effective layer for removing pathogenic micro-organisms. The biomass is formed from populations of algae, diatoms, protozoa, rotifers, and bacteria (4). Also present are extracellular polysaccharides exuded by microbial populations inherent in surface water sources (5), and this polymer formation has been suggested as a source of destabilization for bacteria and clay entering the filter (6).

The importance of *schmutzdecke* on overall filter performance is illustrated by removing it when scraping

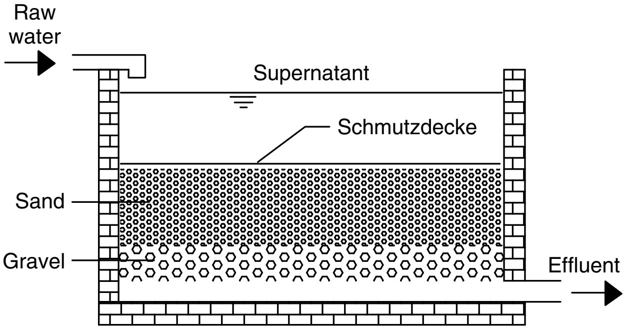

Figure 1. Schematic of a common slow sand filter design.

the top centimeter of media during maintenance; this immediately lessens the head loss caused by biomass growth and returns the flow rate to design levels ($0.1-0.2\ \text{m}^3/\text{m}^2/\text{h}$). After removing the *schmutzdecke*, a ripening period is required to allow new biomass to mature. Effluent is wasted until turbidity and biological criteria are within established limits because influent contaminant removal is diminished during the filter ripening period. Efficient filter ripening can be altered by factors such as ambient and source water temperature, aquatic bacterial populations, and available source water nutrient supply (4).

The combination of biological and physical removal mechanisms in slow sand filters, uninterrupted use of slow sand filters during the 2–18-month filtration cycle, proper filter design, and the diligence of operating personnel produces drinking water of excellent quality (Table 1) from raw water sources with low turbidity (7). Source water quality is an important design consideration when communities consider slow sand filtration as a treatment method. The recommended influent turbidity limit for optimum slow sand filter operation is less than 10 nephelometric turbidity units (NTU), and many designers consider source water that regularly exceeds this limit unacceptable for slow sand filter treatment (8). Raw water sources that occasionally exceed turbidity limits are also regarded with apprehension unless the slow sand filter is augmented by a pretreatment method that reduces influent turbidity. Passive pretreatment systems (multistage filtration) that are effective and inexpensive to operate have been developed to mitigate many slow sand filtration deficiencies.

Table 1. Common Treatment Performance of Slow Sand Filters

Parameter	Removal
Color	30–100%
Turbidity	>90%
Fecal coliform	1–3 log units
Total organic carbon	15–25%
Trihalomethane precursors	<25%
Enteric viruses	2–4 log units
Giardia cysts	2–4 log units
Organic matter	60–75% as COD
Heavy metals	30–95%

Research continues toward better understanding of the biological and physical treatment mechanisms of slow sand filtration (9). Combining basic research on solids penetration (10), pathogen removal (11), and computer modeling (12,13) with operational modifications of sand media (14), filtration rates (15), maintenance and cleaning (16), and corrosion control amendments (17) have led to a substantial increase in the understanding and application of slow sand filtration.

SUMMARY

Slow sand filtration is one of the oldest drinking water treatment techniques and is still a viable method of biological water treatment best suited for raw water sources low in turbidity and suspended solids.

MULTISTAGE DRINKING WATER FILTRATION

Stephen J. Rooklidge
Aurora, Oregon

INTRODUCTION

Multistage drinking water filtration is a combination of roughing filter and slow sand filter unit processes that broadens the use of these passive treatment methods to include source water whose turbidity is higher than that normally suitable for biological filtration. Slow sand filtration is one of the oldest surface water treatment techniques, but it is easily compromised by source water with high turbidity caused by erosional or meteorologic events in the upstream watershed. By providing roughing filter pretreatment, suspended solids are decreased, and the biological integrity of the slow sand filter is maintained with a concomitant extension of the filtration period.

ROUGHING FILTER PRETREATMENT

Roughing filters are generally designed similarly to slow sand filters, except for larger media grain size and faster filtration rates. Roughing filters are usually composed of individual flow-through filter compartments that contain decreasing sizes of gravel in the direction of flow. The crushed gravel media in the roughing filter provide a large surface area for the flowing water to contact, allowing flocculation from particle collision in the circuitous route through the rock and sedimentation within the interstitial media voids. The addition of roughing filter pretreatment maintains the simplicity of slow sand filtration and achieves suspended solids and turbidity removal acceptable for drinking water.

DYNAMIC ROUGHING FILTERS

Passive filter systems in common use near rivers or canals include dynamic roughing filtration (Fig. 1). This design allows gravity flow from source water through a bed of crushed gravel (6 mm average diameter), and the overflow is wasted back to the river channel. A drawback of the design is the need to remove and clean the gravel media when the filter becomes clogged during high turbidity, and this limits dynamic filtration to raw water sources that experience turbidity peaks of less than a few hours in duration. The substantial filtration rate of 5 m/h in these filters is not designed to alter water quality of low turbidity, but instead it is intended to protect downstream filter systems from intermittent peaks of high solids concentrations, effectively shutting off the water supply as the filter medium clogs. These systems require immediate attention by operating personnel or the flow of water to the final filters will cease, and the resulting loss of supernatant in a slow sand filter may dry out the *schmutzdecke* and drastically reduce its filtration cycle.

VERTICAL ROUGHING FILTERS

Vertical-flow filtration can be used downstream of a dynamic filter to further increase solids removal and protect the slow sand filter from clogging. Modern designs use a minimum of three filter compartments; each subsequent compartment contains smaller sizes of gravel. Media size range from average diameters of 20 mm in the first compartment to 4 mm in the last, and they can operate in either upflow or downflow configurations (Fig. 2). The gravel media are submerged under a supernatant water level, and filtration rates vary from 0.3 to 1.0 m/h. Filter velocities between 0.1 and 0.8 m/h were tested on natural river water in Colombia with an average of 50 nephelometric turbidity units (NTU), and removal efficiencies were between 55% and 45%. Challenge experiments were conducted with turbidities greater than 200 NTU, and removal efficiencies ranged from 70% to 90% (1).

Upflow roughing filters are also equipped with decreasing sizes of gravel in the direction of water flow and have drainage chambers in each filter compartment to facilitate regular cleaning. Filter freeboard must be sufficient to produce gravity hydraulic flushing capable of flow velocities greater than 90 m/h (2). Galvis et al. (3) reported 97% suspended solids removal and 80% turbidity removal for raw water with average suspended solids of 100 mg/L and turbidity of 95 NTU.

HORIZONTAL ROUGHING FILTERS

Horizontal-flow roughing filtration has been a particularly successful pretreatment method for suspended solids removal in rural areas of developing nations that have limited availability of skilled operators (4). Raw water enters the filter by an intake weir and flows horizontally through decreasing sizes of media contained in separate

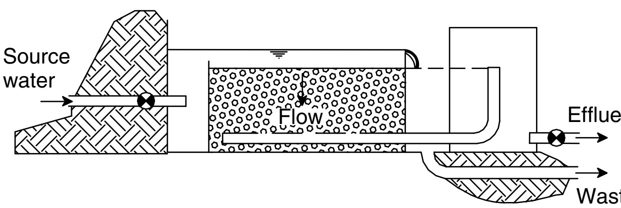

Figure 1. Example of a dynamic roughing filter design.

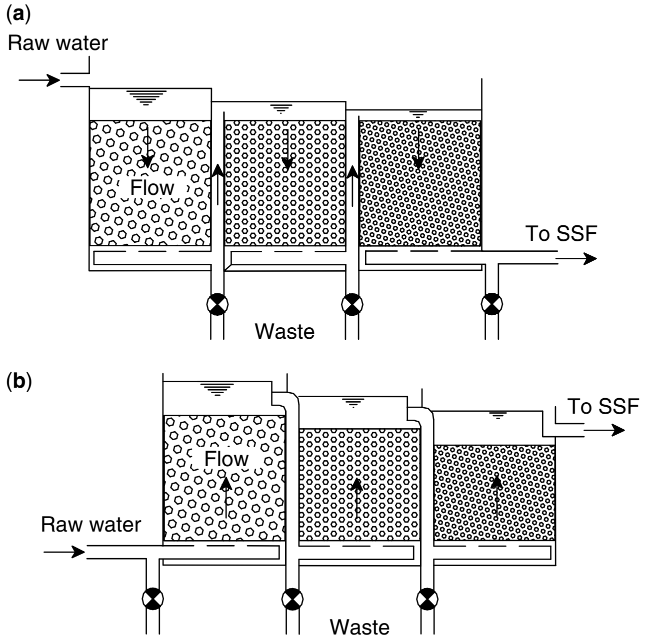

Figure 2. Schematic of downflow (**a**) and upflow (**b**) vertical roughing filters.

compartments (Fig. 3). Flow velocities range from 0.3 to 1.5 m/h, and the media size range and removal efficiencies are similar to vertical-flow filtration. Overall filter length ranges from 5 to 7 m with a filter compartment length ratio of 3:2:1. Typical media depth designs are less than 1 m to facilitate ease of media replacement, and drainage chambers are provided with the same freeboard and flushing velocities as vertical filters. The solids storage capacity for horizontal roughing filters is very large, and adequate filter service life can be years before clogging necessitates media removal (5).

DIRECT ROUGHING FILTRATION

The addition of coagulants to roughing filter influent is regarded as direct roughing filtration. Horizontal roughing filter coagulant injection of 1 mg (Al^{3+})/L as alum decreased raw water influent from 200 NTU to less than 3 NTU at filtration rates of 5–7 m/h (6). Coagulants cause roughing filters to clog much faster than normal (3–5 days), and cleaning process modifications must be designed before this type of treatment can be used reliably in the field. The addition of calcite limestone media in the first compartment of a horizontal roughing filter also aids coagulation, while maintaining the passive nature of the filter system. Source water with 150 NTU clay turbidity was reduced to less than 1 NTU by a limestone-amended multistage filter, and the effluent corrosion control characteristics of neutral pH source water were also enhanced by limestone roughing filter amendments (7).

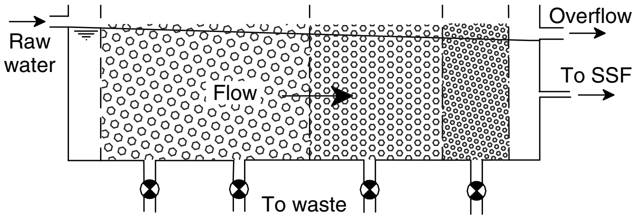

Figure 3. Horizontal flow roughing filter.

SUMMARY

Slow sand filtration is still a viable method of water treatment most suitable for raw water sources low in turbidity and suspended solids. Roughing filter pretreatment prior to slow sand filtration (multistage filtration) has been shown to be an efficient and effective drinking water treatment technique for source water with high turbidity, organic matter, and suspended solids.

MULTISTAGE FILTRATION: AN INNOVATIVE WATER TREATMENT TECHNOLOGY

Dick de Jong
Jo Smet
IRC International Water and
Sanitation Centre
Delft, The Netherlands

The technology of multiple stage filtration (MSF) presented here is a combination of coarse gravel prefiltration and slow sand filtration (SSF). This combination allows treating of surface water that has considerable levels of contamination, well above the levels that can be treated by SSF alone. To improve the performance of MSF, other treatment processes such as simple sedimentation, sand traps, and screens can precede MSF technology. Wherever possible, terminal disinfection needs to be included as a safety barrier after MSF.

MSF retains the advantages of SSF in that it is a robust and reliable treatment method that can be maintained by operators who have low levels of formal education. It is much better suited than conventional chemical water treatment to conditions in rural communities and small and medium size municipalities in the South as well as in more remote areas in the North. The article provides a summary description of the components of MSF systems and the findings of recent research. It gives an overview of cost implications and ends with a selection guide.

SELECTION OF MULTISTAGE FILTRATION CRITERIA

Factors for selecting the *best* surface water treatment include the quality of the water sources, the availability of resources (construction material, sand, gravel, chemicals, financial resources, and land), the socioeconomic and cultural conditions of the community, and the level of institutional support. Careful selection of the water treatment technology is crucial to ensuring sustained good quality water at an acceptable cost to users.

MSF alternatives include the dynamic roughing filtration (DyRF) step and SSF alone or in combination with other pretreatment steps. The most common are up-flow roughing filters in layers (URFL) or in series of two or three units (URFS2, URFS3) (see Fig. 1), down-flow roughing filters (DRF), or horizontal-flow roughing filters (HRF). A comparative study showed that URF is technically and economically preferable to DRF and HRF, although these also present good removal efficiencies (1).

The MSF alternatives are similar in their environmental impact and complexity of operation and maintenance. This implies that one can choose among them using three main selection criteria: the sanitary risk of the water source, the treatment efficiency, and the overall cost. Conventional treatment options such as rapid sand filtration of chemically coagulated water often face problems in managing the systems and availability of chemical products. MSF technology, on the other hand, is well received by communities because it is much simpler to administer, operate, and maintain compared to other treatment systems.

Slow Sand Filtration, the Heart of MSF

Slow sand filtration is the heart of MSF technology. It has been recognized as a simple, reliable, and efficient treatment technology and the most effective as a single unit treatment process. An SSF produces an effluent low in turbidity, free of impurities, and even more important, virtually free of bacteria, enteroviruses, and protozoa. Table 1 presents an overview of the removal efficiencies that may be obtained from SSF technology for different parameters of sanitary importance. These efficiencies have been reported for SSF units operating in temperature zones above 5 °C, at flow velocities between 0.04 and 0.20 m^3/m^2h, filter medium depths above 0.5 m, and effective sand grain sizes between 0.15 and 0.30 mm.

The use of SSF technology often has been determined by the availability of good raw quality water resources, as in different areas of Europe and the United State. However, SSF alone is not a feasible solution for more contaminated surface water sources. It is not a panacea for all water quality problems under all circumstances. In general, two situations can be distinguished under which SSF presents limitations.

- Levels of contamination in the raw water that supersede the treatment capacity to comply with the existing norms or that may result in short filter runs. This relates particularly to high quantities of suspended solids, high coliform counts, and large quantities of algae.
- Conditions that inhibit or reduce the efficiency of the treatment process such as low temperature, low nutrient content, and low oxygen level.

Coarse Gravel Filtration

For more contaminated surface water (i.e., turbidity levels higher then 20NTU), it is necessary to apply good pretreatment modalities to condition the water before it enters the SSF units. Commonly used pretreatment systems include simple sedimentation, microscreening, roughing filtration in gravel filters, and, more recently in Europe, also ozone and activated carbon treatment to reduce the levels of organic material.

In the last few decades, the prospect of using SSF technology in rural communities and small/medium size municipalities has increased because of good research

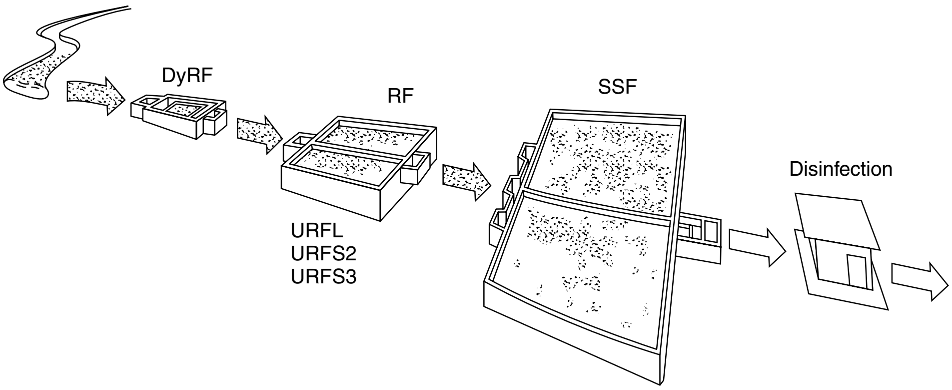

Figure 1. Components of a multi-stage filtration system.

Table 1. Typical Removal Efficiencies of Conventional SSF Units[a]

Water Quality Parameter	Effluent or Removal Efficiency	Comments
Turbidity	<1 NTU	The level of turbidity and the nature and distribution of particles affect treatment capacity and efficiency
Enterobacteria	90 to 99.9%	Affected by temperature, filtration rate, size, uniformity and depth of sand bed, cleaning operation
Enteroviruses and Giardia/Amoeba cysts	99 to 99.99%	High removal efficiencies, even directly after cleaning (removal of the biomembrane (schmutzdecke))
Cercariae	100%	In good operation and maintenance conditions, virtually complete removal is obtained
True color	25 to 30%	Color associated with organic material and humic acids
TOC	<15–25%	TOC, total organic carbon
AOC	<50%	AOC, biodegradable organic carbon
THM precursors	<25%	Precursors of trihalomethanes
Iron, manganese	30 to 90%	Fe^{2+} levels >1 mg/L reduce filter runs

[a] Reference 1.

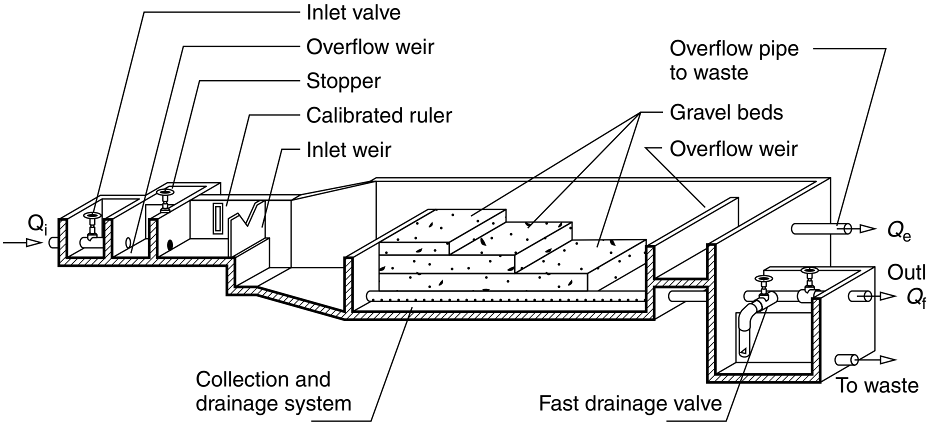

Figure 2. Dynamic roughing filter.

results in roughing filtration (coarse gravel filtration). An important breakthrough in research on pretreatment technology has come from comparative studies of different roughing filtration systems in Colombia (1). Both field testing and full-scale plants were included. The research concluded that for the conditions in Colombia, the combination of DyRF and URF proved to be the best pretreatment option prior to SSF.

PUTTING MSF IN PERSPECTIVE

MSF has advantages similar to SSF in ease of operation and maintenance and production of good water quality. Many rural communities and small/medium size municipalities face problems with conventional surface water treatment using chemicals. MSF technology is then a sustainable and effective treatment alternative (Table 2).

DESCRIPTION OF THE COMPONENTS OF ROUGHING FILTERS

MSF may consist of two or three main filtration stages, depending on the level of contamination of the source. The option with three components, DyRF, URF, and SSF, is indicated in (Fig. 1). In principle, DyRF focuses on reducing suspended solids, particularly removing larger particles and on protecting the subsequent units from high loads of suspended solids. The removal of smaller particles and microorganisms takes place primarily in the next treatment steps. URF can be avoided if good quality surface water is available.

Dynamic Roughing Filters (DyRF) contain a shallow layer of fine gravel in their upper part on top of a layer of coarse gravel that covers the underdrains (total height of the filter bed is about 0.6 m) (see Fig. 2). Water enters the unit and passes through a bed of fine gravel on top of coarse gravel to the drainage system at a filtration rate of some 2 to 3 m^3/m^2h. Moderate levels of suspended solids in the source gradually clog the DyRF. For high suspended solids, clogging happens very quickly. When the gravel bed is completely blocked, raw water will flow over the clogged surface area to waste. In this way, the DyRF acts as a safety valve, and subsequent treatment steps are protected from receiving high suspended solid loads.

Up-flow roughing filters consist of one or more compartments filled with gravel (diameter from 3–24 mm) that reduces in size in the direction of flow. Filtration rates usually range between 0.3 and 0.6 m^3/m^2h (see Fig. 3). A drainage system placed on the bottom of the structure distributes the flow during the filtration period or drains the gravel layers during periods of cleaning and discharges

Table 2. Summary of Considerations for MSF Treatment[a]

Issue	Comment Concerning MSF Treatment
Quality of treated water	It is a good alternative for improving the physical, chemical, and bacteriological quality of the water. In many areas and particularly those that have a less developed infrastructure, MSF may be the only feasible treatment option.
Ease of construction	The relatively simple design facilitates the use of local materials and local skilled manpower. There is no need for special equipment.
Construction cost	Construction in local materials and with local labor reduces the cost. Usually, there is no need for imported materials.
Ease of operation and maintenance	After a short period of training, local operators who have a minimum of formal education can operate and maintain the system.
Cost of operation and maintenance	The cost of operation and maintenance and the requirements in electrical energy are much less than for other systems. There is no need for chemical coagulation products.
Reliability	A low risk of mechanical problems or problems related to changes in raw water quality; in the majority of cases, these can be accommodated without interrupting service.
Cleaning	The cleaning process is simple although laborious but almost always involves low cost, as in most 'potential' countries, labor is relatively cheap.
Requirements of surface area	A conventional chemical and RSF water treatment may require surface areas comparable to an MSF treatment plant.
MSF, the panacea?	There are levels of contamination that interfere with the treatment or that surpass the capacity of MSF.

Table 3. Performance of MSF Systems in Colombia

Performance Indicator	Raw Water Quality	Efficiency Range	Remarks
Turbidity (NTU)	2–15 NTU and peaks over 180 NTU	83–97% <1 NTU in 65–98% of all samples <5 NTU in 98% of all samples	Lower figure was measured in older MSF system.
Suspended solids, mg/L	2–23 and peaks over 390	0.2–2.8 mg/L	
Fecal coliform density, CFU/100 mL	300–60,000	<25 CFU/100 mL in 97% of all samples	
True color, TCU	5–24 and peaks over 180	<15 TCU in 98% of all samples	
Filter run periods		46–178 days	A short filter run due to algae

the water through the drainage system. The impurities are retained at the bottom, and therefore, it is easy to drain. Two alternatives can be identified: up-flow roughing filters in layers (URFL) when the gravel layers of different size are installed in the same unit (total filter bed height 1.2 m) and up-flow roughing filters in series (URFS) when the gravel layers are installed in two or three different units (each filter bed is about 1.2 m high). (See Table 4.)

Downflow roughing filters in series (DRFS) consist of three compartments of gravel reducing in size (2). The performance of the DRFS is similar to that of the URFS in removal efficiency. Maintenance and cleaning are more difficult than for the URF because the sludge tends to accumulate on the surface and in the deeper layers of the bed.

Horizontal roughing filters (HRF) consist of three compartments separated by perforated walls (3). Their performance is similar to that of the URF, but construction costs are higher (1).

PERFORMANCE OF MSF SYSTEMS

MSF performance data (Table 3) are based on seven community-managed MSF systems in Colombia that were monitored for a 7 years. The systems receive water from catchment areas of low or moderate levels of human intervention.

Based on these effluent water qualities, constant dose disinfection with chlorine, as suggested by WHO (4), functions effectively as a final safety barrier.

The findings show that MSF treatment can adapt itself to the type of raw water and the concentration of contamination. The systems have higher removal efficiencies for water that is higher in contamination. This implies that the barriers become more effective if the water to be treated has a higher risk and still can produce a water at a low sanitary risk level. The results on both pilot and full scale clearly indicate the great potential of MSF technology in reducing the physicochemical and bacteriological risk from surface water sources. Nevertheless, it also shows that the technology is not a panacea and has its limitations. Particularly, for high levels of contamination, MSF systems do not always produce water that meets the required quality, and then extra pretreatment steps may be needed.

MSF systems comply with the multibarrier concept: in general, all treatment steps (barriers) together achieve a removal efficiency that is sufficient to ensure low dose disinfection as a final and efficient safety barrier.

The technology is a reliable alternative for treating water of a low or moderate contamination level such

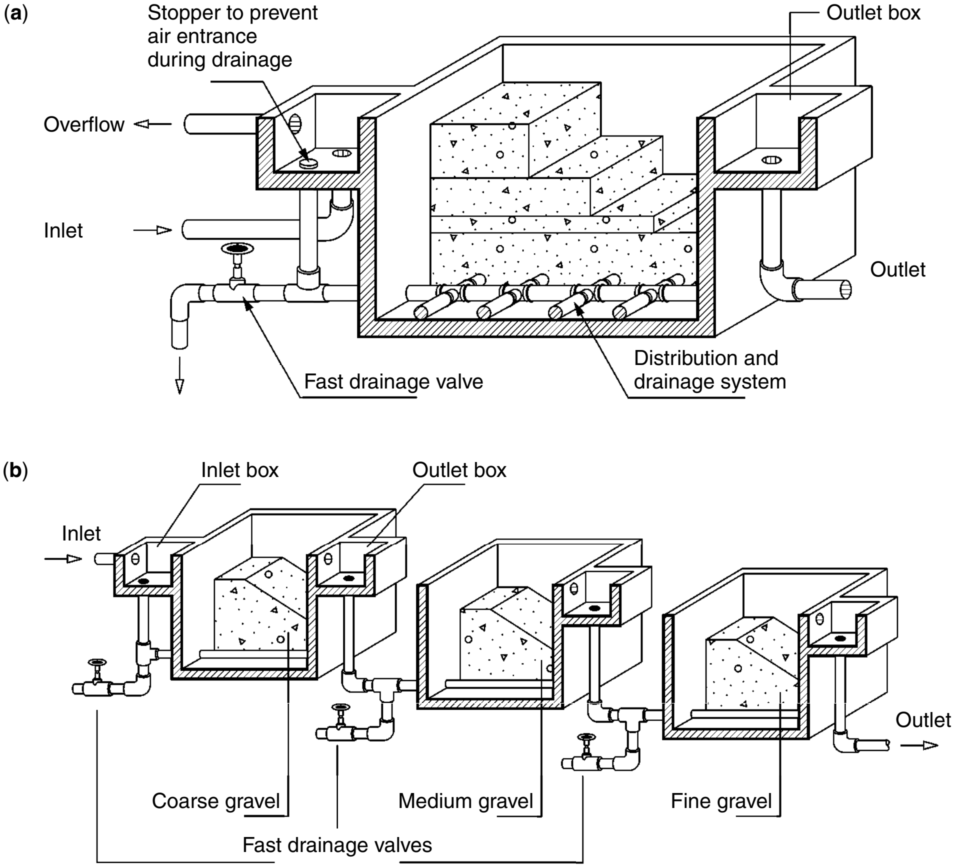

Figure 3. (**a**) Schematic design of an up-flow roughing filter in layers (URFL). (**b**) Schematic design of an up-flow filter in series (URFS).

Table 4. Design Criteria for the MSF Type Designs Used to Establish Construction Volumes for the Cost Model in (Fig. 3)

MSF Component Design Criteria	DyRF	URFL	URFS2	URFS3	SSF
Filtration rate (m^3/m^2h)	2	0.6	0.6	0.6	0.15
Depth of filter medium (m)	0.60	1.2	1.2[a]	1.2[a]	1.05
Filter box height (m)	0.80	1.4	1.4	1.4	2.15
Number of units in parallel	2	2–4	2–4	2–6	4–8
Number of units in series	1	1	2	3	1

[a] Per filter unit.

as received by full-scale plants. However, river water of higher contamination levels can present difficulties. For those conditions, it is essential to study the performance of the MSF system in a pilot plant, before deciding to construct a full-scale plant.

COST ISSUES

Construction costs vary by country. The economy of scale is limited, thus favoring relatively short design periods of some 10 years. Operating and maintenance costs have been estimated on the basis of experience with MSF systems in Colombia. In these plants that are operated under gravity supply, it was found that staff makes up 85% of the cost. Thus, the time involved in the different operating and maintenance tasks are a good basis for assessing the overall cost. The labor requirements for daily and periodic operation and maintenance of MSF systems range between 0.2 and 1.5 equivalent person days per day, depending on the size and composition of the systems. In addition 0.3 equivalent person days are needed for administration, including supervision of the plant operator, planning, customer relations, purchasing, payments, and meetings with sector organizations and local government.

For example, for a system of 10 L/s in Colombia that includes DyRF + URFS2 + SSF, the construction cost would amount to US$ 125,000. The total time required for operation and maintenance of this plant amounts to 1.6 PE (person equivalents per year), 1.0 PE for daily and periodic activities, 0.3 PE for exceptional activities, and 0.3 PE for administration. For 1996, at an average salary of US$150/ month and taking into account the 85% factor, operating and maintenance cost amounted to $(1.6\times150)/0.85 =$ US$ 276/ month.

TECHNOLOGY SELECTION GUIDE

On the basis of the previous considerations, the minimum treatment for surface water of *low sanitary risk*—but requiring more than just disinfection—is a combination of DyRF and SSF. Surface water of a *moderate risk level* requires a URFL or one of the URFS systems in combination with DyRF and SSF. For surface water sources of *high risk levels*, the options of URFS in two or three steps need to be considered in combination with DyRF and SSF.

The findings and design considerations are mainly based on research from Colombia. The biological treatment process involved in MSF technology is important but not easy to predict. In low temperature zones, the efficiencies are lower than indicated here. So, designing MSF under different climatic conditions needs a critical attitude toward design, function and performance. In regions with little experience with MSF technology and/or important uncertainties about the quality of the water sources, it is important to adopt conservative design parameters in the first MSF plants and preferably start with pilot plant experiments to review the functioning of MSF systems under local conditions. A joint learning program, as described by Visscher (5) is recommended. This type of program brings together communities, sector professionals, sector authorities, and other important institutions in the sector, including local universities and research institutions. Together, they review the situation and ensure that the technology can find roots in the new situation.

PARTICULATE MATTER REMOVAL BY FILTRATION AND SEDIMENTATION

RASHEED AHMAD
Khafra Engineering
Consultants
Atlanta, Georgia

The settling efficiency for an ideal condition is independent of the depth and dependent on the tank plan or surface area. In reality, depth is important because it can affect flow stability if it is large and scouring if it is small. The basin depth affects flow-through velocity and allows greater opportunity for flocculant particle contact. Conventional settling facilities at larger water treatment plants are often long, narrow (4 or 5 to 1 length to width ratio) rectangular basins that have theoretical detention times in the range of 1.5 to 3 hours at the design flow rate. Most regulatory agencies specify a minimum detention time and a maximum surface overflow rate. Typical sedimentation surface loading rates for long, rectangular tanks and circular tanks using alum coagulation vary from 500 to 1200 gallon per day per square feet (20 to 48 cubic meters per day per square meter). Regulatory agencies sometimes stipulate that their weir rates should not exceed around 20,000 gallons per day per linear foot (250 cubic meters per day per meter) of weir. Flow-through velocities of 2 to 4 ft/min (0.6 to 1.2 m/min) are usually acceptable for basin depths of 7 to 14 ft (2.1 to 4.3 m).

Particulate matter will settle out of a suspension in one of four different ways, depending on the concentration of the suspension and the flocculating properties of the particles. The various settling regimes of particles are commonly referred to as types 1 to 4. In type 1 settling, also called discrete particle settling, particles have little tendency to flocculate upon contact with each other in a dilute suspension. If the particles flocculate, the settling regime in a dilute suspension is identified as type 2 or flocculant settling. In hindered, zone, or type 3 settling, the particle concentration causes interparticle effects, which might include flocculation, to the extent that the rate of settling is a function of solids concentration. Compression or type 4 settling develops under the layers of zone settling. The rate of compression depends on time and the force caused by the weight of solids above. In sedimentation, particulate matter removal is largely governed by types 1 and 2 settling. However, types 3 and 4 regimes are dominant in clarification and thickening processes.

High-rate settlers such as tube or plate settlers are often added to settling basins to improve their efficiency, especially if flows are to be increased beyond original design conditions. The shallow settling depths and the large surface area provided by tube or plate settlers permit effective sedimentation at detention times of several minutes versus several hours in conventional sedimentation basins. The use of tube or plate settlers in new plant construction minimizes settling basin costs by minimizing the basin size necessary to attain a desired level of treatment. They are generally designed to accept overflow rates ranging from 1400 to 4000 gallons per day per sq ft (55 to 160 cubic meters per day per square meter).

In a conventional water treatment process train, filtration follows sedimentation. Filtration is one of the unit processes used in the production of potable water. Particulate matter that is removed by this process includes micro-organisms (bacteria, viruses, and protozoan cysts), clay and silt particles, colloidal and precipitated humic substances and other organic particulates from natural decay of vegetation, precipitates of aluminum or iron coagulation processes, calcium carbonate and magnesium hydroxide precipitates from lime softening, and iron and manganese precipitates.

A number of different types of filters are used in water filtration, and they are described by various classification schemes. Most common filtration technologies used in water supply systems are rapid sand filtration, slow sand filtration, package plants, diatomaceous earth filtration (precoat filtration), membrane filters, and cartridge filters. High-rate granular filters or rapid sand filters are most widely used in conventional treatment and direct filtration. Slow sand filters have been used in water treatment for several decades, but their use in recent decades has declined because of the inherent low filtration rate, large area requirement, and difficulties in filter cleaning. Membrane and cartridge filtration systems are considered emerging technologies. In recent years, some water treatment plants have replaced granular filters with membrane filters. Package plants, slow sand, diatomaceous earth, membrane, and cartridge filters are considered best suited for small water systems [less than 0.44 cubic meter per s (10 MGD)].

Granular medium filtration is a water treatment process that uses a porous medium through which water passes to remove particulates or suspended solids. For granular medium filtration to be effective, pretreatment of source water is required. Chemical destabilization is an essential prerequisite for effective filtration. Chemicals used for particle destabilization are limited primarily to metal salts or cationic polymers as primary coagulants. Pretreatment may also include aeration or introducing an oxidant if water treatment aims to remove iron or manganese. Sometimes a filter aid polymer is added in the influent to the filter to improve particle capture efficiency.

The U.S. Environmental Protection Agency's (USEPA) Surface Water Treatment Rule (SWTR), promulgated on June 29, 1989 (Federal Register 40 CFR Parts 140 and 141), requires community water systems to disinfect all surface waters and requires filtration for most surface water sources. The 1998 Interim Enhanced Surface Water Treatment Rule (IESWTR) requires that surface water or groundwater systems under the influence of surface waters must produce a turbidity less than or equal to 0.3 NTU in 95% of the measurements taken each month. This rule was later extended to smaller systems as part of the Long Term Enhanced Surface Water Treatment Rule (LTESWTR).

Filtration by granular media consists of three principal mechanisms: (1) transport, (2) attachment, and (3) detachment. *Transport* mechanisms move a particle into and through a filter pore so that it comes very close to the surface of the filter medium or existing deposits where *attachment* mechanisms retain the suspended particle in contact with the medium's surface or with previously deposited solids. *Detachment* mechanisms result from the hydrodynamic forces of flow acting so that a certain portion of the previously attached particles, less strongly adhered to others, is detached from the filter medium or previous deposits and is carried further, deep into or through the filter. Important transport mechanisms include screening, interception, inertial forces, sedimentation, diffusion, and hydrodynamic forces. Attachment of particles to the media surfaces is generally governed by physicochemical and molecular forces. Detachment is caused by the impact of arriving particles on unstable deposits and by hydraulic shear stresses without the influence of arriving particles.

The most common types of filter media used in granular bed filters are silica sand, anthracite coal, and garnet. These may be used alone or in dual- or triple-media combinations. Granular-activated carbon (GAC), another type of medium, has been used to reduce taste and odor in granular beds that serve for both filtration and adsorption. A number of properties of a filter medium affect filtration performance and are important in characterizing the medium. Important media properties include size, shape, density, and hardness. The porosity of the granular bed formed by the grains is also an important governing factor in filtration performance. Selection of filter media type and characteristics is based on a number of design decisions concerning source water quality, pretreatment, and desired filtered water quality. Filter media cleaning requirements and underdrain system options depend on filter configuration and filter media selected. Pilot plant studies using alternative filter media and filtration rates can determine the most effective and efficient medium for a particular water.

A slow sand filter generally consists of a watertight basin containing a layer of sand over a layer of gravel. It is operated at very low filtration rates without coagulation in pretreatment. Smaller grain size and lower filtration rate result in removing the solids almost entirely in a thin layer on the top of the sand bed. This layer, composed of dirt and living and dead micro- and macro-organisms from the water, is called *schmutzdecke* or dirty skin. Most of the solid removal in a slow sand filter takes place in the *schmutzdecke* layer. The dominant removal mechanisms are both physical and biological. A typical filter cycle length may vary from 1 to 6 months (or longer) depending on source water quality and filtration rate. Filtration rates range from 0.016 to 0.16 gpm/sq ft (0.04 to 0.40 m/h). Effective sand sizes range from 0.15 to 0.40 mm, sand uniformity coefficients from 1.5 to 3.6, and initial bed depths from 1.5 to 5.0 ft. The sand is supported on graded gravel 6 to 36 inches deep. Slow sand filters are cleaned by scraping the *schmutzdecke* and a small amount of sand depth. Usually, scraping is done manually but, in some cases, mechanically. The scraped sand is cleaned hydraulically and stockpiled for later reuse. Slow sand filters are very effective in removing turbidity, viruses, and bacteria.

Rapid granular bed filtration consists of passing pretreated water through a granular bed at rates ranging from 2 to 10 gpm/sq ft (5 to 25 m/h). Flow is typically downward through the bed. During the filtration cycle, solids are removed from the water and accumulate within the voids and on the top surface of the filter medium. This accumulation results in clogging and a gradual increase in head loss. When head loss becomes excessive (generally 8–9 ft), filtrate quality begins to deteriorate, and/or the filter cycle reaches a predetermined time limit (usually 3 or 4 days), then rapid filters need cleaning. Dirty/clogged filters may be cleared by scouring the clogged portion or by reversing the flow through the bed. This application of expanding and washing out trapped particles is called backwashing. Backwashing by water fluidization is frequently assisted by a surface wash or an air scour. The most effective backwash is achieved by simultaneous air scour and subfluidization water backwash. Typical backwash rates range from 15 to 23 gpm/sq ft depending on media sizes. The bed expansion varies from 20% to 50%. The backwash usually lasts from 5 to 15 minutes. The air-scour rate varies from 2 to 4 cu ft/min/sq ft (0.6 to 1.2 cu meter/min/sq meter). Underdrain systems are used to support the filter medium, collect filtered water (in downflow filters), and distribute backwash water (and air, if employed). The efficiency of a filter is more sensitive to changes in the filtration rate rather than in the actual rate. Therefore, filtration process control is critical to successful operation. Two basic modes of gravity filter control are commonly found, constant rate and declining rate. Common filter problems include inadequate pretreatment or filter washing, gravel bed upset, air binding, restart after shut down, and filter media replacement. These problems lead to operational difficulties like dirty filter media, mud balls, and mineral deposits. Rapid gravity filters that use coagulation and sedimentation normally have 96.9% to 99.9% bacterial and 99.0% virus removal efficiencies. It is not uncommon for a well-operated filter to produce an effluent turbidity of 0.1 NTU (nephelometric turbidity units).

Precoat filters use a thin layer of very fine material such as diatomaceous earth as a filter medium. In precoat filtration, water to be filtered is passed through a uniform layer of the filter medium that has been deposited (precoated) on a *septum*, a permeable material that supports the filter medium. The filter operation is composed of three cycles: (1) precoating, (2) filtering, and (3) cleaning. When the pressure drop through the filter system reaches a point where continued filtration is impractical, the filtration process is stopped. The filter medium and collected dirt are washed off the septum, a new precoat of filter medium is applied, and filtration continues. Diatomaceous filters are effective in removing cysts, algae, and asbestos. These filters are especially suited for low influent turbidity water and are very effective against *Giardia* cysts.

FILTRATION WATER TREATMENT

Rasheed Ahmad
Khafra Engineering
Consultants
Atlanta, Georgia

All filtration technologies have the same basic objectives: to produce a filtrate that is clear and contains very few particles and to provide a medium-cleaning process so that operation may be continued with the same medium or by replacing the old medium. Particulates that are removed by water filtration process include micro-organisms (bacteria, viruses, and protozoan cysts), clay and silt particles, colloidal and precipitated humic substances and other organic particulates from natural decay of vegetation, precipitates of an aluminum or iron coagulation process, calcium carbonate and magnesium hydroxide precipitates from lime softening, and iron and manganese precipitates.

Rapid gravity filtration consists of passing pretreated water through a granular bed at rates ranging from 2 to 10 gpm/sq ft (5 to 25 m/h) (Fig. 1). Flow is typically downward through the bed. During the filtration cycle, solids are removed from the water and accumulate within the voids and on the top surface of the filter medium. This accumulation results in clogging and a gradual increase in head loss. When head loss becomes excessive (generally 8–9 ft), filtrate quality begins to deteriorate,

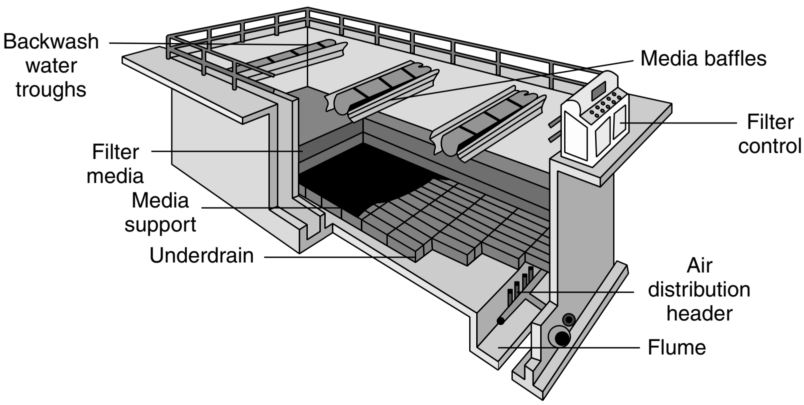

Figure 1. Rapid gravity filter (*Source*: F.B. Leopold Company).

and/or the filter cycle reaches a predetermined time limit (usually 3 or 4 days), then rapid filters need cleaning. Dirty/clogged filters may be cleaned by scouring the clogged portion or by reversing the flow through the bed. This application of expanding and washing out trapped particles is called backwashing. Backwashing by water fluidization is frequently assisted by a surface wash or an air scour. The most effective backwash is achieved by a simultaneous air scour and subfluidization water backwash. Typical backwash rates range from 15 to 23 gpm/sq ft depending on media sizes. The bed expansion varies from 20% to 50%. The backwash duration usually lasts from 5 to 15 minutes. The air-scour rate varies from 2 to 4 cu ft/min/sq ft (0.6 to 1.2 cu meter/min/sq meter).

For rapid gravity filtration to be effective, the source water must be pretreated. Chemical destabilization is an essential prerequisite for effective filtration. Chemicals used for particle destabilization are limited primarily to metal salts or cationic polymers as primary coagulants. Pretreatment may also include aeration or introducing an oxidant if water treatment aims to remove iron or manganese. Sometimes a filter aid polymer is added in the influent to the filter to improve particle capture efficiency. Granular bed filtration consists of three principal mechanisms: (1) transport, (2) attachment, and (3) detachment. *Transport* mechanisms move a particle into and through a filter pore so that it comes very close to the surface of the filter medium or existing deposits where *attachment* mechanisms retain the suspended particle in contact with the medium's surface or with previously deposited solids.

Detachment mechanisms result from the hydrodynamic forces of flow acting so that a certain portion of the previously attached particles, less strongly adhered to others, is detached from the filter medium or previous deposits and carried further, deep into or through the filter.

Important transport mechanisms include screening, interception, inertial forces, sedimentation, diffusion, and hydrodynamic forces. Physicochemical and molecular forces generally govern attachment of particles to media surfaces. Detachment is caused by the impact of arriving particles on unstable deposits and by hydraulic shear stresses without the influence of arriving particles. A number of properties of a filter medium are important in filtration performance and in characterizing the medium. Important media properties include size, shape, density, and hardness. The efficiency of a filter is more sensitive to changes in the filtration rate rather than in the actual rate. Therefore, filtration process control is critical to successful operation.

Several different granular types of filters are classified by various schemes. Filters can be classified by the type of medium (single media, dual media), hydraulic arrangement (gravity or pressure), rate of filtration (rapid or slow), and depth of solids removal (deep or cake). The most common types of filter media used in granular bed filters are silica sand, anthracite coal, and garnet. These may be used alone or in dual- or triple-media combinations. Granular-activated carbon (GAC), another type of medium, has been used in granular beds that serve for both filtration and adsorption to reduce taste and odor.

In recent years, direct filtration has received considerable attention and application in the treating of drinking water. Direct filtration is not preceded by sedimentation. It offers several advantages over conventional treatment of "good-quality" surface water. Because there is no sedimentation process and a lower coagulant dose, the capital and operating costs are lower compared with those of conventional treatment. Sludge volumes are lower, which results in lower chemical costs for sludge treatment and disposal. Because of increased interest in ozone application in potable water, biological filtration has received noticeable attention and application in recent years. Granular filters become biologically active when ozone is used as a preoxidant. Ozone reacts with organic compounds in water and forms several ozonation byproducts such as aldehydes, carboxylic acids, and keto acids, which are relatively easy to biodegrade. By operating filters in the biological mode, these ozonation byproducts can be effectively removed and in turn reduce the potential for bacterial regrowth in distribution systems and formation of chlorination byproducts.

A slow sand filter generally consists of a watertight basin containing a layer of sand over a layer of gravel (Fig. 2). It is operated at very low filtration rates without coagulation in pretreatment. A smaller grain size and lower filtration rate result in solids removal almost entirely in a thin layer on the top of the sand bed. This layer, composed of dirt and living and dead micro- and macro-organisms from the water, is called *schmutzdecke* or dirty skin. Most of the solid removals in slow sand filter take place in the *schmutzdecke* layer. The dominant removal mechanisms are both physical and biological. A typical filter cycle may vary from 1 to 6 months (or longer) depending on the source water quality and the filtration rate. Filtration rates range from 0.016 to 0.16 gpm/sq ft (0.04 to 0.40 m/h). Effective sand sizes range from 0.15

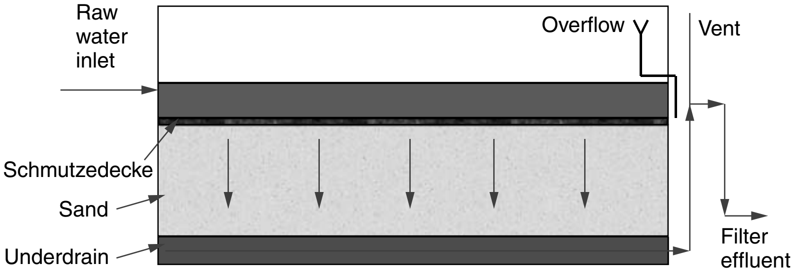

Figure 2. Conventional slow sand filter.

to 0.40 mm, sand uniformity coefficients from 1.5 to 3.6, and initial bed depths from 1.5 to 5.0 ft. The sand is supported on graded gravel 6 to 36 inches deep. Slow sand filters are cleaned by scraping the *schmutzdecke* and a small amount of sand depth. Usually, scraping is done manually but, in some cases, mechanically. The scraped sand is cleaned hydraulically and stockpiled for later reuse.

Rapid rate pressure filters are similar to gravity rapid rate filters, except that the flow enters and exits the filter under pressure (Fig. 3). The filter medium is contained in a steel pressure vessel. The pressure vessel can be vertical or horizontal. Proper backwashing of a pressure filter is more difficult compared with a gravity filter because the filter medium is not conveniently visible to the operator during the backwash operation. Pressure filters tend to be used in small water systems. Many pressure filters are used in industrial water and wastewater filtration. They are also used widely in swimming pool filtration.

Diatomaceous earth filtration, precoat or diatomite, filtration is another water filtration process that works under pressure. It consists of a layer of diatomaceous earth used as a filter medium approximately one-eighth inch thick placed on a septum or filter element. The septum may be placed in a pressure vessel or operated under a vacuum in an open vessel. As the water passes through the filter medium and septum, the suspended particles are captured and deposited. The majority of particles removed by the filters are strained at the surface layer of the filter medium, and some are trapped within the layer. As the filter cycle proceeds, additional filter medium called *body feed* is regularly metered into the influent water in proportion to the solids being removed. Ultimately, a gradually increasing pressure drop through the filter system reaches the point where continued filtration is impractical. The forward filtration process is stopped, the filter medium and collected dirt are washed off the septum, a new precoat of filter medium is applied, and the filtration process continues. Diatomaceous earth filters are widely used in industrial filtration and in swimming pool filtration. They have also been used in municipal potable water treatment, primarily in direct, in-line filtration of high-quality surface water (turbidity 10 NTU or less and acceptable color), and in filtering iron and manganese from groundwater after appropriate pretreatment to precipitate these contaminants. Precoat filters are simple to operate and are effective in removing cysts, algae, and asbestos.

Figure 3. Pressure filter (*Source*: U.S. Filter).

Membrane filtration represents an important set of processes for drinking water treatment. A membrane is a thin layer of natural or synthetic material that can separate substances when a driving force is applied across the membrane. Membranes used for water treatment are commonly made of synthetic organic polymers. Membrane processes for potable water treatment are reverse osmosis (RO), nanofiltration (NF), electrodialysis (ED), ultrafiltration (UF), and microfiltration (MF). Reverse osmosis is used primarily to remove salts from brackish water or seawater. Nanofiltration is used to soften freshwaters and remove disinfection byproduct (DBP) precursors. Electrodialysis is used to demineralize brackish water and seawater and to soften freshwater. Ultrafiltration and microfiltration are used to remove turbidity, pathogens, and other particulates from freshwater (Fig. 4). Membranes are normally classified by solute exclusion size, which is sometimes referred to as *pore size*. Membrane filtration works by passing water at high-pressure through a thin membrane in the form of hollow-fiber or spiral-wound composite sheets. The contaminants are retained on the high pressure side and frequently must be cleaned by reversing the flow and flushing the waste. Periodic chemical cleaning may be required to remove persistent contaminants. Membrane assemblies are contained in pressure vessels or cartridges. Low-pressure membranes in the form of either ultrafiltration (UF) or microfiltration (MF) have become more economical in capital and operating costs and have received increased attention in drinking water application. Fouling of the membrane is the major problem preventing widespread application of this technology.

Cartridge filters traditionally have been applied for point-of-use systems and for pretreatment prior to membrane treatment systems. Composed of membrane, fabric, or string filter media, the filter material is supported by a filter element and housed in a pressure vessel. The application of cartridge filters using either cleanable ceramic or disposable polypropylene cartridge

Figure 4. Microfiltration (MF) system (*Source*: U.S. Filter).

seems to be a feasible method for removing modest levels of turbidity, algae, and microbiological contaminants. As water is filtered through a cartridge filter, the pressure drop increases, which necessitates terminating the filter run. When this process is done, the filter is not backwashed, but the cartridge is thrown away and replaced by a clean filter.

The desire to reduce costs or to treat some waters more effectively is driving the development of new technologies for filtration. Several examples of such proprietary filters include low-head continuous backwash filters, two-stage filtration systems, bag filters, moving media filters, and flotation and filtration systems. A variety of modes of operation are available such as downflow, up-flow, multiple layer, biflow, radial flow, semicontinuous (moving bridge), continuous (media recycle), variable voidage, and pebble matrix.

SYNTHETIC AND NATURAL ORGANIC REMOVAL BY BIOLOGICAL FILTRATION

Rasheed Ahmad
Khafra Engineering Consultants
Atlanta, Georgia

Oligotrophy is important because organic substrates are present in drinking water supplies at microgram per liter levels. Most biological processes are aerobic, which means that dissolved oxygen is present and used as the electron acceptor by the bacteria.

The benefits of biological filtration include decreased potential for bacterial regrowth in the water distribution system, reduced chlorination disinfection byproducts (DBPs), reduced chlorine demand, and decreased corrosion potential. So biological filtration is used to achieve three broad goals: (1) biologically oxidize biodegradable components, making the water biologically stable and reducing the need for excess chlorination; this will in turn reduce the formation of DBP compounds, which are known human carcinogens; (2) biodegrade synthetic organic micropollutants that are harmful to human health; and (3) remove nitrate and nitrite via denitrification. In most drinking water treatment, however, the first two goals are the main objectives of biological filtration. Particulate (silt, clay, precipitates) removal does occur in biological filters even though it may not be an intentional goal.

It is well established that ozonation increases the fraction of natural organic material (NOM) that is biodegradable. The effects of ozonation on NOM include formation of hydroxyl, carbonyl, and carboxyl groups; increased polarity and hydrophilicity; loss of double bonds and aromaticity; and a shift in molecular weight distribution toward lower molecular weight compounds. Thus, an increase in biodegradable organic matter (BOM) on ozonation generally enhances biological activity considerably in filters, after ozonation. Often, biological filtration can reduce BOM concentration to approximately preozonation levels, although this depends on the specifics of biological filters and water quality parameters, and the composition of BOM may be different after biological filtration. Currently identified ozonation byproducts such as aldehydes, carboxylic acids, and keto acids are biodegraded by biological filters that have more than 75% removal efficiency. Several synthetic organic compounds (SOCs) are also substantially biodegraded by the biological filtration process. In particular, phenol, chlorinated phenols, and chlorinated benzenes show significant percentage removals immediately or after a short acclimation period. In general, SOCs that are built on an aromatic structure should be most susceptible to biodegradation, and halogenated aliphatics should be more resistant to biodegradation.

GRANULAR BED AND PRECOAT FILTRATION

Kwok-Keung Au
Greeley and Hansen
Chicago, Illinois

Various filtration processes are used in potable water treatment. Granular bed and precoat filtration processes are described in this article, and focus is on descriptions of these processes and their particle removal efficiencies. Filtration processes are some of the major tools that are used to minimize microbial pathogens in drinking water, so the descriptions of their removal efficiencies contained herein emphasize their removal of microbes. This type of efficiency is characterized by a term called log removal, which is defined as log C_0/C, where C_0 and C are the pathogen concentrations in a filter's inlet and outlet flows, respectively. Thus, a 1-log removal is equivalent to 90% removal. Current drinking water regulations target log removals of pathogens. Filter performance is also based on the amount of turbidity in the filtered water. Turbidity is a measure of water clarity. Turbidity reduces the aesthetic acceptability of drinking water and also shields pathogens from disinfectants that are added downstream of filters.

GRANULAR BED FILTRATION

In this process, water passes through a filter containing a bed of granular material. Particles are removed by different mechanisms, depending, primarily, on the filter medium used and the hydraulic filtration rate. The term "particles," used herein, refers to any particulate contaminants in water. These include very fine inanimate and biological objects and microbial pathogens. Granular filtration can be classified as slow sand filtration or high-rate granular filtration. Slow sand filters are operated at filtration rates of less than 0.4 m/h; the filtration rates for high-rate filters are typically 5 to 25 m/h. The design/operating criteria and particle removal mechanisms for slow sand filtration and high-rate filtration are considerably different, so each process is described in a separate subsection.

Slow Sand Filtration

Slow sand filtration was first developed in England about 200 years ago to protect drinking water consumers from microbe-related health risks. Detailed design guidelines for slow sand filters are available (1). A slow sand filter consists of a layer of sand supported on a graded gravel layer. The gravel layer surrounds a system of perforated pipes that collect the filtered water. The gravel keeps the sand from entering the pipe perforations and, thereby, being lost from the filter. Water passes through the sand and gravel by gravity, normally without being pretreated, and as it does, the sand removes particles. Biological and physicochemical removal mechanisms are believed to be involved (2,3). Specifically, these may include biological action (e.g., ciliate protozoa on the sand grains acting as bacterial predators), particle attachment to the sand grains (e.g., the extracellular macromolecules of microbial particles attaching to the sand grains) and physical straining between sand grains.

The predominant removal location is a thin layer at the top of the sand bed. This biologically active layer is termed the *schmutzdecke*. It contains living and dead micro- and macroorganisms. As filtration progresses, materials removed and biological growths on the sand grains increase the loss of hydraulic head as the water passes from above to below the sand layer. When the head loss reaches a predetermined limit, normally from 1 to 2 m, the filter is removed from service. Before being returned to service, the filter is cleaned usually by scraping about 2 cm of accumulated material and sand from the top layer of the sand bed, which is nominally the *schmutzdecke*. The typical time period between cleanings (called a filter run) varies from 1 to 6 months, depending on the inlet water characteristics and filtration rate. After the sand bed depth is reduced to the lowest acceptable value by multiple scrapings, replacement of the entire sand bed is necessary.

Pretreatment is normally not required for slow sand filtration. However, if the source water has a high concentration of suspended particles, physical pretreatment processes, such as roughing filters or microstrainers, may be employed to prevent rapid clogging of the sand and, thus, maintain reasonable filter run periods.

Virus removal by slow sand filters can range from slightly better than 1 log to as much as 5 logs (4). Fairly good removal of bacteria and protozoa can also be achieved by slow sand filtration. During a pilot-scale study, a new filter removed 0.82 logs of total coliform bacteria and greater than 1.7 logs of *Giardia* (5). After 2 weeks, a microbiological population was established within the sand bed, the removal of total coliforms increased to 4 logs, and no *Giardia* were detected in the filtered water. The calculated reduction of *Giardia* was greater than 2.6 logs.

In a full-scale study at three slow sand filtration plants in Idaho, no *Giardia* were detected in the filtered water at two of the three plants (6). For the one positive sample found at the third plant, 1-log removal of *Giardia* was achieved. In the same study, removal of total coliforms and fecal coliforms varied from 0.81 to 2.30 logs and from 0.29 to 0.52 logs, respectively. These ranges in removal efficiency were influenced by inlet water quality, filtration rate, and media size and depth. Removing *Cryptosporidium* by slow sand filtration is often more difficult than removing *Giardia*. In a full-scale study conducted in British Columbia, the average removal of *Giardia* was 1.16 logs, whereas it was only 0.28 logs for *Cryptosporidium* (7).

The reduction of turbidity by slow sand filtration may be site-specific. Turbidity removal in a pilot study was 1.66 logs or better after the filter was operated for 2 days (8). However, only 0.14 to 0.22 log removal of turbidity was found in another study, even though the reduction of *Giardia* in the same study was as high as 4 logs (5). The authors concluded that this was due to the fine clay particles in the inlet water to the filter. In a full-scale study, between 0 to 0.43 log removal of turbidity was reported (6). This low removal was due to the fine particles in the inlet water and to the large fraction (4% by weight) of fines in the sand medium used in the study.

Under proper design and operating conditions, slow sand filtration can provide a high degree of protection against microbial pathogens. This includes effective removal of viruses, bacteria, and protozoa. If the inlet water is of high quality, pretreatment is normally not required. The construction, operating, and maintenance costs of slow sand filtration are low. However, land requirements are high. This technology is therefore attractive for small systems that treat high-quality surface water.

High-Rate Filtration

High-rate granular filtration is the most widely used filtration process in drinking water treatment. A comprehensive review of this process is available (9). Filter media types include monomedia (typically silica sand but also anthracite coal), dual media (usually anthracite coal over silica sand), and trimedia (commonly anthracite coal over silica sand over garnet). Granular activated carbon is used when both particle removal and adsorption of dissolved organic compounds are desired.

Particle removal by high-rate granular filtration is a physicochemical process that involves two sequential steps, transport and attachment. Particles are initially transported from suspension to within a very close distance of filter media grains, and then attachment of particles to the media grains occurs (10). The transport step depends on the physical–hydrodynamic properties of the system. Process variables such as the size and density of particles, size and depth of filter media, and filtration rate affect transport efficiency. Attachment is controlled by the surface and solution chemistry of the filter media and particle suspension (11). Unfavorable interactions between the particles and the filter media must be avoided so that the particles can attach to the media. Chemical coagulation prior to filtration is used to overcome any unfavorable interactions between the particles and the filter media, and it is the single most important factor in determining filtration efficiency. Optimum coagulation, which is typically defined as the minimum coagulant dose required to achieve the best filtered water quality, should be provided. Without proper chemical coagulation, high-rate filtration works as a simple straining process and is not effective for particle removal.

Depending on the degree of pretreatment of the water before it is applied to the filters, granular filtration can be operated in three different treatment modes: conventional, direct, and in-line. Conventional treatment, appropriate for most source waters, consists of adding coagulant chemicals in rapid mixing basins, flocculation in slow mixing basins, and particle removal in sedimentation basins and filters. When sedimentation is omitted, the treatment mode is termed “direct filtration.” If both flocculation and sedimentation are omitted, the term “in-line filtration” is used. Direct or in-line filtration is used for source waters of consistently good quality, such as those of low turbidity and low color.

Particle removal by high-rate granular filtration occurs within the depth of the granular media (depth filtration) rather than only at the top of the filter media (cake filtration). A filter is cleaned when, during operation, the hydraulic head lost across the filter medium or the filtered water quality reaches unacceptable levels. The cleaning consists of surface washing and backwashing the filter medium. Surface washing is used to break up the mat of particles that has accumulated near the surface of the medium. This is achieved by directing water jets downward toward the filter medium’s surface or causing air bubbles to rise upward through the medium. Backwashing is achieved by a reverse flow of water applied below the medium and rising through the medium bed to flush the particles that have accumulated at the surface and within the filter bed out of the medium and the filter.

After backwashing, filters exhibit an initial period of poor performance (termed the ripening period) before achieving good filtered water quality. The passage of particles during the ripening period can be formidable. The ripening period can last from less than an hour to several hours. Different methods are used to minimize this impact, such as wasting the initial filtered water (filter -to-waste), limiting the initial filtration rate until the filtrate quality is acceptable (slow start), placing the filter in operation after a period of inactivity following backwashing (delayed start), or adding coagulant or polymer chemicals to the backwash water supply.

The importance of chemical pretreatment to removal efficiency by high-rate granular filtration has been emphasized in numerous studies. Without adding any chemicals, the average log removal of *Giardia* was 0.60 logs for conventional treatment and 0.44 logs for in-line filtration in a pilot study (12). In optimum chemical pretreatment, the removal increased to 1.70 logs for conventional treatment and 1.19 logs for in-line filtration. Results from a 2-year study indicated that maintaining optimum coagulation conditions to produce low filtered water turbidity (0.1 to 0.2 NTU) provided effective removal of *Giardia* and *Cryptosporidium* (13). Under optimum coagulation conditions, the average removal of *Giardia* was 3.3 logs or better, and the average removal of *Cryptosporidium* was 2.3 logs or better.

Results from a full-scale study confirmed that a properly operated conventional treatment plant provided a substantial barrier to microbial pathogens (14). Dual media filters were used in this plant. Coagulation was provided using alum and activated silica. Prechlorination was applied at a dosage of 1 mg/L. *Giardia* was detected in only 1 of 32 filtered water samples, and the mean removal was 3.6 logs by sedimentation and filtration. *Cryptosporidium* was detected in 7 of 32 filtered water samples, and the mean removal was 2 logs. *Clostridium perfringens* was detected in 9 of 33 filtered water samples, and the mean removal was 4.4 logs. No human enteric viruses were detected in 32 filtered water samples where the mean removal was 3.1 logs. *Somatic coliphage* was detected in 24 of 32 filtered water samples whose a mean removal was 3.5 logs.

Under proper design and operating conditions, high-rate granular filtration can act as a consistent and effective barrier to pathogenic microbes (15). Providing effective chemical pretreatment is the single most important factor in enhancing treatment efficiency. It is expensive, if not impossible, to remove microbes effectively without the proper chemistry provided by optimum coagulation.

Precoat Filtration

Precoat filtration was originally developed by the United States Army during World War II. The objective was a portable device to remove *Entamoeba histolytica*, a protozoan parasite prevalent in the Pacific war zone, from potable water. Precoat filtration is now accepted by the U.S. Environmental Protection Agency as a filtration technique for potable water treatment. A detailed design and operation manual for precoat filtration has been published (16).

In precoat filtration, water is forced by pressure or pulled by vacuum through a uniform, thin layer of filtering material precoated onto a permeable, rigid supporting structure (septum). As water passes through the precoat filter medium (filter cake) and septum, particles whose sizes are larger than the pore size of the filter medium are strained and removed. Typical filtration rates for this process are about 2.5 to 7 m/h.

During filtration, a slurry (called the body-feed solution) containing the coating material is often continuously added at the filter inlet to maintain filter cake permeability. As the filter cake thickness builds due to captured particles and the added precoat, the hydraulic head lost across the filter cake increases to a level impractical for further filtration. The filter cake is then removed from the support septum and disposed of. The filter is then cleaned and precoated with a new layer of coating materials, and a new filter run is started.

Precoat materials include diatomaceous earth (DE) and perlite; DE is more commonly used in drinking water treatment. DE is composed of fossilized skeletons of microscopic water plants called diatoms and is almost pure silica. Perlite originates as rock formed by the solidification of magma, is composed primarily of alumina silicate, and processed into a fine granular material for use as precoat. The primary removal mechanism of precoat filtration is straining, so its removal efficiency depends to a great extent on the pore size of the coating materials. The median pore size is called the media grade. Diatomite grades used for drinking water treatment have a median pore diameter of about 3 to 17 μm. Other important factors that influence the removal efficiency are chemical pretreatment of the filter medium, filtration rate, and body-feed rate. To maintain reasonable filter run time, the inlet water must be of high quality. Inlet water turbidity levels of less than 10 NTU are desirable, or pretreatment of the source water should be considered.

A pilot study showed complete removal of *Giardia* by both coarse and fine grades of DE in filtration across a wide range of operating conditions (17). Removal of *Cryptosporidium* by a bench-scale DE filter ranged from 3.60 to 6.68 logs, depending on the media grade and filtration rate (18). In a pilot-plant study, complete removal of *Giardia* and 3-log removal of *Cryptosporidium* by DE filtration were reported (19). Based on the results from another pilot-scale study, 6-log removal of *Cryptosporidium* was achieved by DE filtration at rates from 2.5 to 5 m/h (20). In most of the runs, the turbidity level decreased from about 1 NTU in the inlet water to less than 0.1 NTU in the outlet water.

Precoat filtration can remove protozoan parasites very effectively, but chemical pretreatment of coating media with aluminum or iron coagulants or cationic polymers is required to remove submicron-sized microbes such as viruses and some bacteria. In a pilot study, removal of coliforms by untreated DE was about 0.36 logs (19). The removal increased to 0.82 logs for DE coated with an alum dosage of 0.001 g/g DE and to 2 logs with an alum dosage of 0.003 g/g DE. This enhancement was probably due to the enmeshment of the bacteria on the aluminum precipitates. A similar beneficial effect was observed by coating the DE with cationic polymers. When the DE was coated with a polymer dosage of 0.0035 g/g DE, the removal of coliforms was greater than 3.3 logs. The authors concluded that this could be due to increased density of positively charged sites on the polymer-coated DE for adsorption of negatively charged coliforms. An enhancement in virus removal by chemical pretreatment of filter cake has been reported (21). The removal of bacteriophage T2 and poliovirus was about 1 log for an uncoated filter cake. When the filter cake was coated with ferric hydrate or polyelectrolytes, the removal increased to more than 1.7 logs.

Under proper design and routine operating conditions, precoat filtration can remove protozoan parasites such as *Cryptosporidium* and *Giardia* very effectively. Precoat filters can also be effective in removing submicron-sized microbes including viruses and some bacteria, provided that chemical pretreatment of the coating materials is employed.

FLOCCULATION

Rasheed Ahmad
Khafra Engineering
Consultants
Atlanta, Georgia

The flocculation process aggregates destabilized particles into larger and more easily settleable flocs. The coagulation process destabilizes particles through chemical reactions between the coagulant and the suspended colloids, but flocculation is the transport step that causes the necessary collision between destabilized particles. The purpose of the flocculation process is to promote the interaction of particles and to form aggregates that can be efficiently removed in the subsequent separation processes such as sedimentation, flotation, and coarse bed filtration. In practice, flocculation is accomplished by providing a gentle mixing phase that follows the rapid dispersion of coagulants.

There are three major mechanisms of flocculation: perikinetic, orthokinetic, and differential settling. In perikinetic flocculation, the aggregation of particles occurs as a result of random thermal motion (Brownian diffusion) caused by continuous bombardment by surrounding fluid molecules. The driving force for this type of particle movement is the thermal energy of the fluid. This is significant for particles that are 1 to 2 microns in size. In orthokinetic flocculation, the aggregation of particles is caused by induced velocity gradients in the fluid. The suspended particles follow the streamlines at different velocities and eventually lead to interparticle contacts. The velocity gradient is related to the energy dissipated into the water (via mixing). Flocculation by differential settling occurs when particles have unequal settling velocities, and their alignment in the vertical direction makes them tend to collide when one overtakes on other. This collision occurs in sludge blanket or solids contact clarifiers where differential and fluctuating velocities can lead to particle collision and aggregation. In water treatment, the predominant mechanism is orthokinetic flocculation.

In systems that are mixed (velocity gradients are induced), the velocity of the fluid varies both spatially and temporally. The spatial changes in the velocity are termed the *velocity gradient*, G. The unit of velocity gradient is $\sec^{-1}$. In water treatment plants, mean velocity gradients of 10 to 100 $\sec^{-1}$ are typical for flocculation. Flocculation usually follows a rapid mixing process in conventional treatment plants. Flocculation is a time-dependent process that directly affects clarification efficiency by providing multiple opportunities for particles suspended in water to collide through gentle and prolonged agitation. Most water treatment plants provide 20 to 30 min of flocculation time (at 20 °C). An increase in flocculation time does not improve flocculation significantly. The optimum flocculation conditions are those that rapidly form flocs large enough to be separated by settling, flotation, or filtration leaving no residual primary particles or small aggregates. However, rates of flocculation that are too high cause floc breakup. Thus, a balance must be achieved between the velocity gradient G and the flocculation time t, one compensating for the other. In some cases, flocculation is characterized by the dimensionless product Gt (sometimes called the Camp number). Based on observational data from water utilities in the United States, the optimal value of Gt is set between the limits of 10^4 and 10^5. It is desirable to compartmentalize the flocculation process by dividing the basin into two or more defined compartments or stages. Compartments prevent short-circuiting and permit defined zones of reduced energy input or tapered flocculation. Studies have shown that tapered flocculation at a diminishing velocity gradient is more efficient than uniform velocity flocculation.

Flocculation can be achieved by hydraulic methods or mechanical devices. Hydraulic methods are used most often in small plants. Mechanical flocculators cover a broad range of configurations. Mechanical flocculators are preferred by most design engineers in the United States because of their flexibility in varying G values and because they cause low head loss. Mechanical flocculators can be divided into two major types: (1) shaft with turbine or propeller type blades and (2) paddle type with either horizontal or vertical shafts. Turbines can have flat or curved blades that are connected to a disk or shaft (Fig. 1). Propellers are shaped like ships' screws. The blades are mounted on a vertical or inclined shaft. The paddle type consists of blades attached directly to vertical or horizontal shafts (Figs. 2 and 3). In some flocculators, moving blades (rotors) may be complemented by stationary blades (stators) that oppose rotational movement of the entire mass of water within the treatment unit and help suppress vortex formation. Paddles are rotated at slow to moderate speeds of 2 to 15 rpm. The currents generated by them are both radial and tangential. The type of mechanical flocculators influences the shape of flocculation compartments. Vertical flocculators are often associated with square compartments, whereas the horizontal shaft, reel, or paddle flocculators are associated with rectangular compartments. Between each zone or stage of mechanical flocculation, baffles are designed to prevent short-circuiting. Vertical flocculators are more applicable to high-energy flocculation such as direct filtration.

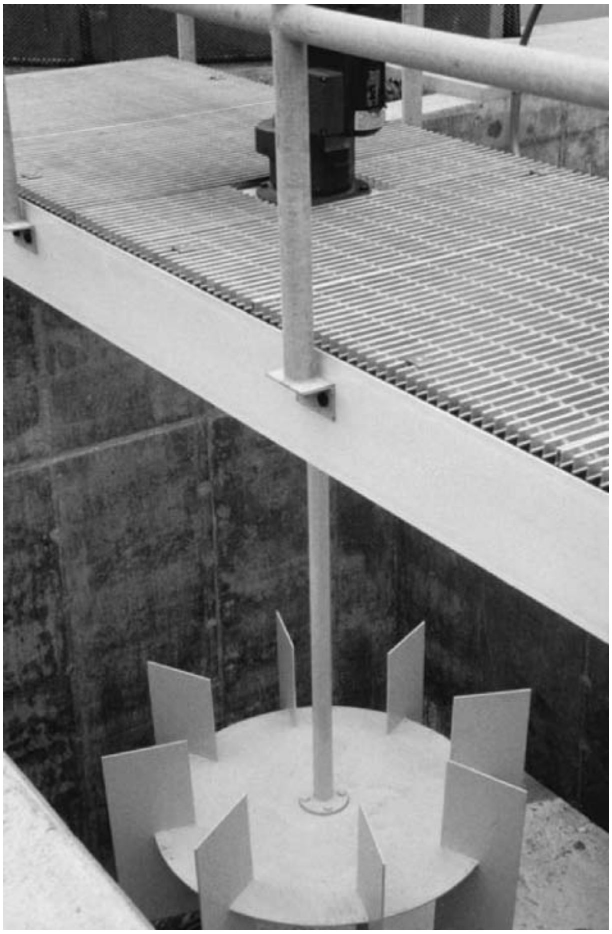

Figure 1. Flat blade turbine type flocculator (*Source*: Dorr Oliver Eimco).

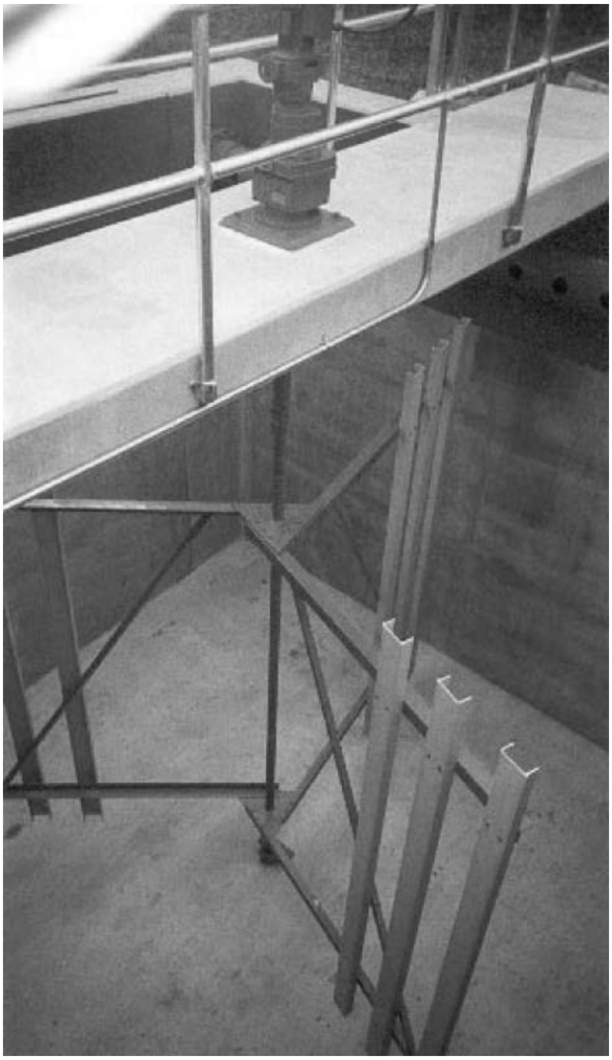

Figure 2. Vertical shaft paddle flocculator (*Source*: Walker Process Equipment, a Division of McNish Corporation).

Hydraulic flocculation methods are simple and effective, especially if flows are relatively constant. Hydraulic flocculation is achieved in baffled channel basins. They can be horizontally baffled (around-the-end flow) or

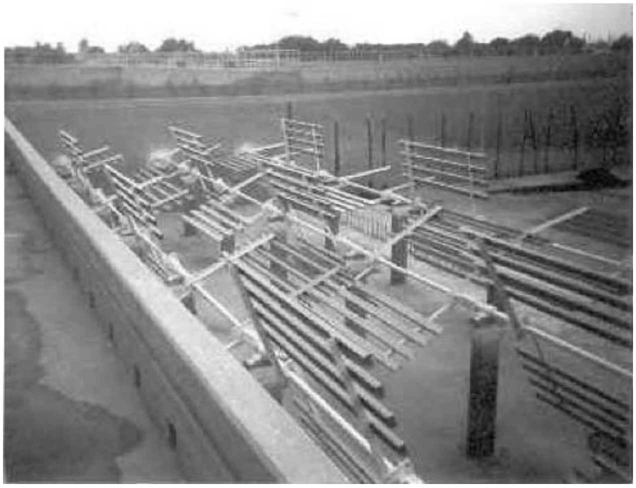

Figure 3. Horizontal shaft paddle flocculator (*Source*: Walker Process Equipment, a Division of McNish Corporation).

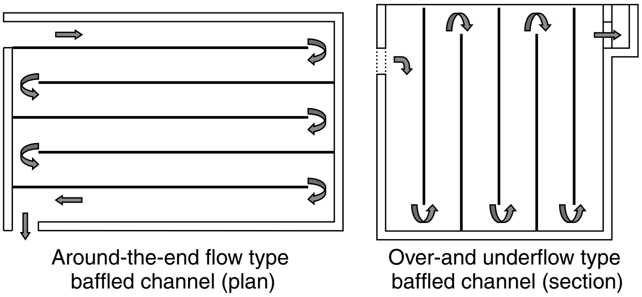

Figure 4. Hydraulic or baffled channel flocculation.

vertically baffled (over- and underflow) channels (Fig. 4). The velocity gradients are purposely intensified in these channels by enforced changes in the direction of flow. When designed properly, baffle channels perform well and exhibit good plug flow characteristics. However, they have two disadvantages: there is a significant head loss across the tank, and the mixing intensity is a function of plant flow rate. Some new water treatment plants in the United States have used a combined system of hydraulic and mechanical flocculation. It offers a large reduction in mechanical flocculator units, so there is a saving in capital and maintenance costs and increased reliability.

Some other types of flocculators are not commonly used in water treatment. Contact flocculation (gravel-packed filter) requires minimal maintenance because it has no moving parts. This type of flocculation system depends on plant flow rate and requires minimal variation in flow rate and water temperature for adequate mixing intensity. Contact flocculation also requires frequent backwashing. Contact flocculation may be applicable for difficult high-suspended-solids water or water with low total dissolved solids that may not respond readily to metal ion coagulants. Diffused air or water jet agitation is used as an auxiliary or temporary flocculation. This system is characterized by a high rate of energy consumption and is an inefficient flocculation process.

Several manufacturers provide proprietary designs that incorporate rapid mixing, flocculation, and settling in one unit, which is sometimes called a solids contact reactor unit. These units perform best in waters that can develop a dense, fast-settling floc, but the process may be difficult to control in some waters. These units have an option for sludge recirculation. Recirculating water treatment sludge may improve efficiency and reduce chemical requirements. The walking beam is another kind of proprietary flocculator. Walking beam flocculators are driven in the vertical direction in reciprocating fashion. The unit contains a series of cone-shaped devices on a vertical rod. The cone devices impart energy to the water as they move up and down, thereby creating velocity gradients.

FLUORIDATION

John E. Dodes
Forest Hills, New York

Fluoridation of water supplies has been a controversial subject for more than 60 years. Much of the debate is concerned with questions of safety, but recently questions have been also raised about the efficacy of fluoridation. More than 35,000 papers on fluoridation have been published in the years since fluoride supplementation was first proposed as a safe and effective way of decreasing tooth decay. The overwhelming conclusion is that fluoride is safe and cost-effective.

TOOTH DECAY

Tooth decay is the most common disease of all humanity. It is the principal cause of tooth loss from early childhood through middle age. And decay continues to be a major problem as we age, particularly root decay which seriously affects the elderly due to receded gums and a general decrease in the amount of saliva. Dental decay not only affects the general health by interfering with the ability to eat and digest certain foods, but it also impacts an individual's emotional and social well-being. Recent surveys have found that more than 94% of adults have had decayed teeth, and 22.5% had root surface decay. In 1997, the United States spent more than $50.6 billion on dental care.

HISTORY OF WATER FLUORIDATION

In 1892, Sir Crichton-Browne advocated augmenting the common diet of his era with fluoride to reduce decay (1). Not until the 1950s, however, did years of research pay off, and it was unequivocally determined that when water contains approximately 1 part of fluoride per million parts of water (1 ppm) which is equivalent to 1 milligram of fluoride per liter of water (1 mg/L), decay rates are reduced by up to 60%. In the 1940s, there was substantial resistance to adding fluoride to community water supplies, even though people had been drinking naturally occurring fluoridated water containing several times the 1-ppm level of fluoride for a lifetime without any negative side effects (2).

The most famous study of the effects of fluoridation was done in the 1940s in Newburgh and Kingston, New York. These cities are located 35 miles apart near the Hudson River; both had populations of about 30,000 and were also similar in their demographics. Newburgh's water supply was fluoridated, and Kingston's was not. After 10 years, the study found that there were no medical differences between the two groups except for the fact that Newburgh's children had almost 60% fewer cavities (2). Many studies have confirmed these findings in the years since.

FLUORIDE

Fluoride is one of the earth's most common elements and is therefore present in variable amounts in all water supplies. It is also found in most plants and animals that we eat. The fluoride concentrations in water supplies within the United States vary from 0.1 to 10 mg/L (3). Ocean water also contains fluoride at concentrations of 1.0 to 1.5 mg/L. This causes a fairly uniform level of fluoride in all seafood.

Fluoride is classified by the National Academy of Sciences as an essential nutrient (4). Unlike many other essential elements that are found in food, water consumption is the most practical, consistent and effective method of fluoride application to the teeth. In growing children, fluoride will be incorporated throughout the entire hard structure (enamel and dentin) of the teeth. This continues until around age 50 when it appears that the spaces available to fluoride in the tooth's structure will be filled. In adults, fluoride will continue to be absorbed by the enamel surface, lending the teeth temporary but substantial resistance to decay. Fluoride is easily absorbed into the blood stream from the gastrointestinal tract and reaches a peak concentration within 20–60 minutes. This level declines rapidly due to the uptake of fluoride by the hard tissues and the removal of fluoride by the kidneys. Approximately 50% of the fluoride that is absorbed is incorporated in the body's teeth and bones within 24 hours.

The amount of decay reduction caused by fluoridation of local water supplies has decreased during the last 40 years probably because of improved dental hygiene and widespread use of fluoride toothpaste. This increase in fluoride availability has led to a reduction in the dose of fluoride supplementation recommended for children living in non-optimally fluoridated communities (Table 1). In 1991, it was found that fluoride reduces the incidence of cavities 20% to 40% in children and 15% to 35% in adults (5).

Table 1. Supplemental Fluoride Dosage (Milligrams of Fluoride per Day)[a]

	Concentration of Fluoride in Water (parts/million)		
Age (years)	0.0 to 0.3	0.3 to 0.6	Over 0.6
Birth to six months	None	None	None
Six months to three years	0.25	None	None
Three to six years	0.50	0.25	None
Six to sixteen years	1.0	0.50	None

THE SAFETY OF FLUORIDE

In 1970, the World Health Organization (WHO) issued a report, "Fluorides and Human Health," that had taken years of research to compile. The WHO wanted to evaluate impartially the vast number of scientific studies of fluoridation that had been published. These papers included population studies, experimental research, animal studies, human autopsy studies, clinical trials, and X-ray research. The WHO expert panel concluded that there was no reliable evidence that drinking water fluoridated at the recommended levels caused any ill health effects. In 1975, the WHO stated, "The only sign of physiological or pathological change in life-long users of optimally fluoridated water supplies .... is that they suffer less from tooth decay" (3).

Fluoride ingested through community water systems has a large margin of safety. It has never been shown that fluoride intake at 1 ppm has any negative effect on disease or death rates. Numerous studies performed before and after supplemental fluoridation have shown no changes in death rates from cancer, heart disease, intracranial lesions, nephritis, cirrhosis, or from any other cause. In addition, the normal disease and death rates of more than 7 million Americans who have lived for generations where the natural fluoride concentration was 2 to 10 mg/L (1 mg/L is the recommended dose), is compelling evidence of fluoridation's safety. Two extensive studies have established that there is no link between fluoridation and Down's syndrome, cleft palate, heart abnormalities, clubfoot, and other common birth defects.

Antifluoridationists have long claimed that fluoride use leads to an increase in cancer rates. Consumer's Union characterized this accusation as “absurd.” It has been shown that fluoride has no mutagenic effect in studies of cattle (7) or mice (8). This makes sense because fluoride is not in the class of electrophilic compounds that can interact with DNA, nor is it likely that the small tissue levels of fluoride present due to fluoridated water supplies could interfere with DNA replication.

It has also been proven that fluoride does not cause allergic reactions. The executive committee of the American Academy of Allergy has stated, “There is no evidence of allergy or intolerance to fluorides as used in fluoridation of community water supplies.”

The effect of fluoridated water on kidney function has been thoroughly investigated, and here again no ill effects have been shown. No kidney changes were detected in a population exposed for a lifetime to water supplies that have fluoride levels of 8 mg/L (1).

Opponents of fluoridation also routinely claim that it causes coronary artery disease. They use data on heart disease rates from Antigo, Wisconsin, to support this claim. Antigo did show increased death rates from heart disease in the period since fluoride was introduced to its water supply in 1949. But, in that same period, the percentage of elderly people living in Antigo doubled, due to longer life spans. Actually, the segment of the population 75 years old or older increased 106% (2). The higher death rates from heart disease amongst the elderly were never factored into the interpretation of the Antigo death-rate data. When this factor is taken into account, the alleged deleterious effect of fluoride disappears. Unfortunately, the population of Antigo believed the scare tactics and false claims of the antifluoridationist movement and voted to end the fluoridation of their water supply. After only 4 years, the decay rates in permanent teeth of second graders rose 183%. A year later, Antigo voted to reinstate fluoridation (2).

FLUORIDE SAFETY MARGINS

Food and water account for 1.2 to 2.6 mg of fluoride ingestion per day. Urban air usually contains less than 1 μg/m^3, an insignificant amount. The margin of safety for fluoride is very large, and toxic effects have not been demonstrated at levels far higher than one could receive in a lifetime of exposure to drinking water containing 8 times the recommended level of 1 ppm. The acute lethal dose for a 150 lb. (70 kg) man is 5 to 10 g of sodium fluoride or 2.3 to 4.5 g of fluoride (9). Chronic overexposure to fluoride at levels over 1 ppm before age 8 can lead to discoloration of the enamel, ranging from barely detectable white flecks to large brown areas. Known as enamel fluorosis, this solely cosmetic problem can be achieved only by ingesting high amounts of fluoride, not by topical application.

THE COST OF FLUORIDATING WATER SYSTEMS

Fluoride protection obtained through community water treatment costs approximately 50 ¢ per person per year (10). This saves an estimated $75 in dental treatment costs (11). The National Preventive Demonstration Program monitored nearly 30,000 children, ages 5 to 14, for 4 years and found that the most cost-effective method of decay prevention was to drink fluoridated water from birth and have sealants applied as needed (12).

THE ANTIFLUORIDATIONIST MOVEMENT

The water supply of the developed world is slowly becoming entirely fluoridated, although overcoming the misinformation promoted by those opposed to fluoridation is a long and difficult process. The resistance to this overwhelmingly endorsed public health benefit tells us a great deal about the psychology of fear, the strength of rumor, and the loss of trust in government and industry. William T. Jarvis, Ph.D., the Executive Director of the National Council Against Health Fraud, has stated,

> These charges seem to grow out of a mentality of distrust. Antifluoridation groups are led by many of the same people who oppose immunization, pasteurization, sex education, mental health programs, and other public health advances. Most are closely connected with sellers of alternatives to medically accepted products and services. The so-called “health food” industry justifies its existence by declaring that our conventional sources of food, water, and health care are misguided.

No studies will satisfy those who are opposed to fluoridation. A vociferous minority, made up mostly of food faddists, cultists, chiropractors, and people who misunderstand what fluoridation is, has developed effective ways of stopping fluoride from being adjusted to optimum levels in water. “Lifesavers Guide to Fluoridation,” a pamphlet by John Yiamouyiannis, Ph.D., is often distributed in communities that are considering fluoridation. It cites 250 references as proof that fluoride is dangerous. However, in 1988, experts from the Ohio Department of Health published “Abuse of the Scientific Literature in an Antifluoridation Pamphlet.” This review traced the references and found that almost half had no relevance to community water fluoridation and that many others actually supported fluoridation but were selectively misquoted and misrepresented.

In 1990, an article in *Newsweek* magazine implied that fluoridation was ineffective and unsafe. The article was a response to the unauthorized and premature release of data from an experiment at the National Institute of Environmental Health Science. The experiment exposed rats and mice to high doses of fluoride. A thorough review of the experiments by a U.S. Public Health Service expert panel concluded that the data were insignificant and that fluoridation posed no risk of cancer or any other disease. Dr. Stephen Barrett, a leading consumer health advocate, called the *Newsweek* article “the most irresponsible analysis of a public health topic ever published by a major national news outlet.”

Fluoride has been a favorite target of those who want to frighten the public into believing that our health system is dangerous and uncaring. They continue to undermine the significant health advances that have been made by public health measures, modern agriculture, and industry. As Consumers Union has concluded,

> The simple truth is that there's no "scientific controversy" over the safety of fluoridation. The practice is safe, economical, and beneficial. The survival of this fake controversy represents one of the major triumphs of quackery over science in our generation (2).

FLUORIDATION RATES AROUND THE WORLD

Tooth decay, or caries, is the most prevalent disease of all humanity, more common than the common cold (13). The cost of tooth decay in human suffering as well as economic expenditures is also enormous, accounting for many billions of dollars. Yet, as we enter the twenty-first century, only a small percentage of the world's population can easily drink fluoridated water. In addition, the majority of bottled water is not fluoridated, and many types of home water filtering devices actually remove the fluoride that may be in the water.

In the United States, 62.2% of the population has access to public water supplies that are optimally fluoridated (14). More than 360 million people worldwide in approximately 60 countries also drink fluoridated water. Dr. C. Everett Kopp, the former Surgeon General of the United States has stated, "Fluoridation is the single most important commitment that a community can make to the oral health of its citizens." It is imperative to continue to fluoridate water systems throughout the world.

GIARDIASIS

Christine L. Bean
University of New Hampshire
Durham, New Hampshire

GIARDIA LAMBLIA

Giardia lamblia is an intestinal flagellated protozoan, which infects the intestinal tract of a wide range of mammals, including humans. Two forms of this protozoan exist, a highly resistant cyst and a motile, feeding trophozoite. Cysts may be found in freshwater surface water supplies as a result of contamination from sewage and animal waste runoff. Trophozoites of this obligate parasite do not typically survive outside the host and are therefore not the major mode of transmission. The cyst form is capable of surviving for long periods of time in cool water supplies and has been responsible for major waterborne outbreaks in the United States.

LIFE CYCLE AND MORPHOLOGY

The life cycle of *Giardia lamblia* begins with the ingestion of the cyst form, which reaches the small bowel, and in response to the low pH, encysts into the motile, feeding trophozoite form. Using flagella and the ventral disk, the trophozoite moves from the small intestine to the duodenum and jejunum where it attaches to the intestinal epithelium. Trophozoites do not seem to penetrate the epithelium and may remain attached to the mucosal surface until it sloughs off the tip of the villus approximately every 72 hours (1). The trophozoites are pear-shaped and have a concave ventral disk, which they use for attachment. They have four pairs of flagella, two nuclei, two axonemes, and two median bodies and are 10 to 20 μm long and 5 to 15 μm wide (see Fig. 1).

Trophozoites encyst as they move down through the colon. During encystation, flagella are retracted, the cytoplasm becomes condensed, and the cyst wall is secreted. This process of encystation is a key step in the life cycle of *Giardia* that allows the organism to survive between hosts outside the human body. The cysts can survive for 3 months in water at 4 °C (2). They are usually oval-shaped and contain four nuclei, axonemes, and median bodies. They measure 11 to 14 μm in length and 7 to 10 μm wide (see Fig. 2).

CLINICAL DISEASE

The cyst form is infectious, and an inoculum of 10 to 100 cysts is required to infect humans (1,3). The incubation time to infection ranges from 12 to 20 days before the acute stage begins, which lasts only a few days. The organisms are present in the duodenal mucosa, but they do not cause

GIARDIA LAMBLIA

Giardia lamblia is an intestinal flagellated protozoan, which infects the intestinal tract of a wide range of mammals, including humans. Two forms of this protozoan exist, a highly resistant cyst and a motile, feeding trophozoite. Cysts may be found in freshwater surface water supplies as a result of contamination from sewage and animal waste runoff. Trophozoites of this obligate parasite do not typically survive outside the host and are therefore not the major mode of transmission. The cyst form is capable of surviving for long periods of time in cool water supplies and has been responsible for major waterborne outbreaks in the United States.

LIFE CYCLE AND MORPHOLOGY

The life cycle of *Giardia lamblia* begins with the ingestion of the cyst form, which reaches the small bowel, and in response to the low pH, encysts into the motile, feeding trophozoite form. Using flagella and the ventral disk, the trophozoite moves from the small intestine to the duodenum and jejunum where it attaches to the intestinal epithelium. Trophozoites do not seem to penetrate the epithelium and may remain attached to the mucosal surface until it sloughs off the tip of the villus approximately every 72 hours (1). The trophozoites are pear-shaped and have a concave ventral disk, which they use for attachment. They have four pairs of flagella, two nuclei, two axonemes, and two median bodies and are 10 to 20 μm long and 5 to 15 μm wide (see Fig. 1).

Trophozoites encyst as they move down through the colon. During encystation, flagella are retracted, the cytoplasm becomes condensed, and the cyst wall is secreted. This process of encystation is a key step in the life cycle of *Giardia* that allows the organism to survive between hosts outside the human body. The cysts can survive for 3 months in water at 4 °C (2). They are usually oval-shaped and contain four nuclei, axonemes, and median bodies. They measure 11 to 14 μm in length and 7 to 10 μm wide (see Fig. 2).

CLINICAL DISEASE

The cyst form is infectious, and an inoculum of 10 to 100 cysts is required to infect humans (1,3). The incubation time to infection ranges from 12 to 20 days before the acute stage begins, which lasts only a few days. The organisms are present in the duodenal mucosa, but they do not cause

Photographs are courtesy of Centers for Disease Control & Prevention National Center for Infectious Diseases Division of Parasitic Diseases DPDx Laboratory Identification of Parasites of Public Health Concern.

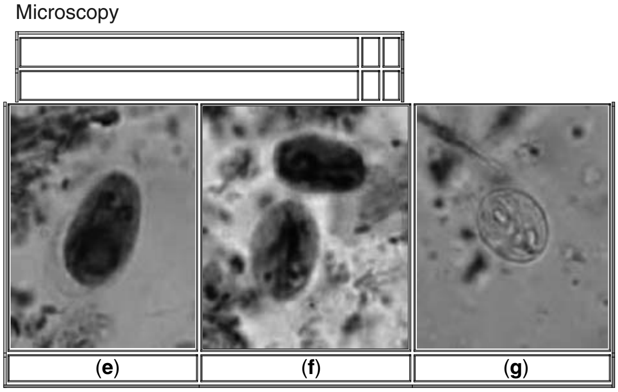

Figure 2. Cysts of *Giardia intestinalis*, stained with iron-hematoxylin (**e, f**) and in a wet mount (**g**) from a patient seen in Haiti). Size: 8 to 12 μm in length. These cysts have two nuclei each (more mature ones will have four). Photographs are courtesy of Centers for Disease Control & Prevention National Center for Infectious Diseases Division of Parasitic Diseases DPDx Laboratory Identification of Parasites of Public Health Concern.

pathology, as they do not penetrate the mucosa. Symptoms of the acute phase can include nausea, anorexia, fever, chills, and a sudden onset of explosive, foul-smelling diarrhea. Stools may have increased amounts of fecal fat and mucus, but no blood is present. Fat absorption may be disrupted because of the presence of trophozoites coating the mucosal lining. Rapid multiplication of trophozoites by binary fission creates a barrier between the intestinal epithelial cells and the lumen causing interference with nutrient absorption (1).

A chronic phase may follow the acute phase and induces symptoms of brief, recurrent diarrhea followed by normal stools or even constipation. Antigenic variation is a factor in the development of this chronic stage as certain surface antigens may allow the organism to survive better in the intestinal tract. Some other patients are asymptomatic and continue to pass cysts in stools.

Giardiasis occurs often in patients with hypogammaglobulinemia, but it has not become the problem it was expected to in AIDS patients. AIDS patients do not seem to be more susceptible to *Giardia* than do healthy people, and when cases occur, treatment is available and effective for this protozoan (1).

In summary, giardiasis causes infection ranging from an asymptomatic carrier state to severe malabsorption syndrome. Factors contributing to the variation in the effects of exposure include the strain of *Giardia,* dose, age of the host, and immune system function of the host.

DIAGNOSIS

Cysts and trophozoite forms are recovered by performing either a flotation or sedimentation procedure to concentrate them from fecal samples. Diagnosis is achieved by demonstrating either form in feces. Once the fecal sample is concentrated, a trichrome stain may be performed to enhance visualization of trophozoite and cyst forms. Fecal concentrates may be examined directly for cyst forms with iodine to enhance visualization. Direct fluorescent antibody (FA) or enzyme-linked immunosorbent assay (ELISA) techniques that incorporate monoclonal antibody-based reagents are also instruments for rapid diagnosis (1).

TREATMENT

Once an infection is diagnosed, treatment is recommended for all cases of *Giardia* for several reasons. First, the infection may cause subclinical malabsorption. The symptoms may be periodic, and if a carrier state develops, asymptomatic carriers are potential sources of infection for others with whom they may come in contact. The treatment of choice is metronidazole for all cases except during pregnancy. Other drugs are available and have been used by infected persons successfully, including paromomycin and tinidazole.

EPIDEMIOLOGY AND PREVENTION

Transmission of viable cyst forms can occur through many modes, including the ingestion of contaminated food or water, direct contact with an infected person such as children in day care centers, any group of people living in close quarters, or through oral/anal sexual practices, especially in male homosexuals. Areas with poor sanitation, such as those that travelers and/or campers may encounter, have resulted in giardiasis being referred to as "traveler's diarrhea." Also, some occupations increase the likelihood of exposure, including sewage and irrigation workers and clinical laboratory workers handling fecal samples. Waterborne outbreaks have occurred in the United States and have been associated with hikers and campers drinking stream water that was contaminated with fecal material from animal reservoirs, such as beavers.

Increased susceptibility has been demonstrated in patients with decreased gastric acidity and with malnutrition in young children in developing countries. The disease is more prevalent in children than in adults and is now reportable to the State Public Health Department and the Centers for Disease Control only in those patients aged 5 years and younger in the United States. The total cases reported in 2002 in the United States was 16,124 (4). Epidemics among adults in this country are seen in association with fecally contaminated food or water. Dogs, cats, and other animals can also carry *Giardia* infection.

To prevent transmission of this disease, personal hygiene must be addressed in all patient populations. Improved sanitation measures can be effective in controlling the person-to-person spread of infection. Travelers are advised to avoid drinking from local water supplies when traveling to foreign countries and to limit intake to bottled water. Iodine disinfection of drinking water as well as the use of filtration systems may serve to allow the decontamination of water sources for campers and travelers.

GRAVITY SEPARATION/SEDIMENTATION

RASHEED AHMAD
Khafra Engineering Consultants
Atlanta, Georgia

Gravity separation or sedimentation is the step in conventional water treatment systems that follows flocculation and precedes filtration. Its purpose is to enhance the filtration process by removing particulate matter. Sedimentation requires that the water flow through a basin at a slow enough velocity to permit the particulate matter to settle to the bottom of the basin before the water exits the basin. The equipment required for this process includes a settling basin of rectangular, square, or circular configuration. The basin includes provisions for inlet and outlet structures and a sludge collection system. In addition, sedimentation systems are optionally equipped with tube or plate settlers to improve performance.

The settling velocity of particles or particulate matter is governed by particle size, shape, density, and water viscosity (which varies with temperature). Stokes' law describes the terminal velocity of discrete spherical particles in a laminar flow regime. In an ideal upflow rectangular settling tank (Figs. 1 and 2), all particles that have a settling velocity greater than the liquid upflow velocity will be captured. This upflow velocity is more commonly called the hydraulic overflow rate or surface loading rate. The surface overflow rate is the primary design parameter for sizing sedimentation basins. This rate is defined as the rate of inflow (Q) divided by the tank surface or floor area (A). Units are typically rated in gallons per day per square foot, gallons per minute per square foot, or cubic meter per hour per square meter. Design hydraulic overflow rates vary with the nature of the settling solids, water temperature, and the hydraulic characteristics of the sedimentation basin.

The settling efficiency for an ideal condition is independent of the depth and dependent on the tank plan

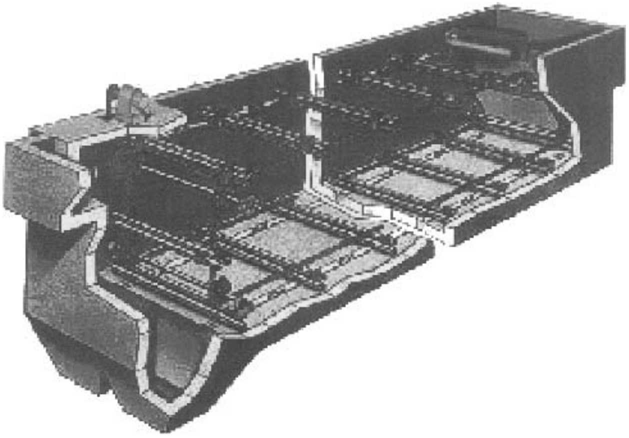

Figure 1. Rectangular sedimentation tank (*Source*: U.S. Filter).

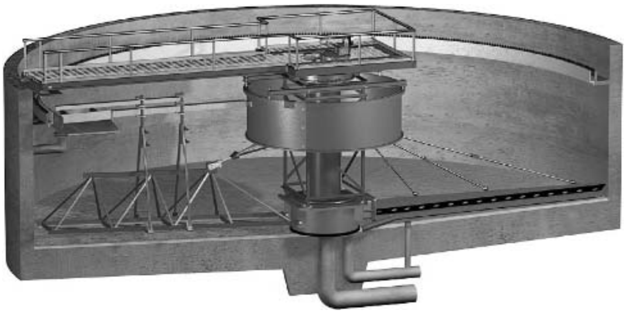

Figure 2. Circular sedimentation tank (*Source*: U.S. Filter).

or surface area. In reality, depth is important because it can affect flow stability if it is large and scouring if small. The basin depth affects flow-through velocity and plays a role in allowing greater opportunity for flocculant particle contact. Conventional settling facilities provided at larger water treatment plants are often long, narrow (4 or 5 to 1 length to width ratio) rectangular basins whose theoretical detention times are in the range of 1.5 to 3 hours at the design flow rate. Most regulatory agencies specify a minimum detention time and a maximum surface overflow rate. Typical sedimentation surface loading rates for long, rectangular tanks and circular tanks using alum coagulation vary from 500 to 1200 gallons per day per square feet (20 to 48 cubic meters per day per square meter). Regulatory agencies sometimes stipulate that weir rates should not exceed around 20,000 gallons per day per linear foot (250 cubic meters per day per meter) of weir. Flow-through velocities of 2 to 4 ft/min (0.6 to 1.2 m/min) are usually acceptable for basin depths of 7 to 14 ft (2.1 to 4.3 m).

Particulate matter settles out of a suspension in one of four different ways, depending on the concentration of the suspension and flocculating properties of the particles. The various settling regimes of particles are commonly referred to as types 1 to 4. In type 1 settling, also called discrete particle settling, the particles have little tendency to flocculate on contact with each other in a dilute suspension when settling. If the particles flocculate, the settling regime in a dilute suspension is identified as type 2 or flocculant settling. In hindered zone, or type 3 settling, the particle concentration causes interparticle effects, which might include flocculation, to the extent that the rate of settling is a function of solids concentration. Compression or type 4 settling develops under the layers of zone settling. The rate of compression depends on time and the force caused by the weight of solids above. In sedimentation, particulate matter removal is largely governed by types 1 and 2 settling. However, types 3 and 4 regimes are dominant in clarification and thickening processes.

High-rate settlers such as tube or plate settlers are often added to settling basins to improve their efficiency, especially if flows are to be increased beyond original design conditions (Figs. 3 and 4). The shallow settling depths and the large surface area provided by tube or plate settlers permit effective sedimentation at detention times of several minutes versus several hours in conventional sedimentation basins. The use of tube or plate settlers in new plant construction minimizes settling basin costs by minimizing the basin size necessary to attain a desired level of treatment. They are generally designed to accept overflow rates ranging from 1400 to 4000 gallons per day per sq foot (55 to 160 cubic meters per day per square meter).

Figure 3. Plate settlers for installation (*Source*: U.S. Filter).

Figure 4. Installed plate settlers (*Source*: U.S. Filter).

In wastewater practice, sedimentation tanks are used in primary and in secondary treatment. They are called primary and secondary clarifiers. For sludge treatment, thickeners are used whose design is also based on sedimentation principles. However, the dominant settling regimes in wastewater treatment are clarification and thickening.

WATER HAMMER

Zacharia Michael Lahlou
Technical Assistance Consultant

Water hammer refers to fluctuations caused by a sudden increase or decrease in flow velocity. These pressure fluctuations can be severe enough to rupture a water main. Potential water hammer problems should be considered when pipeline design is evaluated, and a thorough surge analysis should be undertaken, in many instances, to avoid costly malfunctions in a distribution system. Every major system design change or operation change—such as the demand for higher flow rates—should include consideration of potential water hammer problems. This phenomenon and its significance to both the design and operation of water systems is not widely understood, as evidenced by the number and frequency of failures caused by water hammer.

WHAT IS WATER HAMMER?

Water hammer (or hydraulic shock) is the momentary increase in pressure, which occurs in a water system when there is a sudden change of direction or velocity of the water. When a rapidly closed valve suddenly stops water flowing in a pipeline, pressure energy is transferred to the valve and pipe wall. Shock waves are set up within the system (Fig. 1). Pressure waves travel backward until encountering the next solid obstacle, then forward, then back again (Fig. 2). The pressure wave's velocity is equal to the speed of the sound; therefore it "bangs" as it travels back and forth, until dissipated by friction losses. Anyone who has lived in an older house is familiar with the "bang" that resounds through the pipes when a faucet is suddenly closed. This is an effect of water hammer.

A less severe form of hammer is called surge, a slow motion mass oscillation of water caused by internal pressure fluctuations in the system. This can be pictured as a slower "wave" of pressure building within the system. Both water hammer and surge are referred to as transient pressures. If not controlled, they both yield the same results: damage to pipes, fittings, and valves, causing leaks and shortening the life of the system. Neither the pipe nor the water will compress to absorb the shock.

INVESTIGATING THE CAUSES OF WATER HAMMER

A water transport system's operating conditions are almost never at a steady state. Pressures and flows change continually as pumps start and stop, demand fluctuates, and tank levels change. In addition to these normal events, unforeseen events, such as power outages and equipment malfunctions, can sharply change the operating conditions of a system. Any change in liquid flow rate, regardless of the rate or magnitude of change, requires that the liquid be accelerated or decelerated from its initial flow velocity. Rapid changes in flow rate require large forces that are seen as large pressures, which cause water hammer.

Entrained air or temperature changes of the water also can cause excess pressure in the water lines. Air trapped in the line will compress and will exert extra pressure on the water. Temperature changes will actually cause the water to expand or contract, also affecting pressure. The maximum pressures experienced in a piping system are frequently the result of vapor column separation, which is caused by the formation of void packets of vapor when pressure drops so low that the liquid boils or vaporizes. Damaging pressures can occur when these cavities collapse.

The causes of water hammer are varied. There are, however, four common events that typically induce large changes in pressure:

1. Pump startup can induce the rapid collapse of a void space that exists downstream from a starting pump. This generates high pressures.
2. Pump power failure can create a rapid change in flow, which causes a pressure upsurge on the suction side and a pressure downsurge on the discharge side. The downsurge is usually the major problem. The pressure on the discharge side reaches vapor pressure, resulting in vapor column separation.
3. Valve opening and closing is fundamental to safe pipeline operation. Closing a valve at the downstream end of a pipeline creates a pressure wave that moves toward the reservoir. Closing a valve in less time than it takes for the pressure surge to travel to the end of the pipeline and back is called "sudden valve closure." Sudden valve closure will change velocity quickly and can result in a pressure surge. The pressure surge resulting from a sudden valve opening is usually not as excessive.
4. Improper operation or incorporation of surge protection devices can do more harm than good. An example is oversizing the surge relief valve or improperly selecting the vacuum breaker-air relief valve. Another example is to try to incorporate some means of preventing water hammer when it may not be a problem.

FINDING PRACTICAL SOLUTIONS

The surge pressure must be incorporated with the operating pressure in the design of the pipe. The recommendations and requirements regarding allowances for surge pressure are given in the American Water Works (AWWA) standards and manuals for water supply practice, and vary depending on the type of pipe used. The following tools reduce the effects of water hammer.

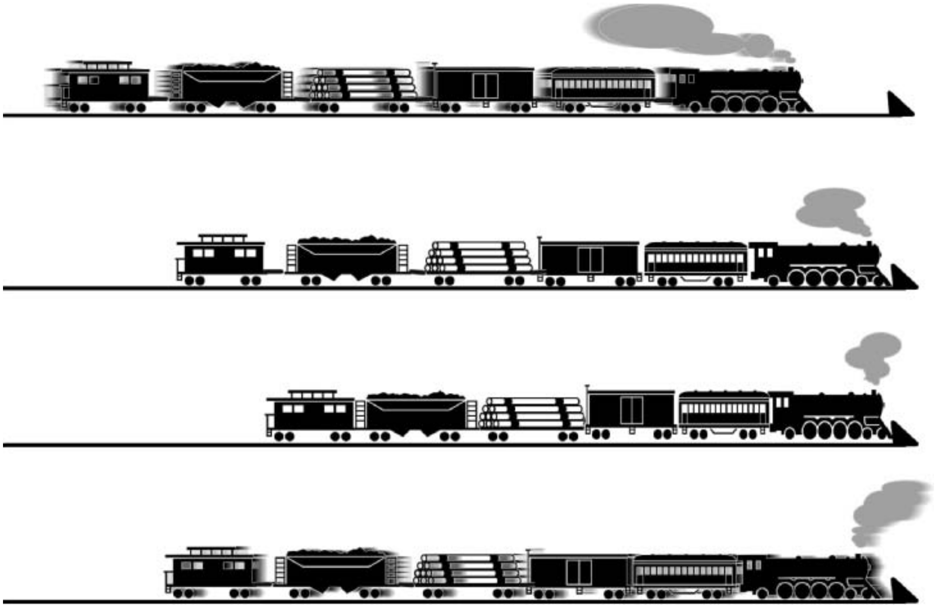

Figure 1. Illustration of water hammer. A column of water acts like a freight train suddenly stopping when an outlet valve is suddenly closed. *Source*: Pickford, John. 1969. *Analysis of Water Surge.* Gordon and Breach Science Publishers.

VALVES

Water hammer often damages centrifugal pumps when electrical power fails. In this situation, the best form of prevention is to have automatically-controlled valves, which close slowly. (These valves do the job without electricity or batteries. The direction of the flow controls them.) Closing the valve slowly can moderate the rise in the pressure when the downsurge wave—resulting from the valve closing—returns from the reservoir.

Entrained air or temperature changes of the water can be controlled by pressure relief valves, which are set to open with excess pressure in the line and then closed when pressure drops. Relief valves are commonly used in pump stations to control pressure surges and to protect the pump station. These valves can be an effective method of controlling transients. However, they must be properly sized and selected to perform the task for which they are intended without producing side effects.

If pressure may drop at high points, an air and vacuum relief valve should be used. All downhill runs where pressure may fall very low should be protected with vacuum relief valves. Vacuum breaker-air release valves, if properly sized and selected, can be the least expensive means of protecting a piping system. A vacuum breaker valve should be large enough to admit sufficient quantities of air during a downsurge so that the pressure in the pipeline does not drop too low. However, it should not be so large that it contains an unnecessarily large volume of air, because this air will have to be vented slowly, increasing the downtime of the system. The sizing of air release valves is, as mentioned, critical.

PUMP

Pump startup problems can usually be avoided by increasing the flow slowly to collapse or flush out the voids gently. Also, a simple means of reducing hydraulic surge pressure is to keep pipeline velocities low. This not only results in lower surge pressures, but results in lower drive horsepower and, thus, maximum operating economy.

SURGE TANK

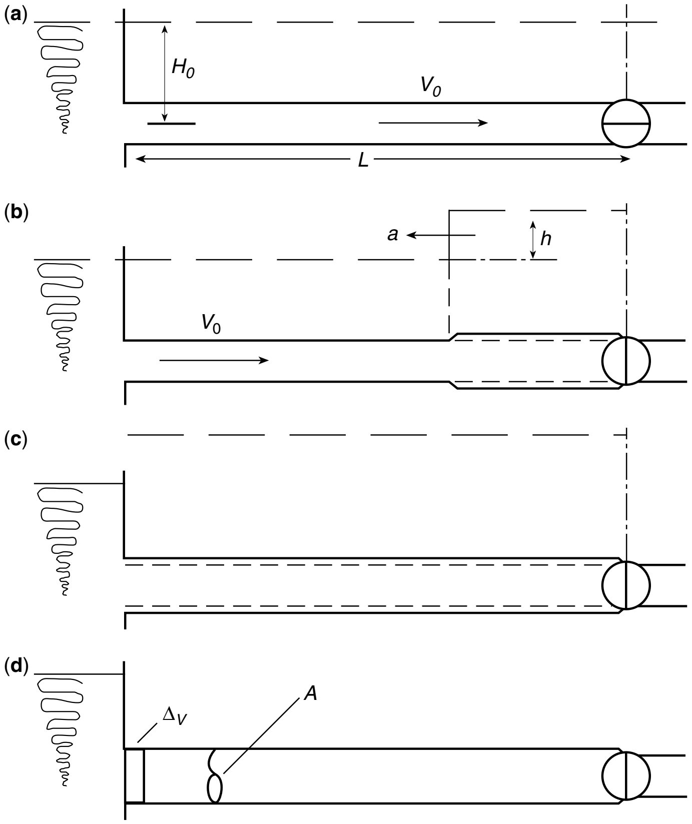
In long pipelines, surge can be relieved with a tank of water directly connected to the pipeline called a "surge tank." When surge is encountered, the tank will act to relieve the pressure, and can store excess liquid, giving the flow alternative storage better than that provided by expansion of the pipe wall and compression of the fluid. Surge tanks can serve for both positive and negative pressure fluctuations. These surge tanks can also be designed to supply fluid to the system during a downsurge, thereby preventing or minimizing vapor column separation. However, surge tanks may be an expensive surge control device.

AIR CHAMBER

Air chambers are installed in areas where water hammer is encountered frequently, and are typically seen behind sink and tub fixtures. Shaped like thin, upside-down bottles with a small orifice connection to the pipe, they are air-filled. The air compresses to absorb the shock, protecting the fixture and piping.

CONCLUSION

Water hammer will continue to challenge engineers, operators, and managers of water systems because it is associated with systems that cannot be exactly defined due to the size and length of the water distribution system with ondulating profile or the lack of definition of the system components such as valves or pumps. There is a need for a more practical approach while research continues



(a)
Valve in open position.

(b)
Valve is shut. A pressure wave moves upstream with velocity "a". At the same time water still enters the pipe with velocity V_0.

(c)
Wave front continues upstream until it reaches the end taking time L/a to reach there. The time 2L/a is known as the "period" of the pipe μ.

(d)
If the total quantity of water that enters the pipe during this time 1/2 μ is ΔV then because it is moving with velocity V_0, $\Delta V = 1/2\ V_0 A\mu$. This whole extra volume of water is occupying the space ($A \times L$) where A is the cross section of the pipe. The resulting increase in pressure or "water hammer" pressure is $P = \mathrm{K}\,\frac{\Delta V}{\Delta L}$.

HAVE YOU READ ALL OUR TECH BRIEFS?

Tech Briefs, drinking water treatment and supply fact sheets, have been a regular feature in the National Drinking Water Clearinghouse (NDWC) publication *On Tap* for more than six years.

A package of *Tech Briefs* is now available as a product. A three-ring binder holds all the current *Tech Briefs* in print. New selections can easily be added to the package as they become available.

To order this free product, call the NDWC at the numbers listed at the bottom of this ad and ask for item #DWPKPE71. Additional copies of fact sheets are also free; however, postal charges may be added. You can also order copies of one or all of the free *Tech Briefs* listed below.

Tech Brief: Organics Removal, item #DWBLPE59;
Tech Brief: Package Plants, item #DWBLPE63;
Tech Brief: Water Treatment Plant Residuals Management, item #DWBLPE65;
Tech Brief: Lime Softening, item #DWBLPE67;
Tech Brief: Iron and Manganese Removal, item #DWBLPE70;

Water Conservation Measures Fact Sheet, item #DWBLPE74;

Tech Brief: Membrane Filtration, item #DWBLPE81;

Tech Brief: Treatment Technologies for Small Drinking Water Systems, item #DWPSPE82;

Tech Brief: Ozone, item #DWBLPE84;

Tech Brief: Radionuclides, item #DWBLPE84;

Tech Brief: Slow Sand Filtration, item #DWBLPE99;

Tech Brief: Ultraviolet Disinfection, item #DWBLPE101;

Tech Brief: Leak Detection and Water Loss Control, item #DWBLPE102;

Tech Brief: Diatomaceous Earth Filtration for Drinking Water, item #DWBLPE108.

Tech Brief: Reservoirs, Towers, and Tanks, item #DWFSOM15

Tech Brief: System Control and Data Acquisition (SCADA), item #DWFSOM20

Tech Brief: Valves, item #DWFSOM21

Tech Brief: Water Quality in Distribution Systems, item #DWFSOM25

HEALTH EFFECTS OF COMMONLY OCCURRING DISINFECTION BYPRODUCTS IN MUNICIPAL WATER SUPPLIES

Raghuraman Venkatapathy
Oak Ridge Institute for Science and Education
Cincinnati, Ohio

Chandrika Moudgal
Brenda Boutin
Robert Bruce
National Center for Environmental Assessment
Cincinnati, Ohio

Disinfectants, such as chlorine, chlorine dioxide, chloramine, and ozone, have been used in drinking water treatment plants throughout the world to disinfect source waters containing disease-causing pathogens. The noteworthy biocidal properties of the disinfectants are somewhat offset by the formation of disinfection byproducts (DBPs) through reactions between the disinfectants and the dissolved organic and inorganic chemicals in raw water.

From the present knowledge of occurrence and health effects, the DBPs of most interest are halomethanes, including trihalomethanes (THMs), haloacetic acids (HAAs), bromate, chlorate, and chlorite, followed by haloacetonitriles, haloacetaldehydes, haloketones, and halonitromethanes (1). In addition, a number of epidemiological studies exist that indicate an association between chronic ingestion of drinking water containing DBPs and increased risk of rectal, bladder, or colon cancer in humans (2–5), but these studies cannot provide information on whether the observed health effects are because of one or more of the hundreds of other DBPs that are also present in drinking water.

Health effects on humans (if available) and animals including general, immunological, neurological, reproductive, and developmental toxicity; mutagenicity [based on the *Salmonella typhimurium* assay (6)]; and carcinogenicity associated with oral exposure to some commonly occurring DBPs are summarized in the sections below. A majority of the health effects observed in these studies were because of exposure to single chemicals at dose levels much above those typically found in drinking water. Hence, health effects associated with drinking water, which typically contains mixtures of DBPs, may be different from those mentioned below.

HALOMETHANES

Data on the health effects of non-THMs are available to a limited extent in the literature. However, THMs, which have been fairly well studied in the literature, are known to induce cytotoxicity in the liver and kidneys of rodents, and to cause cancer in the liver, kidneys, and the large intestine. Most THMs do not induce reproductive or developmental toxicity. In addition, halomethanes are considered to be weak mutagens. Health effects of halomethanes are summarized below.

Chloromethane

Although inhalation of chloromethane may cause damage to the lung and kidneys, no data are currently available for carcinogenic, reproductive, developmental, neurological, and immunotoxicity endpoints because of oral exposures in humans or animals. Chloromethane tested positive for mutagenicity in the *Salmonella typhimurium* assay (7).

Bromomethane

As in the case of chloromethane, direct inhalation of bromomethane may cause seizures and kidney and nerve damage (8). No data exist on health effects because of human oral exposure in the literature. However, limited evidence exists that chronic exposure to bromomethane may occasionally lead to neoplasia in the forestomach at high concentrations in rats (9). At concentrations of 0.4 mg/kg/day (∼40 mg/L) or less, no evidence existed of significant adverse effects in rats (9). Bromomethane tested positive in the *Salmonella* mutagenicity assay (10).

Bromochloromethane

No data on the health effects of oral exposure to bromochloromethane in humans or animals are available in the literature. The only studies that were available in the literature were the *Salmonella* mutagenicity results, which were consistently positive for bromochloromethane (11).

Dibromomethane

No data on the health effects of oral exposure to dibromomethane in humans or animals are available in the literature. Various studies showed a positive response for mutagenicity as measured by the *Salmonella typhimurium* assay (12).

Chloroform

Limited data are available in the literature on death because of oral exposure to pure chloroform in both humans (13) and animals (14–17). Various studies have indicated the liver and kidney as the primary target organs of chloroform toxicity and have observed reversibility in toxic effects on cessation of exposure in both humans (13,18,19) and animals (20,21). However, the doses required to cause toxicity in the liver and kidney were high for both humans and animals. No indications of renal effects were observed in humans (22) and animals (21) because of ingestion of low doses of chloroform. No studies existed on the effect of chloroform exposure on immunological effects in the humans, whereas a few studies documented a reduction in immunity levels in animals exposed to chloroform (23,24). With respect to neurological effects, humans exposed to high concentrations of chloroform immediately fell into a deep coma (13,19), whereas the central nervous system was affected in animals (25,26). An epidemiologic study on drinking water consumption by the population of a small town in northern New Jersey between 1985 and 1988 noticed low birth weight among term babies (27). However, in addition to predominant amounts of chloroform in the drinking water, other THMs were also present in the town's water supply. An equivalent study on animals demonstrated increased resorptions among fetuses at high doses of chloroform in drinking water (20). Other epidemiologic studies have suggested an association between cancer in humans and consumption of chlorinated drinking water predominantly containing chloroform (28–31). However, no concrete evidence exists linking chloroform specifically to the increased incidence of cancer in those studies. In experiments with animals, chloroform has been reported to be carcinogenic in several chronic animal bioassays, with significant increases in the incidence of liver tumors in male and female mice and significant increases in the incidence of kidney tumors in male rats and mice (32,33).

Bromodichloromethane

No studies on the human health effects of bromodichloromethane because of oral exposure were available in the literature. In animals with acute exposures to bromodichloromethane, typical pathological changes observed include fatty infiltration of liver and hemorrhagic lesions in kidney, adrenals, lung, and brain (26). Animals orally exposed to bromodichloromethane show liver and kidney damage followed by death within 2 weeks. Typical signs include increased liver weight, pale discoloration of liver tissue, increased levels of hepatic tissue enzymes in serum, decreased levels of secreted hepatic proteins in blood, and focal areas of inflammation or degeneration (24,34–36). Rats and mice administered oral doses of 150 to 600 mg/kg often displayed acute signs of central nervous system depression, including lethargy, labored breathing, sedation, and flaccid muscle tone, but the signs were reversible several hours after cessation of exposure (25,34,37,38). Ruddick et al. (36) reported fetal and maternal toxicity effects on rats exposed to bromodichloromethane during gestation. With respect to cancer, several epidemiological studies have indicated that an association may exist between ingestion of chlorinated drinking water containing bromodichloromethane and increased risk of cancer in humans (4,5,39), but those studies could not assign the cause of cancer specifically to bromodichloromethane. However, chronic oral studies in animals provide evidence of liver and kidney tumors because of bromodichloromethane exposure (34,40,41).

Dibromochloromethane

No studies exist on human health effects because of oral exposure of dibromochloromethane in the literature. Significant increases in animal mortality have been reported because of acute, subchronic, and chronic oral exposure to dibromochloromethane in the literature (16,26,38,42,43). Typical sites of toxicity in animals exposed to dibromochloromethane include the central nervous system, liver, and kidney (26,43). Oral exposure to dibromochloromethane results in an accumulation of fat in the liver, hepatocyte vacuoles, alterations in serum cholesterol levels, and decreases in serum triglyceride levels followed by liver necrosis at higher doses (16,24,43,44). In addition, tubular regeneration and mineralization leading to nephrosis has been observed in both rats and mice (43). A few studies have examined the potential association between adverse human reproductive outcomes, including spontaneous abortions, stillbirths, and preterm delivery, and the consumption of municipal drinking water containing a mixture of THMs (27,45–53), but they have not been able to implicate dibromochloromethane specifically to the reproductive effects. However, animal studies show an association between reproductive effects and dibromochloromethane in drinking water at high doses. For example, female mice exposed to dibromochloromethane experienced a marked reduction in fertility, with significant decreases in litter size, body weight of the dam and the litter, gestational survival, and postnatal survival (54). Various studies have reported increased incidences of hepatocellular adenomas and carcinomas in mice exposed to dibromochloromethane [summarized in (43)], leading the EPA to classify the chemical as a possible human carcinogen (55).

Bromoform

Several studies in the literature have documented deaths of children because of accidental overdoses of bromoform (when used as a sedative) leading to severe central nervous system depression and respiratory failure (56–58). As in the case of dibromochloromethane, the central nervous system and the liver seem to be the primary sites for bromoform-induced toxicity in animals, leading to liver necrosis and slight nephrosis at higher doses (16,24,43,44). Animal studies that examined the potential of bromoform to induce histological alterations and impair reproductive function indicate that the chemical does not induce any reproductive or developmental effects (59,60). With respect to cancer, an increased incidence of tumors and neoplastic lesions in the large intestines after oral administration of bromoform in rats and intraperitoneal administration in mice was observed, leading the EPA to classify the chemical as a probable human carcinogen (61).

Iodinated THMs

Recently, several iodinated THMs, such as dichloroiodomethane, bromochloroiodomethane, dibromoiodomethane, chlorodiiodomethane, bromodiiodomethane, and iodoform, have been identified in finished water at a few water treatment plants across the United States (1). No human or animal toxicity information on any of the iodinated THMs are available in the literature except for a positive response in the *Salmonella* mutagenicity assay and a negative response for carcinogenicity in mice for iodoform (62).

HALOACETIC ACIDS

Most haloacetic acids of concern have carcinogenic, reproductive, and developmental effects, whereas neurotoxic effects are significant when high doses are used for therapeutic purposes. Carcinogenic effects seem to be limited to the liver at high doses. The health effects of the HAAs are summarized below.

Chloroacetic Acid

Acute exposure of chloroacetic acid by humans may lead to interference with essential enzyme systems in the body, leading to intestinal perforation and peritonitis (63). Rodents exposed to chloroacetic acid orally or by gavage exhibited neurological dysfunction, damage to the respiratory tract including inflammation of the lung and nasal mucosa, metaplasia of the olfactory epithelium, and squamous cell hyperplasia of the forestomach (33,64). In addition, chronic exposure to chloroacetic acid via gavage resulted in myocarditis and mortality because of myocardial failure in rats and hepatic vacuolar degeneration in mice (33,64). No information on the reproductive or developmental effects of chloroacetic acid in animals or humans is available in the literature. With respect to cancer, no significant increase in tumor incidences were reported in studies involving rats and mice exposed to chloroacetic acid (64). In addition, chloroacetic acid was not mutagenic in the *Salmonella typhimurium* assay (64).

Bromoacetic Acid

No studies exist on human health effects because of oral exposure to bromoacetic acid in the literature. Acute exposure of rats to bromoacetic acid lead to various clinical symptoms including excess drinking water intake, hypomobility, labored breathing, and diarrhea (65). No adverse reproductive effects were observed in a spermatotoxicity study involving male rats (65), but developmental effects were observed at high doses in rats (66). Carcinogenic effects of bromoacetic acid have not been evaluated, but the chemical was found to be positive for mutagenicity in the *Salmonella typhimurium* assay (67).

Dichloroacetic Acid

Dichloroacetic acid has been shown to have some beneficial effects in curing a variety of metabolic diseases in humans (68–72). No evidence exists of adverse effects because of acute exposures or exposures at low concentrations in humans. However, limited human experiments coupled with animal studies have indicated that dichloroacetic acid is neurotoxic to humans (70,73). Animals exposed to dichloroacetic acid have been shown to produce developmental, reproductive, neural, and hepatic effects at high doses. Short-term exposure to dichloroacetic acid produced hind-limb paralysis at the highest dose in rats, whereas a significant increase occurred in relative liver and kidney weights and histopathological changes in the brain and testes of dogs (74,75). Reproductive effects include testicular toxicity manifested by distorted sperm heads, fused sperm, and reduced sperm counts in rats exposed to high doses of dichloroacetic acid (75,76), whereas a degeneration of the testicular epithelium and syncytial giant cell formation was noticed in dogs, even at low doses (74). Developmental effects include soft tissue abnormalities in the fetus, interventricular septal defects between the aorta and right ventricle, and urogenital defects in rats (77,78). With respect to cancer, dichloroacetic acid has been shown to be a very effective inducer of hepatic adenomas and carcinomas in both mice and rats at high doses (79–83), thus prompting the EPA to classify the chemical as possibly carcinogenic to humans (84).

Bromochloroacetic Acid

No studies exist on human health effects because of oral exposure to bromochloroacetic acid in the literature. No treatment-related differences in body weight, food and water consumption, clinical observations, or mortality were reported in rats exposed to bromochloroacetic acid for 14 days (85). However, mice showed liver effects including hepatomegaly, glycogen accumulation, and cytomegaly (86). No reproductive, developmental, or embryo toxicity effects were observed in rats treated with low doses of bromochloroacetic acid in a 35-day study (85). However, bromochloroacetic acid at high doses (>600 ppm) produced a consistent decrease in water consumption in both sexes of rats and affected reproductive function in females of both rats and mice (87,88). No data on carcinogenicity were available in the literature; however, bromochloroacetic acid was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (89).

Dibromoacetic Acid

Acute exposures of high doses of dibromoacetic acid by rats lead to several clinical symptoms including excess drinking water intake, hypomobility, labored breathing, diarrhea, and ataxia (65). In addition, histopathological examination of epididymal sperm in surviving animals showed the presence of misshapen and degenerating sperm, and abnormal retention of spermatids (65,90). Male mice exposed to dibromoacetic acid showed an increase in absolute and relative liver weights at doses greater than 125 mg/kg/d (91), whereas female mice showed body weight gain, decrease in thymus weights at 236 mg/kg/d, and increased liver and kidney weights at all tested doses (92). Reproductive effects because of dibromoacetic acid exposure in male rats include adverse effects on caput-sperm count, sperm morphology, and sperm motility, but only marginal changes in reproductive organ weights (90) and decreased fertility as measured by the number of copulations, number of litters, and number of implants and fetuses per litter (93). Immunological effects because of dibromoacetic acid exposure in animals include changes in spleen cell numbers and spleen cell populations, as well as alteration in natural killer cell activity and an antibody-forming cell response to sheep erythrocytes (92). No data on carcinogenicity were available in the literature; however, dibromoacetic acid was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (93).

Trichloroacetic Acid

Acute exposures to trichloroacetic acid by humans can cause severe burning in the mouth, pharynx, and abdomen, and low blood pressure followed by vomiting and diarrhea (94). Animals exposed to high doses of trichloroacetic acid showed liver and kidney effects, including significant increases in relative kidney weight and hepatic peroxisomal beta oxidation activity, and focal areas of hepatocellular hypertrophy and narcosis (95). At lower doses typical of concentrations in drinking water, trichloroacetic acid has been shown to seriously impair water and food consumption (79,81,96,97) and cause liver effects (79,97–99) in experimental animals. Trichloroacetic acid has also been shown to produce reproductive and developmental effects at very high doses in experimental animals, but no effects have been observed at drinking water concentration levels (100–102). With respect to cancer, trichloroacetic acid induces hepatocellular carcinomas, dose-related increases in the incidence of malignant tumors, and precancerous lesions when administered in drinking water to male B6C3F1 mice (79,82,103), but not in rats (104). In addition, trichloroacetic acid has been shown to be negative for mutagenicity in the *Salmonella typhimurium* assay (105).

Bromodichloroacetic Acid

No studies exist on the health effects on humans, and limited studies exist on the health effects on animals, because of oral exposure to bromodichloroacetic acid in the literature. Narotsky et al. (87) reported no maternal toxicity but some developmental toxicity (reduced pup weights) in mice at the highest dose tested. In the only other study (unpublished) available, Bull reported the observance of liver and lung tumors in mice exposed to bromodichloroacetic acid (106). In addition, bromodichloroacetic acid was shown to be weakly positive for mutagenicity in the *Salmonella typhimurium* assay (107).

Dibromochloroacetic Acid

No studies exist on the health effects on humans, and one short-term reproductive and developmental study exists on animals, because of oral exposure to dibromochloroacetic acid in the literature. Results from the reproductive study on rats indicate that although dibromochloroacetic acid produced consistent decreases in food and water consumption in both sexes at doses above 1000 ppm, it did not result in any female reproductive toxicity or any visceral malformation or variations in any pups (108).

Tribromoacetic Acid

No studies exist on the health effects on humans, and one short-term reproductive and developmental study exists on animals, because of oral exposure to tribromoacetic acid in the literature. Results from this reproductive study indicate that tribromoacetic acid at up to 400 ppm marginally reduced water consumption, but it did not affect reproductive function or produce general toxicity in rats of either sex (109). In addition, tribromoacetic acid was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (110).

HALOACETONITRILES

The toxicological effects of haloacetonitriles have not been well studied to date. Although very limited studies exist on the carcinogenicity of this group of chemicals, results of *Salmonella typhimurium* mutagenicity assays are available in the literature. The known health effects of haloacetonitriles are summarized below.

Chloroacetonitrile

No human health studies because of oral chloroacetonitrile exposure are available in the literature. Among the haloacetonitriles, chloroacetonitrile was shown to be metabolized to cyanide in rats and excreted as thiocyanate to the greatest extent (111). Chloroacetonitrile was shown to induce cytotoxic effects and oxidative stress in cultured rat gastric epithelial cells *in vitro* (112). In rat studies, slight decreases in maternal weight gain occurred during the treatment period and in the birth weights of pups born to rats given 55-mg/kg chloroacetonitrile orally on gestation days 7–21 (113). No other evidence of developmental or reproductive effects was reported in the literature. The IARC evaluated the carcinogenic potential of chloroacetonitrile and concluded that inadequate evidence exists for classification purposes, and they were hence assigned to group 3: The agent is not classifiable as to its carcinogenicity to humans (113,114). In addition, chloroacetonitrile was shown to be negative for mutagenicity in the *Salmonella typhimurium* assay (115).

Bromoacetonitrile

No human health studies because of oral bromoacetonitrile exposure are available in the literature. Rats exposed to high doses of bromoacetonitrile (>500 ppm) in drinking water resulted in significant reductions in body weight and reductions in feed and water consumption (116). At lower doses, study results indicated that a significant aversion to bromoacetonitrile in the water existed and suggested that the chemical may be a possible mild renal toxicant at 100 ppm as evidenced by an increase in blood urea nitrogen, and a potential reproductive toxicant at the same dose as evidenced by increased post-implantation loss (116). No studies on the carcinogenicity potential of bromoacetonitrile are available in the literature. However, bromoacetonitrile was shown to be negative for mutagenicity in the *Salmonella typhimurium* assay (117).

Dichloroacetonitrile

No human health studies because of oral dichloroacetonitrile exposure are available in the literature. In rats exposed to dichloroacetonitrile in corn oil by gavage, increased mortality was observed at 33-mg/kg/d dose, whereas decreased body weight, lower organ weight, and organ-to-body weight ratios were observed for spleen and gonads at higher doses (118). However, no serum chemistry changes indicative of adverse effects were seen at sublethal doses (118). Reproductive effects in rats because of dichloroacetonitrile exposure by gavage during gestation include significantly reduced percentage of females delivering litters, increased resorption rates, reduced mean birth weight of pups, and reduced maternal weight gain (119). Developmental effects in rats exposed to dichloroacetonitrile resulted in soft tissue anomalies, including an intraventricular septal defect in the heart, hydronephrosis, fused ureters and cryptorchidism, and skeletal abnormalities such as fused and cervical ribs (120). The IARC evaluated the carcinogenic potential of dichloroacetonitrile and concluded that inadequate evidence exists for classification purposes, and they were hence assigned to group 3: The agent is not classifiable as to its carcinogenicity to humans (113,114). However, dichloroacetonitrile was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (121).

Bromochloroacetonitrile

No human health effect studies because of oral bromochloroacetonitrile exposure are available in the literature. In rats exposed to bromochloroacetonitrile in corn oil by gavage, reduced mean birth weight of pups and reduced postnatal weight gain were observed to a much lesser extent than rats exposed to dichloroacetonitrile (119). Christ et al. (122) reported maternal toxicity and urogenital, skeletal malformations at doses above 65 mg/kg/d and total litter loss at 45 mg/kg/d in rats, whereas lower doses resulted in shorter fetal crown-rump lengths, reduced fetal weights, and increased frequency of cardiovascular malformations. Female mice treated with bromochloroacetonitrile showed a significant increase in the incidence of lung adenomas; however, the authors cautioned that a large variation in background incidence of lung tumors was also observed in the same species (123). However, bromochloroacetonitrile was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (124).

Dibromoacetonitrile

No human health effect studies because of oral dibromoacetonitrile exposure are available in the literature. In rats exposed to dibromoacetonitrile in corn oil by gavage, increased mortality was observed at 45-mg/kg/d dose (118). However, no serum chemistry changes indicative of adverse effects were seen at sublethal doses (118). Reproductive effects in rats exposed to dibromoacetonitrile were similar to effects observed in rats exposed to bromochloroacetonitrile (119). In addition, exposure to dibromoacetic acid reduced water consumption in male and female rats exposed to doses greater than 50 ppm; however, no other reproductive effects were observed in the animals (125). Female mice treated with dibromoacetonitrile showed only a marginal increase in the incidence of lung adenomas (123). In addition, dibromoacetonitrile was shown to be weakly positive for mutagenicity in the *Salmonella typhimurium* assay (126).

Trichloroacetonitrile

No human health effect studies because of oral trichloroacetonitrile exposure are available in the literature. Reproductive effects in rats because of trichloroacetonitrile exposure by gavage during gestation include a significantly reduced percentage of females delivering litters, increased resorption rates, reduced mean birth weight of pups, and reduced maternal weight gain (119). Developmental effects observed in rats include embryolethality with doses as low as 7.5 mg/kg/d and soft tissue abnormalities, including fetal cardiovascular anomalies and cardiovascular and urogenital malformations with a 15-mg/kg/d dose (127). Female mice treated with trichloroacetonitrile showed a significant increase in the incidence of lung adenomas; however, the authors cautioned that a large variation in background incidence of lung tumors was also observed in the same species (123). In addition, trichloroacetonitrile was shown to be weakly positive for mutagenicity in the *Salmonella typhimurium* assay (128).

HALOACETALDEHYDES AND HALOKETONES

Trichloroacetaldehyde is the most common haloacetaldehyde found in drinking water. Other acetaldehydes and haloketones found at low concentrations include dichloroacetaldehyde, bromochloroacetaldehyde and tribromoacetaldehyde, chloropropanone, and di-, tri-, and tetrahalopropanones. Limited toxicity data are available for the halogenated aldehydes and ketones other than trichloroacetaldehyde. Chloroacetaldehyde exposure causes hematological effects (129) and liver tumors (130) in rats. Exposure of mice to 1,1-dichloropropanone resulted in liver toxicity (131). Some halogenated aldehydes and ketones are potent inducers of mutations in bacteria (132–139). Other halogenated aldehydes, e.g., 2-chloropropenal, have been identified as tumor initiators in the skin of mice (131). The haloketones have not been tested for carcinogenicity in drinking water. However, 1,3-DCPN acted as a tumor initiator in a skin carcinogenicity study in mice (131). The health effects of trichloroacetaldehyde are summarized below.

Trichloroacetaldehyde Monohydrate

The primary effect seen with ingestion of trichloroacetaldehyde monohydrate or chloral hydrate in humans is central nervous system depression, the basis of its use in therapeutics (140–142). At high doses, chloral hydrate produces cardiac arrhythmias (141–144) and liver damage (140,145), whereas at lower doses, high incidences of direct hyperbilirubinemia were observed in newborns (146). In animals, hepatocellular necrosis has been observed in rats dosed with 1200-mg/L chloral hydrate (147), whereas mice displayed hepatomegaly at a dose of 144-mg/kg/d chloral hydrate (148). In a reproductive study, Klinefelter et al. (149) observed a significant decrease in the percentage of motile sperm in rats exposed to 188-mg/kg/d chloral hydrate, whereas Saillenfait et al. (101) observed developmental effects *in vitro* using a rat whole-embryo culture system. A chronic bioassay in female mice showed a slight increase in the severity grade of hyperplasia and a slight increase in the incidence of adenoma in the pituitary gland pars distalis at the highest exposure tested, whereas some evidence existed that chloral hydrate causes hepatocellular tumors in male mice (150). As a result of a lack of human carcinogenic studies and inadequate animal studies, the EPA has classified chloral hydrate as a Group C or possible human carcinogen (151). In addition, chloral hydrate was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (152).

MISCELLANEOUS CHEMICALS

Many other DBPs that are found in low concentrations can be found in drinking water. DBPs whose health effects have been summarized below include MX, chloropicrin, and the inorganic chemicals bromate, chlorate, and chlorite.

MX (3-Chloro-4-(Dichloromethyl)-5-Hydroxy-2(5H)-Furanone)

No human health effect studies because of oral MX exposure are available in the literature. In acute animal studies, mice that died within 24 hours of receiving a dose of 128 mg/kg MX were found to have enlarged stomachs with moderate hemorrhagic areas in the forestomach (153). In a second study, very limited mortality was observed in mice administered a dose of 144 mg/kg (154). Other effects observed in the study included focal epithelial hyperplasia in the stomach, vacuolation of the superficial villus epithelium in the duodenum and jejunum, increased numbers of mitotic figures in the liver, and some cytotoxicity in the urinary bladder (154). Meier et al. (155) observed reduced hepatic levels of catalase, cytochrome P450 reductase, aminopyrine demethylase, and aromatic hydrocarbon hydroxylase, thereby leading to potential modifications of metabolism of various xenobiotics and endogenous biochemicals in rats exposed to 64-mg/kg/d MX for 14 days. Vaittinen et al. (156) observed some lethality, hypersalivation, wheezing respiration, emaciation, tangled fur, increased water consumption, decreased body weights and food consumption, elevated plasma cholesterol, increased relative weights in the liver and kidneys, and increased urine excretion in rats dosed with 75-mg/kg/d MX for 14 weeks. MX administered to rats in drinking water for 104 weeks showed dose-dependent increases in tumors of the lung, mammary gland, hematopoietic system, liver, pancreas, adrenal gland, and thyroid (157). In addition, chloral hydrate was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (158).

Chloropicrin

Humans exposed orally to chloropicrin produced severe nausea, vomiting, colic, diarrhea, respiratory problems, and sometimes death (159,160). Health effects in rats orally exposed to chloropicrin include significantly reduced mean body and thymus weights and death because of pulmonary complications at high doses and dose-related histological changes in the stomach including forestomach inflammation, necrosis, acantholysis, hyperkeratosis, and ulceration (161). Oral developmental and reproductive animal studies were not available in the literature, but an inhalational study on rats and rabbits reported developmental toxicity in both species manifested as reduced fetal body weight, and maternal toxicity manifested in rats by mortality, reduction in body weight gain, and, in rabbits, by mortality, abortion, and inhibition of body weight gain and food consumption (162). In cancer studies involving rats and mice, proliferative lesions of the squamous epithelium of the forestomach, including carcinoma, papilloma, acanthosis, and hyperkeratosis, were observed in the dosed animals (163). However, owing to the short survival time of the dosed animals, conclusive evidence of carcinogenicity could not be established (163). However, chloropicrin was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (164).

Chlorite

No treatment-related effects were observed in humans exposed to rising doses of chlorite in drinking water (165). Short-term toxicity studies in rats, mice, cats, and monkeys indicated oxidative stress and signs of hemolytic anemia with decreases in red blood cell count, hemoglobin concentration, and hematocrit (166–171). The study results also indicated that although the changes in the blood parameters decreased in severity with duration of exposure, signs of oxidative stress remained elevated. Reproductive and developmental effects because of 100-mg/kg/d chlorite exposure include reduced conception rate and number of pups alive at weaning in mice (172) and vaginal and urethral bleeding, decreased body weight and food consumption, and mortality in rats (173,174). However, no effects were observed in animals dosed with chlorite at drinking water concentration levels. Chronic oral studies in rats showed no evidence of carcinogenicity (175), whereas mouse studies showed an increase in liver and lung tumors in male mice (176,177). However, the relatively short study duration and high mortality in the controls made the study interpretation difficult, leading the EPA to classify chlorite as a Group D chemical: not classifiable as to human carcinogenicity because of inadequate data (151). However, chlorite was shown to be positive for mutagenicity in the *Salmonella typhimurium* assay (178).

Chlorate

There have been a few reports of chlorate poisoning with evidence of oxidative damage to erythrocytes, methemoglobin formation, and hemolytic anemia in humans (179–182). In animals, high acute doses of 1000 mg/kg/d or higher induced methemoglobinemia and discoloration of the kidneys in dogs (183,184), but no consistent effects were noted in rats exposed to 10-mg/kg/d chlorate for 12 months (168). In an NTP study on reproductive and developmental effects because of chlorate exposure, transient changes in maternal food intake, urinary color, and/or output were noted at >100 mg/kg/d, but clear evidence of maternal toxicity was observed only at doses greater than 475 mg/kg/d in the screening study (185). In addition, chlorate did not cause any significant treatment-related developmental toxicity under the conditions of this study. In the lone cancer study available in the literature, a statistically insignificant increase in incidence of renal cell tumors in the N-ethyl-N-hydroxyethylnitrosamine-initiated rats treated with sodium chlorate was observed, but no effect was observed with potassium chlorate (186). In addition, chlorite was shown to be negative for mutagenicity in the *Salmonella typhimurium* assay (187).

Bromate

Clinical signs of bromate poisoning in humans include anemia, hemolysis, renal failure, and hearing loss (188,189). Acute toxic effects of bromate in rats, mice, and hamsters include suppressed locomotor activity, ataxia, tachypnoea, hypothermia, diarrhea, lacrimation and piloerection, hyperemia of the stomach, congestion of lungs, and damage to renal tubules including necrosis in the proximal tubular epithelium (189). Elevated levels of glutamate-oxalate transaminase, glutamate-pyruvate transaminase, lactate dehydrogenase, alkaline phosphatase, and blood urea nitrogen were observed in blood samples of rats exposed to bromate for 13 weeks (189,190). An NTP study on reproductive and developmental toxicity in rats indicated no reproductive effects in females but suggested that bromate may be a selective male reproductive toxicant at 250-ppm dose or higher (191). Cancer studies on rats indicated tumors at multiple sites including the kidney, thyroid, and the peritoneum (175,176,192), leading the EPA to classify bromate as a probable human carcinogen (193). However, bromate was shown to be weakly positive for mutagenicity in the *Salmonella typhimurium* assay (178).

MODELED TOXICITY ESTIMATES

Quantitative structure activity relationships (QSARs) may be used to estimate toxicities of many DBPs that lack experimental data in the literature. Commercial QSAR software packages such as DEREK (LHASA Ltd., Leeds, UK), CASE and MULTICASE (MultiCase Inc., Cleveland, OH), COMPACT (School of Biological Sciences, University of Surrey, UK), HazardExpert (Compudrug Ltd., Budapest, Hungary), ONCOLOGIC (Logichem Inc., Boyertown, PA), and TOPKAT (Accelrys Inc., Birmingham, MA) are able to predict the toxicities of a wide variety of chemicals for a number of health endpoints. In this section, TOPKAT has been used to estimate various toxicological endpoints for DBPs of health concern. Table 1 lists the rodent carcinogenicity based on the weight of evidence, Salmonella mutagenicity, rat developmental toxicity, lethal dose that causes 50% mortality in a rat study population, and the lowest dose that causes an adverse effect in rats. The procedure for estimating the endpoints using TOPKAT and its potential limitations are listed in Venkatapathy et al. (195) and Moudgal et al. (196,197).

HEALTH EFFECTS OF MICROBIAL CONTAMINANTS AND BIOTOXINS IN DRINKING WATER

Raghuraman Venkatapathy
Oak Ridge Institute for Science and Education
Cincinnati, Ohio

Brenda Boutin
Chandrika Moudgal
Robert Bruce
National Center for Environmental Assessment
Cincinnati, Ohio

Although drinking water quality has increased dramatically over the last century because of better treatment of raw water through processes such as disinfection, protection of source waters, and better sewage disposal practices, increasing pressure on available water sources through factors such as increased population, increased consumption, inadequate sewage treatment, runoffs, confined feedlot operations, and floods have resulted in a heavier load of contaminating micro-organisms into many water treatment plants. Established disinfection and filtration techniques may not always remove such microbial contaminants from drinking water. Although a majority of these contaminants are harmless, a few of them are pathogens and may cause diseases in populations exposed to the contaminated drinking water, especially in sensitive individuals and in the immunocompromised.

Drinking water pathogens that have been implicated in waterborne diseases include algae, bacteria, fungi, protozoa, and viruses. Waterborne diseases are usually acute in nature, are rarely fatal, and are often characterized by gastrointestinal symptoms (1). The severity and duration of illness is generally greater in weakened immune systems such as in children, the elderly, people on chemotherapeutic drugs, and those with AIDS (1).

ALGAE

Unlike other waterborne micro-organisms, such as bacteria, viruses, protozoa, and fungi, algae use photosynthesis as their primary mode of nutrition. Algae are not pathogenic to humans, but some species produce biotoxins that may be harmful to humans at high enough concentrations. In particular, algae produce toxins that affect the liver (hepatotoxins) and the nervous system (neurotoxins). The most environmentally relevant toxins are produced by cyanobacteria.

Cyanobacteria

Cyanobacteria, or blue-green algae, have characteristics of both algae and bacteria, and they generally occur in calm, nutrient-rich waters. People may be exposed to cyanobacterial toxins by drinking or bathing in contaminated water. Symptoms include skin irritation, stomach cramps, vomiting, diarrhea, fever, sore throat, headache, muscle and joint pain, blisters, and liver damage (2). Species that produce hepatotoxins include some strains of *Microcystis, Anabaena, Oscillatoria, Nodularia, Nostoc, Cylindrospermosis*, and *Umezakia*, whereas some strains of *Aphanizomenon* and *Oscillatoria* produce neurotoxins (2). Although physical methods of coagulation and filtration may remove cyanobacteria from water, ozonation and treatment with permanganate are necessary to destroy the toxins (2).

BACTERIA

Bacteria are cylindrical or spherical single-celled microorganisms that possess no nucleus. Common types of pathogenic bacteria that are found in drinking water include *Salmonella, Shigella, Campylobacter, Legionella, Escherichia coli, Vibrio cholerae*, and *Pseudomonas*. The health effects of common bacterial pathogens are described below.

Aeromonas

Aeromonas is an opportunistic bacterium that is commonly found in ground and surface waters, sewage, biofilms, and filtration units, and it may occasionally cause enteritis, septicemia, colitis, and puncture wound infections, particularly in the immunocompromised (3–6). Several species of *Aeromonas* may exist in the source waters including *A. bestiarum, A. caviae, A. eucrenophilia, A. hydrophilia, A. media, A. popoffii, A. salmonicida, A. schubertii*, and *A. veronii* (7). *Aeromonas* in water may be controlled through filtration and disinfection with chlorine, whereas *Aeromonas* in biofilms are relatively resistant to chlorination (8).

Campylobacter

C. coli and *C. jejuni* are found in sewage, ground and surface waters, and biofilms and are behind one of the most common bacterial causes of enteritis (3,9,10). *Campylobacter* may be controlled through chlorination (11).

Escherichia Coli

Of the more than 140 known serotypes of *E. coli*, 11 serotypes are known to cause gastrointestinal and other diseases in humans, including enteritis, colitis, kidney disease, and hemolytic uremic syndrome (3,9,12). The serotype *E. coli* O157:H7 is known to cause bloody diarrhea in infants (13). *E. coli* is generally transmitted through sewage and ground and surface waters, and it may be effectively controlled through disinfection (14).

Legionella

Of the 25 identified species of *Legionella*, a few may cause a type of pneumonia called Legionnaire's disease (13). The majority (90%) of the cases of Legionnaire's disease in the United States are caused by *L. pneumophila*, which is transported through ground and surface waters and aerosolized water, such as in hot water cooling towers, and is known to cause legionellosis, nosocomical and respiratory infections, pneumonia, and Pontiac fever (3,9,15,16). Free-floating *Legionella* may be effectively controlled through treatment with ozone, chlorine dioxide, and UV light, but *Legionella* inside suspended particles or free-living amoeba may be immune to disinfection (17).

Mycobacterium

Various species of NTM or nontuberculosis causing *Mycobacterium*, including *M. avium complex* (MAC), *M. chelonei, M. fortuitum, M. gordonae, M. kansasii, M. marinum, M. paratuberculosis, M. phlei*, and *M. xenopi*, are disseminated through biofilms, sewage, ground and surface waters, air, biofilms, and aerosolized water and can cause nosocomial infections, septicemia, skin lesions, various pulmonary diseases, and lymphadenitis, particularly in the immunocompromised (3). In addition, MAC colonizes water distribution systems, thereby recontaminating treated drinking water and generally infects the immunocompromised (3). *Mycobacterium* is relatively resistant to disinfection and can survive in hot water (18).

Pseudomonas

P. aeruginosa and *P. pseudomallei* are commonly found in ground and surface waters, sewage, and biofilms, and they cause various gastrointestinal, nosocomial, and respiratory infections in the immunocompromised (3,9). *Pseudomonas* may be disinfected through chlorination or UV treatment (19).

Salmonella

A majority of the waterborne *Salmonella* species are commonly found in sewage and surface waters and are pathogenic to humans. *S. enteritidis, S. montevideo B*, and *S. typhimurium* cause gastroenteritis and salmonellosis, whereas *S. typhi* and *S. paratyphi* (A & B) cause typhoid and paratyphoid fevers, respectively (9,20). *Salmonella* may be controlled by disinfection (21,22).

Shigella

S. sonnei, S. flexneri, S. boydii, and *S. dysenteriae* are found in sewage and ground and surface waters and may cause dysentery in exposed individuals (9,23). *S. sonnei* causes the bulk of waterborne infections among the four *Shigella* species listed above. Common disinfection processes are effective against controlling *Shigella* in drinking water.

Vibrio

V. cholerae is the most well known of the *Vibrio* species. It causes cholera, an acute intestinal disease with diarrhea, vomiting, and dehydration, and it is found in sewage and ground and surface waters (9,20). Severe cases of cholera may be fatal if left untreated for a few hours. *V. fluvialis, V. mimicus, V. parahaemolyticus*, and *V. vulnificus* are transmitted though surface waters and marine life and may cause enteritis and gastroenteritis (9). *Vibrio* may effectively be disinfected through treatment with chlorine (24).

Yersinia Enterocolitica

Y. enterocolitica is found in sewage and surface water and is carried by animals and humans (9). It can cause gastrointestinal illness including enteritis (9). *Y. enterocolitica* can be controlled through the use of chlorine (25).

FUNGI

Species such as *Aspergillus, Penicillium, Alternaria, Candida, Trichophyton*, and *Cladosporium* have been isolated from chlorinated water and service mains (26,27). Inhalation of large numbers of fungal spores can cause respiratory diseases, including pneumonia, fever, and meningoencephalitis, especially in the immunocompromised (28,29). Fungal spores are relatively resistant to chlorine (30), but a combination of coagulation, slow sand filtration, and disinfection can reduce the number of spores to a limited extent (31).

PROTOZOA

Protozoa are single-celled nucleated organisms that are typically larger than bacteria and lack a cell wall. Protozoa that are waterborne and pathogenic to humans are often found as resistant forms that protect themselves from environmental stresses (13). Common protozoa found in drinking water include *Giardia, Entamoeba*, and *Cryptosporidium*. The health effects associated with exposure to protozoa are described below.

Acanthamoeba

Acanthamoeba is a group of amoebae found in sewage and drinking water that can cause meningoencephalitis and amebic keratitis (9,32,33) and have been associated with causing cutaneous lesions and sinusitis in the immunocompromised (33). *Acanthamoeba* are relatively resistant to disinfection and have to be removed through filtration (34).

Cryptosporidium

Cryptosporidium, especially *C. parvum*, is commonly found in ground and surface waters, sewage, and springs and causes cryptosporidiosis in humans (9,35,36). Cryptosporidiosis may be severe and chronic in the immunocompromised and may hasten death (37). *Cryptosporidium* is resistant to disinfection by chlorine and chloramines, although ozone, chlorine dioxide, and filtration are more effective (38,39).

Cyclospora

C. cayetanensis is found in sewage and surface waters and causes gastroenteritis including diarrhea, abdominal cramping, decreased appetite, and fever (40). The symptoms may be chronic and unremitting in the immunocompromised (41). *Cyclospora* may be resistant to chlorine and have to be removed through filtration (42).

Entamoeba

E. histolytica is found in drinking water contaminated by sewage and causes amoebic dysentery with symptoms ranging from acute bloody diarrhea and fever to mild gastroenteritis (9,13). The effects of disinfection on *Entamoeba* are unknown. However, *Entamoeba* cysts are less robust than those of some other types of protozoa.

Giardia

G. lamblia are found in ground and surface waters, sewage, and springs and cause giardiasis, a gastrointestinal disease manifested by diarrhea, fatigue, and cramps (9,43). *Giardia* cysts can remain infective in water for 1 to 3 months, depending on the temperature (13). *Giardia* cysts are resistant to chlorine disinfection but may be removed through filtration (44).

Microspora

Microsporidia, especially *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*, are fairly common in the environment and may cause microsporidiosis in humans, especially the immunocompromised (45,46). Symptoms include diarrhea and illnesses of the respiratory tract, urogenital tract, eyes, kidneys, liver, or muscles (45–47). *Microsporidia* spores are more susceptible to disinfection using chlorine than *Cryptosporidia* (48).

Naegleria

N. fowleri is an opportunistic amoeba that is primarily found in ambient waters, drinking water, and recreational facilities that contain warm water, such as swimming pools, and causes primary amoebic meningoencephalitis (PAM), a fatal disease that leads to death within 72 hours after the appearance of symptoms (9,49). However, no reported occurrences of *Naegleria* outbreaks through drinking water in the United States exist, although there have been several fatalities from *N. fowleri* contacted through recreational water (49). Data suggest that disinfection through chlorination may not be effective in removing *Naegleria* at the doses typically used in treatment plants (50). However, exposure to *Naegleria* may be reduced by avoiding contact with warm waters.

Toxoplasma

T. gondii is found in surface waters and may cause toxoplasmosis in fetuses and the immunocompromised (51). Although *Toxoplasma* oocysts originate from cat feces, transmission may also come from tissue or meat of other infected animals (51). Symptoms include fever, swelling of the lymph glands, blindness, mental retardation, and encephalitis (52). Although chlorination is not effective against *Toxoplasma*, filtration may be used in removing the organism (53).

VIRUS

Viruses are a large group of infectious agents that consist of a protein coat and a nucleic acid core. Most pathogenic waterborne viruses cause gastrointestinal diseases, whereas others may cause serious sequelae such as diabetes. Pathogenic viruses found in drinking water include adenoviruses, caliciviruses, Norwalk virus, coxsackieviruses, echovirus, hepatitis viruses, poliovirus, and rotavirus. The health effects of common viruses are described below.

Adenovirus

Adenoviruses are transported through ground and surface waters, sewage, and mucus and cause gastroenteritis, pharyngitis, conjunctivitis, and the common cold, especially in children (9). Adenoviruses are relatively resistant to disinfectants (13).

Astrovirus

Astroviruses are small, star-like viruses that are transported through ground and surface waters and sewage and cause gastroenteritis, especially in very young children and in the immunocompromised (9,54). Astroviruses are resistant to disinfection, but infection may be prevented through frequent handwashing (55).

Calicivirus

The calicivirus, including the Norwalk virus, is a common cause of gastroenteritis and is transported through ground and surface waters and sewage (9). Illness is generally mild, although gastroenteritis-induced dehydration may cause death in infants and young children (9). Ozone disinfection is effective against the caliciviruses (56).

Enterovirus

The most common enteroviruses (viruses that are found in the intestine) include the coxsackieviruses, echoviruses, and the polioviruses. Enteroviruses are generally found in ground and surface waters and sewage (9). Coxsackieviruses and echoviruses produce a variety of illnesses, including meningitis, enteritis, cold, fever, and heart disease (9). The polioviruses cause poliomyelitis, a paralytic disease (9). Enteroviruses may be resistant to chlorination (57).

Hepatitis Virus

Hepatitis A and E viruses cause infectious hepatitis, an illness characterized by inflammation of liver, fever, abdominal pain, weakness, and a lack of appetite (3,9). Hepatitis E infections are mild except for pregnant women, who may have a fatality rate of about 39% (13). Hepatitis A virus may be more resistant to disinfection than other enteric viruses (58).

Rotavirus

Rotaviruses are found in sewage and ground and surface waters and cause acute gastroenteritis, especially in children (3,9). Rotaviruses may be removed through filtration or inactivated by chlorine, chlorine dioxide, and ozone (59–61).

DRINKING WATER AND PUBLIC HEALTH PROTECTION

Daniel A. Okun
(from *Drinking Water Regulation and Health*, Wiley 2003)
University of North Carolina
Chapel Hill, North Carolina

INTRODUCTION

The provision of drinking water for communities is an urban utility, but a utility with a difference. As with other urban utilities, such as electricity and gas, water for household use is a necessity that cannot readily be obtained by urban householders for themselves. The difference is that, while water may satisfy many household needs, including drinking, it has the potential of spreading disease, often without the knowledge of the consumer. As a result, water supplies have become subject to regulations for assuring adequate quality, regulations that are not faced by other municipal public utilities.

Beginning with the water supply for Rome some 2000 years ago, the responsibility for water supply and its quality rested with the community. During the nineteenth century, with the beginning of the industrial era and the rapid growth of cities, public water supplies began to be provided by private entrepreneurs who sought profit in providing an essential service, frequently in competition with others. In the interest of getting a larger share of the market, they might provide a water of better quality than a competitor. The experiences with the provision of water for London from the Thames in the 1850s illustrate that the selection of the source of a water supply is important. Then Dr. John Snow took advantage of the competition between two water suppliers to prove that water was responsible for the transmission of cholera.

As cities grew, the need for large capital investments to provide adequate water supplies of high quality resulted in most cities abandoning private utilities when it became clear that they did not have the financial resources for the construction of the reservoirs, the long transmission lines, and the treatment plants. Decisions for selection of sources and treatment, which were introduced in the late nineteenth—early twentieth century, became the responsibility of the community, and not a regulatory body.

Treatment in the form of filtration and then chlorination was widely introduced, although not primarily through regulation. City officials recognized that they had an obligation to their constituencies to provide water that would not spread typhoid and cholera. Some cities were slow to assume this responsibility, and, in the United States, some newly organized state health agencies began to institute regulations. The choice of sources between a costly high-quality upland supply and a polluted source and the treatment to be provided was local.

The first nationwide water quality regulations in the United States were introduced by the federal government in 1909 to assure the safety of water to which the public was exposed in interstate and international traffic. Many states adopted these regulations even for smaller cities that did not have train or bus service. These federal regulations were upgraded over the years, and the bulk of this chapter is devoted to the nature of these regulations at the federal level until the passage of the Safe Drinking Water Act (SDWA) in 1974, after the U.S. Environmental Protection Agency (USEPA) became responsible for ensuring the safety of all public water supplies.

This article recounts the high points in the history of the role that urban water supplies play in the health of those who are obliged to drink from public supplies, beginning with concerns with the water supply for Rome, followed by the story of the cholera outbreaks in London that led to the recognition that water was responsible for the spread of infectious disease, the introduction of successful public health measures to control infectious disease, and the explosion of the chemical revolution that became responsible for the spread of chronic disease through ingestion of public water supplies (1).

WATER SUPPLY FOR THE CITY OF ROME

Among the major ancient cities of the world, none was better provided with water for its citizens than Rome. Initially, the city obtained its water from the Tiber River, which ran through the city. When it was apparent that the water had become heavily polluted, Appius Claudius built an aqueduct, the Aqua Appia, in 312 B.C. from the Tiber, about 11 miles upstream. Some 40 years later, the need was so great that a second aqueduct, 40 miles long, the Anio Novis, was built. Sextus Julius Frontinus, the water commissioner of Rome, wrote two books describing the water works of the city and their management (2). By A.D. 305, 14 aqueducts were serving the city.

The aqueducts fed the city by gravity with relatively short sections passing over valleys on stone arches, some three tiers high. Many of them carried water into the twentieth century. Such aqueducts remain throughout Europe and the Middle East as monuments to the early Romans.

The water from the aqueducts passed through large cisterns and from these was distributed through lead pipes to other cisterns, to public buildings, baths, and fountains, and to a relatively small number of private residences. Incidentally, they also built stone sewers to carry off wastewater from bathtubs and toilets in the larger buildings.

Frontinus questioned the wisdom of Augustus, whom he considered a most cautious ruler, in building one of the aqueducts, the Alsietinian, because the quality of its water was very poor and not suitable for the people. He speculated that Augustus built the aqueduct to serve nonpotable purposes and thereby "to avoid drawing on better sources of supply." The most important nonpotable use was for a *naumachia*, an artificial lake that was used for exhibitions of sham naval battles (Fig. 1). This is also current practice in American cities that erect stadia for baseball, football, and basketball on behalf of the team owners. The surplus nonpotable water was used for landscape irrigation and fountains. Words from an inscription state: "I gave the people the spectacle of a naval combat.... Besides the rowers, three thousand men fought in these fleets."

Thus, Rome can claim to be the first city to employ a dual distribution system and to base the use of its water supply on its quality. The water quality from the aqueducts was variable, and the Marcia aqueduct carried the best water. Frontinus points out that it was "determined to separate (the aqueducts) and then to arrange that the Marcia should serve wholly for drinking purposes, and that the others should be used for purposes adapted to their special qualities."

It is interesting to note that, in 1958, some 2000 years later, the United Nations Economic and Social Council enunciated a policy (3): "No higher quality water, unless there is a surplus of it, should be used for a purpose that can tolerate a lower grade."

THE MIDDLE AGES AND THE INDUSTRIAL REVOLUTION

Beginning in the sixth century, the Roman Empire began to disintegrate and, up to the fourteenth century, infectious diseases rode rampant throughout Europe. Leprosy, bubonic plague, smallpox, diphtheria, measles, influenza, and countless other afflictions were epidemic, particularly

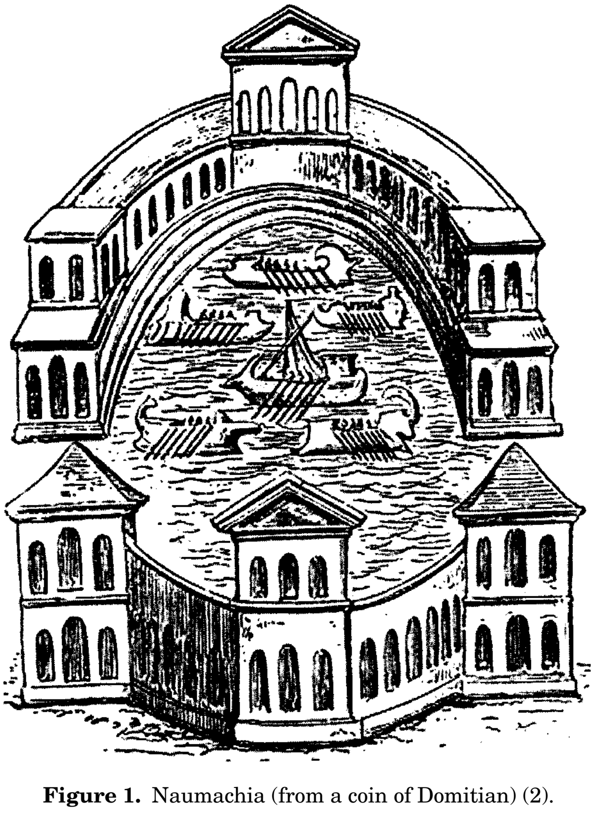

Figure 1. Naumachia (from a coin of Domitian) (2).

in the cities. Water was only one of the many vectors for the spread of disease. Knowledge of the specific vectors was limited, and food received the most attention. Quarantine was the principal approach to control of the spread of disease. The lack of proper sanitation and the dense urban populations were largely responsible for the epidemics and there was little focus on water quality and its availability.

The major accomplishment toward the end of the Middle Ages was the establishment of hospitals, often for specific diseases, by local governments and workers' guilds. Little of importance with regard to the water environment and the public health emerged during that period.

THE GREAT SANITARY AWAKENING

In the middle of the nineteenth Century, the causes of the many common diseases of the day that afflicted the growing urban populations that accompanied the Industrial Revolution were still unknown. Water was beginning to be piped to houses of the well-to-do while the poor either carried their water from wells or bought water from purveyors who obtained the water at the most convenient sources. When the water was contaminated, which was its general condition in urban areas, the spread of disease was inevitable.

A more significant and serious situation resulted from the growing installation rate of piping and then water closets in homes and commercial establishments. In addition to the impact of a poor quality water for drinking was the necessity for disposing of the discharges of these new flush toilets. London had found it necessary to construct storm sewers to drain the streets to permit the conduct of commerce. The obvious solution was to discharge the household wastes from the toilets to the storm sewers, which, in turn, discharged directly into the Thames River, which ran through London and served as a source of water for several private companies that distributed the water to households.

London was exemplary of the unsavory and squalid conditions in all cities in the early years of the century. The medical fraternity believed that the diseases were spread by poisons in the miasmatic air emanating from the "bowels of the earth." The Thames at London at that time was a tidal river and the heavily polluted waters would flow very slowly to sea. In warm periods, Londoners avoided crossing London Bridge because the air was so foul. A headline of the period read "India is in Revolt and the Thames Stinks." The drapery in the Houses of Parliament, located on bank of the Thames, needed to be soaked in chloride of lime to make the meeting room tolerable, and stirred the Parliament to establish the first of many committees to see to alleviating the situation.

Two cholera outbreaks in the summer of 1854 were the greatest in London's history. The first developed in Soho, a densely populated section in the heart of the city. Dr. John Snow, then physician to Queen Victoria Hospital, and reasonably the first epidemiologist, undertook to mark the deaths in the summer of 1953. In 2 days, 197 people died, and after 10 days more than 500 people died in an area only 250 yards across (4). Plotting the deaths on a map of the area (Fig. 2), the result resembled a target, with the greatest concentration of hits at the center. A church-owned well on Broad Street was identified at the site as being the source of the water ingested by the victims. The water had appeared to be of excellent quality. A woman living about a mile away regularly sent a cart to carry water to her home; she and a guest from outside London died of cholera in that epidemic.

Dr. Snow examined the well site and concluded that a tannery on property owned by the church had a cesspool for discharge of its wastewaters. He ordered the church to remove the handle on the pump, ending the epidemic, but, by that time, the epidemic might well have been spent. At any rate, this demonstration was the first to suggest that drinking water was the source of the cholera. This was generations before the germ theory of disease had been elucidated, and Snow's other studies in London were even more convincing. The John Snow Pub is on the site of the Broad Street pump, and these data decorate its walls.

Annual death rates from cholera among households using Thames River water ranged from 10 to 110 per 10,000 households in 1832, increasing to 200 per 10,000 among those taking water from the downstream reaches of the river. While this justified the inference that water was responsible, Dr. Snow found a more definitive proof during the 1854 epidemic. Two private water companies, the Southwark and Vauxhall Company and the Lambeth Company were in direct competition, serving piped water to the same area near the center of London but on the south side of the river. These water companies were characterized as "by far the worst of all those that take their water from the Thames, with 120 to 180 deaths per 10,000 households in 1849 for each of the two companies" (6). In 1852, however, the Lambeth Company, to attract more customers, improved the aesthetic quality of the Thames River water by moving its intake upstream above the heaviest pollution from London.

Snow's data showed that, in the 1854 epidemic, the death rate among those using Lambeth water was 37 deaths per 10,000 households as compared with 315 per 10,000 households for those using the intake downstream. During that period, the death rate in all of London was 59 per 10,000 households (256,423 deaths) among those taking water from all sources in London.

In addition to establishing that the cholera outbreaks were caused by drinking water, Snow demonstrated the importance of source selection. As is pointed out below, almost a century later, some cities still chose to take water from run-of-river sources when better sources were available primarily because it was less costly. Professor Fair, in presenting his philosophy about water supply, characterized the issue by declaring that he "preferred the virginal to the repentant," a paraphrase of the philosophy of Allen Hazen, possibly the most important engineer in the early history of water supply in the United States, who put it: "Innocence is better than repentance." (7).

THE EMERGENCE OF WATER AS A PUBLIC HEALTH ISSUE

The Industrial Revolution, beginning in the late eighteenth century in Britain and extending to Europe and the United States, was responsible for an explosive increase in

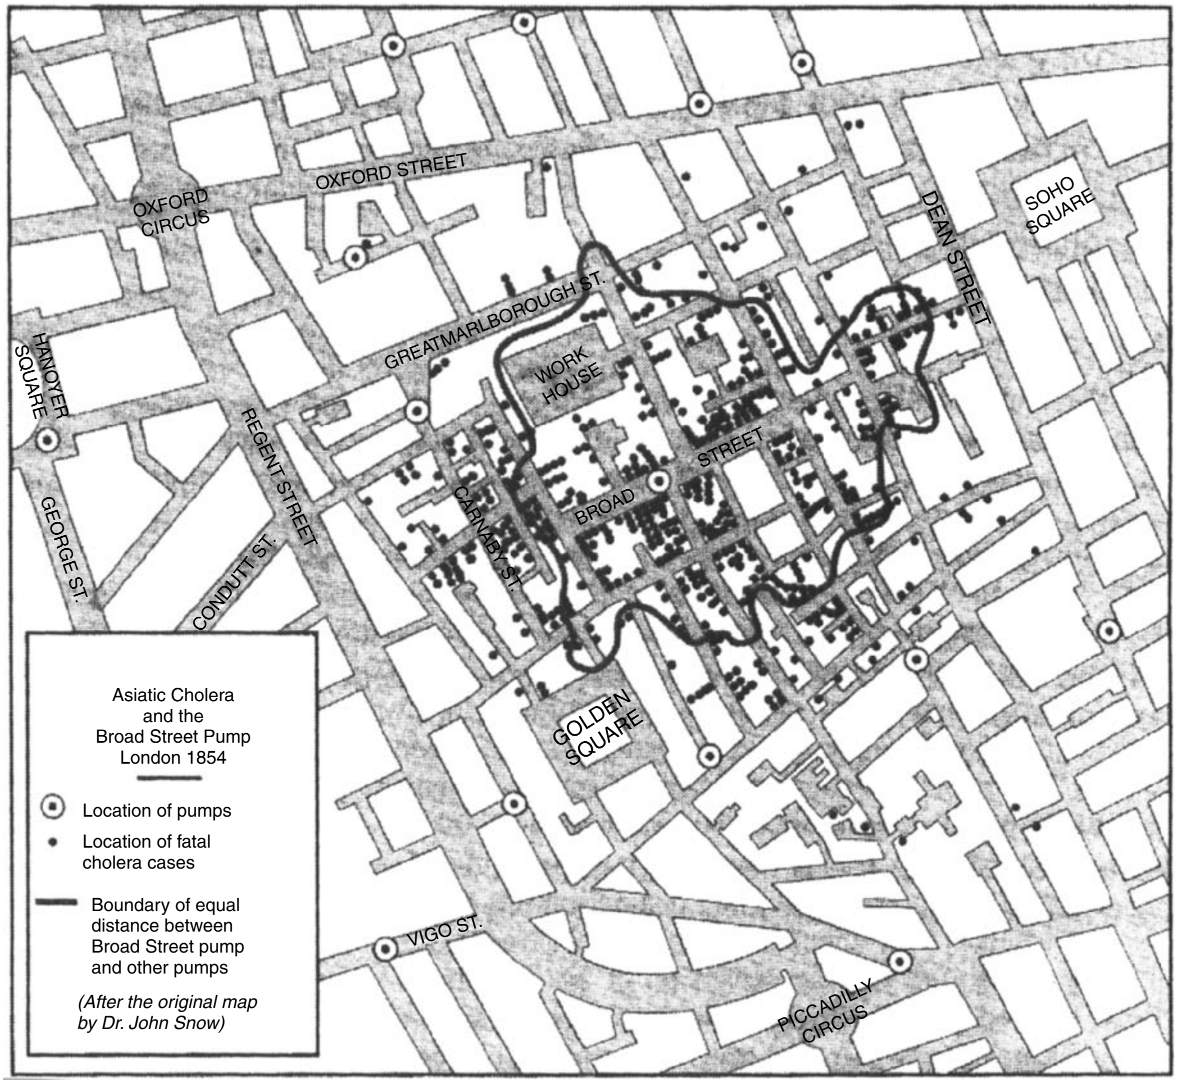

Figure 2. Map of Soho showing the location of those who died from cholera within the vicinity of the Broad Street pump in London 1854 (5).

urbanization with the development of the slums so "celebrated" by Dickens. It did eventually result in the English government and the northeastern states in the United States establishing agencies for addressing the terrible health conditions that emerged. Massachusetts, Pennsylvania, and New York established health boards to improve housing conditions; this resulted in the establishment of regulations for water supply and disposal of household wastes (Fig. 3).

These efforts at regulating activities that might damage the environment led to the establishment of the public health movement. Two figures of lasting fame: Sir Edwin Chadwick, a lawyer, in England (8), and Lemuel Shattuck, a physician (9) in Massachusetts, who was inspired by Chadwick, were responsible for the creation of regulatory agencies and laws protecting the public from the wide range of microbial and chemical contaminants that inevitably found their way to the nearby streams and rivers that were drawn upon for water supply. Shattuck's plan for the board of health for Massachusetts called for its membership to be composed of two physicians, one counselor-at-law, one chemist or natural philosopher, one civil engineer, and two persons of other professions or occupations. This comprehensive view of the needs for an agency for the protection of the public health was the springboard for the establishment of a sanitary engineering specialty within civil engineering. Shattuck had pointed out that competence in "planning and constructing public works" was essential to the provision of water supply and the disposal of household wastes.

In 1886, the Massachusetts legislature passed "An Act to Protect the Purity of Inland Waters" and, to implement the Act, it called for the establishment of an engineering department in the State Board of Health. Among its activities was the establishment of the Lawrence Experiment Station, the first of its kind, which was instrumental in attracting engineers, chemists, and biologists from the Massachusetts Institute of Technology, many of whom were responsible not only for spreading the study of water-related diseases and their control but also

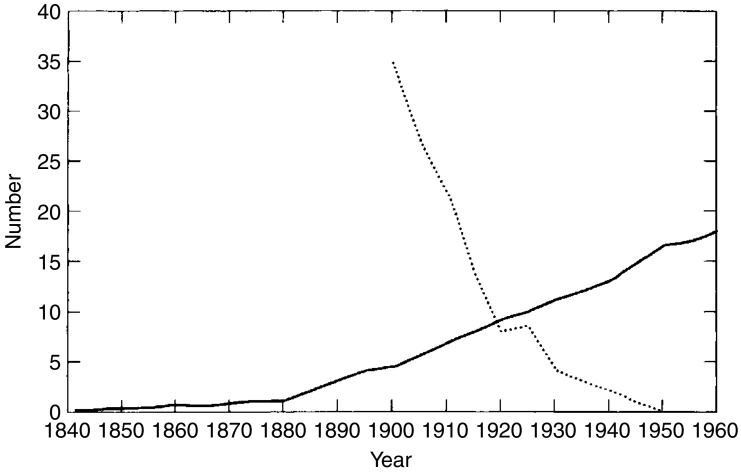

Figure 3. Simultaneous decline in typhoid fever death rate and rise in number of community water supplies in the United States (——deaths per 100,000 population; water supplies: 1000s) (*Source*: F. W. Pontius).

in the introduction of community water supply systems. From a total of only 17 water supply systems in the state in 1869, the number grew to 138 in 1890 while the annual death rate from typhoid fever in the state dropped from 89 per 100,000 in 1873 to 37 in 1890, and by 1940 to 0.2 (Fair 1945).

Despite the appearance of regulatory agencies, many years passed before they played a significant role in the monitoring of municipal water supply and wastewater collection, treatment, and disposal systems. Actually, there was, is, and should be far less need for regulation of drinking water quality than for regulation of wastewater discharges.

In the early days of public water supplies, most were privately owned and needed to meet the requirements of the communities they served. When they were inadequate to the task, sometimes because they failed to satisfy the communities they served, but more generally because the rapid growth of the cities called for capital investments beyond the capacity of the private purveyors to meet, the community government became responsible for the water supply. When the community government itself was providing the water, there seemed to be little need for regulating the performance of their own utility as its objectives would naturally be to protect its citizenry from public health risks.

A good example of this was the early history of the water supply for London, as mentioned above, where the private companies were generally loathe to invest in improvements. At the end of the nineteenth century, a Metropolitan Water Board (MWB) was created to take over responsibility for the water supply of London from eight private companies. In some other cities in England, private water companies continued to serve satisfactorily and continue to this day. The MWB established new technology and were seen to be at the leading edge of water supply technology and they set their own standards which were emulated by other communities.

In the case of New York City, its early private purveyors also were inadequate to their responsibilities. The driving forces were the need to have water to prevent epidemics of yellow fever (which were not related to water) and to fight fires. One of the last private efforts was that inspired by Aaron Burr, who promised a water supply as a condition of establishing the Bank of the Manhattan Company, the predecessor of the Chase Manhattan Bank. He had little interest in providing water and “this brilliant and unprincipled man suffered a series of political disasters that plunged him ... to ruin and exile.” (10). Burr’s plans were doomed.

The city finally decided to develop its own supply and, after extensive study had to choose between two possible sources: the Bronx River very near the city and the Croton River some 40 miles distant. The former was considerably lower in cost but the latter promised a much better quality of water and a greater quantity for the future. The City Board of Water Commissioners Committee on Fire and Water, addressing this question in 1835 opted for the Croton and for public ownership in this language (10):

> The question remains, ought the Corporation of the City of New York Committee to embark on this great work? The Committee are firmly of the opinion, that it ought to be done by no other body, corporate or personal. ... The control of the water of the City should be in the hands of this Corporation, or in other words, in the hands of the *people*.

The City celebrated the delivery of high-quality water from the Croton Aqueduct to New York City by gravity at high pressure in ample quantity in 1842, then one of the largest water supplies in the world. It still provides about 15% of the water that the City uses. This costly choice was made by the city officials not to meet a regulation but to serve their constituency well. Another example is the city of Cincinnati, Ohio, which installed granular activated carbon (GAC) filtration in the 1980s though it is not required by regulations. Many cities do more than the existing regulations require because the regulations tend to be years behind our knowledge. Water officials desiring to serve their community best may find it wise to anticipate quality problems that will not be addressed by regulations for years. Unfortunately, the reception given new regulations is not always one of appreciation by many water officials but of concern for the costs that may be involved. Industry groups such as the American Water Works Association (AWWA) often challenge regulations that are in the process of being promulgated to reduce public health risks because it would increase costs and water rates.

On the other hand, regulations for the quality and quantity of discharges of wastewaters to receiving waters are necessary, because the cost burden falls on the community while those who benefit are generally residents of other communities and not liable for the costs. This is also one of the reasons why the Clean Water Act (CWA) and similar earlier programs have been obliged to meet a significant share of the costs.

THE BEGINNING OF WATER TREATMENT

The relationship between source, water quality, and disease was demonstrated in the United States but much later than cholera in England and with much lower typhoid fever rates. Kober (11) made a study of typhoid rates in American cities from 1902 through 1908, summarized in Table 1. New York City, with its upland supply, had the lowest rate of the 61 cities with 15 typhoid deaths per 100,000 while Pittsburgh, with its run-of-river supply, suffered the highest death rate, 120 per 100,000.

Filtration of water was introduced well before the turn of the nineteenth century in Europe, where run-of-river supplies were more common. An eightfold increase of filtration in the United States reduced the typhoid death rate from water supply from 1900 to 1913 by 55% (12).

The availability of filtration mistakenly seemed to make the need for selecting better sources unnecessary. Philadelphia, which had been taking water from run-of-river sources and had been one of the last of the large U.S. cities to adopt filtration, was suffering a typhoid death rate of 75 per 100,000 into the twentieth century. The city officials had contended that filtration was not as effective as boiling the water. In 1900, a reform mayor was determined to address the issue. A panel of distinguished engineers prepared “a report that was characterized as not having any surprises.” (13). It recommended filtration and continued use of water from the lower Delaware and Schuylkill Rivers. The report stated that “Water from upcountry sources might be preferable but the great cost of building aqueducts and reservoirs made that option very expensive and really unnecessary since filtration would provide safe water.”

In 1911, before the filters were operational, a typhoid outbreak in Philadelphia resulted in 1063 deaths. After filtration, the death rate dropped to 13 per 100,000, still a relatively high figure.

Philadelphia still takes most of its water from the “mouth” (more properly, the “anus”) of the Delaware River and has had to adopt Herculean methods to deliver water of good quality ever since. A multimedia study of environmental health risks in Philadelphia in the 1980s determined that the water supply posed the highest risk of all sources of pollution in the city. Since then improved treatment processes along with stricter USEPA standards have been introduced.

Many cities have no alternatives and are obliged to draw from run-of-river sources. Slow sand filtration became the treatment of choice in Massachusetts in the 1870s. In the 1890s, the Louisville Water Company, which took water from the Ohio River, introduced sedimentation of the water prior to filtration. For better removal of turbidity, they introduced chemical coagulation and rapid sand filtration.

The introduction of chlorination for disinfection of water for municipal water supply took place in Boonton, New Jersey, in 1908 following decades of study of the use of chlorine in Europe and the United States (14). It clearly was the greatest step in the reduction of the transmission of infectious diseases via water supply.

An example of the role of chlorine was the effect it had in a city drawing water from a clear lake. Chlorine reduced the annual typhoid death rate from about 20 to 2 per 100,000 population, which was then reduced to virtually zero with the addition of filtration (Fair et al. 1968). Together with pasteurization of milk and better handling of human wastes, typhoid virtually disappeared in the United States by the middle of the twentieth century.

Table 1. Typhoid Rates in American Cities, 1902 Through 1908

Source	Number of Cities	Death Rate per 100,000
Groundwater	4	18.1
Impoundments and protected watersheds	18	18.5
Small lakes	8	19.3
Great lakes	7	33.1
Mixed surface and groundwater	5	45.7
Run-of-river supplies	19	61.6

THE CHEMICAL REVOLUTION

While infectious disease was brought under control, although other diseases emerged later, two other problems arose. The first was that water treatment tools were believed to be so effective, engineers became sanguine about the need to seek waters of high quality; treatment would make it safe. The conventional treatment of the midtwentieth century, which remains the conventional treatment now, at the beginning of the twenty-first century—chemical coagulation, rapid sand filtration, and chlorination—does little to remove the trace synthetic organic chemicals in ambient water resulting from the post World War II surge in industrial development what has been labeled the “chemical revolution” (1).

The second problem is truly ironic—the life-saving treatment, chlorination, increases the risk from synthetic organic chemicals created by the chlorine itself. Other disinfection byproducts have surfaced and added to the problem of the trace synthetic organic chemicals discharged from industry and households using a wide range of such chemicals for house and garden.

The first published material about disinfection byproducts (DBPs) emanated from Rook's work at the Rotterdam water treatment plant, which drew water from the mouth of the Rhine River (15). While it had been picked up quickly by USEPA, the potential had been recognized 5 years earlier. Dr. Joshua Lederberg, a Nobel Prize geneticist, who had been somewhat active in drinking water issues, wrote a 1969 syndicated column in the Washington Post. One column was headlined "We're so accustomed to using chlorine that we tend to overlook its toxicity" (16):

> What little we do know of the chemistry of chlorine reactions is portentous. It should sometimes react . . . to form substances that may eventually reach and react with genetic material, DNA, of body cells . . . That chlorine is also intended to inactivate viruses should provoke questions about the production of mutagens in view of the close similarity between viruses and genes.

USEPA was created in 1970, but Lederberg failed in attempts to attract funds to follow this up with his research team. The discovery of trihalomethanes and other disinfection byproducts and concerns regarding the potential cancer risks associated with chloroform would be a major driving force behind passage of the 1974 SDWA.

THE INTRODUCTION OF REGULATIONS

In the absence of regulations, many cities adopted practices that were believed to be the most appropriate for their own conditions on the recommendations of professional engineers and water scientists. As noted above, the spread of disease had been controlled in large measure by the quarantine of the sick. It was not unreasonable, therefore, for federal authority over the control of the spread of disease via water to be initially addressed by the U.S. Congress in the Interstate Quarantine Act of 1893 (17).

Under the Act, the surgeon general of the U.S. Public Health Service (USPHS) was empowered "to make and enforce such regulations as are necessary to prevent the introduction, transmission, or spread of communicable disease from foreign countries into the states or possessions, or from one state or possession into any other state or possession."

Interstate regulations were first promulgated in 1894 with the first water-related regulation adopted in 1912, which prohibited the use of the common cup on carriers in interstate commerce (18).

The first federal drinking water standards were adopted in 1914. The USPHS was then part of the U.S. Treasury Department and was charged with responsibility for the health care of the sailors of the Merchant Marine. The surgeon general of the USPHS recommended and the Treasury Department adopted standards for drinking water to be supplied to the public on interstate carriers, then called "Treasury Standards." Because the group that was charged with developing the standards could not agree on physical and chemical parameters, only a bacterial standard of 100 microorganisms per milliliter was adopted. The organism adopted was *Bacteria coli*, now known as *Escherichia coli*. It was further stipulated that not more than one of five 10-mL portions (2 *Bacteria coli* per 100 mL) would be permitted (19). These coliform organisms were not themselves pathogenic but, originating in large numbers in the human colon and found in feces, they served as a surrogate for enteric pathogens because they were more resistant to removal and were present in large numbers and, if they were not present, it could be inferred that the enteric pathogens likely would not be present. Many local and state officials adopted the standard and monitored the water systems that served interstate carriers for themselves and on behalf of the Treasury Department. A federal commitment was made in 1915 to review the regulations on a regular basis.

By 1925, most large cities drawing water from run-of-river sources were already using filtration and chlorination and having little difficulty in meeting the 1914 coliform standard of 2 $100\,\mathrm{mL}^{-1}$ (2 coliforms per milliliter). Following a principle of attainability, the standard was tightened to 1 $100\,\mathrm{mL}^{-1}$. In addition, standards were established for physical and some chemical constituents, including lead, copper, zinc, and dissolved solids (20).

The 1925 standards introduced the concept of relative risk. The preamble stated in part:

> The first step toward the establishment of standards which will ensure safety of water supplies conforming to them is to agree upon some criterion of safety. This is necessary because "safety" in water supplies, as they are actually produced, is relative and quantitative, not absolute. Thus, to state that a water supply is "safe" does not necessarily signify that no risk is ever incurred in drinking it. What is usually meant, and all that can be asserted from any evidence at hand is that the danger, if any, is so small that it cannot be discovered by available means of observation.

In 1941, an advisory committee for revision of the 1925 standards was assembled by the USPHS, composed of representatives of federal and state agencies, scientific associations, and members at large, which produced the 1942 standards (21). One new initiative was the introduction of requirements for monitoring microbial water quality in the distribution system, with specifications for the minimum number of samples to be collected each month according to the size of the community. Specifications for the laboratories and procedures involved were provided.

Maximum permissible concentrations were established for lead, fluoride, arsenic, and selenium as well as for salts of barium, hexavalent chromium, heavy metals, and other substances having deleterious physiological effects. Maximum concentrations where other alternative sources were not available were set for copper, the total of iron and manganese, zinc, chlorides, sulfates, phenolic compounds, total solids, and alkalinity.

Only minor changes were introduced in 1946 (22). Publication in the *Federal Register* was introduced, assuring more rapid dissemination of changes that might be made, one of which was the authorization in March 1957 of the use of the membrane filter procedure for the bacteriological examination of water samples.

World War II (for the United States, 1942–1946) was the first war where deaths of American troops by infectious disease did not exceed deaths in combat. Steps had been introduced to reduce exposure to mosquitoes that were responsible for malaria and other related diseases in the tropics and facilities were provided to assure chlorination of the drinking water. In the postwar period, and driven by the need to make up for years during which the construction of state-side water-related civilian infrastructure had been dormant, attention was turned to making heavy investments for urban water supply.

The need for standards was apparent. Dr. Abel Wolman (23) addressed this issue thus:

> From its beginning, society by one means or another, has surrounded itself with restraints. These have had, for the most part, empiric origins—moral, ethical, economic, or spiritual. All the restraints have had the common basis of an assumed benefit to the particular society establishing them. As societies became more complex and more sophisticated, efforts towards both standardization and restraint became more frequent, more necessary, and presumably more empiric, although examples of the last are not as numerous as one might expect.

He then went on to characterize the types of standards that are necessary:

- Regularization of techniques of measurement;
- Establishment of limits of concentration or density of biologic life and physical and chemical constituents;
- Regularization of administrative practice;
- Regularization of legislative fiat; and
- Specification of materials.

The increasing complexity of the issues is exemplified in all that follows, including not only in the specific regulations required but also in the methodologies of reaching consensus among the many stakeholders involved. The beginning of the "chemical revolution" and regulating the thousands of synthetic organic compounds (SOCs) that are being invented annually and that find their way into the environment and into waters drawn on for drinking began with the 1962 update of the federal Drinking Water Standards.

The establishment of the 1962 USPHS standards involved examining many new issues, including two important problems not previously addressed: radioactivity and SOCs. A new 18-member Advisory Committee was established representing 13 professional and scientific organizations that included consulting engineers, state officials, industry, academics, and water utility executives as well as personnel from the Food and Drug Administration and the U.S. Geological Survey. In addition, 10 officers of the USPHS formed a Technical Subcommittee that, with a six-member Task Force on Toxicology, were advisory to the main Committee (24).

The 1962 USPHS standards were by far the most comprehensive to that date. They included three physical characteristics, odor, color, and turbidity; the last was the most controversial. The turbidity was established at 5 units over the objections of many on the committee from communities that were filtering their waters and who recommended 1 unit, which they could easily meet. Representatives from the northeast, where impounded surface sources were used without filtration, would have had to provide filtration, a measure they believed unnecessary. The bacteriological quality requirement was modified, essentially allowing no more than a monthly average of one coliform per milliliter when the membrane filter technique is used.

The chemical standards were the most difficult to address. Fourteen parameters were listed, but the SOC problem was resolved with the introduction of a Carbon Chloroform Extract (CCE) standard of $0.2\,\mathrm{mg\,L^{-1}}$. A manual was prepared describing the procedure to be used; adsorption of organics by passing a sample of the water through a granular activated carbon (GAC) filter and then desorbing the filter with chloroform (25). The standard was meaningless as a measure of public health risk, because SOCs could not be distinguished from natural organics that are generally of little health consequence, except when they are precursors for chlorination and the creation of trihalomethanes (THMs). But the CCE standard was an attempt to address the SOC problem. The treatment to be provided to remove SOCs was the installation of GAC filters in the treatment train. Forty years later, only a handful of GAC filter plants are being used for treating the most vulnerable public water supplies, those drawing from run-of-river sources. It can be assumed that, at this writing, few supplies that draw from large rivers are removing SOCs that may be present.

The 1962 Standards did introduce two principles that had not been incorporated in previous standards. The first was that "The water supply should be taken from the most desirable source which is feasible, and effort should be made to prevent or control pollution of the source." The second issue was the absence of regulations related to availability of service. A community might be found to be violating the standards if one of the standards is not met but no violation is involved if water service is curtailed because of drought or mechanical failure. The 1962 Standards state "Approval of water supplies shall be dependent in part on: . . . adequate capacity to meet peak demands without development of low pressures or other health hazards."

The 1962 Standards were accepted by all the states, with minor modifications either as regulations or guidelines, but were binding only on about two percent of the communities, those that served interstate carriers (26).

PRELUDE TO THE 1974 SAFE DRINKING WATER ACT

On June 3, 1968, the keynote speaker at the Annual Conference of the AWWA quoted from a report of the Secretary of the U.S. Department of Health Education and Welfare (27): "Fifty million Americans drink water that does not meet Public Health Service drinking water standards. Another 45 million Americans drink water that has not been tested by the Public Health Service."

The AWWA officials were reluctant to publish the paper because it appeared to be too critical of the water supply industry. They acceded only when the author happily agreed to allow rebuttals (28). The task force that prepared the report was not satisfied that the USPHS drinking water standards adequately reflect the health need of the people of the United States. Several issues troubled them.

Little information is available on the health implications of trace substances that may produce disease after exposure over long periods of time. Health experts have repeatedly pointed out that grave, delayed physical manifestations can result from repeated exposure to concentrations of environmental pollutants so small that victims do not report symptoms to a physician.

Furthermore, an individually acceptable amount of water pollution, added to a bearable amount of air pollution, plus nuisances from noise and congestion, can produce a totally unacceptable health environment. It is entirely possible that the biological effects of these environmental hazards, some of which reach individuals slowly and silently over decades or generations, will first begin to reveal themselves after their impact has become irreversible.

In a prescient paper on cancer hazards, Hueper (29) stated:

> It is obvious that with the rapidly increasing urbanization and industrialization of the country and the greatly increased demand on the present resources of water from lakes, rivers, and underground reservoirs, the danger of cancer hazards will grow considerably within the foreseeable future.

Hueper (29) went on to report that studies in Holland revealed that cities drawing water from polluted rivers had higher cancer death rates than those taking water from higher-quality underground sources. At about the same time, the Genetic Study Section of the National Institutes of Health (30) reported that a number of widely used chemicals are known to induce genetic damage in some organisms and that chemicals mutagenic to one species are likely to be mutagenic to others. They believed that when large populations are exposed to highly mutagenic compounds, and they are not demonstrably mutagenic to individuals, the total number of deleterious mutations in the whole population over an extended period of time could be significant.

In 1969, at the beginning of a review of the 1962 standards, the USPHS Bureau of Water Hygiene undertook a comprehensive survey of water supplies in the United States, known as the Community Water Supply Study (CWSS) (31). A total of 969 public water systems, representing about five percent of the total number of systems in the United States serving 18 million people, about 12% of the population being served, were tested (32). About 41% of the systems served did not meet the guidelines in the 1962 Standards. Deficiencies were found in source protection, disinfection, clarification, pressure in the distribution systems, and combinations of these. The small systems, mainly those serving fewer than 500 people, had the greatest difficulty in maintaining water quality. The study revealed that several million people were being supplied with water of inadequate quality and about 360,000 people were being supplied with potentially dangerous drinking water.

The results of the CWSS generated interest in federal legislation that would bring all community water systems under the purview of federal regulations. In 1972, a report of an investigation of the quality of Mississippi River water, as withdrawn from the Carrolton filtration plant in New Orleans, extracted by GAC filtration and a solvent, revealed 36 organic chemicals in the finished water (33). Later, the U.S. General Accounting Office, an agency of the Congress, released a report of the results of an investigation of 446 community water supply systems in six states around the country and found that only 60 of them fully complied with the bacterial and sampling requirements of the 1962 Standards (34). Bacteriological and chemical monitoring were inadequate in five of the states.

In addition to government concern, public organizations and the press had begun to give attention to water supply issues. A three-part series in *Consumer Reports* drew attention to the organic contaminants in New Orleans drinking water (35) Several points were made at the outset of the series that are appropriate today:

> New Orleans, like many other American cities gets its drinking water from a heavily polluted source.... Many industries discharge their wastes into the river and many upriver cities discharge their sewage into it ... runoff from farmland carries a wide variety of pesticides, herbicides, fertilizers, and other agricultural chemicals that swell the Mississippi's pollution burden.
>
> Few New Orleans residents are alarmed. They have been repeatedly assured by city officials that their water, processed according to established water-treatment principles, meets the drinking water standards of the US Public Health Sevice and is "safe." And so it probably is, if one takes "safe" to mean that the water won't cause typhoid, cholera, or other bacterial diseases—the diseases that the standard water treatment is designed to prevent.
>
> In 1969, the Federal Water Pollution Control Administration sampled New Orleans drinking water.... Thirty six (organic compounds) were identified; others were found but could not be identified.
>
> Three of the organic chemicals (chloroform, benzene, and bis-chloroethyl ether) were carcinogens, shown to cause cancer in animal experiments. Three others were toxic, producing liver damage in animals when consumed even in small quantities for long periods. The long-term effects ... are unknown.

The Environmental Defense Fund (EDF) conducted an epidemiologic study in the New Orleans area that compared cancer death rates from communities using lower Mississippi River water as a source with those from nearby communities that were using groundwater sources. The report indicating higher cancer rates among those using the Mississippi River Water was released to the press on November 7, 1974 (36–38). Further publicity followed on December 5, when Dan Rather on CBS aired nationally a program titled "Caution, drinking water may be dangerous to your health." It is interesting to note that upon learning of this situation and the passage of the SDWA, the City of Vicksburg, which had been drawing its water from the Mississippi River, shifted its source to groundwater.

These events, together with the revelation at the time that the chlorine used to make water microbiologically safe would create a family of compounds, trihalomethanes, that were themselves believed to be carcinogenic, led to the passage of the 1974 SDWA.

DRINKING WATER IN DEVELOPING COUNTRIES

The safety of drinking water cannot be examined without considering the problems of drinking water supply and safety in the countries of Asia, Africa, and Latin America. In the industrialized world, attempts are being made to eliminate the use of chlorine for disinfection. Several cities in the Netherlands have abandoned chlorine and other disinfectants entirely because of their concern for DBPs. On the other hand, the situation in the developing world is so serious that the availability of chlorine for every water supply would reduce infant mortality by about 90%.

In 1991, cholera broke out in the Pacific coast of Peru, most probably introduced by maritime traffic from Asia by the discharge of ballast water into the coastal zone from which fish are taken for food, often eaten uncooked. Within two weeks, most of the Peruvian coast, where half of the 22 million Peruvians reside, was host to the disease. Of the some 322,000 cases reported for the year, 55% occurred in the first 12 weeks of the epidemic. The case fatality rate was 0.9% signifying about 30,000 deaths in 1991. By the end of the year, 15 other countries in the Americas, including the United States and Canada, had reported outbreaks caused by the same strain of cholera (39).

Because of its explosive and urban character, contaminated water was identified as the medium for the rapid spread and the intensity of the disease in the cities. Most of the cities had conventional water treatment plants with filtration for water drawn from surface sources. Investigation revealed that chlorination was curtailed and often entirely absent when well water was used. Some Peruvian officials blamed the USEPA for the failure to use chlorine because it had been trumpeting the cancer risks associated with chlorine in water supplies (40).

A serious cholera outbreak occurred in early 2001 in KwaZulu-Natal in the Republic of South Africa, with more than 30,000 cases and some 100 deaths (41). At the height of the outbreak, more than 1000 cases were being reported daily. The reason stated was that the people do not have access to tapwater and are obliged to rely on water from very polluted streams. Even where “bleach” is available, it is not used because it is believed to interfere with fertility. Boiling is not feasible, as firewood is scarce.

In 1980, only 44% of the total population of the developing countries was being served with water by any means, including carrying water of questionable quality long distances from standposts. In urban areas, 69% of the population was being served and very little of that can be considered safe because few cities maintained 24-hour service. When water pressure in distribution pipes is absent, which is most of the day, treated drinking water inevitably becomes contaminated from infiltration of groundwater that is highly contaminated because sewerage systems are absent or in poor condition.

International agencies such as the World Health Organization, the World Bank, the regional development banks, and the developed countries along with the developing countries designated the 1980s the “international drinking water supply and sanitation decade,” during which special efforts were to be made to bring water to the people of the developing world. Ten years later, the population in the developing countries with water supplies had increased to 69%, but the number of people unserved in urban areas had increased by 31 million (42). The rate of urbanization in Asia Africa and Latin America is so great that, even with intensified financial support in grants and loans, the number of urban residents without water service is growing. More important is that those who are counted as having water service do not have safe water by any standard. All that is required to reduce the infant death rate is the type of treatment facilities and their operation and maintenance that was conventional in the industrial world almost a hundred years ago.

Given the nature of world travel today, it is clearly in the self-interest of the industrialized countries to help the developing countries provide water that at least meets 1925 U.S. standards. This would reduce infectious disease that is the major health risk to people and visitors in these countries.

THE FUTURE OF PUBLIC WATER SUPPLY

The history of the monitoring and control of drinking water quality from its earliest days through the present has lessons for those charged with protecting the public health, particularly for those responsible for providing the drinking water to their constituents. This volume demonstrates, if nothing else, that setting standards is a difficult and lengthy procedure. It may be many years, even decades between the time a new risk surfaces and regulations for its control are established and many years more before they are published. Also, years must be allowed for constructing the necessary facilities for eliminating the risks. It behooves the professionals in water utility leadership to educate themselves concerning new risks and prepare to address them before the standards appear in the *Federal Register*. The object is to minimize health risks to the public. Failure, or the perception of failure, drives the public to bottled water with its own risks and costs that are a hardship for a sizable fraction of the population.

A not unrelated issue that is growing in importance as our population ages is the significant percent of the population that is more vulnerable to contaminants by virtue of compromised immune systems. Standards for this population may need to be promulgated.

A similar solution is now being proposed in addressing the quality of water suitable for the potable reuse of wastewaters. Wastewaters contain a large number and a great variety of SOCs. The California Department of Health Services is proposing for the regulation of water quality for groundwater recharge with reclaimed wastewater to potable water aquifers drawn on for drinking water that total organic carbon (TOC) limits be set (43). Again, the carbon compounds may be innocuous or toxic, but in any case a maximum contaminant level (MCL) for TOC of wastewaters is hardly appropriate to assure drinking water safety.

This principle carried over to the 1976 USEPA National Interim Primary Drinking Water Regulations, referred to by this language in Appendix A as "background used in developing the national interim primary drinking water regulations":

> Protection of water that poses no threat to the consumer's health depends on continuous protection. Because of human frailties associated with protection, priority should be given to selection of the purest source. Polluted sources should not be used unless other sources are economically unavailable, and then only when personnel, equipment, and operating procedures can be depended upon to purify and otherwise continually protect the drinking water supply.

This principle is being ignored today, in part because of our faith in treatment technology. Reclaimed wastewater is being proposed as a source for drinking water supplies. Wastewater is hardly likely to be the purest source, and its use for potable reuse is resisted by consumers. Use of reclaimed wastewater for nonpotable purposes is currently being practiced in many hundreds of communities in the United States (44,45), and will be increasingly considered for relieving the pressure on limited high-quality resources.

1962 U.S. PUBLIC HEALTH SERVICE STANDARDS

From *Drinking Water Regulation and Health*, Wiley 2003

Adoption of the 1962 U.S. Public Health Service standards was completed by publication in the Federal Register, March 6, 1962 (pp. 2152–2155). The full text of these standards is provided below.

PREFACE BY THE ADVISORY COMMITTEE

Domestic water supplies should protect the health and promote the well-being of individuals and the community. In this report on the revision of the 1946 edition of the USPHS drinking water standards, the objective of the committee is to recommend minimum requirements for reaching these goals. The USPHS drinking water standards were first adopted in 1914 to protect the health of the traveling public. The general and widespread use of these standards since that time has led to a series of revisions that have been applicable to water supplies generally. The development of atomic energy and other technological advances require that these standards again be revised. To carry out this revision, the chief sanitary engineer of USPHS appointed the undersigned advisory committee. A technical subcommittee of USPHS officers and a toxicological task force were established to collect information and prepare suggestions for the consideration of the advisory committee.

In preparing this report on the revision of the standards, the committee established the following guidelines:

1. The proposed standards should be discussed widely, and due cognizance should be given to international and other standards of water quality before a final report is submitted.
2. A new section on radioactivity should be added.
3. Greater attention should be given to the chemical substances being encountered increasingly, in both variety and quantity, in water sources.
4. In establishing limits for toxic substances, intake from food and air should be considered.
5. The rationale employed in determining the various limits should be included in an appendix.
6. The proposed format, with the exceptions noted above, should not differ greatly from the present standards.
7. The standards should be generally acceptable and should be applicable to all public water supplies in the United States, as well as to those supplies used by carriers subject to USPHS regulations.
8. The following two types of limits used in previous editions should be continued:
    a. Limits that, if exceeded, shall be grounds for rejection of the supply. Substances in this category may have adverse effects on health when present in concentrations above the limit.
    b. Limits that should not be exceeded whenever more suitable supplies are, or can be made, available at reasonable cost. Substances in this category, when present in concentrations above the limit are either objectionable to an appreciable number of people or exceed the levels required by good water quality control practices.
9. These limits should apply to the water at the free-flowing outlet of the ultimate consumer.

This revision of the drinking water standards includes, for the first time, limiting concentrations of radioactivity in water. The effects on large population groups of chronic exposure to low levels of radioactivity are not yet well defined. The limits presented herein are an effort to derive conservative values from the best information now available and may be adjusted upward or downward as new and better data become available.

The committee has taken cognizance of the growing problem of potentially harmful chemicals in sources of drinking water. Limits for several new chemicals have been added, including a gross limit for the concentration of some types of synthetic chemicals. It was not feasible, however, to include limits for all the many chemicals that have varying degrees of toxic potential. Consideration was given to the more common chlorinated hydrocarbon and organophosphate insecticides, but the information available was not sufficient to establish specific limits for these chemicals. Moreover, the concentrations of these chemicals, where tested, have been below those that would constitute a known health hazard. The committee believes that pollution of water supplies with such contaminants can become significant and urges that the problem be kept under closer surveillance. Further, the committee recommends that regulatory actions be taken to minimize concentrations of such chemicals in drinking water.

In view of the accelerating pace of new developments affecting water quality, the committee recommends that a mechanism be established for continual appraisal and appropriate revision of the standards. It also recommends that USPHS intensify its continuing studies toward the development of basic information on the relationship of the biological, chemical, physical, and radiological aspects of water quality to health.

Membership of the Advisory Committee

U.S. Public Health Service: O. C. Hopkins, Chairman
U.S. Public Health Service: George W. Burke, Jr., Secretary
Federal Food and Drug Administration: L. M. Beacham, Jr.
U.S. Geological Survey: S. K. Love
Air Transport Association of America: K. L. Stratton

Drinking Water Standards

Definition of Terms. The terms used in these standards are as follows:

Adequate protection by natural means involves one or more of the following processes of nature that produce water consistently meeting the requirements of these standards: dilution, storage, sedimentation, sunlight, aeration, and the associated physical and biological processes that tend to accomplish natural purification in surface waters and, in the case of groundwaters, the natural purification of water by infiltration through soil and percolation through underlying material and storage below the ground water table.

Adequate protection by treatment is anyone or any combination of the controlled processes of coagulation, sedimentation, sorption, filtration, disinfection, or other processes that produce a water consistently meeting the requirements of these standards. This protection also includes processes that are appropriate to the source of supply; works that are located, designed, and constructed to eliminate or prevent pollution; and conscientious operation by well-trained and competent personnel whose qualifications are commensurate with the responsibilities of the position and acceptable to the reporting agency and the certifying authority.

Certifying authority is the surgeon general of USPHS or his duly authorized representatives. (Reference to the certifying authority is applicable only for those water supplies to be certified for use on carriers subject to the USPHS regulations—42 CFR Part 72.)

The coliform group includes all organisms considered in the coliform group as set forth in *Standard Methods for the Examination of Water and Wastewater*, current edition [11th ed., 1960], prepared and published jointly by the American Public Health Association, American Water Works Association, and Water Pollution Control Federation.

Health hazards are conditions, devices, or practices in the water supply system and its operation that create, or may create, a danger to the health and well-being of the water consumer. An example of a health hazard is a structural defect on the water supply system, whether of location, design, or construction, that may regularly or occasionally prevent satisfactory purification of the water supply or cause it to be polluted from extraneous sources.

Pollution, as used in these standards, is defined as the presence of any foreign substance (organic, inorganic, radiological, or biological) in water which tends to degrade its quality so as to constitute a hazard or impair the usefulness of the water.

Reporting agencies are the respective official state health agencies or their designated representatives.

The standard sample for the bacteriological test shall consist of

1. For the bacteriological fermentation tube test, five standard portions of either: (a) 10 mL or (b) 100 mL
2. For the membrane filter technique, not less than 50 mL

Water supply system includes the works and auxiliaries for collection, treatment, storage, and distribution of the water from the sources of supply to the free-flowing outlet of the ultimate consumer.

Source and Protection

The water supply should be obtained from the most desirable source feasible, and effort should be made to prevent or control pollution of the source. If the source is not adequately protected by natural means, the supply shall be adequately protected by treatment.

Frequent sanitary surveys shall be made of the water supply system to locate and identify health hazards that might exist in the system. The manner and frequency of making these surveys, and the rate at which discovered health hazards are to be removed, shall be in accordance with a program approved by the reporting agency and the certifying authority.

Approval of water supplies shall be dependent in part on

a. Enforcement of rules and regulations to prevent development of health hazards
b. Adequate protection of the water quality throughout all parts of the system, as demonstrated by frequent surveys
c. Proper operation of the water supply system under the responsible charge of personnel whose qualifications are acceptable to the reporting agency and the certifying authority
d. Adequate capacity to meet peak demands without development of low pressures or other health hazards
e. Record of laboratory examinations showing consistent compliance with the water quality requirements of these standards

For the purpose of application of these standards, responsibility for the conditions in the water supply system shall be considered to be held by

a. The water purveyor, from the source of supply to the connection to the customer's service piping.
b. The owner of the property served and the municipal, county, or other authority having legal jurisdiction, from the point of connection to the customer's service piping to the free-flowing outlet of the ultimate consumer.

Bacteriological Quality

Sampling. Compliance with the bacteriological requirements of these standards shall be based on examinations of samples collected at representative points throughout the distribution system. The frequency of sampling and the location of sampling points shall be established jointly by the reporting agency and the certifying authority after investigation by either agency, or both, of the source, method of treatment, and protection of the water concerned.

The minimum number of samples to be collected from the distribution system and examined each month should be in accordance with the number in (Fig. 1) for the population served by the system. For the purpose of uniformity and simplicity in application, the number determined from (Fig. 1) should be in accordance with the following: for a population of 25,000 or less, to the nearest 1; 25,001–100,000, to the nearest 5: and more than 100,000 to the nearest 10.

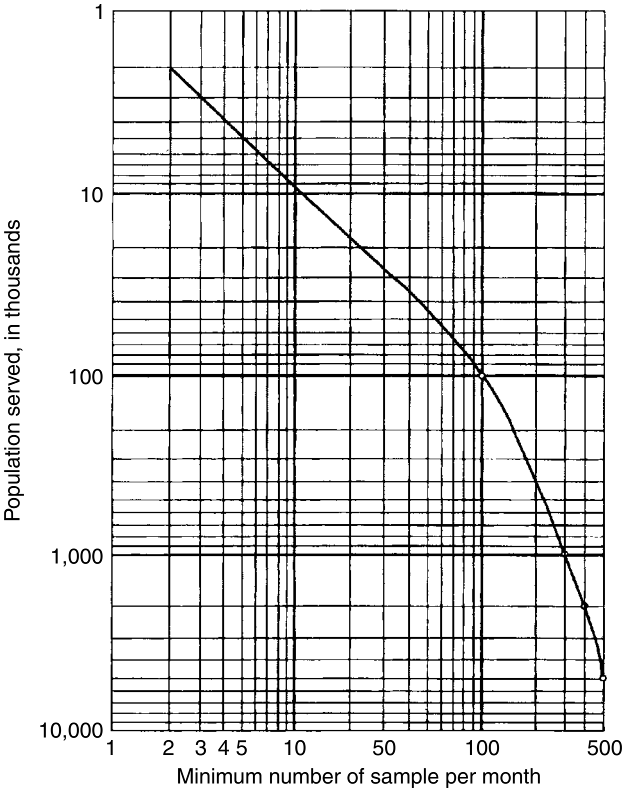

Figure 1. Relation between minimum number of samples to be collected per month and population served.

In determining the number of samples examined monthly, the following samples may be included, provided all results are assembled and available for inspection, and the laboratory methods and technical competence of the laboratory personnel are approved by the reporting agency and the certifying authority:

a. Samples examined by the reporting agency
b. Samples examined by local government laboratories
c. Samples examined by the water works authority
d. Samples examined by commercial laboratories

The laboratories in which these examinations are made and the methods used in making them shall be subject to inspection at any time by the designated representatives of the certifying authority and the reporting agency. Compliance with the specified procedures and the results obtained shall be used as a basis for certification of the supply.

Daily samples collected following a bacteriologically unsatisfactory sample as provided in Secs. 3.21, 3.22, and 3.23 shall be considered as special samples and shall not be included in the total number of samples examined. Neither shall such special samples be used as a basis for prohibiting the supply, provided that

1. When waters of unknown quality are being examined, simultaneous tests are made on multiple portions of a geometric series to determine a definitive coliform content.
2. Immediate and active efforts are made to locate the cause of pollution.
3. Immediate action is taken to eliminate the cause.
4. Samples taken following such remedial action are satisfactory.

Limits. The presence of organisms of the coliform group as indicated by samples examined shall not exceed the following limits:

When 10-mL standard portions are examined, not more than 10% in any month shall show the presence of the coliform group. The presence of the coliform group in three or more 10-mL portions of a standard sample shall not be allowable if this occurs

a. In two consecutive samples.
b. In more than one sample per month when less than twenty are examined per month.
c. In more than 5 per cent of the samples when twenty or more are examined per month.

When organisms of the coliform group occur in three or more of the 10-mL portions of a single standard sample, daily samples from the same sampling point shall be collected promptly and examined until the results obtained from at least two consecutive samples show the water to be of satisfactory quality.

When 100-mL standard portions are examined, not more than 60% in any month shall show the presence of the coliform group. The presence of the coliform group in all five of the 100-mL portions of a standard sample shall not be allowable if this occurs:

a. In two consecutive samples.
b. In more than one sample per month when less than five are examined per month.
c. In more than 20 percent of the samples when five or more are examined per month.

When organisms of the coliform group occur in all five of the 100-mL portions of a single standard sample, daily samples from the same sampling point shall be collected promptly and examined until the results obtained from at least two consecutive samples show the water to be of satisfactory quality.

When the membrane filter technique is used, the arithmetic mean coliform density of 0 standard samples examined per month shall not exceed 1 per 100 mL. Coliform colonies per standard sample shall not exceed 3 per 50 ml, 4 per 100 mL, 7 per 200 mL, or 13 per 500 mL in

a. Two consecutive samples.
b. More than one standard sample when less than 20 are examined per month.
c. More than 5% of the standard samples when 20 or more are examined per month.

When coliform colonies in a single standard sample exceed the above values, daily samples from the same sampling point shall be collected promptly and examined until the results obtained from at least two consecutive samples show the water to be of satisfactory quality.

Physical Characteristics

Sampling. The frequency and manner of sampling shall be determined by the reporting agency and the certifying authority. Under normal circumstances, samples should be collected one or more times per week from representative points in the distribution system and examined for turbidity, color, threshold odor, and taste.

Limits. Drinking water should contain no impurity that would cause offense to the sense of sight, taste, or smell. Under general use, the following limits should not be exceeded: turbidity, 5 units; color, 15 units; and threshold odor number, 3 units.

Chemical Characteristics

Sampling. The frequency and manner of sampling shall be determined by the reporting agency and the certifying authority. Under normal circumstances, analyses for substances listed below need be made only semiannually. If, however, there is some presumption of unfitness because of the presence of undesirable elements, compounds, or materials, periodic determinations for the suspected toxicant or material should be made more frequently, and an exhaustive sanitary survey should be made to determine the source of the pollution. Where the concentration of a substance is not expected to increase in processing and distribution, available and acceptable source water analyses performed in accordance with standard methods may be used as evidence of compliance with these standards.

Where experience, examination, and available evidence indicate that particular substances are consistently absent from a water supply or below levels of concern, semiannual examinations for those substances may be omitted when approved by the reporting agency and the certifying authority.

The burden of analysis may be reduced in many cases by using data from acceptable sources. Judgment concerning the quality of water supply and the need for performing specific local analyses may depend in part on information produced by such agencies as (1) USGS, which determines chemical quality of surface water and groundwater of the United States and publishes these data in *Water Supply Papers* and other reports, and (2) USPHS, which determines water quality related to pollution (or the absence of pollution) in the principal rivers of the United States and publishes these data annually in *National Water Quality Network*. Data on pollution of waters as measured by carbon chloroform extracts (CCES) may be found in the latter publication.

Limits. Drinking water shall not contain impurities in concentrations that may be hazardous to the health of the consumers. It should not be excessively corrosive to the water supply system. Substances used in its treatment shall not remain in the water in concentrations greater than required by good practice. Substances that may have deleterious physiological effect, or substances for which physiological effects are not known, shall not be introduced into the system in a manner that would permit them to reach the consumer.

The chemical substances shown in Table 1 should not be present in a water supply in excess of the listed concentrations where, in the judgment of the reporting agency and the certifying authority, other more suitable supplies are or can be made available.

The presence of substances in excess of the concentrations listed in Table 2 shall constitute grounds for rejection of the supply.

Fluoride. When fluoride is naturally present in drinking water, the concentration should not average more than the appropriate upper limit shown in Table 3. Presence of fluoride in average concentrations greater than two times the optimum values in Table 3 shall constitute grounds for rejection of the supply. Where fluoridation (supplementation of fluoride in drinking water) is practiced, the average fluoride concentration shall be kept within the upper and lower control limits shown in Table 3. In addition to the sampling required by Sec. 5.1, fluoridated and defluoridated supplies shall be sampled with sufficient frequency to determine that the desired fluoride concentration is maintained.

Table 1. A Water Supply with Concentrations Exceeding These Limits Should Be Avoided If Possible[a]

Substance	Concentration (mg/L)
Alkyl benzene sulfonate (ABS)	0.5
Arsenic (As)	0.01
Chloride (Cl)	250.0
Copper (Cu)	1.0
Carbon Chloroform extract (CCE)	0.2
Cyanide (CN)	0.01
Fluoride (F)	—[b]
Iron (Fe)	0.3
Manganese (Mn)	0.05
Nitrate (NO_3)[c]	45.0
Phenols	0.001
Sulfate (SO_4)	250.0
Zinc (Zn)	5.0

[a] Refer to Section 5.2.1 (in this Appendix).
[b] See Section 5.2.3.
[c] In areas in which the nitrate content of water is known to be in excess of the listed concentration, the public should be warned of the potential dangers of using the water for infant feeding.

Table 2. A Water Supply with Concentrations Exceeding These Limits Should Be Rejected[a]

Substance	Concentration (mg/L)
Arsenic (As)	0.05
Barium (Ba)	1.0
Cadmium (Cd)	0.01
Chromium (Cr^{6+})	0.05
Cyanide (CN)	0.2
Fluoride (F)	—[b]
Lead (Pb)	0.05
Selenium (Se)	0.01
Silver (Ag)	0.05

[a] Refer to Section 5.2.2.
[b] See Section 5.2.3.

Radioactivity

Sampling. The frequency of sampling and analysis for radioactivity shall be determined by the reporting agency and the certifying authority after consideration of the likelihood of significant amounts being present. Where concentrations of ^{226}Ra or ^{90}Sr may vary considerably, quarterly samples composited over a period of 3 months are recommended. Samples for determination of gross activity should be taken and analyzed more frequently. As indicated in Sec. 5.1, data from acceptable sources may be used to indicate compliance with these requirements.

Limits. The effects of human radiation exposure are viewed as harmful and any unnecessary exposure to ionizing radiation should be avoided. Approval of water supplies containing radioactive materials shall be based on the judgment that the radioactivity intake from such water supplies when added to that from all other sources will not result in an intake greater than the radiation protection guidance recommended by the Federal Radiation Council and approved by the President. Water supplies shall be approved without further consideration of other sources of radioactivity intake of ^{226}Ra and ^{90}Sr when the water contains these substances in amounts not exceeding 3 and 10 $\mu\mu$Ci/L, respectively. When these concentrations are exceeded, a water supply shall be approved by the certifying authority if surveillance of total intakes of radioactivity from all sources indicates that such intakes are within the limits recommended by the Federal Radiation Council for control action.

The Federal Radiation Council, in its Memorandum for the President, Sept. 13, 1961, recommended that "routine control of useful applications of radiation and atomic energy should be such that expected average exposures of suitable samples of an exposed population group will not exceed the upper value of Range II (20 $\mu\mu$Ci/day of ^{226}Ra and 200 $\mu\mu$Ci/day of ^{90}Sr).

Table 3. Recommended Fluoride Control Limits[a]

Annual Average of Maximum Daily Air Temperature[b], °F	Recommended Control Limits for Fluoride Concentration, mg/L		
	Lower	Optimum	Upper
50.0–53.7	0.9	1.2	1.7
53.8–58.3	0.8	1.1	1.5
58.4–63.8	0.8	1.0	1.3
63.9–70.6	0.7	0.9	1.2
70.7–79.2	0.7	0.8	1.0
79.3–90.5	0.6	0.7	0.8

[a] Refer to Section 5.2.3.
[b] Based on temperature data obtained for a minimum of 5 years.

In the known absence[1] of ^{90}Sr and alpha emitters, the water supply is acceptable when the gross beta concentrations do not exceed 1000 $\mu\mu$Ci/L. Gross beta concentrations in excess of 1000 $\mu\mu$Ci/L shall be grounds for rejection of supply except when more complete analyses indicate that concentrations of nuclides are not likely to cause exposures greater than the Radiation Protection Guides as approved by the President on recommendation of the Federal Radiation Council.

Recommended Analytical Methods

Analytical methods to determine compliance with the requirements of these standards shall be those specified in *Standard Methods for the Examination of Water and Wastewater*, APHA, AWWA, and WPCF, New York, current edition [11th ed., 1960], and those specified as follows:

Barium. Rainwater, F. H., and L. L. Thatcher: *Methods for the Collection and Analysis of Water Samples*, USGS, Water Supply Papers, 1454, Govt. Printing Office, Washington, DC.

Carbon Chloroform Extract (CCE). *Method for Determining the Carbon Chloroform Extract (CCE) in Drinking Water*, R. A. Taft San. Eng. Center, USPHS, Cincinnati (1961).

Radioactivity. *Laboratory Manual of Methodology; Radionuclide Analysis of Environmental Samples*, Tech. Rept. R59-6, R. A. Taft San. Eng. Center, USPHS, Cincinnati; and Methods of Radiochemical Analysis, Tech. Rept. 173, Joint WHO-FAO Committee, World Health Organization (1959).

Selenium. Magin, C. B., et al.: Suggested Modified Method for Colorimetric Determination of Selenium in Natural Water, J. Am. Water Workd Assoc. 52:119 (Sept. 1960).

Organisms of the Coliform Group. All of the details of techniques in the determination of bacteria of this group, including the selection and preparation of apparatus and media, the collection and handling of samples, and the intervals and conditions of storage allowable between collection and examination of the water sample, shall be in accordance with *Standard Methods for the Examination of Water and Wastewater*, current edition, and the procedures shall be those specified therein for

1. Membrane Filter Technique, standard test, or
2. Completed Test, or
3. Confirmed Test, procedure with brilliant green lactose bile broth.
4. Confirmed Test, procedure with Endo or eosin methylene blue agar plates.[2]

---

[1] Absence is taken here to mean a negligibly small fraction of the above specific limits where the limit for the unidentified alpha emitters is taken as the listed limit for ^{226}Ra.

[2] The Confirmed Test is allowed, provided the value of this test to determine the sanitary quality of the specific water supply being examined is established beyond reasonable doubt by comparisons with Completed Tests performed on the same water supply.

ION EXCHANGE AND DEMINERALIZATION

National Drinking Water
Clearinghouse

Ion exchange and membrane processes are becoming used extensively in water and wastewater treatment. Ion exchange is primarily used for the removal of hardness ions, such as magnesium and calcium, and for water demineralization. Reverse osmosis (RO) and electrodialysis, both membrane processes, remove dissolved solids from water using membranes.

ION EXCHANGE AND DEMINERALIZATION ARE BECOMING WIDELY USED

Ion exchange units can be used to remove any charged (ionic) substance from water, but are usually used to remove hardness and nitrate from groundwater.

Water is pretreated to reduce the suspended solids and total dissolved solids (TDS) load to the ion-exchange unit. Methods of pretreatment include:

- filtration,
- coagulation and filtration,
- cold lime with or without soda ash,
- hot lime with or without soda ash,
- evaporation or distillation,
- electrodialysis,
- RO,
- continuous deionization,
- ultrafiltration,
- degasification, or
- combinations of the above.

(Source: Owens, 1995)

RO systems are compact, simple to operate, and require minimal labor, making them suitable for small systems. They are also suitable for systems where there is a high degree of seasonal fluctuation in water demand.

Electrodialysis is a process that also uses membranes. However, in electrodialysis, direct electrical current is used to attract ions to one side of the treatment chamber. Electrodialysis systems include a source of pressurized water, a direct current power supply, and a pair of selective membranes.

ION EXCHANGE

Ion exchange effectively removes more than 90 percent of barium, cadmium, chromium (III), silver, radium, nitrites, selenium, arsenic (V), chromium (VI), and nitrate. Ion exchange is usually the best choice for small systems that need to remove radionuclides.

Advantages

- Ion exchange process, like reverse osmosis, can be used with fluctuating flow rates.

- Effluent contamination is virtually impossible.
- Large variety of specific resins are available from suppliers. Each resin is effective in removing specific contaminants.

Limitations

- Ion exchange waste is highly concentrated and requires careful disposal.
- Potential for unacceptable levels (peaks) of contamination in effluent.
- Usually not feasible with high levels of TDS.
- Pretreatment required for most surface waters.
- Ion exchange units also are sensitive to the presence of competing ions. For example, influent with high levels of hardness will compete with other cations (positive ions) for space on the exchange medium, and the exchange medium must be regenerated more frequently.

Process

Inorganics removal is accomplished through adsorption of contaminant ions onto a resin exchange medium. As the name implies, one ion is substituted for another on the charged surface of the medium, which is usually a synthetic plastic resin. This resin surface is designed as either cationic or anionic (negatively charged). The exchange medium is saturated with the exchangeable ion before treatment operations.

During ion exchange, the contaminant ions replace the regenerant ions because they are preferred by the exchange medium. When there are no ions left to replace the contaminant ions, the medium is regenerated with a suitable solution, which resaturates the medium with the appropriate ions. Because of the required "down time," the shortest economical regeneration cycles are once per day.

The resin exchange capacity is expressed in terms of weight per unit volume of the resin. The calculation of the breakthrough time for an ion exchange unit requires knowledge of the resin exchange capacity, the influent contaminant concentration, and the desired effluent quality.

Equipment

Typical ion exchange units consist of prefiltration, ion exchange, disinfection, storage, and distribution elements (see Fig. 1).

Chemicals

Sodium chloride is often used to regenerate the exchange medium in ion exchangers because of the low cost of the chemical. However, this can result in a high sodium residual in the finished water, which may be unacceptable for individuals with salt restricted diets. This problem can be avoided by using other regenerant materials, such as potassium chloride.

REVERSE OSMOSIS (RO)

RO can effectively remove nearly all inorganic contaminants from water. It removes more than 70 percent of arsenic (III), arsenic (IV), barium, cadmium, chromium (III), chromium (VI), fluoride, lead, mercury, nitrite, selenium (IV), selenium (VI), and silver. Properly operated units will attain 96 percent removal rates. RO can also effectively remove radium, natural organic substances, pesticides, and microbiological contaminants. RO is particularly effective when used in series. Water passing through multiple units can achieve near zero effluent contaminant concentrations.

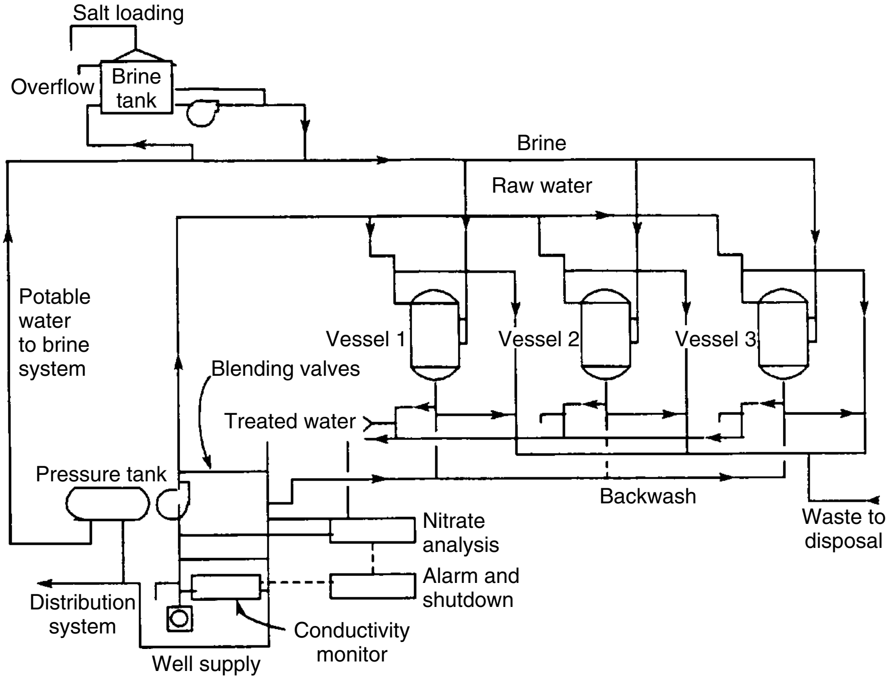

Figure 1. Ion exchange treatment system. *Source*: U.S. Environmental Protection Agency, 1989.

Advantages

- Removes nearly all contaminant ions and most dissolved non-ions.
- Relatively insensitive to flow and TDS level, and thus suitable for small systems with a high degree of seasonal fluctuation in water demand.
- RO operates immediately, without any minimum break-in period.
- Low effluent concentration possible.
- Bacteria and particles are also removed.
- Operational simplicity and automation allow for less operator attention and make RO suitable for small system applications.

Limitations

- High capital and operating costs.
- Managing the wastewater (brine solution) is a potential problem.
- High level of pretreatment is required in some cases.
- Membranes are prone to fouling.

Process

RO removes contaminants from water using a semipermeable membrane that permits only water, and not dissolved ions (such as sodium and chloride), to pass through its pores. Contaminated water is subject to a high pressure that forces pure water through the membrane, leaving contaminants behind in a brine solution. Membranes are available with a variety of pore sizes and characteristics.

Equipment

Typical RO units include raw water pumps, pretreatment, membranes, disinfection, storage, and distribution elements (see Fig. 2). These units are able to process virtually any desired quantity or quality of water by configuring units sequentially to reprocess waste brine from the earlier stages of the process. The principal design considerations for reverse osmosis units are:

- operating pressure,
- membrane type and pore size,
- pretreatment requirements, and

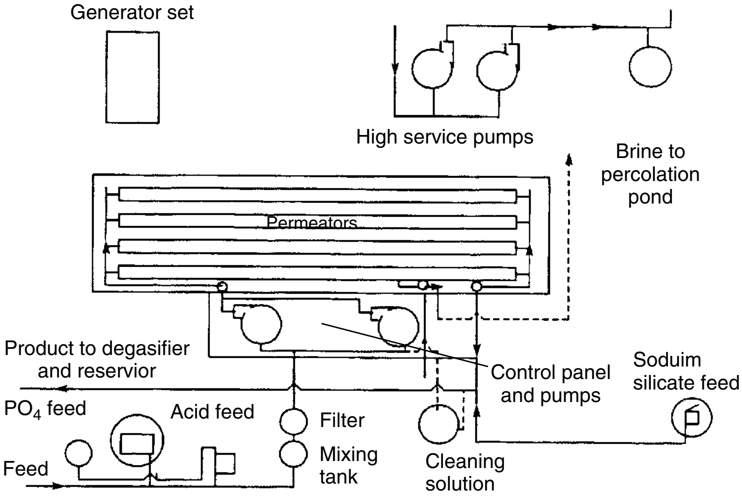

Figure 2. Schematic of a reverse osmosis system. *Source: U.S. Environmental Protection Agency, 1989.*

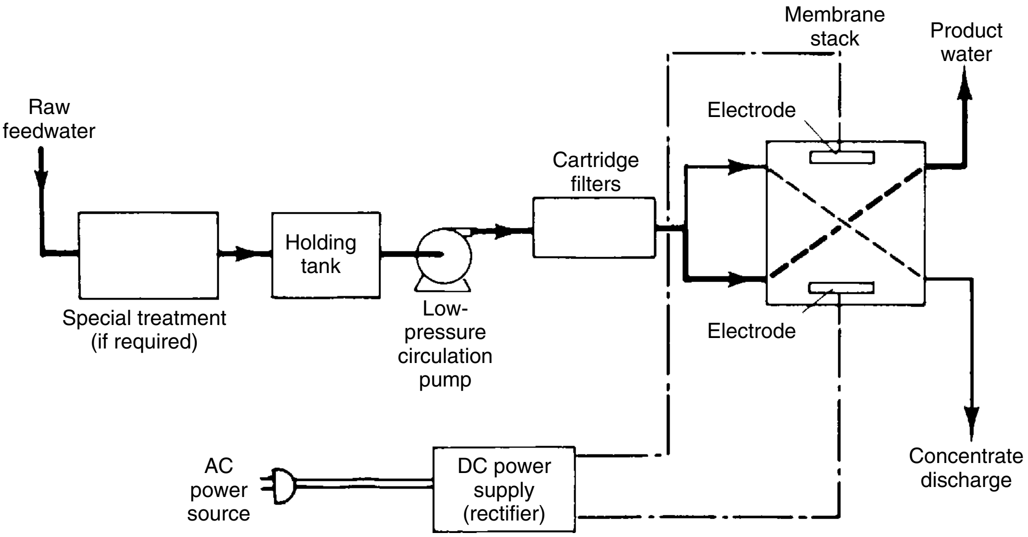

Figure 3. Basic components of an electrodialysis unit. *Source: U.S. Agency for International Development, 1980.*

- product conversion rate (the ratio of the influent recovered as waste brine water to the finished water).

Electrodialysis

Electodialysis is very effective in removing fluoride and nitrate, and can also remove barium, cadmium, and selenium (see Fig. 3).

Advantages

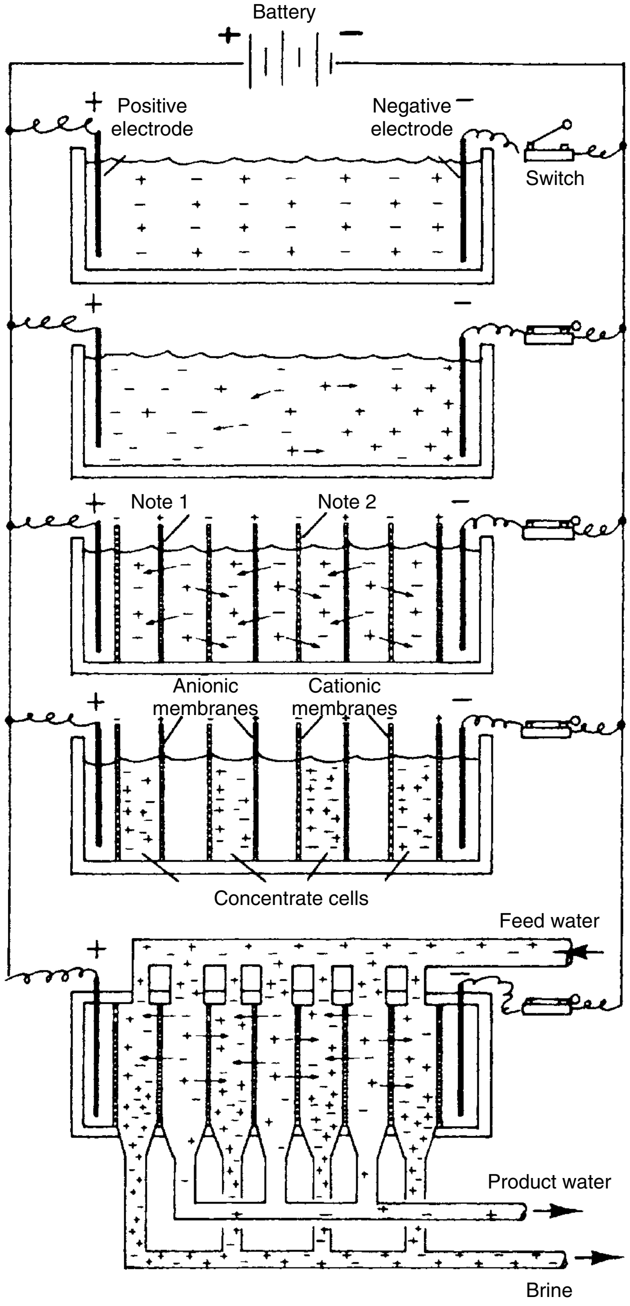
- All contaminant ions and most dissolved non-ions are removed.
- Relatively insensitive to flow and TDS level.
- Low effluent concentration possible.

Limitations

- High capital and operating costs.
- High level of pretreatment required.
- Reject stream is 20–90 percent of feed flow.
- Electrodes require replacement.

Process

The membranes adjacent to the influent stream are charged either positively or negatively, and this charge attracts counter-ions toward the membrane. The membranes are designed to allow either positively or negatively charged ions to pass through the membrane, thus ions



Many of the substances which make up the total dissolved solids (TDS) in brackish water are strong electrolytes. When dissolved in water they ionize; that is, the compounds dissociate into ions which carry an electric charge. Typical of the ions in brackish water are Cl^{-1}, Na^{+1}, HCO_3^{-1}, Mg^{+2},$SO4^{-2}$, and Ca^{+2}. These ions tend to attract the dipolar water molecules and to be diffused in times, fairly evenly throughout a solution.

If two electrodes are placed in a solution of ions and energized by a battery orother direct current source, the current is carried through the solution by the charged particles and the ions tend to migrate to the electrode of the opposite charge.

If alternately fixed charged membranes (which are selectively permeable to ions of the opposite charge) are placed in the path of the migrating ions, the ions will be trapped between the alternate cells formed.

Note 1: A positively fixed charge (anionic) membrane will allow negative ions to pass, but will repel positive ions.

Note 2: A negatively fixed charge (cationic) membrane will allow positive ions to pass, but will repel negative ions.

If this continued, almost all the ions wiould become trapped in the alternate cells (concentrate cells). The other cells, which lack ions, would have a lower level of dissolved constituents and would have a high resistance to current flows.

The phenomenon illustrated above is used in electrodialysis to remove ions from incoming saline water on a continuous basis. Feedwater enters both the concentrate and product cells. Up to about half of the ions in the product cells migrate and are trapped in the concentrate cells. Two streams emerge form the device: One of concentrated brine and the other with a much lower concentration of TDS (product water).

Figure 4. Movement of ions in the electrodialysis process. *Source: U.S. Agency for International Development, 1980.*

move from the product water stream through a membrane to the two reject water streams (see Fig. 4).

Equipment

The three essential elements of the system are (1) a source of pressurized water, (2) a direct current power supply, and (3) a pair of selective membranes. The average ion removal varies from 25 to 60 percent per stage. Multistage units can increase the efficiency of removal. Many membrane pairs are "stacked" in the treatment vessel.

Chemicals

Fouling of membranes may limit the amount of water treated. Fouling is caused when membrane pores are clogged by salt precipitation or by physical obstruction of suspended particulates. Particulates, suspended in water, can be removed in pretreatment but salts that exceed their solubility product at the membrane surface must be controlled chemically by pH reduction (to reduce carbonate concentration) or chelation of metal ions (by use of phosphate, for example). A reversal of the charge on the membranes, a process called electrodialysis reversal (EDR), helps to flush the attached ions from the membrane surface, thus extending the time between cleanings.

Where Can I Find More Information?

Information on ion exchange/demineralization was primarily obtained from two sources: Environmental Pollution Control Alternatives: Drinking Water Treatment for Small Communities, *EPA/625/5-90/025; and* Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities, *EPA/625/4-89/023. Both may be ordered free from the U.S. Environmental Protection Agency Office of Research and Development at (513) 569-7562.*

These publications also may be ordered from the National Drinking Water Clearinghouse (NDWC); however, copying costs apply. The first book, item #DWBKGN09, an 82-page publication, costs $11.82; and the second, item #DWBKDM04, a 209-page book, costs $30.05. Shipping and handling charges also apply.

For further information or to order copies of "Tech Brief: Ion Exchange and Demineralization," item #DWBLPE56, "Tech Brief: Filtration," item #DWBLPE50, "Tech Brief: Disinfection," item #DWBLPE47, or "Tech Brief: Corrosion Control," item #DWBLPE52 call the NDWC at (800) 624-8301 or (304) 293-4191. These fact sheets are available at no cost, except for shipping and handling charges.

THE STATE OF THE WATER INDUSTRY—2004

STEVE MAXWELL
TechKNOWLEDGEy Strategic Group
Boulder, Colorado

The water and wastewater treatment industry continues to be an evolving and often unpredictable business, and the year 2003 did not disappoint. The ongoing corporate consolidation in the industry produced surprises and new directions, whereas the headlong rush toward privatization seemed to falter, or at least slow a bit. Water resource issues and water management controversies continued to climb onto the front pages of the popular media; water quality scares, water rights battles, and water security issues gained significant public exposure. Wide-ranging debate over how to best fund the vast future capital needs of the water business began to take center stage. The extensive regional droughts of 2002 are still fresh in the minds of many people. And, although water stocks outperformed the general stock market this year, there still seem to be no big winners emerging. Below, we highlight the key industry developments of the past year, review the current characteristics of the market, and discuss the evolving drivers behind this business.

OVERVIEW

Studies and reports announcing the certainty and severity of future water challenges continue to be issued from the federal government, the various water-related trade associations, and environmental think tanks around the country. Earlier in the year, and to much fanfare, the American Council of Engineering Companies (ACEC) gave the water infrastructure system of the country a general grade of "D," and—supplementing numerous prior studies—the Congressional Budget Office predicted that we will need to spend more than $800 billion over the next 20 years to fix this problem. The increasing focus of concern among water industry and municipal officials is how to reconcile the difference between *current* spending rates and projected *future* needs—how to finance the "gap" that is becoming increasingly clear. As one observer put it, sometimes it seems that the fluid of most concern in this industry is not water, but red ink.

Although the trend to greater consolidation continued, 2003 may be remembered as the year in which the much-ballyhooed "foreign invasion" of recent years began to reverse directions. After practically tripping over each other in the rush to acquire assets during the late 1990s, many major European water companies began to shed major U.S. water businesses during the year. Although perhaps not totally unexpected, these divestitures constituted a major shift in the competitive dynamics and transactional trends in the business. In sum, several major players that have long been viewed as the prominent buyers in the industry, suddenly appeared to turn (at least partially) into sellers.

The reasons behind this shift are varied and complex (see discussion below), but it seems clear that a large-scale game of "musical chairs" is starting to happen in this industry. A considerable rearrangement of key assets

The information contained in this report has been obtained from sources believed to be reliable: however, their accuracy or completeness cannot be guaranteed. The opinions expressed herein are solely those of *The Environmental Benchmarker and Strategist*. Neither this report nor any opinion expressed herein should be construed as a solicitation to sell or acquire any of the securities or other investments mentioned herein.

is already starting to happen—in general, away from foreign companies and back toward domestic ownership. And, unfortunately for these foreign companies who were buying several years ago, average valuations in the industry are now lower (see Table 1), and the dollar has slid significantly against the Euro during the past couple of years.

Another longer term trend in the market—greater municipal outsourcing and private contract operation—also seemed to begin to shift direction or become less clear this year. The pace of privatization has been rapid during the past decade or so, and many analysts believe it was the perceived privatization opportunity that effectively drove much of the acquisition frenzy of the late 1990s. The last few years, however, have seen a gradual slowdown in this trend and an increasingly widespread reconsideration of the benefits of privatization of public water treatment operations. Starting with the much-publicized cancellation of Atlanta's water privatization plan and the postponement of programs in cities such as New Orleans and Stockton, the whole concept of water privatization has taken a major hit in public opinion circles during the past couple of years. For the first time in several years, the volume of outsourcing contracts in the country was actually down, and fairly sharply down, in 2003.

Nonetheless, the business of private contract operation is still projected to be one of the fastest growing market niches in the whole water industry. The forces behind privatization remain strong primarily because of the difficult position of municipalities. Public works managers are between a rock and a hard place—costs, technical requirements, and regulatory complexities continue to increase, but the general public remains resistant to increasing taxes and user's fees. As the contract operations firms point out, often the best solution to this dilemma

Table 1. 40 Publicly Traded Companies with Interests in the Water Industry

may be to turn to private companies to finance, build, and operate their water or wastewater systems.

From the perspective of Wall Street, the water industry was relatively stronger this year, and most water funds and indices outperformed in generally stronger markets. But even though performance was stronger, we still have not seen any really "big winners" in the industry—stocks that have returned investors many times their original investment. However, the professional stock-pickers assure us that there *will* be such companies emerging in the near future (Table 1).

An emerging issue in the water industry—one that is likely to loom considerably larger in the future—is the appropriate balance of the federal government and local authorities in the financing and management of water resources in this country. Groups like AMSA (the Association of Metropolitan Sewerage Agencies) claim that the federal government is sidestepping the whole issue of clean water. In an aggressive public information campaign that the group began to mount in 2003, they pointed out that in 1980, over half of the total capital investment in clean water came from federal funds, whereas today that figure is less than 10%.

Certainly, watershed management and water quality are interstate issues—water quality and management issues rarely follow state boundaries. Another lobbying group, the Water Infrastructure Network—a coalition of various elected officials, water utilities, and water resource groups—points out that clean water supports $50 billion per year in water-based recreation, $300 billion per year of coastal tourism, $45 billion in commercial fishing, and of course, hundreds of billions in basic manufacturing and industry. Despite the obvious criticality of water to the overall economy, so far there are few indications that the federal government plans to address the complex funding issues facing the business.

And other new challenges continue to arise and bedevil the U.S. water industry. Following the events of 9/11 and the discovery of potential terrorist interest in public drinking water supplies, security quickly moved to the forefront of immediate challenges facing the industry. Although there has been a lot of discussion about security threats, most of the work remains to be done, and most of the dollars still need to be spent—one more increment to the total cost of providing the public with acceptable drinking water.

A related problem also received new visibility this year—the issue of backup electrical power in the water system. During the massive northeastern blackout of August 14, several major cities that rely primarily on pumping for water distribution (as opposed to cities like New York with largely gravity-fed systems) were without sufficient water for several hours. An outbreak of fire during that particular day, for example, in downtown Cleveland or Detroit, could have been catastrophic. Installation of sufficient backup power for pumping and distribution has quickly become a high priority at many water systems across the country.

Technology development and implementation continues to be an active area, attracting many new players, and holding out hope for future solutions. The full-scale commercialization of membrane filtration is a good example—more and more water and wastewater utilities are now examining this technology, as its costs have come down dramatically in recent years. Although the much-discussed Tampa desalination plant suffered extensive operating problems this year, including the bankruptcy filing of its operator, the market for this particular technology—particularly in desalination and water reuse applications—remains strong. Other areas include *in situ* repair and relining of aging distribution pipelines; "smart" monitoring, metering, and system control software; and a wide range of other new treatment, distribution, and conservation technologies.

In response to these changing social, political, and economic drivers, the water industry continues to undergo gradual evolution and coalescence. With such dramatic changes occurring in technology, asset ownership, regulation, and public concern, the water industry seems certain to remain in a constant state of change for the foreseeable future.

Another way to gauge the impact of these changes on the commercial industry is to look back at our list of public companies in *The Environmental Benchmarker and Strategist* from just 5 short years ago, in late 1998. The experiences of these companies—most of which have now disappeared from the ranks of the public companies—illustrates some general trends in the industry since that time:

- Air and Water Technologies—sold by Vivendi in 2000
- American Water Works—purchased by Thames Water/RWE in 2001
- Aquarion—purchased in 1999 by Yorkshire Water (now Kelda)
- Azurix—Enron's heralded entry into the water industry; dead three years later
- BetzDearborn—purchased by Hercules, later sold to General Electric in 2002
- Cadiz—company virtually disappeared after major water storage program was nixed by the state of California in 2002
- Culligan—acquired by U.S. Filter in 1998, and now for sale again
- E-One—sold to Precision Castparts in the late 1990s
- Hach—acquired by Danaher Corporation in 1998
- Nalco—bought by Suez in 1999 and sold to private investors in 2003
- Osmonics—acquired by General Electric in 2003
- Recovery Engineering—acquired by Procter and Gamble in 1998
- Stone and Webster—filed for bankruptcy, assets acquired by Shaw Group
- Thermo Instrument Systems—collapsed back into parent Thermo Electron
- US Filter—acquired by Vivendi, spun into Veolia subsidiary, most of its noncontract services businesses now for sale again

- U.S. Liquids—suffered through extreme financial difficulties, selling off assets, and now trading at a few cents per share
- United Water—remaining traded stock acquired by Suez in 2001
- Western Water—like Cadiz, has shrunk down considerably, perhaps a company before its time in water rights trading
- Zurn—company was sold to U.S. Industries in 1998

MARKET SIZE AND GROWTH CHARACTERISTICS

According to recent Department of Commerce statistics, the water and environmental business in this country comprises more than $200 billion of revenues per year, encompasses some 115,000 companies and organizations, and employs more than 1.4 million workers. More specifically, the water and wastewater industry is generally estimated at around $90 to $100 billion per year; the comparable world market is about five times as large, or around $500 billion.

Estimates of the true size of this business vary, largely due to one key reason—it is a tough business to define and "encircle"—definitions differ, and even where they do not differ, market estimates still vary widely. Perhaps the most thoroughly researched and widely cited numbers on the overall domestic water industry are those published annually by Environmental Business International, as shown in Table 2.

Because it is such a broad and varied business, it is not meaningful to try to capture the overall industry's growth rate in a single figure either; different sectors of the business are growing at considerably different rates. For example, the more mature chemicals sector and infrastructural supply businesses (pumps, pipes, tanking, and so on) are probably growing in the 2% to 3% range. The water and wastewater utility sectors, which comprise the largest individual source of revenues in the industry, largely reflect population and GNP growth and show growth in the 3% to 4% range. Other businesses, tied to the upgrading and replacement of our vast water infrastructure, such as consulting engineering and instrumentation/monitoring, show slightly higher growth in the 6% to 8% range.

On the other hand, other sectors of the business boast growth well above these rates. The contract operations and outsourcing sector of the business has demonstrated growth in the 15% to 20% range for several years and even given the recent slowdown is still likely to average something in the 8% to 10% range. And although the overall treatment technology sector shows average growth of around 5%, there are certain niches—such as the membrane treatment and advanced oxidation technologies—which are currently enjoying growth more in the 10% to 15% range.

Table 2. Size of the Water Industry (Revenues in Millions)

Business Segment	2003 Revenue	'04–'06 Growth
Water treatment equipment	$8,860	4–6%
Delivery equipment	$8,880	2–3%
Chemicals	$3,660	0–1%
Contract operations	$2,290	6–10%
Consulting/engineering	$6,090	5–6%
Maintenance services	$1,640	3–5%
Instruments/monitoring	$800	5–7%
Analytical testing	$480	2–4%
Wastewater utilities	$30,780	3–4%
Drinking water utilities	$32,650	3–4%
Total U.S. water industry	$96,130

KEY MARKET DRIVERS

As we have discussed, a handful of key factors—economic and social demands and political realities—are driving the overall development of the water industry. These drivers, in turn, are giving rise to various trends and effects that will likely dominate the water industry for years to come. Some of the key factors are listed below.

Water Scarcity and Water Quality Problems Are Growing

This is clearly the critical core issue behind this entire industry and the ultimate driver behind the challenges and growth projected for the water business over the coming decades. The gradual development of this situation has resulted from decades (indeed, centuries) of unfettered industrial expansion, continuing population growth, and a careless and uninformed belief that the environment would take care of itself. We do not need to recite the statistics again here, as they are well known—the millions of children who die each year because of unsanitary water conditions, the major cities of the world that still discharge their untreated wastes directly into the natural waterways, the number of people even in the United States who still drink water that is out of compliance with the Safe Drinking Water Act, and so on. Hundreds of studies have pinpointed the lack of sufficient clean water as one of the most serious threats facing humankind.

Public Awareness and Concerns Are Growing

As these water scarcity and quality problems have become more serious and more apparent, the public has become better informed and more concerned about the water problems that their children and grandchildren may inherit. One needs only to look at the pages of the popular press to see how broad and widespread this recognition is becoming. Stories about water scarcity or pollution problems are common headlines and have even become the stuff of popular Hollywood entertainment. As the general public becomes more aware and concerned about water, peoples' demands and perceptions will become a more important driver in determining the shape of the business. (One need only look at the explosive growth of the bottled water industry over the past few years to see how significantly customer perceptions—rightly or wrongly—can create and drive new markets.)

Regulatory Controls and Enforcement Are Growing

In turn, as public awareness and concern have grown, it has translated inexorably into greater government review, legislation, and regulatory control. Although environmental regulation and enforcement have waxed and waned during the past three decades, when it comes to drinking water, the public is insistent on ever-stronger regulatory protection of our water resources. For example, there were just nine new bodies of regulations, or rules, implemented between 1974 and 1996. Since the 1996 reauthorization of the Safe Drinking Water Act (SDWA), there have been more than 10 new rules implemented.

Under the SDWA, some key ongoing areas of regulatory development include the disinfection byproduct rule, the interim enhanced surface water treatment rule, the arsenic rule, and the groundwater rule. On the *waste*water side of the business, the primary governing legislation is the Clean Water Act, where key trends have included a more intense focus on *nonpoint* source runoff, continuing implementation of the total maximum daily load (TMDL) regulations, and programs geared toward combined and sanitary sewer overflow regulations to control wet weather runoff in metropolitan areas. Overlying these strictly regulated areas is the growing concern about potentially "introduced" compounds—terrorism—and all of the security concerns regarding primary drinking water supplies that have arisen as a result of 9/11. And finally, although the pace and intensity vary, regulatory controls are also becoming stronger in most other regions of the globe.

Meeting These Needs Is Going to Require Huge Expenditures

Finally, for municipalities and industry to comply with these regulations and to maintain and expand water infrastructure, huge capital expenditures will be required over the coming decades. As we have mentioned, numerous studies have predicted how large this expenditure must be; the estimates vary, but it is definitely in the hundreds and hundreds of billions of dollars. These dollars represent a huge challenge to this country, but they also constitute a huge opportunity for firms that serve the water and wastewater treatment industry.

KEY INDUSTRY TRENDS

These drivers, in turn, are leading to various trends and developments, both in terms of how the economy uses water and in terms of supply and demand within the commercial water technologies and services industry.

Continuing Consolidation and Ownership Changes

The water industry has been experiencing a dramatic rearrangement of ownership and increasing consolidation, as firms strategically position to address these opportunities. The dizzying pace of transactions the last few years—particularly those involving the larger domestic players and major foreign acquirers—has dramatically altered the face of this industry.

On the other hand, it would be easy to get the impression—particularly in the last few months—that events may actually be headed in the other direction. Quite abruptly, several key buyers (who have pumped hundreds and hundreds of millions of dollars into U.S. water acquisitions in recent years) seem to be reversing direction and deciding to spin off key businesses. In September, Suez announced that it had sold its Nalco water treatment unit to a group of private equity investors for $4.2 billion—roughly the same price for which it had acquired the business 4 years earlier. In its announcement, the company cited a narrowing strategic focus and the need of the parent organization to reduce its debt.

But the real surprise came in late September, when Veolia's U.S. Filter unit announced plans to sell off many businesses it had acquired through the 1990s. U.S. Filter has been the "king" of the emerging water industry for more than a decade, having conducted dozens of consolidating acquisitions during the 1990s, before being acquired by Veolia (Vivendi) in 1999. Although many had expected the company to spin off a few units here and there as it continued to focus its business, few expected a divestiture of this magnitude. Veolia cited considerations similar to those of Suez—the need to reduce high debt at the parent company level and further strategic concentration on its historical core business in contract operations and outsourcing services.

As of early February 2004, the sale of U.S. Filter's businesses is still ongoing. Everpure, the firm's water filtration products business, recently sold to Pentair Corporation at a very high price–$215 million for a business doing $60 million in revenue per year and producing some $20 million of EBITDA per year. The well-known Culligan subsidiary has attracted interest, but to date, it has not been sold. The remaining bulk of U.S. Filter's equipment business, which represents $1.2 billion in revenues, also remains on the block. U.S. Filter's preference that the business be sold as one piece, and the likelihood that it will trade at a multiple of greater than one times revenues, has obviously restricted the pool of capable and interested buyers. There simply are not many buyers financially capable of undertaking that large a purchase.

Some of the major British water companies also have begun to divest various units, again, primarily equipment and product businesses. In other recent transaction news:

- Ionics, one of the larger remaining independent players in the water industry, acquired Ecolochem, a private water treatment company, at a value of more than three times revenues. This was a large deal for Ionics, which has been struggling financially during the last 2 years.
- ITT Industries maintained its rapid pace of expansion in the industry, buying several more small players, but also commencing a bid for the major German ultraviolet treatment technology firm Wedeco. Wedeco had approximately $150 million of revenue in its latest fiscal year. ITT remains one of the most active buyers in the U.S. water market.

- Pentair acquired WICOR, a unit of Wisconsin Energy that produces water systems, filtration products, and swimming pool products and services. The deal was priced at $850 million in cash for a company generating approximately $750 million in revenues. At the same time, Pentair announced the divestiture of some of its other nonwater-related businesses, culminating a dramatic strategic repositioning of the firm into almost a water industry "pure play."
- Philadelphia Suburban Water company, now the largest independent investor-owned utility in the country, continues to make additional acquisitions. Most recently, it acquired several businesses from Allete Water in North Carolina. Philadelphia Suburban also changed its name to Aqua America to reflect its new and broader strategy.
- Finally, as always, there are also numerous smaller deals occurring, including the acquisition of Flowmatic, a reverse osmosis component manufacturer, by Watts Water, and the sale of Waterlink's remaining Barneby Sutcliffe operation to Calgon Carbon Corporation.

So many major assets are up for sale at the same time that the competitive situation in the water treatment equipment industry has been turned upside down. It will be interesting to watch where these various assets end up and to see which companies step forward to be major players in the next generation of this industry. Most observers are betting on the various diversified U.S. companies mentioned above—ITT Industries, GE Water, Pentair, and perhaps several others who have not yet made their first move. But the big questions remain—how can companies that were committed buyers turn into sellers in just a few short years? Was something wrong with their business strategies? Will the new owners of these assets be more logical owners than the previous ones? And most importantly, what will be the ultimate impact of this massive ownership rearrangement on employees, shareholders, and finally, the customer?

The Pace of Privatization and Outsourcing Begins to Slow

As mentioned before, one of the most controversial aspects of the water industry today involves the transfer of water management, treatment, and distribution operations from public to private control. Although private operation of water and wastewater utilities has been common in parts of Europe for decades, increasing privatization in North America and other parts of the world seems to be generating increasingly bitter political debate. During the past couple of years, it has become considerably less clear how far privatization will actually proceed in this country. The highly publicized misfortunes of several large projects like Atlanta, combined with an active and organized opposition movement, has forced a wholesale reevaluation of water and wastewater privatization. A number of large projects have been shelved or put on hold, and the whole nature of private contract operations is undergoing a major shift.

As a result, although the industry had been growing at rates of as high as 25% per year, considerably lower growth is now expected. As an example of how tough the last year was, one industry publication recently indicated that the U.S. contract operations business had seen the number of contracts drop off by 20%, whereas the *value* of the contracts declined by almost 73% during the year. OMI and Thames stand to lose as much as $300 million if their project in Stockton, California, is unwound. United Water was a big loser with the Atlanta job and with PRASA in Puerto Rico, which would have been one of the world's largest privatization projects.

The contract operations business also seems to be experiencing somewhat of a shift from a major "big-city" project orientation to smaller and shorter term contracts for smaller municipalities. The firms that have focused on this latter type of business seem to be doing reasonably well, whereas the firms that have focused on the huge projects seem to be having a more difficult time. Nonetheless, many firms continue to believe that contract operators have a very important and growing role to play in the industry. Veolia/U.S. Filter is obviously still very optimistic about the potential to manage the larger privatization jobs successfully and profitably, as indicated by its current effort to strategically reposition the firm primarily as a contract services provider.

And, in the bigger scheme of things, it is important to note that the simple threat of privatization has already forced widespread efficiencies by itself—a sort of "de facto" privatization. In summary, despite the concerns of labor organizations and various public interest groups, the urgency of infrastructural needs and the political barriers against major tax increases make it seem likely that privatization will continue to grow. At the same time, it is clear that private operators are going to be judged by a very demanding and critical public. A few other key trends are also important to note in any broad review of this industry.

Increased Focus on Water Recycling and Reuse. There are continuing and inexorable pressures toward greater water reuse and recycling systems—an obvious but as yet largely untapped means of addressing water shortages. With technologies readily available today, wastewater can easily be cleaned to levels where it can be recycled back into primary usage and at steadily declining costs. Examples of new wastewater reuse projects are coming out regularly now—typically for irrigation projects, or for more innovative applications, such as one recent project where treated wastewater was injected into the ground to act as a barrier against seawater intrusion to protect underground freshwater aquifers in Southern California.

Direct reuse of wastewater, particularly for drinking, is still a bit of a stretch for most Americans (and indeed is only commercially practiced in a small handful of locations around the world). However, this resistance is primarily due to poor understanding of the hydrologic cycle and our nation's current water usage patterns. For example, on some major river systems in the United States, water is used and reused up to 20 times as it travels to the sea. The discharge water from one wastewater treatment plant contributes to the raw water intake for a primary drinking water plant a few miles downstream. As a result of 30 years of steady progress under the Clean Water Act, the discharged waters from wastewater treatment plants are often cleaner than the rivers and streams they flow into. This type of *indirect* reuse of wastewater for drinking (after it has flowed in and out of a river, or into and out of an underground aquifer, and then through a treatment process) is clearly widespread and is obviously "acceptable" to most Americans.

An interesting statistic to remember when evaluating the long-term impact of wastewater reuse to extend our primary water resources is that only a tiny percentage of our primary water supply is actually used for drinking. Compared with the roughly 1200 gallons of water per capita per day that it currently takes to power the U.S. economy, an individual typically drinks less than a gallon a day. This leaves 1199 gallons per person per day that could be recovered without anyone ever having to drink "recycled" wastewater. Hence, even if only small incremental gains could be made in nonpotable water reuse, overall water availability could be substantially impacted. Over the longer term, we will move beyond our "linear" thinking of today and develop a more "circular" philosophy of water usage.

Conservation and Efficient Water Use

Closely related to improving our water reuse habits as a nation is the whole area of conservation of water and more efficient usage of water. During the droughts of 2002, many of us were forced to see how efficient we could become—and most of us found that it was not that difficult to save quite a bit of water. Indeed, water conservation ideas are only beginning to take advantage of the "low-hanging fruit." As water prices rise, there will be increasing incentives for people to use water more carefully and for industrial companies to retool their manufacturing systems to use less water.

OUTLOOK FOR THE FUTURE

As we have said many times, the challenges and requirements of the water industry are likely to be one of the most pressing problems facing humankind over the next century. The primary and overriding conclusion that falls out of the foregoing discussion is the inevitability of continuously rising water prices over the longer term future; as water becomes more scarce, there seems to be no alternative. Water is still very inexpensive—ridiculously cheap in many ways. And, at least in the United States, we are still on the highly inelastic portion of the demand curve for water, where increases in price have relatively little impact on usage. This inescapable conclusion and the vast scale of the world's water problems were highlighted in a special report in the July 2003 issue of the respected British newsweekly *The Economist*, which concisely concluded that water is "ill-governed and colossally under-priced." Discouragingly, the study also reported that the United States is the most wasteful nation on the earth in water usage.

As prices continue to increase, decisions about water usage will necessarily begin to take on greater economic significance. This will force us to focus on more efficient water usage and demand management techniques, technologies such as membrane desalination, and practices such as improved water conservation and recycling. All of these are already happening, but in the future, water expenditures will make up a larger and larger share of the GNP.

Water will increasingly be recognized as an economic good. However, exactly what that means is subject to varying interpretation. Some argue that water should be treated as a fully tradeable market commodity, subject to the general forces of supply and demand in an unregulated market—that water's value is essentially the same as its free market price. On the other hand, there is the antimarket argument—that water should be exempt from market forces because it is an essential prerequisite to life. Adherents to this philosophy argue that water is a basic human right and that forces greater than the free market are required to ensure that everyone has enough clean water to live.

Over the long term, some sort of intermediate position is likely to prevail—water should be treated as a scarce resource, which means that we have to balance economic and social objectives and carefully allocate water to its myriad uses. Market incentives can be a powerful means of properly managing and allocating a scare resource, but in the case of water, we must ensure that such markets are sufficiently regulated to protect social equity as well.

In closing, consider the following "big questions"—many more of which will continue to emerge in the future:

- Water is being transferred from American agriculture to American cities at an alarming rate. Farmers in the southwest are increasingly finding that current economics suggest that they stop farming and sell their underlying water rights to neighboring cities. What are the long-term implications of allowing our farmlands to dry up to slake the thirst of our ever-expanding cities?
- Why do we as a society treat such vast amounts of water to drinking quality standards when less than 1% is actually used for drinking? Should we really be incurring the capital costs of providing drinking quality water for fire fighting, mixing cement, washing cars, or watering yards?
- As sedimentary deposits fill the massive reservoirs that we have constructed during the last 60 to 80 years, how will we continue to provide controlled water supplies to the arid southwestern part of the country? We have become experts at building dams. What do we do with them when they no longer function?

So ... the water industry is full of challenges, but it is also full of opportunities. Water is an essential prerequisite of life, and we are not going to find any substitutes for it. The amount of freshwater on this earth is relatively fixed, and we need to become much smarter and more efficient in our usage of that scarce resource. For creative, innovative, and well-managed firms, the water industry offers unrivaled opportunities.

THE GLOBAL DESALINATION MARKET: TRENDS AND OUTLOOK FOR THE FUTURE

Lisa Henthorne and Eric Jankel

The desalination market has reached an all-time high in terms of growth in capacity, primarily due to the fact that the cost to desalinate water continues to decrease and now stands at less than $2.00 per thousand gallons of produced clean drinking water. Remarkably, in 2001, over 845 million gallons per day (gpd) of new capacity was contracted for installation worldwide, making it the highest recorded year in contracts for new installations. The final numbers for 2002 are expected to be even higher. Prior to 1996, an average of about 265 million gpd of new capacity was contracted per year, which rose to about 500 million gpd average per year in the years between 1996 and 2000. As a result, this is a very exciting time to be involved in the desalination market. Presently, approximately 8.5 billion gpd of desalination capacity has been installed or contracted through the conclusion of calendar year 2001 in 9500 plants worldwide.

The desalination market is in a state of rapid change. Membrane plants using seawater as a source and reverse osmosis (RO) as a process are being designed and constructed with capacities that were unheard of as recently as 1-5 years ago. Examples include the Ashkelon, Israel, and Fujuirah, U.A.E., plants of 87 million gpd and 45 million gpd, respectively. Unit capacities for multiple stage flash (MSF) distillation units are approaching 20 million gpd each. The Middle East has traditionally been the focus of desalination, predominantly using thermal technology such as MSF, but today large-scale desalination plants are being built throughout the world; plants outside the Middle East prefer RO technology. As a result, there is a broad-based shift occurring, from thermal technologies to membrane technologies for desalination applications. In 1990, 60% of the world's existing desalination capacity used thermal technologies, whereas at the end of 2001, this had dropped to 47%; the remaining capacity uses membrane technology.

Worldwide, desalination installed capacity has grown at an average rate of 10.6% per year over the last 30 years. In more recent few years, the growth rate has begun to increase. The key drivers behind the tremendous growth in the desalination market can be summarized as follows:

1. Significant reductions in the cost of desalting water due to
   - improved productivity and reduced cost of membrane elements in reverse osmosis;
   - increased efficiencies and economies of scale improvements in thermal processes;
   - the global trend toward privatization of water/power projects; and
   - improved energy recovery devices, which reduce the net energy requirement for reverse osmosis.
2. Changing demographics, specifically, population growth in arid, semiarid areas, and water-deficient areas.
3. Continuing increased standards of living in water-deficient areas.
4. Environmental concerns and increasing regulatory requirements that are forcing water suppliers to examine and use alternative sources of raw water.
5. Concerns and reaction to sustained drought conditions; seawater desalination is a drought-proof source of raw water.
6. Increased demand for high-grade water for industrial and commercial applications.

There are several recent desalination activities of particular note going on around the world. Due to increasing revenues as the price of crude oil has risen, construction of new desalination capacity and refurbishment of installed desalination capacity in the Gulf States is taking place at a rapid pace, especially in the U.A.E. The first large-scale (90 million gpd) privatized wastewater reuse RO plant is under construction in Kuwait using ultrafiltration (UF) as a pretreatment.

For the first time, a large-scale seawater RO plant (25 million gpd) has begun operating in North America, in Tampa Bay, Florida. At least 10 more large-scale seawater RO plants are in the planning stages in California, Texas, and Florida. Large-scale (40 million gpd) nanofiltration (NF) plants are also pending startup of operations in the United States.

The growth of both thermal and membrane technologies is shown graphically in (Fig. 1).

The primary factor behind the increasing growth of membrane desalination is the rapidly declining cost of membranes. A U.S. government-funded research and development program in the early 1960s developed and commercialized the first membrane-based RO process. The membranes that resulted from this effort became commercially available in the 1970s. Continued development and improvements in membrane productivity and reduction in pricing of the membranes due to competition among key manufacturers has continued through today. Now, over 200 hundred RO and nanofiltration products are available. Today, membrane-based reverse osmosis has become an extremely competitive and cost-effective means of producing large volumes of very high quality water.

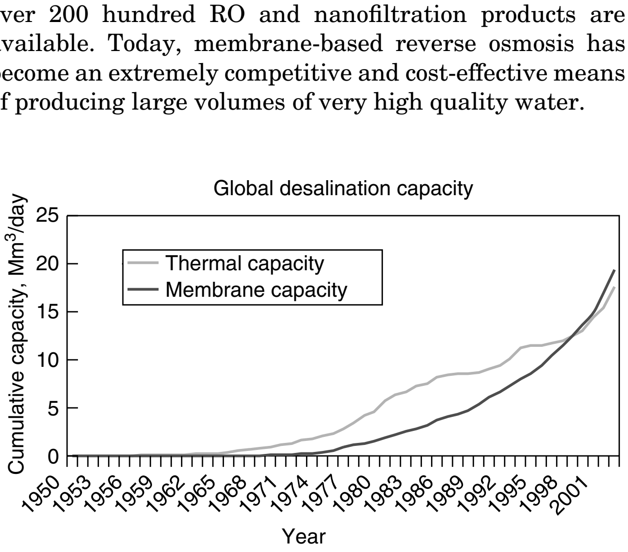

Figure 1. Cumulative capacity of all desalting technologies installed worldwide between 1950 and 2001 with projected plants in 2002.

Another way to evaluate the impact of the improvement in RO membrane properties on the cost of membrane technology is to consider the amount of water produced per unit capital cost. Figure 2 illustrates the increase in water produced using seawater desalination for the same capital investment, compared over time since 1980. These data indicate that for the same capital investment, approximately 27 times more water can be produced today using RO membranes than was possible in 1980.

Capital costs for membrane technology vary considerably based on the feedwater source and technology used. Table 3 provides a range of typical capital costs based on facilities contracted over the last few years and over a range of throughput capacities.

The privatized total water cost for seawater desalination using RO technology in large-scale facilities is generally in the $2.00 per thousand gpd price range.

A key recent project, which may portend future market trends and innovative approaches to membrane desalination in the United States, is the Tampa Bay Water program. This regional water utility, which supplies 225 million gallons per day of water to a five-county area, was required by regulators to reduce the pumping of groundwater at the same time that it faced a sustained period of drought. The utility responded by asking the industry to propose new alternatives for operating on a privatized basis. Through a long and arduous process, four bidders submitted tenders to supply a 25-million gpd desalination system. There are unique site-specific factors that contribute to the $2 per 1000 gpd price, including salinity fluctuations below average seawater levels (from 16,000 to 32,000 mg/L) and colocation; the adjacent power plant provides warmed cooling water and shared intake/outfall. The facility was developed by a privatized developer, Poseidon Resources, but ownership was transferred to Tampa Bay Water prior to the plant commissioning in May 2003.

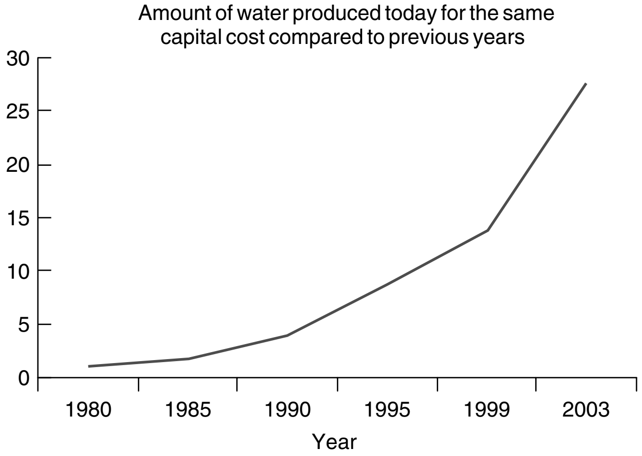

Figure 2. Change in water produced using seawater RO technology for the same capital investment over time.

Table 3. Range of Capital Costs for Membrane Desalination Plants (2001–2003)

Technology	Feedwater Source	Cost, $/gpd
NF	Wells with hardness and salinity	$1.13–$1.51
RO	Brackish wells	$1.13–$1.89
RO	Brackish surface	$1.51–$2.65
RO	Seawater	$2.84–$4.54
RO	Municipal wastewater	$2.27–$4.16

Covanta Water constructed the plant and would have operated the facility under a 25-year agreement with Tampa Bay Water. However, under a settlement agreement recently executed, Covanta has been expelled as the operator due to problems with the performance testing. Hydranautics, the RO membrane supplier used some unique design features for the facility, including a partial second pass to optimize product water quality. There are over 10,000 RO membranes installed at the facility, and their total energy demand is about 14 MW. Presently, the plant is experiencing difficulty in achieving successful pretreatment using the Covanta proprietary dual-sand filtration process.

The desalination market has a very bright future and should offer vast opportunities for private companies. The Middle East is still the largest market for desalination systems, maintaining approximately 49% of the worldwide contracted capacity. Figure 3 shows the percentage that each of the key regions of the world comprise, based on their desalination capacity contracted or installed through 2001.

Prospects for the continuing growth of the use of desalination technology are very optimistic. In the big picture, the availability of freshwater in the earth's hydrologic cycle is fixed; at the same time, the global population is growing, especially in arid and semiarid areas; standards of living are generally rising; existing sources of fossil groundwater are being depleted; surface supplies are being more stringently regulated; and the economic, political, and environmental costs of developing new sources of surface supply are increasing.

Reverse osmosis applications are anticipated to continue growing at roughly 11% to 12% in the future, and nanofiltration capacity is expected to grow at about 16%

per year. Thermal technologies and electrodialysis are anticipated to grow at lesser rates in the future. Over the period from 2004 to 2009, there will be over six billion gpd of new desalination capacity contracted at a capital investment of between $15 and $25 billion, as determined by our current evaluation and projections for the overall world desalination market.

FINANCIAL PERFORMANCE OF WATER COMPANIES

(*Note*: The data used to construct the charts and analysis in Tables 4–8 are from early February 2004.)

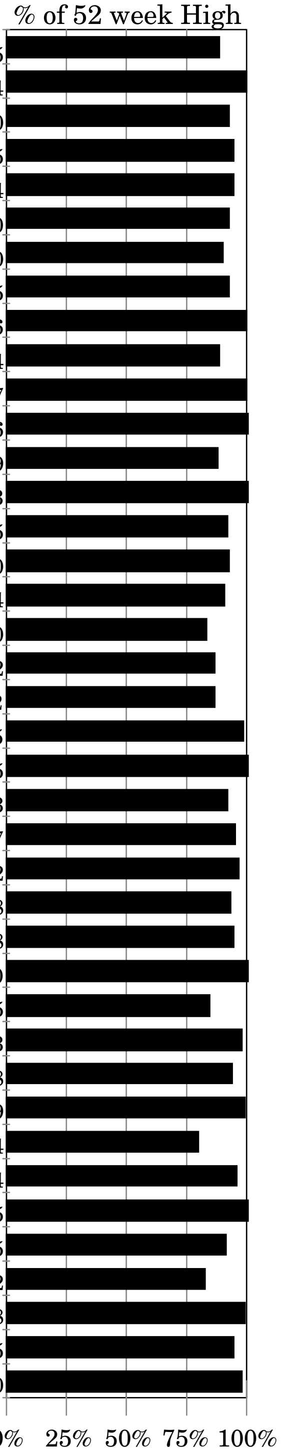
Table 8 demonstrates the recent strength in the broader stock market; most of the water firms traded at or near their 52-week highs, as was the overall market in early February. Table 7 is also a reflection of the price of the individual company's stock; most water firms show a P/E ratio between 15 and 20. The exceptions are a handful of firms, like Glacier Water and Great Lakes Chemicals, who have negative earnings for the trailing 12-month period used in these calculations, and for whom this is hence not a relevant measure.

Table 8. Stock Price Performance

Company	Price
American States	$25.55
Ameron	$39.04
Aqua America	$21.00
Artesian Resources	$28.25
Badger Meter	$37.34
Calgon Carbon	$19.90
California Water	$28.00
Clarcor	$42.25
Clorox	$49.66
Cuno	$41.24
Danaher	$94.67
Dionex	$54.66
FlowServe	$19.99
Fluor	$40.83
Franklin Electric	$59.85
Glacier Water	$20.10
Great Lakes Chemical	$25.24
Insituform Tech.	$16.00
Ionics	$28.52
Isco	$ 8.52
ITT Industries	$77.05
Layne Christenson	$13.25
Lindsay Mfg.	$24.83
Metpro	$17.07
Middlesex Water	$20.42
Millipore	$49.88
Pall	$26.28
Pentair	$53.40
Robbins & Myers	$19.75
SJW Corporation	$97.63
Southwest Water	$13.98
Suez SA	$21.69
Tetra Tech	$21.84
Thermo Electron	$28.34
URS	$28.95
Valmont Industries	$21.95
Vermont Pure Hldgs.	$ 3.42
Veolia Envir.	$28.98
Waterpik	$12.65
Watts Industries	$22.60



There is one important note about the Equity valuations in Table 7—the sometimes overlooked effect of simple arithmetic in ratio calculations. One of the inherent difficulties in interpreting either P/E ratios (or EBITDA multiples) is the effect of a very small value in the denominator. Generally speaking, companies with higher P/Es are perceived to be more valuable; however, this applies only within given ranges of "reasonableness." For example, the very high estimated P/E ratios for Layne Christenson or Vermont Pure are more the result of tiny earnings than intense interest in and demand for the stock. Detailed understanding of the company's individual economic circumstances and some judgment are needed to interpret what an individual P/E ratio really means.

Two different measures of profitability are shown in Table 4, operating profit as a percentage of revenue and return on equity. As can be seen, many companies in the water industry generate operating profits between 10% and 15%, which is higher than most other environmental companies. It is also clear that the water utility companies, as regulated local monopolies, have uniformly higher operating profits; see Artesian Resources, Aqua America, American States, and SJW. Return on equity measures not only general profitability, but also the relative balance of debt and equity in financing the company. Table 5 shows two key figures from a company's balance sheet, the current ratio, or ratio of currents assets to current liabilities, and the longer term debt to equity ratio. A higher current ratio usually implies a stronger short-term financial situation. As detailed in the cover story, note the relatively much higher debt levels of both key French companies. Veolia and Suez.

Table 6 illustrates two rough productivity measures—the amount of earnings (actually EBITDA is used here) and revenue that a company manages to generate per employee. Interestingly, when compared in this manner, water companies show a wide range of variation. Consulting and engineering firms, for example, typically show revenues per employee in the $100,000 to $150,000 range, whereas equipment manufacturers may show considerably higher figures. Note again the relatively high earnings per employee that the drinking water utilities are able to produce.

IRON AND MANGANESE REMOVAL

National Drinking Water
Clearinghouse

Iron and manganese are common in groundwater supplies used by many small water systems. Exceeding the suggested maximum contaminant levels (MCL) usually results in discolored water, laundry, and plumbing fixtures. This, in turn, results in consumer complaints and a general dissatisfaction with the water utility.

There are secondary standards set for iron and manganese, but these are not health related and are not enforceable. The secondary (aesthetic) MCLs for iron and manganese are 0.3 milligrams per liter (mg/L) and 0.05 mg/L, respectively.

Small water plants may choose to either sequestrate or remove iron and manganese. Sequestration only works for combined iron and manganese concentrations up to 1.0 mg/L and only in cases where the treatment is not permanent. Removal is usually achieved through ion exchange or oxidation/filtration. There are a number of chemical oxidants and filtration media available that can be used in various combinations

WHAT PROBLEMS ARE CAUSED BY IRON AND MANGANESE?

Small amounts of iron are often found in water because of the large amount of iron present in the soil and because corrosive water will pick up iron from pipes. Clothing washed in water containing excessive iron may become stained a brownish color. The taste of beverages, such as tea and coffee, may also be affected by iron. Manganese produces a brownish color in laundered clothing, leaves black particles on fixtures, and—as with iron—affects the taste of beverages, including coffee and tea.

Well water from the faucet or tap is usually clear and colorless. However, when water containing colorless, dissolved iron is allowed to stand in a cooking container or comes in contact with a sink or bathtub, the iron combines with oxygen from the air to form reddish-brown particles (commonly called rust). Manganese forms brownish-black particles. These impurities can give a metallic taste to water or to food.

The rusty or brown stains on plumbing fixtures, fabrics, dishes, and utensils cannot be removed by soaps or detergents. Bleaches and alkaline builders (often sodium phosphate) can make the stains worse. Over time, iron deposits can build up in pressure tanks, water heaters, and pipelines, reducing the quantity and pressure of the water supply.

Iron and/or manganese in water creates problems common to many water supply systems. When both are present beyond recommended levels, special attention should be paid to the problem. How iron and manganese are removed depends on the type and concentration and this helps determine the best procedure and (possible) equipment to use.

WHAT IS THE CHEMISTRY OF IRON AND MANGANESE IN WATER SYSTEMS?

Iron (Fe) and manganese (Mn) can be present in water in one of three basic forms:

1. Dissolved: ferrous (Fe^{2+}) and manganous (Mn^{2+})
2. Particulate: ferric (Fe^{3+}) and manganic (Mn^{4+}) states
3. Colloidal: very small particles (difficult to settle and filter).

The predominance of one form over another is dependent on the pH, Eh (redox potential), and temperature of the water. Knowledge of the forms or states of iron and manganese can help finetune a given treatment practice for these metals.

WHAT ARE THE MOST COMMON TREATMENT PROCESSES?

The majority of iron and manganese treatment systems employ the processes of oxidation/filtration. The oxidant chemically oxidizes the iron or manganese (forming a particle), and kills iron bacteria and any other disease-causing bacteria that may be present. The filter then removes the iron or manganese particles (Fig. 1).

Oxidation followed by filtration is a relatively simple process. The source water must be monitored to determine proper oxidant dosage, and the treated water should be monitored to determine if the oxidation process was successful.

Oxidation

Before iron and manganese can be filtered, they need to be oxidized to a state in which they can form insoluble complexes. Oxidation involves the transfer of electrons from the iron, manganese, or other chemicals being treated to the oxidizing agent. Ferrous iron (Fe^{2+}) is oxidized to ferric iron (Fe^{3+}), which readily forms the insoluble iron hydroxide complex $Fe(OH)_3$. Reduced manganese (Mn^{2+}) is oxidized to (Mn^{4+}), which forms insoluble (MnO_2).

The most common chemical oxidants in water treatment are chlorine, chlorine dioxide, potassium permanganate, and ozone. Oxidation using chlorine or potassium permanganate is frequently applied in small groundwater systems. The dosing is relatively easy, requires simple equipment, and is fairly inexpensive.

Chlorination is widely used for oxidation of divalent iron and manganese. However, the formation of trihalomethanes (THMs) in highly colored waters may be a problem. Chlorine feed rates and contact time requirements can be determined by simple jar tests.

As an oxidant, potassium permanganate ($KMnO_4$) is normally more expensive than chlorine and ozone, but for iron and manganese removal, it has been reported to be as efficient and it requires considerably less equipment and capital investment. The dose of potassium permanganate, however, must be carefully controlled. Too little permanganate will not oxidize all the iron and manganese, and too much will allow permanganate to enter the distribution system and cause a pink color. Permanganate can also form precipitates that cause mudball formations on filters. These are difficult to remove and compromise filter performance.

Ozone may be used for iron and manganese oxidation. Ozone may not be effective for oxidation in the presence of humic or fulvic materials. If not dosed carefully, ozone can oxidize reduced manganese to permanganate and result in pink water formation as well. Manganese dioxide particles, also formed by oxidation of reduced manganese, must be carefully coagulated to ensure their removal.

A low-cost method of providing oxidation is to use the oxygen in air as the oxidizing agent in a tray aerator. Water is simply passed down a series of porous trays to provide contact between air and water. No chemical dosing is required, which allows for unattended operation. This method is not effective for water in which the iron is complexed with humic materials or other large organic molecules. Oxygen is not a strong enough oxidizing agent to break the strong complexes formed between iron and manganese and large organic molecules. Furthermore, the rate of reaction between oxygen and manganese is very slow below pH values of 9.5.

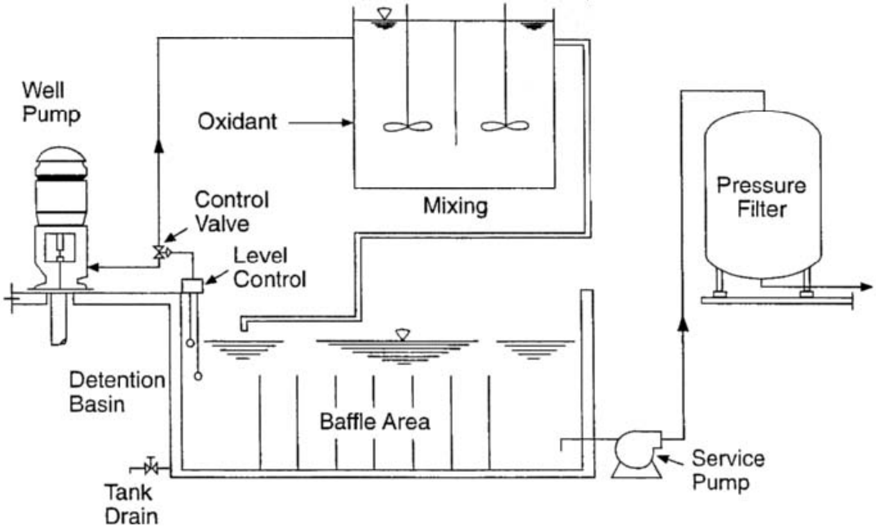


Figure 1. Chlorination, detention, and filtration (iron and manganese removal).

The presence of other oxidizable species in water hinders oxidation of the desired reduced compounds. Volatile organic chemicals, other organic compounds, or taste- and odor-causing compounds may result in an oxidant demand. This additional oxidant demand must be accounted for when dosing the oxidant. The expense of operation derives from the chemical use in most cases, and therefore is directly related to the source water quality.

Filtration

In general, manganese oxidation is more difficult than iron oxidation because the reaction rate is slower. A longer detention time (10 to 30 minutes) following chemical addition is needed prior to filtration to allow the reaction to take place.

There are different filtration media for the removal of iron and manganese, including manganese greensand, anthra/sand or iron-man sand, electromedia, and ceramic.

Manganese greensand is by far the most common medium in use for removal of iron and manganese through pressure filtration. Greensand is a processed material consisting of nodular grains of the zeolite mineral glauconite. The material is coated with manganese oxide. The ion exchange properties of the glauconite facilitates the bonding of the coating. This treatment gives the media a catalytic effect in the chemical oxidation-reduction reactions necessary for iron and manganese removal. This coating is maintained through either continuous or intermittent feed of potassium permanganate.

Anthra/sand (also iron-man sand) are other types of media available for removal of iron and manganese. They consist of select anthracite and sand with a chemically bonded manganese oxide coating. Unlike manganese greensand, these media are conditioned in the filter after media installation.

Electromedia provides a slightly different option from the manganese oxide coated media. This is a proprietary multi-media formulation which uses a naturally occurring zeolite and does not require potassium permanganate regeneration.

Finally, macrolite, unlike the other media discussed so far, is not a naturally occurring material which then undergoes processing for iron and manganese removal purposes. It is a manufactured ceramic material with a spherical shape and a rough, textured surface. The principal removal mechanism is physical straining rather than contact oxidation or adsorption.

Each medium has its advantages and disadvantages. Selection of a medium and oxidant should be based on pilot testing in which all necessary design criteria can be determined. Pressure filtration system manufacturers who offer the indicated media also offer fully automated systems.

ARE THERE ALTERNATIVE TREATMENTS?

Sequestration

Sequestration is the addition of chemicals to groundwater aimed at controlling problems caused by iron and manganese without removing them. These chemicals are added to groundwater at the well head or at the pump intake before the water has a chance to come in contact with air or chlorine. This ensures that the iron and manganese stays in a soluble form.

If the water contains less than 1.0 mg/L iron and less than 0.3 mg/L manganese, using polyphosphates followed by chlorination can be an effective and inexpensive method for mitigating iron and manganese problems. No sludge is generated in this method. Below these concentrations, the polyphosphates combine with the iron and manganese preventing them from being oxidized. Any of the three polyphosphates (pyrophosphate, tripolyphosphate, or metaphosphate) can be used.

To determine the best polyphosphate to use and the correct dosage, a series of samples at different concentrations may be prepared. Chlorine is added, and the samples are observed daily against a white background. The right polyphosphate dose is the lowest dose that does not noticeably discolor the water samples for four days.

Applying sodium silicate and chlorine simultaneously has also been used to sequester iron and manganese.

However, while this technique is reliable in the case of iron treatment, it has not been found to be effective in manganese control.

Ion Exchange

Ion exchange should be considered only for the removal of small quantities of iron and manganese because there is a risk of rapid clogging. Ion exchange involves the use of synthetic resins where a pre-saturant ion on the solid phase (the "adsorbent," usually sodium) is exchanged for the unwanted ions in the water (see Ion Exchange and Demineralization Tech Brief #DWBLPE56). One of the major difficulties in using this method for controlling iron and manganese is that if any oxidation occurs during the process, the resulting precipitate can coat and foul the media. Cleaning would then be required using acid or sodium bisulfate.

Other

Systems that have a lime-soda ash softening plant do not need a separate iron and manganese removal plant. The high pH during softening allows rapid oxidation and precipitation of the iron and manganese as well as incorporation in the calcium and magnesium precipitates. Similarly, surface water treatment plants using coagulation, flocculation, sedimentation, and filtration also will remove iron and manganese as long as they make certain the iron and manganese get oxidized. Oxidation is sometimes a problem because of the presence of organic matter.

Finally, biological treatment methods are being pilot tested at different locations. Biological treatment methods are used extensively in European countries, such as the Netherlands, France, and Germany, and are advantageous primarily when water simultaneously contains iron, manganese, and ammonia.

HOW CAN IRON AND MANGANESE PROBLEMS BE MINIMIZED IN DISTRIBUTION MAINS?

Problems due to iron and manganese in distribution mains may be minimized by:

- prior removal by appropriate treatment,
- protecting iron/steel mains with bituminous linings, or using noncorrosive materials,
- avoiding dead-end mains,
- avoiding disturbances in the water flow, and
- flushing periodically.

EXTRATERRITORIAL LAND USE CONTROL TO PROTECT WATER SUPPLIES

LAUREL PHOENIX
Green Bay, Wisconsin

Cities continually need water to grow. If they are located near a river, lake, or groundwater source, they will use these closest sources first. Some cities, however, have needed to search for water far beyond their boundaries, typically looking for rivers, large lakes, or valleys suitable for damming to create reservoirs. Because these distant areas are in different political jurisdictions that may fight a city in its quest for water, a state may step in and give a city the power it needs to expropriate and subsequently control lands outside its municipal boundaries.

A city needing water from a new source may need extraterritorial control over land in that area in order to (1) establish the source, (2) maintain access to the source, and (3) maintain quality of the source. In establishing the source, a city can face numerous obstacles. There may be a small community using or living next to the water supply the city wants. It may not want to share that water or allow the city to put intake pipes into the water. It may worry that a drawdown of lake levels would change the shape of the shoreline, expose muddy littoral slopes (making it ugly), distance waterfront properties from the water, and make piers and docks useless. This would have a negative impact on property values around the lake. Future effects on property values would result if the city was given land use control authority in the watershed that would constrain the economic growth potential of the local community. Or what if the small community is in a valley bottom instead? It certainly will not want a dam and reservoir to drown its homes and businesses. Forcing an entire community to move not only destroys homes, businesses, farmlands, and forests, but also makes many local citizens lose their jobs and their social networks. Any community would naturally fight the forfeiture of its own potential economic growth to benefit a bigger city's economic growth.

The second step, maintaining access to the source, means that a city would need the right to travel over any properties necessary to maintain and repair miles of pipeline or to manage any dams.

It is the third step, maintaining quality of the source, which requires the most extraterritorial control of the source watershed. Different land uses create different nonpoint source pollution that can contaminate the source water. The city seeking the new water source will want to prevent watershed land uses that contaminate the source and require more money to treat the water. Inadequately treated municipal sewage, failing septic tanks, or farms with animals can all contribute *Escherichia coli (E. coli)* to the water source. Sediment from farm field erosion, steep building sites, or building too close to the water source can cause siltation of the reservoir and reduce the reservoir's storage capacity. Moreover, sediment adds to turbidity levels, and these total dissolved solids (TDS) can reach a high enough level that a drinking water treatment plant would have to shut down its intake pipes. Parasites such as *Cryptosporidium parvum* and *Giardia* spp., which cause cryptosporidiosis and giardiasis in humans, require extremely expensive filtration treatment, so cities that can keep a watershed very clean can obtain a filtration waiver from the Environmental Protection Agency (EPA) and avoid spending billions on filtration plants.

Because land use decisions most closely affect property values and the economic potential of a community, land use controls have historically been the right of local governments to decide. To give this decision-making power to another local government essentially gives the smaller community unequal rights in their state, a loss of control in determining their future, and a transfer of wealth to the larger city.

It is an extraordinary step for a state to give one local government extraterritorial control over another local government, as this gives the equivalent of limited state power to some local governments. Because of the critical nature of water supplies to cities, and because larger cities are a state's economic engines, a state will often pass legislation to allow establishment and access to a new water source. Some states have gone further to give extraterritorial land use control over communities in the source watershed to maintain the source water quality. To provide a few examples of extraterritorial land use controls, Boston, New York, and Syracuse are described here.

BOSTON

The Quabbin Reservoir is the largest and most recently developed water supply for the greater metropolitan area of Boston. The Swift River in western Massachusetts was impounded by a dam to flood a valley in the early 1930s. The Watershed Protection Act, 350 CMR 11 (to read the complete regulations, see http://www.mass.gov/mdc/350CMR11.html), delineates a variety of restrictions on land use in the four towns within the watershed in order to protect its water quality. Land has been categorized by proximity to a tributary or reservoir, presence of wetlands, areas overlying aquifers, and so on to distinguish the degree of regulation for each zone. The first buffer zone (within 400 ft of the reservoir or within 200 ft from a tributary or other surface water) is the Primary Protection Zone. No new construction, excavation, or grading is allowed. Dumping of any substance is illegal, and no new paving can be laid. Substances defined as pollutants cannot be manufactured, stored, applied, or dumped in this zone.

The second buffer zone is the Secondary Protection Zone. This includes vegetated wetlands, floodplain lands, land lying over selected aquifers, and any land between 200 and 400 ft of tributaries or surface waters. Development density is controlled (determined by X bedrooms per X acres), wetlands cannot be disturbed, and certain chemicals cannot be stored, used, or dumped. Sewage treatment facilities may not dump their effluent, leach fields must be at least 4 ft above the water table, liquid petroleum can only be stored in a structure that can hold 125% of the petroleum tank capacity, and this structure must be placed over a poured concrete floor. Storage or use of hazardous or solid waste beyond what a typical house would use is prohibited. Road salt, fertilizers, and pesticides must be stored indoors. No boat and car washing or servicing businesses are allowed, and no junkyards are allowed. The construction of impervious surfaces is limited to 10% of a lot. Recreational activities are limited in the land surrounding the reservoir. For example, hiking is allowed, but snowmobiles and off-road vehicles are not. Boats are not allowed on the lake, and no domestic animals or horseback riding are allowed.

NEW YORK

In 1905, the state legislated the creation of the New York City Board of Water Supply, which would be in charge of researching and developing bigger and cleaner water supplies for the city. New York City dammed several valleys in the Catskill mountains, inundating villages and farms. These dams were completed by 1927, and more dams were built in neighboring valleys that feed the Delaware River by the 1960s. All of these reservoirs were linked together by pipelines, and gravity flow delivered the water to the city boundaries. After years of contention between the watershed towns and New York City, the Final Rules and Regulations to protect the city's water supply became law on May 1, 1997 (to read the complete regulations, see http://www.ci.nyc.ny.us/html/dep/html/ruleregs/finalrandr.html). Because there is heavy pressure to develop land in these watersheds, these final rules and regulations list prohibited land uses, but the city agreed that it would never use the power of eminent domain to prevent new development in these areas. Rather, it would seek out willing sellers from which to purchase lands, and then it would leave these lands undeveloped. Development in these watersheds must be guided by proximity to water, slope of building lots, percentage of impervious area, and other requirements similar to that mentioned for the Quabbin watershed. Other pressures that New York City could have exerted were resolved by city-funded programs. For example, the city is paying to replace failing septics for houses and businesses. In addition, extra funding has been found to upgrade public sewage treatment plants to prevent their effluent from degrading the water quality of the reservoirs. Farms receive assistance on manure management and other farm activities that reduces their nutrient, sediment, and pesticide contributions to the reservoirs.

The New York City watershed agreement is distinct from how Boston's water authority controls the Quabbin watershed. The dynamics of the residents are different, as there are far more people living or wanting to live in the Catskill area. This means the Catskill residents have all the more potential money to lose if land use regulations in their watershed virtually eliminated the potential for economic growth.

SYRACUSE

The city of Syracuse, New York receives its water from Skaneateles Lake, one of the Finger Lakes of New York. Relative to Quabbin watershed or the Catskill watersheds, this lake lies in a much smaller watershed with a low-density population. There is a small but wealthy village that relies on tourism, a lake surrounded by large-lot estates, and a small amount of farmland. There are no industries or sewage treatment plants that discharge into this lake.

Syracuse has several tools to protect its water source. The watershed regulations (to read the complete regulations, see http://www.syracuse.ny.us/deptWater.asp), for example, allow Syracuse to test yearly for failing septic systems on every lakeshore property. The city also established two programs to protect water quality, the Skaneateles Lake Watershed Land Protection Program (SLWLPP) and the Skaneateles Lake Watershed Agricultural Program (SLWAP). The SLWLPP provides funds to buy permanent conservation easements from environmentally significant properties from willing sellers. The SLWAP helps farmers in the watershed create voluntary Whole Farm Plans that reduce nonpoint source pollution from these farms while saving farmers money.

THE CHOICES OF EXTRATERRITORIAL CONTROL

The ways in which these three cities exerted their extraterritorial control is influenced by how many citizens live in the watersheds now and how locals used their political voice to soften the heavy-handedness that total land use controls engender. Consequently, New York City and Syracuse had to develop more cooperative and voluntary solutions between municipalities to protect the water source without impoverishing the communities along their shores.

LEAK DETECTION AND WATER LOSS CONTROL

Zacharia Michael Lahlou
Technical Assistance
Consultant

Utilities can no longer tolerate inefficiencies in water distribution systems and the resulting loss of revenue associated with underground water system leakage. Increases in pumping, treatment and operational costs make these losses prohibitive. To combat water loss, many utilities are developing methods to detect, locate, and correct leaks.

Old and poorly constructed pipelines, inadequate corrosion protection, poorly maintained valves and mechanical damage are some of the factors contributing to leakage. One effect of water leakage, besides the loss of water resources, is reduced pressure in the supply system. Raising pressures to make up for such losses increases energy consumption. This rise in pressure makes leaking worse and has adverse environmental impacts.

Of the many options available for conserving water, leak detection is a logical first step. If a utility does what it can to conserve water, customers will tend to be more cooperative in other water conservation programs, many of which hinge on individual efforts. A leak detection program can be highly visible, encouraging people to think about water conservation before they are asked to take action to reduce their own water use. Leak detection is an opportunity to improve services to existing customers and to extend services to the population not served.

In general, a 10 to 20 percent allowance for unaccounted-for-water is normal. But a loss of more than 20 percent requires priority attention and corrective actions. However advances in technologies and expertise should make it possible to reduce losses and unaccounted-for-water to less than 10 percent. While percentages are great for guidelines, a more meaningful measure is volume of lost water. Once the volume is known, revenue losses can be determined and cost effectiveness of implementing corrective action can then be determined.

Figure 1. Shawn Menear, a graduate student in technology education at west virginia university, uses geophones to listen for water main leaks. Similar to a doctor or nurse's stethoscope, geophones are an inexpensive leak detection device used by water utilities.

BENEFITS OF LEAK DETECTION AND REPAIR

The economic benefits of leak detection and repair can be easily estimated. For an individual leak, the amount lost in a given period of time, multiplied by the retail value of that water will provide a dollar amount. Remember to factor in the costs of developing new water supplies and other "hidden" costs.

Some other potential benefits of leak detection and repair that are difficult to quantify include:

- increased knowledge about the distribution system, which can be used, for example, to respond more quickly to emergencies and to set priorities for replacement or rehabilitation programs;
- more efficient use of existing supplies and delayed capacity expansion;
- improved relations with both the public and utility employees;
- improved environmental quality;
- increased firefighting capability;
- reduced property damage, reduced legal liability, and reduced insurance because of the fewer main breaks; and
- reduced risk of contamination.

CAUSES OF LEAKS

Water produced and delivered to the distribution system is intended to be sold to the customer, not lost or siphoned from the distribution system without authorization. Not long ago, water companies sold water at a flat rate without metering. As water has become more valuable and metering technology has improved, more and more water systems in the U.S. meter their customers. Although all customers may be metered in a given utility, a fairly sizable portion of the water most utilities produce does not pass through customer meters. Unmetered water includes unauthorized uses, including losses from accounting errors, malfunctioning distribution system controls, thefts, inaccurate meters, or leaks. Some unauthorized uses may be identifiable. When they are not, these unauthorized uses constitute unaccounted-for water. Some unmetered water is taken for authorized purposes, such as fire fighting and flushing and blowoffs for water-quality reasons. These quantities are usually fairly small. The primary cause of excessive unaccounted-for water is often leaks.

CALCULATING UNACCOUNTED-FOR WATER

Unaccounted-for water is the difference between water produced (metered at the treatment facility) and metered use (i.e., sales plus non-revenue producing metered water). Unaccounted-for water can be expressed in millions of gallons per day (mgd) but is usually discussed as a percentage of water production:

$$\textbf{Unaccounted} - \textbf{for water}\ (\%) = \frac{(\text{Production} - \text{metered use}) \times 100\%}{(\text{Production})}$$

There are different types of leaks, including service line leaks, and valve leaks, but in most cases, the largest portion of unaccounted-for water is lost through leaks in the mains. There are many possible causes of leaks, and often a combination of factors leads to their occurrence. The material, composition, age, and joining methods of the distribution system components can influence leak occurrence. Another related factor is the quality of the initial installation of distribution system components. Water conditions are also a factor, including temperature, aggressiveness, and pressure. External conditions, such as stray electric current; contact with other structures; and stress from traffic vibrations, frost loads, and freezing soil around a pipe can also contribute to leaks. All water plants will benefit from a water accounting system that helps track water throughout the distribution system and identifies areas that may need attention, particularly large volumes of unaccounted-for water.

LEAK DETECTION AND REPAIR STRATEGY

There are various methods for detecting water distribution system leaks. These methods usually involve using sonic leak-detection equipment, which identifies the sound of water escaping a pipe. These devices can include pinpoint listening devices that make contact with valves and hydrants, and geophones that listen directly on the ground. In addition, correlator devices can listen at two points simultaneously to pinpoint the exact location of a leak. (See Figs. 1 and 2.)

Large leaks do not necessarily contribute to a greater volume of lost water, particularly if water reaches the surface; they are usually found quickly, isolated, and repaired. Undetected leaks, even small ones, can lead to large quantities of lost water since these leaks might exist for long periods of time. Ironically, small leaks are easier to detect because they are noisier and

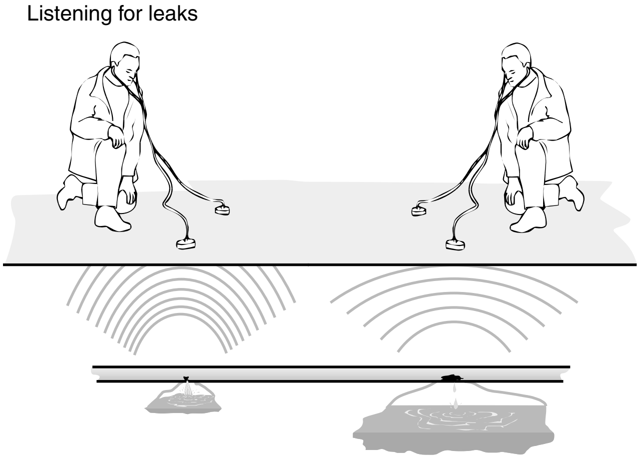

Figure 2. An important goal of leak detection is to find exactly where a leak is located. Typically, the louder the noise, the closer you are to the leak. Small leaks under high pressure usualy make more noise than larger leaks under low pressure. In fact, many large leaks make almost no sound whatsoever.

easier to hear using hydrophones. The most difficult leaks to detect and repair are usually those under stream crossings.

Leak detection efforts should focus on the portion of the distribution system with the greatest expected problems, including:

- areas with a history of excessive leak and break rates;
- areas where leaks and breaks can result in the heaviest property damage;
- areas where system pressure is high;
- areas exposed to stray electric current and traffic vibration;
- areas near stream crossings; and
- areas where loads on pipe exceed design loads.

Of course, detecting leaks is only the first step in eliminating leakage. Leak repair is the more costly step in the process. Repair clamps, or collars, are the preferred method for repairing small leaks, whereas larger leaks may require replacing one or more sections of pipe.

On average, the savings in water no longer lost to leakage outweigh the cost of leak detection and repair. In most systems, assuming detection is followed by repair, it is economical to completely survey the system every one to three years.

Instead of repairing leaking mains, some argue it is preferable to replace more leak-prone (generally older) pipes. Selecting a strategy depends upon the frequency of leaks in a given pipe and the relative costs to replace and repair them.

Deciding whether to emphasize detection and repair over replacement depends upon site-specific leakage rates and costs. In general, detection and repair result in an immediate reduction in lost water, whereas replacement will have a longer-lasting impact to the extent that it eliminates the root cause of leaks.

The most important factor in a leak detection and repair program is the need for accurate, detailed records that are consistent over time and easy to analyze. Records concerning water production and sales, and leak and break costs and benefits, will become increasingly important as water costs and leak and break damage costs increase and as leak detection and rehabilitation programs become more important. In order to optimize these programs by allocating funds in such a way that results in the greatest net benefits, adequate information is needed on which to base decisions and determine needs. Three sets of records should be kept: (1) monthly reports on unaccounted-for water comparing cumulative sales and production (for the last 12 months, to adjust discrepancies caused by the billing cycle); (2) leak-repair report forms; and (3) updated maps of the distribution system showing the location, type, and class of each leak.

COORDINATING LEAK DETECTION AND REPAIR WITH OTHER ACTIVITIES

In addition to assisting with decisions about rehabilitation and replacement, the leak detection and repair program can further other water utility activities, including:

- inspecting hydrants and valves in a distribution system;
- updating distribution system maps;
- using remote sensor and telemetry technologies for ongoing monitoring and analysis of source, transmission, and distribution facilities. Remote sensors and monitoring software can alert operators to leaks, fluctuations in pressure, problems with equipment integrity, and other concerns; and
- inspecting pipes, cleaning, lining, and other maintenance efforts to improve the distribution system and prevent leaks and ruptures from occurring. Utilities might also consider methods for minimizing water used in routine water system maintenance.

BEYOND LEAK DETECTION AND REPAIR

Detecting and repairing leaks is only one water conservation alternative; others include: meter testing and repair/replacement, rehabilitation and replacement programs, installing flow-reducing devices, corrosion control, water pricing policies that encourage conservation, public education programs, pressure reduction, requests for voluntary cutbacks or bans on certain water uses, and water recycling.

LIME–SODA ASH PROCESSES

Roger C. Viadero Jr.
West Virginia University
Morgantown, West Virginia

INTRODUCTION AND PROCESS OVERVIEW

As in other chemical water softening technologies, the objective of the lime–soda ash process is to precipitate polyvalent cations from solution by pH adjustment. In water treatment applications, Ca^{2+} and Mg^{2+} are the two major cations of concern, though Fe^{2+}, Fe^{3+}, Al^{3+}, and Mn^{2+} may also be present at problematic concentrations, depending on the properties of soil or geological material encountered by the surface or groundwater. Typically, a total hardness ranging from 75–120 mg/L as $CaCO_3$, is sought in domestic water softening.

Total [water] hardness (TH) is composed of carbonate and noncarbonate fractions, where carbonate hardness (CH) is the equivalent concentration (meq/L or mg/L as $CaCO_3$) of polyvalent cation species associated with carbonate ions [e.g., $Mg(HCO_3)_2$]. Similarly, noncarbonate hardness (NCH) is the equivalent concentration of all aqueous phase cations not associated with carbonate species, such as the "free" ions Ca^{2+}, Mg^{2+}, and Al^{3+}.

In this process, lime and soda ash are added to solution, Ca^{2+} precipitates as $CaCO_3(\downarrow)$, and Mg precipitates as $Mg(OH)_2(\downarrow)$. To precipitate $CaCO_3$, the pH of the water must be raised to approximately 10.3. Similarly, $Mg(OH)_2(\downarrow)$ forms when the pH is raised above 11. When there is not enough naturally occurring bicarbonate alkalinity ($HCO_3{}^-$) in water to form the $CaCO_3$ precipitate, alkalinity must be added (typically as Na_2CO_3).

CHEMICAL REACTIONS OF LIME–SODA ASH SOFTENING

Initially, any free acids in the water must be neutralized prior to raising the pH for cation precipitation. In natural waters, which are generally considered in equilibrium with the atmosphere, CO_2 and H_2CO_3 (carbonic acid) are the primary free acids of concern (1).

Typically, hydrated lime, $Ca(OH)_2$, is used to neutralize the weak acid, as presented in Equations 1 and 2. When added to water, lime initially dissociates into its constituent ions, Ca^{2+} and OH^-. Free calcium forms, so water hardness is actually increased. However, as the pH is raised, free calcium ions are used to form $CaCO_3(\downarrow)$, and the hardness imparted to the water by lime dissociation is removed.

$$Ca(OH)_2 + H_2O \longleftrightarrow Ca^{2+} + 2OH^- + H_2O \qquad (1)$$

$$CO_2 + Ca(OH)_2 \longleftrightarrow CaCO_3(\downarrow) + H_2O \qquad (2)$$

Following the neutralization of free acids, carbonate hardness due to calcium is removed, as presented in Equation 3. When the pH is less than 8.3, bicarbonate is the dominant carbonate species that contributes to alkalinity; thus, the dominant calcium carbonate species is $Ca(HCO_3)_2$.

$$Ca^{2+} + 2HCO_3{}^- + Ca(OH)_2 \longleftrightarrow 2CaCO_3(\downarrow) + 2H_2O \qquad (3)$$

By adding hydrated lime, the pH is raised to ~10.3, which results in converting bicarbonate to carbonate ions and facilitates calcium precipitation as $CaCO_3$ (limestone).

Similarly, carbonate hardness associated with magnesium is removed by raising the pH to ~11 and precipitating magnesium as a hydroxide; however, the process occurs in two steps because $MgCO_3$ is soluble in water, as in Equations 4a and 4b.

$$Mg^{2+} + 2HCO_3{}^- + Ca(OH)_2 \longleftrightarrow MgCO_3 + CaCO_3(\downarrow) + 2H_2O \qquad (4a)$$

$$Mg^{2+} + CO_3{}^{2-} + Ca(OH)_2 \longleftrightarrow Mg(OH)_2(\downarrow) + CaCO_3(\downarrow) \qquad (4b)$$

At this point, the pH is ~11. Consequently, the pH does not need to be increased any further to enable the removal of noncarbonate hardness associated with calcium, Ca^{2+}. However, carbonate must be added to the system to form the calcium carbonate precipitate. Carbonate is added as soda ash, and the following reaction occurs:

$$Ca^{2+} + Na_2CO_3 \longleftrightarrow CaCO_3(\downarrow) + 2Na^+ \qquad (5)$$

Note that "free" Na^+ ions do not contribute to water hardness.

When removing noncarbonate hardness due to magnesium, both lime and soda ash are required; lime is added to provide the OH^- ions necessary to precipitate Mg as $Mg(OH)_2(\downarrow)$, and soda ash is needed to precipitate calcium.

$$Mg^{2+} + Ca(OH)_2 \longleftrightarrow Mg(OH)_2(\downarrow) + Ca^{2+} \qquad (6a)$$

$$Ca^{2+} + Na_2CO_3 \longleftrightarrow CaCO_3(\downarrow) + 2Na^+ \qquad (6b)$$

After removing Ca^{2+} and Mg^{2+} from solution, the pH is near 11, and $CO_2(g)$ is added to reduce the pH to ~9.2–9.7 and thus, remove excess lime.

$$CO_2 + Ca(OH)_2 \longleftrightarrow CaCO_3(\downarrow) + H_2O \qquad (7a)$$

$$Mg(OH)_2(\downarrow) + CO_2 \longleftrightarrow MgCO_3 + H_2O \qquad (7b)$$

$CO_2(g)$ is then added to reduce the water to a finished pH of ~8.6. (2,3).

Based on the relationships in Equations 1–7, the equivalent concentrations of lime and soda ash required are given by the following (2):

$$[Ca(OH)_2] = [CO_2] + [HCO_3{}^-] + [Mg^{2+}] + \text{excess} \qquad (8)$$

$$[Na_2(CO_3)] = [Ca^{2+}] + [Mg^{2+}] - \text{alkalinity} \qquad (9a)$$

$$\text{Alkalinity} = [HCO_3{}^-] + [CO_3{}^{2-}] + [OH^-] - [H^+] \qquad (9b)$$

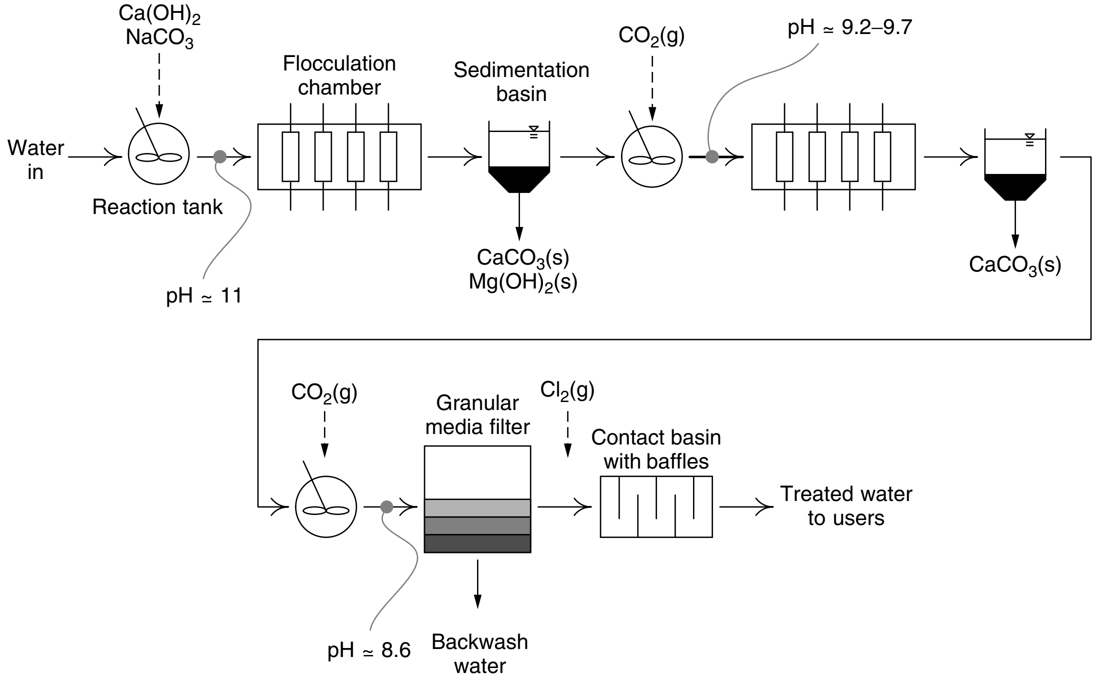

Figure 1. Schematic of typical layout of lime–soda ash softening process used in domestic water treatment.

PROCESS IMPLEMENTATION AND LIMITATIONS

The layout of a typical softening process in domestic water treatment is presented in (Fig. 1) (2). In this process, two flocculation basins and two sediment basins are required for the formation, precipitation, and subsequent removal of colloidal-particles. However, filtration is generally necessary after flocculation and sedimentation to remove the smallest particles that escape gravity settling. Due to the number of unit operations required in this process, capital costs can be high (2,3).

Further, Mg^{2+} is more expensive to remove than Ca^{2+}; thus, it is common to leave as much Mg in the water as feasible. Additionally, it is more costly to remove noncarbonate hardness than carbonate hardness because we must add $CO_3{}^{2-}$ (as Na_2CO_3; see Equation 6b) to facilitate the formation of the calcium carbonate precipitate. Consequently, as much noncarbonate hardness is left in the water as possible (2,3).

It is not possible to remove all Ca and Mg using lime–soda ash softening due to (1) the solubility of $CaCO_3(\downarrow)$ and $Mg(OH)_2(\downarrow)$, (2) limitations of mixing and contact, and (3) the lack of sufficient time for reaction kinetics to reach completion.

In general, the minimum calcium and magnesium hardnesses attainable in the lime–soda ash softening process are 30 and 10 mg/L as $CaCO_3$, respectively, though process economics is a major driving force in setting actual process end points (3). To attain treatment goals in a timely fashion, an excess of lime above stoichiometric requirements is supplied. Based on experience, a lime excess of ~20 mg/L, as $CaCO_3$, is typically recommended. It has been found that magnesium concentrations in excess of 40 mg/L, as $CaCO_3$, cause scaling in domestic hot water heaters. However, due to the expense of Mg removal, treatment is not generally carried out to achieve a Mg concentration much lower than 40 mg/L, as $CaCO_3$. When it is necessary to remove magnesium to between 20 and 40 mg/L, as $CaCO_3$, an additional lime excess must be added equivalent to the amount of magnesium removed. However, through experience, it has been found that the addition of lime in excess of 40 mg/L, as $CaCO_3$, does not provide appreciably improved reaction kinetics. As a result, the application of other advanced unit operations such as ion exchange would be needed to reduce water hardness further (2). Further detailed discussion of lime–soda ash water softening processes is presented by Reh (4).

LIME SOFTENING

National Drinking Water
Clearinghouse

Hard water can cause scaling problems in water heaters and soap does not lather well in hard water. Therefore, some water utilities soften water to improve its quality for domestic use. Lime softening is best suited to groundwater sources, which have relatively stable water quality. The combination of variable source water quality and the complexity of the chemistry of lime softening may make lime softening too complex for small systems that use surface water sources.

Although lime softening has been used successfully by groundwater systems serving fewer than 3,000 people, it is unlikely to be suitable for treating groundwater in systems serving 500 or fewer people unless those systems have some form of contract or satellite operation that would enable a trained operator to monitor the treatment process. Prefabricated lime softening equipment is available for small systems. Also, there is an American Water Works Association Standard for quicklime and hydrated lime (ANSI/AWWA B202-93) that provides purchasers, manufacturers, and suppliers with the minimum requirements, including physical, chemical, packaging, shipping, and testing requirements.

Either hydrated lime [$Ca(OH)_2$] or quicklime (CaO) may be used in the softening process. The choice depends upon economic factors, such as the relative cost per ton of the two materials as well as the size and equipment of the softening plant. Hydrated lime is generally used more in smaller plants because it stores better and does not require slaking (producing a chemical change in lime by combining it with water) equipment. On the other hand, quick-lime costs less per ton of available calcium oxide and is thus more economical for use in large plants.

Softened water has high causticity and scale-formation potential; hence, recarbonation is employed to reduce pH and mitigate scaling of downstream processes and pipelines. Onsite combustion generation of carbon dioxide (CO_2) or liquid CO_2 is the most common source of carbon dioxide for recarbonation.

WHAT IS HARD WATER?

"Hardness" in water is primarily the result of concentrations of calcium and magnesium. Thus, some water utilities remove calcium and magnesium to soften the water and improve its quality for domestic use. Other ions that produce hardness include iron, manganese, strontium, barium, zinc, and aluminum, but these ions are generally not present in significant quantities. Therefore, total hardness is usually defined as the sum of magnesium and calcium hardness in milligrams per liter (mg/L), as calcium carbonate ($CaCO_3$). Total hardness can also be differentiated into carbonate and noncarbonate hardness. Carbonate hardness is the portion of total hardness present in the form of bicarbonate salts [$Ca(HCO_3)_2$ and $Mg(HCO_3)_2$] carbonate compounds ($CaCO_3$ and $MgCO_3$).

Noncarbonate hardness is the portion of calcium and magnesium present as noncarbonate salts, such as calcium sulfate ($CaSO_4$), calcium chloride ($CaCl_2$), magnesium sulfate ($MgSO_4$), and magnesium chloride (MgCl). The sum of carbonate and noncarbonate hardness equals total hardness.

What may be "hard" water in one area may be perfectly acceptable water in another area. In general, the degree of hardness is classified as follows:

Hardness	mg/L as $CaCO_3$
Soft	0 to 75
Moderate	75 to 150
Hard	150 to 300
Very hard	Above 300

Source: *Water Treatment Plant Design*, 1998.

For most applications, total hardness of 120 mg/L or less and magnesium hardness of 40 mg/L or less appear to be acceptable design criteria for softening facilities.

HOW DOES THE LIME-SOFTENING PROCESS WORK?

In the lime-softening process, the pH of the water being treated is raised sufficiently to precipitate calcium carbonate and, if necessary, magnesium hydroxide. The normal pH of water is between 6.5–8.5. In small systems, lime softening is typically practiced by adding hydrated lime to raw water to raise the pH to approximately 10. This removes calcium carbonate, essentially limestone. If magnesium removal is also required, the pH during softening needs to be closer to 11. Lime-softening systems need not be pilot tested for small systems using groundwater sources. Jar testing to determine appropriate process pH and chemical doses is sufficient. Doses of these chemicals should not change greatly over time unless the groundwater is subject to periodic infiltration by surface water that changes in quality. Lime-softening systems do need to be pilot tested if used on surface water sources with variable quality.

WHAT PRETREATMENT IS USED?

The principal types of pretreatment used before lime softening are aeration and presedimentation.

Aeration may be used to remove carbon dioxide from the source water before softening. This is only applicable to groundwaters where carbon dioxide concentrations are relatively high. Lime removal of carbon dioxide in source water adds to operation costs because of chemical expenses and increased calcium carbonate residuals.

Induced draft or open tray aeration is often used and may reduce the carbon dioxide level to 10 mg/L or less. Aeration also oxidizes iron and manganese; clogging of the aeration tray is a problem.

Presedimentation is used primarily by those plants treating high turbidity surface waters.

WHAT ARE THE MONITORING AND OPERATING REQUIREMENTS?

Regulatory monitoring requirements for lime softening plants depend on whether the source water is surface water or groundwater. Process monitoring requirements should focus on measurement of pH, hardness, and alkalinity for plants treating groundwater. In addition, filtered water turbidity monitoring is needed at the plants treating surface water for compliance purposes, as well as to manage filter operation.

One of the difficult aspects of lime softening is the operation and maintenance of lime feeders and lines carrying lime slurry to the point of application. In addition, plant operators must understand lime softening chemistry. Measurement of pH must be accurate, and the operator must know that the pH meter is properly calibrated. Failure to maintain the proper pH in softened water prior to filtration at a lime softening plant could result in precipitation or excess lime in the filter beds and formation of calcium carbonate deposits within the filters.

WHAT ARE THE CHEMICAL REQUIREMENTS?

The amount of lime required to remove carbonate hardness and magnesium can be calculated using in the following equation:

$$\mathrm{CaO(lb/mil\ gal)} = 10.6\ \mathrm{CO_2(mg/L)} + 4.7[\mathrm{alkalinity(mg/L)} + \mathrm{magnesium\ hardness(mg/L)} + X]$$

Where CaO is 100 percent pure, CO_2 is expressed as CO_2, alkalinity is expressed as $CaCO_3$, and X is the required excess hydroxide alkalinity in mg/L as $CaCO_3$. The magnesium hardness shown is the amount to be removed by softening, and not the amount present. Desired excess alkalinity can be determined from the magnesium hydroxide solubility relationship: it is typically in the range of 30 to 70 mg/l and is often estimated at 50 mg/L expressed as $CaCO_3$.

WHAT ARE OTHER SOFTENING ALTERNATIVES?

The selection of lime, lime-soda ash, or caustic soda softening is based on cost, total dissolved solids criteria, sludge production, carbonate and noncarbonate hardness, and chemical stability. Water containing little or no noncarbonate hardness can be softened with lime alone. However, water with high noncarbonate hardness may require both lime and soda ash to achieve the desired finished water hardness. Softening with lime or lime-soda ash is generally less expensive than caustic softening. Caustic soda softening increases the total dissolved solids of treated water, while lime and lime-soda ash softening often decrease total dissolved solids. Caustic soda softening produces less sludge than lime and lime-soda ash softening. Caustic soda does not deteriorate during storage, while hydrated lime may absorb carbon dioxide and water during storage, and quicklime may slake in storage causing feeding problems. The final selection is

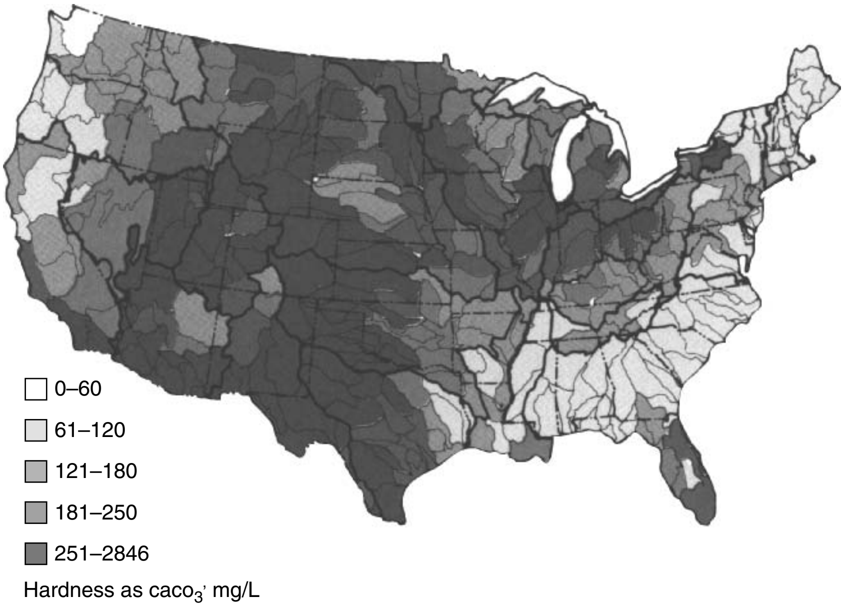

Figure 1. Average water hardness in the continental united states. Courtesy of the U.S. Geological Survey, Report 78-200.

generally based on cost, water quality, and owner and operator preference.

WHAT ARE THE BENEFITS OF SOFTENING?

Potential benefits of softening water at a central treatment plant include the following:

- reducing dissolved minerals and scale-forming tendencies,
- reducing consumption of household cleaning agents,
- removing radium 226 and 228,
- removing arsenic and uranium,
- removing heavy metals,
- supplementing disinfection and reducing algal growths in basins,
- removing certain organic compounds and reducing total organic carbon (TOC),
- removing silica and fluoride,
- removing iron and manganese,
- reducing turbidity of surface waters in conjunction with the hardness precipitation process,
- increasing the Langelier Saturation Index, useful for corrosion control under some conditions, and
- possibly removes *Giardia Lamblia* cysts.

ARE THERE CONCERNS ABOUT SOFT WATER?

In most cases, for consumer use, relatively soft water is preferable; however, it does have several disadvantages. Excessively soft water can cause corrosion in pipes. This corrosion can shorten the service life of pipes and household appliances and can result in toxic materials, such as lead and cadmium, being dissolved in drinking water. The decision to soften a water supply depends completely on the community. Drinking water regulations do not generally require softening.

WHAT ABOUT LIME SOFTENING RESIDUALS?

All water softening plants, large or small, are now required to refrain from directly discharging any wastes—liquid or solid—into rivers or streams. Where abandoned stone quarries, sand and gravel pits, or coal mines are available nearby, it may be possible to dispose of the sludge for many years without any serious difficulty. In areas where there are abandoned coal-strip mines, pumping the sludge into these areas may be a logical and convenient solution. If acid waters are leaching out of the mine into the watershed, as many such mines do, the waste sludge can help in abating serious stream pollution by neutralizing the acid water. Such neutralization may offer a great potential savings in material treatment cost to the state.

Selection of lime, lime-soda ash, or caustic soda chemical precipitation process must adequately address the disposal of generated sludges. Ultimate disposal of lime or caustic sludges now includes options, such as discharge to sanitary sewers, drying lagoons, and land application.

In some cases, sludge is discharged directly into a community's sewage system. Such a discharge must be done with the approval of the municipal sewage department, since not all systems can accommodate this alkaline waste, at least in the volume produced. In other instances, the discharge of such sludge could prove beneficial in neutralizing other acid trade wastes entering the same system. A few small plants are permitted to discharge directly into the community's storm sewer system, although this method has been phased out in most cases.

Lagooning is another practical solution. If the sludge can be dried to approximately 50 percent moisture content in lagoons, the annual requirement will be approximately

0.5 to 1.0 acre-feet per 100 mg/L hardness removed for every million gallons per day (MGD). Also, multiple lagoons used on a fill and let dry sequence, or filling from one end and withdrawing or decanting from the other, often result in better drying of the sludge.

Increasing ingenuity is necessary for sludge disposal, since lagooning, one of the most common practices, is becoming less frequent due to the dearth of available land and soaring land costs. Therefore, other methods are being increasingly employed.

An attractive method for a water plant located in a farming area is to use land application of the sludge on farm fields where the soil pH is too low for optimal plant growth. In addition to providing a desirable pH for plant growth, lime-softening sludge is generally a pure source of calcium carbonate with varying small amounts of magnesium hydroxide and provides an effective source of liming material for farmers. It has a neutralizing value for soil acids in excess of most agricultural liming materials.

ION EXCHANGE—USE OF MAGNETIC ION EXCHANGE RESIN FOR DOC REMOVAL

MARIN SLUNJSKI
Orica Watercare
Regency Park, SA, Australia

BACKGROUND

Conventional treatment by flocculation has a low efficiency of around 30% for DOC removal, although this can be increased to 50% by enhanced coagulation. Alternative treatment processes more effective at DOC removal include granular-activated carbon (GAC) adsorption and membrane filtration technologies, specifically nanofiltration. The latter process requires a pretreatment stage to remove suspended solids prior to membrane filtration.

ION EXCHANGE FOR DOC REMOVAL

Much of the DOC is acidic and amenable to removal by ion exchange. The DOC molecules are large (apparent molecular weight from 0.5 kD to more than 10 kD) and have a high negative charge density (10–15 meq/g DOC).

MIEX® resin is very small, five times smaller than conventional resins. This allows it to be easily dispersed in water. It is a macroporous, strong base anion exchange resin that, together with its small size, facilitates rapid DOC exchange during both DOC removal from water and resin regeneration.

The reaction mechanism is shown in Fig. 1. The resin is suspended in water containing low concentrations of DOC and other inorganic anions. The resin's affinity for the DOC molecules shifts the equilibrium to DOC uptake. The reaction is very efficiently reversed by treating the resin with a solution of high chloride concentration, such as brine.

This resin is specially formulated to include a magnetic component that allows individual resin beads to interact like small magnets, a feature that is the basis for the unique handling characteristics of the MIEX® resin and for the innovative engineering of this ion exchange process.

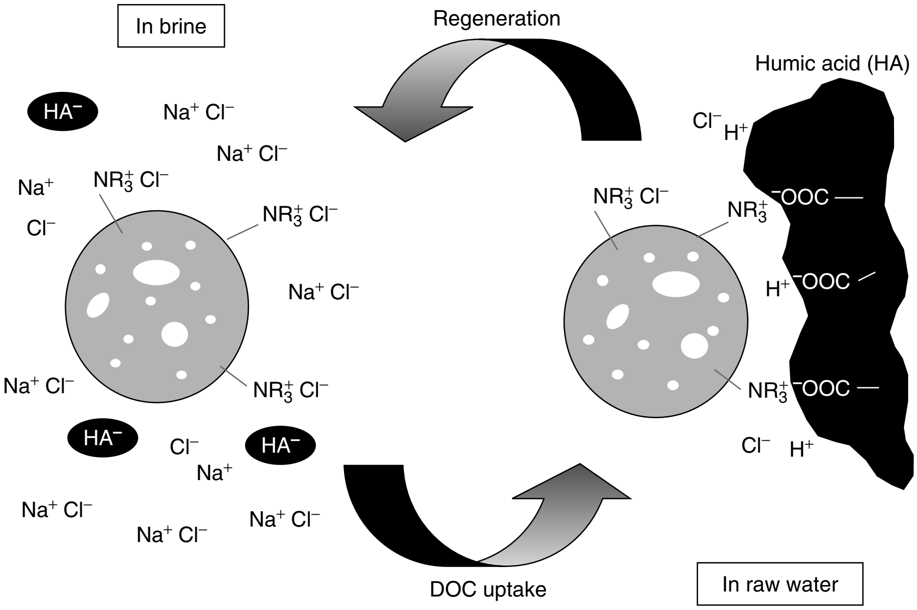

Figure 1. Standard DOC exchange mechanism.

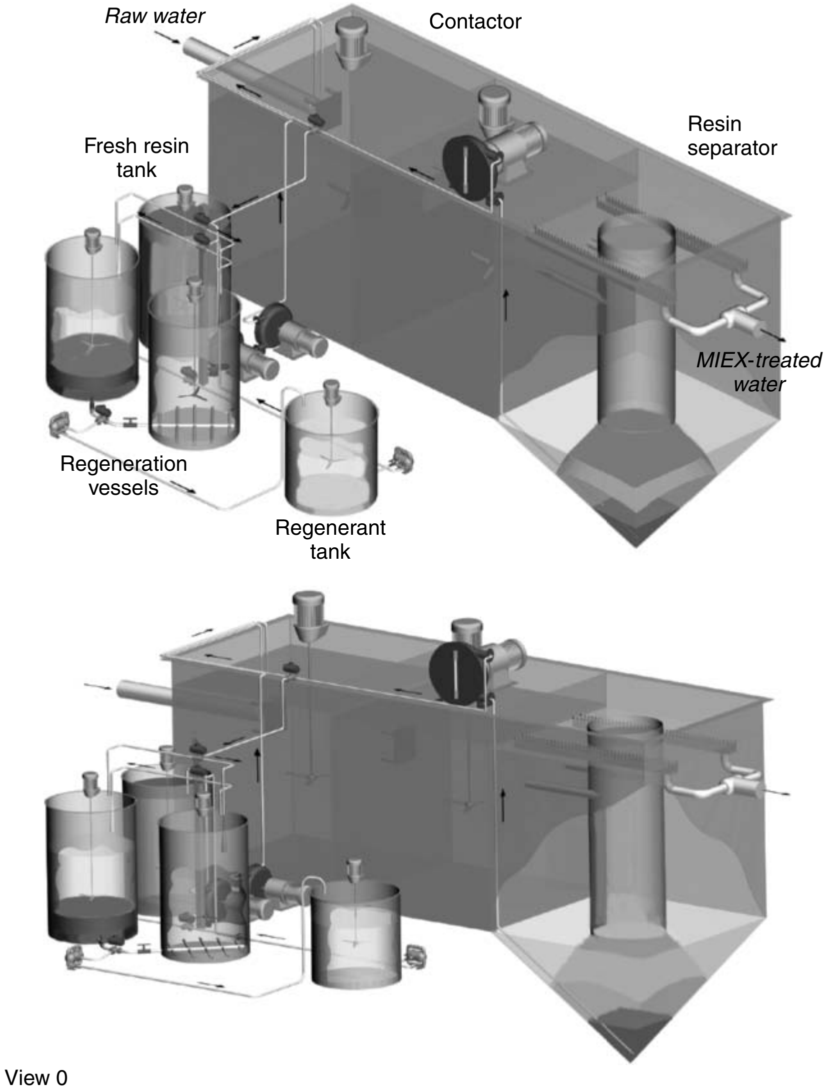

Figure 2. Diagram of 1-mL/day (0.265 mgd) MIEX® resin plant.

MIEX® RESIN IN DRINKING WATER TREATMENT

The MIEX® resin treatment process employs conventional water treatment plant facilities, including a stirred resin contact tank and gravity settlers, as shown in Fig. 2. The resin is dosed into raw/untreated water at a concentration required to achieve a specific water quality. Resin concentrations are in the range of 5–20-mL settled resin per L water (1.25–5.0-g dry weight resin per L). The retention time in the flow-through contacting tanks ranges from 10 to 30 minutes, which is sufficient to achieve more than 50% DOC removal.

The suspension of resin in water from the contacting tanks flows by gravity into a separator. The separator feed well is designed to provide conditions that promote agglomeration of individual resin beads under their magnetic forces. The agglomerates formed are heavy enough to settle to the bottom of the separator against water upflow rates between 5 and 15 $m^3/m^2/h$ (2–6 gpm/ft^2). In this process, more than 99.95% of the resin fed into the separator is recovered in the concentrated (~300 mL-settled resin per L) separator underflow referred to as resin recycle.

In addition to keeping the plant footprint small, the high upflow rate in the resin separator is required to flush out effectively turbidity introduced into the MIEX® plant with raw water. Because a small amount of the resin attrited by pumping and mixing is carried over from the separator with treated water, turbidity increases through the MIEX® process by about 1–2 NTU.

The resin recycle from the separator is directed back to the contacting tanks for another DOC uptake cycle. To maintain the resin's capacity for DOC removal, a small amount of the recycled resin, typically 10% of the total resin flow, is continuously diverted to resin regeneration and is replaced by the same amount of fresh (regenerated) resin. In this way, each resin bead is, on average, contacted by water 10–20 times before being diverted to regeneration.

The DOC-laden resin is stored in a regeneration vessel until a preset settled resin volume is reached. This triggers switching over the resin off-take to the second regeneration

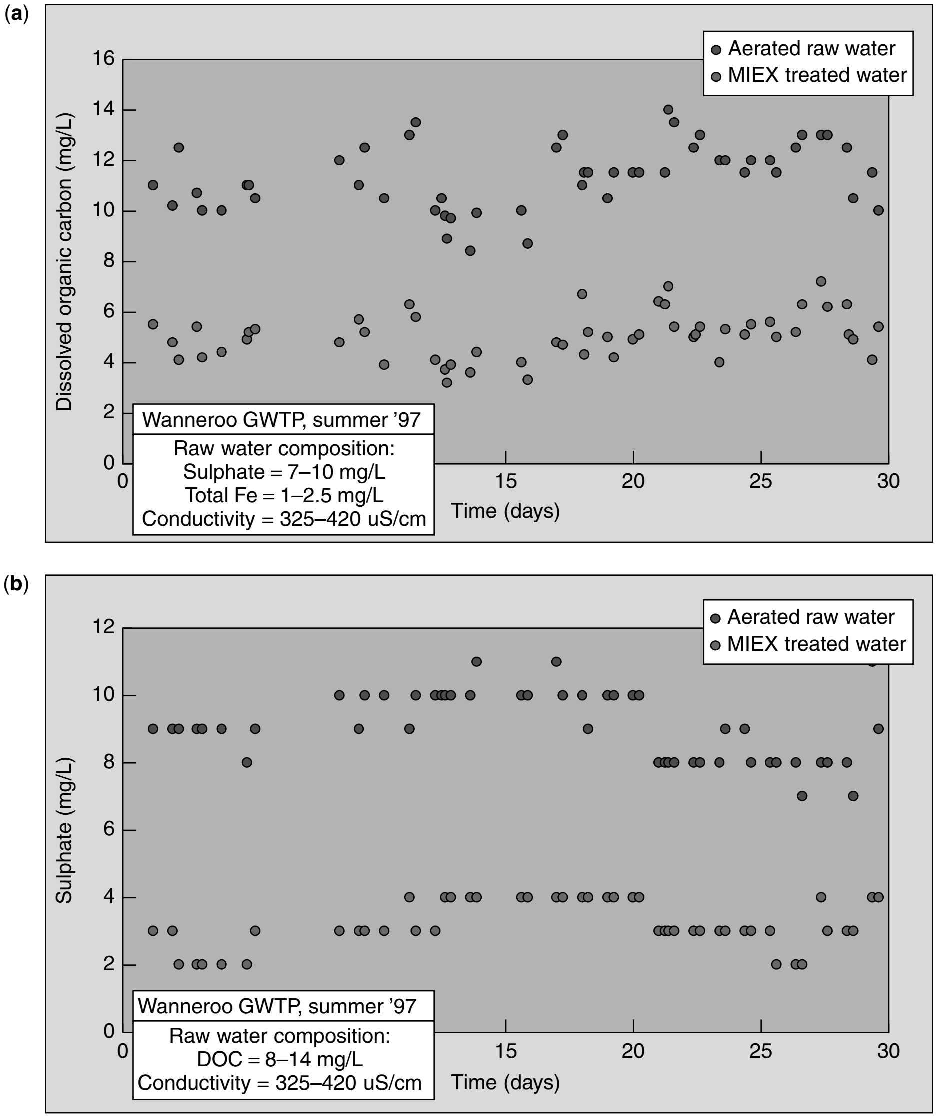

Figure 3. DOC and sulfate removal results.

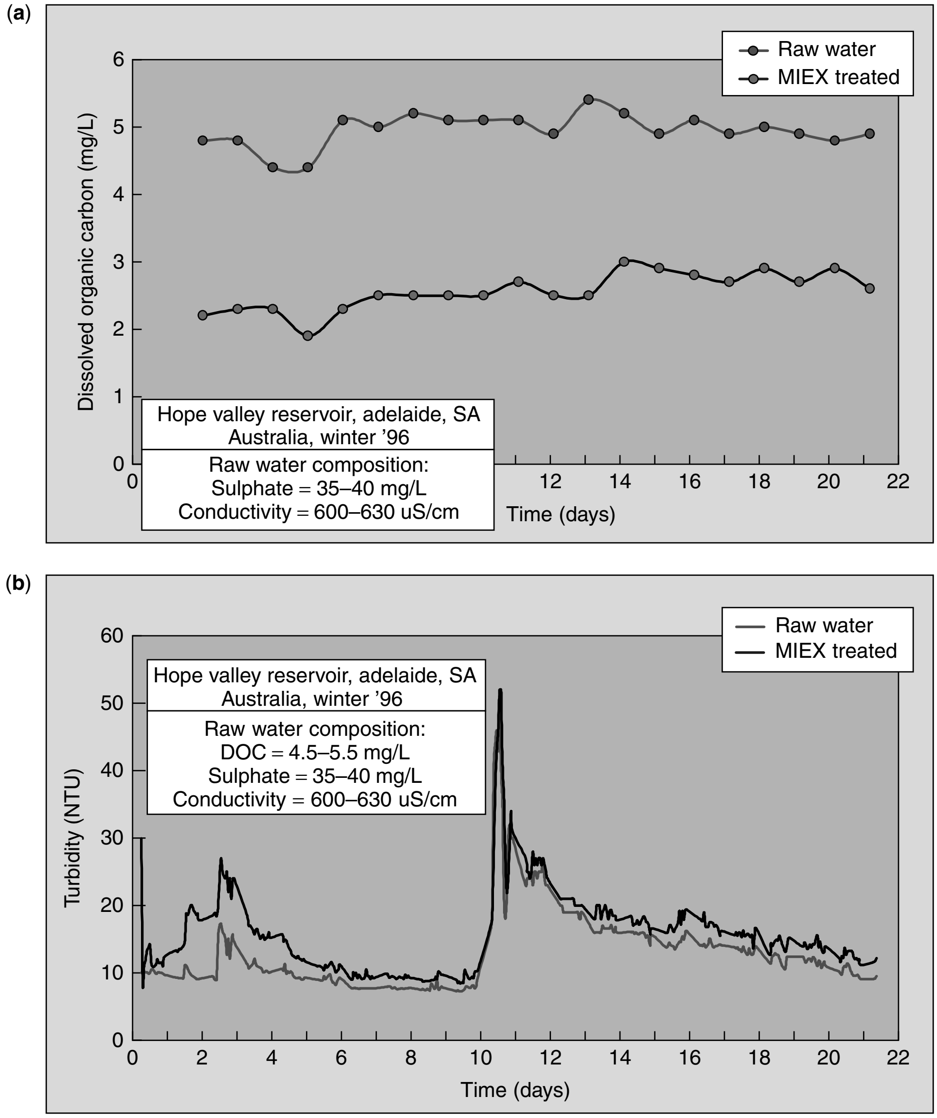

Figure 4. Effect of turbidity on MIEX® resin DOC removal.

vessel, and the start of regeneration in the full vessel. The regeneration is a sequential process comprising draining of carrier water, mixing resin with regenerant, draining of used regenerant, optional rinsing of regenerated resin with water, resuspending of regenerated resin in water, and transferring it into the fresh resin tank.

The basic regenerant is 120-g/L NaCl solution dosed at 3:1 brine to resin volume. Depending on the raw water quality, in some cases, pH modified regenerations using small additions of NaOH and HCl are beneficial. The consumption of salt for regeneration and waste regenerant production is minimized by reusing the regenerant a number of times. Salt usage is from 50-kg to 80-kg NaCl per mL water treated depending on conditions, and salt is adjusted after each use.

RESULTS OF MIEX® TREATMENT

Due to the steady-state nature of operation, this process produces water of constant quality. The high resin preference for DOC anions removes no other anions (bicarbonate, nitrate, etc.), except for sulfate removed in appreciable quantities (Fig. 3).

DOC removal is undisturbed by excursions of raw water turbidity, as shown in Fig. 4. This process is not designed to remove turbidity and may actually contribute 1–2 NTU due to a small amount of resin carryover (Fig. 4b).

Under typical process conditions, MIEX® resin preferentially removes the smaller molecular weight (MW) fraction of DOC. This makes it complementary to alum coagulation, which is known to be more efficient in removing the larger MW fraction of DOC, as shown in Fig. 5.

Pretreatment with MIEX® resin usually results in 50–60% DOC removal. This in turn results in even higher reductions in the alum dose required for turbidity removal. Alum used for turbidity removal will remove a further 20–30% DOC. The combined MIEX®/low-dose alum treatment can remove an overall 80–90% DOC. The low residual DOC levels result in a 50–60% reduction in chlorine demand compared with using

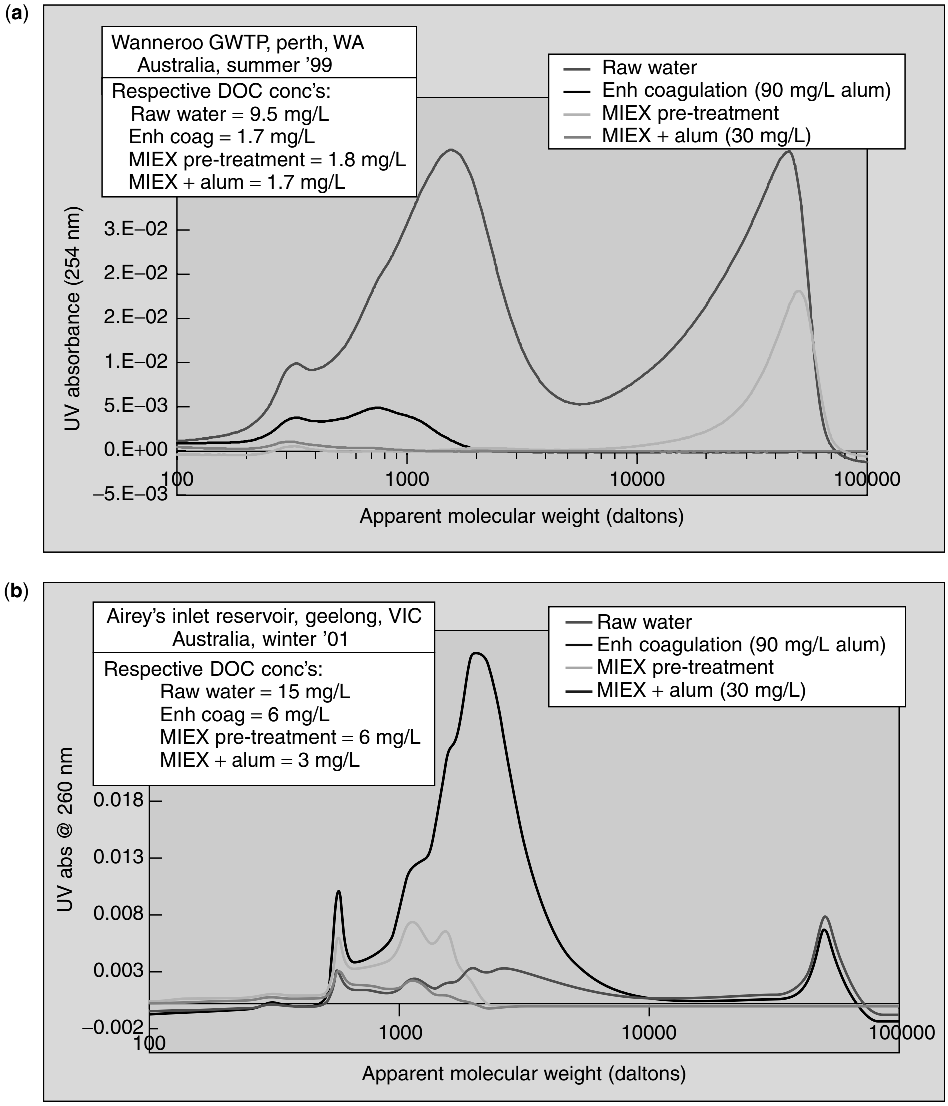

Figure 5. Effect of MIEX® on NOM's apparent molecular weight.

only conventional alum treatment. However, the main benefit of more efficient DOC removal from the combined MIEX®/coagulation process is the reduction in disinfection byproducts formed (Fig. 6).

PROCESS CAPITAL AND OPERATING COSTS

The MIEX® plant uses conventional water treatment infrastructure and equipment. There is no need for pressure columns or complicated piping/valve arrangements. Due to the high settler loading rate, the plant footprint is small, and the production rate high—the average water retention time in the plant is in the range of 40 min to 1 h.

Furthermore, the plant requires only 10% of the resin inventory compared with a conventional system based on the 10–15 min empty EBCT[3] generally recommended for DOC removal (1). This results in further reductions in plant capital costs. There is also no need for periodical replacement of the complete resin inventory, as it is continuously refreshed with small additions of makeup resin.

The main operating cost is resin makeup, the replacement of resin carried over from the separator. The actual resin loss is a physical parameter determined by the plant design and operating conditions. At a separator rise rate of 7 m/h, the loss rate is estimated at 4.5-L settled resin per mL treated water (4.5 gal/mg).

Another significant cost is salt for resin regeneration. Depending on the regeneration process design and raw water quality, the actual salt consumption ranges between 50- and 300-kg NaCl per mL treated water (420–2500 lb/mg). Because only small amounts of NaOH and HCl are used for occasional pH modified regenerations, these chemical costs are minor. The MIEX® plant power consumption is about 50 kW per mL treated water (190 kW/MG).

Finally, there may be some costs for disposal of spent regenerant. This waste stream can be as small as 50–200 L per mL water treated (gal/mg) based on a

---

[3] EBCT—empty bed contact time: time to treat the amount of water equal to the resin bed volume.

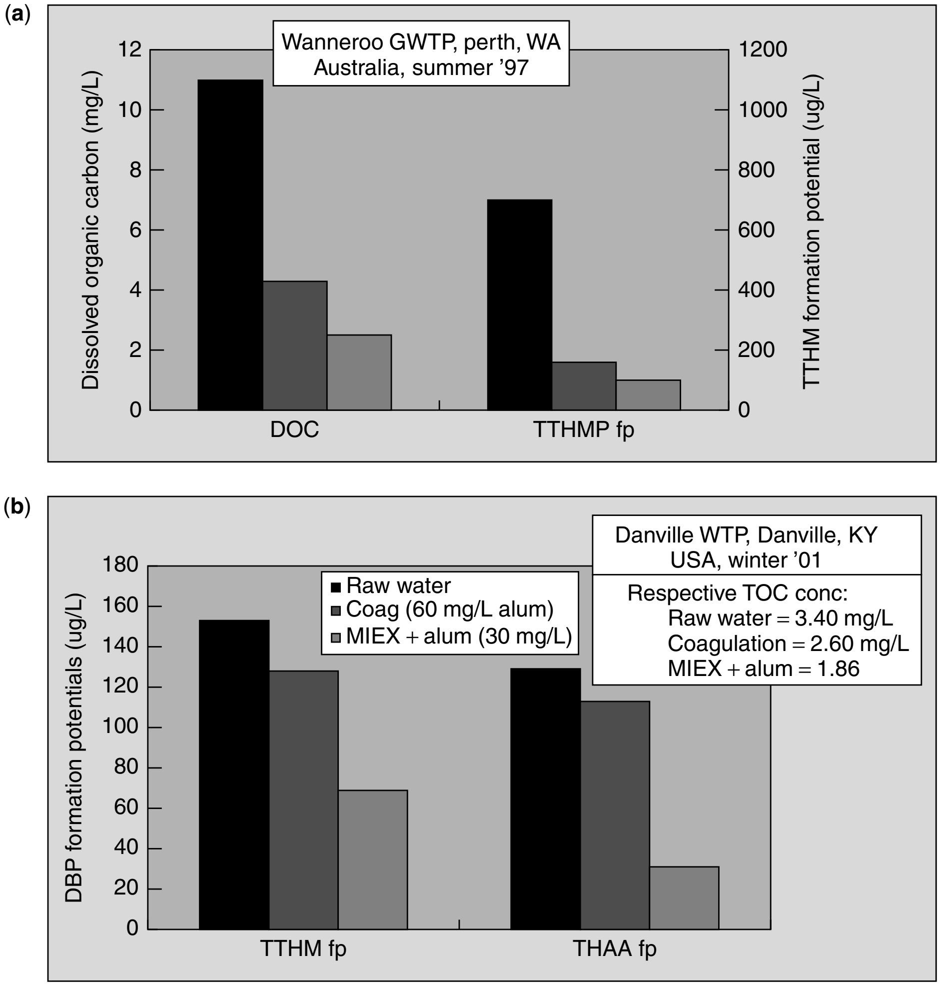

Figure 6. Effect of MIEX® on disinfection byproduct formed.

spent brine concentration of 30-g/L DOC and depending on the amount of DOC removed from raw water by the MIEX® resin. There are a number of disposal options available—sewering, deep well injection, deep ocean outfalls, and evaporation, depending on a particular plant site.

In conclusion, the process based on the MIEX® resin represents a simple, economical option for upgrading water treatment plants to improve removal of DOC and disinfection byproduct precursors. The process can easily be combined with an existing coagulation treatment plant either as an add-on greenfield plant or retrofitted into the existing infrastructure.

It is also possible to combine the MIEX® resin process as the single color/DOC removing step followed by turbidity removal using microfiltration (1,2). This solution is particularly attractive as a "chemical-free" water treatment process.

MEMBRANE FILTRATION

National Drinking Water
Clearinghouse

A membrane or, more properly, a semipermeable membrane, is a thin layer of material capable of separating substances when a driving force is applied across the membrane.

Once considered a viable technology only for desalination, membrane processes are increasingly employed for removal of bacteria and other microorganisms, particulate material, and natural organic material, which can impart color, tastes, and odors to the water and react with disinfectants to form disinfection byproducts (DBP). As advancements are made in membrane production and module design, capital and operating costs continue to decline.

The pressure-driven membrane processes discussed in this fact sheet are microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO).

MEMBRANE FILTRATION: ALTERNATIVE TO CONVENTIONAL FILTRATION

Membrane filtration systems' capital costs, on a basis of dollars per volume of installed treatment capacity, do not escalate rapidly as plant size decreases. This factor makes membranes quite attractive for small systems. In addition, for groundwater sources that do not need pretreatment, membrane technologies are relatively simple to install, and the systems require little more than a feed pump, a cleaning pump, the membrane modules, and some holding tanks. According to a 1997 report by the National Research Council, most experts foresee that membrane filtration will be used with greater frequency in small systems as the complexity of conventional treatment processes for small systems increases.

NEW REGULATIONS FAVOR MEMBRANE TECHNOLOGIES

Membrane processes have become more attractive for potable water production in recent years due to the increased stringency of drinking water regulations. Membrane processes have excellent separation capabilities and show promise for meeting many of the existing and anticipated drinking water standards. The Surface Water Treatment Rule (SWTR) and the anticipated Groundwater Disinfection Rule have led to the investigation of UF and MF for turbidity and microbial removal. The new Disinfectants/Disinfection Byproduct (D/DBP) rules have increased interest in NF and UF membranes for DBP precursor removal.

Potable water treatment has traditionally focused on processes for liquid-solid separation rather than on processes for removing dissolved contaminants from water. Thus, the effect of the 1996 Safe Drinking Water Act (SDWA) amendments has been to encourage water treatment professionals to consider the more unconventional treatment processes, such as membrane technologies, alone, or in conjunction with liquid-solid separation, to meet current regulations.

COMPARING MEMBRANE FILTRATION SYSTEMS

While all types of membranes work well under proper conditions, choosing the most appropriate membrane for a given application still remains crucial (see Fig. 1). In many cases, selection is complicated by the availability of new types of membranes, applications, or by site-specific conditions. Bench and pilot tests are powerful tools for situations where process risks and uncertainties exist or the cost impacts from problems are potentially high.

Membrane classification standards vary considerably from one filter supplier to another. What one supplier sells as a UF product, another manufacturer calls a NF system. It is better to look directly at pore size, molecular weight cutoff (MWCO), and applied pressure needed when comparing two membrane systems.

MWCO, which can be regarded as a measure of membrane pore dimensions, is a specification used by membrane suppliers to describe a membrane's retention capabilities.

MICROFILTRATION (MF)

MF is loosely defined as a membrane separation process using membranes with a pore size of approximately 0.03 to 10 microns, a MWCO of greater than 100,000 daltons, and a relatively low feedwater operating pressure of approximately 100 to 400 kPa (15 to 60 psi). Representative materials removed by MF include sand, silt, clays, *Giardia lamblia* and *Cryptosporidium* cysts, algae, and some bacterial species (see Fig. 2 and Table 1). MF is not an absolute barrier to viruses; however, when used in combination with disinfection, MF appears to control these microorganisms in water.

The primary impetus for the more widespread use of MF has been the increasingly stringent requirements for removing particles and micro-organisms from drinking water supplies. Additionally, there is a growing emphasis on limiting the concentrations and number of chemicals that are applied during water treatment. By physically removing the pathogens, membrane filtration can significantly reduce chemical addition, such as chlorination.

Another application for the technology is for removal of natural or synthetic organic matter to reduce fouling potential. In its normal operation, MF removes little or no organic matter; however, when pretreatment is applied, in-creased removal of organic material, as well as a retardation of membrane fouling can be realized.

Two other applications involve using MF as a pretreatment to RO or NF to reduce fouling potential. Both RO and NF have been traditionally employed to desalt or remove hardness from groundwater.

Process

MF membranes provide absolute removal of particulate contaminants from a feed stream by separation based

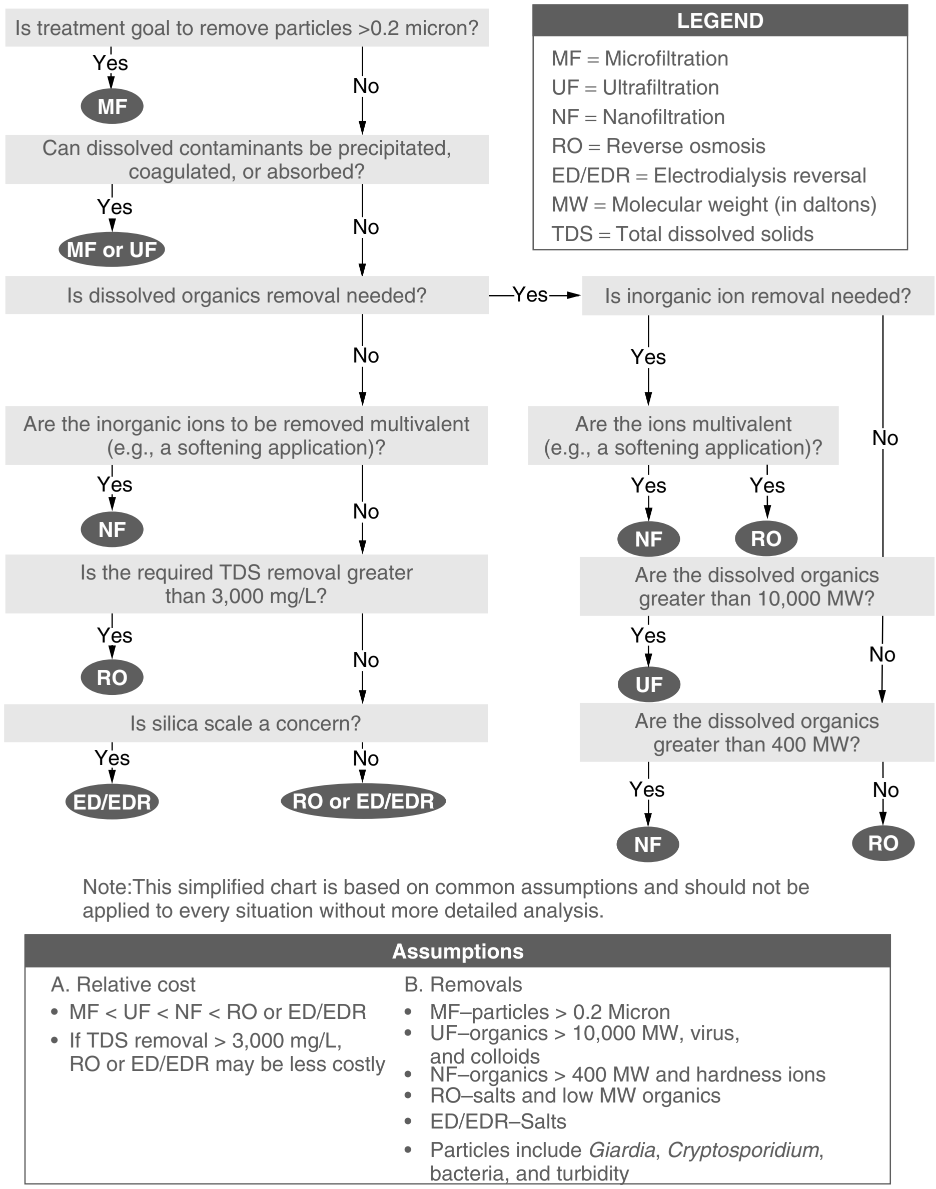

Figure 1. Generalized membrane process selection chart. *Reprinted from* Proceedings of the 1993 Membrane Technology Conference, *by permission.Copyright* © 1993, *American Water Works Association*.

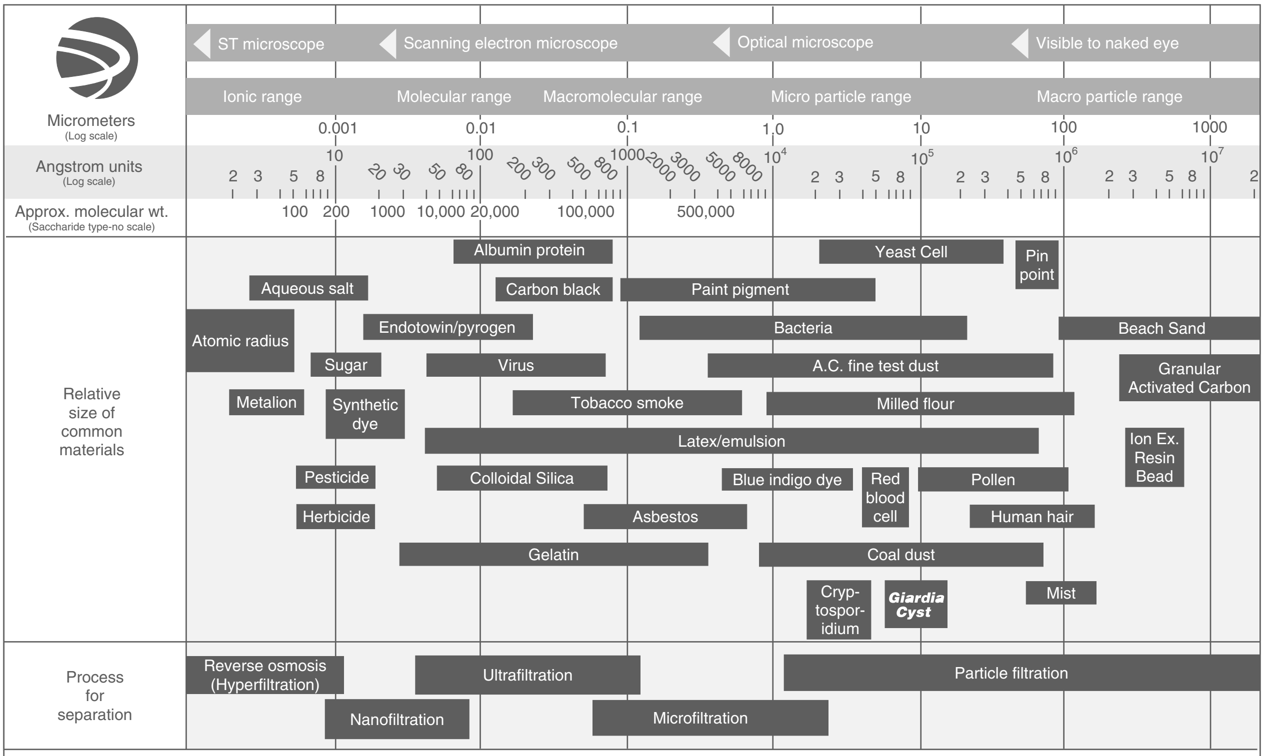
on retention of contaminants on a membrane surface. It is the "loosest" of the membrane processes, and as a consequence of its large pore size, it is used primarily for removing particles and microbes and can be operated under ultralow pressure conditions.

In the simplest designs, the MF process involves prescreening raw water and pumping it under pressure onto a membrane. In comparison to conventional water clarification processes, where coagulants and other chemicals are added to the water before filtration, there are few pretreatment requirements for hollow-fiber systems when particles and microorganisms are the target contaminants.

Prefilters are necessary to remove large particles that may plug the inlet to the fibers within the membrane module. More complex pretreatment strategies are sometimes employed either to reduce fouling or enhance the removal of viruses and dissolved organic matter. In such cases, pretreatment by adding coagulants or powdered activated carbon (PAC), has been employed. In some cases, the cake layer built up on the membrane during the water production cycle can remove some organic materials.

It may be necessary to adjust the feedwater pH by chemical dosing prior to membrane filtration in order to maintain the pH within the recommended operating range for the membrane material employed. It should be noted that pH adjustment is not required for scaling control, since MF membranes do not remove uncomplexed dissolved ions.

MF membranes, under the most conservative conditions, appear to act as an absolute barrier to selected bacteria and protozoan cysts and oocysts. Unlike UF however, MF does not remove appreciable densities of viruses. Therefore, it is necessary to complement MF with a postmembrane disinfection process. Chemical disinfection may



Note: I Micron (1×10^{-6} meters) ≈ 4×10^{-5} Inches (0.00004 inches)
I Angstrom unit = 10^{-10} Meters = 10^{-4} Micrometers (microns)

Table 1. Surface Water Treatment Compliance Technology: Membrane Filtration

Unit Technologies	Removals: Log Giardia & Log Virus	Raw Water, Pretreatment & Other Water Quality Issues
Microfiltration (MF)	Very effective Giardia, >5–6 log; Partial removal of viruses (disinfect for virus credit).	High quality or pretreatment required. Same note regarding TOC.
Ultrafiltration (UF)	Very effective Giardia, >5–6 log; Partial removal of viruses (disinfect for virus credit).	High quality or pretreatment required (e.g., MF). TOC rejection generally low, so if DBP precursors are a concern, NF may be preferable.
Nanofiltration (NF)	Very effective, absolute barrier (cysts and viruses).	Very high quality or pretreatment required (e.g., MF or UF to reduce fouling/extend cleaning intervals). See also RO pretreatments, below.
Reverse Osmosis (RO)	Very effective, absolute barrier (cysts and viruses).	May require conventional or other pretreatment for surface water to protect membrane surfaces: may include turbidity or Fe/Mn removal; stabilization to prevent scaling; reduction of dissolved solids or hardness; pH adjustment.

Source: U.S. Environmental Protection Agency, 1998.

be employed by applying chlorine, chlorine dioxide, or chloramines; however, long contact times are required to inactivate viruses.

Equipment

For municipal-scale drinking water applications, the commercially available membrane geometries that are the most commonly employed are spiral wound, tubular, and hollow capillary fiber. However, spiral-wound configurations are not normally employed for MF due to the flat-sheet nature of the membrane, which presents difficulties in keeping the membrane surface clean. Unlike spiral-wound membranes, hollow-fiber and tubular configurations allow the membrane to be backwashed, a process by which fouling due to particulate and organic materials is controlled.

Membrane "package" plants are normally employed for plants treating less than one million gallons per day (mgd). The components of the plant may include prescreens, a feed pump, a cleaning tank, an automatic gas backwash system, an air compressor, a membrane integrity monitor, a backwash water transfer tank, a pressure break reservoir, an air filter for the gas backwash, controls for the programmable logic controller, and a coalescer.

Operation and Maintenance

In MF, there are two methods for maintaining or re-establishing permeate flux after the membranes are fouled:

- Membrane backwashing: In order to prevent the continuous accumulation of solids on the membrane surface, the membrane is backwashed. Unlike backwashing for conventional media filtration, the backwashing cycle takes only a few minutes. Both liquid and gas backwashing are employed with MF technology. For most systems, backwashing is fully automatic. If backwashing is incapable of restoring the flux, then membranes are chemically cleaned. The variables that should be considered in cleaning MF membranes include: frequency and duration of cleaning, chemicals and their concentrations, cleaning and rinse volumes, temperature of cleaning, recovery and reuse of cleaning chemicals, neutralization and disposal of cleaning chemicals.
- Membrane pretreatment: Feedwater pretreatment can be employed to improve the level of removal of various natural water constituents. It is also used to increase or maintain transmembrane flux rates and/or to retard fouling. The two most common types of pretreatment are coagulant and PAC addition.

ULTRAFILTRATION (UF)

UF involves the pressure-driven separation of materials from water using a membrane pore size of approximately 0.002 to 0.1 microns, an MWCO of approximately 10,000 to 100,000 daltons, and an operating pressure of approximately 200 to 700 kPa (30 to 100 psi). UF will remove all microbiological species removed by MF (partial removal of bacteria), as well as some viruses (but not an absolute barrier to viruses) and humic materials (see Fig. 2 and Table 1). Disinfection can provide a second barrier to contamination and is therefore recommended.

The primary advantages of low-pressure UF membrane processes compared with conventional clarification and disinfection (postchlorination) processes are:

- No need for chemicals (coagulants, flocculants, disinfectants, pH adjustment);
- Size-exclusion filtration as opposed to media depth filtration;
- Good and constant quality of the treated water in terms of particle and microbial removal;
- Process and plant compactness; and
- Simple automation.

Fouling is the limiting phenomenon responsible for most difficulties encountered in membrane technology for water treatment. UF is certainly not exempt from this fouling control problem. Therefore, membrane productivity is still an important subject, which should be thoroughly researched in order to have a better understanding of this phenomenon and its mechanisms.

Process

UF is a pressure-driven process by which colloids, particulates, and high molecular mass soluble species are retained by a process of size exclusion, and, as such, provides means for concentrating, separating into parts, or filtering dissolved or suspended species. UF allows most ionic inorganic species to pass through the membrane and retains discrete particulate matter and nonionic and ionic organic species.

UF is a single process that removes many water-soluble organic materials, as well as microbiological contaminants. Since all UF membranes are capable of effectively straining protozoa, bacteria, and most viruses from water, the process offers a disinfected filtered product with little load on any post-treatment sterilization method, such as UV radiation, ozone treatment, or even chlorination.

Unlike RO, the pretreatment requirement for UF is normally quite low. Fortunately, due to the chemical and hydrolytic stability of UF membrane materials, some of the pretreatments essential for RO membranes, such as adjustment of pH or chlorine concentration levels, do not apply. However, it may be necessary to adjust the pH to decrease the solubility of a solute in the feed so that it may be filtered out.

UF is designed to remove suspended and dissolved macromolecular solids from fluids. The commercially available modules are therefore designed to accept feedwaters that carry high loads of solids. Because of the many uses for UF membranes, pilot studies are normally conducted to test how suitable a given stream is for direct UF.

Water containing dissolved or chelated iron and manganese ions needs to be treated by an adequate oxidation process in order to precipitate these ions prior to UF membrane filtration, as with all membrane processes. This is recommended to avoid precipitation of iron and manganese in the membrane, or even worse, on the permeate side of the membrane (membrane fouling during the backwash procedure). Preoxidation processes generally used include aeration, pH adjustment to a value greater than eight, or addition of strong oxidants, such as chlorine, chlorine dioxide, ozone, or potassium permanganate.

Natural organic matter (NOM) is of great importance in potential fouling of the UF membrane and, consequently, in permeate flux that can be used under normal operating conditions. Thus, it is an interesting design option to use PAC or coagulants to pretreat the water to remove NOM and, consequently, decrease the surface of membrane needed.

Equipment

UF membranes can be fabricated essentially in one of two forms: tubular or flat-sheet.

Package plants, skid-mounted standard units that allow significant cost savings, are usually employed for plants treating less than 1.5 mgd. The primary skid-mounted system components may include an auto-cleaning prefilter, raw water pump, recirculation pump, backwash pump, chlorine dosing pump for the backwash water, air compressor (valve actuation), chlorine tank, chemical tank (detergent), programmable logic controller with program and security sensor (high pressure, low level, etc.)

Operation and Maintenance

The UF membrane plant may be divided into several subcategories:

- Raw water intake and pressure pumps;
- Pretreatment, which includes prescreening, prefiltration, and pH adjustment (if required) or any of the needed pretreatments;
- UF units;
- Chemical cleaning station, backwash station (which uses chlorinated product water), chlorine station, conditioner/preservative station; and
- Line for discharging or treatment of back wash water.

Operation and performance of a UF membrane plant are greatly influenced by raw water quality variations. Turbidity as well as Total Organic Carbon (TOC) of the raw water are water quality parameters of major importance that drive operation mode and membrane flux for all the UF plants presently in operation worldwide.

NANOFILTRATION (NF)

NF membranes have a nominal pore size of approximately 0.001 microns and an MWCO of 1,000 to 100,000 daltons. Pushing water through these smaller membrane pores requires a higher operating pressure than either MF or UF. Operating pressures are usually near 600 kPa (90 psi) and can be as high as 1,000 kPa (150 psi). These systems can remove virtually all cysts, bacteria, viruses, and humic materials (see Fig. 2 and Table 1). They provide excellent protection from DBP formation if the disinfectant residual is added after the membrane filtration step. Because NF membranes also remove alkalinity, the product water can be corrosive, and measures, such as blending raw water and product water or adding alkalinity, may be needed to reduce corrosivity. NF also removes hardness from water, which accounts for NF membranes sometimes being called "softening membranes." Hard water treated by NF will need pretreatment to avoid precipitation of hardness ions on the membrane.

More energy is required for NF than MF or UF, which has hindered its advancement as a treatment alternative.

Process

NF membranes have been observed to operate on the principle of diffusion rather than sieving as with MF and UF membranes.

Operation and Maintenance

Operational parameters of membranes include the physical and chemical properties of the membrane, the pore size or molecular weight cut-off (MWCO), and configuration.

REVERSE OSMOSIS (RO)

RO systems are compact, simple to operate, and require minimal labor, making them suitable for small systems. They are also suitable for systems where there is a high degree of seasonal fluctuation in water demand.

RO can effectively remove nearly all inorganic contaminants from water. RO can also effectively remove radium, natural organic substances, pesticides, cysts, bacteria, and viruses (see Fig. 2 and Table 1). RO is particularly effective when used in series. Water passing through multiple units can achieve near zero effluent contaminant concentrations. Disinfection is also recommended to ensure the safety of water.

Some of the advantages of RO are:

- Removes nearly all contaminant ions and most dissolved non-ions,
- Relatively insensitive to flow and total dissolved solids (TDS) level, and thus suitable for small systems with a high degree of seasonal fluctuation in water demand,
- RO operates immediately, without any minimum break-in period,
- Low effluent concentration possible,
- Bacteria and particles are also removed, and
- Operational simplicity and automation allow for less operator attention and make RO suitable for small system applications.

Some of the limitations of RO are:

- High capital and operating costs,

- Managing the wastewater (brine solution) is a potential problem,
- High level of pretreatment is required in some cases,
- Membranes are prone to fouling, and
- Produces the most wastewater at between 25–50 percent of the feed.

Process

RO removes contaminants from water using a semipermeable membrane that permits only water, and not dissolved ions (such as sodium and chloride), to pass through its pores. Contaminated water is subject to a high pressure that forces pure water through the membrane, leaving contaminants behind in a brine solution. Membranes are available with a variety of pore sizes and characteristics.

Equipment

Typical RO units include raw water pumps, pretreatment, membranes, disinfection, storage, and distribution elements. These units are able to process virtually any desired quantity or quality of water by configuring units sequentially to reprocess waste brine from the earlier stages of the process. The principal design considerations for reverse osmosis units are:

- operating pressure,
- membrane type and pore size,
- pretreatment requirements, and
- product conversion rate (the ratio of the influent recovered as waste brine water to the finished water).

WASTE STREAM DISPOSAL

Waste stream disposal is a significant problem in many areas. Unlike conventional treatment processes, in which approximately 5 to 10 percent of the influent water is discharged as waste, membrane processes produce waste streams amounting to as much as 15 percent of the total treated water volume. (See Table 2.) Because little or no chemical treatment is used in a membrane system, the concentrate stream usually contains only the contaminants found in the source water (although at much higher concentrations), and for this reason the concentrate can sometimes be disposed of in the source water. Other alternatives include deep well injection, dilution and spray irrigation, or disposal in the municipal sewer. These alternatives are usually necessary for NF wastes, which usually contain concentrated organic and inorganic compounds. Regardless of the type of membrane, disposal must be carefully considered in decisions about the use of membrane technology. Applicable local discharge regulations must be respected.

MEMBRANE INTEGRITY TESTING

One of the most critical aspects of employing membrane technology is ensuring that the membranes are intact and

Table 2. Surface Water Treatment Compliance Technology: Membrane Filtration

Unit Technologies	Complexity: Ease of Operation (Operator Skill Level)	Secondary Waste Generation	Other Limitations/ Drawbacks
Microfiltration	Basic: increases with pre/post-treatment and membrane cleaning needs.	Low-volume waste may include sand, silt, clay, cysts, and algae.	Disinfection required for viral inactivation.
Ultrafiltration	Basic: increases with pre/post-treatment and membrane cleaning needs.	Concentrated waste: 5 to 20 percent volume. Waste may include sand, silt, clays, cysts, algae, viruses, and humic material	Disinfection required for for viral inactivation.
Nanofiltration	Intermediate: increases with pre/post-treatment and membrane cleaning needs.	Concentrated waste: 5 to 20 percent volume.	Disinfection required under regulation, and recommended as a safety measure and residual protection.
Reverse Osmosis	Intermediate: increases with pre/post-treatment and membrane cleaning needs.	Briney waste. High volume, e.g., 25 to 50 percent. May be toxic to some species.	Bypassing of water (to provide blended/stabilized distributed water) cannot be practiced at risk of increasing microbial concentrations in finished water. Post-disinfection required under regulation, is recommended as a safety measure and for residual maintenance. Other post-treatments may include degassing of CO_2 or H_2S, and pH adjustment.

Source: U.S. Environmental Protection Agency, 1998.

continuing to provide a barrier between the feedwater and the permeate or product water. There are several different methods that can be employed to monitor membrane integrity, including:

- Turbidity monitoring,
- Particle counting or monitoring,
- Air pressure testing,
- Bubble point testing,
- Sonic wave sensing, and
- Biological monitoring.

WATER METERS

Zane Satterfield
Vipin Bhardwaj
NDWC Engineering Scientist

Any viable business must be able to determine how much product it is making and selling and if that product is profitable. Water is a business. And, the best way for a water utility to measure or account for the water produced and then sold is by using water meters. This Tech Brief, discusses the different types of meters, their applications, and their importance for a water utility business.

WHY ARE METERS IMPORTANT?

Water meters are important to a utility for several reasons:

1. They make it possible to charge customers in proportion to the amount of water they use.
2. They allow the system to demonstrate accountability.
3. They are fair for all customers because they record specific usage.
4. They encourage customers to conserve water (especially as compared to flat rates).
5. They allow a utility system to monitor the volume of finished water it puts out.
6. They aid in the detection of leaks and waterline breaks in the distribution system.

A system without meters is like a taxi without a fare counter. Without a meter, it costs the same to drive around the block as it does from New York to Los Angeles.

TYPES OF METERS

Meters are classified into two basic types: positive displacement and velocity. Each of these meter types has variations, leading to the perception that there are several different kinds. Meters that feature both positive displacement and velocity are known as compound meters. The unit of measurement is usually in gallons but sometimes in cubic feet.

POSITIVE DISPLACEMENT METERS

In this type of meter, a known volume of liquid in a tiny compartment moves with the flow of water. Positive displacement flow meters operate by repeatedly filling and emptying these compartments. The flow rate is calculated based on the number of times these compartments are filled and emptied. The movement of a disc or piston drives an arrangement of gears that registers and records the volume of liquid exiting the meter. There are two types of positive displacement meters: nutating disc and piston.

Nutating disc meters have a round disc that is located inside a cylindrical chamber. The disc is mounted on a spindle. The disk nutates, or wobbles, as it passes a known volume of liquid through the cylindrical chamber. The rotating motion of the disk is then transmitted to the register that records the volume of water that went through the meter (see Fig. 1 below).

Piston meters have a piston that oscillates back and forth as water flows through the meter. A known volume of water is measured for each rotation, and the motion is transmitted to a register through an arrangement of magnetic drive and gear assembly.

Positive displacement meters are sensitive to low flow rates and have high accuracy over a wide range of flow rates. Positive displacement meters are used in homes, small businesses, hotels, and apartment complexes. They are available in sizes from 5/8" to two inches.

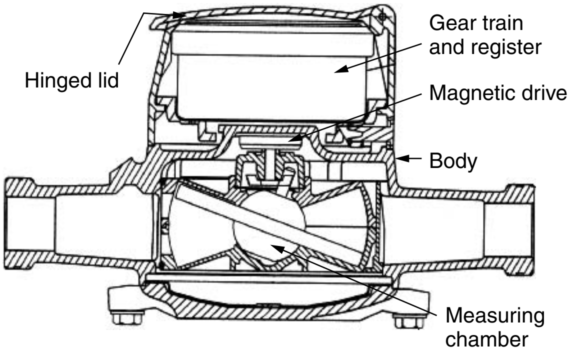

Figure 1. Nutating-disk meter with plastic housing. *Source*: AmericanWater Works Association. *Water Transmission and Distribution. Principles and Practices of Water Supply Operations*, 2nd Edition.

VELOCITY METERS

Velocity meters operate on the principle that water passing through a known cross-sectional area with a measured velocity can be equated into a volume of flow. Velocity meters are good for high flow applications.

Velocity meters come in different types, including turbine, multi-jet, propeller, ultrasonic, venture, and orifice meters. These meters are available in sizes of two inches and larger with the exception of multi-jet meters, which are between 5/8" and two inches.

Turbine meters have a rotating element that turns with the flow of water. Volume of water is measured by the number of revolutions by the rotor.

Venturi meters have a section that has a smaller diameter than the pipe on the upstream side. Based on a principle of hydraulics, as water flows through the pipe, its velocity is increased as it flows through a reduced cross-sectional area. Difference in pressure before water enters the smaller diameter section and at the smaller diameter "throat" is measured. The change in pressure is proportional to the square of velocity. Flow rate can be determined by measuring the difference in pressure. Venturi meters are suitable for large pipelines and do not require much maintenance.

Orifice meters work on the same principle as venturi meters, except that, instead of the decreasing cross-sectional area, there is a circular disk with a concentric hole. Flow rate is calculated similarly to the venturimeter by measuring the difference in pressures.

Ultrasonic meters send sound waves diagonally across the flow of water in the pipe. Changes in the velocity of water are converted electronically to change in flow rate.

Magnetic meters have an insulated section through which water flows. The flow of water induces an electrical current that is proportional to the velocity and hence the flow rate.

Propeller meters have a fan-shaped rotor that spins with the flow of water. A recorder is attached to the rotor to register the readings.

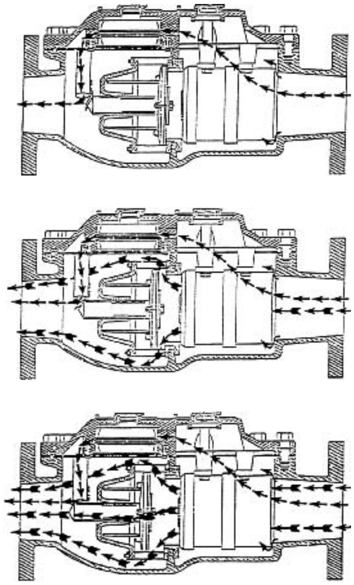
Multi-jet meters have tangential openings in a chamber to direct the water flow across a rotor with many vanes. Flow is measured proportional to the speed of the rotor.

COMPOUND METERS

In some cases, it is necessary to have a combination meter—both a positive displacement meter and velocity meter installed together—to be able to measure high and low flows. Low flows are measured through positive displacement while high flows are measured by velocity. A valve arrangement directs flows into each part of the meter (see Fig. 2).

METER INSTALLATION

Meters are installed either in outdoor meter pits (also known as meter wells) or inside the building served. Although it is common to have a meter installed in the basement, it is better to have the meter located at the curb or property line because of easy access for reading or maintenance. It is sometimes difficult to gain access to the



Low flow: All of the water passes through the nutating disk measuring element.

Crossover: As the control valve opens under higher flow rates, water passes through both measuring elements while the disk-side throttling begins.

Full flow: At high flow rates the control valve is fully open. The bulk of the water passes through the turbine measuring element, and the disk-side is throttled to a minimal amount.

Figure 2. Compound meter. *Source*: American Water Works Association, *Water Transmission and Distribution, Principles and Practices of Water Supply Operations*, 2nd Edition.

residence or building when no one is there. Nevertheless, it may be necessary due to extreme cold weather to have the meter located indoors to prevent frost damage. Large meters are usually installed in concrete or block vaults preferably out of traffic areas, but they also can be installed inside.

General guidelines for installing meters are:

- In outdoor meter pits, the face of the meter should be between 18 and 24 inches from the ground surface or top of the meter pit lid.
- Meter pits or wells should have six to 12 inches of gravel at the bottom to help with drainage.
- Large meter pits should have a drain or a sump pump if a drain is not possible. There should never be standing water in a meter pit or well.
- If at all possible, the meter pit or well should not be located in an area prone to flooding.
- The meter setting should have a shut-off valve on both sides of the meter (i.e., the customer's side and the water main side).
- If possible, the meter should be installed in a horizontal position.
- The meter should be easily accessible for service, inspection, and reading even if meter reading is via remote sensing equipment.
- Protect the meter from freezing.
- Always be mindful of public safety. Don't have the meter lid sticking up or have it too low so that it creates a hole.
- Install seals on the meter to reduce tampering and indicate when tampering does occur.

The following suggestions apply to larger meter vaults or pits:

- Large meter pits should also have a drain or a sump pump if a drain is not possible. There should never be standing water in a meter pit or well.
- To prevent disruption of service when replacing or repairing large meters, there should be a bypass that can also be metered. Having the bypass metered would be similar to a manifold set-up where you have two or more meters in parallel making service of one meter easy without service disruption or lost revenue.
- Large meter installations should have good structural support to prevent stress on the water line. Also there should be at least 10 times the pipe diameter of straight pipe before the meter and five times the pipe diameter of straight pipe after the meter.
- Some large meters recommend or require a strainer to be installed ahead of the meter.
- With large meters that are located in concrete vaults or pits, ideally, the meter face should be located over the hatchway to help with reading the meter, possibly reading the meter without even entering the pit. This will also help in lifting the meter from the pit. Remember, if the meter reader has to enter the meter vault or pit, this is considered a confined space entry and the proper safety procedures must be followed.

Small meter installation is easier with a meter yoke (also known as a meter setter). Meter yokes have different configurations and can have any combination of built-in check valves, regulators, and lockable shutoff valves. Utilities should have their own set specifications with illustrations depicting proper meter installations.

METER READING

There are two common types of water meter registers: circular and straight. Either of the meters can be manufactured to read in gallons or cubic feet. The circular register is somewhat more difficult to read.

The straight register is what is seen on newer meters and is read like a car's odometer. On some larger meters there will be a multiplier on the register face or the meter itself. The multiplier will be noted as 10X, 100X, or 1000X depending on the size of the meter. The multiplier indicates that the meter reader must multiply what is read by the number noted 10, 100, or 1,000. For example, if the register displays the number 975 and the multiplier is 10X, then the meter reading is 9750 gallons.

There are several different ways meter reading can be accomplished.

- Direct read is, as the name suggests, an individual directly reading the register.
- Remote reading is done through an electronic signal, usually with a wire to a separate station where the individual could either direct read or touch read.
- Touch read or plug-in readers use a handheld device that takes the electronic signal from plugging-in or touching the remote station and translates it into the number of gallons used. The remote station can even be on top of the meter pit lid. The readings are stored

on the hand-held device until the meter reader gets back to the office to be downloaded to a computer.

- A newer development is automatic meter reading, which enables the meter reader to drive down the street and obtain the readings from the meters usually through radio transmission.

SELECTING A METER

Meters are selected using several factors: flow rate, size of pipe, pressure loss and safety considerations, such as fire service regulations. For sizes of one inch and smaller and low flow rates, positive displacement types of meters are common. For residential uses, 5/8" or 3/4" meters are used.

For medium flows, such as in apartment buildings, businesses, and public buildings, positive displacement meters in sizes of 1", 11/2", or two inches are used. In sizes of two and three inches, either, displacement, multi-jet, or turbine types of meters can be used. In the three- to four-inch size range, the meter type depends on the average flow rate. If the flow rate is between five and 35 percent of maximum flow rate, the positive displacement type is better. If the flow rates are going to be 10 to 15 percent of the maximum capacity, a turbine type should be used. If close accuracy at low flows is important, but large flows also have to be measured, a compound meter is best.

For large flows, velocity meters are more appropriate. Turbine meters are suitable for large flows where minimum flow rate is above 10 to 20 percent of maximum rating. Turbine meters have low pressure loss at high flow rates. Propeller meters are suitable for large mainlines or for pump station discharge.

METER TESTING AND MAINTENANCE

For meters to be effective, they must accurately read the amount of water flowing through them. Proper testing and maintenance procedures should be in place to assure accuracy.

Master meters—meters at the treatment plant that measure the largest water volumes—are the highest priority in the meter testing and maintenance program. These meters determine how much water is produced or sold and should be tested once a year. (More often if large amounts of water are measured through the meter.)

Industrial and commercial meters are the second testing and maintenance priority in the system. "The most expensive water loss in the distribution system is associated with under registration of industrial and commercial water meters, rather than leaks," says Jeff Bennett utility inspector with the West Virginia Public Service Commission. "Lost water sales are lost revenue at the retail rate. Lost water due to leaks is only the loss of the cost to produce the water."

Bennett also points out, "a two-inch meter will, at a minimum, provide as much revenue as eight residential meters, while a six-inch meter will provide at least as much revenue as 50 residential meters. Since large meters provide considerably more revenue per meter, it only makes 'cents' to test them more frequently."

Meters larger then two inches are usually tested in-place using a calibrated field test meter. To be able to field test a meter, there must be a tap and an isolation valve immediately downstream from the meter. This temporary connection can be made with a fire hose. Even new meters should be tested.

Master meters in water plants are, in some cases, difficult or impossible to test using a field test meter. In these situations, a draw-down test can be conducted, which involves comparing a known volume of water pumped out of a tank (clearwell) to the volume recorded on the meter being tested.

Although residential meters may be the final priority in the testing and maintenance program, in small systems, they may be the most important. The residential meters can be broken down to the ones that have high usage and the ones that don't. It only makes sense to concentrate on residential meters that have high usage because of a big family or multiple occupants compared to residential meters that never reach the minimum bill because of single occupancy of an elderly person.

The majority of residential meters are the positive displacement type, which almost always slow down when they are worn or encrusted by minerals or debris. With residential meters, the testing program should either consist of periodic testing on a test bench or a complete change-out program.

Residential meters should be checked, cleaned, and calibrated every seven to 10 years or as indicated by your state primacy agency. If your system does not have a meter test bench, check with a neighboring system or shop around for a company that can do testing on a certified test bench.

Testing and maintenance of the meters depends on the quality and quantity of the water. If adverse conditions, such as high minerals or large flows are encountered, meters will require more frequent attention. Water that has high levels of minerals will affect the operation of a meter over time. This should be taken into account with a system's preventive maintenance program by cleaning the meter to extend its life and to improve the accuracy of the meter.

Maintenance requirements will vary depending upon the material used in the meter components. Although plastic meters are less expensive, more maintenance and more frequent replacement may be necessary.

If your water system does not have any meters for residential connections, and you want to start metering it, a typical cost would be $280 for connection (house). The price breaks down as follows:

• Direct read 5/8" meter	**$40**
• Tandem meter setter (yoke) able to accept regulator	**$90**
• Pressure regulator (3/4" typical size)	**$40**
• Meter well (pit)	**$25**
• Meter frame and lid	**$35**
• Corporation-stop	**$15**
• 6" service saddle	**$35**
• Total for each connection	**$280**

If the system has 200 residential connections, the total material cost would be $56,000. With a meter life expectance of 15 years, it would take less than $1.50 per connection per month to recoup the cost.

If your system already has meters, but doesn't have a good maintenance program, here is an example of revenue lost due to a slow residential meter (assuming a 4,500 gallons per month rate at a cost of $25.00):

Loss with a meter 3 percent slow = $0.75 per month or $9.00 per year **for one meter**.

Loss with a meter 5 percent slow = $1.25 per month or $15.00 per year **for one meter**.

In some small systems, city buildings, golf courses, municipal swimming pools, and even the water plant are not charged. These connections should be metered to account for all treated water.

Keep in mind that if your system has a sewer utility, the loss is compounded, because most sewer utilities rely on water meters to bill for the sewer service. In these cases having an inaccurate water meter will have a direct impact on sewer revenue.

MICROBIOLOGICAL CONCERNS OF DRINKING WATER DISTRIBUTION SYSTEMS

Mohammad R. Karim
American Water, Quality Control and Research Laboratory
Belleville, Illinois

Mark W. LeChevallier
American Water
Voorhees, New Jersey

Drinking water in a distribution system may contain microbes that enter the distribution system through treatment breakthrough, regrowth, or contamination of water in the system. The majority of these organisms are harmless. However, pathogenic organisms may also be present. A number of waterborne disease outbreaks related to distribution systems have been reported. Many factors contribute to the regrowth and contamination of drinking water in distribution systems. This article discusses the factors that contribute to microbial regrowth and contamination of distribution systems. To ensure protection of public health, these factors should be adequately addressed to safeguard drinking water from contamination in distribution systems.

INTRODUCTION

The purpose of a drinking water distribution system is to deliver water that is safe and acceptable in odor, taste, and appearance. Most drinking water utilities rely on the "multiple-barrier concept" as the guiding principle for providing safe water. Traditionally, the barriers have included (1) source water protection; (2) coagulation, flocculation, and sedimentation; (3) filtration; (4) disinfection; and (5) protection of water in the distribution system. These barriers are used to duplicate microbial removal capabilities by succeeding process steps so that sufficient backup systems are available to permit continuous operation in the face of normal mechanical failures. The distribution system is considered the final and one of the most important barriers in the multiple-barrier concept for providing safe drinking water.

After the treatment process, the microbiological quality of drinking water is at its highest; however, as the treated water travels through the distribution system, the microbiological quality of the water may deteriorate through three basic mechanisms: (1) breakthrough from treatment plants, (2) microbial growth/regrowth, and (3) contamination within the distribution system. This article discusses the microbiological concerns of drinking water distribution systems.

OUTBREAKS FROM DISTRIBUTION SYSTEM DEFICIENCIES

From 1971 to 1998, 619 drinking waterborne disease outbreaks were reported in the United States due to microbiological, chemical, or unknown etiology (1). Of the 619 waterborne disease outbreaks, 113 outbreaks and 21,058 reported cases of illness or 13 deaths were from distribution system contamination. Increasingly, concern has been raised regarding the adequacy of distribution system barriers. Distribution system deficiencies were associated with 30.3% of the community outbreaks (1). Lippy and Waltrip (2) reported that nearly 37% of the community outbreaks from 1946 to 1980 were due to failures of a distribution system. Craun and McCabe (3) reported that distribution system deficiencies accounted for most of the waterborne hepatitis outbreaks (10 out of 17 outbreaks) in public water systems from 1946 to 1970. Contamination of mains during construction or repair and cross-connections were cited as some of the primary causes of distribution deficiencies. In recent years, waterborne disease outbreaks due to distribution system deficiencies have had disastrous consequences. For example, an outbreak of hemorrhagic *Escherichia coli* serotype 0157:H7 occurred in Cabool, MO during December 1989 and January 1990 and resulted in 243 cases of diarrhea and 4 deaths (4). It was concluded that the illness was caused by contaminants that entered the distribution system through two major pipe breaks and 43 service meter failures that occurred during unusually cold weather.

ETIOLOGICAL AGENTS OF OUTBREAKS RELATED TO DRINKING WATER DISTRIBUTION SYSTEMS

Microbiological and chemical contaminants were associated with 75 and 38 outbreaks, respectively, for the 113 reported outbreaks caused by distribution system deficiencies from 1971 to 1998 (1). Of the outbreaks caused by microbial contaminants, bacteria were responsible for 21%, protozoa for 17%, viruses for 8%, and unknown etiological agents for 54% of outbreaks (Fig. 1). The bacterial agents identified were *Salmonella, E. coli* 0157:H7, *Shigella, Campylobacter, Salmonella typhimurium,* and *Vibrio cholerae*. The protozoan agents identified were *Giardia* and *Cyclospora*. Viruses identified were norovirus and hepatitis A.

MICROBIAL OCCURRENCE IN THE DISTRIBUTION SYSTEM

Drinking water in a distribution system may contain many microbes that enter the system through treatment breakthrough, regrowth, or contamination of water in the system. The majority of these organisms are harmless and not many have the potential to be pathogenic. However, pathogens may also pass into drinking water in a distribution system. Two types of pathogens may be present in the drinking water—primary pathogens (those that inhabit the gastrointestinal tract) and opportunistic pathogens (microorganisms that may exist as part of a normal body microflora but under certain conditions may cause disease in compromised hosts such as immunocompromised individuals). Primary pathogens include *Salmonella, E. coli* 0157, *Shigella, Yersinia, Campylobacter*, enteric viruses, and protozoan parasites such as *Giardia* and *Cryptosporidium*. These organisms may cause a variety of diseases including gastroenteritis, typhoid, paratyphoid fever, dysentery, cholera, hepatitis, paralysis, and meningitis.

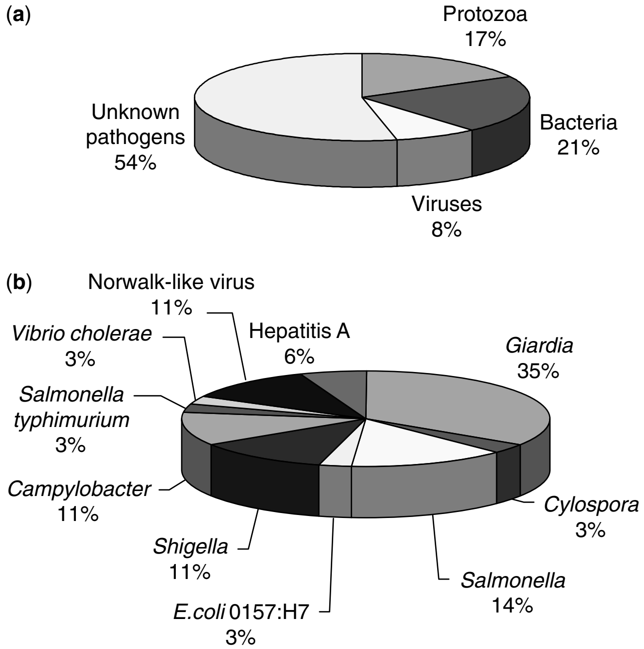

Figure 1. (**a**) Etiological agents for U.S. waterborne disease outbreaks caused by distribution system deficiencies from 1971–1998; (**b**) percent of outbreaks caused by the specific microbial etiology from 1971–1998. Data from Reference 1.

Opportunistic pathogens that may occur in a drinking water distribution system include *Klebsiella pneumoniae, Pseudomonas aeruginosa, Legionella pneumophila, Aeromonas hydrophila, Citrobacter spp., Enterobacter spp., Moraxella spp., Mycobacterium avium* complex, *Staphylococcus aureus*, fungi, and yeast (4,5). These organisms may cause diseases such as pneumonia, meningitis, septicemia, gastrointestinal illness, and respiratory tract infection.

Factors Contributing to Distribution System Contamination

Because of the expansive nature of a distribution system, that has many miles of pipe, storage tanks, and interconnections with industrial users, opportunities for contamination do exist. A list of possible sources of distribution system contamination is presented in Table 1. Cross-connections are recognized as a major risk to water quality, but their probability of occurrence is low due to vigilant cross-connection control programs. However, complete cross-connection control is difficult to achieve, and many systems face challenges in maintaining an effective cross-connection control program in the face of dwindling resources and personnel cutbacks.

Inadequate separation of water mains and sewers may contribute to distribution system contamination through broken or leaking water mains. Engineering standards call for a separation of 10 ft between drinking water and sewer pipelines, although separations can be as little as 18 inches if the pipelines are placed on different levels (6). In saturated soil, microbes can move several meters in short periods of time (7). This transport could be aided by water flowing out of the sewer line. Because it is not uncommon for water systems to lose more than 10% of total production through leaks in pipelines (8), opportunities exist for water to intrude through these portals.

Despite the best efforts to repair main breaks using good sanitary procedures, main breaks are an opportunity

Table 1. Sources of Distribution System Contamination

- Cross-connection
- Inadequate separation of water main and sewer
- Contamination of broken or leaking water main
- Contamination of mains during construction/repair
- Back-siphonage
- Contamination of distribution storage
- Intrusion of contaminants due to pressure transients

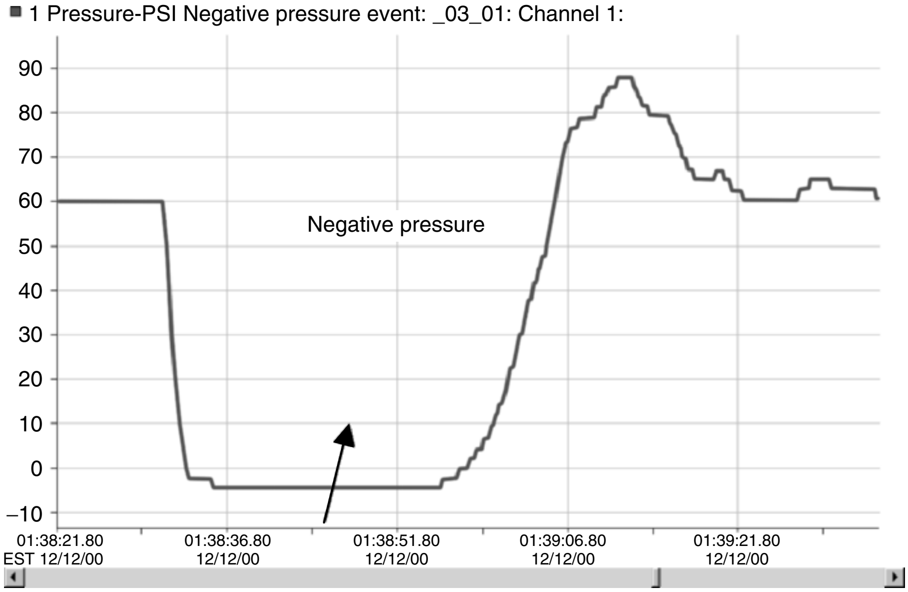

Figure 2. A negative pressure transient in a drinking water distribution system following a power outage. The negative pressure lasted approximately 22 seconds before static pressures were restored.

for contaminants to enter a distribution system. Utilities typically isolate the affected section, super chlorinate, and flush the repaired pipe. However, flushing velocities may not always be achievable to remove all contaminated debris, and microbiological tests to check the final water quality may not detect contaminating organisms. McFeters et al. (9) reported high levels of injured coliform bacteria, not detectable by standard coliform techniques, following the repair of a main break. Resampling at the site 1 week later showed high levels of the coliform bacteria, detectable only using m-T7 agar, a medium specially designed to recover chlorine-injured coliforms.

Installation of backflow devices to prevent the entry of contaminated water is an important distribution system barrier. Due to cost considerations, backflow devices are primarily installed on commercial service lines where the facility uses potentially hazardous substances (4). Examples of such facilities include hospitals, mortuaries, dry cleaners, and industrial users. It is not common that all service connections have backflow devices, so the possibility of back-siphonage exists at these points. In addition, installation of backflow devices for all service connections would make routine checking of the devices nearly impossible and without routine inspection, the proper functioning of the units cannot be determined. Even when backflow devices have been installed, contamination has occurred. The failure of a backflow check valve allowed water stored for fire protection to enter the Gideon, Missouri, distribution system (4). A broken vent in the storage tank allowed birds to enter and contaminate the water with *Salmonella*. Three people died due to *Salmonella* infection.

Pressure transients in drinking water pipelines are caused by an abrupt change in the velocity of water. These events are also termed “surges” or “water hammer.” These pressure transients are waves that have both positive and negative amplitude. They can draw transient negative pressures in a distribution system that last only for seconds and may not be observed by conventional pressure monitoring. Circumstances that produce these pressures waves may commonly occur in every water system. Because these waves travel through the distribution system, the transient negative pressure wave can momentarily draw water back into the pipe at any point where water is leaking out of the system. Depending on the size of the leaks, the volume of intrusion can range from one to hundreds of gallons (10,11). A negative pressure surge in a distribution system has been documented (12). A negative pressure surge wave was observed following a power outage that suddenly shut down a pumping station (Fig. 2). The rapid change in water velocity resulted in a negative pressure that lasted for approximately 22 seconds until static pressures were restored. Pressure transients can be caused by main breaks, sudden change in demand, uncontrolled pump starting or stopping, opening and closing of a fire hydrant, power failure, air valve slam, flushing operations, feed tank draining, and other conditions.

If pathogens are present at the exterior of the distribution pipelines, they may enter into the system due to hydraulic pressure gradients or during construction, repair, cross-connections, and conditions or activities where the system is open to the atmosphere or the environment. Karim et al. (12) reported the presence of microbial indicator and pathogens adjacent to distribution systems. Total coliform and fecal coliform bacteria were detected in water and soil samples adjacent to distribution systems in about half of the samples, indicating the presence of fecal contamination (Fig. 3). *Bacillus* was found in almost all the samples, which is not a surprise because it is a normal soil organism. Viruses were detected using culturable methods in 12% of the soil and water samples and by molecular methods in 19% of the soil samples and 47% of the water samples. When these data are combined, 56% of the samples were positive for viruses

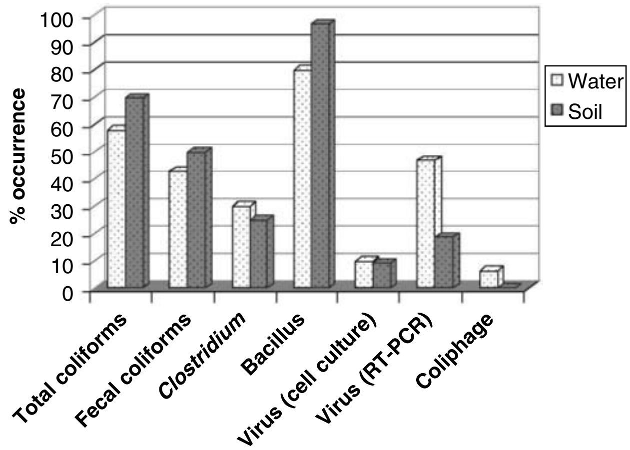

Figure 3. Occurrence of microorganisms in water and soil samples adjacent to distribution system pipelines.

either in the water or the soil. Sequence analysis showed that these viruses were predominantly enteroviruses (the vaccine strain of poliovirus), but Norwalk and hepatitis A viruses were also detected, providing clear evidence of human fecal contamination immediately exterior to the pipe. This data suggest that opportunities could exist for pathogens to intrude into the distribution system and emphasize the need to maintain an effective disinfectant residual in all parts of the distribution system (13).

MICROBIAL REGROWTH IN A DISTRIBUTION SYSTEM

Recent studies have examined data from more than 90 water systems to determine the factors that contribute to microbial growth in drinking water (14,15). These studies have shown that the occurrence of coliform bacteria can be related to the following factors: filtration, temperature, disinfectant type and residual, assimilable organic carbon (AOC) level, corrosion control, and pipe material selection.

Filtration

Four unfiltered surface water systems included in a study (14) accounted for 26.6% of the total number of bacterial samples collected but represented 64.3% (1013 of 1576) of the positive coliform samples. Although the results do not suggest that treatment was inadequate (e.g., coliforms were not related to breakthrough of treatment barriers), the data suggested that filtration may be an important factor in preventing coliform regrowth. Following the study, one of the systems installed filtration, and distribution system coliform levels were reduced by a factor of 3 during the following 18-month interval.

Temperature

Temperature is an important factor in microbial growth. On average, the occurrence of coliform bacteria was significantly higher when water temperatures were >15 °C. (14). However, the minimum temperature at which microbial activity was observed varied from system to system. Systems that typically experienced cold water had increases in coliform occurrences when water temperatures ranged near 10 °C. The strains of coliform bacteria in these systems may be better adapted to grow at lower temperatures (psychrophiles).

Disinfectant Residual and Disinfectant Level

Maintenance of a disinfectant residual throughout a distribution system is intended to produce conditions unfavorable for bacterial survival in drinking water. Choosing the appropriate disinfectant or improper application of disinfectant can affect bacterial growth conditions. For filtered systems, there was a difference between systems that maintained free chlorine residual and systems that used chloramines (14). For systems that used free chlorine, 0.97% of 33,196 samples contained coliform bacteria, whereas 0.51% of 35,159 samples from chloraminated systems contained coliform bacteria (statistically different at $p < .0001$). The average density of coliform bacteria was 35 times higher in free chlorinated systems compared to chloraminated water [0.60 colony forming units (cfu)/100 mL for free chlorinated water, compared to 0.017 cfu/100 mL for chloraminated water]. Previous research hypothesized that chloramines may be better able to penetrate into distribution system biofilms and inactivate attached bacteria (16,17).

In addition to the type of disinfectant used, the residual maintained at the end of the distribution system was also associated with coliform occurrences (14). Systems that maintained dead-end free chlorine levels <0.2 mg/L or monochloramine levels <0.5 mg/L had substantially more coliform occurrences than systems that maintained higher disinfectant residuals. However, systems that had high AOC levels needed to maintain high disinfectant residuals to control coliform occurrences. Therefore, maintenance of a disinfectant residual alone did not ensure that treated waters would be free of coliform bacteria.

AOC Level

The combined results from two surveys of AOC levels in North American drinking water systems are shown in (Fig. 4) (14,15). The levels (summarized as the geometric mean based on 12 to 36 samples) range from 20 to 214 µg/L. The results also indicate that the majority of the total AOC results from the growth of the test organism,

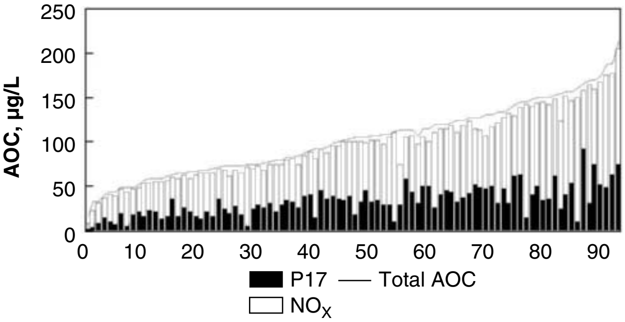

Figure 4. AOC levels in 94 North American water systems.

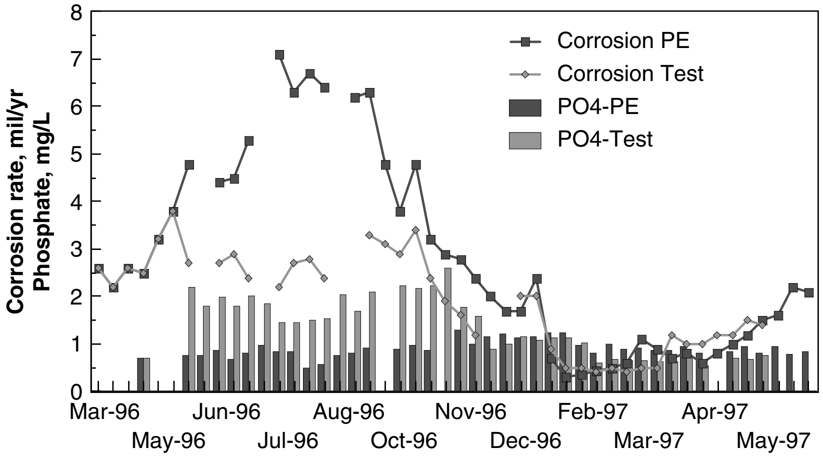

Figure 5. Increasing phosphate levels can reduce corrosion rates.

Spirillum sp., strain NOX. This $\mathrm{AOC}_{\mathrm{NOX}}$ fraction is influenced by disinfection practices (chlorine, ozone, etc.) and suggests that changes in these practices (i.e., the type of disinfectant, the point of application, dose) can impact AOC levels in finished drinking water.

High levels of AOC can stimulate bacterial growth in distribution system biofilms. On average, free chlorinated systems with AOC levels greater than 100 μg/L had 82% more coliform positive samples, and the coliform densities were 19 times higher than in free chlorinated systems that had average AOC levels less than 99 μg/L. However, high levels of AOC alone do not dictate the occurrence of coliform bacteria in drinking water; they are only one factor.

Corrosion Control and Pipe Materials

Most systems do not measure corrosion rates on a daily basis, so this parameter is difficult to evaluate on a full scale. However, recent research has demonstrated that corrosion of iron pipes can influence the effectiveness of chlorine-based disinfectants in inactivating biofilm bacteria (17,18). Therefore, the choice of pipe material and the accumulation of corrosion products can dramatically impact the ability to control the effects of biofilms in drinking water systems.

Figure 5 shows the average monthly corrosion rates [in mils (thousandths of an inch) per year] in a system in Illinois. The conventional plant effluent corrosion rate showed marked seasonal variations. Corrosion rates were highest during the summer months when, traditionally, coliform occurrences the highest. Similar seasonal variations have been observed in other systems (19). This variation in rates of corrosion is important because the corrosion products react with residual chlorine and prevent the biocide from penetrating the biofilm and controlling bacterial growth. Studies have shown that free chlorine is impacted to a greater extent than monochloramine, although the effectiveness of both disinfectants is impaired if corrosion rates are not controlled (17,18). Increasing the phosphate-based corrosion inhibitor dose, especially during the summer months, can help reduce corrosion rates. In full-scale studies, systems that used a phosphate-based corrosion inhibitor had lower coliform levels than systems that did not control corrosion (14).

CONCLUSION

Drinking water in a distribution system may contain microbes that enter the distribution system through treatment breakthrough, regrowth, or contamination of water in the system. The majority of these organisms are harmless. However, pathogenic organisms may also be present in drinking water. A number of waterborne disease outbreaks related to distribution systems have been reported. Factors that may contribute to distribution system contamination include cross-connections, inadequate separation of water mains and sewers, contamination of broken or leaking water main, contamination of mains during construction/repair, back-siphonage, contamination of distribution storage, and intrusion of contaminants due to pressure transients. Factors that may contribute to regrowth include filtration, temperature, disinfectant type and residual, assimilable organic carbon (AOC) level, corrosion control, and pipe material selection. To ensure the protection of public health, these factors should be adequately addressed to safeguard drinking water from contamination in a distribution system.

NITRIFICATION OF POTABLE WATER USING TRICKLING FILTERS

D.V. Vayenas
University of Ioannina
Agrinio, Greece

Gerasimos Lyberatos
University of Patras
Patras, Greece

INTRODUCTION

It is well established that nitrogen in the form of ammonia must be removed from wastewater before it is disposed of, as well as from potable water before it can be consumed. When ammonia is discharged to an aquatic environment, it leads to oxygen consumption (nitrogenous oxygen demand) that causes fish death. Furthermore, ammonia must be removed before water is disinfected with chlorine because ammonia reacts with chlorine and produces chloramines, which have been found to be carcinogenic (1,2).

Ammonia may be removed chemically or biologically. Nitrification, the key biological process for ammonia oxidation, is carried out by two different nitrifying bacteria (aerobic, autotrophs), *Nitrosomonas* and *Nitrobacter*. The overall reaction may be written as:

$$NH_4{}^+ + 2O_2 \rightarrow NO_3{}^- + H_2O + 2H^+ \tag{1}$$

According to this reaction, it takes 4.57 g of oxygen to oxidize 1 g of $NH4^+{-}N$. The two bacterial groups are each responsible for a single step in the oxidation of ammonia to nitrate, according to the following reaction scheme:

Nitrosomonas:

$$NH_4{}^+ + \frac{3}{2}O_2 \rightarrow NO_2{}^- + 2H^+ + H_2O \tag{2}$$

Nitrobacter:

$$NO_2{}^- + \frac{1}{2}O_2 \rightarrow NO_3{}^- \tag{3}$$

Nitrification is typically used for tertiary treatment of wastewater and for pretreatment of potable water. Nitrifying bacteria are characterized by low specific growth rates. Trickling filters provide a support medium for biofilm growth, thus allowing the possibility of maintaining nitrifying bacteria at high hydraulic loadings. Wastewater treatment using biofilms grown on support media was the first continuous flow bioprocess employed by sanitary engineers nearly a century ago. As the wastewater flows over the biological slime in a nitrifying trickling filter, ammonia as well as dissolved oxygen diffuse into the biofilm where they are metabolized by the bacteria. The essential processes are mass transport and bioconversion. Modern trickling filters often use plastic support media that attain better performance but at a substantially higher cost than filters based on rock. Nitrification of potable water is a relatively new process, and only limited information is available. Pozzuolana and Biolite filters have been used to nitrify potable water (3).

Trickling filter operation is based on the following principles: The organic material present in the wastewater is degraded by a population of microorganisms attached to the filter medium (Fig. 1). Organic material from the liquid is adsorbed onto the biological film or slime layer. In the outer portions of the biological slime layer (0.1 to 0.2 mm), the organic material is degraded by aerobic microorganisms. As the microorganisms grow, the thickness of the slime layer increases, and the diffused oxygen is consumed before it can penetrate the full depth of the slime layer. Thus, an anaerobic environment is established near the surface of the medium. As the slime layer increases in thickness, the adsorbed organic matter is metabolized before it can reach the microorganisms near the medium face. As a result of having no external organic source available for cell carbon, the microorganisms near the medium face enter into an endogenous phase of growth and lose their ability to cling to the medium surface. The liquid then washes the slime off the medium, and a new slime layer starts to grow (Fig. 1). This phenomenon of losing the slime layer is called “sloughing” and is primarily a function of the organic and hydraulic loading on the filter. In modern trickling filters, the hydraulic loading rate is adjusted to maintain a slime layer of uniform thickness (4).

THE EFFECT OF SUPPORT MATERIAL ON NITRIFYING TRICKLING FILTERS FOR POTABLE WATER TREATMENT

The advantages of trickling filters include low maintenance, inexpensive installation, and great tolerance of variations in hydraulic and organic loads. As mentioned earlier, the bacteria responsible for oxidizing ammonia to nitrate are autotrophic organisms that have very slow specific growth rates. Thus, their stabilization on a support material and the development of biofilm structures enables the permanent existence of these organisms in the filter and the possibility of maintaining nitrifying bacteria at high hydraulic loadings. The filter medium is of such great importance for the function of biofilters that several experiments have been carried out to study and compare different filter media types (5,6). The support materials used in trickling filters are either granulated or fixed media. Granulated media are small separate elements (rock, gravel, sand, and plastic elements); fixed media consist of larger constructions with connected areas. Several factors are important in the function of trickling filters, but the most important is selection of the appropriate filter medium. Among the selection criteria for filter media in trickling filters are void ratio, specific surface area, homogeneous water flow, and cost.

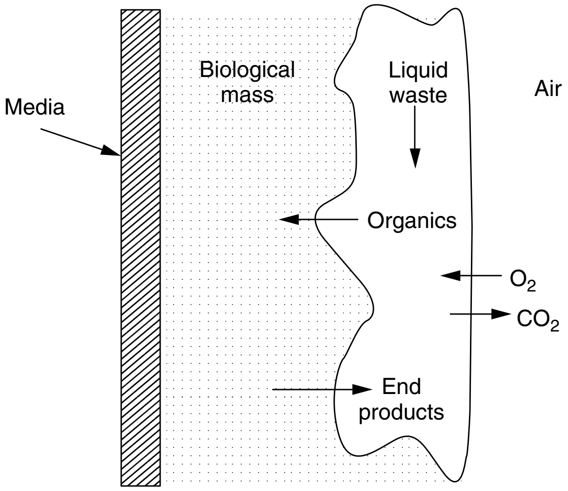

Figure 1. Schematic of the cross section of a biofilm in a trickling filter.

The use of plastic filter media drastically increases the installation cost of a nitrifying trickling filter. Plastic filter media are specially designed to provide high void space and high specific surface area. Thus, they are very attractive for wastewater treatment, where the high organic and ammonia load and the presence of suspended solids leads to the formation of very thick biofilm structures (150–2000 μm) (7, 8). To reduce the cost of the process in this case, we can use large diameter gravel instead of plastic media, resulting in low specific surface area and consequently huge constructions.

For potable water, the ammonia load is rather low (usually 0.5–2 mg/L) almost without any organic load and with a very low concentration of suspended solids. As a result, the biofilm remains very thin (50–200 μm) (9), and the use of small gravel becomes feasible thus resulting in higher specific surface areas and very compact constructions; the use of small gravel enables more area for biofilm growth per volume unit in a trickling filter. Hence, the use of small-sized gravel is very attractive due to the minimal cost of this material and its availability. On the other hand, small-sized gravel leads to small void ratios and all the problems mentioned before.

Quartz sand was the first material used for filtration and is still the basic material in many existing filters. Sand may be combined with anthracite, garnet, and schists of varying porosity, provided that these materials have low friability and low loss in acid (3). Gravels consist mainly of calcitic and silicic salts. For trickling filters, and sand filters, the use of silicic materials is the most common.

INFLUENCE OF RECIRCULATION ON THE EFFICIENCY OF A NITRIFYING TRICKLING FILTER FOR POTABLE WATER TREATMENT

Recirculation in biological filter process is usually considered to reduce nutrient loading on the filter, increase the wettability of the filter, and result in a more even bioconversion along the filter depth. Vayenas and Lyberatos (10) studied the influence of recirculation on the efficiency of a pilot-scale nitrifying trickling filter for potable water treatment. This filter exhibited excellent performance for the ammonia concentrations usually encountered in potable water even for high values of hydraulic loading (9). The pilot-scale filter has, of course, limitations on ammonia and hydraulic loading. For high hydraulic loading (680 m^3/m^2 d), the filter floods; for high ammonia concentration (above 5 mg/L), pore clogging due to bacterial mass becomes a serious problem and the filter requires frequent backwashing.

Experimental results and model predictions showed that for low hydraulic loading (110 m^3/m^2 d), recirculation leads to lower filter efficiency even for high inlet ammonia concentrations. For intermediate hydraulic loading (225 m^3/m^2 d) and for low inlet ammonia concentrations (2 mg/L), recirculation leads to inferior performance, whereas for high inlet ammonia concentration (15 mg/L), the filter performance is improved and the recycle ratio increases. Finally, for high hydraulic loading (450 m^3/m^2 d), recirculation improves the filter efficiency for any values of ammonia concentration and recycle ratio. The higher the recycle ratio, the better the filter performance.

These results are expected because essentially complete conversion is obtained for low loadings. Recirculation evens out ammonia concentrations along the filter depth and leads to higher effluent concentrations. For high loadings, lower overall conversions are expected in the absence of recirculation. In these instances, recirculation leads to better exploitation of the total filter depth. In conclusion, recirculation can improve the efficiency of the filter only for high or intermediate values of hydraulic loading and high ammonia concentrations.

IRON AND MANGANESE INHIBITION OF BIOLOGICAL AMMONIA REMOVAL FROM POTABLE WATER

Water sources that contain ammonia often may also contain iron and manganese. Ammonia, iron, and manganese may be removed chemically or biologically from a water supply. Biological removal of these pollutants is preferable because there is no need to add extra chemicals and the volume of the sludge generated is appreciably smaller and hence easier to handle (3). The simultaneous biological removal of the three elements is very difficult mainly due to the different redox potential values needed to oxidize them. Gouzinis et al. (11) studied the simultaneous removal of ammonia, iron, and manganese from potable water using a pilot-scale trickling filter and the influences these pollutants have on filter performance and efficiency. They concluded that iron has a strong negative effect on ammonia removal whereas ammonia has very low impact on iron removal. They also concluded that for low ammonia concentrations (1 mg/L), the presence of manganese does affect ammonia removal. The influence of manganese becomes sensible at an ammonia concentration of 2 mg/L; at higher ammonia concentrations, manganese strongly affects ammonia removal. The main conclusion of that work was that iron should be removed before ammonia and manganese oxidation. For low iron concentrations, oxidation by extended aeration can reduce iron, and subsequent biological ammonia and manganese removal can be carried out without any problems. For higher iron concentrations, an initial biological iron oxidation stage should be necessary.

MODELING AND DESIGN OF NITRIFYING TRICKLING FILTERS FOR POTABLE WATER TREATMENT

The design of trickling filters is much more difficult than design for homogeneous processes (e.g., activated sludge process) because design engineers must take extra care with respect to the attachment of microorganisms to the surface of the filter medium, the filter medium's influence on the process, nutrient and oxygen transport from the air and the liquid phase through the biofilm structure, biomass detachment, pore clogging and filter flooding, and filter backwash.

The design of biological trickling filters was initially based on empirical or semiempirical models. For many years, design engineers had limited success in applying fairly simple design equations to modeling trickling filter performance. The first approaches were based on NRC equations (12), Eckenfelder's equation (13), or Atkinson's model (14). Later, detailed mathematical steady-state models for describing the biofilm processes were proposed by Vaughan and Holder (15), Benefield and Molz (16), Logan et al. (17) and Gujer and Boller (18). These models were more accurate and offered a better understanding of the mechanisms of biofilm development, but there was still uncertainty in the model parameter values.

Vayenas and Lyberatos (9) developed a simple steady-state model for ammonia removal from potable water that predicts the ammonia concentration profile and the mean biofilm thickness profile along the filter depth. The model considers that the filter may be divided into a number of equal size compartments, for each of which homogeneous conditions may be assumed. The model also considers a somewhat different mechanism for biofilm development because ammonia concentrations in potable water are usually low and sloughing is not so intense as in wastewater treatment. It is worth noting that the model includes analytical recursive equations concerning ammonia concentration and predicts filter performance very well for all operating conditions that were tested. Figure 2 presents a typical ammonia concentration profile along the filter depth and the corresponding model predictions.

The dynamics of nitrifying trickling filters can be divided into fast and slow modes. Slow modes are caused by the growth and decay of the organisms

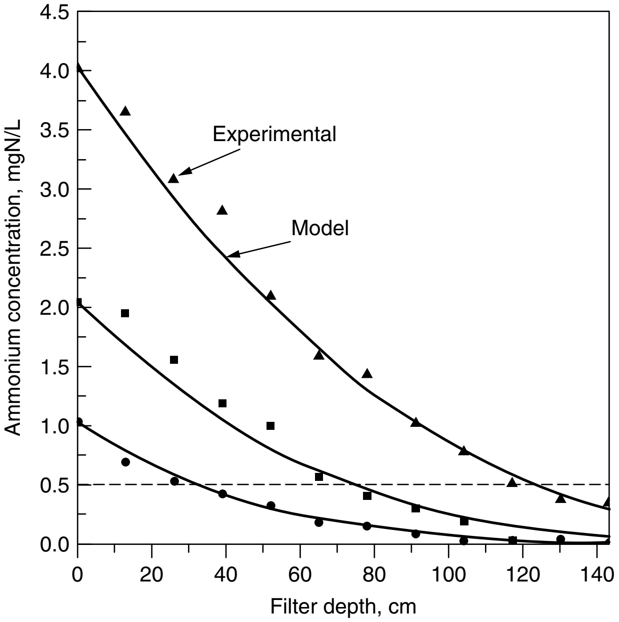

Figure 2. Experimental data and model predictions based on the model of Vayenas and Lyberatos (9) for an ammonia concentration profile in a pilot-scale nitrifying trickling filter for potable water treatment (hydraulic loading 225 m^3/m^2 d) (19).

in the biofilm; fast modes are caused mainly by the hydraulics and mass transfer resistances in the biofilm (20,21). The fast dynamics of nitrifying trickling filters for tertiary wastewater has been described by Kissel et al. (22), Wanner and Gujer (23), and Wik (20,21), and experimental evidence has been presented by Wik (20,21).

Vayenas et al. (24) developed a dynamic model to describe nitritification and nitratification in trickling filters. Their results showed that after an organic or hydraulic loading shock, nitrifying trickling filters reach a new steady state for ammonia-, nitrite-, and nitrate nitrogen concentrations in only a few minutes, whereas biofilm thickness requires a very long time to reach steady state (Fig. 3).

Additionally, Vayenas et al. (24) predicted the biofilm thickness and concentration profiles of ammonia, nitrite, and nitrate inside the biofilm structure (Fig. 4).

Recently, Tekerlekopoulou and Vayenas (25), using the steady-state version of the dynamic model of Vayenas et al. (24), constructed the operating diagram of a nitrifying trickling filter, thus defining the operating conditions for complete and safe nitrification (Fig. 5).

Figure 5 contains the three critical lines of 0.5, 0.1, and 10 mg/L for ammonia-, nitrite-, and nitrate-nitrogen (26). The diagram in (Fig. 5) is the operating diagram of the system and shows the effect of inlet ammonia concentration and hydraulic load on ammonia-, nitrite- and nitrate-nitrogen concentrations. The operating diagram is particularly useful when one wants to compare experimental observations made in a bioreactor with the predictions of a mathematical model describing the system. In the various regions of the operating diagram, different behaviors of the system are observed. In the diagram shown in (Fig. 5), there are six regions in each of which one or more of the ammonia-, nitrite-, and nitrate-nitrogen concentrations is below the maximum permitted limit, as shown below:

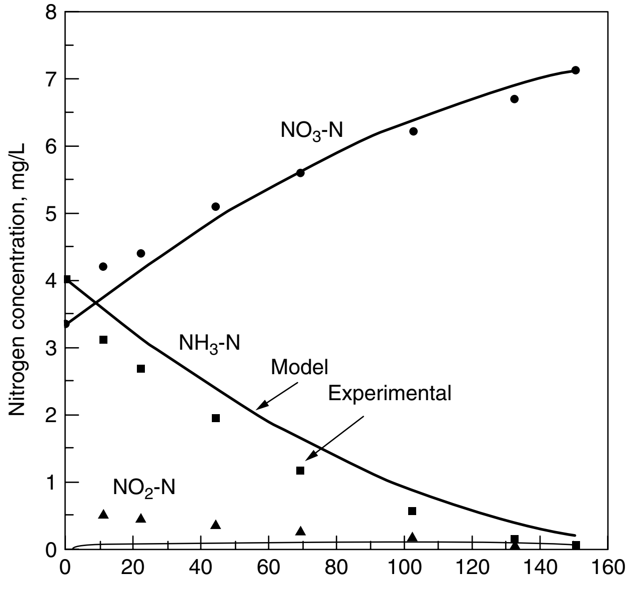

Figure 3. Predicted and experimental concentration profiles of ammonia-, nitrite- and nitrate-nitrogen (hydraulic loading: 225 m^3/m^2 d; feed concentrations: $NH_3 - N = 4$ mg/L, $NO_2 - N = 0$ mg/L, and $NO_3 - N = 3.36$ mg/L) (24).

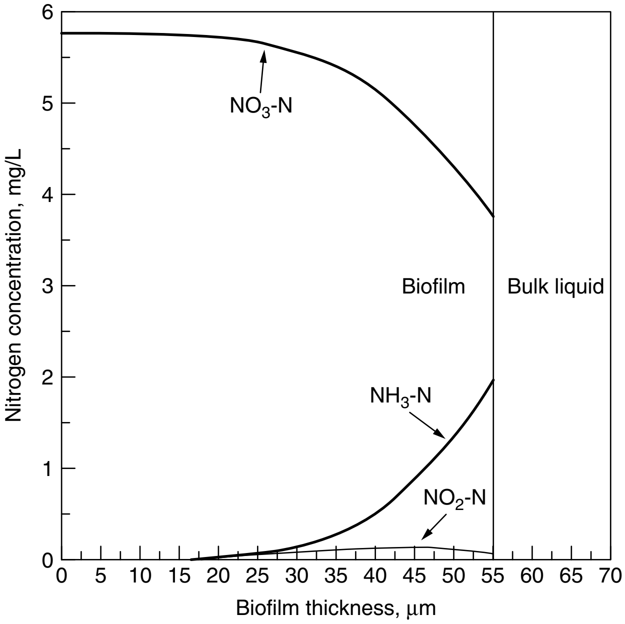

Figure 4. Ammonia-, nitrite-, and nitrate nitrogen concentration profiles along the biofilm thickness near the top of the filter (hydraulic loading: 225 m^3/m^2 d: feed concentrations: $NH_3 - N = 3$ mg/L, $NO_2 - N = 0$ mg/L, and $NO_3 - N = 3.36$ mg/L) (24).

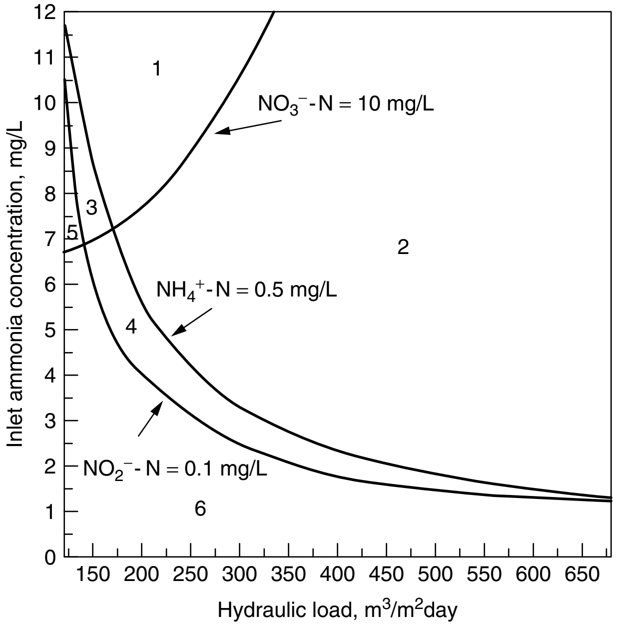

Figure 5. Operating diagram of a pilot-scale nitrifying trickling filter (25).

Region 1. All outlet concentrations are above the maximum permitted limits
Region 2. Outlet $NO^{-}{}_3$-N concentration below the maximum permitted limit
Region 3. Outlet $NH^{+}{}_4$-N concentration below the maximum permitted limit
Region 4. Outlet $NH^{+}{}_4$-N and $NO^{-}{}_3$-N below the maximum permitted limits
Region 5. Outlet $NH^{+}{}_4$-N and $NO^{-}{}_2$-N below the maximum permitted limits
Region 6. All outlet concentrations are below the maximum permitted limits

According to (Fig. 5), to achieve complete nitrification, one should combine the operating conditions so that the system would always remain in Region 6. The operating diagram of the system provides an overview of the process limitations where the areas of safe/complete nitrification operation are defined. According to the operating diagram, complete nitrification at low flow rates can be achieved even for ammonia feed concentrations up to about 6.5 mg/L, whereas at high flow rates, complete nitrification is possible only for ammonia feed concentrations up to about 2 mg/L.

ORGANIC REMOVAL

National Drinking Water
Clearinghouse

Some small drinking water systems face contamination of raw water by natural or synthetic organic chemicals (SOCs). Natural organic materials might be present in water supplies, especially from surface water sources. Dissolved organics may cause taste, odor, or color problems in a community's drinking water, resulting in consumer complaints. Sources of SOCs include leaking underground gasoline/storage tanks, agricultural runoff containing herbicides or pesticides, solid waste or hazardous waste landfills, and improperly disposed chemical waste. The technologies most suitable for organic contaminant removal in drinking water systems are granular activated carbon (GAC) and aeration.

GAC has been designated by the U.S. Environmental Protection Agency (EPA) as the best available technology (BAT) for synthetic organic chemical removal. Various kinds of GAC are available for removing organics from drinking water. The most frequently used carbon in U.S. treatment plants is coal-based carbon because of its hardness, adsorption capacity, and availability. Some peat and lignite carbons have been used also.

Aeration systems that might be suitable for small drinking water systems include packed column aeration, diffused aeration, and multiple-tray aeration. Recent technologies that use aeration for organics removal include mechanical aeration, catenary grid, and Higee aeration.

Table 1 presents operational conditions for the organics treatment technologies most suitable for small systems.

SOME TECHNOLOGIES FOR ORGANIC REMOVAL IN SMALL SYSTEMS:

A. Activated Carbon

Description. Activated carbon is carbon that has been exposed to very high temperatures, creating a vast network of internal pores.

Two types of activated carbon, granular and powdered, have been used widely in drinking water treatment. Powdered activated carbon (PAC), which is most often used for taste and odor control, is added directly to the raw water and removed by settling in sedimentation basins.

GAC removes many organic contaminants as well as taste and odor from water supplies.

Performance/Advantages. Organics that are readily adsorbed by activated carbon include:

- aromatic solvents (benzene, toluene, nitrobenzenes);
- chlorinated aromatics (PCBs, chlorobenzenes, chloroaphthalene);
- phenol and chlorophenols;
- polynuclear aromatics (acenaphthene, benzopyrenes);
- pesticides and herbicides (DDT, aldrin, chlordane, heptachlor);
- chlorinated aliphatics (carbon tetrachloride, chloroalkyl ethers); and
- high molecular weight hydrocarbons (dyes, gasoline, amines, humics).

Table 1. Organic Treatment Technologies Suitable for Small Systems

Technology	Level of Operational Skill Required	Level of Maintenance Required	Energy Requirements
Granular Activated Carbon (GAC)	Medium	Low	Low
Packed Column Aeration (PCA)	Low	Low	Varies
Diffused Aeration	Low	Low	Varies
Multiple-Tray Aeration	Low	Low	Low
Mechanical Aeration	Low	Low	Low
Catenary Grid	Low	Low	High
Higee Aeration	Low	Medium	High

Source: U.S. Environmental Protection Agency, 1989.

Limitations. Organics that are poorly adsorbed by activated carbon include:

- alcohols;
- low molecular weight ketones, acids, and aldehydes;
- sugars and starches;
- very high molecular weight or colloidal organics; and
- low molecular weight aliphatics.

GAC is not effective in removing vinyl chloride from water. In addition, because of the long empty bed contact time (EBCT) required, radon removal at the treatment plant scale is not feasible. However, at the residential scale, GAC systems are cost-effective for radon removal.

Several operational and maintenance factors affect the performance of GAC. Contaminants in the water can occupy GAC adsorption sites, whether they are targeted for removal or not. Also, adsorbed contaminants can be replaced by other contaminants with which GAC has a greater affinity. Therefore, the presence of other contaminants might interfere with the removal of the contaminants of concern.

A significant drop in the contaminant level in influent water will cause a GAC filter to desorb, or slough off, adsorbed contaminants because GAC is an equilibrium process. As a result, raw water with frequently changing contaminant levels can result in treated water of unpredictable quality.

Bacterial growth on the carbon is another potential problem. Excessive bacterial growth may cause clogging and higher bacterial counts in the treated water. Bacterial levels in the treated water must be closely monitored, and the final disinfection process must be carefully controlled.

Process. Activated carbon removes contaminants through adsorption, primarily a physical process in which dissolved contaminants adhere to the porous surface of the carbon particles. The adsorption process can be reversed relatively easily. The ease of reversing adsorption is another key factor in activated carbon's usefulness because it facilitates the recycling or reuse of the carbon.

GAC can be used as a replacement for existing media (such as sand) in a conventional filter, or it can be used in a separate contactor (a vertical steel pressure vessel used to hold the activated carbon bed).

GAC contactors require monitoring to ensure that they work effectively. A GAC monitoring system should include:

- laboratory analysis of treated water to ensure that the system is removing organic contaminants,
- monitoring of headloss (the amount of energy used by water in moving from one point to another) through the contactors to ensure that backflushing (reversing

the flow to remove trapped material) is performed at appropriate times,

- bacteria monitoring of the contactor's effluent (since bacteria can grow rapidly within the activated carbon bed),
- turbidity monitoring of the contactor's effluent (to determine if suspended material is passing through GAC bed).

After a period of months or years, depending on the concentration of contaminants, the surface of the pores in the GAC can no longer adsorb contaminants. The carbon must then be replaced. The GAC vendor will be able to provide guidance concerning when to replace the GAC. Disposing of carbon with contaminants that are classified as hazardous wastes will dramatically increase disposal costs.

Equipment/Design. The typical GAC unit can be similar in design to either gravity or pressure filters. In some communities, the sand in existing filters has been either partially or completely replaced with GAC. Media depth of up to 10 feet is needed to ensure adequate removal of potentially harmful organic contaminants. Activated carbon filters can be designed to treat hydraulic loadings of 2 to 10 gallons per minute per square foot (gpm/ft^2). Sufficient detention time in the filter must be provided to achieve the desired level of the organic contaminant removal. The detention time is determined by the volume of the GAC filter divided by the flow rate. This is referred to as the EBCT since the volume of carbon in the bed is not considered. For adequate removal of most organic contaminants to occur, the EBCT should be about 10 minutes. EBCTs less than 7.5 minutes are generally ineffective.

GAC is available in different grades of effectiveness. Low-cost carbon requires a lower initial capital outlay but must be replaced more often, resulting in higher operating costs.

B. Aeration

Description. Aeration, also known as air stripping, mixes air with water to volatilize contaminants (turn them to vapor). The volatilized contaminants are either released directly to the atmosphere or treated and released. Aeration is used to remove volatile organic chemicals and can also remove radon.

Equipment. A small system might be able to use a simple aerator constructed from relatively common materials instead of a specially designed aerator system. Examples of simple aerators include:

- a system that cascades the water or passes it through a slotted container,
- a system that runs water over a corrugated surface, or
- an airlift pump that introduces oxygen as water is drawn from a well.

Other Aeration Types

Packed Column Aeration. Packed column aeration (PCA) or packed tower aeration (PTA) is a waterfall aeration process that drops water over a medium within a tower to mix the water with air. The medium is designed to break the water into tiny droplets and to maximize its contact with tiny air bubbles for removal of the contaminant. Air is also blown in from underneath the medium to enhance this process (see Fig. 1).

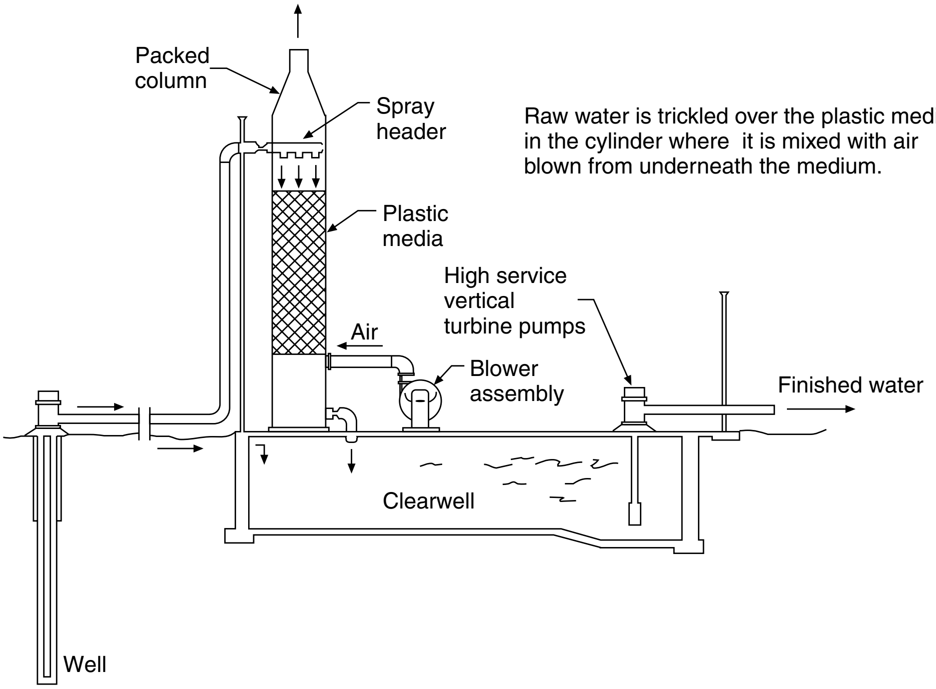

Figure 1. Packed tower aeration system.

Systems using PCA may need pretreatment to remove iron, solids, and biological growth to prevent clogging of the packing material. Post treatment such as the use of a corrosion inhibitor, may also be needed to reduce corrosive properties in water due to increased dissolved oxygen from the aeration process.

Packed columns usually operate automatically and need only daily visits to ensure that the equipment is running satisfactorily. Maintenance requirements include servicing pump and blower motors and replacing air filters on the blower, if necessary.

PCA exhaust gas may require treatment to meet air emissions regulations, which can significantly increase the costs of this technology.

Diffused Aeration. In a diffused aeration system, a diffuser bubbles air through a contact chamber for aeration. The diffuser is usually located near the bottom of the chamber. The air introduced through the diffuser, usually under pressure, produces fine bubbles that create water-air mixing turbulence as they rise through the chamber.

The main advantage of diffused aeration systems is that they can be created from existing structures, such as storage tanks. However, they are less effective than packed column aeration, and usually are employed only in systems with adaptable existing structures.

Multiple Tray Aeration. Multiple tray aeration directs water through a series of trays made of slats, perforations, or wire mesh. A blower introduces air from underneath the trays.

Multiple tray aeration units have less surface area than PCA units. This type of aeration is not as effective as PCA and can experience clogging from iron and manganese, biological growth, and corrosion problems.

Multiple tray aeration units are readily available from package plant manufacturers.

Mechanical Aeration. Mechanical aeration uses mechanical stirring mechanisms to mix air with the water. These systems can effectively remove volatile organic chemicals (VOCs).

Mechanical aeration units need large amounts of space because they demand long detention times for effective treatment. As a result, they often require open-air designs, which can freeze in cold climates. These units also can have high energy requirements. However, mechanical aeration systems are easy to operate and are less susceptible to clogging from biological growth than PCA systems.

Catenary Grid. Catenary grid systems are a variation of the packed column aeration process. The catenary grid directs water through a series of wire screens mounted within the column. The screens mix the air and water in the same way as packing materials in PCA systems.

These systems can effectively remove VOCs. They have higher energy requirements than PCA systems, but their more compact design lowers their capital cost relative to PCA.

Higee Aeration. Higee aeration is another variation of the PCA process. These systems pump water into the center of a spinning disc of packing material, where the water mixes with air.

Higee units require less packing material than PCA units to achieve the same removal efficiencies. Because of their compact size, they can be used in limited spaces and heights. Current Higee systems are best suited for a temporary application of less than 1 year with capacities up to 380 liters (100 gallons) per minute.

WHERE CAN I FIND MORE INFORMATION?

Information in this fact sheet was primarily obtained from three documents:

- *Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities*. EPA/625/4-89/023;
- *Small Community Water and Wastewater Treatment*, EPA/625/R-92/010; *and*
- *Environmental Pollution Control Alternatives: Drinking Water Treatment for Small Communities*, EPA/625/5-90/025.

All publications can be ordered free from the U.S. Environmental Protection Agency Office of Research and Development at (513) 569-7562.

The NDWC offers these documents as well, but at a cost to help recover photocopying and other expenses. *Technologies for Upgrading Existing or Designing New Drinking Water Treatment Facilities*, item #DWBKDM04, a 209-page book, costs $30.05. *Small Community Water and Wastewater Treatment*, item #DWBKRE03, a 95-page book, costs $ 13.65. The third book, *Environmental Pollution Control Alternatives: Drinking Water Treatment for Small Communities*, item #DWBKGN09, an 82-page publication, costs $11.82. Shipping and handling charges apply.

Also, the NDWC's Registry of Equipment Suppliers of Treatment Technologies for Small Systems (RESULTS) is a public reference database that contains information about technologies in use at small water systems around the country. For further information on accessing or ordering RESULTS, call the NDWC at (800) 624-8301 or (304) 293-4191.

OZONE

National Drinking Water
Clearinghouse

New water treatment goals for disinfection byproducts (DBP) and for microbial inactivation will increase the need to consider new disinfection technologies. Ozone is an attractive alternative. This technology has evolved and improved in recent years, thereby increasing its potential for successful application. It is important to note that ozone, like other technologies, has its own set of advantages and disadvantages that show up in differing degrees from one location to the next

WHAT IS OZONE?

Ozone is a colorless gas that has an odor most often described as the smell of air after a spring electrical thunderstorm. Some people also refer to the odor as similar to the smell of watermelons. Ozone (O_3) is an extremely unstable gas. Consequently, it must be manufactured and used onsite. It is the strongest oxidant of the common oxidizing agents. Ozone is manufactured by passing air or oxygen through two electrodes with high, alternating potential difference.

WHAT REGULATIONS GOVERN OZONE?

In the next century, small water systems will need to use disinfection methods that are effective for killing pathogens without forming excessive DBP. Disinfection byproduct compliance is more likely to be a problem for small water systems treating surface water than for those treating groundwater because surface water sources tend to contain more natural organic matter that forms byproducts when mixed with disinfectants. In August 1997, the U.S. Environmental Protection Agency (EPA) listed ozone as a “compliance” in the requirements of the Surface Water Treatment Rule for all three sizes of small drinking water systems.

ADVANTAGES

Using ozone to treat water has many advantages, including the following:

- Possesses strong oxidizing power and requires short reaction time, which enables the germs, including viruses, to be killed within a few seconds;
- Produces no taste or odor;
- Provides oxygen to the water after disinfecting;
- Requires no chemicals;
- Oxidizes iron and manganese;
- Destroys and removes algae;
- Reacts with and removes all organic matter;
- Decays rapidly in water, avoiding any undesir able residual effects;
- Removes color, taste, and odor; and
- Aids coagulation.

LIMITATIONS

The use of ozone to treat water has some limitations:

- Toxic (toxicity is proportional to concentration and exposure time);
- Cost of ozonation is high compared with chlorination;
- Installation can be complicated;
- Ozone-destroying device is needed at the exhaust of the ozone-reactor to prevent toxicity and fire hazards;
- May produce undesirable aldehydes and ketones by reacting with certain organics;
- No residual effect is present in the distribution system, thus postchlorination is required;
- Much less soluble in water than chlorine; thus special mixing devices are necessary; and
- It will not oxidize some refractory organics or will oxidize too slowly to be of practical significance.

DISINFECTION

Design of an ozone system as primary treatment should be based on simple criteria, including ozone contact concentrations, competing ozone demands, and a minimum contact time (CT) to meet the required cyst and viral inactivation requirements, in combination with EPA recommendations.

Systems that need to provide CT to comply with the Ground Water Disinfection Rule, but are also having problems with DBP or maintaining distribution system residuals, should consider using ozone as the primary disinfectant and then chloramines for distribution system protection.

Ozone has been observed to be capable of disinfecting *Cryptosporidium*, and there is significant interest in this aspect of its application. Available data indicate that a significant increase in ozone dose and CT may be required as compared with past practices. Therefore, these needs should be considered in planning.

Iron and Manganese Removal

The standard oxidation-reduction potential and reaction rate of ozone is such that it can readily oxidize iron and manganese in groundwater and in water with low organic content. Groundwater systems that have iron levels above 0.1 milligrams per liter (mg/L) may have iron complaints if ozonation or chlorination is added.

Excessive doses of ozone will lead to the formation of permanganate, which gives water a pinkish color. This soluble form of manganese (Mn) corresponds to a theoretical stoichiometry of 2.20 mg O_3/mg Mn. Stoichiometry is the determination of the proportions in which chemical elements combine or are produced and the weight relation in a chemical reaction.

Color Abatement

Because humic substances are the primary cause of color in natural waters, it is useful to review the reactions of ozone with humic and fulvic acids. According to different authors, ozone doses of 1 to 3 mg O_3/mg C lead to almost complete color removal. The ozone dosages to be applied in order to reach treatment goals for color can be very high. It is interesting to note that when the ozone dosage is sufficient, the organic structure is modified such that the final chlorine demand can decrease.

Control of Taste and Odor

The National Secondary Drinking Water Regulations recommend that the threshold odors number (TON) be 3 or less in finished water. It has been shown that ozone can be effective in treating water for taste and odor problems, especially when the water is relatively free from radical scavengers.

It has also been observed that ozone, in combination with other downstream treatment processes, especially granular activated carbon (GAC) filtration, can greatly increase taste and odor treatment efficiency and reliability. Again, the cause of taste and odor compounds, as well as the source water to be treated, need to be carefully considered prior to designing a treatment system. Analysis and possibly pilot-scale experimentation may be required to determine the optimum choice of ozone and downstream treatment.

Elimination of Synthetic Organic Chemicals

Ozone or advanced ozonation processes can remove many synthetic organic chemicals (SOC). This removal leads to the chemical transformation of these molecules into toxic or nontoxic byproducts. Such transformation can theoretically lead to complete oxidation into carbon dioxide (CO_2); however, this is rarely the case in water treatment. Any observable reduction in total organic carbon (TOC) is due either to a small degree of CO_2 formation (for example, decarboxylation of amino acids) or the formation and loss of volatile compounds through stripping.

Effects on Coagulation

It is important to understand that the coagulating effects of ozone go beyond any direct oxidative effects on organic macro-pollutants. For this reason, one must be wary of studies claiming improved removal of organic matter when the data are based solely on color removal or ultraviolet (UV) absorbtion. Also, when studying the removal of DBP (for example, trihalomethanes), one must be careful to incorporate controls permitting the separate evaluation of ozone's direct effects. Finally, the coagulating effects of ozone may not be observed with all water. Whenever considering the use of ozone as a coagulant aid, the pre-ozonation effects should be critically evaluated in pilot studies incorporating the proper controls.

Algae Removal

Ozone, like any other oxidant, such as chlorine or chlorine dioxide, has a lethal effect on some algae or limits its growth. Ozone is also capable of inactivating certain zooplankton, e.g., mobile organisms, *Notholca caudata.* Such organisms must first be inactivated before they are removed by flocculation and filtration.

Byproducts

The alternative use of ozonation has generated much interest because of its ability to avoid the formation of halogenated organics inherent in the practice of chlorine treatment. However, raw water quality significantly affects ozonation results and could lead to the formation of other undesirable byproducts. Brominated byproducts are a major concern in source waters containing bromide. Ozonation produces its own byproducts, such as aldehydes, ketones, and carboxylic acids.Assuming equivalent disinfection, benefit is achieved as long as the health concerns for the new products are less than those for the chlorine byproducts.

Personnel Requirements

Personnel time requirements for system cleaning may be fairly substantial. However, recent advancements in ozonation technology include use of high purity oxygen feed systems, rather than ambient air-feed systems. Ozonation treatment is therefore said to run cleaner and require less cleaning-related maintenance than had the earlier versions of this technology.

No Residual

Ozone will not provide a disinfecting residual that protects finished water in the distribution system. Therefore, the role of chlorine as a disinfecting agent is not entirely replaced, and its use in either the free chlorine or chloramine form will be required for this purpose in many locations.

Process and Equipment

The basic elements of an ozone system include ozone generation, feed gas preparation, ozone contacting, and ozone off-gas destruction components. While many of these components can involve a high degree of sophistication in large facilities, less complex alternatives are available for smaller systems. Figure 1 (see below) shows the five basic components of an ozonation system. To insure effectiveness and safety simultaneously, all components must be taken into account when designing/installing an ozone system. Central to the ozonation system is the ozone generator itself, which in turn is connected to an appropriate power supply. Instrumentation and controls for ensuring the effective and safe operation of the total system may be added to the five-component system shown in (Fig. 1).

Feed Gas Preparation

The feed gas preparation component is critical, as a high-quality gas stream is required for the generator to

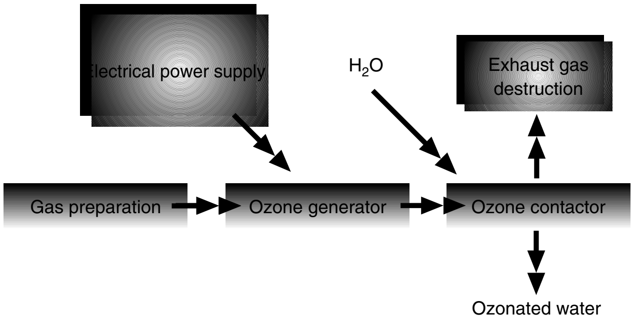

Figure 1. Basic components of an ozonation system. *Source*: "Ozone Treatment of Small Water Systems" 1999.

perform properly. This requires a gas stream that is low in moisture and particles. In older air-feed systems, the feed gas preparation systems for small systems tended to rely on high-pressure compressors that produce a pressurized feed stream, which is easier to dry and can accom- modate simpler, less maintenance-intensive drying devices than were typically applied in larger systems where lower-pressure compressors are typically used.

Alternatives for application of oxygen-rich feed gas streams have also emerged for small system applications in recent years. These include purchasing liquid oxygen and using small package oxygen-generation systems that are based on pressure swing adsorption. The use of these oxygen-enriched feed streams allows improved electrical efficiency in ozone generation and yields a product stream with a higher ozone content.

Ozone Contactors

Since ozone is only partially soluble in water, once it has been generated it must contact water to be treated. Many types of ozone contactors have been developed for this purpose.

Ozone contacting for disinfection has typically been accomplished in deep, multistage contactors that employ fine bubble diffusers. Newer alternatives have emerged that provide an option for small systems through the use of side-stream injection technologies that eliminate the need for fine bubble injection. Package units are available that include a gas separator that fuses and eliminates excess gas that results from ozone addition and a venturi jet that is used to inject and blend the ozone with a solution feed stream. These systems allow the alternative of injecting ozone into an enclosed vessel or a pipe. Note that materials need to be compatible with ozone. One possibility in this regard is the use of stainless steel. Several other contacting configurations, including turbine mixers, have been developed and may provide benefits as well.

Exhaust Gas Destruction

Ozone off-gas destruction is the final major component in the ozonation process. This system is required to remove ozone from spent off-gas streams, which are collected and treated prior to discharge into the atmosphere. Both catalytic and thermal destruction devices are used for this purpose or by passage through GAC.

How Safe is Ozone?

EPA notes that ozonation technology requires careful monitoring for ozone leaks, which pose a hazard in the work place. As with any other chemical, the Occupational Health and Safety Administration (OSHA) has established maximum contaminant inhalation guidelines for ozone in the work place. Ozone concentration of 0.1 part per million inhaled during an eight hour work period in a work area is the maximum limit set by OSHA regulations.

OZONE WITH ACTIVATED CARBON FOR DRINKING WATER TREATMENT

Rasheed Ahmad
Khafra Engineering Consultants
Atlanta, Georgia

The removal of organic compounds by adsorption on activated carbon is very important in water purification. Removal of organic compounds from the drinking water supply results in reduction in taste and odor and in DBP precursors and removal of volatile organic compounds (VOCs) and synthetic organic compounds (SOCs). Activated carbon supports a higher rate of biodegradation than sand or nonactivated carbon. The advantages of activated carbon include (1) enrichment of oxygen by sorption, (2) enrichment of the substrate in a biofilm, and (3) extended adsorption resulting from bioregeneration and development of a biofilm that can degrade less biodegradable but adsorbable organics.

In recent years, there has been a lot of emphasis on finding alternative disinfectants to free chlorine because of the carcinogenic nature of the halogenated disinfection byproducts (DBPs). Ozone has come up as an alternative disinfectant because of its distinct beneficial effects in water purification. However, ozonation raises two design issues. First, ozone produces byproducts that may eventually be regulated by environmental agencies; these include aldehydes, organic acids, and peroxides. Second, ozone increases the biodegradability of natural organic matter (NOM), which can lead to bacterial regrowth in distribution systems. The engineering solution to both problems has been to recommend that ozonation precede filtration. In this way, the filter can be used to promote biodegradation of NOM and ozonation byproducts; the process has been referred to as biological filtration. The filter could be either an adsorbing medium, the most common of which is granular-activated carbon (GAC), or a nonadsorbing medium, typically a combination of anthracite and sand. If activated carbon is used, the interaction between adsorption and biodegradation becomes important. Activated carbon removes contaminants by adsorption, whereas a microbial population removes biodegradable components. It is observed frequently that adsorbability is affected negatively by ozonation but positively by biodegradation.

Activated carbon coupled with an ozone pretreatment can be used in a treatment process either in a filter–adsorber or postfilter–adsorber configuration. Filter-adsorbers basically integrate filtration and adsorption processes into a single process. In other words, a filter–adsorber is a dual medium filter in which the top layer is GAC and the bottom layer is sand. Postfilter-adsorbers are simply granular-activated carbon columns that are employed after a conventional filtration process. Both filter–adsorbers and postfilter–adsorbers become biologically active when ozone precedes the treatment process. An ozone-activated carbon filtration system (e.g., a filter-adsorber) will enable removal of turbidity, organics, pesticides, and organic micropollutants. It will be biologically stable and can help in preventing bacterial regrowth in distribution systems. Postfilter–adsorbers normally do not remove turbidity because they are designed for organics removal.

OZONE–BROMIDE INTERACTIONS

M. Siddiqui
University of Utah
Salt Lake City, Utah

As utilities consider changing their primary disinfection practices from free chlorine to ozone to provide pathogen control while minimizing chlorinated disinfection by-product (DBP) formation, the potential for producing ozonation DBPs like bromate ion must be addressed. This article focuses on the interactions, not only of molecular ozone and bromide ion, but also of radical species with bromide ion. The data evaluations include discussions of reaction products, potential for bromate ion formation, reaction kinetics, and the effect of various water quality parameters and treatment conditions on bromate ion formation. Based on evaluation of existing data, areas requiring new or intensified research efforts are identified.

An additional aspect of this article is a presentation of most available data on the minimization of bromate ion formation during ozonation. A summary of bromate ion removal processes after ozonation has been incorporated.

SOURCES AND OCCURRENCE OF BROMIDE ION

Bromide ion (Br^-) in drinking water supplies has no direct public health ramifications; however, its presence during water-treatment disinfection can lead to the formation of DBPs such as bromate ion (BrO_3^-). Hence, bromide ion is a precursor to the formation of bromate ion and other brominated oxidation/disinfection by-products. An understanding of the sources and levels of bromide ion in different source waters is crucial for an understanding of the bromate ion formation potential in drinking waters. If bromide ion is present in source waters, it is difficult to remove it economically during drinking water treatment.

Bromide ion can enter water sources from dissolution of geologic sources, from saltwater intrusion into surface water and aquifers, and from human activities. Methyl bromide and ethylene dibromide are used to fumigate crops and soil and as additives to leaded gasoline. Once in soil, they break down into inorganic forms that subsequently are leached by agricultural runoff into ground waters; bromide ion concentrations may attain 0.01–6 mg/L (1). Bromide ion is also associated with salt-spreading on roads during the winter, and some fertilizers are known to contain iodate and bromate ions. Other bromide ion containing compounds can enter water through sewage and industrial effluents (2). Electrolytic chlorine obtained from salt contains bromine estimated at a level of 2 mg/L (3).

Amy et al. (4) conducted a nationwide survey of bromide ion in source waters throughout the United States, and found an average concentration of almost 100 μg/L. In a study of more than 35 water treatment facilities that were selected to provide a broad range of source water qualities and treatment processes, influent bromide ion levels ranged from 10–3000 μg/L (5). Legube et al. (6) found bromide ion concentrations in the influents of 23 different European utilities ranging from 12–210 μg/L, and Kruithof et al. (7) found bromide ion concentrations in Dutch waters ranging from 10–240 μg/L. Considering that the average bromide ion concentration in U.S. waters is approximately 100 μg/L, it is expected that detectable bromate ion can form in a majority of waters that are subjected to ozonation. A Cl^-/Br^- ratio of about 300:1 is indicative of seawater influence.

MEASUREMENT OF BROMATE ION

Ion chromatography is the predominant analytical technique for bromate ion measurement at such low concentrations. Several techniques have been described to reach the required level of sensitivity for measuring bromate ion (8–11).

Siddiqui et al. (11), Legube et al. (6), and Kuo et al. (9) measured bromate ion with detection limits of 2 μg/L, 2 μg/L, and 5 μg/L, respectively, using a conductivity detector without preconcentration and employing a borate eluent (100–150 μL sample loop). They also employed Ag cartridges to remove chloride prior to injection. Legube et al. (6) followed a sequence of steps to measure bromate ion. Each sample was first filtered using membrane filters to remove suspended solids, then filtered through Ag filters to remove Cl^-, and finally was acidified and stripped of bicarbonate as carbon dioxide by helium to avoid interference from the bicarbonate peak.

Gordon et al. (12) developed a non-ion chromatographic method using chlorpromazine to determine bromate ion in ozone-treated waters. In the presence of bromate ion, chlorpromazine oxidizes forming a relatively stable colored product that can be monitored at 530 nm. Chemical masks are described to minimize potential interference from nitrite and chloride ions.

BROMATE ION FORMATION: PATHWAYS AND MECHANISMS

During the oxidation and/or chemical disinfection of natural waters containing bromide ion with ozone, bromate ion can be formed at concentrations ranging from 0 to 150 μg/L under normal water treatment conditions. During ozonation, bromide ion is first oxidized by dissolved ozone to hypobromite ion (OBr^-) which is then further oxidized to bromate ion. The reaction is pH-dependent because OBr^- is in equilibrium with hypobromous acid (HOBr). OBr^- builds up rapidly during ozonation and becomes the main reservoir for bromate. Hypobromite reacts further with ozone to form bromide ion (77%) and bromate ion (23%) in pure aqueous solutions.

The molecular ozone mechanism does not account for OH radicals formed as secondary oxidants from decomposed ozone during water treatment. Richardson et al. (13) and Yates and Stenstrom (14) indicate that there is a radical pathway which is influenced by both pH and alkalinity. The $OH\cdot$ radical and, to a lesser degree, the carbonate radical pathway ($CO_3\cdot^-$) may be more important than the molecular ozone pathway. Oxidants such as OH and CO_3^- radicals may interact with intermediate bromine species leading to the formation of BrO radicals which eventually undergo disproportionation to form hypobromite and bromite (BrO_2^-). Bromate ion is then formed through oxidation of bromite by ozone. The radical mechanism for the formation of bromate ion includes two decisive reaction steps still involving molecular ozone: the formation of hypobromite and oxidation of bromite (15). In contrast, Yates and Stenstrom (14) suggest that $BrO\cdot$ is formed primarily by the direct reaction of ozone with $Br\cdot$, which is formed by the oxidation of Br^- by $OH\cdot$. Siddiqui et al. (16) assumed that rate constants obtained by Haag and Hoigne (17) through molecular ozone pathways may intrinsically take into account bromate ion formation through both molecular ozone and radical pathways.

Bromate ion formed through reactions with molecular ozone contributes in the range of 30–80% to overall bromate ion formation in natural organic matter (NOM)-containing waters. Ozekin et al. (18) report up to 65% and 100% bromate formation through a radical pathway in NOM-free and NOM-contaning waters, respectively. Differences in NOM-containing waters can be attributed to differences in the characteristics of NOM. A change in mechanism as a function of pH and the competitive roles of the free radical (one-electron transfer) mechanism above pH 7 versus oxygen-atom (two-electron transfer) mechanisms help explain both the large variations in bromate ion yield and the sensitivity to reactor design, concentration of NOM, and ozone/bromide ion concentrations (19). In summary, bromate ion formation can occur through both radical and molecular ozone pathways depending on NOM concentration in source waters. This is an important finding that will have strong implications for bromate ion control strategies.

BROMATE FORMATION: EFFECT OF WATER QUALITY PARAMETERS AND TREATMENT CONDITIONS

Several studies have demonstrated that several water quality and ozonation parameters affect the formation of bromate ion. A better mechanistic understanding relating these parameters to bromate ion formation is critical to control its formation during ozonation.

Bromide Ion Concentration

An important difference from the chlorine system exists in that Br^-, unlike Cl^-, reacts with ozone at a significant rate and this reaction is independent of pH because Br^- is not protonated in water. At low pH (≤ 6), the bromine formed is relatively inert to ozonation ($k < 10^{-3}$ M^{-1} s^{-1}), and nearly all of the Br^- is present as HOBr. In the absence of NOM (or other substances that react rapidly with HOBr), all of the Br^- can eventually be recovered as bromate ion when ozonated. The ranges of bromate ion levels found by different investigators for various bromide ion-containing waters are summarized in Table 1.

Siddiqui and Amy (21) have shown that there is a threshold bromide ion concentration below which no detectable (<2 μg/L) bromate ion formation occurs. This threshold level is dependent on pH, ozone dose, DOC, and alkalinity of the water being ozonated and hence will vary from source to source. Siddiqui and Amy (21) have shown a bromide ion threshold concentration of 0.25 mg/L for an O_3/DOC ratio of 1.5:1 at pH 7.5 for groundwater with a DOC of approximately 4 mg/L. Krasner et al. (23) indicated that bromide ion levels of ≥0.18 mg/L yield measurable levels of bromate ion when a target ozone residual for disinfection is met.

Ozone Dose

The ozone dose plays a critical role in the formation of bromate ion. Increasing ozone dose increases the formation of bromate ion until all bromide ion is converted to bromate ion (21). If sufficient ozone is added to meet the ozone demand of a water, bromate ion will be produced if there is sufficient bromide ion (≥100 μg/L). However, according to Krasner et al. (23) and Siddiqui et al. (21), appropriate staging of ozone through two or three chambers can minimize ozone residual and bromate ion formation in full-scale ozone contactors. Siddiqui and Amy (24) and Kruitof et al. (7) have shown that there is an ozone threshold concentration below which no bromate ion formation occurs. For pretreated Meuse River water with a DOC content of 2.4 mg/L, the lowest ozone dose at which bromate ion could be detected was 1.0 mg/L over a pH range of 6.8–7.8 (7, Table 2.4). Optimization of ozone dose for preoxidation or disinfection should take into account the formation potential of bromate ion.

Alkalinity

An important factor controlling the half-life of ozone in natural waters is alkalinity. Addition of alkalinity increases the formation of bromate ion (16). Their research has shown that the contribution to bromate ion formation due to carbonate radicals at pH 8.5 was much more predominant than at pH 6.5 (30% vs. 5%). This is presumably due to a shift toward HCO_3^- ions from CO_3^{2-} ions and higher production of OH radicals. CO_3^{2-} ions react about 30 times faster with OH radicals than HCO_3^- ions and therefore have a larger scavenging effect.

In summary, during ozonation, part of the ozone added reacts directly with bromide ion, and a part of it decomposes to radicals which further react with carbonate alkalinity to produce carbonate radicals. The higher the pH, the faster the decomposition rate of ozone (initiated by OH^-), and the faster the formation of bromate ion. Additionally, it is accelerated by a chain reaction for which the bromine species radicals formed act as carriers. Because of this chain reaction, dissolved ozone decay depends on bromate ion yielding radical intermediates which additionally catalyze the decomposition of ozone and alkalinity which scavenge the OH radicals. Alkalinity quenches the chain reaction resulting in an increase in ozone half-life.

Natural Organic Matter

The reaction of ozone with NOM can occur by direct reaction or by radical processes. The ozone decomposition and OH radical yield from NOM is influenced by the type and concentration of NOM in natural waters. Direct consumption of ozone is greater when the UV absorbance

Table 1. Summary of Bromate Ion Formation Potential in Different Source Waters

(due to electrophilic and nucleophilic sites) of the source water is significant, resulting in decreased bromate ion. The radical process is initiated by active sites present in humic substances or formed during ozonation of nucleophilic sites and by hydroxide ions. Amy et al. (22) have shown that bromate ion formation, with all factors equal except NOM, varies from source to source. Amy et al. (22) studied more than seven different source waters containing a wide range of NOM characteristics. Krasner et al. (23) suggest that at fixed CT (Concentration of Disinfectant × Time of Contact) values, BrO_3^- increases with NOM.

In summary, the presence of NOM may accelerate ozone consumption and can reduce bromate ion formation potential. Besides pH, NOM concentration, measured as dissolved organic carbon (DOC), is influential; a higher Br^-/DOC ratio enhances bromate ion over organo-Br formation. The formation of bromate ion in NOM-containing waters is predominantly through a radical pathway rather than by the molecular ozone pathway.

Temperature

The effects of temperature are several: (1) dissolved ozone (DO_3) is more stable at lower temperatures, (2) increasing temperature increases the reaction rate constant, and (3) the pK_a of the HOBr/OBr^- system is temperature dependent. Siddiqui and Amy (21), Amy et al. (22), and Kruithof et al. (7) have observed an increase in bromate ion concentration as temperature increases. Kruitof et al. (7) studied bromate ion formation at two different temperatures (5 and 20 °C) in Meuse River water in bench-scale experiments and found a significant increase in bromate ion formation potential upon increasing the temperature from 5 to 20 °C. Siddiqui and Amy (21) indicated that increasing either ozonation temperature or incubation temperature had a positive effect on the formation of bromate ion. An increase in ozonation temperature produced more bromate ion than a corresponding increase in incubation temperature. This may be partially attributable to bromate ion formation occurring in less than 10 minutes.

In summary, increasing temperature generally increases the formation of bromate ion during drinking water treatment. Hence, more bromate ion formation may be expected in summer months than in winter months for the same applied ozone dose.

Reaction Time

Perhaps more than any other factor, reaction time is most important. Amy et al. (22) and Yamada (25) have shown that most bromate ion formation occurs within about 5 minutes, although its formation can continue over 30 minutes, suggesting that bromate ion forms mainly through the radical pathway. Control strategies to minimize bromate ion formation must take into account its kinetic time frame. Reaction rate increases upon the addition of H_2O_2 and at elevated pH levels, strengthening the argument that radicals are responsible for bromate ion formation. Bromate ion formation occurs only in the presence of DO_3, so maintaining an appropriate amount of DO_3 is critical to minimizing bromate ion formation. A small increase in DO_3 can result in a severalfold increase in bromate ion formation.

BROMATE ION MINIMIZATION STRATEGIES

Given preliminary health information and the potential of a low MCL for bromate ion, control options require careful optimization to achieve low concentrations in ozonated waters containing significant levels of bromide ion. A better understanding of the mechanisms of bromate ion minimization strategies is required to control its formation during ozonation. Bromate ion can be minimized by chemical factors (chemical addition) or physical/hydrodynamic factors (contactor design).

pH Depression

Bromate ion concentration increases as pH increases. Reducing the pH of water before ozonation impacts bromate formation minimization in a number of ways. At $pH < 7$, oxidized bromide ion is primarily in the form of HOBr, thus minimizing bromate ion formation, and at $pH>8.0$, the efficiency of OH radical generation from ozone decomposition increases. Siddiqui et al. (21) showed that decreasing the pH from 8 to 6 lowered the ozone dose required for disinfection by 33% for a source water containing 3.5 mg/L DOC. In addition, because ozone residuals are more stable at lower pH levels, a lower ozone dose is required to achieve the same CT value at a reduced pH, compared to ozonation at ambient pH.

Draft drinking water regulations in the United States will tentatively specify a best available treatment (BAT) of pH adjustment for bromate ion minimization. The major constraint to this BAT is the acid cost for high alkalinity waters, and the subsequent need to adjust pH after treatment for corrosion control. As an example, Krasner et al. (23) indicated that treating State Project Water (CA) at an average flow of 520 mgd could potentially reduce the ozone dose for minimum disinfection from 1.7 to 1.0 mg/L, resulting in an ozone cost savings of approximately $0.8 million per year. The estimated chemical costs, however, would be approximately $4 million and $2 million per year, respectively, for the acid to reduce the pH from 8 to 6 and the caustic to raise the pH back to 8.0 prior to distribution.

Ammonia Addition

Ammonia addition theoretically can tie up bromine (HOBr/OBr^-) as bromamine and can exert a free radical demand; however, the complexity of bromamine chemistry has yielded mixed BrO_3^- formation results in lab and pilot studies. Ammonia addition may result in a time-lag minimization of BrO_3^- formation in low DOC waters because of additional reactions with ammonia (reaction of ammonia with bromine proceeds faster than oxidation of bromamine and bromide ion by ozone). Glaze et al. (26) and Siddiqui and Amy (21) observed up to a 30% decrease in bromate ion formation upon the addition of ammonia at pH levels near 7.0. Siddiqui et al. (27) indicated that the effect of ammonia addition on bromate ion formation is more predominant in low

DOC groundwaters. They attribute this to a majority of bromate ion formation in NOM-containing waters proceeding through the radical pathway.

Hydrogen Peroxide

At low pH levels ($pH < 7$), production of OH radicals and subsequent consumption of H_2O_2 by OH radicals is slower, thereby decreasing the rate of decomposition of ozone and enhancing the rate of bromate ion formation. At high pH values ($pH > 9$), the degree of dissociation of H_2O_2 to HO_2^- becomes apparent, and the decomposition of H_2O_2 by the reaction of O_3 with HO_2^- proceeds fast. The amount of bromate ion formed increases as long as the synergistic effect of OH radicals and molecular ozone is maintained. If the H_2O_2 concentration is too high, the half-life for ozone is too small for the formation of bromine species and eventually bromate ion.

Siddiqui and Amy (21) and Krasner et al. (23) have observed an increase in bromate ion formation, whereas Daniel et al. (28) and Kruitof et al. (7) have observed a decrease in bromate ion formation upon the addition of H_2O_2.

The differences in H_2O_2 effects on bromate ion formation may be attributed to differences in ozonation pH, H_2O_2 concentration maintained during ozonation, and the DOC content of the source waters. Excess H_2O_2 decreases the DO_3 concentration (less CT value) resulting in reduced bromate ion formation. On the other hand, if an optimal amount of H_2O_2 with respect to O_3 is present, bromate ion formation increases. In some full-scale plants, the addition of ozone is automated based on ozone residual at the outlet of the ozone contactors. Maintaining a constant residual with and without the addition of peroxide implies an increase in applied ozone which leads to an increase in bromate ion concentration.

Contactor Hydrodynamic Factors

Gas–liquid contactor hydrodynamics plays a critical role in bromate ion formation; it influences mass transfer rates, peak ozone residuals, spatial-temporal concentration gradients, and liquid backmixing phenomena. A number of conditions may be imposed on the operation of a full-scale contactor to minimize bromate ion formation. These contactor operating conditions may include contactor operation at low residual ozone concentrations and minimal backmixing.

Krasner et al. (23) and Siddiqui et al. (24) demonstrated that staging ozone application within a full-scale contactor or splitting ozone application in a pilot-scale ozone contactor can optimize ozone residual throughout the contactor as well as result in less bromate ion formation. This strategy minimizes bromate ion formation but may require larger ozone doses to ensure the same disinfection.

The ozone-content of the carrier gas and ozonation contact time affect the formation of bromate ion in laboratory-scale reactors (24). In full-scale experiments, Gramith et al. (29) observed higher bromate ion formation in an eductor system (6% ozone) than in an air-fed system (1.5% ozone). These differences in bromate ion production by the two different configurations indicate the sensitivity of bromate ion formation to ozone contactors and differences in mass transfer of ozone.

BROMATE ION REMOVAL

Several different options to remove bromate after its formation, applicable to surface water treatment plants contemplating the use of ozone at various points of application, have been evaluated by Siddiqui et al. (11): ferrous iron reduction, granular activated carbon (GAC) surface reduction, ultraviolet irradiation (UV) and high energy electron beam irradiation. In all processes, chemical analysis of the treated water showed the formation of bromide ion, indicating that chemical reduction of bromate to bromide ion is the significant mechanism. Bromate removal by activated carbon has been shown to be carbon specific, and not all the carbons have shown the ability to reduce bromate to bromide. The use of ferrous iron appears more promising because it also acts as a coagulant for removing disinfectant by-product precursors.

SUMMARY

Bromate ion formation occurs through both a molecular ozone and a free radical pathway. Most authors have shown that pH, bromide ion concentration, temperature, and alkalinity favor bromate ion formation whereas DOC has been shown to decrease bromate ion formation. pH depression reduces the formation of bromate ion, but this technique may not be cost-effective for high alkalinity source waters and may favor organobromine compounds. Different types of NOM can exert different ozone demands and associated different bromate ion formation potentials. Addition of ammonia has produced mixed results. Clearly, optimization of pH to minimize bromate ion formation by ammonia addition requires further study because the stability of different bromamine species depends on the pH of the water. Bromate ion can be minimized by manipulating ozone contactor design and operation. Appropriate staging of ozone through two or more chambers and optimizing the hydrodynamics of the ozone contactor can minimize ozone residual and bromate formation.

MUNICIPAL WATER SUPPLY: OZONATION

JAEHONG KIM
Georgia Institute of Technology
Atlanta, Georgia

OZONE IN WATER TREATMENT

Since the first full-scale application of ozone for water treatment in late 1800s, ozone has been widely used in municipal water supplies in many countries. The primary goal of the ozonation process in water treatment is often disinfection, but ozonation is also used in many other applications, including taste and odor control, color removal, oxidation of manganese and iron, flocculation enhancement, oxidation of natural organic matter (NOM) and accompanying promotion of its biodegradability, and control of chlorination byproducts (1). Recently, the application of ozone as a disinfectant has been receiving more attention because of its effectiveness in treating pathogens, such as oocysts of the protozoan parasite *Cryptosporidium parvum*, which have shown strong resistance to chlorine-based disinfectants (2,3).

In water treatment, ozone can be applied either at the early stage of treatment (i.e., preozonation) or after other treatment processes, including conventional processes such as coagulation/flocculation and sedimentation. Ozone is sometimes used with hydrogen peroxide or UV to promote the formation of hydroxyl radicals in advanced oxidation processes (AOPs). Due to the increased biodegradability of organic matter after ozonation, ozonation is typically followed by biological filtration to remove biodegradable organic matter and to minimize microbial regrowth in the distribution system. Ozone decomposes relatively fast, so secondary disinfectants such as free chlorine and monochloramine are often applied after ozonation to provide residual disinfectant in the distribution system.

OZONE CHEMISTRY

Ozone is a strong oxidant with a standard redox potential of 2.07 V in aqueous solution (4). Ozone has four resonance structures thus allowing it to act as both an electrophile and as a nucleophile (5). Because ozone is a highly selective oxidant, its use in water treatment allows it to inactivate pathogenic microorganisms selectively, oxidize manganese and iron, and react with organic matter that contains olefins, amines, sulfides, and phenolic functional groups. Reactions with ozone are generally categorized into electron-transfer, oxygen atom transfer, or ozone addition processes (6). Inorganic compounds such as ferrous ion (Fe^{2+}) tend to react with ozone primarily through oxygen atom transfer, but ozone addition to a saturated bond followed by rearrangement and formation of carboxylic acid is typical of ozone reactions with organic matter. The rate constants of ozone reactions with various inorganic and organic compounds in the aqueous phase can be found in the literature (6–8). The reactions of ozone with NOM are complicated and not well understood primarily due to the heterogeneity of NOM. Ozone reactions with NOM are known to reduce aromatic carbon content, selectively reduce phenolic carbon content, and can lead to the formation of smaller molecular weight carboxylic acids and aldehydes (9–11).

Ozone is not stable in water and has a half-life ranging from seconds to hours depending on the water quality. In addition to the various reactions between ozone and organic and inorganic constituents in water, aqueous phase ozone undergoes a chain-type decomposition that results in the formation of secondary oxidants such as hydroxyl radicals ($\cdot OH$), ozonide radicals ($HO_3\cdot/O_3{}^-\cdot$), and superoxide radicals ($HO_2\cdot/O_2{}^-\cdot$). The mechanism of ozone decomposition has been studied for decades. Figure 1 shows one plausible mechanism, constructed from the literature, of ozone decomposition in the absence of organic matter (12–18). The rate of ozone decomposition in the aqueous phase depends strongly on pH because ozone decomposition is initiated by hydroxide ion. In the presence of alkalinity, carbonate radicals are formed (19–22), as shown in Fig. 1. In natural waters, ozone and secondary oxidants react with naturally occurring organic and inorganic matter. Such reactions may result in consumption of ozone and secondary oxidants as well as formation of other secondary oxidants such as hydrogen peroxide, ozonide, and superoxide radicals (23,24), therefore adding considerable complexity to the decomposition mechanism shown in Fig. 1. Overall, ozone decay in natural water is a combined effect of ozone decomposition and reaction with aqueous constituents. The kinetics of ozone decay in natural waters is often characterized as an initial fast decrease in ozone concentration followed by a slower phase where ozone follows a first-order decrease in concentration (25).

The contribution of hydroxyl radical, the major secondary oxidant, to the overall oxidation potential during ozone application has often been expressed as R_{ct}, the ratio between hydroxyl radicals and ozone (26). In the case of AOPs, the intent is to form hydroxyl radicals typically to react with inorganic and organic compounds that are resistant to ozone.

BY-PRODUCT FORMATION

A variety of organic byproducts such as aldehydes, ketones, keto aldehydes, carboxylic acids, keto acids, hydroxyl acids, alcohols, and esters are formed during ozonation of natural waters (27). In the presence of bromide, various brominated organic by-products are formed. Bromate ($BrO_3{}^-$) is one of the by-products formed during ozonation of bromide-containing waters. Bromate formation follows a complex set of reactions involving several bromine species such as $HOBr/OBr^-$, $BrO\cdot$, and $BrO_2{}^-$ as intermediates (28–30). Formation of bromate during ozonation has been one of the major concerns in using ozone in drinking water treatment. Bromate is currently regulated at 10 μg/L in the United States and the European Union (31,32) due to its potential carcinogenicity (33).

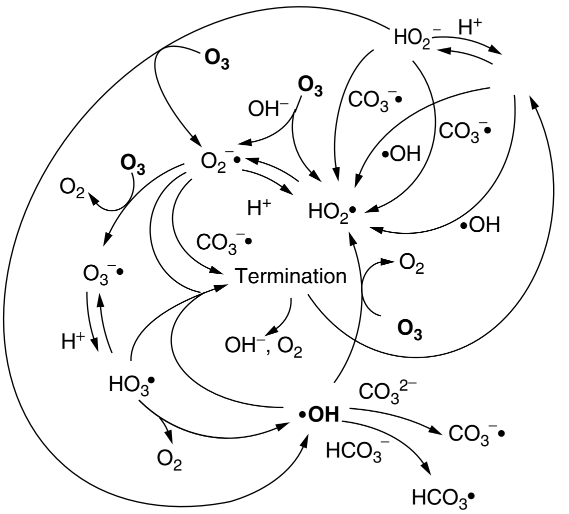

Figure 1. Mechanism of ozone decomposition in aqueous solution.

OZONE CONTACTOR

Ozone is generally produced on site from air or pure oxygen by electrical discharge using ozone generators. A typical ozone concentration in the gas phase is 15 g/m^3 when air is used, but concentrations as high as 150 g/m^3 can be achieved when pure oxygen is used. The gaseous phase ozone is then transferred into water in ozone contactors that typically provide 10–20 min of contact time. Ozone is relatively insoluble in water (e.g., Henry's law constant at 20 °C is 100 atm/M), so efficient transfer of ozone to water is an important factor in designing ozone contactors. There are several different types of ozone contactors used for disinfection, depending on the methods of ozone introduction and modes of contacting with water. The most typical configuration is a multichamber bubble-diffuser contactor, though other types of contactor configurations such as rapid mixers, submerged turbines, pipeline injectors, packed towers, and deep U-tubes are also used (1). In the multichamber bubble-diffuser contactor, one or more of the upstream chambers in these units are transfer chambers in which ozone gas is introduced through a set of ceramic or stainless steel diffusers installed at the bottom of the unit. The remaining downstream chambers are used as reactive chambers for additional contact with residual dissolved ozone. A transfer chamber can be designed for operation in either countercurrent flow (water and gas flowing in opposite

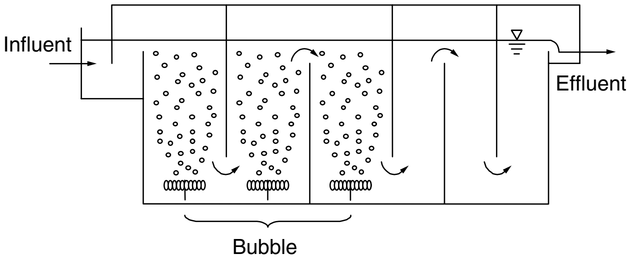

Figure 2. Schematic of full-scale ozone bubble-diffuser contactor located in Oakland, CA.

directions) or cocurrent flow (both water and gas flowing in the same direction) configuration. The transfer portion of a bubble diffuser contactor can consist of countercurrent and cocurrent flow chambers of similar size connected in series (34) or countercurrent flow chambers connected by small reactive upflow chambers (35). The residual ozone in the effluent of the contactor can be destroyed by hydrogen peroxide or activated carbon. A schematic of a typical ozone contactor is shown in Fig. 2. Off-gas from the contactor may contain residual ozone, which is subsequently treated by heat and/or catalyst for further destruction.

The design of an ozone bubble-diffuser contactor requires decisions such as selecting the number and distribution of transfer and reactive chambers, water column height, chamber cross-sectional area, number and type of diffusers, gas flow rate, and ozone gas concentration. The choice of contactor configuration and operating conditions can affect the hydrodynamics and mass transfer, which in turn can impact the ozone concentration throughout the ozone contactor. In addition, the performance of the contactor is also affected by certain water quality parameters, primarily those affecting the kinetics of ozone decomposition, such as temperature, pH, natural organic matter content, and alkalinity. Computer simulation has often been employed to model the complex phenomena involved in process design and optimization (25,36).
