patients with osteoarthritis and with rheumatoid arthritis, a more detailed study was made.

In another series of observations, McClellan and Comstock found that radon added to the bath was also absorbed through the skin, both from baths of plain water and, to a greater degree, from baths in the naturally carbonated mineral water. Both carbon dioxide and radon are important substances in many spas about the world. The demonstration that they are actually absorbed from the water of the bath supports the conclusion that the absorbed carbon dioxide or radon plays a role in the physiologic changes observed.

Table 5 presents the results of treatment for patients with osteoarthritis analyzed in relation to the total amount of treatment received. The total amount of treatment was gauged by the number of mineral water baths, because for practically all patients it represented the major feature of the program. Even with 10 baths or less, some patients showed improvement, but the proportion of those who were not improved was much higher than in the other groups. When the patients received 11–21 baths, there was some increase in the percentage of patients who obtained benefit. When the baths were continued longer, over 21 in number, there was considerable increase in those who showed moderate improvement. When the treatment program extended beyond what is usually considered two average courses of treatment, little additional benefit was evident.

It is interesting to note that the variation of improvement was essentially in keeping with the figures, noted in the larger groups of patients. With the variety of conditions in the remaining 20% of the patients, it was impossible to apply this detailed analysis because of the relatively small numbers.

Moving southwest 45 miles west of Albany is Sharon Springs, New York. Although now open only a few weeks per year, at one time the sulfur magnesium and calcium waters were waters utilized in over 82,000 treatments a year during the 12-week season. After WWII and up to the present day, many of the victims of the German concentration camps, predominantly Hasidic Jews, and currently the Russian victims of similar camps use the water of Sharon Springs for recovery and rejuvenation. Most are paid for by the medical services of their countries of origin. The sulfur water is particularly beneficial for rheumatoid and osteoarthritis, skin problems, and general revitalization of the body.

It is common to find calcium and magnesium waters in close proximity to the sulfur springs. The calcium–magnesium balance is one of the most important balances in the body, along with the sodium chloride and acid alkalinity (pH, also adjustable with the use of water). The type of magnesium and calcium found in the water is ideally suited to the human body. Several qualified sources (6) have stated that the use of natural calcium and magnesium water maintains that ratio at ideal levels.

In closing, although this entry is certainly not a complete and comprehensive discussion of all the medicinal uses and statistics, it is an example of water's inherent natural medicinal qualities.

A HISTORY OF HAWAIIAN FRESHWATER RESOURCES

M. Eric Benbow

Albert J. Burky
University of Dayton
Dayton, Ohio

INTRODUCTION

The present economy of the Hawaiian Islands is primarily dependent on tourism. Visitors spend millions of dollars at hotels, in shopping malls and shops, at restaurants, and travel to and from islands. This money provides the economic foundation for many local Hawaiian families, and it serves to drive the state's economy. However, the economy has not always been based on tourism, but rather on the agricultural strength of sugar cane from the late nineteenth century through most of the twentieth century. Historically, the rise of agriculture was based on freshwater, the resource that drives tourism and expanding commercial development today. However, the surface waters and aquifers are limited, and a balanced concern exists for the effects of continued freshwater withdrawal from these sources. In particular, the streams of Hawaii are home to many endemic organisms (found only in Hawaii) that are threatened by continued surface water withdrawal. Many of the aquifers are being overpumped, increasing the salinity of groundwater resources and sometimes influencing surface flows.

For this topic, we provide a brief historical description of the geological origin and predominate climate patterns of the Hawaiian Islands, an introduction to endemism and the freshwater ecosystems, early Hawaiian cultural use and contemporary freshwater management, the expansion of sugar cane as a catalyst for freshwater exploitation, the cultural consequences of sugar cane expansion, and existing political struggles. We conclude with a short discussion about the future of Hawaiian freshwater resources, one of delicate balance and immediate concern.

GEOLOGICAL ORIGIN

The Hawaiian Islands have grown from a permanent "hot spot" located at an unknown depth beneath the Pacific Ocean seafloor. As it has been difficult to determine detailed information on this hot spot, the geological formation of Hawaii remains partly theory (1). The hot spot is a huge lake of melted rock under tremendous pressure in the Earth's mantle where molten rock erupts, accumulates on the ocean floor, and finally emerges from the ocean surface after millions of years (2). The hot spot is believed to remain stationary, but the outer crustal plate has been shifting (1). The shifting plates, timing of eruptions, and sea level changes have resulted in a chain of submerged and remnant volcanic islands to the northwest (Emperor Seamount Chain) of Midway Atoll, and the existing main Hawaiian Islands to the southeast (2).

The largest Hawaiian Islands are the most recently formed. The two oldest are Kauai and Niihau, with Oahu and the islands of Maui Nui (Maui, Molokai, Lanai, and Kahoolawe) sequentially younger moving southeast, and the appropriately named Big Island (or Hawaii) that is volcanically active (Fig. 1) (3,4). A new island about 1000 m (called Loihi) below the ocean surface is developing off the southern coast of the Big Island (5). As one travels from the northwest to the southeast, the existing islands become younger, larger, taller, and less eroded.

CLIMATE PATTERNS

Remotely located in the Pacific Ocean, the climate and precipitation patterns of Hawaii are dependent on predominant wind patterns and ocean currents. The Trade Winds (Prevailing Westerly Winds) blow across the Hawaiian Islands in a northeasterly to southwesterly direction, with stronger intensity occurring during the drier summer months (Fig. 1) (6). As these winds move across the ocean collecting water vapor, they move up, around, and sometimes over the mountains. As the air moves to higher altitudes, it cools, clouds form, and it rains, causing a rain shadow effect responsible for perennially wet northeastern shores (windward) opposite dry southwestern shores (leeward) (6). High rainfall, lush tropical rainforest vegetation, rushing streams, and abundant cascades and waterfalls characterize the windward sides, whereas the leeward sides have little rainfall and desert lands of dry-tolerant shrubs and cacti. The spatial distribution of precipitation combined with steep elevational gradients and ocean currents create climate patterns conducive for biome and ecosystem variety in a relatively small geographical area, ecosystems where many organisms evolved and are found nowhere else on Earth.

HAWAIIAN ECOSYSTEMS AND ENDEMISM

The variety of ecosystems and biomes in Hawaii area a result of five general characteristics: (a) geographic

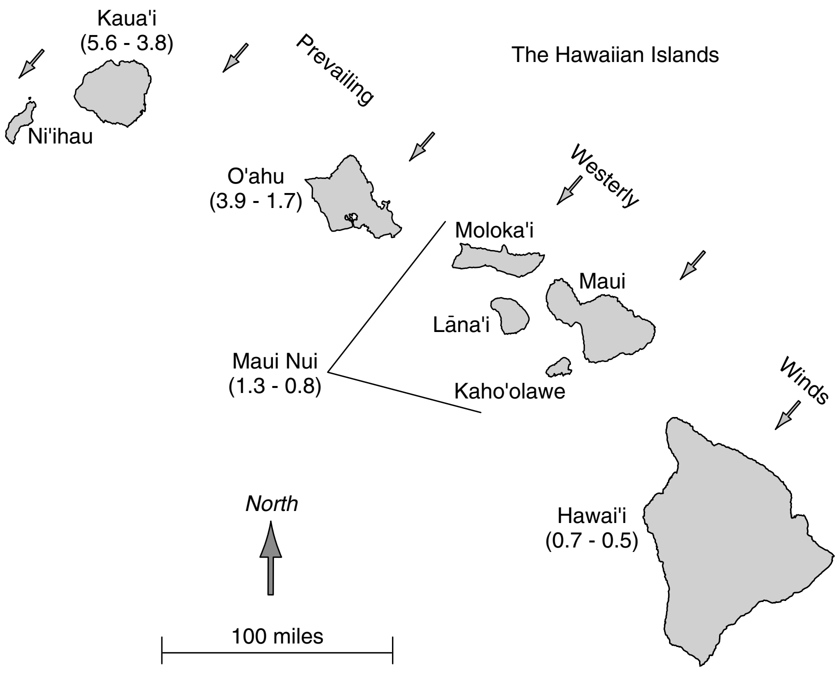

Figure 1. A map of the main Hawaiian Islands. Approximate island (or island group) ages are given in parentheses below the island name. Island ages are in millions of years and were estimated from two sources (3,4). Maui, Moloka'i, Lana'i, and Kaho'olawe were once a single island called Maui Nui until about 0.4–0.3 million years ago.

isolation, (b) small relative size and area, (c) recent age, (d) unique evolution, and (e) climate patterns (7). The Hawaiian Islands are some of the most isolated land masses in the world, which kept original immigrant species dispersal minimal (8). Relatively few species became established, but those that did underwent rapid speciation in the absence of many variables typical of mainland ecosystems (7). For example, some birds and many insects are flightless in response to evolving in predator absence (8). Many species never evolved effective defenses against predators or aggressive alien competitors, making the endemic flora and fauna easy prey, or out competed by introduced species that evolved with aggressive predators and competitors. Hawaii has approximately 10,000–15,000 endemic and indigenous species with over 30% of the total threatened or endangered species in the United States (4,7). In light of this, appropriate conservation, preservation, and management are needed to protect these rare habitats and endemic communities. The freshwater communities are threatened by continued and expanding riparian (land adjacent to a stream or river) habitat destruction, surface water removal, and introduced and invasive species.

HAWAIIAN STREAM ANIMAL COMMUNITIES

Hawaiian streams respond to unpredictable rainfall events that determine flow volume changes over short- and long-term time periods. The geology is commonly porous and precipitation quickly saturates riparian soils, creating rapid and high-volume surface runoff. Flash floods are common throughout the year. The local name for a flood is “freshet”, indicative of the historical description, and contemporary observations of scoured and rearranged stream channels moved by tremendous hydrodynamic forces. It is thought that many Hawaiian stream organisms have evolved specialized life cycles (e.g., amphidromy, see below) to accommodate these unpredictable and frequently extreme events (9–11).

AMPHIDROMY

The native Hawaiian fish, shrimp, prawn, and snail species have a diadromous life cycle, meaning they migrate between freshwater and seawater (1). These native species are amphidromous, a subcategory of diadromy (Fig. 2) (12,13). Adults reproduce in streams, eggs hatch, and embryos (now called larvae) drift to the ocean for growth and development into postlarvae (from 10–30 mm body length) over several months (14–16), and then migrate back into the streams. In amphidromy, the purpose of migration is not for immediate breeding as in diadromy (e.g., salmon); instead, postlarvae, not adults, migrate into freshwater to feed, grow, and remain for the rest of their existence through multiple reproductive events (12,17,18).

There are four endemic and one indigenous amphidromous fish species in Hawaiian streams (Table 1) (16,19,20). The pelvic fins of the gobies are fused and form a ventral sucker used to cling to rocks and climb waterfalls as postlarvae and early juveniles (16,21). One fish species has been reported to climb single waterfalls >100 m high and combined waterfalls totaling a height of 300 m (19). The native shrimp, snails, and prawns (Table 1) also have the ability to climb waterfalls (20). Postlarval migration has been found to be directly related to stream discharge (22,23).

OTHER ENDEMIC STREAM ANIMALS

The native stream organisms have closely related marine relatives, and it is evident that the freshwater species

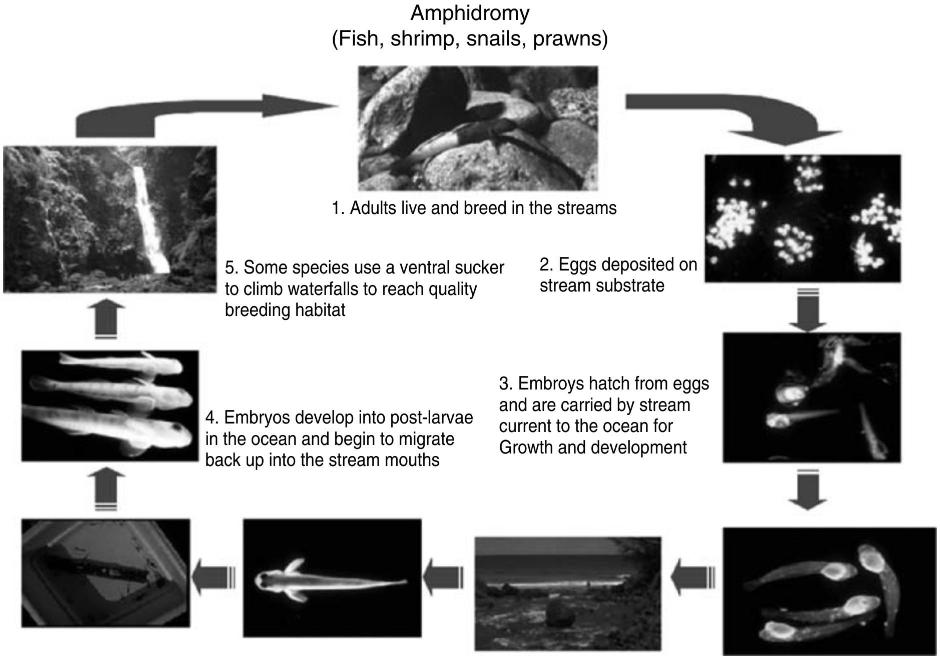

Figure 2. A schematic depicting the amphidromous life cycle of the native fish, snails, shrimp, and prawns found in Hawaiian streams. The life cycle requires postlarval development in the ocean and a migration back into the streams that is not immediately for breeding.

evolved from marine habitats (Table 1) (10,16,24,25). Some examples of this can be found in stream insect communities consisting of midges, *Telmatogeton* (Chironomidae); beach flies, *Procanace* (Canacidae); and shore flies, *Scatella* (Ephydridae), which are thought to have radiated into streams from ancestral intertidal habitats (26–28). The Hawaiian *Telmatogeton* complex is unique with all five endemic species restricted to freshwater, the only representatives of an exclusively marine intertidal subfamily worldwide (26–29).

Another important insect group is the endemic damselflies of the *Megalagrion* complex. This genus has shown rapid speciation in concert with specific freshwater and terrestrial habitats (30–32). Contrary to many other aquatic insects of Hawaii, the endemic damselflies are thought to have evolved from one freshwater ancestor to Hawaii (31,32). As a result of recent extinctions, numerous research initiatives have been carried out to understand the evolution, biology, and conservation of this unique group of insects (31,32). Other freshwater organisms are reported in Table 1.

SURFACE WATER REMOVAL

The streams of Hawaii are habitat to relatively recently evolved communities with close marine ancestors (e.g., fish, snails, shrimp, and some insects) and/or isolated populations that have undergone rapid speciation (e.g., the damselflies). For millennia, these systems connected the mountains to the ocean along what is called in Hawaiian the mauka—makai continuum. The physical connection was the flowing streams supporting the biological connections of the amphidromous species. However, many streams were heavily diverted in the late 1800s for irrigating an expanding sugar cane industry. Stream flow removal and riparian degradation has had the following effects: (a) destroying and eliminating breeding habitat for all stream animals, (b) preventing amphidromous egg and larval drift to the ocean, (c) obstructing postlarval recruitment back into the streams, and (d) facilitating invasive species establishment (9,22,33–35). Water is a critical and limited resource, not only to humans but also to the native stream organisms. Balancing these will take compromise and scientifically based freshwater resource management.

FRESHWATER RESOURCE USE AND MANAGEMENT

Historic Management

The ahupua’a system was the first freshwater management system in Hawaii. Developed by the ali’i (chiefs) of the first Hawaiians 1500–1600 years ago, it maintained adequate freshwater resources for the entire population of each island. The ahupua'a was what now is considered a watershed and extended from the headwater springs into the ocean. Along this mauka—makai continuum, the land along the stream was divided into pie-like slices called 'ili kuponos, that were designated to maka'ainana (commoners) and overseen by a chief-appointed konohiki. The commoners did not own the land or water, for they only maintained them for the chiefs. Each konohiki was appointed to a single ahupua'a, and each 'ili kupono was divided into kalo lo'i (taro patches). Stream water was diverted by pani wai (diversions) and carried through small 'auwai (ditches) to the lo'i. The lo'i were connected in a stair-step manner by additional ditches maintained by the responsible commoners. If the ditches were not maintained upstream, all downstream lo'i would be affected. Contrary to contemporary freshwater management, the stream water was always returned to the stream before it entered the ocean, and was never carried out of the watershed. Therefore, the water continually connected the highest mountain reaches to the lowland settlements near the sea, maintaining the mauka—makai continuum.

The early Hawaiians understood the connectivity of the land, freshwater, and sea. The ahupua'a system maintained adequate freshwater resources for human use while balancing ecological function. Hawaiians also understood the power and importance of water to their culture. For example, the Hawaiian word for water, wai, is the root for wealth (waiwai) and law (kanawai) (36). Over the next 60 years, native Hawaiians would find just how important water could be to foreigners, or haoles—those without breathe, or mana (spirit). The sugar cane industry completely changed freshwater resource management: water would be removed from the ahupua'a, along with much of the native Hawaiian culture.

Contemporary Management

The influence of western missionaries and merchants shifted the Hawaiian perception of water from a shared resource to a commodity that provided maximum use and greatest reward to plantation owners (37). After the arrival of Captain James Cook in 1778, freshwater management changed little until the The Great Mahele of 1848, enacted by King Kamehameha III under heavy influence by the decedents of original missionaries, the new owners of the sugar cane industry (and pineapple later). The Great Mahele was the first act to privatize land and water in Hawaii. For nearly 25 years the kings of Hawaii attempted to negotiate reciprocity treaties with the United States In 1876, King Kalakaua finally established a reciprocity treaty assuring duty-free exchange between Hawaii and the United States, giving sugar companies a competitive edge in the world market and giving Pearl Harbor to the United States, which was the same year of the first water licenses, the creation of the first private water company, and the construction of the diversion-ditch systems, which relocated millions of gallons of water from the windward watersheds to leeward sugar cane fields. According to Wilcox (36), one pound of sugar takes approximately 4000 pounds, or 500 gallons, of water.

The growth of sugar cane and pineapple took over and "transformed Hawaii from a traditional, insular, agrarian, and debt-ridden society into a multicultural, cosmopolitan, and prosperous one" (36). During this time, the number of sugar plantations rose from 5 in 1857 to 90 in 1884 (36). From the late 1870s to the mid-1900s, the Hawaiian sugar cane industry continued to grow, in part because of political access to surface and groundwater resources. By the early 1900s, almost every stream on the windward sides of each island was at least partially diverted, and in 1920, the sugar cane industry was diverting >800 mgd and pumping an additional 400 mgd from aquifers (36). Almost 20 years later, the entire city of Boston was only consuming 80 mdg (36). The privately developed surface water of Hawaii was quite different from publicly controlled surface water development of the western United States, which put control of water into the hands of western businessmen, those who would eventually contribute to the overthrow of the last Hawaiian Monarchy. (Several books are available that describe the sequence of events that led to the overthrow (38–40).)

With the developing agricultural industry, the population and ethnic diversity expanded as well. A larger labor force was needed to construct the ditches and diversions and work the agricultural fields. For cheap labor, the agricultural companies looked to Japan, China, and other Asian nations. This immigration resulted in several ethnic populations living and working on plantation property, creating mixed nonHawaiian communities that are the roots of the ethnic diversity found in Hawaii today. As the population and successful industries increased, the popularity of the islands grew in the mid-1900s, whereas the sugar cane industry met fierce competition from other nations, and has resulted in the slow demise of the former economic strength. With the buildup and maintained military presence of Pearl Harber from World War II, the economic focus of Hawaii saw a change from agriculture to military establishment to tourism that is now the economic base of the state. Along the southwestern coast of each island, numerous hotels, shopping malls, golf courses, and restaurants have been developed because most people prefer to vacation on the sunny, dry side of the island. However, similar to the sugar cane scenario, water is not readily available on the leeward side. Therefore, water remains diverted from streams, or pumped from dwindling freshwater aquifers, in order to accommodate tourists, water the green lawns, and fill hotel swimming pools and spas.

A BRIEF INTRODUCTION TO HAWAIIAN WATER LAW

Water Rights

The expansion of the sugar industry resulted in many water disputes between sugar companies, various landowners, and native Hawaiians. These disputes helped recognize the following water rights: (a) appurtenant, (b) riparian, (c) prescriptive, and (d) surplus (41). Appurtenant rights developed from ancient rights and were officially declared in the earliest Hawaiian water case, Peck vs. Baily (1867). This case determined that if land was entitled by a landowner to cultivate taro, than some stream water was also. Riparian rights permit water use to those who own land next to a stream; however, use must be reasonable and not harmful to other landowners (42). In riparian law, the focus is on maintaining stream integrity while allowing landowner priority uses (e.g., domestic drinking and washing) over nonpriority uses (e.g., irrigation, mining) (41). Both appurtenant and riparian water rights consider water as a common good. Prescriptive and surplus water rights address private ownership of water sources.

Prescriptive water rights are granted if a party has proven using water "belonging" to another party for an extended and continuous period of time (e.g., 20 years) (37). Surplus water is defined as the amount of water in a stream not covered by any prior water right (37). In court, cases of surplus water were heard independently, which precluded the establishment of defined standards for future disputes. For example, in the case of Hawaiian Commercial & Sugar Co. v. Wailuku Sugar Co. (1904), the court ruled that surplus water traveling through an ahupua'a belonged to the private land owner, but in Carter v. Territory (1917), the court concluded that surplus water was to be used reasonably according to riparian principles, thus shared among landowners. The inconsistent rulings and absence of an established in-stream flow standard left the status of surplus waters questionable until the state code in 1987.

Summary of Case Law

From the 1850s to the 1980s, the water rights of Hawaii were evolving according to case law, yet no standard criteria for the allocation, transport, and quantity of freshwater was resolved. There were several political, economical, and social reasons for no established criteria. First, the rise of the sugar cane industry boosted the economy, and with it came political power to the foreign owners. Second, during this period, the Hawaiian Islands shifted from a monarchy to a republic to a U.S. Territory, and finally became a U.S. state, which created an atmosphere of economic and political change that left many native Hawaiians in a state of social and political confusion (36), where they did not resist changes in water law, as it was not in their culture to protest actions of the King. As a result of this, there was difficulty in establishing a cause-effect relationship, and many of the villages most affected were too small to fight the wealthy plantation owners (36,37).

In 1978, the Hawaii State Constitution mandated that a water code and commission be established to manage water resources. And in the late 1980s, a Hawaii State Water Code and the Commission on Water Resource Management was passed by the Hawaii State Legislature (37). The State Water Code became a regulatory mechanism for state agencies and counties and required the Commission to monitor and guide water allocation by establishing minimum in-stream flow standards that were to enhance, protect, and re-establish beneficial in-stream uses. Current trends have been developing during the 1990s that are testing the utility of the Hawaii State Water Code. The first of several cases, and a landmark case for future petitions, was the Waiahole Combined Contested Case Hearing. In this case, the Hawaii Supreme Court ruled for the establishment of minimum in-stream flow standards and than any additional flow secondarily allocated for other uses. In-stream flow standards are currently being investigated. The Waiahole Ditch Case was the first test of the State Water Code, yet many similar cases are being petitioned at the time of this writing. The diminishing sugar industry is opening a new chapter in Hawaiian case law, a chapter that must not only consider economics but also "traditional and customary Hawaiian rights, protection and procreation of fish and wildlife, ecological balance, scenic beauty, public recreation, beneficial in-stream uses, and public interest" (36).

SUMMARY AND SYNTHESIS

The history of Hawaiian water resource issues is complex. The system of surface water management went through a dramatic change with the explosion of agriculture and the associated political power of missionary descendents; however, this explosion was inherently dependent on privately developed surface waters—a feedback proliferation of each other. The surface water development from the late 1800s through the mid-1900s drained watersheds of both water and native Hawaiian culture. The efficient removal of water high in the watersheds left a trickle downstream for native taro farmers. With the construction of massive diversion-ditch systems, native Hawaiians emigrated from the ahupua'a to build ditches and work sugar cane fields. At the same time, thousands of immigrants from China, Japan, and the Philippines melted into the sugar cane plantation farms, changing the demographics of Hawaii. The push by sugar businessmen to get an extended reciprocity treaty secured rights of Pearl Harbor to the United States; it also led to the coup of the Hawaiian Monarchy. At the same time, streams were being impacted by water removal and rapid riparian destruction, negatively affecting the native biological communities of the mauka–makai continuum.

The degradation of stream habitats in Hawaii has become an increasingly important issue to many native Hawaiians, scientists, private organizations, and individuals. Water resources have been, and will continue to be, a highly debated political issue. Water is necessary for agricultural, industrial, and municipal uses throughout Hawaii; however, in order to maintain the unique biodiversity of the streams, a compromise must be made between continued development and conservation. Thus, the future of the Hawaii's freshwater ecosystems and economic security is dependent on wise freshwater management and allocation, which should not be made in a scientific vacuum. Objective and sustainable answers can only be achieved with a solid scientific base, one free from political bias that has been the history of Hawaiian freshwater resources.

GROUND WATER

ACID MINE DRAINAGE: SOURCES AND TREATMENT IN THE UNITED STATES

Jeffrey G. Skousen
West Virginia University
Morgantown, West Virginia

Acid mine drainage (AMD) occurs when metal sulfides are exposed to oxidizing conditions. Leaching of reaction products into surface waters pollute over 20,000 km of streams in the United States alone. Mining companies must predict the potential of creating AMD by using overburden analyses. Where a potential exists, special handling of overburden materials and quick coverage of acid-producing materials in the backfill should be practiced. The addition of acid-neutralizing materials can reduce or eliminate AMD problems. Placing acid-producing materials under dry barriers can isolate these materials from air and water. Other AMD control technologies being researched include injection of alkaline materials (ashes and limestone) into abandoned underground mines and into buried acid material in mine backfills, remining of abandoned areas, and installation of alkaline recharge trenches. Chemicals used for treating AMD are $Ca(OH)_2$, CaO, NaOH, Na_2CO_3, and NH_3, with each having advantages under certain conditions. Under low-flow situations, all chemicals except $Ca(OH)_2$ are cost effective, whereas at high flow, $Ca(OH)_2$ and CaO are clearly the most cost effective. Floc, the metal hydroxide material collected after treatment, is disposed of in abandoned deep mines, refuse piles, or left in collection ponds. Wetlands remove metals from AMD through formation of oxyhydroxides and sulfides, exchange and organic complexation reactions, and direct plant uptake. Aerobic wetlands are used when water contains enough alkalinity to promote metal precipitation, and anaerobic wetlands are used when alkalinity must be generated by microbial sulfate reduction and limestone dissolution. Anoxic limestone drains are buried trenches of limestone that intercept AMD underground to generate alkalinity. Under anoxia, limestone should not be coated with Fe^{+3} hydroxides in the drain, which decreases the likelihood of clogging. Vertical flow wetlands pretreat oxygenated AMD with organic matter to remove oxygen and Fe^{+3}, and then the water is introduced into limestone underneath the organic matter. Open limestone channels use limestone in aerobic environments to treat AMD. Coating of limestone occurs, and the reduced limestone dissolution is designed into the treatment system. Alkaline leach beds, containing either limestone or slag, add alkalinity to acid water. At present, most passive systems offer short-term treatment and are more practical for installation on abandoned sites or watershed restoration projects where effluent limits do not apply and where some removal of acid and metals will benefit a stream.

Acid mine drainage (AMD) forms when sulfide minerals deep in the earth are exposed during coal and metal mining, highway construction, and other large-scale excavations. Upon exposure to water and oxygen, sulfide minerals oxidize to form acidic products, which then can be dissolved in water. The water containing these dissolved products often has a low pH, high amounts of dissolved metals such as iron (Fe) and aluminum (Al), and sulfate.

The metal concentrations in AMD depend on the type and quantity of sulfide minerals present, and the overall water quality from disturbed areas depends on the acid-producing (sulfide) and acid-neutralizing (carbonate) minerals contained in the disturbed rock. The carbonate content of overburden determines whether there is enough neutralization potential or base to counteract the acid produced from pyrite oxidation. Of the many types of acid-neutralizing compounds present in rocks, only carbonates (and some clays) occur in sufficient quantity to effectively neutralize acid-producing rocks. A balance between the acid-producing potential and neutralizing capacity of the disturbed overburden will indicate the ultimate acidity or alkalinity that might be expected in the material upon complete weathering.

Approximately 20,000 km of streams and rivers in the United States are degraded by AMD, but sulfide minerals occur throughout the world causing similar problems. About 90% of the AMD reaching streams originates in abandoned surface and deep mines. No company or individual claims responsibility for reclaiming abandoned mine lands and contaminated water flowing from these sites is not treated.

Control of AMD before land disturbance requires an understanding of three important factors: (1) overburden geochemistry, (2) method and precision of overburden handling and placement in the backfill during reclamation, and (3) the postmining hydrology of the site.

OVERBURDEN ANALYSES, HANDLING, AND PLACEMENT

Premining analysis of soils and overburden are required by law (1). Identifying the acid-producing or acid-neutralizing status of rock layers before disturbance aids in developing overburden handling and placement plans. Acid-base accounting provides a simple, relatively inexpensive, and consistent procedure to evaluate overburden chemistry. It balances potential acidity (based on total or pyritic sulfur content) against total neutralizers. Samples containing more acid-producing than acid-neutralizing materials are “deficient” and can cause AMD, whereas those rock samples with the reverse situation have “excess” neutralizing materials and will not cause AMD. Rock layers with equal proportions of each type of material should be subjected to leaching or weathering analyses (2). Kinetic tests such as humidity cells and leach columns are important because they examine the rate of acid-producing and neutralization reactions. This information from kinetic tests can supplement information given by acid-base accounting and help regulators in permitting decisions (3).

The prevailing approach to control AMD is to keep water away from pyritic material. Once overburden materials have been classified, an overburden handling and placement plan for the site can be designed.

Segregating and placing acid-producing materials above the water table is generally recommended (2,4). Where alkaline materials overwhelm acid-producing materials, no special handling is necessary. Where acid-producing materials cannot be neutralized by onsite alkaline materials, it is necessary to import a sufficient amount to neutralize the potential acidity or the disturbance activity may not be allowed.

Postmining Hydrology

The hydrology of a backfill and its effect on AMD are complex. Generally, the porosity and hydraulic conductivity of the materials in a backfill are greater than those of the consolidated rock overburden that existed before mining, and changes in flow patterns and rates should be expected after mining (5). Water does not move uniformly through the backfill by a consistent wetting front. As water moves into coarse materials in the backfill, it follows the path of least resistance and continues downward through voids or conduits until it encounters a barrier or other compacted layer. Therefore, the chemistry of the water from a backfill will reflect only the rock types encountered in the water flow path, and not the entire geochemistry of the total overburden (6).

Diverting surface water above the site to decrease the amount of water entering the mined area is highly recommended. If it cannot be diverted, incoming water can be treated with limestone to improve water quality. Under certain conditions, pyritic material can be placed where it will be rapidly and permanently inundated, thereby preventing oxidation. Inundation is only suggested where a water table may be reestablished, such as below drainage deep mines (see WET COVERS).

CONTROL OF AMD

Acid mine drainage control can be undertaken where AMD exists or is anticipated. Control methods treat the acid-producing rock directly and stop or retard the production of acidity. Treatment methods add chemicals directly to acidic water exiting the rock mass. Companies disturbing land in acid-producing areas must often treat AMD, and they face the prospect of long-term water treatment and its liabilities and expense. Cost-effective methods, which prevent the formation of AMD at its source, are preferable. Some control methods are most suited for abandoned mines, and others are only practical on active operations. Other methods can be used in either setting.

Land Reclamation

Backfilling (regrading the land back to contour) and revegetation together are effective methods of reducing acid loads from disturbed lands (7). Water flow from seeps can be reduced by diversion and reclamation, and on some sites where flow may not be reduced, water quality can change from acid to alkaline by proper handling of overburden. Diverting surface water or channeling surface waters to control volume, direction, and contact time can minimize the effects of AMD on receiving streams. Surface diversion involves construction of drainage ditches to move surface water quickly off the site before infiltration or by providing impervious channels to convey water across the disturbed area.

Alkaline Amendment to Active Disturbances

Certain alkaline amendments can control AMD from acid-producing materials (8–11). All alkaline amendment schemes rely on acid-base accounting or kinetic tests to identify the required alkalinity for neutralization of acidic materials. Special handling of overburden seeks to blend acid-producing and acid-neutralizing rocks in the disturbance/reclamation process to develop a neutral rock mass. The pit floor or material under coal is often rich in pyrite, so isolating it from groundwater may be necessary by building highwall drains (which move incoming groundwater away from the pit floor) or placing impermeable barriers on the pit floor. Acid-forming material can be compacted or capped within the spoil (12).

If insufficient alkalinity is available in the spoil, then external sources of alkalinity must be imported (13,14). Limestone is often the least expensive and most readily available source of alkalinity. It has a neutralization potential of between 75% and 100%, and it is safe and easy to handle. On the other hand, it has no cementing properties and cannot be used as a barrier. Fluidized bed combustion ashes generally have neutralizing amounts of between 20% and 40%, and they tend to harden into cement after wetting (15). Other power-generation ashes, like flue gas desulfurization products and scrubber sludges, may also have significant neutralization potential, which make them suitable alkaline amendment materials (16). Other materials, like kiln dust, produced by lime and cement kilns, or lime muds, grit, and dregs from pulp and paper industries contain neutralization products (10). Steel slags, when fresh, have neutralizing amounts from 45% to 90%. Slags are produced by several processes, so care is needed to ensure that candidate slags are not prone to leaching metal ions like Cr, Mn, and Ni. Phosphate rock has been used in some studies to control AMD. It may react with Fe released during pyrite oxidation to form insoluble coatings (17), but phosphate usually costs much more than other calcium-based amendments and is needed in about the same amounts (18).

Alkaline Recharge Trenches

Alkaline recharge trenches (19) are surface ditches or cells filled with alkaline material, which can minimize or eliminate acid seeps through an alkaline-loading process with infiltrating water. Alkaline recharge trenches were constructed on top of an 8-ha, acid-producing coal refuse disposal site, and after 3 years, the drainage water showed 25% to 90% acidity reductions with 70% to 95% reductions in Fe and sulfate (20). Pumping water into alkaline trenches greatly accelerates the movement of alkalinity into the backfill and can cause acid seeps to turn alkaline (21).

Dry Barriers

Dry barriers retard the movement of water and oxygen into areas containing acid-producing rock. These “water control” technologies (4) include impervious membranes, dry seals, hydraulic mine seals, and grout curtains/walls. Surface barriers can achieve substantial reductions in water flow through piles, but generally they do not control AMD completely. Grouts can separate acid-producing rock and groundwater. Injection of grout barriers or curtains may significantly reduce the volume of groundwater moving through backfills. Gabr et al. (22) found that a 1.5-m-thick grout wall (installed by pumping a mixture of Class F fly ash and Portland cement grout into vertical boreholes near the highwall) reduced groundwater inflow from the highwall to the backfill by 80%, which results in some seeps drying up and others being substantially reduced in flow. At the Heath Steele Metal Mine in New Brunswick, a soil cover was designed to exclude oxygen and water from a tailings pile (23). It consisted of a 10-cm gravel layer for erosion control, 30-cm gravel/sand layer as an evaporation barrier, 60-cm compacted till (conductivity of 10^{-6} cm/sec), 30-cm sand, and pyritic waste rock. This barrier excluded 98% of precipitation, and oxygen concentrations in the waste rock dropped from 20% initially to around 1%. At the Upshur Mining Complex in West Virginia, Meek (12) reported covering a 20-ha spoil pile with a 39-mil PVC liner, and this treatment reduced acid loads by 70%.

Wet Covers

Disposal of sulfide tailings under a water cover, such as in a lake or fjord, is another way to prevent acid generation by excluding oxygen from sulfides. Wet covers also include flooding of aboveground tailings in ponds. Fraser and Robertson (24) studied four freshwater lakes used for subaqueous tailings disposal and found that the reactivity of tailings under water was low and that there were low concentrations of dissolved metals, thereby allowing biological communities to exist.

Alkaline Amendment to Abandoned Mines

Abandoned surface mines comprise huge volumes of spoil of unknown composition and hydrology. Abandoned underground mines are problematic because they are often partially caved and flooded, cannot be accessed, and have unreliable or nonexistent mine maps. Re-handling and mixing alkalinity into an already reclaimed backfill is generally prohibitively expensive.

Filling abandoned underground mine voids with nonpermeable materials is one of the best methods to prevent AMD. Underground mine voids are extensive (a 60-ha mine with a coal bed height of 1.5 m and a recovery rate of 65% would contain about 600,000 m^3 of voids), so fill material and the placement method must be cheap. Mixtures of Class F fly ash and 3–5% Portland cement control subsidence in mined-under residential areas and these slurries are generally injected through vertical boreholes at between 8- and 16-m centers. Pneumatic (air pressure) and slurry injection for placing fly ash in abandoned underground mines can extend the borehole spacing to about 30 m (25). On reclaimed surface mines still producing AMD, researchers in Pennsylvania saw small improvements in water quality after injecting coal combustion residues into buried pods of pyritic materials.

Remining and Reclamation

“Remining” means returning to abandoned surface or underground mines for further coal removal. Where AMD occurs, remining reduces acid loads by (1) decreasing infiltration rates, (2) covering acid-producing materials, and (3) removing the remaining coal, which is the source of most of the pyrite. Hawkins (26) found contaminant loads of 57 discharges from remined sites in Pennsylvania to be reduced after remining and reclamation. Short-term loads were sometimes increased during the first six months after remining and reclamation, but reduction in loads after six months resulted from decreased flow rather than large changes in concentrations. Ten remining sites in Pennsylvania and West Virginia were reclaimed to current standards (which included eliminating highwalls, covering refuse, and revegetating the entire area), and all sites had improved water quality (15).

CHEMICAL TREATMENT OF AMD

If AMD problems develop during mining or after reclamation, a plan to treat the discharge must be developed. A water treatment system consists of an inflow pipe or ditch, a storage tank or bin holding the treatment chemical, a valve to control its application rate, a settling pond to capture precipitated metal oxyhydroxides, and a discharge point. At the discharge point, water samples are analyzed to monitor whether specified parameters are being attained. Water discharge permits (NPDES) on surface mines usually require monitoring of pH, total suspended solids, and Fe and Mn concentrations. The type and size of a chemical treatment system is based on flow rate, pH, oxidation status, and concentrations of metals in the AMD. The receiving stream’s designated use and seasonal fluctuations in flow rate are also important. After evaluating these variables over a period of time, the operator can consider the economics of different chemicals.

Six chemicals treat AMD (Table 1). Each is more or less appropriate for a specific condition. The best choice depends on both technical (acidity levels, flow, and the types and concentrations of metals) and economic factors (chemical prices, labor, machinery and equipment, treatment duration, and interest rates). Enough alkalinity must be added to raise pH to between 6 and 9 so insoluble metal hydroxides will form and settle out. Treatment of AMD with high Fe (ferric) concentrations often affords coprecipitation of other metals with the Fe hydroxide, thereby removing them from AMD at a lower pH. Limestone has been used for decades to raise pH and precipitate metals in AMD. It has the lowest material cost and is the safest and easiest to handle of the AMD chemicals. Unfortunately, it is limited because of its low solubility and tendency to develop an external coating, or armor, of $Fe(OH)_3$ when added to AMD. Fine-ground limestone may be dumped in streams directly or the limestone may be pulverized by water-powered rotating drums and metered into the stream. Limestone has also treated AMD in anaerobic (anoxic limestone drains) and aerobic environments (open limestone channels).

Table 1. Chemical Compounds Used in AMD Treatment

Common Name	Chemical Name	Formula	Conversion Factor[a]	Neutralization Efficiency[b]	2000 Cost[c] $ per Mg or L Bulk	<Bulk
Limestone	Calcium carbonate	$CaCO_3$	1.00	30%	$11	$16
Hydrated Lime	Calcium hydroxide	$Ca(OH)_2$	0.74	90%	$66	$110
Pebble Quicklime	Calcium oxide	CaO	0.56	90%	$88	$264
Soda Ash	Sodium carbonate	Na_2CO_3	1.06	60%	$220	$350
Caustic Soda (solid)	Sodium hydroxide	NaOH	0.80	100%	$750	$970
20% Liquid Caustic	Sodium hydroxide	NaOH	784	100%	$0.06	$0.16
50% Liquid Caustic	Sodium hydroxide	NaOH	256	100%	$0.29	$0.33
Ammonia	Anhydrous ammonia	NH_3	0.34	100%	$330	$750

[a] The conversion factor may be multiplied by the estimated milligrams acid/yr to get milligrams of chemical needed for neutralization per year. For liquid caustic, the conversion factor gives liters needed for neutralization.

[b] Neutralization efficiency estimates the relative effectiveness of the chemical in neutralizing AMD acidity. For example, if 100 Mg of acid/yr was the amount of acid to be neutralized, then it can be estimated that 82 Mg of hydrated lime would be needed to neutralize the acidity in the water (100(0.74)/0.90).

[c] Price of chemical depends on the quantity being delivered. Bulk means delivery of chemical in a large truck, whereas < Bulk means purchased in small quantities. Liquid caustic prices are for liters. Others in milligrams.

Lime

Hydrated lime is common for treating AMD. As a powder, it tends to be hydrophobic, and extensive mechanical mixing is required for dissolution. Hydrated lime is particularly useful and cost effective in large-flow, high-acidity situations where a lime treatment plant with a mixer/aerator is constructed to help dispense and mix the chemical with the water (27). Hydrated lime has limited effectiveness if a very high pH (>9) is required to remove ions such as Mn. Unfortunately, increasing the lime rate increases the volume of unreacted lime that enters the floc-settling pond.

Pebble quicklime (CaO) is used with the Aquafix Water Treatment System using a water wheel concept (28). A water wheel is turned based on water flow, which causes a screw feeder to dispense the chemical. This system was initially used for small and/or periodic flows of high acidity because CaO is very reactive, but water wheels have been attached to large silos for high-flow/high-acidity situations. Tests show an average of 75% cost savings over NaOH systems and about 20% to 40% savings over NH_3 systems.

Soda Ash

Soda ash (Na_2CO_3) generally treats AMD in remote areas with low flow and low amounts of acidity and metals. This choice is usually based on convenience rather than on chemical cost. Soda ash comes as solid briquettes and is gravity fed into water through bins. The number of briquettes used per day is determined by the rate of flow and quality of the water. One problem is that the briquettes absorb moisture, expand, and stick to the corners of the bin and will not drop into the stream. For short-term treatment, some operators use a much simpler system that employs a wooden box or barrel with holes that allows water inflow and outflow. The operator simply fills the barrel with briquettes on a regular basis and places the barrel in the flowing water. This system offers less control of the amount of chemical used.

Caustic Soda

Caustic soda (i.e., lye, NaOH) is often used in remote low-flow, high-acidity situations, or if Mn concentrations in the AMD are high. The system can be gravity fed by dripping liquid NaOH directly into the AMD. Caustic is very soluble, disperses rapidly, and raises the pH quickly. Caustic should be applied at the surface of ponds because the chemical is denser than water. The major drawbacks of using liquid NaOH for AMD treatment are high cost and dangers in handling.

Ammonia

Ammonia compounds (NH_3 or NH_4OH) are extremely hazardous. NH_3 is compressed and stored as a liquid but returns to the gaseous state when released. Ammonia is extremely soluble, reacts rapidly, and can raise the pH of receiving water to 9.2. At pH 9.2, it buffers the solution to further pH increases, and therefore very high amounts of NH_3 must be added to go beyond 9.2. Injection of NH_3 into AMD is one of the quickest ways to raise water pH, and it should be injected near the bottom of the pond or water inlet because NH_3 is less dense than water. NH_3 is cheap, and a cost reduction of 50% to 70% is usually realized when NH_3 is substituted for NaOH (29). Major disadvantages of using NH_3 include (1) the hazards; (2) uncertainty concerning nitrification, denitrification, and acidification downstream; and (3) consequences of excessive application rates, which cause toxic conditions to aquatic life.

Costs of Treating AMD

Costs were estimated for five treatment chemicals under four sets of flow and acid concentration conditions [Table 1 from Skousen et al. (30)]. Na_2CO_3 had the highest labor requirements (10 hours per week) because the dispensers must be filled by hand and inspected frequently. Caustic had the highest reagent cost per mole of acid-neutralizing capacity, and Na_2CO_3 had the second highest. Hydrated lime treatment systems had the highest installation costs of the five chemicals because of the need to construct a lime treatment plant and install a pond aerator. However, the cost of $Ca(OH)_2$ was very low, and the combination of high installation costs and low reagent cost made $Ca(OH)_2$ systems particularly appropriate for long-term treatment of high-flow/high-acidity conditions.

For a 5-year treatment, NH_3 had the lowest annual cost for the low-flow/low-acid situation. Pebble quicklime had about the same cost as the NH_3 system, but slightly higher installation costs. Caustic was third because of its high labor and reagent costs, and Na_2CO_3 was fourth because of high labor costs. Hydrated lime was the most expensive because of its high installation costs. At high-flow/high-acidity, the $Ca(OH)_2$ and CaO systems were clearly the cheapest treatment systems (annual costs of about $250,000 less than NH_3, the next best alternative).

After chemical treatment, the treated water flows into sedimentation ponds so metals in the water can precipitate. All AMD treatment chemicals cause the formation of metal hydroxide sludge or floc. Sufficient residence time of the water (dictated by pond size and depth) is important for adequate metal precipitation. The amount of metal floc generated depends on water quality and quantity, which in turn determines how often the ponds must be cleaned. Knowing the chemical and AMD being treated will provide an estimate of the stability of metal compounds in the floc. Floc disposal options include (1) leaving it submerged indefinitely, (2) pumping or hauling it to abandoned deep mines or to pits dug on surface mines, and (3) dumping it into refuse piles. Pumping flocs onto land and letting them age and dry is a good strategy for disposal, because they become crystalline and behave like soil material.

Each AMD is unique, requiring site-specific treatment. Each AMD source should be tested with various chemicals by titration tests to evaluate the most effective chemical for precipitation of the metals. The costs of each AMD treatment system based on neutralization (in terms of the reagent cost, capital investment, and maintenance of the dispensing system) and floc disposal should be evaluated to determine the most cost-effective system.

PASSIVE TREATMENT OF AMD

Active chemical treatment of AMD is often an expensive, long-term proposition. Passive treatment systems have been developed that do not require continuous chemical inputs and that take advantage of natural chemical and biological processes to cleanse contaminated mine waters. Passive technologies include constructed wetlands, anoxic limestone drains, vertical flow wetlands (also known as SAPS), open limestone channels, and alkaline leach beds (Fig. 1). In low-flow and low-acidity situations, passive systems can be reliably implemented as a single permanent solution for many AMD problems.

Constructed Wetlands

Wetlands are of two basic types: aerobic and anaerobic. Metals are retained within wetlands by (1) formation of metal oxides and oxyhydroxides, (2) formation of metal sulfides, (3) organic complexation reactions, (4) exchange with other cations on negatively charged sites, and (5) direct uptake by living plants. Other beneficial reactions in wetlands include generation of alkalinity caused by microbial mineralization of dead organic matter, microbial dissimilatory reduction of Fe oxyhydroxides and SO_4, and dissolution of carbonates.

Aerobic wetlands consist of relatively shallow ponds (<30 cm) with wetland vegetation. Aerobic wetlands promote metal oxidation and hydrolysis, thereby causing precipitation and physical retention of Fe, Al, and Mn oxyhydroxides. Successful metal removal depends on dissolved metal concentrations, dissolved oxygen content, pH and net acidity of the mine water, the presence of active microbial biomass, and detention time of the water in the wetland. The pH and net acidity/alkalinity of the water are particularly important because pH influences both the solubility of metal hydroxide precipitates and the kinetics of metal oxidation and hydrolysis. Therefore, aerobic wetlands are best used in conjunction with water that contains net alkalinity to neutralize metal acidity.

Anaerobic wetlands consisting of deep ponds (>30 cm) with substrates of soil, peat moss, spent mushroom compost, sawdust, straw/manure, hay bales, or other organic mixtures, often underlain or admixed with limestone. Anaerobic wetlands are most successful when used to treat small flows of acidic water. Anaerobic wetlands use chemical and microbial reduction reactions to precipitate metals and neutralize acidity. The water infiltrates through a thick permeable organic subsurface that becomes anaerobic because of high biological oxygen demand. Other chemical mechanisms that occur *in situ* include metal exchanges, formation and precipitation of metal sulfides, microbial-generated alkalinity, and formation of carbonate alkalinity (because of limestone dissolution). As anaerobic wetlands produce alkalinity, they can be used in net acidic and high dissolved oxygen (>2 mg/L) AMD. Microbial mechanisms of alkalinity production are critical to long-term AMD treatment. Under high acid loads (>300 mg/L), pH-sensitive microbial activities are eventually overwhelmed. At present, the sizing value for Fe removal in these wetlands is 10 gs per day per meter squared (31).

Sorption onto organic materials (such as peat and sawdust) can initially remove 50% to 80% of the metals in AMD (32), but the exchange capacity declines with time. Over the long term, metal hydroxide precipitation is the predominant form of metal retention in a wetland. Wieder (33) reported up to 70% of the Fe in a wetland to be composed of Fe^{+3} oxyhydroxides, whereas the other 30% is reduced and combined with sulfides (34).

Sulfate reducing bacteria (SRB) reactors have been used to generate alkalinity by optimizing anaerobic conditions. Good success has been noted for several systems receiving high and low flows (35,36).

Anoxic Limestone Drains

Anoxic limestone drains are buried cells or trenches of limestone into which anoxic water is introduced. The limestone raises pH and adds alkalinity. Under anoxic conditions, the limestone does not coat or armor with Fe hydroxides because Fe^{+2} does not precipitate as $Fe(OH)_2$ at pH 6.0. Faulkner and Skousen (37) reported both successes and failures among 11 anoxic drains in WV. Failures resulted when ferric iron and Al precipitate as hydroxides in the limestone causing plugging and coating.

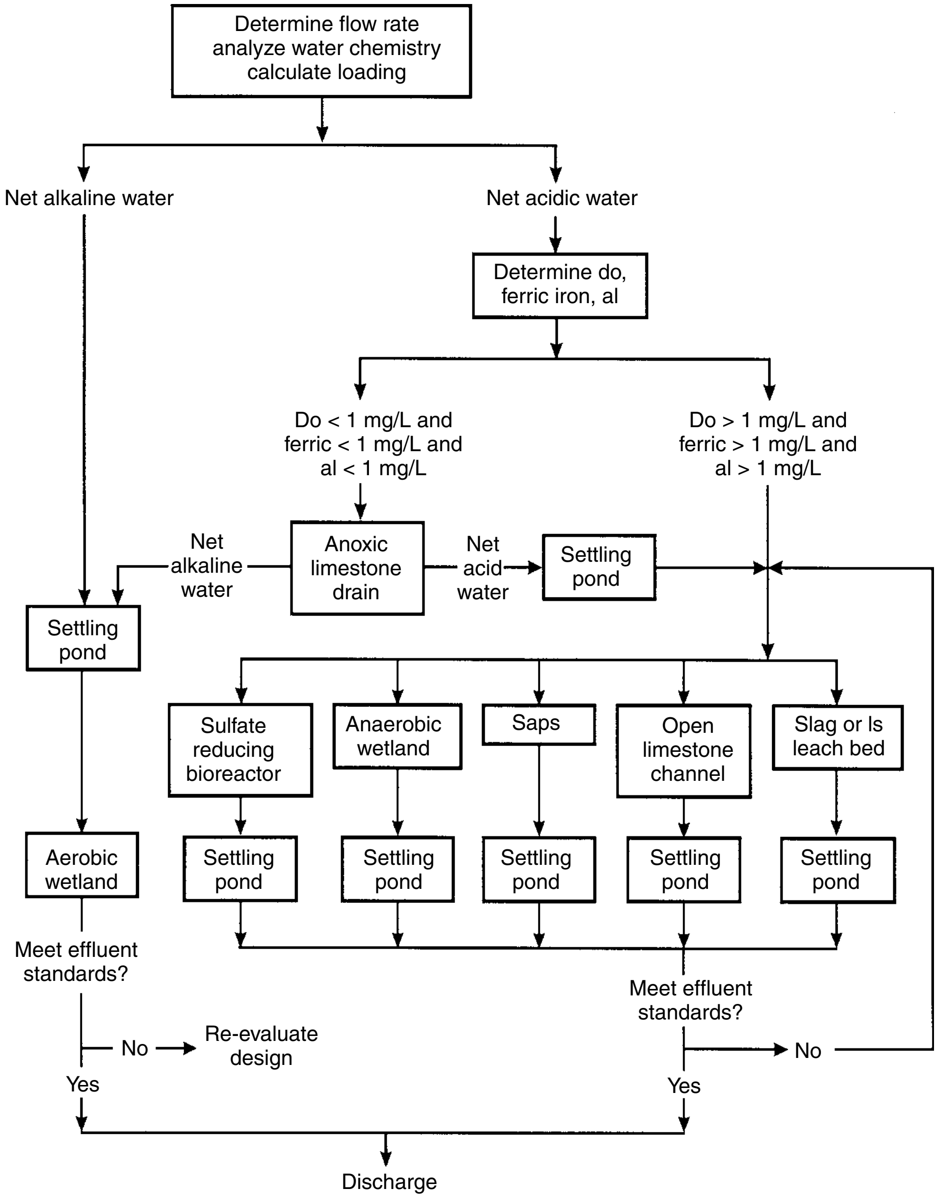

Figure 1. Diagram of possible passive treatment systems to treat mine water based on water flow and chemistry.

Longevity of treatment is a major concern for anoxic drains, especially in terms of water flow through the limestone. Selection of the appropriate water and environmental conditions is critical for long-term alkalinity generation in an anoxic drain. Eventual clogging of the limestone pore spaces with precipitated Al and Fe hydroxides, and gypsum is predicted (38). For optimum performance, no Fe^{+3}, dissolved oxygen, or Al should be present in the AMD. Like wetlands, anoxic limestone drains may be a solution for AMD treatment for specific water conditions or for a finite period after which the system must be replenished or replaced.

Vertical Flow Wetlands

In these modified wetlands [called SAPS by Kepler and McCleary (39)], 1 to 3 m of acid water is ponded over an organic compost of 0.2 to 0.3 m, underlain by 0.5 to 1 m of limestone. Below the limestone are drainage pipes that convey the water into an aerobic pond where metals are precipitated. The hydraulic head drives ponded water through the anaerobic organic compost, where oxygen stripping as well as Fe and sulfate reduction can occur before water entry into the limestone. Water with high metal loads can be successively cycled through additional wetlands. Iron and Al clogging of limestone and pipes can be removed by flushing the system (40). Much work is being done on these wetlands presently, and refinements are being made for better water treatment.

Open Limestone Channels

Open limestone channels are another means of introducing alkalinity to acid water (41). We usually assume that armored limestone ceases to dissolve, but Ziemkiewicz et al. (42) found armored limestone to be 50% to 90% effective in neutralizing acid compared with unarmored limestone. Seven open channels in the field reduced acidity in AMD by 4% to 62% compared with a 2% acid reduction in a sandstone channel. Open limestone channels show promise for neutralizing AMD in watershed restoration projects and AML reclamation projects where there can be only a one-time installation cost, little to no maintenance is required, and water exiting the system does not have to meet water quality standards. Long channels of limestone can convey acid water to a stream or other discharge point. Cross sections of channels can be designed with calculated amounts of limestone (which will become armored) to treat the water. Open limestone channels work best on steep slopes (>20%), where flow velocities keep metal hydroxides in suspension, thereby limiting plugging. If constructed correctly, open limestone channels should be maintenance free and provide AMD treatment for decades.

Alkaline Leach Beds

Limestone, when placed in an open pond or leach bed, will dissolve slowly over time and continually add alkalinity to water unless the limestone gets coated with metal hydroxides, thereby reducing its dissolution rate (41). Therefore, limestone treatment in aerobic systems works best in low-pH, metal-free water, and can add alkalinity to streams before encountering acid water downstream (42). As limestone generally reacts relatively slowly under field conditions, steel slag, a byproduct of steel making and composed of hydrated amorphous silica and calcium compounds, can be used as an alkaline material to add alkalinity to water. Steel slags have high neutralization potentials (from about 50–70%), can generate exceptionally high levels of alkalinity in water, and do not armor (43). Steel slag fines can be used in leach beds. Effluents from slag leach beds attain high pH (>10) and have alkalinity concentrations in the thousands of milligrams/liter. Slag leach beds may receive AMD directly, or effluent from "fresh water" beds may be combined with an AMD source downstream to treat acid indirectly.

SUMMARY

Acid mine drainage occurs when metal sulfides are oxidized. Leaching of reaction products into surface waters pollute over 20,000 km of streams in the United States alone. Companies must predict AMD before mining by using overburden analyses. On sites where a potential exists, special handling of overburden materials and quick coverage of acid-producing materials in the backfill should be practiced. Alkaline addition with materials such as kiln dust and FBC ash can reduce or completely eliminate AMD problems. Other control techniques include dry barriers, wet barriers, injection of alkaline materials into underground mines, remining of abandoned areas, and alkaline recharge trenches. Five chemicals typically treat AMD, and each has characteristics that make it suitable for specific applications. Companies must select a chemical that treats the water adequately and cost-effectively. Passive systems are low maintenance systems that are implemented on abandoned mine land and stream restoration projects. Certain systems are more suited to specific water quality and show good success where the acid levels do not overwhelm the system.

AQUIFERS

THOMAS HARTER
University of California
Davis, California

GENERAL DEFINITION

An aquifer is a geologic formation or geologic unit from which significant amounts of groundwater can be pumped for domestic, municipal, or agricultural uses. The four major types of rock formations that serve as aquifers are unconsolidated sand and gravel, sandstone, carbonate rocks, and fractured volcanic rocks. Aquifers may also occur in other geologic formations, particularly in fractured zones of igneous, metamorphic, or sedimentary rocks.

ORIGIN OF THE WORD

The word aquifer was probably adopted around the early twentieth century from the French word aquifère, which originates from the two Latin words aqua (water) and ferre (to carry, to bear). Hence, literally translated from Latin, aquifer means 'that which carries water.'

FURTHER DEFINITIONS

There is no strict definition of the hydrogeologic attributes or volumetric extent necessary to make a geologic formation or geologic unit an aquifer. Rather, the term aquifer is used for local formations that have relatively higher permeability than surrounding formations. Geologic units that form an aquifer in one setting may therefore not be considered to constitute an aquifer in other settings. For example, a small intermontane valley aquifer that consists of very shallow, sandy loam deposits a few feet thick may supply enough water to maintain a pumping rate of 0.5–2 gallons per minute, enough for domestic water supply wells and some stock supply wells. This may be significantly more water than would be provided by the hardrock formations underlying and bounding such a shallow aquifer. In contrast, the same sandy loam deposits of the same thickness would not be considered an aquifer if they were part of an unconsolidated sedimentary sequence in a larger alluvial basin, where gravel and sand aquifers yield from 50 to more than 1,000 gallons per minute.

ROLE OF AN AQUIFER IN THE HYDROLOGIC CYCLE

Aquifers are part of the hydrologic cycle. They receive water through

- recharge from precipitation,
- recharge from irrigation return water,
- seepage from rivers and streams,
- lateral transfer of water from neighboring aquifer basins, and
- leakage from aquifer formations situated either above or below the aquifer.

Water that collects in aquifers from those sources over periods of years, decades, centuries, and even millennia is discharged back to the surface through (Fig. 1)

- springs,
- subsurface discharge into rivers and streams,
- lateral outflow to downgradient aquifers,
- vertical leakage to overlying or underlying aquifers, and
- man-made wells.

LIMITATION TO FORMATIONS WITH APPROPRIATE WATER QUALITY

The term aquifer is applied to formations that produce low to moderate salinity water (appropriate for domestic, municipal, or agricultural uses). Geologic formations containing exclusively brackish or saline groundwater (even if they are made of highly permeable material) are typically not referred to as aquifers unless the salinity was induced through human activity (e.g., in seawater intrusion, which is the advance of saline seawater into an overpumped aquifer).

AQUIFER SIZE

Aquifers can be vastly different in size: a small local aquifer in a mountainous setting may be only a few feet thick and extend over an area of a few acres to tens of acres. Other aquifers span entire regions. For example, the Ogallala aquifer in the western-central United States underlies most of the High Plains region, which extends

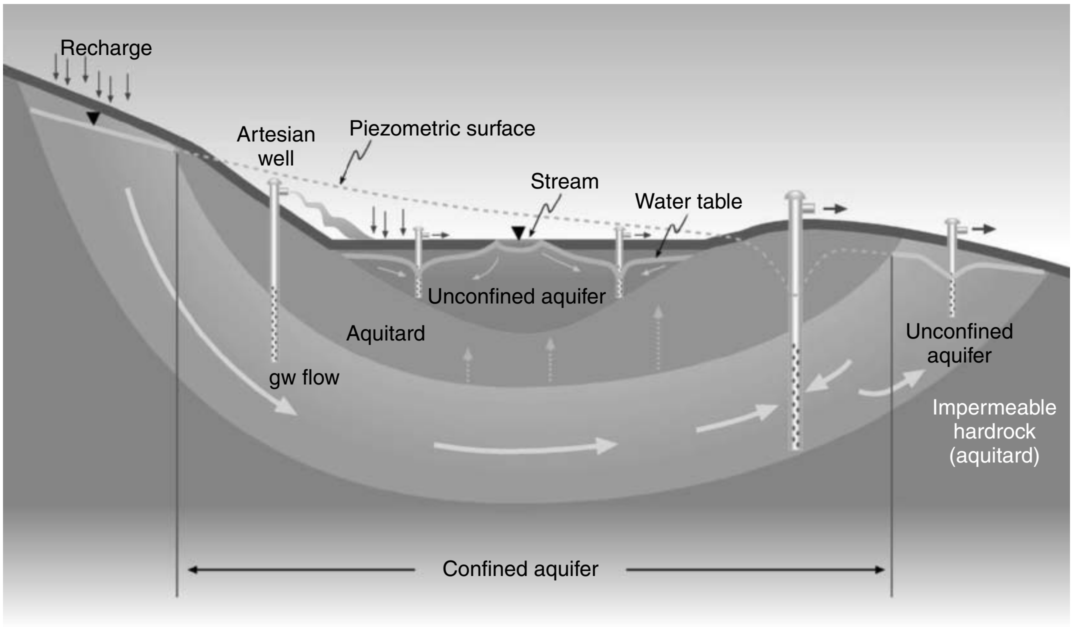

Figure 1. Schematic representation of uncontinued aquifers, confined aquifers, aquitards, and aquicludes. Blade vertical arrows indicate recharge. Black horizontal arrows indicate pumping. Light colored arrows indicate the direction of groundwater movement.

eastward from the Rocky Mountains through parts of Texas, Oklahoma, Colorado, Kansas, and Nebraska. The aquifer consists of alluvial sediments, predominantly sands and gravel. It is an important production aquifer.

An aquifer is characterized by its geologic extent (regional extent and thickness), the type of geologic formations that makes up the aquifer, the hydraulic conductivity, the transmissivity (which is defined as the product of hydraulic conductivity and aquifer thickness), the specific yield (the drainable porosity), the specific storage (the amount of water and rock compressed by hydrostatic pressure in a confined aquifer, see below), and the specific capacity (specific capacity is the amount of water pumped from a well per foot of water level drawdown created by pumping). The hydraulic conductivity of aquifers typically ranges from 1 m/day to more than 100 m/day. The specific capacity of wells located in aquifers may range from less than 0.1 gpm/ft (small, low-yielding aquifers suitable for domestic water supplies) to more than 100 gpm/ft (large production aquifers suitable for municipal and irrigation pumping).

AQUIFER CHARACTERIZATION

The amount of water that can be pumped from an aquifer depends primarily on four parameters: the hydraulic conductivity (also called the permeability) of the aquifer, the thickness of the aquifer, the specific yield or specific storage of the aquifer (related mostly to its porosity), and the amount of competition for water between wells. All four of these may change from location to location. The amount of pumping wells and the rate at which wells are pumping may be different from area to area; the thickness of the aquifer naturally changes with the thickness of the geologic formation. With respect to hydraulic conductivity, porosity, and specific yield or specific storage, hydrogeologists have found that small variations that occur in the geologic composition of aquifer formations often result in large localized changes in hydraulic conductivity. This latter phenomenon is referred to as “natural aquifer heterogeneity.” As a result of all this variability, each well within the same aquifer will have a different specific capacity. Sometimes, the specific capacity of wells can vary quite significantly from well to well, especially in fractured rock aquifers, but also in unconsolidated aquifers with sand and gravel.

Hydraulic conductivity, thickness, and specific yield or specific storage of an aquifer are determined indirectly by using literature values available for specific geologic formations, by using computer models in conjunction with local observations of groundwater fluxes or groundwater table fluctuations, or directly by performing an aquifer test (pumping test).

AQUIFERS, AQUITARDS, AND AQUICLUDES

Aquifers are the major hydrogeologic units within the hydrogeologic framework of a region from which groundwater is or can be extracted. The description of local or regional hydrogeology centers around the description of aquifers, that is, of those geologic formations with the highest significance—locally or regionally—with respect to (potential) groundwater production. Geologic formations that bound aquifers are referred to as aquicludes or aquitards. Aquicludes are, for all practical purposes, impermeable. Important aquicludes are thick, continuous clay formations and unfractured igneous rocks. Aquitards are geologic formations that have a lower hydraulic conductivity than adjacent (aquifer) formations and therefore act as a partial barrier to groundwater flow between overlying aquifers. Aquitards can consist of material similar to aquifers, but either the amount of fine sediments is much larger (in unconsolidated formations) relative to the aquifer formation, or the degree of fracturing and size of fractures is smaller than that in the aquifer formation (in hardrock formations).

CONFINED AND UNCONFINED AQUIFERS

Aquifers can be either unconfined or confined, depending on the existence of an overlying aquitard or aquiclude. In an unconfined aquifer, there is no overlying aquitard or aquiclude. Recharge to the aquifer from the land surface or from and to streams is not restricted. The water table moves freely up and down, depending on the water stored, added to, or removed from the unconfined aquifer. The water level in a borehole drilled into an unconfined aquifer will be the same as the water level in the aquifer (if we ignore the effects of the capillary fringe).

In a confined aquifer, on the other hand, water is "sandwiched" between two aquitards or between an aquitard and an aquiclude above and below the aquifer. Water in a confined aquifer is under hydrostatic pressure created by the weight of the overlying geologic formations and the water pressure created by the higher water levels in the usually remote recharge area of a confined aquifer. Due to the pressure in a confined aquifer, the water level in a borehole drilled into a confined aquifer will rise significantly above the top of the aquifer. An artesian well occurs where the pressure is so large that the water level in a well drilled into the confined aquifer rises above the land surface. A confined aquifer does not have a water table—it is completely filled with groundwater. The water level in wells drilled into a confined aquifer, instead, corresponds to the hydrostatic pressure head or potentiometric surface of the aquifer, which is located higher than the upper boundary of the aquifer itself. If the hydrostatic pressure head falls below the top of the confined aquifer, it becomes unconfined.

An aquifer that is confined by an aquitard rather than an aquiclude is referred to as a "leaky aquifer" or a "semiconfined aquifer." The aquitard is not always a contiguous layer of less permeable material. Local accumulations of multiple, smaller clay lenses and other clay-rich or otherwise impermeable layers dispersed within a more permeable formation may render the entire formation an aquitard. The actual low permeable lenses are not contiguous, but the overall effect of their presence within such a heterogeneous formation on the regional aquifer below is identical to that of a continuous aquitard formation.

PERCHED WATER TABLE

Occasionally, water collects above an impermeable or low permeability layer within the unsaturated (aerated) zone and forms a "perched" water table. By definition, a "perched" water table is a saturated groundwater zone separated from the aquifer below by a zone that is unsaturated or aerated. This should not be confused with an unconfined shallow aquifer that is separated from a deeper confined aquifer through thick but saturated layers of clay.

ARTIFICIAL RECHARGE OF UNCONFINED AQUIFER

INTRODUCTION

Groundwater plays a major role in augmenting water supply to meet the ever-increasing domestic, agricultural, and industrial demands. Increasing dependence of water supply on groundwater resources is resulting in increasing use of aquifers as a source of fresh water supply and subsurface reservoir for storing excess surface water. Aquifers are the geological formations that can store water as well as allow the flow of significant amount of water through their pores under ordinary field conditions. If the aquifer is bounded by two impermeable formations from top and bottom, it is called a confined aquifer. If the upper boundary of the aquifer is the water table, it is called an unconfined aquifer. The advantage of unconfined aquifers over confined aquifers to serve as a subsurface reservoir is that the storage of groundwater in large quantity is possible only in unconfined aquifer, which is because the storativity of the unconfined aquifer is linked to the porosity and not to the elastic properties of the water and solid matrix, as in case of the confined aquifer (1). Also, the vast surface area of the unconfined aquifer above the water table is available to receive the surface applied recharge, whereas in case of the confined aquifer, only a small open area exposed near to the ground surface or leaky portion of the aquifer boundary is available to receive the recharge (Fig. 1). This article deals with the artificial recharging of unconfined aquifer and related problems.

Natural replenishment of aquifers occurs very slowly. Therefore, withdrawal of groundwater at a rate greater than the natural replenishment rate causes declining of groundwater level, which may lead to decreased water supply, contamination of fresh water by intrusion of pollutant water from nearby sources, seawater intrusion into the aquifer of coastal areas, etc. To increase the natural replenishment, artificial recharging of the aquifer is becoming increasingly important in groundwater management. The artificial recharge may be defined as an augmentation of surface water into aquifers by some artificially planned operations. The source of water for recharge may be direct precipitation, imported water, or reclaimed wastewater. The purpose of artificial recharging

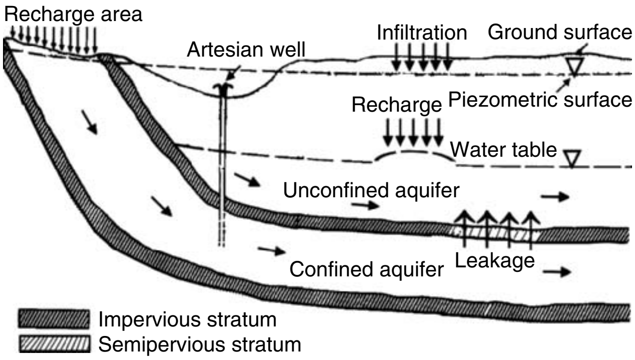

Figure 1. Aquifer types.

of groundwater systems has been to reduce, stop, or even reverse the declining trend of groundwater level; to protect fresh groundwater in coastal aquifers against saline water intrusion from the ocean; and store surface water, including flood or other surplus water, imported water, and reclaimed wastewater for future use.

RECHARGE METHODS

A variety of direct surface, direct subsurface, and indirect recharge techniques have been developed to recharge groundwater systems. The choice of a technique depends on the source of water, quality of the water, the type of aquifer, topographical condition, etc. The most widely practiced methods are direct surface techniques, which include surface flooding in basins, ponds, lakes, ditches, trenches, and furrow systems; stream and channel modification; and bunds (2–5). Trenches are constructed mostly in foothill regions to arrest the runoff and put it into the aquifers for storage. Stream channel modification involves alteration in the course of stream flow to detain stream flow and increasing the stream bed area for recharging purposes. Construction of check dams across the stream flow is one technique of stream channel modification. It enhances artificial recharge in two ways. Above the dam, impoundments enhance recharge by increasing the recharge area and detaining water for a longer period by reducing the rate of water flow. Below the dam, recharge is enhanced through exposure of a larger area than the original area of stream channel flow. Bunds, which are small earthen barriers, are constructed in agricultural lands with slopes to facilitate impounding of runoff for a longer duration, thereby increasing recharge. In indirect subsurface recharge techniques, water is injected directly into an aquifer through (a) natural openings in the aquifers, (b) pits or shafts, and (c) wells. In contrast to the direct surface techniques, groundwater recharge by indirect subsurface techniques is practiced mostly for recharging the confined aquifer and where the topography or existing land use, such as in urban areas, makes recharge by surface flooding impractical. Indirect recharge techniques involve special cases in which potable water supply is provided by river bank or sand dune filtration of generally polluted river water (6,7).

In many cases, excess recharging leads to the growth of water table near the ground surface and causes several types of environmental problems, such as water logging, soil salinity, etc. In these situations, proper management of groundwater resources is needed to overcome the shortage of water supply on one hand and to prevent the environmental problems on the other hand. In order to address the management problem, one must be able to predict the response of the aquifer system to any proposed operational policy of groundwater resources development such as artificial recharging. Such problems are referred to as forecasting problems. Their solution will provide the new state of the groundwater system. Once the new state is known, one can check whether the related recharge scheme is feasible. Then one can compare responses of different proposed recharge schemes in order to select the best scheme that can meet the preset objectives of groundwater resources development without disturbing the regional water balance and without creating any kind of environmental problems. The forecasting problems are effectively tackled by application of modeling techniques. A model is the simplified representation of a complex real physical system and the processes taking place in it. It can be physical (for example, a laboratory sand pack model), electrical analog, or mathematical. Development and applications of mathematical models are much easier than the other two types of models. Therefore, mathematical models are mostly in use today for solving groundwater management problems.

MATHEMATICAL MODELING

Modeling begins with a conceptual understanding of the physical problem (in this case, groundwater flow in the unconfined aquifer). The next step is translating the physical problem into a mathematical framework resulting in equation forms that describe the groundwater flow. Mathematical models may be deterministic, statistical, or some combination of the two. Deterministic models retain a good measure of physical insight while permitting any number of problems of the same class to be tackled with the same model. Here, discussion will be confined to deterministic models.

Formulations of groundwater flow equations are based on the conservation principles dealing with mass and momentum. These principles require that the net quantity of mass (or momentum) entering or leaving a specified volume of aquifer during a given time interval be equal to the change in the amount of mass (or moment) stored in the volume. Groundwater flow equations are formulated by combining the equation of motion in the form of Darcy's law, which follows principle of conservation of momentum with the mass balance equations, also known as continuity equations, which follows the principle of conservation of mass. Some mathematical models commonly used for solving the forecasting problem in the presence of recharge are discussed below:

2-D groundwater flow in an inhomogeneous anisotropic unconfined aquifer with a horizontal base is described by the following equation (1,8):

$$\frac{\partial}{\partial x}\left(K_x h\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial y}\left(K_y h\frac{\partial h}{\partial y}\right)+N(x,y,t)=S_y\frac{\partial h}{\partial t} \qquad (1)$$

in which h is the variable water table height measured from the horizontal base of the aquifer, K_x and K_y are the hydraulic conductivities in x and y directions, respectively, S_y is the specific yield, t is time of observation, and $N(x, y, t)$ is the sum of all recharge rates from distributed sources (recharge basins, ponds, streams, etc.) and withdrawal rates from distributed sinks (wells, leakage boundaries, etc.) and is represented by

$$N(x,y,t) = \begin{cases} \sum_{i=1}^{n} N_i(t) & \text{for } x_{i1} \le x \le x_{i2}, y_{i1} \le y \le y_{i2} \\ o & \text{elsewhere} \end{cases} \tag{2}$$

where n is the total number of basins, $N_i(t)$ is the time-varying recharge (or pumping) rate for the ith basin (or well, respectively), and x_{i1}, x_{i2}, y_{i1}, and y_{i2} are the coordinates of ith basin (or well). $N_i(t)$ is positive for recharge to the aquifer and negative for pumping.

For an inhomogeneous isotropic aquifer, Eq. (1) becomes

$$\frac{\partial}{\partial x}\left(K\,h\frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(K\,h\frac{\partial h}{\partial y}\right) + N(x,y,t) = S_y\frac{\partial h}{\partial t} \tag{3}$$

Equations (1 and 3) are nonlinear second-order partial differential equation. The nonlinearity is because of the presence of h as a coefficient of partial derivatives on the left-hand side. Solving these equations because of nonlinearity is possible only by numerical methods, such as finite difference, finite element, and boundary elements (1,9,10). These equations need to be linearized for their analytical solution.

For homogenous isotropic aquifers ($K = \text{constant}$), Eq. (3) can be written in the following two forms:

$$K\left[\frac{\partial}{\partial x}\left(h\frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(h\frac{\partial h}{\partial y}\right)\right] + N(x,y,t) = S_y\frac{\partial h}{\partial t} \tag{4}$$

$$\frac{\partial^2 h^2}{\partial x^2} + \frac{\partial^2 h^2}{\partial y^2} + \frac{2N(x,y,t)}{K} = \frac{S_y}{Kh}\frac{\partial h^2}{\partial t} \tag{5}$$

Two procedures of lineraization are commonly used to facilitate analytical solutions of Eqs. (4 and 5). According to the first procedure, i.e., the Baumann procedure of lineraization, if the variation in h is much less than the initial height of the water table h_0, then the coefficient h appearing on the left-hand side of Eq. (4) can be replaced by h_0 (11). Then Eq. (4) can be rewritten as

$$T\left(\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2}\right) + N(x,y,t) = S_y\frac{\partial h}{\partial t} \tag{6}$$

where $T = Kh_0$ (known as transmissivity). Now, Eq. (6) is linear in h. Sometimes the mean depth of saturation is also used in place of h_0.

In the second procedure, i.e., the Hantush procedure of linearization, h appearing in the denominator on the right-hand side of Eq. (5) is replaced by the weighted mean of the depth of saturation $\overline{h}$, a constant of linearization that is approximated by $0.5[h_0 + h(t_e)]$, and t_e is the period at the end of which $\overline{h}$ is to be approximated (12). Then, Eq. (5) becomes

$$\frac{\partial^2 h^2}{\partial x^2} + \frac{\partial^2 h^2}{\partial y^2} + \frac{2N(x,y,t)}{K} = \frac{S_y}{K\overline{h}}\frac{\partial h^2}{\partial t} \tag{7}$$

Now, Eq. (7) becomes linear in h^2. By substituting a new variable H, defined as $H = h^2 - {h_0}^2$, into Eq. (7) gives

$$\frac{\partial^2 H}{\partial x^2} + \frac{\partial^2 H}{\partial y^2} + \frac{2N(x,y,t)}{K} = \frac{S_y}{K\overline{h}}\frac{\partial H}{\partial t} \tag{8}$$

GROUNDWATER FLOW EQUATIONS FOR SLOPING AQUIFER

2-D groundwater flow in a sloping unconfined aquifer is described by (13,14)

$$\frac{\partial^2 s}{\partial x^2} + \frac{\partial^2 s}{\partial y^2} - 2a\frac{\partial s}{\partial x} + \frac{2N(t)}{K} = \frac{1}{\Re}\frac{\partial s}{\partial t} \tag{9}$$

where $s = h^2$, $a = \theta/2D$, $\theta = $ slope of the base, $D = $ the mean depth of saturation, $\Re = KD/S_y$, $x, y = $ space coordinates, $t = $ time of observation, and $N(t) = $ time varying rate of recharge.

One-dimensional groundwater flow equations can be obtained by substituting zero for the derivative of y in the above equations. These equations are used to predict the water table fluctuations in response to artificial recharge from strip basins, canals, channels, etc.

GROUNDWATER FLOW EQUATIONS IN CYLINDRICAL COORDINATES

These types of equations are used to describe groundwater flow induced by recharging through circular-shaped recharge basins/wells and is given by (15,16).

$$S\frac{\partial h}{\partial t} = -\frac{1}{r}\frac{\partial}{\partial r}(rq) + N(r) \tag{10}$$

where q is defined by Darcy's law as

$$q = -Kh\left(\frac{\partial h}{\partial r}\right) \tag{11}$$

The groundwater flow equations presented here are in the form of partial differential equations having an infinite numbers of solutions. To obtain a unique solution for a particular problem, more information about the aquifer's parameters, geometry of the flow domain and recharge basins, duration and rate of recharge rate, and initial and boundary conditions are needed. These values can be deduced from field as well as experimental methods (1,17,18).

Initial Conditions

Initial conditions describe distribution of h at all points of the flow domain at the beginning of the investigation, that is, at $t = 0$, which is expressed as

$$h = \psi(x,y,0) \tag{12}$$

where ψ is a known value of h for all points of the flow domain.

Boundary Conditions

These conditions describe the nature of interaction of the flow system with its surroundings. Three types of boundary conditions are generally encountered in groundwater flow problems.

- Dirichlet boundary condition—In this case, h is prescribed for all points of the boundary for the entire period of investigation, which is expressed as

  $$h = \psi\ (x, y, t) \tag{13}$$

  where $\psi\ (x, y, t)$ are known values of h at all points on the boundary.
- Neumann boundary condition—This type of boundary condition prescribes the flux across the boundary of the flow system and can be expressed as

  $$q = \psi_1\ (x, y, t) \tag{14}$$

  where $\psi_1\ (x, y, t)$ are known values at the boundary. A special case of this boundary condition is the no flow boundary condition in which flux is zero. This condition occurs at impermeable surface or at the groundwater divide, a surface across which no flow takes place.
- Cauchy boundary condition—This boundary condition is encountered at the semipervious boundary layer between the aquifer and an open water body such as a river. As a result of the resistance to the flow offered by the semipervious boundary that lies between the aquifer and the river, the water level in the river differs from that in the aquifer on the other side of the semipervious boundary. In this case, the flux is defined by

  $$q = K' \frac{h - h_0}{b} \tag{15}$$

  where h is the head at $x = 0$, h_0 is the water level in the river, and b and K' are the thickness and hydraulic conductivity of the semipervious boundary, respectively.

The purpose of solving a groundwater flow equation is to obtain the values of $h(x, y, t)$. Generally, two types of methods, namely analytical methods and numerical methods, are used for this purpose. Numerical methods are used to solve the nonlinear groundwater flow equation to tackle the real field problems, and analytical methods are used to solve the linearized form of groundwater flow equations. Analytical methods commonly used for the solution of groundwater problems include Fourier transforms, Laplace transforms, integral balance methods, method of separation of variables, approximate analytic methods, etc. Details about these methods can be found in many books (19–25). Most of the analytical solutions developed earlier for this purpose were based on the assumption of constant recharge. Warner et al. (26) have reviewed the performance of some such analytical solutions (27–31). However, the rate of recharge largely depends on the infiltration rate, which initially decreases because of swelling and dispersion of soil particles. After some time, the infiltration rate increases because of the release of air entrapped into soil pores and reaches to a maximum value. Then, it starts decreasing because of clogging of soil pores beneath the bottom of the basin. Recharge rate also follows a more or less similar pattern of variation with some time lag and less intensity. When it falls below a prescribed low value, the recharge operation is discontinued for some time. After drying and, if necessary, scrapping of the silted base of the basin, a high recharge rate closer to its initial value is rejuvenated in the next phase of recharge operation (1,32–34). Zomorodi (35) has also shown that the analytical solution of Dagan (36), which is based on the assumption of constant recharge rate, fails to predict the recession of the water table caused by decrease in the recharge rate. Therefore, it would be more appropriate to consider recharge rate as time-dependent to simulate the actual field conditions. Some solutions have been developed for the time-varying recharge cases in which the decreasing rate of recharge has been represented by two linear elements (37–39) or by exponential function (14,16,40–44). However, approximation of time-varying recharge by two linear elements or exponential function is possible only for one recharge cycle. However, recharge is applied intermittently for more than one cycle separated by dry periods. Manglik et al. (45), Rai et al. (46), Manglik and Rai (48), and Rai and Manglik (49) used a general scheme of recharge approximation for any number of recharge cycles. In this scheme, time-varying recharge is approximated by a number of linear elements of different lengths and slopes depending on the nature of variation of recharge rate. Later on, this scheme was modified to represent rates of recharge from any number of basins. In mathematical form, this scheme can be represented by

$$N_i(t) = \begin{cases} r_{ij}t + c_{ij} & t_j \le t \le t_{j+1} [j = 1, 2, \cdots, k-1] \\ r_{ik}t + c_{ik} & t \ge t_k \qquad [j = k] \end{cases} \tag{16}$$

where r_{ij} and c_{ij} are the slope and intercept of the jth line element of the recharge rate for the ith basin and k is the number of elements. The advantage of this scheme of recharge approximation is that any type of variation in the recharge rate for any number of recharge cycles from any number of recharge basins of different dimensions located anywhere within the flow domain can be approximated with the help of the required number of linear elements of different lengths and slopes depending on the nature of variation of recharge rate. By using this recharge scheme, several analytical solutions to describe water table fluctuation in different flow systems representing different physical conditions have been developed (50–53). The following analytical solution given by Manglik and Rai (50) is considered as an example to demonstrate the application of these solutions in prediction of water table fluctuation in the presence of time-varying recharge and pumping,

$$h^2(x,y,t) = h_0^2 + \frac{8a}{K\pi^2}\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\frac{1}{mn}\sin\left(\frac{m\pi\, x}{A}\right)\sin\left(\frac{n\pi\, y}{B}\right)$$

$$\sum_{i=1}^{\mathrm{N}}\left[\cos\frac{m\pi\, x_{i2}}{A} - \cos\frac{m\pi\, x_{i1}}{A}\right] \tag{17}$$

$$\left[\cos\frac{n\pi\, y_{i2}}{B} - \sin\frac{n\pi\, y_{i1}}{B}\right]\left[\sum_{j=1}^{k-1}R_{ij} + R_{ik}\right]$$

in which A and B are the length and width of the aquifer, $a = K\bar{h}/S_y$, and m and n are integers representing number of Fourier coefficients. $\lambda = \frac{a\,\pi^2}{4}\left[\frac{m^2}{A^2} + \frac{n^2}{B^2}\right]$

$$R_{ij} = \frac{r_{ij}}{\lambda}[t_{j+1}\exp\{-\lambda(t-t_{j+1})\} - t_j\exp\{-\lambda(t-t_j)\}]$$
$$-\left(\frac{r_{ij}}{\lambda^2} - \frac{c_{ij}}{\lambda}\right)[\exp\{-\lambda(t-t_{j+1})\} - \exp\{-\lambda(t-t_j)\}]$$
$$R_{ik} = \frac{r_{ik}}{\lambda}[t - t_k\exp\{-\lambda(t-t_k)\}]$$
$$-\left(\frac{r_{ik}}{\lambda^2} - \frac{c_{ik}}{\lambda}\right)[1 - \exp\{-\lambda(t-t_k)\}]$$

This solution is obtained by solving Eq. (8) with recharge/pumping rates defined by Eq. (16) and subjected to the horizontal water table as an initial condition and Dirichlet boundary condition. In order to demonstrate the application of Eq. (17) in the prediction of water table fluctuation, we consider an example in which an unconfined aquifer of 10 × 10 km^2 dimension is having two recharge basins of dimension 60 × 40 m^2 and 50 × 50 m^2 centered at (4470 m, 4500 m) and (5875 m, 5530 m), respectively, and two wells each of 10 × 10 cm^2 dimension centered at (5000 m, 4500 m) and (5000 m, 5500 m), respectively. The pattern of time-varying recharge rate and pumping rate are shown in Fig. 2. The recharge operation for both the basins consists of two wet periods and one dry period, each of 20 days duration. During the first wet period, the rate of recharge decreases from its initial value of 0.8 m d^{-1} to a lower value of 0.7 m d^{-1} after 2 days. It again increases and attains maximum value of 0.9 m d^{-1} on the fourth day. After that, it starts decreasing and reduces to zero on twentieth day. The second cycle of recharge operation begins on the fortieth day and continues until the sixtieth day. The nature of variation of recharge rate for the second cycle is considered similar to the first cycle. Pumping of groundwater at a rate of 10^5 m d^{-1} from each well is considered for two periods. The first period is from the tenth to the twentieth day, and the second period is from the fortieth to the fiftieth day after a gap of 20 days. Numerical values of other controlling parameters are $h_0 = 20$ m, $K = 8$ m d^{-1}, and $S_y = 0.20$. Two water table profiles computed for $t = 45$ days along a line parallel to the x-axis at $y = 4500$ m are shown in Fig. 3. These profiles pass through the center of one recharge basin and one well centered at (4470 m, 4500m) and (5000 m, 4500 m). The profile represented by the dotted curve is in response to recharge only. Hence, it shows only growth of groundwater mound. The profile represented by continuous curve shows growth as well as depression of the water table at the respective site of recharging and pumping. This example demonstrates the capabilities of prediction of water table variations in response to time-varying recharge and withdrawal.

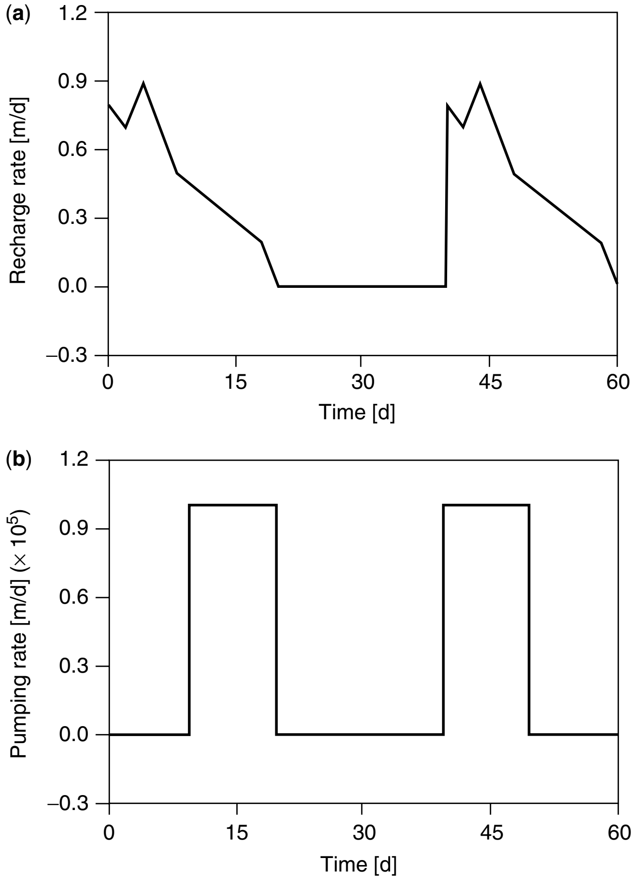

Figure 2. Nature of time-varying (**a**) recharge, and (**b**) pumping rates.

Accurate estimation of the varying recharge rate is a major problem in groundwater resources management. If the time history of water table variation at a site of an observation well is known, then analytical

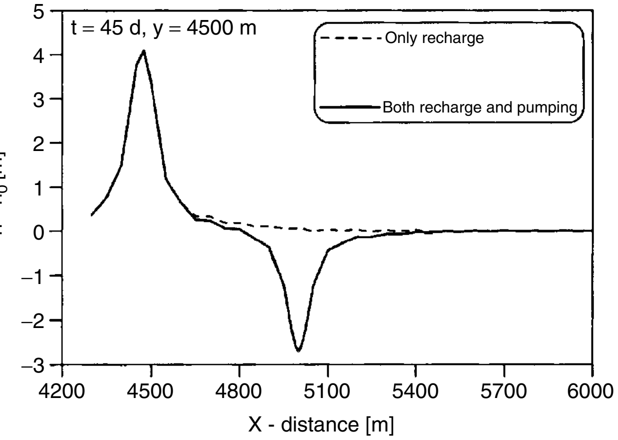

Figure 3. Water table profiles in the presence of only recharge (dashed curve), and both recharge and pumping (solid curve).

solutions can be used for the estimation of varying recharge rate by making a judicious selection of recharge rate using trial and error method, such that the computed water table variation matches well with the observed one. Although the application of analytical solutions is restricted to the relatively homogeneous isotropic aquifer system having boundaries of simple geometrical shapes, their application is fast and simple in comparison with that of the numerical methods. Analytical solutions are also useful for other purposes, such as analysis of the effects of various controlling parameters, such as aquifers properties, initial and boundary conditions, intensity and duration of recharge rate, shape, size, and location of a recharge basin, etc., on the response of the aquifer system. Such information is very essential for the judicious selection of a suitable recharge scheme out of many proposed schemes to achieve the preset objectives of groundwater resource management.

GROUNDWATER AND ARSENIC: CHEMICAL BEHAVIOR AND TREATMENT

David B. Vance

Mill Valley, California

INTRODUCTION

Arsenic is not an abundant element in the earth's crust; the average crustal concentration of arsenic is 1.8 mg/Kg (1) to 5 mg/Kg (2). Arsenic ranks as the 52nd element in abundance, between tin and molybdenum (1). However, through geogenic processing of crustal materials, arsenic can be concentrated in soils to a typical range of 2 to 20 mg/Kg (3) to 1 to 50 mg/Kg (2), with concentrations as high as 70 mg/Kg being unremarkable (3). Human activity generates anthropogenic arsenic, which makes it the third most common regulated inorganic contaminant found at U.S. Superfund sites.

Arsenical copper was in use by 4000 BC, and the toxic effects of arsenic were documented by early Greek writers. More recently, arsenic has been linked to skin, bladder, and other cancers (4). The U.S. Environmental Protection Agency (USEPA) lowered the arsenic standard in drinking water from 50 μg/L to 10 μg/L, effective January 23, 2006.

Modern usage of arsenic includes formulation of pesticides and herbicides, decolorization of glass, paint manufacturing, the production of semiconductors, and the treatment/preservation of wood. Pressure treated lumber was commonly treated for decades using copper-chromium-arsenate (CCA). This product, also called "green wood," has been used for foundation lumber and more recently as wood for outdoor children's play structures and picnic tables. The CCA wood is being phased out for toxicity concerns and environmental reasons. Many of the pressure treatment lumber facilities have significant soil and groundwater contaminated with arsenic as well as chromium.

CHEMICAL CHARACTER

Although arsenic occurs in more than 20 minerals, only a few are commonly found in ore deposits (5). Arsenic may occur as a semimetallic element (As^0), arsenate (As^{5+}), arsenite (As^{3+}), or arsine (As^{3-}). The biogeochemistry of arsenic involves adsorption, biotransformation, REDOX reactions, and precipitation-dissolution processes (6,7).

The chemical character of arsenic is labile and readily changes oxidation state or chemical form through chemical or biological reactions that are common in the environment. Therefore, rather than solubility equilibrium controlling the mobility of arsenic, it is usually controlled by REDOX conditions, pH, biological activity, and adsorption/desorption reactions. Arsenic in groundwater most often occurs from geogenic sources, although anthropogenic arsenic pollution does occur. Geogenic arsenic is almost exclusively an arsenite or arsenate. The most oxidized pentavalent form, arsenic, forms oxyanions ($H_3ASO_4{}^-$, $H_2ASO_4{}^-$, H2ASO4-, $HASO_4{}^{2-}$, $ASO_3{}^-$). These arsenic oxyanions are isomorphous with oxyanions of phosphorous, substituting for phosphate in both marine organisms and phosphate deposits (4). Arsenite is the trivalent form that also forms a series of oxyanions that change specific configuration and charge with pH. Of critical importance with regard to the controls of the mobility of arsenite is the fact that at a pH of 9.5 or lower, the arsenite oxyanion is not charged. This result obviates all ionic interactions of the species.

Common arsenic minerals are arsenopyrite (FeAsS), enargite (Cu,AsS), proustite (Ag,AsS), and lollingite ($FeAs_2$). Late-stage magmatic crystallization (pyrometasomatic and hydrothermal stages) contributes to arsenic-rich sulfides. In sedimentary rocks, arsenic is commonly found adsorbed onto fine-grained sedimentary rocks, such as iron and manganese oxides (4). According to the U.S. Geological Survey, arsenic concentrations in sedimentary iron-ores range from 65 to 650 mg/Kg (8). Arsenic is also associated with sedimentary pyrite at concentrations of 100 to 77,000 mg/Kg (6).

Anthropogenic arsenic may have any form including organic arsine species. Groundwater in acidic to intermediate volcanic rocks, or in sediments derived from those rocks, will often have arsenic concentrations exceeding 50 μg/L.

Figure 1 illustrates the difference in molecular structure between arsenate and arsenite. The double bond oxygen in the arsenate molecule influences its ability to become ionized through the of hydrogen ions. The process is termed dissociation. A negative charge develops on the arsenate molecule when dissociation occurs. The double bond oxygen increases the capacity to delocalize that charge, which cases the loss of hydrogen ions. The propensity for ionization is expressed by the constant of dissociation, pKa. The pKa value, which is a negative log, shows a greater degree of dissociation with a smaller value.

For arsenate and arsenite, pKa values are as follows:

$$\text{Arsenate- } H_3ASO_4 \quad pK_1 = 2.19 \quad pK_2 = 6.94$$

$$pK_3 = 11.5$$

$$\text{Arsenite- } H_3ASO_3 \quad pK_1 = 9.20 \quad pK_2 = 14.22^*$$

$$pK_3 = 19.22^*$$

The pH at which these ionization steps occur is significantly different between arsenate and arsenite, as illustrated in Fig. 2 (10,11). Figure 2 also shows the control of REDOX potential (Eh) on the arsenate/arsenite transition. This Eh/pH relationship is key in understanding arsenic mobility in groundwater and the effectiveness of arsenic water treatment systems.

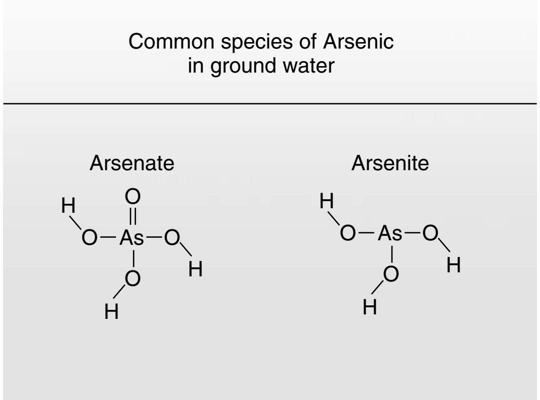

Figure 1. Difference in molecular configuration of arsenate and arsenite.

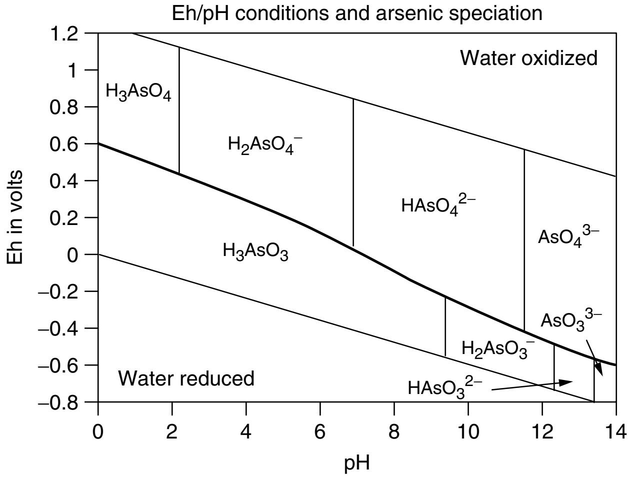

Figure 2. Control of arsenic speciation by Eh and pH conditions.

Arsenic Immobilization

The previous section described the conditions under which arsenic can become an ionized species. The most commonly recognized adsorption reactions are based on ion exchange between charged adsorption sites and charged soluble ions. However, London Van der Waals bonding is another mechanism that is also responsible for adsorption. This type of bonding is the result of complex interactions among the electron clouds of molecules, molecular polarity, and attractive forces of an atomic nucleus for electrons beyond its own electron cloud. Consequently, some degree of immobilization can occur with soluble species that are not ionized. Arsenic immobilization through ionic adsorption can be controlled within normal oxidizing Eh/pH conditions. London Van der Waals bonding is complex to the point of unpredictability except for arsenic

---

*These pKa values are extrapolated from the strength of oxygen acid rules (9).

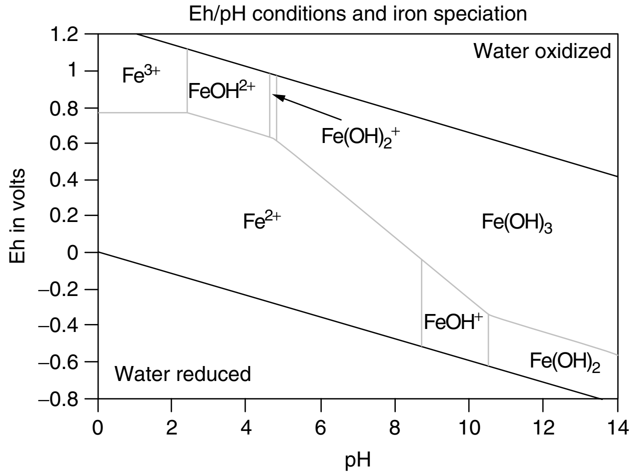

Figure 3. Iron speciation as controlled by Eh/pH conditions.

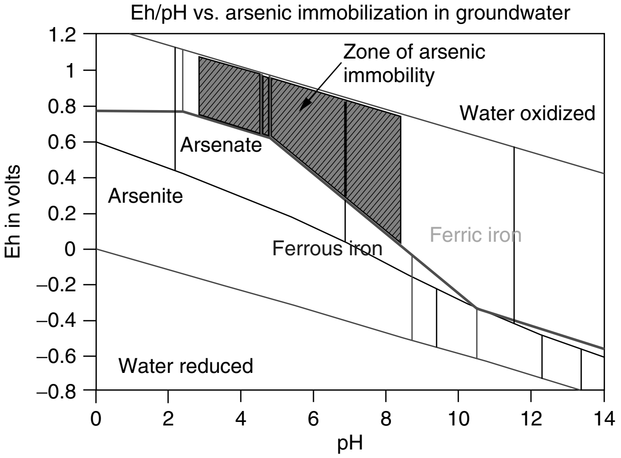

Figure 4. Arsenic mobility in groundwater as controlled by the effect of Eh/pH conditions on the speciation of arsenic and iron.

mobility at extreme Eh/pH conditions that can be obtained in industrial settings, but not in groundwater.

Components of soil that participates in both types of adsorptive reactions include clays, carbonaceous material, and oxides of iron, aluminum, and manganese. In the most shallow soils, the organic fractions typically dominate, whereas at greater depths, iron oxyhydroxides play the principal adsorptive role.

The typical iron content of soil ranges from 0.5% and 5%. Not only is iron common, but as with arsenic, it is also labile and readily reflects changes in surrounding Eh/pH conditions. This relationship for iron is illustrated in Fig. 3 (12).

Ferric hydroxide acts as an amphoteric ion exchanger. Depending on pH conditions, the ferric hydroxide has the capacity for cation or anion exchange. Given the average iron concentration in soil and soluble arsenic concentrations in groundwater at 50 μg/L, ferric hydroxides in sediment can potentially adsorb 0.5 to 5 pounds of arsenic per cubic yard of aquifer matrix, which may then act as a significant potential reservoir for arsenic release under changing Eh/pH conditions.

ARSENIC IN GROUNDWATER

Arsenic concentrations up to 12,000 μg/L have been reported for the St. Peter aquifer in eastern Wisconsin (4). In this case, the oxidation of arsenic sulfides in a sulfide cement horizon (SCH) within the aquifer is a source of the high arsenic concentrations.

Figure 4 superimposes the Eh/pH relationship for the arsenic and iron systems; it illustrates the conditions under which arsenic will be immobilized in a groundwater system. Of equal importance, it illustrates how arsenic adsorbed to ferric hydroxides in sediment can be released at exposure to groundwater that is chemically reducing. Two effects would be at work: Arsenate is reduced to arsenite that will not remain ionically bound to the geologic substrate, and ferric iron is reduced to ferrous, which is soluble under normal pH conditions. Outside the immobilized zone, arsenic mobility is variable. London Van der Waals bonding of arsenite is in effect, but it is not sufficient to assure complete immobilization.

WATER TREATMENT SYSTEMS

Introduction

Following is a brief review of various technologies used for the removal of arsenic from drinking water and industrial wastewater. Table 1 summarizes the effectiveness of each and gives the source for the information.

Arsenite Oxidation

As previously described, the ionization chemistry of arsenic in groundwater precludes the removal of arsenite by ion exchange within normal pH ranges. Other technologies including coprecipitation, electrodialysis, and reverse osmosis are also affected by arsenite's dissociation profile. One solution to this problem is an oxidation step to form arsenate. Figure 5 illustrates the Eh/pH range required for this process. Oxidation, particularly of drinking water, may be problematic. Chemical residues of the oxidant, byproducts from oxidation of other organic or inorganic species, reagent costs, and operational issues are all factors. Oxygen would be ideal, as it is thermodynamically capable of this oxidizing step. The kinetics for oxidizing arsenic compounds in groundwater are exceedingly slow (22). It is possible to use gas diffusion technologies that slowly release dissolved oxygen into aquifers and that have demonstrated the capacity to convert anaerobic groundwater systems into aerobic systems within 3 to 6 months (23). This process will convert soluble ferrous iron to insoluble ferric iron oxides capable of attracting arsenate to their surfaces. The oxidation of arsenite is complex and may take additional time or the presence of other abiotic or biological (24) stimulants. In Bangladesh, *in situ* concentrations of arsenic less than 0.1 mg/L were readily removed by the oxygenation of groundwater; concentrations greater than that had only 50% removal (25).

Other chemicals can affect arsenite oxidation including free chlorine, hypochlorite, ozone, permanganate, and hydrogen peroxide with ferrous iron.

Table 1. Effectiveness of Arsenic Water Treatment Methods

Treatmenttechnology	Initial Arsenic Concentration	Final Arsenic Concentration*	Reference
Iron Coprecipitation	Oxidized Arsenic 56 mg/L	10 μg/L	(13)
	Arsenate 350 μg/L	6 μg/L	(14)
	Arsenite 350 μg/L	140 μg/L	(14)
	Arsenate 560 μg/L	10 μg/L	(15)
	Arsenate 300 μg/L	6 μg/L	(16)
	Arsenite 300 μg/L	138 μg/L	(16)
Alum Coprecipitation	Arsenate 350 μg/L	74 μg/L	(14)
	Arsenite 350 μg/L	263 μg/L	(14)
	Arsenate 300 μg/L	30 μg/L	(16)
	Arsenite 300 μg/L	249 μg/L	(16)
Lime Precipitation	Arsenate 500 mg/L	4 mg/L	(17)
	Arsenite 500 mg/L	2 mg/L	(17)
	Arsenate 2 mg/L	20 μg/L	(17)
	Arsenite 2 mg/L	160 μg/L	(17)
Activated Alumina	Arsenate 100 μg/L	4 μg/L	(18)
	Arsenite 100 μg/L	Ineffective	(18)
	Arsenate 57 μg/L	ND at pH 6.0	(19)
	Arsenite 31 μg/L	Ineffective	(19)
Ion Exchange	Arsenate 100 mg/L	<800 μg/L	Vance
	Arsenate 68 mg/L	12.2 to 0 mg/L	(20)
Reverse Osmosis	Arsenite 37 μg/L	7 μg/L	(19)
	Arsenate 51 μg/L	1.5 μg/L	(19)
Electrodialysis	Arsenite 188 μg/L	136 μg/L	(19)
Sulfide Precipitation	Arsenate 132 mg/L	26 mg/L	(21)
Activated Carbon	Arsenite 500 μg/L	300 μg/L	(21)

*The current limit for drinking water is 50 μg/L.

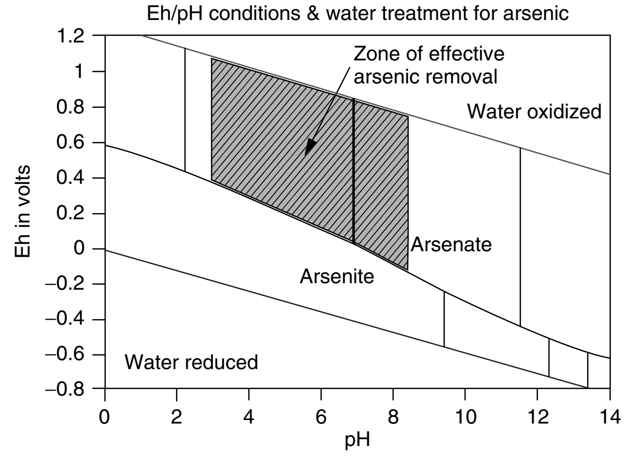

Figure 5. Eh/pH range required for effective treatment of soluble arsenic.

Iron Coprecipitation

Coprecipitation of arsenate with ferric iron is recognized as overall the most effective and practical existing method of arsenic removal. Ferric iron coprecipitation is particularly useful in the mining industry, where large amounts of ferric iron and arsenic can be byproducts of production or refining. Adding ferric iron salts for the treatment of drinking water is usually necessary. Figure 4 shows that arsenate is readily removed by iron coprecipitation and the Eh/pH conditions that must be maintained to effect that removal. Because of London Van der Waals bonding, ferric iron coprecipitation of arsenite is also moderately effective, with 50% removal at a pH of 7.0 (26).

The use of iron hydroxides for the coprecipitation of arsenic in industrial wastewater (in which arsenic is in the mg/L range) requires iron dosage four to eight times higher than that of the soluble arsenic; a greater iron dosage yields no further benefit (27).

Alum Coprecipitation

Suspended aluminum salts (alum) can remove arsenate via mechanisms similar to those for ferric hydroxides. However, it is less effective over a narrower pH range for arsenate removal and is ineffective for removal of arsenite (16).

Lime Precipitation

In testing by Nishimura and Tozawa (17), removal of arsenic with lime precipitation was feasible, but not necessarily practical. High concentrations of arsenic were removed to concentrations of 2 and 4 mg/L for arsenate and arsenite, respectively. Removal to lower levels required a second treatment step in which initial arsenic concentrations of 2 mg/L were lowered to 20 μg/L for arsenate and 160 μg/L for arsenite. However, to achieve these removal efficiencies, the lime dosage was between 5 and 15 g/L.

Activated Alumina

Activated alumina can be effective for the removal of arsenate under moderately acidic pH conditions

(5.5 to 6.0). High levels of competing anions such as sulfate significantly reduce the effectiveness of activated alumina (18). The use of activated alumina for complete arsenite removal is ineffective because of the nonionic character of arsenite in that pH range (see Fig. 1). Some initial arsenite removal is observed because of London Van der Waals bonding, but compared with arsenate adsorption, this capacity is rapidly exhausted.

Ion Exchange

Ion exchange has the potential for soluble arsenic removal. Anion exchange resins are available in two basic forms, weak base and strong base. Many weak-base anion exchangers are capable of significant adsorption because of London Van der Waals bonding in addition to ion exchange, which gives them a higher level of adsorptive capacity for nonionic arsenite. The author has evaluated anion exchange resins for arsenate removal. The most effective activation was in the hydroxyl form. Chloride and acetate were also tested. Weak base resins had higher loading capacities than did strong base (6% vs. 4.8%), but they did not have adequate removal efficiencies (75% vs. 99+% for the strong base resin). Anion exchange resins are also prone to chromatographimg because of the presence of competing anions in the treated water. However, ion exchange is an area of intense research where the development of anionic chelating exchange resins or ion exchange polymers may dramatically improve the technology for arsenic treatment.

Reverse Osmosis

Reverse osmosis (RO) has been shown to have a removal efficiency greater than 97%. Electrodialysis was only 73% effective. When used to treat 100% arsenite, removal was only 28% (19).

Other

Rosehart (21) evaluated a series of removal technologies including activated carbon and sulfide precipitation. Neither performed at a level adequate for use in the treatment of drinking water.

CONCLUSIONS

The behavior of arsenic in groundwater and industrial wastewater is dominated by REDOX and pH conditions. Under a limited range of specific Eh/pH conditions, the ability to predict total immobility of arsenic in groundwater and in water treatment systems exists (see Figs. 4 and 5). Except for those conditions, arsenic will be partially mobile, the magnitude of which is difficult to predict.

Implications of this behavior include:

- Arsenic treatment without control of Eh/pH is likely to be ineffective.
- The injection of water in a reduced oxidation state into sediments with adsorbed arsenic may cause a dramatic mobilization of arsenic into the groundwater.
- If ferric iron sludges used for the coprecipitation of arsenic are disposed under improper Eh/pH conditions, arsenic will remobilize. *In situ* remediation via recovery or stabilization of arsenic contaminated groundwater should be focused on Eh control through chemical or biological methods

Site-specific arsenic chemistry including source, mobility, migration, fate, and transport is complex. Any *in situ* treatment of groundwater containing arsenic should be evaluated carefully with laboratory bench tests, computer groundwater modeling, and field pilot tests before full-scale remediation is attempted.

TREATMENT OF ARSENIC, CHROMIUM, AND BIOFOULING IN WATER SUPPLY WELLS

WALTER W. LOO
Environmental & Technology Services
Oakland, California

JASON J. WEN
City of Downey
Downey, California

INTRODUCTION

Arsenic

Arsenic has been used as a component of pesticides and thus may enter streams or groundwater through waste disposal or agricultural drainage. Arsenic is also present in volcanic gases and is a common constituent of geothermal or spring water.

As small amounts of arsenic can be toxic to humans, it is considered a highly undesirable impurity in water supplies; an upper concentration limit of 50 μg/L, established in 1976 by the U.S. EPA, has now been lowered to 10 μg/L.

Arsenic may form metal arsenides in which its oxidation state is negative (1). Arsenic may also form sulfides and can be present as an accessory element in sulfide ore deposits. In solution in water, the stable forms are arsenate (As^{5+}) or arsenite (As^{3+}) oxyanions. A pH–E_h diagram showing fields of dominance of aqueous arsenates (1) indicates that the monovalent arsenate anion $H_2AsO_4^-$ is expected to predominate between pH 3 and 7 and the divalent species $HAsO_4^{2-}$ takes over from pH 7 to 11. Mildly reducing conditions favor the uncharged arsenite ion $HAsO_2$ (aq).

Chromium

Chromium is an inorganic element that is used in electroplating, leather tanning, wood treatment, pigment manufacture, and cooling tower treatment for corrosion control. Chromium can contaminate drinking water sources through discharges from industries, leaching from hazardous waste sites, or it may occur naturally from the erosion of natural deposits. Two forms of chromium can occur in water sources: chromium (III) and chromium (VI). Chromium (III) is an essential nutrient at trace concentrations. Chromium (VI) is toxic and is the basis for setting the chromium drinking water standard. The ratio of the two forms can vary quite a bit in natural waters. Evidence also exists to suggest that chromium (VI) may be converted to chromium (III) in the human body, particularly in the acidic digestive system.

The U.S. Environmental Protection Agency (EPA) classified chromium (VI) as a human carcinogen by inhalation. In 1991, it reviewed the existing standard for total chromium and the most recent scientific research available. As a result, the EPA actually raised the maximum contaminant level from 50 to 100 parts per billion as total chromium, based on its conclusion that chromium (VI) is not carcinogenic by ingestion.

In California, the drinking water standard is 50 parts per billion for total chromium [the sum of chromium (III) and chromium (VI)]. A public health goal is a "risk assessment" of the concentration of a contaminant in drinking water that poses no significant health risk to the consumer. The recommended public health goal determined by the Cal/EPA Office of Environmental Health Hazard Assessment (state health experts) for total chromium is 2.5 parts per billion.

Well Biofouling

Iron and manganese biofouling (usually associated with "iron bacteria") are common in water supply wells and attached appurtenances. Although biofouling sometimes has no overt symptoms, it may cause clogging, corrosion, and water quality degradation. These problems pose a considerable challenge to water utilities and well owners in North America and around the world. Precise estimates of increased operational and mitigation costs resulting from damage and loss of efficiency from well biofouling are not available. Nevertheless, it is believed to be widespread, costly, underreported, and not adequately remedied in actual practice, resulting in frequent operating problems. Although preventive maintenance would be more cost-effective, the most common approach to iron biofouling problems in wells is crisis management. Preventive maintenance is seldom employed, however, because suitable maintenance monitoring methods and practical protocols for detecting iron and manganese biofouling problems before they severely affect well production and water quality have not been available (2).

Understanding the cause of water well deterioration and developing ways to sustain water well environments is important in maintaining and improving the quality of life in rural areas. The deterioration of well yield and water quality is a concern to individuals, small communities, and industries that rely on water wells as their principal source of water. Currently, when the quality or quantity of water produced declines dramatically, wells are often abandoned, or treatments are applied with little understanding of the cause of these problems. The cost of replacing these wells can have a significant economic impact on well owners. Correctly identifying the cause of water well problems offers the possibility of effective treatment and maintenance instead of well abandonment. Losses in water well production and water quality have traditionally been attributed to the chemical and physical properties of the water well environment. Many of these problems can be solved by well-established diagnostic and rehabilitative techniques. However, less recognized is that groundwater contains microorganisms such as bacteria, and the activities of these microorganisms also cause significant water well problems. Water well deterioration caused by microbiological activity is termed biofouling. Installing and pumping a well increases the level of oxygen and nutrients in the well and in the surrounding aquifer, encouraging bacterial cells, which are naturally present in groundwater, to anchor themselves to surfaces in the well and around the well intake. Once attached, these bacteria quickly multiply and colonize these surfaces. The bacterial colonies form a gel-like slime or biofilm that captures chemicals, minerals, and other deposits, such as clays and silts, moves to the well during pumping, and forms biomasses.

Some of the byproducts of bacterial growth, such as oxidized iron and manganese, also accumulate in these secretions, which leads to the production of the red or black slimes often found in toilet tanks or observed on pumps and discharge lines when they are pulled from a well. Biofouling of a water well occurs when biofilms accumulate a sufficient amount of debris to interfere with water flow and affect water quality. If uncontrolled, well biofouling can affect well performance in various ways. Biofilms and the debris they collect can quickly coat, harden, and plug the well screen, the sand pack, the surrounding aquifer material, and may even plug water lines and affect the performance of household treatment systems. In addition, the bacteria living within the biofilm can increase the rate of iron oxidation and iron buildup in the well and distribution pipes, which leads to occasional discoloration of well water. Biofouling can also result in the production of odors such as rotten egg or fishy smells, changes in taste, and corrosion of steel and iron casings and pipes. Once developed, a biomass can protect the bacterial cells from environmental changes such as changes in pH, temperature, and fluid velocities, making treatment chemicals less effective and removal of plugging material more difficult, which emphasizes the importance of regular well maintenance. A number of field and laboratory tests exist that can be used to monitor water quality and biological activity in groundwater. If performed regularly 1 month after the well is installed and then once every 6 months, these tests indicate when water quality is changing or when biological activity is increasing. Changes in water quality and increased levels of biological activity indicate that well maintenance is required. Ideally, appropriate well maintenance chemicals should be applied before well performance is significantly affected. Establishing a monitoring schedule, where pumping water levels and well pumping rates are recorded, is also an effective way to identify when preventive maintenance measures are no longer effective and well rehabilitation is required.

Extracellular slimes are composed largely of polysaccharides and, in general, are the major component of the biofouling mass. Biomass associated with viable active cells is a relatively minor component. Figure 1 illustrates how the maximum level of biological activity commonly occurs under redox conditions that are at the periphery of oxidation in the E_h range of -50 to $+150$ mV. Biofouling can be complex and caused by a variety of bacteria. However, the appearance and odor of bacterial slimes are diagnostic.

ARSENIC TREATMENT

Of the 14 treatment technologies that the EPA reviewed, five are relevant technologies for small systems—ion exchange, activated alumina, and membrane technologies (reverse osmosis, nanofiltration, and electrodialysis reversal). Seven alternative technologies are categorized as still emerging (iron oxide-coated sand, granular ferric hydroxide, iron filings, sulfur-modified iron, greensand filtration, iron addition with microfiltration, and conventional iron/manganese removal). The last two technologies—coagulation/filtration and lime softening—are used primarily in larger systems and are not expected to be installed solely for arsenic removal.

Ion Exchange

Ion exchange, in particular, will probably be a very common technology used to comply with the arsenic regulation. It is recommended for systems with low sulfate (<120 mg/L) and total dissolved solids (TDS). The effect of competing ions drives the regeneration frequency and, in turn, the cost. Ions that compete with arsenic are sulfate (the most significant competitor), fluoride, selenium, and nitrate. Systems that have high levels of these contaminants may need a pretreatment phase as well. The EPA has data on co-occurrence but would like to hear how much competition is occurring in the field and how

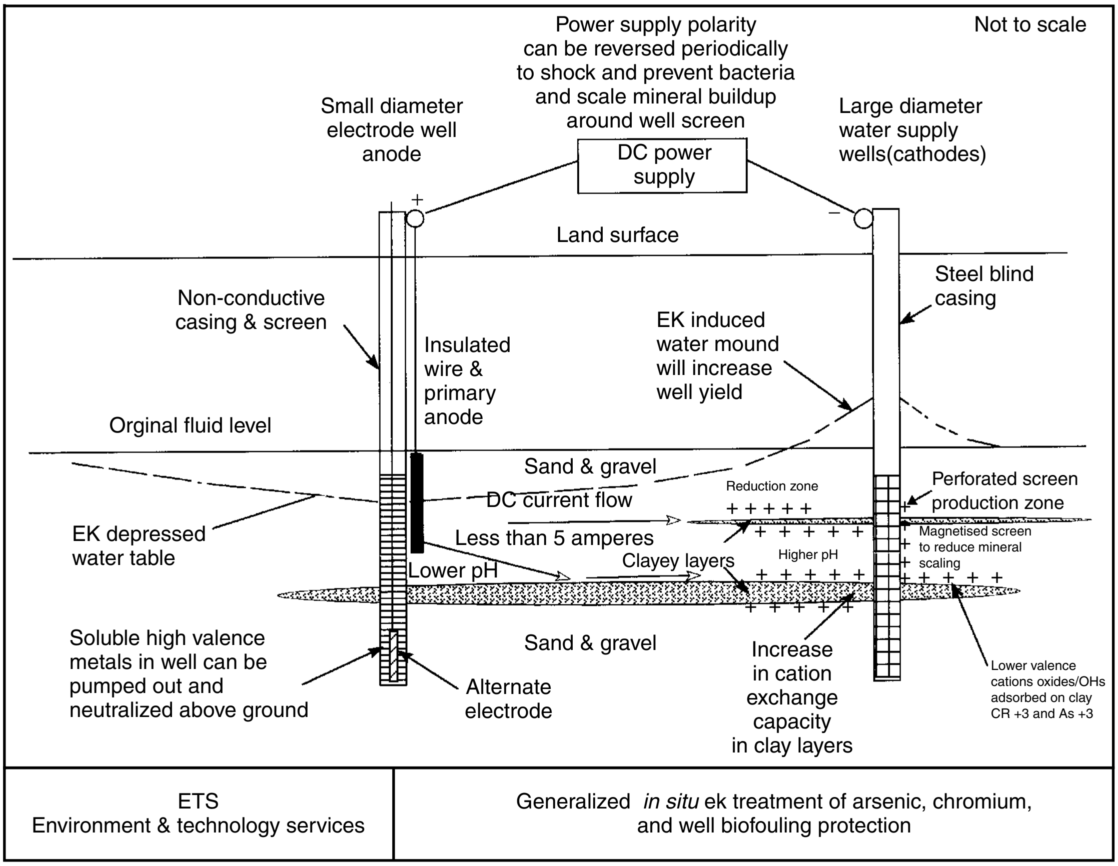

Figure 1. Generalized *in situ* EK treatment of arsenic, chromium, and well biofouling protection.

viable people think this technology would be. The waste stream, or brine, can be reused, which reduces the volume of waste and increases its concentration. The following are frequently asked questions about ion exchange:

1. How often is regeneration feasible? Will it vary by size category?
2. Can the EPA cap sulfate at 120 mg/L? Where is the TDS cap?
3. How often will an ion exchange system need regeneration? How long does it take to regenerate? Can you afford to have two systems to switch back and forth during regeneration? How much back-up water supply is necessary to provide water during regeneration? Do you have that much storage capacity available? How much regeneration is feasible for small systems? Daily, once a week, once a month? Can we expect variation by size?
4. Should we calculate costs for different removal percentages assuming full stream treatment or blending for ion exchange? Can all sources be treated at one location? Do different wells/streams serve different parts of the system?

Coagulation/filtration and lime softening are intended for larger systems. If small systems install these technologies, the EPA expects it would be in package plant form to reduce costs. A package plant is one bought "off-the-shelf" versus one custom designed for a site. A well-trained operator is needed to run these technologies; an off-site operator could utilize remote telemetry. The EPA does not expect these technologies to be installed only for arsenic removal, but if there is another contaminant in the water, it may be practical. Sludge disposal needs to be considered and may be an issue for small systems. Again, the EPA would like information from those experienced with these types of technologies.

All the technologies looked at and discussed so far work best when the arsenic is in the form of arsenic (V). **Pretreatment** converts arsenic (III) to arsenic (V). Surface water tends to favor arsenic (V), but groundwater tends to contain arsenic (III). Data shows that chlorine and potassium permanganate are effective in oxidizing arsenic (III) to arsenic (V). Possible problems include the existence of chlorine, which increases the potential to create disinfection byproducts, and membrane fouling of subsequent treatments such as RO. The EPA's Office of Research and Development is researching other preoxidants (including ozone and hydrogen peroxide, which are expected to be effective) to provide more data in the next few months.

Point of use (POU)/Point of entry (POE) devices may be appropriate for small systems serving 10,000 or fewer and are new elements of the SDWA. POE is whole-house treatment, whereas POU treats water at the tap. The EPA is looking at these devices as possible compliance technologies to meet the new MCL for small systems. Some of the nontransient, noncommunity systems with large flows of water might use POE and POU devices to treat the minor part of the flow provided for potable use. The POE/POU technologies that are available for arsenic removal are smaller versions of reverse osmosis, activated alumina, and ion exchange. Note that POU/POE technologies must be maintained by the public water system. Therefore, the need exists for substantial recordkeeping. It also increases the responsibility on the part of customers, as it requires them to facilitate entry into their homes by the utility for maintenance. The water utility is ultimately responsible for ensuring that these devices are maintained properly. The EPA is trying to determine the system size cutoff where centralized treatment would be more affordable than POU and POE devices.

Waste Disposal will be an important issue for both large and small plants. If a plant is located inland and uses membrane technologies, operators may have to pretreat prior to discharge. If the plant is discharging to a sanitary sewer because of the membranes, there may be very high salinity in the discharge as well as high levels of arsenic that might be above local sewer regulations. Ion exchange, reverse osmosis, and activated alumina treatment brines will be even more concentrated (on the order of 30,000 TDS) and more than likely will require pretreatment prior to discharge to either a receiving body of water or the sanitary sewer.

CHROMIUM TREATMENT

Reverse osmosis (RO) systems can often improve the quality of water. Reverse osmosis water treatment has been used extensively to convert brackish water or seawater to drinking water, to clean up wastewater, and to recover dissolved salts from industrial processes. It is becoming more popular in the home market as homeowners become increasingly concerned about contaminants that affect their health, as well as about nonhazardous chemicals that affect the taste, odor, or color of their drinking water. People considering the installation of a water treatment system to reduce toxic chemicals should first have their water tested to determine how much, if any, hazardous compounds are in the water. Public water supplies are routinely monitored and treated as required under the federal Safe Drinking Water Act and state regulations. Private water systems should be tested at the owner's initiative based on knowledge of land use and contamination incidents in the area (3).

Reducing Contaminants Through RO

Reverse osmosis reduces the concentration of dissolved solids, including a variety of ions and metals and very fine suspended particles such as asbestos, that may be found in water. An RO device may be installed following a water softener to reduce the concentration of sodium ions exchanged for hardness ions. RO also removes arsenic (As), chromium (Cr), nitrate (NO_3^-), certain organic contaminants, some detergents, and specific pesticides.

The Reverse Osmosis Process

In reverse osmosis, a cellophane-like membrane separates purified water from contaminated water. An understanding of osmosis is needed before further describing RO. Osmosis occurs when two solutions containing different quantities of dissolved chemicals are separated by a semipermeable membrane that allows only some compounds to pass through. The osmotic pressure of the dissolved chemical causes pure water to pass through the membrane from the dilute to the more concentrated solution. In reverse osmosis, water pressure applied to the concentrated side forces the process of osmosis into reverse. Under enough pressure, pure water is "squeezed" through the membrane from the concentrated to the dilute side. Salts dissolved in water as charged ions are repelled by the RO membrane. Treated water is collected in a storage container. The rejected impurities on the concentrated side of the membrane are washed away in a stream of wastewater, not accumulated as on a traditional filter. The RO membrane also functions as an ultrafiltration device, screening out particles, including microorganisms, that are physically too large to pass through the membrane's pores. RO membranes can remove compounds in the 0.0001 to 0.1 micron size range (thousands of times smaller than a human hair).

Design of an RO System

Although reverse osmosis is simple, a complete water treatment system is often complex, depending on the quality of the incoming water before treatment and the consumer's needs. Most home RO systems are point-of-use (POU) units placed beneath the kitchen sink to treat water for cooking and drinking. Point-of-entry (POE) systems that treat all water entering the household are more expensive to purchase and operate than POU systems.

A typical home reverse osmosis system consists of pretreatment and posttreatment filters as well as an RO membrane, flow regulator, storage container for the treated water, and dispensing faucet. The pressure for RO is usually supplied by the feed line pressure of the water system in the home, but a booster pump may be needed to produce an adequate volume of treated water. A sediment prefilter is essential for removing relatively large sand grains and silt that may tear or clog the RO membrane or clog a pump or flow regulator. Water softeners are used in advance of the RO system when household water is excessively hard. If the water is chlorinated or contains other oxidizing chemicals such as bromine, an activated carbon prefilter is needed to protect membranes sensitive to these chemicals.

To remove certain pesticides and organic solvents, activated carbon (AC) posttreatment must be included in the system. A standard AC filter positioned after the storage tank removes compounds that cause unpleasant taste and odors, including those from the tank or plastic tubing, just before water is dispensed. To remove high levels of organic chemicals such as trihalomethanes, volatile organic chemicals, and chloramines, an additional prolonged contact carbon filter (PCCF) is placed between the RO membrane and the storage tank. Combining an activated carbon filter with RO expands the range of chemicals the system can remove. Furthermore, AC treatment is improved because RO removes compounds that adversely affect AC adsorption.

The storage tank, tubing, and dispensing faucet should be made of plastic, stainless steel, or other nontoxic materials. The low pH and mineral content of RO-treated water may corrode copper pipes and allow lead to leach into the drinking water from brass components.

RO Membrane Materials

The most common RO membrane materials are polyamide thin film composites (TFC) or cellulosic types [cellulose acetate (CA), cellulose triacetate (CTA), or blends]. Very thin membranes are made from these synthetic fibers. Membrane material can be spiral-wound around a tube, or hollow fibers can be bundled together, providing a tremendous surface area for water treatment inside a compact cylindrical element. Hollow fiber membranes have greater surface area (and therefore greater capacity) but are more easily clogged than the spiral-wound membranes commonly used in home RO systems.

The flux, or capacity, of the RO membrane indicates how much treated water it can produce per day. Typically, RO membranes for home systems are rated in the range of 10 to 35 gallons per day. Thus, under standard operating conditions, it could take from 2 to 6 hours to fill a two and-a-half-gallon storage tank. CA/CTA membranes have adequate capacity for most households, but TFC membranes should be used if large volumes of treated water are needed.

RO membranes are rated for their ability to reject compounds from contaminated water. A rejection rate (% rejection) is calculated for each specific ion or contaminant as well as for reduction of total dissolved solids (TDS). It is important that consumers know their specific requirements for water quality when buying a system. For example, high rejection rates are essential when high nitrates or lead concentrations in the water must be brought below the EPA maximum contaminant or action levels.

Efficiency of RO Systems

The performance of an RO system depends on membrane type, flow control, feed water quality (e.g., turbidity, TDS, and pH), temperature, and pressure. The standard at which manufacturers rate RO system performance is 77 °F, 60 pounds per square inch (psi), and TDS at 500 parts per million (ppm). Only part of the water that flows into an RO system comes out as treated water. Part of the water fed into the system is used to wash away the rejected compounds and goes down the drain as waste. The recovery rate, or efficiency, of the system is calculated by dividing the volume of treated water produced by the volume of water fed into the system. If not properly designed, RO systems can use large quantities of water to produce relatively little treated water. Most home RO systems are designed for 20% to 30% recovery (i.e., 2–3 gallons of treated water are produced for every 10 gallons put into the system). Home RO systems can operate at higher recovery rates but doing so may shorten membrane life. The flow regulator on the reject stream must be properly adjusted. If the flow is slow, the recovery rate is high, but RO membranes are easily fouled if concentrated impurities are not washed away quickly enough. If the flow is too fast, the recovery rate is low and too much water goes down the drain. Overall water quality affects the efficiency of an RO system and its ability to remove specific contaminants. The higher the TDS, the lower the recovery rate of treated water. The amount of treated water produced decreases by 1% to 2% for every degree below the standard temperature of 77 °F. An RO system supplied with well water at a temperature of 60 °F produces only three-quarters of the volume it would produce at 77 °F. For an RO system to function properly, there must be enough water pressure. Although most home RO systems are rated at 60 pounds per square inch, the incoming feed line pressure of many private water systems is less than 40 psi. The RO system must work against back pressure created in the storage tank as it fills with water and compresses the air in the tank. The RO device must also overcome osmotic pressure, bonding between water molecules, and dissolved impurities; the higher the TDS level, the greater the osmotic pressure. The net water pressure at the RO membrane can be calculated by subtracting back pressure and osmotic pressure from feed line pressure. If the net water pressure at the membrane is lower than 15 psi, treated water production is less efficient and contaminant rejection rates are lower. Auxiliary pumps can be added to the treatment system to boost pressure and improve the quality and quantity of water produced. High-quality RO systems have valves that shut off the flow whenever storage tank pressure reaches two-thirds of the feed pressure; at that point, low net water pressure can result in low rejection rates. In some systems, once the storage tank is filled, surplus treated water is discarded; water loss from such units is frequently excessive. A system that automatically shuts off when the pressure on the tank reaches a given level saves water.

Maintenance of an RO System

An RO system must be well maintained to ensure reliable performance. Clogged RO membranes, filters, or flow controls decrease water flow and systems performance. If fouling is detected in early stages, the membrane can often be cleaned and regenerated. The cleaning procedure varies depending on the type of membrane and fouling. Completely clogged or torn RO membranes must be replaced. In addition, pre- or postfilters must be replaced once a year or more often, depending on the volume of water fed through the system and the quality of the feed water. Damage to RO membranes cannot be easily seen. The treated water must be analyzed periodically to determine whether the membrane is intact and doing its job. Many systems now have a built-in continuous monitor that indicates a high TDS level, a sign that the system is not operating properly. It may also be necessary to test regularly for specific health-related contaminants such as nitrates or lead. Microorganisms, dead or alive, can clog RO membranes. To prevent biofouling, RO units must be disinfected periodically with chlorine or other biocides provided by the manufacturer. Continuous chlorination can be used with cellulosic membranes to protect the system from biofouling and eliminate the particle-trapping slime that worsens other forms of fouling such as scaling. Chlorine and other oxidizing disinfectants are harmful to thin film composite membranes. If the feed water is chlorinated, an activated carbon unit must be used to remove the oxidizing chemicals before they reach the TFC membrane. Activated carbon (AC) prefilters should not be used on nonchlorinated water supplies because they provide a place for microorganisms to multiply and lead to increased biofouling of the RO membrane surface. It is important to replace AC filters periodically following the manufacturer's instructions, especially after an extended shutdown period during which microorganisms can flourish.

Choosing an RO System

Homeowners who are thinking about buying reverse osmosis systems should determine their initial water quality and their goals in adding water treatment systems. RO removes many inorganic impurities from drinking water, especially nitrate. Its effectiveness depends not only on the type of membrane but on feed water quality, temperature, pressure, and flow control, as well as the type and concentration of specific contaminants to be removed. A typical RO system consists of a sediment filter, pump, reverse osmosis membrane, flow regulator, storage tank, final activated carbon filter (for taste and odors), and dispensing faucet. An AC prefilter is sometimes needed for dechlorination. RO is commonly used to treat only the water used for drinking and cooking at the point of use rather than at the point of entry for all household use. RO membrane types vary in their ability to reject contaminants and differ in capacity (the volume of treated water produced per day). Water pressure is an important factor in determining the RO system's rejection rate, capacity, and recovery rate (amount of treated water produced per amount of feed water used). Maintenance of an RO system is essential for reliable performance. High levels of TDS and microorganisms in the system are commonly the cause of fouled membranes. Treated water should be monitored for TDS and the level of any specific contaminants that may affect health.

A list of home water treatment devices certified by various Department of Health Services can be found on their websites.

BIOFOULING TREATMENT

Historically, there have been three approaches to the declining operation of a water well of any common type. One is to simply abandon the well and install a new well of similar or greater capacity to replace the abandoned well. A second involves attempting to change the operating techniques (e.g., pump times, volumes, sequences of up- and downtimes, and control flow by drawdown limitations) or change some components in the well (e.g., pump, screen) in the hope that the well will recover from the observed problem. The third is to attempt an analytical approach to the problem by determining

—first, the cause;

—second, confirm that the effects witnessed can be related to the cause identified;

—and third, determine and apply a treatment strategy that counteracts the cause and allows the well to function as designed.

Increasing economic and environmental costs and concerns are now restricting the ability of a well user simply to replace a failing well. Economic concerns relate to the increasing costs involved in well replacement and the growing sensitivity for maximizing the use of each well installation by extending its useful life (i.e., environmental sustainability). Environmental concerns are being brought to the fore because groundwaters are no longer seen as an infinite resource. In some areas, aquifers are now being heavily depleted by the demand, and there is little flexibility to provide additional capacity. Another major environmental concern is the impact of various forms of pollution on well fields. In the past decades, general attitudes may be summarized by an "out of sight, out of mind" approach in which groundwater was given a lower status than surface waters. Various chemical leakages from industry, agriculture, and various service industries were not considered as important as those in surface waters. When a pollutant impacted surface water, the effects could often be relatively quickly appreciated through radical eutrophication, deteriorating water quality, and water unacceptable to users. One major difference between surface and groundwaters is the fact that the former flows as large unconfined masses whereas the latter moves as a confined mass within porous media. This difference is very critical to the current understanding of groundwater flow and quality.

It is not easy to appreciate the complex interactions that occur between flowing groundwater and the media through which it is passing as it moves to a well, a spring, or interfaces with another aquifer. For the last century, it has been popularly believed that groundwater is essentially sterile (devoid of biological activity) and that all activities within an aquifer may be explained almost exclusively by a combination of physical and chemical processes. Today, the hydrology of groundwater systems still leans heavily on this assumption. Through the science of subsurface microbiology (the study of microorganisms in the crust of the planet), it is now becoming increasingly evident that groundwater movement and quality are affected by microbiological interactions. In the past decades, these have been ignored, and one of the major consequences has been that the effects of these microorganisms as biological filters (interface) have been ignored. Pollutants within a groundwater system may become entrapped (and possibly degraded) within these biological filters and so not appear in the groundwater resurfacing through a well. Environmental monitoring of the product (postdiluvial, after the "event") water from a well may not necessarily give an "accurate" picture of the chemical loading in the transient (causal) water itself. There has been a tendency for groundwater users to rely on product ("biofiltered") water for environmental assessment, and yet this water may not accurately allow a risk assessment for that well (due to bioentrapment of some chemicals of concern).

In the next two decades, the realization of the nature of the biological interfaces within and around water wells may cause much tighter environmental constraints to be placed on new well installations, which would mean that greater attention would be paid to extending the service life of existing wells through preventive maintenance and effective rehabilitative programs. The mindset that a water well is a physical object set within a chemical and physical world has to change. This mindset has generated a "traditional" attitude that a dysfunctional well is simply a result of chemically driven corrosion, encrustation, clogging processes, or the physical collapse of the system (through such events as "silting up" and "collapsed" aquifer and well structures).

Acidization has commonly been applied as a remediation technique to dissolve and disperse the clogs and encrustations, and various disinfectants (such as different formulations of chlorine) were used to control any coliform and other bacteria that may be growing down the borehole (and presents a potential health risk). Slime formations were considered by many to be simply physical-chemical accumulates that may result in clogging, encrustation, and corrosion. Even today, camera logging a water well is considered sufficient to view all biological and much of the chemical deposits (e.g., silts and salts) that can be causing problems around a well. Please see the section on the "Preliminary Diagnosis of Biological Fouling of Water Wells Using TV Camera Logging Methods."

Combinations of disinfectants, selected acids and even, in more recent times, dispersants (a.k.a. wetting agents) have become part of the arsenal of weapons used to rehabilitate problems in a well. One of the findings from these actions has been that "no one size fits all" and that each well should be treated as unique and requires customization of the treatment parameters to optimize maintenance practices. This approach stems from observations that each well can be characterized as different from other wells in the same field. Many instances exist where two wells of the same construction and characterization placed within feet (meters) of each other in supposedly the same aquifer formation bear very different characteristics. An unfortunate result of this is that a treatment may be successfully applied to one well in a field but that same treatment may fail on a neighboring well of exactly the same characteristics in construction, operation, and mode of failure (4).

INNOVATIVE *IN SITU* TREATMENT

In situ electrokinetic treatment of chromium, arsenic, and biofouling may provide a cost-effective solution (5). The electrokinetic treatment process involves applying direct current (dc) in a medium (soil and water). The flow of electrons from anode to cathode creates a migration of cations in the medium toward the cathode. The electrolysis of water creates a higher pH and oxidizes the metal or reduces its valence, which renders the metal into a nontoxic form near the cathode. Clayey material may show a dramatic increase in cation exchange capacity under a high pH near the cathode.(6–8) The proposed electrokinetic process can be applied both *in situ* and *ex situ*. Figure 1 presents a more realistic distribution of the various valence states of metals under the proposed *in situ* electrokinetic influence.

Besides the treatment of metals, the beneficial side effects of the *in situ* EK treatment are as follows:

- The well itself is set up as a cathode, so iron bacteria will not live on the surface of the well casing and perforation because of the high pH.
- The electrokinetically induced water migration toward the cathode (well) may induce an increase in hydraulic head, thus increasing well yield.

No such treatment has been tried on chromium, arsenic, and manganese in a saturated medium to date. There are many successes of the proposed EK process in the laboratory and in soil. However, we have successfully demonstrated the electrokinetic control of selenium and boron in clayey saturated media at two sites in the Panoche Irrigation District, Central Valley, California. We believe that the same EK control can be applied to chromium, arsenic, and biofouling because of the similarity of the multiple valence forms to those of selenium and boron. Due to the simplicity of the cathode and anode setup, we believe that the proposed EK processes will prove cost-effective. The proposed *in situ* EK treatment (once set up) is permanent. It has a one-time capital cost and minimum long-term maintenance costs. The continuous operating electricity demand will not exceed 50 amperes at 30 to 100 Vdc or 1500 to 5,000 watts per site.

ARTESIAN WATER

David P. Commander
Water and Rivers Commission
East Perth, Australia

Artesian water is groundwater that flows freely at the surface from an artesian bore or well. The name artesian comes from the flowing wells constructed in the twelfth century at the Carthusian monastery near Lilliers in the northeastern French province of Artois.

The term "artesian" has also been extended to refer to artesian aquifers, in which the groundwater is under a sufficient pressure head to flow at the surface, and to artesian basins, sedimentary basins that may contain artesian aquifers. The term subartesian refers to the situation where the water level rises above the top of the aquifer but is below ground surface.

The artesian condition is, however, an accident of topography, not necessarily a property of the water, the bore, or the aquifer. For this reason, it is preferable now to use the term "confined" to refer to the aquifer. "Confined" implies the presence of a low permeability confining bed above the confined aquifer, which allows a positive (above ground) hydraulic head to be maintained. Rarely, flowing water can be obtained from an unconfined aquifer without a confining bed, provided there is a sufficient upward head gradient.

Artesian water is common in sedimentary basins, where there are extensive aquifers overlain by confining beds. The classic artesian basin is shaped like a saucer; the aquifer crops out around the elevated margins of the basin, where it can be recharged by rainfall or stream flow (see Fig. 1). The cities of London and Paris lie at the centers of their basins and were among the first cities to exploit artesian water on a large scale. The Great Artesian Basin in eastern Australia is one of the largest examples; it is 1500 km across. However, artesian conditions can occur in other geological formations.

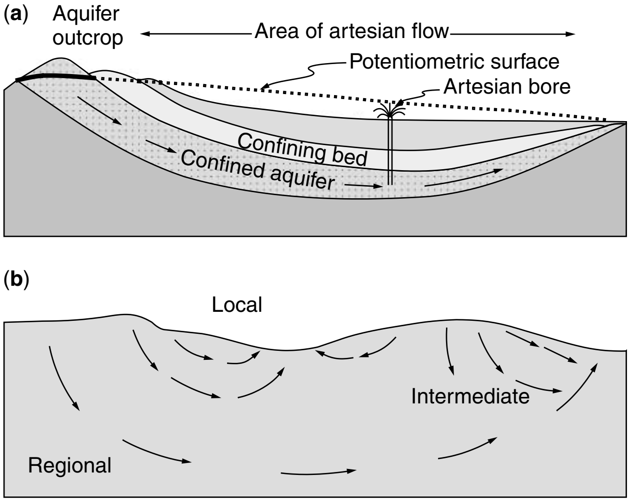

Figure 1. Groundwater flow in a classical artesian basin (**a**) contrasting with cross-formational flow in local, intermediate, and regional flow systems in a nonclassical basin (**b**).

The phenomenon of free-flowing groundwater was first documented sometime in the first millennium B.C. at Dakhla Oasis in the western desert of Egypt, during the course of progressively deepening hand-dug wells. The first to explain the correct nature of artesian wells were Mahammad Karaji (died 1016) and al Biruni (973–1048), but in Europe, the explanation had to await an understanding of the hydrologic cycle. In 1691, Bernadino Ramazzini (1633–1714) described the artesian wells that were commonplace in the Italian city of Modena. He drew a geologic section, although it appears he envisaged underground rivers rather than porous strata as the water source. In 1715, Antonio Vallisnieri (1661–1730), President of the University of Padua, reasoned that rainfall on the mountains was the source of the artesian water at Modena and illustrated his work with geologic sketches of the Alps made by Johann Scheuchzer.

The existence of artesian water began to be widely appreciated in Europe in the early 1800s, after French engineers introduced Chinese drilling technology. The success of the Grenelle artesian bore near Paris, in which water rose to a height of 33 meters and flowed at the rate of 4000 cubic meters per day stimulated the development of artesian water. In the absence of suitable pumps, the availability of free-flowing water was an important economic factor in opening up new lands for agriculture and pastoral use in the Americas and Australia. The existence of the Great Artesian Basin in Eastern Australia was postulated in 1881. Proved by drilling in 1887, it rapidly led to pastoral development. The recognition of waterborne diseases and the contamination of shallow water supplies in cities was also an incentive to developing artesian supplies of clean drinking water in the Eastern United States, Europe, and Australia by the turn of the century.

Such was the impact of free-flowing water on the public that drilling for artesian water was often carried out in geologically unfavorable places (and despite professional advice); the perception was widely held that artesian water would be encountered, providing the boring was deep enough.

Geologic textbooks of the mid- to late 1800s illustrated the structure of classical artesian basins such as the Paris and London Basins, although it was recognized by the end of the century that flowing wells could also occur under different conditions. A series of papers by U.S. Geological Survey authors provided detailed explanations of artesian water. Thomas Chamberlin's classic paper (1), which is recognized as the beginning of the science of hydrogeology in North America, systematically laid down the conditions under which artesian flows would be obtained: the presence of a pervious stratum, impermeable beds above and below, an inclination of the beds so that the edge is higher than the surface at the well, and adequate rainfall.

Chamberlin's observations can now be qualified somewhat. Few, if any, confining beds are now considered completely impermeable, and in many places, the confining beds yield significant amounts of water by leakage to adjacent artesian aquifers. Tóth (2) has drawn together ideas on regional hydraulic continuity, recognizing cross-formational flow in which it is not necessary to have inclined beds to produce artesian conditions. In many artesian basins, the water is of great antiquity, a million and a half years in the case of the discharge from the Australian Great Artesian Basin, although current rainfall is necessary to maintain the hydraulic head in recharge areas.

In 1928, Oscar Meinzer's paper on the elasticity of artesian aquifers drew together much of the work from the intervening period, demonstrating the concept of elastic storage, whereby flowing water is released by the reduction in hydraulic head and compressibility of the aquifer matrix (3).

However, there were many who denied the conventional theory (held in the main by Geological Surveys) that the origin of the water was meteoric and that the pressure was related to the elevation of the water table in outcrop areas of artesian aquifers. In Australia, distinguished academic geologists such as J. W. Gregory (1906) and Alexander du Toit (1917) invoked juvenile and connate water, rock pressure, and gas bubbling to explain the origin of water and pressure. These ideas were supported by American geologists whose oil-field experience led to the concept of closed and hydraulically isolated systems.

There is still debate surrounding the explanation for the origin of artesian pressure, stimulated by studies of nonclassical basins such as the Hungarian Basin, and this has led to a better understanding of basin hydrodynamics.

Studies of the Great Artesian Basin clearly show the hydraulic continuity of aquifers over large distances and the observed potentiometric heads that decline gently away from the recharge areas. Furthermore, isotopic age dating using chlorine-36 indicates a transit time across the basin of 1.5 million years that correlates with hydrodynamic modeling.

Artesian water is released from elastic storage, and as the pressure is reduced, the aquifer matrix bears more of the hydrostatic pressure. Thus, subsidence occurs in most situations where the compressibility of the aquifer is much greater than that of water itself. Artesian flows may also lead to irreversible consolidation of aquifers, particularly in geologically recent environments that are not fully consolidated. In large artesian systems such as the Great Artesian Basin, free-flowing water is effectively mined from elastic storage, as there is little potential to induce more recharge on the timescale of abstraction. Maintenance of artesian head is the priority for management, given the economic consequences once bores cease to flow. In the Great Artesian Basin, a program is underway to cap and control the flow of artesian bores to maintain the aboveground pressure and to prevent the waste of water, which had been allowed to flow many kilometers in open "bore drains" to water livestock.

Owing to the great depths from which it may come, artesian water is often much warmer than the shallow groundwater and may have to be cooled before use. A feature of artesian bores is that the head of water varies according to the temperature. A bore may cease to flow after the water is shut in and the water column cools. Artesian flows may also cease after degassing in a shut-in bore. Artesian flows are also affected by barometric pressure changes.

Artesian water may also be relatively highly mineralized, owing to the long travel time, and contain gases and dissolved iron, which may precipitate at the surface. The words may, therefore, have a bad connotation in terms of drinking water.

MODELING CONTAMINANT TRANSPORT AND BIODEGRADATION IN GROUNDWATER

Sascha E. Oswald
UFZ Centre for Environmental Research
Leipzig-Halle, Germany

INTRODUCTION

What Is a Groundwater Contaminant?

When dealing with contaminant transport modeling, we have to be clear from the beginning that almost any substance could be a contaminant. It all depends on the nature of the object which may be at risk and in which concentrations the substance is present. This object often is the human being, and sometimes a special one, like a baby, but sometimes also other living organisms, or even a habitat or ecosystem that may be endangered. The concentration, or more precisely the intake, can determine whether a substance is harmless or even an essential nutrient, or harmful, for example, in case of chloride or zinc. That is the toxicological perspective. From a chemical perspective, there are organic and inorganic contaminants; from a physical perspective, there are dissolved and particulate or free-phase contaminants, and biologically, there are a variety of animals, microorganisms and viruses, or nonliving substances, that could be harmful and thus could be contaminants. In the following, we focus only on the more familiar type of contaminant in groundwater, that is an organic, dissolved, non living substance, and refer the reader otherwise to more comprehensive descriptions of groundwater contaminants.

Why Model Contaminant Transport?

Contaminants released into the subsurface may be spread by transport in groundwater to locations further away. That is why assessing the transport of a contaminant may be useful. A typical objective may be to protect the groundwater resource itself from contamination or to protect somebody who could be affected by the contaminated groundwater. The latter case is the basis for the source—pathway—receptor approach to risk assessment, which judges the impact of a contaminant by its pathway from a source to a particular receptor that will be potentially harmed by the contaminant. Modeling is only one way to assess contaminant transport, but can describe a complex situation in detail and thus may allow predictions.

Why Model Biodegradation?

Biodegradation is an important factor in the fate of organic contaminants and may reduce the concentration and also the total mass of a contaminant. Although several processes can contribute to the natural attenuation of contaminants, biodegradation is often the main process by which mass may be destroyed; other processes such as sorption merely retain the contaminant mass for later release. Therefore, modeling monitored as well as enhanced natural attenuation, usually has to include biodegradation modeling.

Processes

The key processes to be modeled are advection, dispersion, sorption, and degradation by microbes. However, further processes could also be relevant, for example, ion exchange, precipitation and dissolution of minerals, speciation, and surface-complexation.

Modeling Basis and Related Modeling (Flow, Transport, Hydrogeochemical)

The basis for transport modeling is flow modeling; transport modeling itself is the basis for modeling contaminant transport and biodegradation (see Fig. 1). Often in more general terms this is called reactive transport modeling, which includes transport plus biodegradation and/or hydrogeochemical modeling. To model a field scale problem of reactive transport appropriately, one should plan this as a set of modeling tasks building up to this challenging undertaking.

Scale and Type of Transport

The scale of the problem is an important factor when building a model because it influences the modeling concept and the modeling tools to be chosen. Scales may range from pore scale, for pore blocking by bacterial conglomerates, to regional scale, for agricultural contaminants. Here, we focus on an intermediate to subregional scale, such as a contaminant plume originating from a point source or a remediation operation on a site scale. The processes included in a contaminant transport model may be special transport processes such as fracture networks, multiple porosity behavior, or preferential flow paths, but we will limit the discussion to the standard, equivalent porous medium approach.

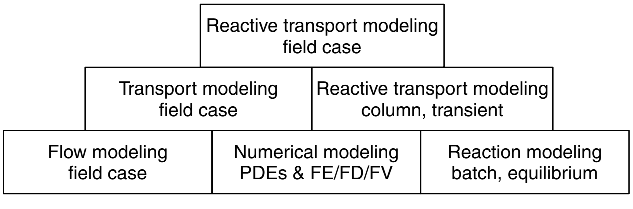

Figure 1. Key pyramid for achieving reactive transport modeling on a field scale.

THE BASIC CONCEPTS

A modeling project starts with the definition of its aims and purpose, and subsequently the modeling concept is built up. Conceptualization of the problem will probably require consideration of several aspects, especially in reactive transport modeling.

Chemistry

The chemical nature of the contaminant, the groundwater, and the aquifer may determine the fate of a contaminant to a high degree. The presence of electron acceptors that are usually needed for the degradation of organic contaminants, electron donors, enables certain reactions to occur in principle. The groundwater pH and redox condition determine which reactions actually can occur at a certain location. All of these may vary spatially and temporally. Also, the occurrence of other contaminants may affect the fate of a particular contaminant substantially. Furthermore, the presence of organic matter, charged surfaces, and minerals in the aquifer constitute pools for sorption of solute species. Altogether, this should be taken into account when defining the set of chemical species and the possible reactions.

It should also be mentioned that chemical reactions are treated as either equilibrium or kinetic reaction, depending on how their rates compare to advection and diffusion timescales and rates; equilibrium is faster than transport, and kinetic is slower. These two reaction types imply different resulting behavior, and also different types of equations, parameters, and numerical solution techniques; more details may be found in the literature on hydro(geo)chemical modeling.

Microbiology

Biodegradation implies that there is a biological activity by which degradation occurs, as opposed to chemical degradation. Populations of bacteria in aquifers constitute biota able to perform degradation in groundwater. Usually, there is a microbial community in an aquifer that has some diversity but is not really flourishing compared to soil or the biosphere. Both features are likely to be affected by biodegradation. The bacteria will try to biodegrade the contaminant when they can gain energy or carbon by this. The way they achieve the biodegradation is via enzymes, which they release or at least make available inside the cell. The kinetics of these enzymes can be described by the Michaelis–Menten formula, which is the starting point for equations used to describe biodegradation in groundwater.

In a constant microbial population feeding on a contaminant that is present in abundance as well as all other substances needed for the reaction, the rate of biodegradation is set by the enzymes available and is a constant in this quasi-steady-state scenario. This means the enzymes are saturated by the contaminant as a substrate, and this biodegradation kinetics is called *zero-order degradation*. Here, the degradation rate, that is, the change of the contaminant concentration C with time due to biodegradation, is a constant:

$$\frac{\partial C}{\partial t} = const. \tag{1}$$

However, often the contaminant, as the substrate for the bacteria, is not present in abundance, but its availability for the reaction is limited, similar to the concentration of the enzymes. Due to the mass action law, the reaction rate is proportional to the contaminant concentration. This results in a *first-order degradation* with first-order rate constant λ, where

$$\frac{\partial C}{\partial t} = \lambda C \tag{2}$$

Note that a radionuclide decays according to the same type of equation. In both cases, a half-life can be defined based on λ: $T_{1/2} = \ln 2/\lambda$.

The concentration of substrate may decrease during biodegradation, or perhaps the contaminant is not present in large quantities. Hence, a more realistic approach is to account for both former cases. A way of doing so is an empirical form of the Michaelis–Menten kinetics, called Monod degradation kinetics

$$\frac{\partial C}{\partial t} = \mu_{\max}\frac{C}{k + C} \tag{3}$$

where k is the half saturation constant and $\mu_{\max} = \lambda \cdot k$ is the maximum possible degradation rate constant. For small C, $C << k$, the degradation rate is proportional to C, whereas for large C, $C >> k$, it levels off to the constant rate $\mu_{\max}$, as in zero-order degradation.

An even more realistic concept takes into account that bacterial enzymes do not perform the degradation by themselves but merely facilitate a reaction between contaminant and another substance, usually an electron acceptor with concentration EA. The latter has to be present at the same place and time as the contaminant to allow the reaction to proceed. Then the degradation is described by the double Monod formulation:

$$\frac{\partial C}{\partial t} = \mu_{\max}\frac{C}{k_C + C} \cdot \frac{EA}{k_{EA} + EA} \tag{4}$$

And finally, to add some microbiology to it, bacterial populations can grow and die. Furthermore, they can be attached to grain surfaces and even create biofilms, or be transported with the water flow, or a mixture of both. This may affect the biodegradation very much, because the degradation rate is basically proportional to the amount of active bacteria in a unit volume, called X. This is taken into account when using the following equation, which constitutes *higher order degradation* behavior:

$$\frac{\partial C}{\partial t} = \mu_{\max}X\frac{C}{k_C + C} \cdot \frac{EA}{k_{EA} + EA}$$

and

$$\frac{\partial X}{\partial t} = const \cdot \frac{\partial C}{\partial t} \tag{5}$$

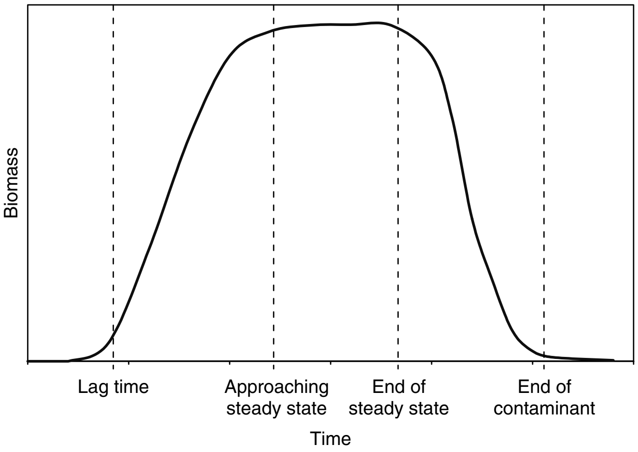

Figure 2. Example of the development of a bacterial population that is degrading a contaminant.

A typical case is that a certain type of bacteria is present in small quantities (see Fig. 2). This population starts to grow, when environmental conditions are favorable for them: there is a contaminant they can feed on and an electron acceptor they can use for the degradation reaction. It takes a particular time, until the size of the population reaches a level that makes a real difference in the contaminant concentration. Then its growth slows down, for example, when one of the substances for the degradation reactions becomes limiting. This could lead to a steady population of microbes, especially because bacteria grow but also die. Finally, when the environmental conditions change again, for example, by final consumption of the contaminant, the decay of bacteria is larger then their growth, and the population declines.

Sometimes the degradation product of a contaminant is a contaminant itself, and so on. Then a whole chain of degradation has to be taken into account, for example, in the biodegradation of PCE (1). Such a chain may be modeled on the basis of first-order degradation of each member of the chain. In this case, it is mathematically a process similar to chains of radioactive decay. However, it could also be modeled as a set of components, which are linked by the degradation-production term, and each could follow any of the mentioned degradation kinetics.

A further possible process is inhibition of a particular biodegradation process by the presence of relevant amounts of a certain substance, for example, oxygen, or of the contaminant itself, which would be called self-inhibition. To account for inhibition, an additional term can be added to the biodegradation equation, which reduces the degradation rate for this case.

A range of processes could also be included in modeling biodegradation, if they are relevant for the specific problem: (1) transport of dissolved species into a biofilm of bacteria; (2) bacterial attachment and detachment to the solid matrix; (3) sorbed contaminants may not be degraded, as long as they are bound to surfaces or organic matter; and (4) bacteria may even feed on a contaminant in a solid phase, on the other hand.

Geochemical and microbial processes are closely linked in groundwater. Microbial activity is based on the availability of substrates, electron acceptors, redox and pH conditions, yet influences all these conditions, and thus may initiate additional geochemical processes, such as precipitation of minerals. Therefore, a realistic and detailed model of biodegradation reactions in groundwater must also include a set of geochemical reactions.

Dispersion

Hydrodynamic dispersion may seem a minor issue relative to those discussed before. Nevertheless, dispersion at the plume fringe can be a key factor in biodegradation, even more than for a nonreactive contaminant. The velocity-based mechanical dispersion creates mixing between species necessary for reaction on a scale depending on longitudinal and transverse dispersivities. Molecular diffusion does the same on smaller scales down to the pore scale and may even dominate hydrodynamic transverse dispersion, especially in the vertical direction. By its nature, biodegradation at plume fringes tends to create, or at least maintain, high concentration gradients of the consumed species, as opposed to dispersion that smooths them.

Here, the relevance of dispersion is stressed, but for modeling approaches, we refer to transport modeling literature. However, it should be clear that only part of biodegradation happens at the plume fringes and part in the plume core where electron acceptors still may be stored as minerals.

MATHEMATICAL MODELING APPROACHES

Analytical Modeling

The solution of contaminant transport and biodegradation equations by analytical methods is possible for only a limited number of problems that are also simple in terms of boundary conditions, geometry, and biodegradation concepts. Nevertheless, they are very useful in answering basic questions, and they are quick, accurate, and straightforward to implement; Domenico and Schwartz (2) give a good collection of such solutions. Hence, it should always be checked first, if an analytical approach can address the particular modeling objective. The U.S. Environmental Protection Agency (EPA) provides the spreadsheet model *Bioscreen* based on analytical solutions, which, for example, allows obtaining quickly an impression of the effects of parameter values, different reaction models, and source zone extent (3). Finally, these types of approaches are used widely for risk assessment, but rather due to their simplicity and swiftness, than for their general applicability.

Numerical Modeling

Numerical modeling is based on techniques such as finite difference, finite element, or relatives of them. Only a few aspects are presented here that are specific to modeling reactive transport and other coupled equations.

- Reactive processes can be fast or slow compared with timescales of transport processes in aquifers or columns. Fast reactions are treated as an equilibrium process and may be described mathematically by thermodynamic mass action laws; kinetic reactions might be formulated as biodegradation kinetics, as before. Incorporating both imposes additional numerical challenges.
- The slow part of the reaction system is described via partial differential equations, and the fast part via nondifferential equations. There are different ways of combining them (4).
- Transport and reactions can be treated as sequential numerical steps or in one single step. The former is the less accurate method, even if the sequential steps are iterated, and may also require small time steps, whereas the latter is slower and needs more memory (5).
- Biodegradation can be handled as a single step, but alternatively also as a first step providing intermediate products followed by one or several processes of electron acceptor consumption. In the latter case, the first step is usually treated as slow, and the second step as fast. For a current literature survey of one- versus two-step, approaches, see Brun and Engesgaard (6).

NUMERICAL MODELING TOOLS

Purpose

A broad range of codes, packages, and modules deals with transport and biodegradation modeling. They are applied usually to modeling problems that are studied in greater detail, and more complex processes have to be included in the modeling concept. The selection of a modeling tool for a particular study should be governed by the aim of the study, but in practice also depends on the availability of programs and the familiarity of the modeler with particular codes.

Types

One-dimensional geochemical codes can calculate transport and speciation together with a comprehensive list of geochemical reactions, including biodegradation. One of these codes, PHREEQC (7), is probably the most frequently used program with these specifications. It is a thoroughly tested, well maintained and growing program, offers a lot of features including graphical user interface and inverse modeling, and is taught frequently in courses around the world.

For two-dimensional applications, existing numerical programs typically come from an engineering background and include flow and transport modeling with added capabilities for reactive transport. The most famous and most widely used program package in this category is the MODFLOW family (8). Here, several packages for reactive transport simulations have been added to the flow simulation packages: MT3D (9), RT3D (10), and PHT3D (11) and may be applied via one of the commercial MODFLOW packages with a graphical user-interface. Alternatively, BIOPLUME III is a noncommercial code to simulate natural attenuation of hydrocarbons in two dimensions (12).

Furthermore, there are other programs, which are designed especially to deal with complex, three-dimensional reactive transport simulations incorporating a lot of real complexity. These are often research codes rather than commercially spread programs, and thus they may be less well documented, less user-friendly, less easily available, and restrictions may apply for their use. But they represent the state of the art with respect to a comprehensive biochemical interpretation of field scale biodegradation modeling, and their use is often free of charge. Some examples of codes falling in this category are presented in Table 1.

An important note: The programs named so far represent a snapshot of today. However, these programs are a type of software that may be further developed in the future, but their development may also be discontinued or follow a different route. Therefore they should be seen as examples rather than unchanging recommendations. However, there are organizations that offer up-to-date programs in contaminant transport and biodegradation modeling, and even offer some of them free on-line. Two of them are the U.S. Geological Survey (USGS) (http://water.usgs.gov/software/ground_water.html) and the U.S. Environmental Protection Agency (EPA) (http://www.epa.gov/ada/csmos.html).

Handling

One should be aware that the hard work only starts after selecting the software fitting the purpose and the budget and learning how to run it. At that time, one has to specify actual parameter values, and this issue is even more important for reactive transport modeling than for other types of modeling in groundwater. There are more parameters involved, and often their values are difficult to obtain. This is one of the big and crucial problems in reactive transport modeling, especially for field cases: How to get the parameter values for biodegradation and the large number of components involved? Field tests are expensive and potentially give ambiguous results due to the dynamics and heterogeneity of biodegradation and plumes, but lab tests represent the field site only to a degree. For example, degradation rates found in the lab are typically higher, even by one or two orders of magnitude, than those fitted to field degradation. Nevertheless, laboratory tests can yield valuable information: (1) The biodegradation concept and relative importance of processes seem to be a valid starting point for field case modeling. (2) There are parameters that are more transferable to the field than rate constants, which are, for, example half saturation constants and inhibition coefficients. (3) Modeling of a lab experiments forces the modeler to get a complete and consistent picture of processes involved and parameters to be quantified.

Table 1. Examples of Numerical Programs as Tools for Sophisticated, Three-Dimensional Reactive Transport Simulation in Groundwater. This is not a Complete List of Such Codes

Name	Place or Organization of Development	Reference
BIO3D & BIONAPL3D	University of Waterloo, Canada	(13,14)
CRUNCH	Lawrence Livermore National Laboratory/Pacific Northwest National Laboratory, USA	(15)

TBC	University of Heidelberg, Germany	(17)
UG	IWR, University of Heidelberg, Germany	(18)

There will almost always be some parameters in reactive transport modeling that have to be fitted, preferably by inverse modeling, but maybe also by adjusting them by hand. Both ways work better when more data are available on all aspects of the problem. In any case, the sensitivity of the model to the choice of the parameter values has to be assessed thoroughly, and the fitted values have to be checked afterward for their plausibility, at least if no boundary limits have been used for parameter fitting. The sensitivity of parameters and the range of sensible parameter values determine the inherent uncertainty of the model. However, stochastic approaches are required for these complex, coupled, and nonlinear systems to get a real handle on the range of possible outcomes of certain model properties. Unfortunately, this adds heavily on top of the numerical load required anyway, and thus often a stochastic assessment has to be based on simplified conceptual models.

This leads us to the fact that the hardware for reactive transport modeling is still a limitation in dealing with complex problems, besides the problem of appropriate parameter values. On a standard PC of the current generation, even one-dimensional simulations may take hours to days to complete. This illustrates the need to enhance calculation power by using parallel processing capabilities for these simulations, especially for two-dimensional and three-dimensional problems. However, besides access to such hardware, this also requires software that can run on multiple processors at the same time.

Finally, modeling also means that the user has to deal with modeling results and has to interpret them. One aspect is that numerical modeling results should be frequently checked for consistency and accuracy, which is true even more for reactive transport modeling than for pure transport modeling. Another aspect is that often a large amount of data is produced, which leads to the necessity to visualize intelligently and efficiently the usually time-dependent data to obtain the best interpretation, especially for two- and three-dimensional data sets.

CLOSING REMARKS

This article is only an introduction to the field and touches on several subjects. For an excellent and clear book to get into this topic, we recommend Zheng and Bennett (19). Furthermore, the IAHS red book series provides a cross section of contemporary scientific contributions, for example, Thornton and Oswald (20) for natural and enhanced attenuation of contaminants or Stauffer et al. (21) and Kovar and Hrkal (22) for a broad range of issues on groundwater flow and contaminant transport modeling.

Acknowledgments
Dr. Ian Watson of the Department of Civil and Structural Engineering, University of Sheffield, UK, helped in reviewing and improving this entry.

BIOFOULING IN WATER WELLS

Stuart A. Smith
Smith-Comeskey Groundwater
Science LLC
Upper Sandusky, Ohio

BIOFOULING EFFECTS ON PRODUCTION EFFICIENCY AND WATER QUALITY

Biofouling as a term has its origins in pre-World War II studies of marine fouling and generally refers to coating, encrustation, and corrosion associated with the attachment of organisms to surfaces, including human-engineered structures. The phenomenon arises from the tendency of life across all known kingdoms to cling to and use surfaces. Biofouling takes many forms, ranging from bacterial-viral films plaguing urinary tracts to fouling of water intakes and other maritime structures (and even baleen whales) by films that also include macroorganisms such as barnacles and zebra mussels.

Biofouling of water wells and associated downstream systems tends to result from the formation of biofilms by bacteria. It is now widely recognized that biofouling is the first or second most costly deteriorating factor for groundwater systems in North America (1–3), and the problem has been recognized as important worldwide (4–6) for many years (7), although not universally accepted.

The composition of biofilms in any particular water well most likely echoes the populations of microflora in the associated aquifer and earth materials through which recharge passes. Those that thrive or persist are adapted to the environmental conditions in the well and contributing aquifer and vary by aquifer conditions (3,8). Where conditions permit, biofilm communities may closely resemble those in surficial soils, or they may be distinct.

In transmissive media systems such as aquifers and associated water wells, an important function of biofilms is to manipulate oxidation-reduction gradients and to accumulate and recycle resources (nutrients, metals, and organic carbon). One result of this activity is the deposition of reactive metal oxides and sulfides and rapid transformation of other redox-sensitive species, particularly in the nitrogen and sulfur series. The oxides are bulky solids and, along with slimes, contribute to blocking pore spaces and various engineered apertures.

The best known form of well water biofouling, iron and manganese biofouling, develops from both direct microbial function and indirect or passive interactions among biofilm, aqueous solutions, and surfaces. Ferrous iron compounds [Fe(II)] or ions (Fe^{2+}) can also be oxidized to the ferric [Fe(III)] state by nonbiological (abiotic) oxidants such as chlorine or oxygen, so the precipitation of iron by bacterial action is often hard to distinguish from abiotic processes, and both mechanisms are considered to operate in wells (8). Autooxidation of Mn in ambient ground waters is not favored due to the high E_h of the Mn(II)–Mn(IV) transformation (approx. +600 mV at pH 7.0), thus the transformation is presumptively mediated by the presence of biofilms. The formation of metal oxides is synergistic: as reactive iron oxihydroxides such as ferrihydrite are formed, more metal oxides deposit abiotically. Bacterial extracellular polymer (ECP) slimes that sequester metal ions and metal oxide colloids are involved in these interactions in a process analogous to iron sequestration treatments used to control iron precipitation.

The formation of iron sulfides and sulfur-oxidizing biofilms are two other significant water well biofouling phenomena where sulfide is present in groundwater. Sulfide is formed by microbial sulfate-reducing respiration and secondarily in some systems by putrefaction. Iron sulfides (which form dense black deposits) form spontaneously when aqueous sulfide ions come in contact with Fe^{2+} in solution. Sulfide oxidizers commonly form biofilms in the water columns of wells accessing sulfide groundwater. These biofilms can be highly viscous and have high integrity, easily blocking apertures. Chlorine and chlorine-based disinfectants can react with such components of the biofilm to produce halogenated organics.

Sulfides and other particles, such as calcite redeposited from solution (often also mediated by microbial activity), enhance the clogging potential of these biofilms. In some systems, mineral FeS_x clogs occur at the lower redox potentials that favor them (typically in the aquifer), and sulfur-oxidizer slimes form at higher E_h and pH (typically in the well water column).

Other less commonly described forms of metal oxidizing biofouling have been described, including aluminum biofouling (9). Aluminum hydroxide is coprecipitated with sulfate in high-organic-carbon white deposits. The composition varies according to variations in aeration. A variation is aluminum complexed in biofilms, often with iron deposited. Similar deposits have been described for samples from North Carolina in the United States.

Biofouling becomes a matter of public health concern when biofilms harbor or permit the proliferation of pathogens or indicator bacteria. If biofilms harbor and enhance survival of pathogens, they may result in illness. If the biofilms resist disinfection treatments, pathogens may avoid destruction. A recognized practical problem is positive results in total coliform tests that can be attributed to adaptive biofilm microflora that grow in commonly used growth media that is intended to be selective for the total coliform group of bacteria.

BIOFOULING EFFECTS ON WELL WATER SYSTEMS AND WATER QUALITY

Biofouling affects well water quality and well and water system metallic components in a variety of ways. Often the earliest manifestation of biofouling is the water quality degradation that accompanies mass bacterial growth and associated iron, manganese, and sulfur transformations. Typical symptoms are

- "red" or "black" water, increased turbidity (often far above typical groundwater), transiently high chlorine demand, and taste and odor problems that can result in a lack of confidence in the quality of the water supply.
- alteration of water quality in pumped samples. Biofouling can have a significant impact on the representativeness of groundwater samples from wells. Fluctuating Fe and Mn levels occur as Mn and Fe complexed with ECP may occur in suspension and can be detected in high levels in analytical results from unfiltered samples. Iron biofilms efficiently remove Fe and Mn, as well as other metals, from solution through chelation and deposition on reactive Fe(III) and Mn(IV) oxide mineral surfaces (6,8).

Chemical digestion of Fe- and Mn-biofilm samples indicate the presence of metals (e.g., Pb, As, Se) not detected in associated water samples (8). Thus, sample water pumped from biofouled wells can have metal levels lower than ambient ground water outside of the influence of the well (2,10–12).

- Work summarized in Smith (3) and subsequent work in alluvial aquifers and engineered systems (13) shows that (1) low total Fe (at or below the 300-μg/L standard) and (2) total Fe:Mn ratios of samples near 1:1 or upset (i.e., Mn:Fe >1:1) are typical of pumped water samples from biofouled water wells in microbially active alluvial aquifers.
- Elevated iron and manganese concentrations in pumped groundwater are also typically the result of bacterial activities in the aquifer, including respiratory Fe(III) and Mn(IV) reduction in the presence of abundant organic carbon and also corrosion of metal equipment. If unfiltered samples containing biofilm colloids are digested, very high Fe and Mn levels may be recorded (13).
- Biofilm influences have significant impacts on oxidation-reduction potential (3,8,13) and explain discrepancies between E_h values calculated from different couples and between calculations and measured values (8).
- Corrosion is enhanced by biofilm action and may occur where corrosion-incrustation index calculations predict that it would not occur. Such microbially influenced corrosion (MIC; 14) can also affect materials not expected to be subject to corrosion, accelerates well aging, and contributes corrosion-product constituents to water samples (15).
- Intermittent total coliform positive test results, mostly caused by bacteria not necessarily part of the total coliform group, but possessing the galactosidase enzyme.

It is important to note that corroding, encrusting, and nonencrusting biofouling effects, as well as test results that pose health concerns, often occur simultaneously.

BIOFOULING EFFECTS ON SYSTEM HYDRAULIC PERFORMANCE

In a well, biofouling phenomena may encrust or loosely plug well borehole intake areas and screens, pumps, and other downstream equipment. The initial process is the formation of a biofilm on surfaces in the well (casing, screen, pump) and in the aquifer in the vicinity of the well. The time course of this process to result in water quality or pumping problems may vary considerably, depending on site-specific conditions:

- Clogging (both formation/well and pump/discharge systems). Well clogging is usually expressed as reduced specific capacity (yield in volume/time unit versus drawdown during pumping).
- Corrosion: Cathodic depolarization of steel surfaces, erosion by organic acids, and intergranular cracking corrosion of stainless steels.
- Biofilms on interior pipe walls become increasingly hard or thicker over time. This tuberculation (the entire complex of corrosion/encrustation) can reduce the hydraulic capacity of a system. Tubercles increase hydraulic resistance by reducing diameter and by increasing the roughness of the interior surface of the pipe, dramatically increasing the energy cost to pump.
- Moreover, encrustations pack around lineshafts and bearings inside column pipe and reduce shaft life due to increased friction and reduced cooling. These developments may be aggravated by well operating choices (8).
- Biofouling shares top troublemaking honors with abrasion and clogging by silt and sand in groundwater systems for water supply, long-term dewatering, and on-site treatment to remove contamination (1,16,17). In fact, the two problems are frequently interactive (1,18–20), and biofilms may immobilize solid-phase silica (8), contributing to clogging.

With regard to well hydraulic performance,

- Reductions in specific capacity due to biofouling vary locally, but annual reductions are on the order of 1 to 3.4 on Long Island, NY, ranging up to 47% annually (21), for example.
- Considerable biofouling buildup can occur before well specific capacity is impacted.
- Wells accessing aquifers with low hydraulic conductivity (K) show faster and more enhanced performance decline compared to wells in formations with higher K.
- Higher Fe and Mn levels, particularly when oxidizing conditions prevail, can accelerate performance decline, although rapid biofouling clogging can occur at low levels. Higher total P, sulfate and organic carbon are also associated with enhanced biofouling development and clogging (6,8,22).

See related items, EVALUATION OF MICROBIAL COMPONENTS OF BIOFOULING, and WELL MAINTENANCE, for diagnostic methods and their applications where biofouling occurs in wells.

INTRODUCTION

Globally, the use of groundwater for various purposes is enormous. It is used as potable, industrial (especially cooling), and irrigation water on a huge scale. At least twelve megacities (population over 10 million) could not function without groundwater, and typically at least 25% of the water for these cities comes from aquifers (1). China alone has over 500 cities, and two-thirds of the water for them comes from aquifers.

Despite this importance, the number of instances of groundwater contamination due to accidental spills or unsatisfactory disposal is beyond counting. Up to a certain point, contamination can be attenuated by natural processes, especially biodegradation. In this regard, the biologically active zone is the vadose (unsaturated) zone where attenuation rates are highest. Contaminant removal continues in the saturated zone but usually at much lower rates, and migration of contaminants to the saturated zone can disperse the contaminants. Although it brings about dilution, this latter process often cannot be relied upon for complete decontamination.

Beyond a threshold, this natural attenuation cannot continue, and a decision has to be made whether or not to intervene with cleanup technology. This decision is now based on risk assessment. Risk assessment usually uses source–pathway–receptor analysis, and its outcome also determines, which treatment technology is to be used if treatment is necessary.

RISK ASSESSMENT

The objective of source–pathway–receptor analysis is the identification of the linkage(s) between them. Risk-based remedial design has as an objective the selection of the strategy to break the linkages and thus remove the risk. If, for example, there is a source of pollution and potential receptors (usually human) but no pathway to link them, or the pathway(s) can be blocked, then the risk is removed. If the receptor is human, then it is more likely that the risk will be removed by treating the source.

WHERE IS THE BOUNDARY BETWEEN GROUNDWATER AND SOIL TREATMENT?

Necessarily, if groundwater is to be treated by in-situ technologies, then the boundary between soil and water treatment becomes blurred, especially for vadose zone treatment.

SOME STATISTICS

The U.S. EPA has a recorded history of the treatment technologies applied to contaminated soil and groundwater at Superfund and other priority sites, which is updated through annual status reports (ASRs). As this history spans several decades, it is instructive to examine the record to identify the main technologies and trends in usage. Figure 1 shows that ex situ pump and treat methods have dominated groundwater treatment. This involves pumping the groundwater to the surface and selecting a treatment. Monitored natural attenuation (MNA) is not regarded as an engineered technology (2), but it is briefly described.

Specifically at Superfund sites (Fig. 2), *in situ* groundwater treatment remedies have been chosen 169 times at 135 sites (3). Air sparging has been chosen most frequently, followed by bioremediation. However, a comparison of those projects at the predesign, design, or installation stages (preoperational or future) and the operational and complete (current and historical) shows that the popularity of bioremediation has increased and that of air sparging has dropped dramatically.

Groundwater remedy type	Number of sites
Pump and treat	713
In situ treatment	135
Monitored natural attenuation	201
Other	822

Figure 1. Total number of sites with a groundwater remedy (3). Sites may be included in more than one category.

IN SITU BIOREMEDIATION TECHNOLOGIES

The treatment of groundwater in-situ has several advantages and disadvantages compared to pump and treat. The advantages include reduced site disturbance, which is crucial when a site is still being used; remediation around or under buildings without disturbance; and reduced worker exposure to volatile compounds. The quoted disadvantages include that site assessment must fully describe the hydrogeology and contaminant distribution, leading to increased cost; difficulty in control of reaction conditions; difficulty in accurately predicting end points; and therefore, the need for careful monitoring of the process. As it is difficult to take samples during *in situ* treatment, then it is difficult to assess if contamination hot spots have been remediated.

Additionally, in bioremediation, several other factors must be considered. Regularly quoted advantages of bioremediation are

- It is often less expensive than other techniques.
- Because the contaminants are mineralized, they are permanently eliminated.
- Long-term liability is thus eliminated.
- It has "green" credentials, representing a sustainable option.

Likewise, there are quoted disadvantages:

- Bioremediation cannot treat all contaminant types; most notably heavy metals cannot be biodegraded.
- Low permeability soil makes in-situ bioremediation of groundwater untenable.
- It may be too slow in certain circumstances.

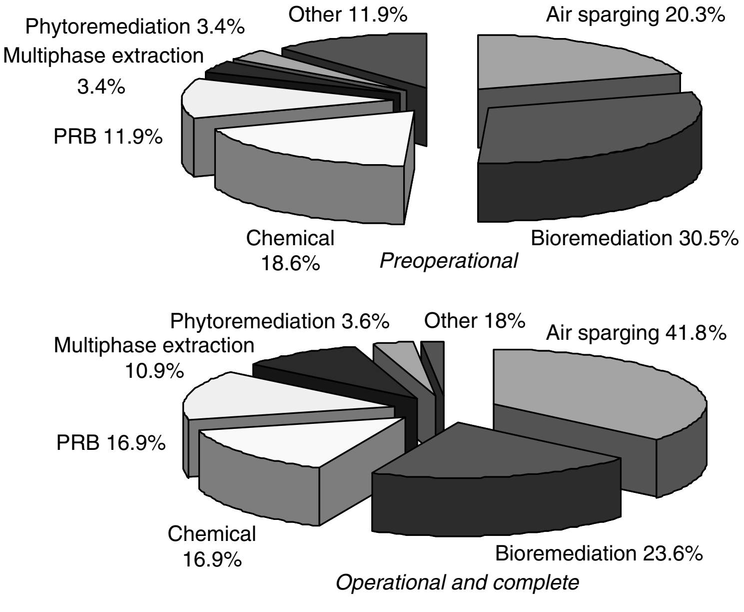

Figure 2. *In situ* groundwater treatment projects by technology, fiscal years 1982–2002 (adapted from Reference 3).

- It is often regarded as "incomplete" in that the contaminants may not be removed completely.
- Physicochemical conditions that are not ideal for microbial growth can slow the process down considerably.
- There is a worry that metabolites may be toxic.

As a result, the suitability of bioremediation has to be assessed case by case, and small-scale treatability studies are required (4), which adds to the time and expense of a project.

Aerobic or Anaerobic?

More than any other factor, it is likely that oxygen limitation occurs in groundwaters, and the most rapid biodegradation processes normally involve oxygenase enzymes (5). The supply of oxygen for *in situ* bioremediation adds considerably to the expense and the technical difficulty. This supply involves the use of either blowers or vacuum pumps to draw air through the system. A measure of the pivotal role of oxygen is in the use of hydrogen peroxide to enhance aeration. That its use has been considered at all is remarkable: concentrations of H_2O_2 above 100 to 200 mg/L are toxic to microorganisms; it can be consumed very quickly, limiting treatment to the regions near the injection well; a groundwater circulation system must be created; and good soil permeability is essential.

Recent advances in the knowledge of anaerobic biodegradation microbiology have opened up the prospect of greater acceptance of anaerobic bioremediation where maintaining aerobic conditions is not feasible. The existence of microorganisms capable of coupling the anaerobic reduction of Fe^{3+} to the oxidation of organic compounds shows promise (6). Virtually our entire knowledge of anaerobic metabolism of hydrocarbons has been gained since around 1990 (for reviews, see References 7 and 8). Several alkylbenzenes, alkanes or alkenes, are anaerobically biodegraded by denitrifying, ferric iron-reducing or sulfate-reducing bacteria. Another group of anaerobic hydrocarbon-degrading bacteria are "proton reducers" that rely on syntrophic associations with methanogens (8). As some of the most significant groundwater pollutants are chlorinated solvents, then a role for microbial reductive dehalogenation is feasible. Although slow, even the reductive dechlorination of dioxins is possible (9). A recent discovery has shown that even benzene can be oxidized completely under anaerobic conditions by pure cultures, using nitrate as the electron acceptor (10). Benzene is a particular problem in groundwater because it is relatively soluble and mobile.

Monitored Natural Attenuation

This technique involves monitoring the natural physical, chemical, and biological processes in soil and groundwater that are used to destroy a pollutant or limit its spread or migration (11). In nearly all situations, however, microbial reactions are the dominant processes driving natural attenuation (12), so it can be considered a long-term *in situ* bioremediation process.

Monitored natural attenuation may be useful where natural processes within the polluted area are effective in stabilizing or reducing the size of a contaminated groundwater plume, but there cannot be unacceptable impacts or risks to receptors. Monitoring and modeling are used to enable predicting the rate of attenuation and the rate of migration of the pollutant with some degree of confidence. The overall cost-effectiveness of MNA must take into consideration the long-term expenses involved in monitoring compared to the cost of a more intrusive approach, which is likely to be more costly during operational remediation, but requires no long-term monitoring.

Bioventing

This method uses indigenous microbes to biodegrade organic contaminants in the unsaturated zone above the water table. Technically, then, it is an *in situ* source treatment for contaminated soil (13), but it can be considered here as it inevitably results in soil water remediation. Bioventing is, after all, designed to remove contamination from the vadose zone to prevent future contamination of groundwater.

It combines supplying extra oxygen with vapor extraction to induce forced airflow through the contaminated area and enhance natural biodegradation (Fig. 3). Air is blown into the center of the area of contaminated soil above the water table and sucked out through peripheral boreholes to off-gas treatment prior to emission to the atmosphere. In its engineering manifestations, it closely resembles soil vapor extraction (SVE), but the two technologies have fundamentally different goals. SVE endeavors to maximize volatilization of low molecular weight contaminants, with some incidental bioremediation. Bioventing, however, endeavors to maximize biodegradation of the contaminant(s) regardless of molecular weight, with some incidental volatilization (14).

To enhance the biological process, nutrients can be supplied to the contaminated area. The injection of oxygen stimulates the microbes in the contaminated soil to

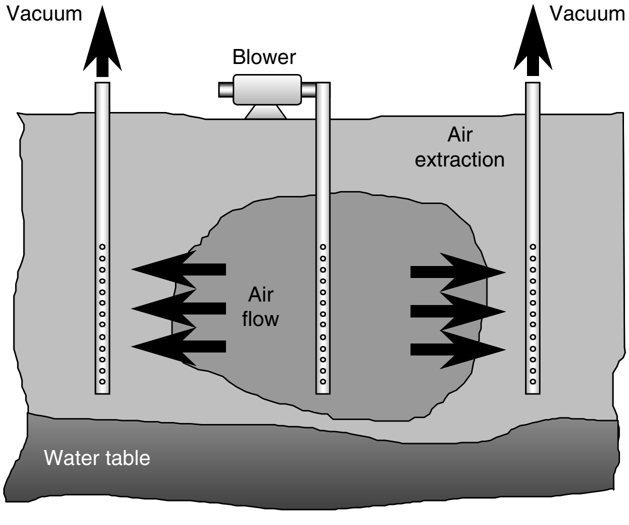

Figure 3. Bioventing.

degrade the organic contaminants to CO_2 and water. The process also mobilizes volatile compounds (either present in the soil or produced during biodegradation) to move toward boreholes, making extraction simpler.

Bioventing has now been used successfully at over 1000 sites and seems best suited to the bioremediation of middle distillate fuels such as diesel and jet fuel (15), but also nonchlorinated solvents, some pesticides, wood preservatives, and other organic chemicals have been removed. It is not successful in limited permeability soils, and application to the saturated zone relies on the water level being reduced (16). However, it can be successfully combined with biosparging.

Biosparging

Biosparging is similar to bioventing, in that air is injected, but in this case it is introduced below the water table (in the saturated zone) (Fig. 4) to increase the dissolved oxygen concentration in the groundwater and thus stimulate the activity of the indigenous microorganisms, thereby stimulating aerobic bioremediation. It can also have a similar stimulatory effect in the unsaturated zone. Like bioventing, nutrients may be added to enhance the biological process.

The success of the technique depends on adequate diffusion of the injected air away from the boreholes into the surrounding groundwater and soil. The location and number of boreholes depend primarily on the subsurface soil structure and permeability, and like bioventing, biosparging is best suited to permeable soils (16). Like bioventing, biosparging uses equipment that is readily available and easy to install.

Pump and Treat

The contaminated aqueous phase from the saturated zone is pumped, via a recovery well, to a treatment tank on the surface. In the treatment tank, nutrients, oxygen, and other electron acceptors (e.g., sulfate and nitrate) are added before the groundwater is pumped back into the ground via an injection well and recirculated through the contaminated zone (Fig. 5). The oxygen and nutrients in the injected groundwater stimulate the microbes in the contaminated zone to biodegrade contaminants dissolved in the groundwater and present in the soil. Groundwater extraction and injection continue until monitoring data show that the remedial objectives have been achieved. Technically, then, when pump and treat is operated as a bioremediation technology, it combines features of ex situ (water is pumped to the surface) and *in situ* (biological treatment continues underground).

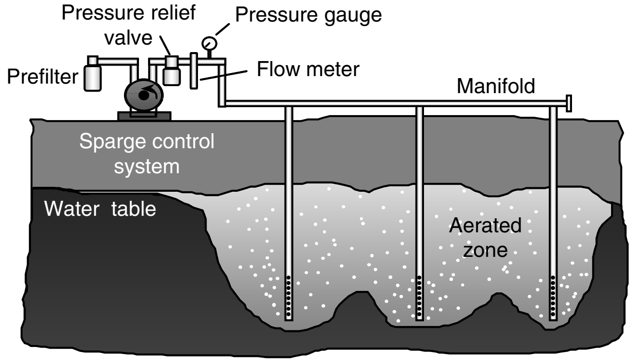

Figure 4. Biosparging.

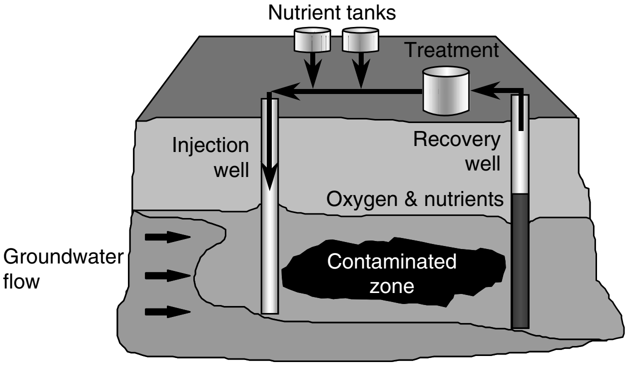

Figure 5. Pump and treat.

Pump and treat is a technology of great flexibility because the surface treatment need not be biological. In fact, a treatment train employing a variety of different technologies is possible at the surface. A much higher degree of process control is possible at the surface, for example, temperature, pH. For these reasons, pump and treat has historically been a very popular treatment for contaminated groundwater. However, there have been frequent questions over the efficacy of pump and treat, probably because, as the technology has become accepted, expectations have become too high (17).

Permeable Reactive Barriers

A PRBs consists of a reactive material that is placed in the path of flowing groundwater (Fig. 6), and due to the permeability of the chosen reactive material, it removes contaminants from the flow as the groundwater passes through. These barriers allow the passage of water while prohibiting the movement of contaminants. Agents within the barrier are materials such as zero-valence metals, for example, Fe^0, chelators, sorbents, and microbes (18). The contaminants are either degraded or retained in concentrated form by the barrier material, which may need to be replaced periodically.

PRBs have considerable flexibility in that combined chemical and biological treatments are possible within

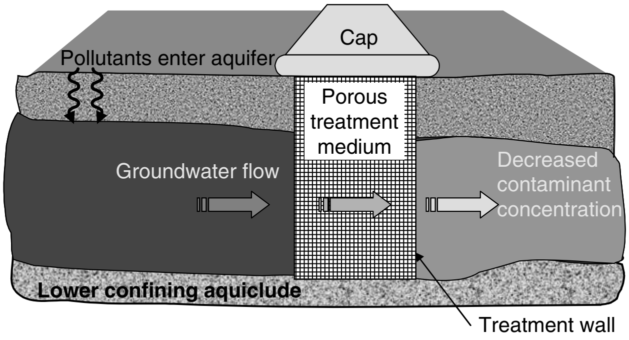

Figure 6. Permeable reactive barrier.

the same barrier, or barriers can be sequenced. For example, a contaminated aquifer beneath a petrochemical site may typically contain both chlorinated solvents and petroleum hydrocarbons. The chlorinated compounds may be removed by zero-valence iron in the permeable reactive barrier. With time, the permeable barrier will become colonized by bacteria, and bioremediation of petroleum hydrocarbons will occur, given the correct conditions. Alternatively, hydrocarbon-oxidizing bacteria may be deliberately added (the practice of bioaugmentation). Another aspect of the flexibility of the PRB is that in many cases it can be installed at working sites with minimal disruption to normal operations.

COSTS

The costs of all remediation technologies are constantly shifting and vary greatly from country to country. So quoted figures per tonne or per cubic meter of contaminated groundwater or soil would soon be out of date. Rather, it should be possible to identify economies of scale if confidence is gained in a technology and it is used increasingly at full scale. This confidence in bioremediation has been lacking in the past, and in many parts of the world, it is still not accepted at full scale.

If a technology is following a typical economies of scale pattern, then the more it is used, the more costs will decrease. The US EPA (19) examined the correlation between unit costs and quantity treated for six different soil and groundwater remediation technologies: bioremediation, thermal desorption, soil vapor extraction, on-site incineration, pump and treat, and permeable reactive barriers. Some important findings were reported:

1. Four of the six technologies (bioventing, thermal desorption, soil vapor extraction and pump and treat) evidenced a correlation between unit cost and quantity treated, thus exhibiting an economies of scale pattern.
2. Bioventing had the best correlation of these four technologies.
3. No other bioremediation technology exhibited any such correlation.
4. Pump and treat groundwater remediation systems showed a correlation for both unit capital costs and unit average operating costs.

The lack of correlation for the other bioremediation technologies may simply result from lack of data from a sufficiently large number of full-scale projects, but the signs are encouraging that bioventing has proven to be a market success.

PROCESS LIMITATIONS OF *IN SITU* BIOREMEDIATION OF GROUNDWATER

DAVID B. VANCE
ARCADIS G&M, Inc.
Midland, Texas

JAMES A. JACOBS
Environmental Bio-Systems, Inc.
Mill Valley, California

Based on the origin and susceptibility to microbial interaction, hydrocarbons may be divided into two broad classes: petroleum hydrocarbons and complex chlorinated hydrocarbons.

Petroleum hydrocarbons are largely associated with the production, storage, or use of fuels, lubricants, and chemical feedstocks. Petroleum hydrocarbons have been demonstrated to be biodegradable by numerous species of bacteria. Over a period of 3.5 billion years, bacteria have been able to evolve genetic resources that allow some of them to potentially use petroleum hydrocarbons as a source of food.

Complex industrial hydrocarbons include chlorinated aliphatic and aromatic hydrocarbons, MTBE, pesticides and herbicides, and polymers. These new synthetic compounds have been manufactured for about 100 years. Bacteria have not had time to evolve the genetic information required to utilize them as a source of food. Due to recalcitrance to microbial attack, these complex industrial chemicals are termed xenobiotic.

Successful *in situ* bioremediation of groundwater has been demonstrated at sites impacted with petroleum hydrocarbons. The most successful method of application has been through stimulation of indigenous microbial species. Microbial stimulation is the process of ensuring that environmental conditions, nutrient availability, and requirements for an electron acceptor are adequate in the contaminated portions of the aquifer.

The most common cause for failure of saturated zone *in situ* bioremediation is the lack of adequate mass transport of the electron acceptor (usually oxygen). In this regard, the physical setting of the site is critical. Overall permeability and the scale and degree of heterogeneity are the factors governing the advective and diffusional transport rates of contaminants and remediation reagents in the subsurface. If mass transport rates are too low, saturated zone *in situ* bioremediation is not a viable option.

Given adequate mass transport properties, site-specific microbiological conditions can also impact the process. Unfortunately, the presence of indigenous microbes and efficient mass transport may still prove insufficient for effective bioremediation. Specific reasons for the poor performance of *in situ* bioremediation systems relate to unoptimized subsurface conditions.

There is uncertainty with regard to the effect of hydrocarbon availability on the effectiveness of biodegradation. Can bacteria degrade hydrocarbons adsorbed to surfaces or degrade hydrocarbons with low levels of solubility? Or must the hydrocarbon be solubilized before it can be biodegraded? Contradictory laboratory evidence and field evidence have been published for both scenarios. With the predominance of evidence indicating that solubilization must take place, degradation reactions with extracellular bacterial exudates are much less likely.

The answer is likely consortia specific and dependent on the ability of the bacteria to synthesize appropriate biosurfactants. This ability may be absent in some instances.

Although petroleum hydrocarbons are amenable to primarily aerobic biodegradation, for it to occur the indigenous bacteria must have the appropriate genetic information. This genetic information is specific and precise. The presence of a specific hydrocarbon will stimulate the synthesis of an oxygenase enzyme that is expressly configured to react with that stimulating hydrocarbon.

For remediation, indigenous microbes generally possess the genetic information required for appropriate enzyme production and the contaminant will stimulate the production of those enzymes. General microbial stimulation has the potential to produce a large amount of biomass that may not take part in the biodegradation process and actually cause harm through biofouling and plugging of injection wells, galleries, or surrounding formations. There is potential to lose critical subsurface mass transport capabilities.

BACTERIAL TRANSPORT

There are practical limits to the degree of cleanup obtainable using bioremediation. Hydrocarbons at the low parts per million (ppm) level may not be capable of supporting significant levels of microbial activity even under stimulation. Sites with relatively high levels of hydrocarbon impact may actually be better candidates for bioremediation than those lightly impacted at levels slightly above regulatory action levels. Toxicity related to the presence of heavy metals, such as chromium, arsenic, or lead, or low temperature of the groundwater have been observed to inhibit bacterial growth in a variety of settings. Stimulating electron acceptors must also be available at sufficient concentrations; native sulfate concentrations less than about 20 mg/L do not stimulate sulfate reducing bacteria even in the presence of usable carbon substrates.

Xenobiotic industrial compounds are often recalcitrant to direct aerobic microbial attack. However, over the last 20 years a biodegradation process termed co-oxidation (or cometabolism) has been successfully demonstrated by researchers. For example, the aerobic degradation of trichloroethylene (TCE) has been accomplished using monooxygenase and dioxygenase enzymes produced through the use of petroleum hydrocarbons as a metabolizable substrate (food source) and stimulus for enzyme production. This general process is termed co-oxidation and the hydrocarbon substrate used as a food source is the cometabolite. Many different hydrocarbon substrates have been observed to stimulate the generation of cooxidation enzymes. The currently known cometabolic substrates fall into two broad classes:

1. Analog substrates, which are hydrocarbons that have a geometry similar to the targeted xenobiotic compound.
2. Methanotrophic (which is different than methanogenic) microbial systems have proved particularly effective at generating xenobiotic active enzymes.

Enzymes with co-oxidizing potential have a strong natural affinity for the hydrocarbon that originally stimulated its generation. The enzyme is genetically tailored to the compound used as a food source. Over 300 mol of methane are required to biodegrade 1 mol of TCE via co-oxidation. The efficiency of the co-oxidation process is extremely poor. Under field conditions where mass transport is a critical success factor, a 300-fold decrease in the effectiveness of the reactants in the contaminated zone often can be impractical.

Accurate assessment of potential limiting factors such aerobic terminal electron acceptor (dissolved oxygen), geochemical conditions (pH, temperature, conductivity), and macronutrients (orthophosphate and ammonia as nitrogen) should be documented as part of the bioremediation evaluation process. Bioremediation is a dynamic process requiring monitoring of the hydrological, geochemical, and biological conditions over the life of a project.

NATURAL ATTENUATION: GROUNDWATER REMEDIATION BY NO ACTION

In a time of reappraisal for the allocation of financial resources to environmental action, a question of ever increasing importance is the consequence of no action concerning the release of petroleum or chlorinated hydrocarbons into groundwater. An important portion of that answer comes from the application of site-specific health based risk assessments. However, in instances where human consumption or exposure is not an issue, no action may be a reasonable alternative, even at elevated dissolved contaminant concentrations. The issue then becomes the determination of the consequence of no action under conditions where the sole process for remediation is natural attenuation.

The physical, chemical, geological, and biological processes that take place in a contaminated aquifer are complex. In most instances, a “native” aquifer is in a long-standing state of chemical equilibrium between the groundwater and the geologic matrix through which it flows. The release of anthropogenic hydrocarbons into an aquifer upsets that equilibrium. The dissolved concentration of the contaminant as it migrates through the aquifer is controlled by adsorption, dispersion, volatilization, and degradation. Adsorption affects the overall residence time of the release and dispersion affects the downgradient shape and dissolved concentration in the plume. Only volatilization and degradation contribute to the removal of contaminant from the aquifer, and at low concentrations degradation is the dominant mechanism for attenuation.

The mechanisms for attenuation through degradation can be broadly divided into two categories, biological and abiotic chemical action. This discussion is predicated on relatively “normal” groundwater conditions under which biological action proceeds at a rate orders of magnitude greater than abiotic processes. Extremes of pH, redox conditions, ionic strength, or temperature may make an exception to that generalization. Transformation can be chemically complex, dependent on the environmental conditions described above and affected by aquifer heterogeneity related to granular or fracture variability.

The factor controlling the rate of aerobic degradation is the availability of oxygen and the rate at which it can be introduced into the groundwater (through the groundwater–table interface) or the rate at which oxygen-rich groundwater can pass through the zones of adsorbed contamination. Each pound of petroleum hydrocarbons requires about 3.08 pounds of oxygen for complete degradation (1).

Typical *in situ* aerobic decay rates for groundwater are in the range of 35 μg/L·d (equivalent to about 0.5 oz/d per cubic yard of aquifer matrix).

Natural attenuation occurs both in the source zone and in the dissolved phase plume. In the source zone, oxygen will be rapidly consumed and portions of the aquifer will then host anaerobic degradation. Anaerobic degradation is limited by the availability of appropriate anaerobic electron acceptors such as nitrate, sulfate, or iron. When their availability is limited, degradation will stop after the production of aliphatic and aromatic organic acids; similarly, at low levels of dissolved oxygen (DO), aerobic degradation may also stop with the production of organic acids. The intrinsic biodegradation process and the alternative terminal electron acceptors are shown in Fig. 1 (2).

Optimum aerobic biodegradation occurs with the dissolved oxygen above 2 mg/L. Below that, the aerobic degradation rate of aromatic hydrocarbons will decrease dramatically. Conversely, under complete anaerobic conditions, nitrate reducing, iron reducing, and suflate reducing bacteria can effectively degrade hydrocarbons. However, at DO concentrations as low as 0.1–0.4 mg/L, anaerobic degradation rates will be reduced to just a few percent of optimum.

Because of all the mechanisms described above, hydrocarbon plumes tend to achieve a stable shape and size even when there is a continuous source of free phase hydrocarbon release. Steady state is achieved when the area of the plume edge is great enough to provide for a natural degradation rate equivalent to the rate of hydrocarbon infiltration. The edges of the dissolved plume do not have enough DO to support optimum rates of aerobic degradation but have too much DO to allow for optimum anaerobic degradation. The interior of a plume will support anaerobic natural attenuation, which is typically limited by the availability of iron in the mineral matrix and sulfate in the native groundwater and to a lesser extent the mineral matrix as well. However, once the source of hydrocarbon has been removed, a dissolved plume will narrow and dissipate from the edges inward, due to the availability of DO from groundwater along those edges.

The selection of a no action natural attenuation option should be based on an appropriate analysis of data gathered during the assessment of the site. First-order decay rates are appropriate for the evaluation of degradation kinetics at low concentrations, less than 1 ppm (an appropriate level to assume at the periphery of a plume). Given first-order decay rates, the analysis has a focus that is twofold—the effect of attenuation over time and the effect over distance.

Attenuation over time is measured at the edges of a plume using concentration measurements gathered repeatedly from specific monitor wells. The minimum recommended time is one year, with quarterly sampling from the selected monitor wells. The data for each well is then semilog plotted as log concentration against time. The slope of the line is the first-order decay constant in percent per day.

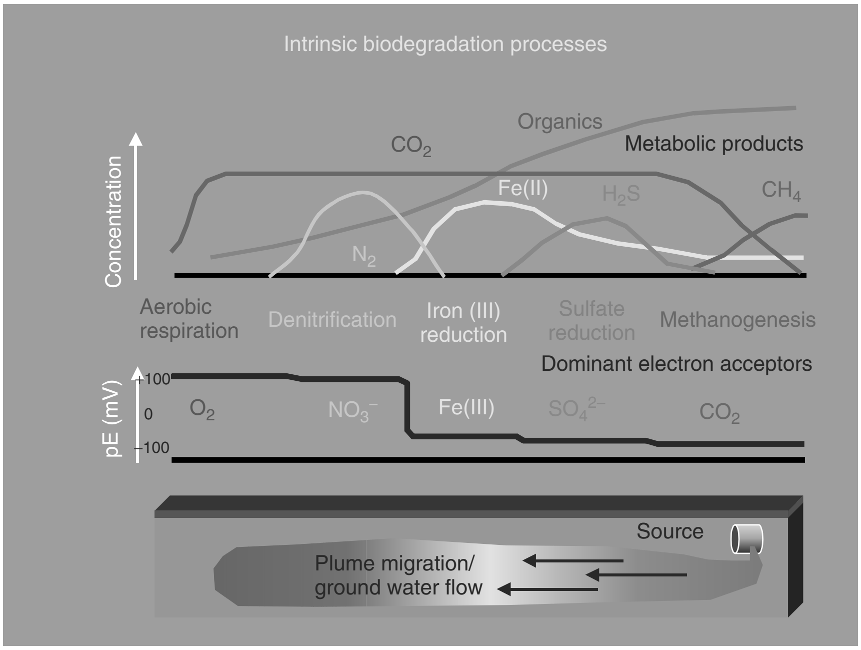

Figure 1. Intrinsic biodegration process (2). Petroleum hydrocarbons are referred to as organics in the diagram.

Attenuation with distance more accurately incorporates the effects of aquifer heterogeneity. Data for this analysis is obtained from a minimum of three monitoring wells, preferably along the long axis of the plume. This data is semilog plotted as log concentration versus distance. The slope of this line is equal to the decay constant divided by the groundwater velocity.

With this data, decisions can be made based on the site-specific contaminant dynamics under no action natural attenuation. This, in conjunction with a health based risk assessment, can allow for sound decision-making by the business and regulatory community.

In summary, the adoption of a no action alternative is most applicable to the dissolved phase plume only. Except for volumetrically small releases, it will still be necessary to remove or remediate the source zone of an impacted aquifer, after which natural attenuation may be a reasonable approach to the residual dissolved phases. Also implicit in this approach is that no action does not preclude the performance of requisite assessment activity, which can represent a significant long-term liability in some cases. Nonetheless, after proper source abatement, assessment, and analysis, the reliance on natural attenuation mechanisms for the final stages of cleanup is a cost effective and, if properly managed, environmentally sound resolution to aerially extensive dissolved phase hydrocarbon contamination.

NATURAL ATTENUATION: THE EFFECT OF PUMP AND TREAT REMEDIATION

In situ groundwater remediation has matured over the past 25 years, particularly with regard to understanding the dynamics of the interactions between contaminants, the impacted saturated soil matrix, and microbiological activity. Recent interest in the phenomenon of natural attenuation has served to illustrate the variety of microbial ecosystems that are present in a contaminant plume, each system determined by redox conditions and availability of electron acceptors. While natural attenuation is an attractive alternative to those responsible for groundwater contamination, the regulating communities are more skeptical. The need for proactive groundwater pumping remediation and the efficacy of natural attenuation pose a potentially complex balance that is governed by the subsurface conditions of each individual site. There is no universal applicable rule for the resolution of that balance. It is the responsibility of remediation designers to make those site-specific determinations and to provide the regulating community with information sufficient to support the proactive and the natural attenuation portions of each individual cleanup. Our purpose here is to point out some of the most significant factors impacting that balance.

The first and most dominant control is the nature of the saturated soil matrix. Several factors must be evaluated for remedial design:

1. The degree and scale of sediment heterogeneity, which determines how much and what portion of a contaminated aquifer can be affected with advective groundwater flow. Low permeability regions must rely on diffusional transport, which will dominate the overall remediation rate in the treatment zone.
2. The time of exposure to the contaminant is a direct function of the impact of heterogeneity described above. The contaminant will diffuse into the nonadvective portions of the aquifer soil matrix. At a minimum, remediation will take as long as the initial exposure. Due to the adsorptive retardation reactions, remediation is likely to take longer than the exposure time.

3. The geochemical composition of the soil matrix is also a factor in remedial design. Carbonaceous material and clays have a much higher propensity for the adsorption of organic contaminants. Iron oxides, in turn, have high adsorptive capacity for metal contaminants. Iron and sulfur minerals may be sources of electron acceptors as redox conditions are modified through the interaction of indigenous microbial populations and the contaminant.
4. The background geochemical makeup of the groundwater as well as that in the contaminant plume is an important remedial design factor. Dissolved oxygen, sulfate, nitrate, and iron can all potentially serve as alternate terminal electron acceptors to aid in the degradation of organic contaminants. Ferrous iron, hydrogen sulfide, and carbon dioxide are indicative end products of those reactions.
5. The distribution of the organic contaminant is another factor affecting remedial design. Free phase hydrocarbons should be recovered proactively with an extractive technology (pump and treat) or in the case of CVOCs possibly an *in situ* chemical oxidation injection technology. In cases where impact is shallow, excavation and disposal is still an extremely viable option.

The treatment of dissolved and adsorbed hydrocarbons is the point at which the balance between proactive remediation and natural attenuation must be determined.

One of the most important contributions that a pump and treat system makes to the *in situ* remediation of contaminated groundwater is plume capture and hydraulic control in the source zone and the core of the dissolved and adsorbed plumes. Background groundwater that is drawn through the plume perpendicular to the natural groundwater flow direction must also be evaluated.

In the past, the focus of pump and treat remediation has been on how it acts to flush and remove the contaminant. The contributions made by recent developments on the mechanisms of natural attenuation reside in the role of electron acceptors present at background concentrations within the aquifer. From the exterior to the interior of a plume, the specific electron acceptor zones are aerobic, denitrification, sulfate/iron reducing, and methanogenic.

The boundary between each specific redox zone and the active electron acceptor is controlled by the kinetics of the degradation process in each zone and the advective transport rates of groundwater through that zone. In most instances, the dominant effect is the groundwater transport rate.

The natural concentrations of these electron acceptors cover a wide range. Natural oxygen levels commonly range from 2 to 8 mg/L. Groundwater sulfate concentrations in soils derived from sedimentary rocks are typically in the 25-mg/L range, with higher values of several hundred mg/L not uncommon. Ferric oxides are commonly present in soils in the range of 0.5–5%; the ability of indigenous iron reducing bacteria to access that iron will vary from location to location. Given adequate permeability and the presence of appropriate electron acceptors, natural enhancement of pump and treat systems is possible and worth the relatively inexpensive analyses (some of which can be done with field kits) required to evaluate.

NATURAL ATTENUATION: TRANSVERSE DISPERSION AS THE NATURAL DRIVING FORCE

Dispersion is the process by which the interface of contaminated groundwater with native groundwater does not remain abrupt. The leading edge of a contaminant plume will arrive at a given point more rapidly than it would if advection alone were the acting driving force. The mean transport velocity of the contaminant mass remains the same, but concentration gradients are setup. This occurs simultaneously with the phenomenon of the contaminant occupying, with time, an increasing volume of groundwater. There are two fundamental types of dispersion—longitudinal and transverse. Both are accentuated by the inhomogeneous and anisotropic physical configuration of the permeable matrix within a groundwater system. There is also a contribution to both from diffusional transport as well.

Longtitudinal dispersion is caused by differences in groundwater velocity through pore spaces that vary in width or tortuosity. The result is dispersion that occurs along the direction of groundwater flow. Transverse dispersion is driven by groundwater flowing around individual particles in the aquifer matrix; the effect occurs perpendicular to the groundwater flow direction. Transverse dispersion is effective in mixing contaminated groundwater with native groundwater at the edges of an elongated plume and occurs only when there is a point source of contamination. In the context of natural attenuation, longitudinal dispersion is purely a dilution phenomena; transverse dispersion provides an influx of electron acceptors.

Both types of dispersion are dependent on horizontal and vertical variations in permeability. Increasing anisotropy and heterogeneity increase the magnitude of dispersion. Groundwater velocity also plays a role: At low velocities the effects of diffusion may equal those of dispersion.

The ratio of longitudinal to transverse dispersivity ranges from 1 to 24; most commonly, horizontal transverse dispersivity is 20% to 10% of the longitudinal dispersivity, and vertical transverse dispersivity is 2% to 1% of the longitudinal dispersivity. Instead of "football" shaped plumes, this difference in vertical and horizontal dispersivity tends to generate plumes that in three dimensions are "surfboard" shaped. The determination of the specifics of the effect of dispersivity on a contaminant concentration at a given time and location in an aquifer is an extremely complex process that requires detailed knowledge of the physical configuration of the aquifer matrix and solution to partial differential equations for final values. In many instances, a purely empirical approach is the only practical means of assessment rather than modeling.

The physical scale that is examined also has an impact: values of dispersivity change as one examines an aquifer on the scale of inches, feet, or thousands of feet.

Transverse dispersion is what serves to physically mix groundwater containing contaminants with adjacent groundwater that is unimpacted and contains natural electron acceptors. The phenomenon is probably best understood in terms of angle of divergence, that is, the angle between the two edges of the plume as it migrates from a point source. In granular materials that angle can be as low as 2° and in groundwater flowing through fracture systems as high as 20°. The most accurate determination of the angle of divergence is from information gathered as close as possible to the point representing the source of contamination.

The picture we normally have of a contaminant plume as it migrates away from a point source is one that is (in the two horizontal dimensions) tear drop shaped. The plume initially spreads downgradient and cross gradient until some point is reached at which the distal edges of the plume first travel parallel to the advective groundwater flow direction, and then begin to turn inward to the plume axis and close.

The distal portion of the plume is the dominant area where longitudinal dispersion (as well as transverse dispersion) is in effect. Adsorption and other attenuation reactions also take place, but for the purposes of this discussion those effects are ignored. Under pure hydrodynamic effects, a plume should dilute itself taking the shape of a cone at a constant angle of dispersion. This assumes that the nature of the geologic matrix and groundwater velocity stay constant, which is unlikely, especially in the vertical component. The most common result is that the downgradient shape of the plume is a consequence of attenuation caused by the migration of electron acceptors into the margins of the plume through the force of transverse dispersion—not through purely hydrodynamic flow effects.

NATURAL ATTENUATION: METHANOGENIC SYSTEMS

The ultimate no action alternative may be the use of methanogenic microbial systems. In this case, the electron acceptor is the contaminating hydrocarbon that may contribute to the degradation of petroleum and xenobiotic hydrocarbons There is a difference between methanotrophic bacteria and methanogenic bacteria. Methanotrophs use oxygen to oxidize methane into carbon dioxide (CO_2). Methanotrophic bacterial systems have received a great deal of attention over the last 15 years since it has been found that methane monooxygenase (the enzyme generated by methanotrophs to react with methane) can degrade a wide variety of chlorinated hydrocarbons. The process is known as cometabolism and is definitely an aerobic process.

Methanogenesis is the process of degrading hydrocarbons with the end product being methane (CH_4) gas and carbon dioxide. The general reaction is as follows:

$$2\text{C (organic contaminant)} + 2H_2O \rightarrow CO_2 + CH_4$$

This is a strictly anaerobic process; methanogenic bacteria are poisoned by the presence of oxygen at levels as low as 0.18 mg/L of soluble oxygen (as O_2).

The redox conditions under which these two different microbial systems operate are literally at opposite ends of the spectrum: methanotrophic reactions occur at the Eh range of +250 mV while methanogenic reactions occur at the Eh range of −200 mV.

As an aside, methanogenic bacteria are one of the three classes of bacteria termed Archaebacteria, which are representative of organisms that first appeared on Earth some 3.5 billion years ago. Although their activity is inhibited by oxygen, these bacteria are robust enough to appear in a wide variety of natural locations such as the intestinal tracts of ruminant mammals like cows, sewage digesters, groundwater, and soil.

The concentrations of methane and carbon dioxide are expressed as mole percent. This data is somewhat remarkable since this should be a difficult reaction to initiate. Oxygen, nitrate, and sulfate are all toxic or inhibitory to methanogenic activity. That means that at any site at which evidence of methanogenesis is present (methane gas), there has been a series of biodegradation reactions that have consumed the alternative electron acceptors. Migrating from the exterior to the interior of a plume, the type of redox conditions (Eh) will change from + 250 mV to − 200 mV, with oxygen, nitrate, ferric iron, and sulfate progressively being consumed.

The degradation of chlorinated xenobiotic compounds under methanogenic conditions is particularly enhanced via reductive dehalogenation reactions that involve substitution of hydrogen in the CVOC carbon chain. This can take place from the direct actions of bacteria and from the presence of molecular hydrogen that is produced from water during the methanogenic process.

Conceptually, methanogenesis might be considered "the ultimate of no action alternatives." The physical/chemical requirement for the removal of all other potential terminal electron acceptors infers that the hydrodynamics of such a system are relatively quiescent. The transport of alternate electron acceptors into the core of the contamination plume must be at a rate slow enough to allow for the consumption of all alternate electron acceptors before the methanogenic core zone is reached.

If this situation occurs, it can be a positive argument for absolutely no action involving pump and treat systems. That would increase groundwater velocities, introducing inhibitory electron acceptors into the active methanogenic zone. Groundwater systems in fine grained soils, where transport properties are poor, would be ideal for the exploitation of methanogenic degradation.

Of course, one problem with methanogenic degradation is the kinetics of the process. Methanogenic degradation occurs at rates that are orders of magnitude slower than the rates seen with other electron acceptors. However, at some sites with poor transport conditions or inaccessibility (i.e., a deep groundwater table), this may still be a reasonable alternative.

The number and types of hydrocarbons degraded under methanogenic conditions are very limited. Some laboratory studies have demonstrated the methanogenic degradation of toluene and *o*-xylene with no degradation of *m*-xylene, *p*-xylene, ethylbenzene, or benzene. Others have found evidence of degradation of benzene with recalcitrance toward other compounds.

The methanogenic process appears to be extremely selective and not capable of the complete degradation of all contaminants present in a typical hydrocarbon plume on the order of years. In addition, there is likely a great deal of microbial heterogeneity with specific degradation capacity varying from location to location. In instances where a specific compound has been released (such as toluene used as a solvent), methanogenesis may be a viable natural attenuation process. It also has value in the natural dehalogenation of chlorinated compounds.

In instances where an aquifer has good transport qualities and a supply of natural electron acceptors, natural attenuation alone can be a viable process and acceptable to the regulatory community. However, responsible parties must be prepared for the long-term monitoring that will often be required in support of a natural attenuation program—more accurately termed monitored natural attenuation by the regulating community. In other cases, supplementation of electron acceptors or improvement of groundwater dynamics through pump and treat may provide an adequate minimal approach. But, in most instances, methanogenesis as the "ultimate of no action alternatives" is not going to be practically applicable.

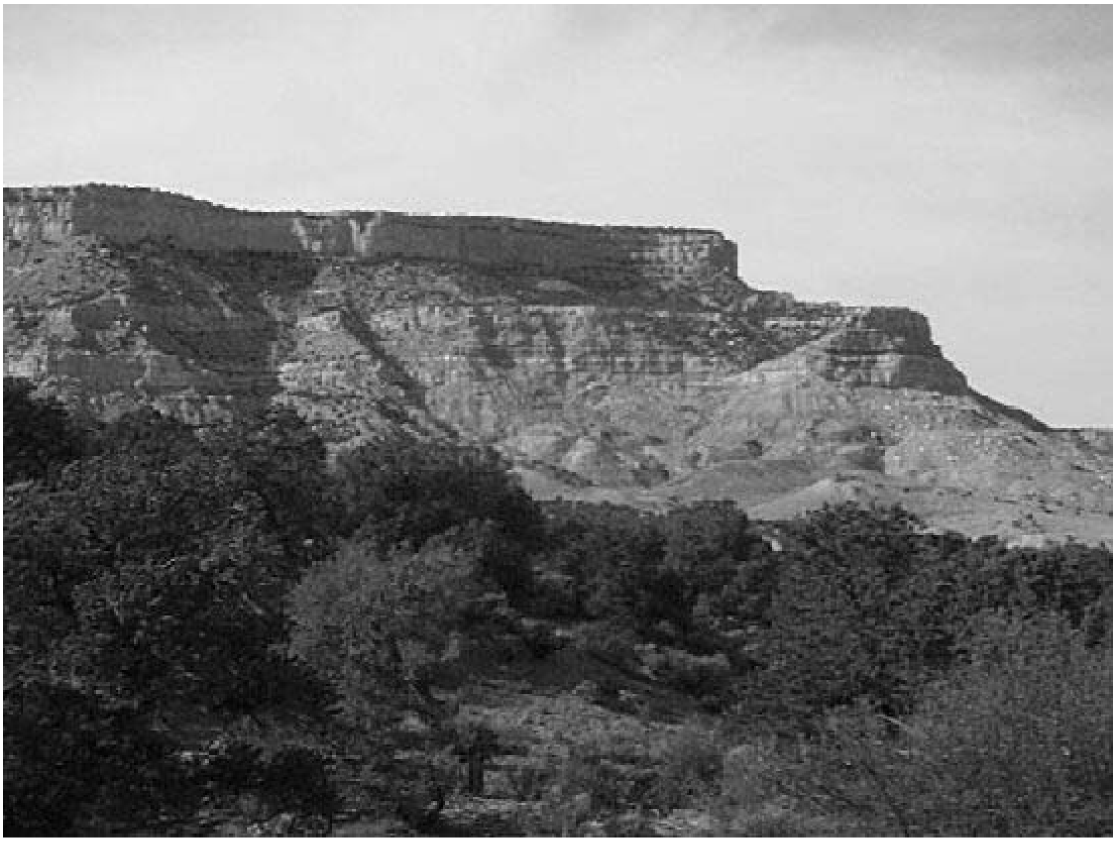
BLACK MESA MONITORING PROGRAM

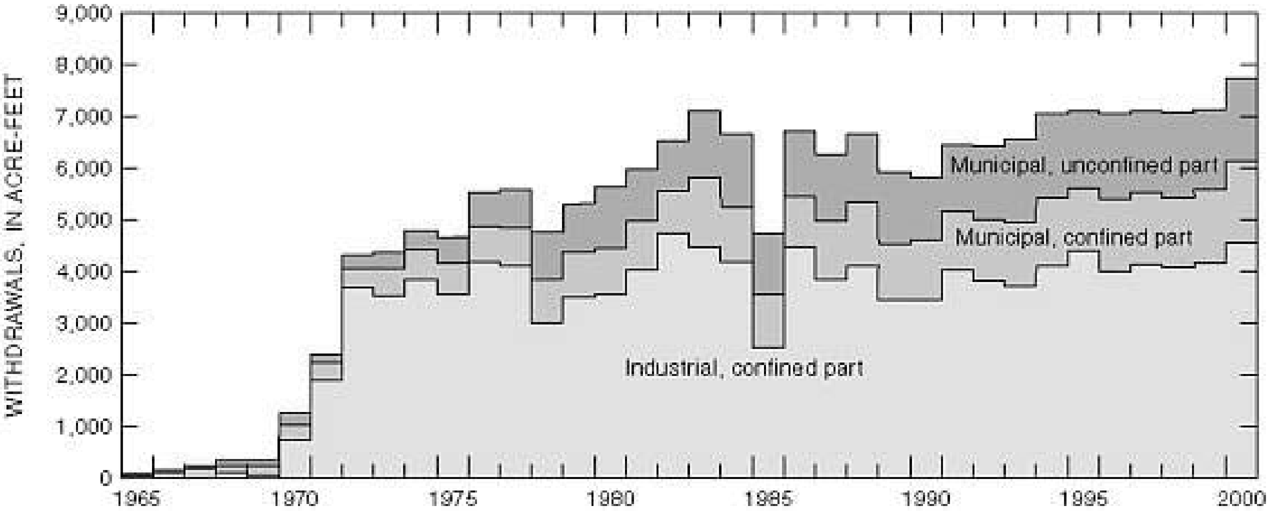
Bureau of Indian Affairs and
Arizona Department of Water
Resources—U.S. Geological
Survey

PROBLEM

The N aquifer is the major source of water for industrial and municipal users in the 5,400 square-mile Black Mesa area of northeastern Arizona. The aquifer consists of three rock formations-the Navajo Sandstone, Kayenta Formation, and Wingate Sandstone, which are hydraulically connected and function as a single aquifer.

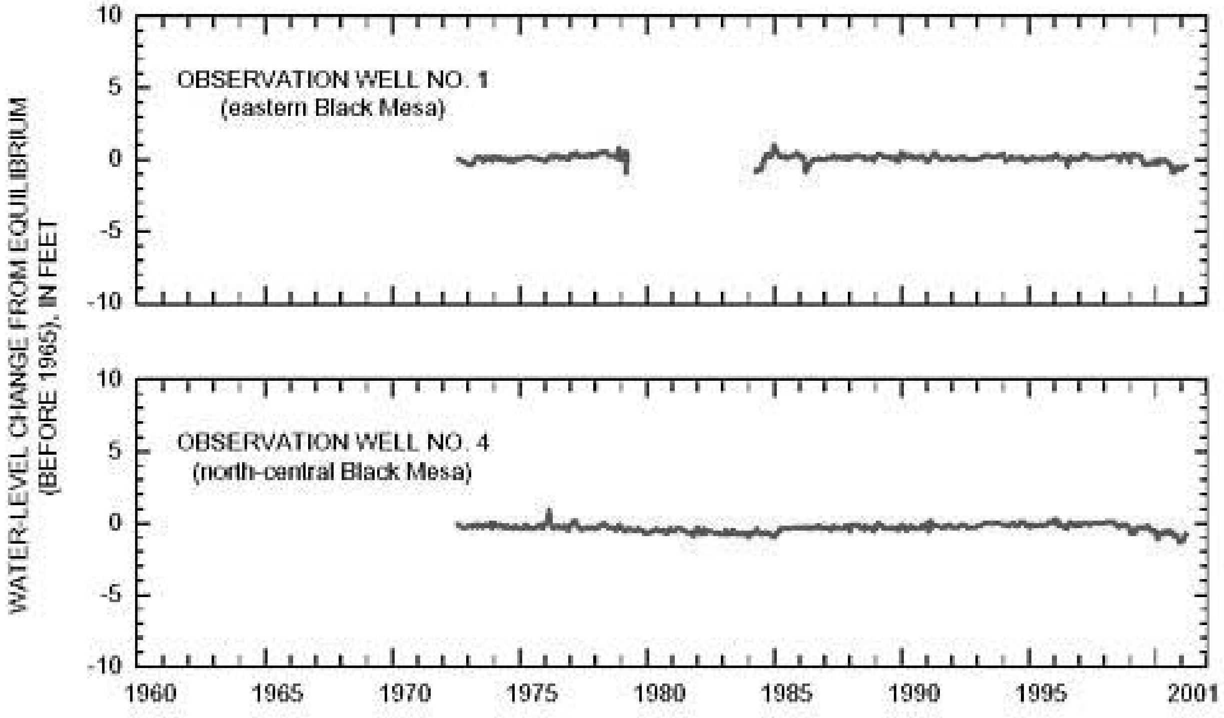
Annual withdrawals from the N aquifer for industrial and municipal use have increased from about 70 acre-ft in 1965, to 4,300 acre-ft in 1972, to 7,700 acre-ft in 2000. The Navajo Nation and Hopi Tribe live in the Black Mesa area, and they depend on ground water from the N aquifer to





Withdrawals from the N aquifer, Black Mesa area, Arizona, 1965–2000.

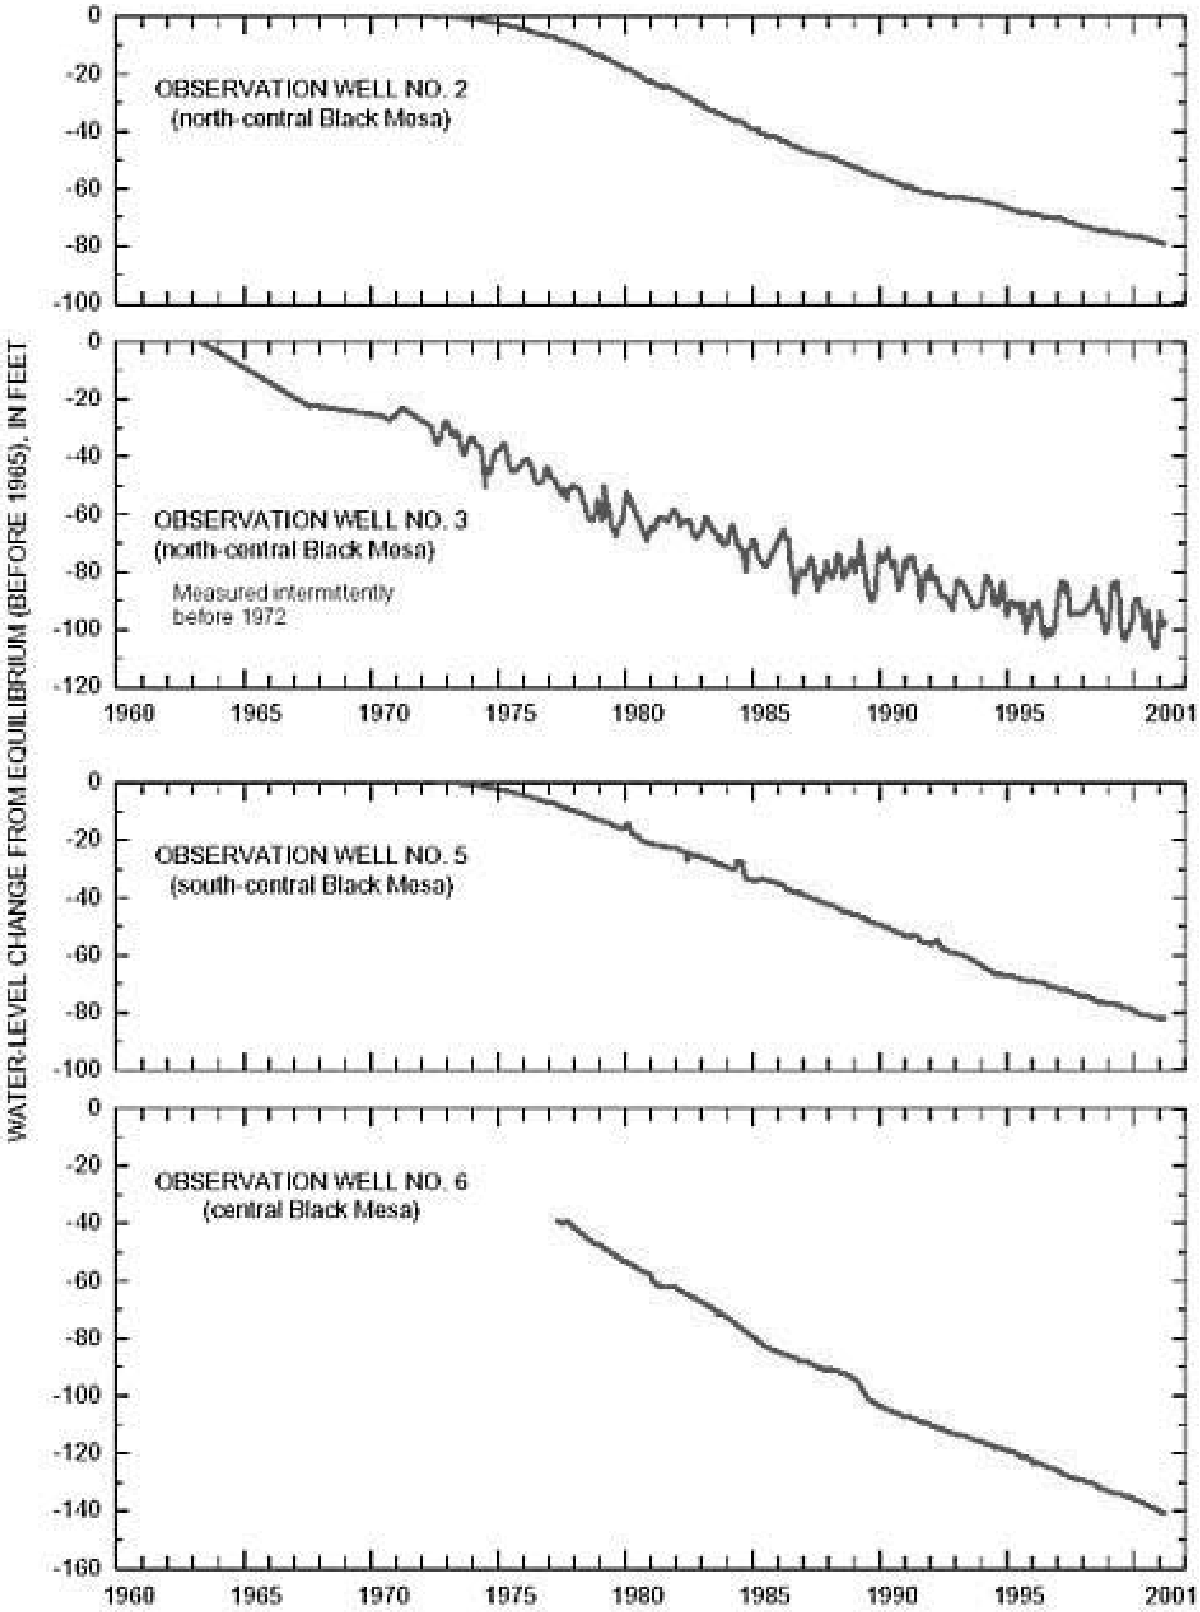
HYDROGRAPHS FOR WELLS IN UNCONFINED AREA



meet municipal, domestic, livestock, and irrigation needs. In addition, the springs and streams fed by groundwater discharge are an important part of their culture. Peabody Western Coal Company began operating a strip mine in the northern part of Black Mesa in 1968. The company withdraws water from the N aquifer for a slurry pipeline to transport coal to a powerplant in Laughlin, Nevada. Withdrawals by the company accounted for about 70–80 percent of the total withdrawals in the early and mid 1970's and have been about 60 percent of the total withdrawals from 1978 to 2000.

The Navajo Nation and Hopi Tribe have been concerned about the effect of this increasing pumpage on long-term water supply, discharge in streams and springs,

HYDROGRAPHS FOR WELLS IN CONFINED AREA



and quality of ground water. This concern led to the establishment of a long-term program in 1971 to monitor ground-water levels, ground-water discharge, ground-water quality, and surface-water discharge. From the 1960's to 2001, water levels in the N aquifer declined by over 50 feet in 9 of 19 long-term monitoring wells in confined areas. No large changes have been detected in ground-water levels in unconfined areas, ground-water discharge, ground-water quality, or surface-water discharge.

OBJECTIVE

To collect hydrologic data in a monitoring network that is designed to determine the long-term effects of industrial and municipal ground-water withdrawals on the N aquifer.

APPROACH

A long-term monitoring program has been established to collect hydrologic data in the Black Mesa area. Data are collected that describe the ground-water system, surface-water flow, and ground-water quality. Continuous measurements of ground-water levels have been made in six wells since 1972. Continuous data describing streamflow have been collected for 23 years in Moenkopi Wash, and for 3 to 6 years in three other streams. Once a year, ground-water levels are measured in about 26 wells, discharge is measured from 4 springs, and water-quality data are collected from 12 wells and 4 springs. Annual ground-water withdrawal data are collected from about 35 municipal well systems. Peabody Western Coal Company provides annual ground-water withdrawal data for industrial use.

These hydrologic data are entered into a computer data base. A report is prepared each year of the program. The report contains the data collected each year, and it shows comparisons of annual and long-term changes in ground-water levels, ground-water discharge, surface-water flow, and water quality. Long-term water-level changes in the six continuous-observation wells show that water levels in those confined areas have declined 80 to 140 feet and water levels in those unconfined areas have not changed.

RELEVANCE AND BENEFITS

The long-term available supply of water in the Black Mesa area is critical to many parties. The Hopi Tribe and Navajo Nation use water to meet their needs for public supply, irrigation, and livestock. In addition, sustained springflow and streamflow are important to their culture. Peabody Western Coal Company uses water to transport coal in a slurry pipeline to a powerplant. The hydrologic data collected in this monitoring program are needed to understand the available water supply and the effects of industrial and municipal ground-water withdrawals.

The U.S. Geological Survey has a commitment to provide data and information to Indian Tribes and other Interior Department Agencies. The Office of Surface Mining of the Interior Department uses the data from this program to facilitate their oversight and regulation of the coal mining operations of Peabody Western Coal Company.

The long-term ground-water, surface-water, and water-quality data collected for this program provides an important opportunity to investigate and gain a better understanding of a hydrologic system of bedrock geology in an arid climate in which there are many competing water-use interests.

BRINE DEPOSITS

Stephen M. Testa
Mokelumne Hill, California

INTRODUCTION

Brines are warm to hot, saturated to nearly saturated, highly saline, ocean and lake waters, containing Ca, Na, K, and Cl and minor amounts of other elements, typical of pore fluids in restricted basins. From an oceanographic perspective, brine is seawater that, due to high evaporation rates or freezing, contains more than the usual amount of dissolved salts, typically about 35%. A brine lake is essentially a salt lake. Brine lakes, like the Dead Sea, the Great Salt Lake in Utah, the Mono Lake region in northern California, and the Salton Sea region in southern California, develop as a result of high evaporation rates in an arid desert that lacks an outlet to the ocean (Fig. 1). The salt is derived from either minerals washed out of the surrounding watershed or from a geological deposit or area previously connected to the ocean.

A brine cell or pocket is a small inclusion usually the shape of an elongated tube about 0.05 mm in diameter that contains residual liquid more saline than seawater. A brine pit is a salt well or opening at the mouth of a salt

Figure 1. Mono Lake, a terminal brine lake situated in northeastern California. Tufa occurs at saline lakes worldwide, but not in the abundance and variety in shape as at Mono Lake. Mono brine shrimp are unique to this lake.

spring, from which water is taken to be evaporated for making salt.

Brines also occur in the subsurface notably as subsurface oil-field waters and geothermal mineralizing fluids. Subsurface brines in sandstone and other porous rocks are largely regarded as connate or buried seawater. Some brines also form locally by solution of rock salt beds.

SEAWATER BRINES

Seawater is relatively complex, but also relatively concentrated (1). Its principal ions are Na^+, Mg^{2+}, Ca^{2+}, K^+, Cl^- and $SO_4{}^{2-}$. Minor constituents include the elements Br, Sr, F, Ar, Li, Rb, I, Al, Fe, Zn, and Mo. Variable minor constituents include C, N, O, Si, P, and Ba. Seawater brines become more concentrated by evaporation, and in this process, deviation from ideal chemical behavior is greater (2). Microscopic cavities in such minerals as halite contain trapped brines representative of ancient seawater. Due to the protection of the brine provided by the halite crystal, such water has not undergone any significant chemical changes. The ionic ratios in these trapped brines are similar in composition to evaporating modern seawater.

Three properties of seawater and its brines predominant in evaporate production are concentration, density, and vapor pressure. Total salts are commonly stated in salinity, reflecting the resulting concentration from evaporation. The evaporation rate, however, indicates how much brine has undergone concentration via evaporation. Brine density is most important in its control of the circulation pattern in evaporate basins. The density of brines derived from seawater rises sharply from the 1.03 g/cm^3 of normal seawater to 1.29 g/cm^3 at the beginning of halite deposition. Vapor pressure is also important in its control of the rate of evaporation. Other properties include heat capacity, light transparency, and viscosity. Brines have substantially lower heat capacity, slightly lower thermal conductivity, and are less transparent to light than seawater.

BRINE OCCURRENCES

Geologically, brines are generated in a variety of environments and under varying sedimentary processes (2). Two main types of evaporate deposits are recognized: capillary evaporites and open-water evaporites (3). Capillary evaporites precipitate from interstitial brines that have a preexisting sedimentary layer. They contain remains of the host sediment, so capillary evaporites are always more or less dirty. Open-water evaporites precipitate from exposed water bodies. The detrital fraction, which is often eolian derived, makes up a small portion of these salt layers, so open-water evaporites are generally very clean.

The primary depositional settings are (1) coastal intertidal and supratidal zones called sabkhas, (2) small lagoons on coasts and atolls, (3) large deep-water marine basins, (4) sub-sea-level basins with inflow of marine water, and (5) nonmarine interior basins. Tectonically, these deposits occur along continental margins and shelves, interior shallow and deep cratonic basins, and rifted continental margins.

Brine deposits are typically extremely localized and reflect their unique conditions of formation. Brine deposits including salt are derived from four primary sources: seawater, sedimentary bedded deposits, surface playa deposits, and salt domes. Such areas and conditions include deserts of the southwestern United States, High Andean salares, Middle Eastern sabkhas, the East African Rift Valley, and subsurface Permo-Triassic deposits.

Recent studies have discovered brine pools on the seafloor within the Gulf of Mexico. These deposits are characterized by a distinct surface and shoreline. The pools are derived from the Luann Salt Layer and form in crater-like depressions that contain very concentrated brines and methane. These pools also support dense peripheral mussel beds.

Extensive evidence also exists that brines commonly form deep along midocean ridge hydrothermal systems. Such occurrences result from heating of sea-water-derived hydrothermal fluids at supercritical conditions, although it is not clearly understood how these brines are stored in the crust. One widely accepted model is the development of dense brines formed by formation of a two-layer system, whereas a recirculating brine layer underlies a single-phase seawater cell. If the temperature of the seawater cell remains high enough for substantial supercritical two-phase separation, the brine layer will grow. Should temperatures drop into the single-range region, the brine layer erodes.

Brines have also been recently discovered on other planets within our solar system. A growing body of evidence indicates that an ocean exists but is hidden beneath the icy crust of Jupiter's moon, Europa. Hydrated salts are indicated by spectral evidence and thermal evolution models of Europa's interior and laboratory studies of meteorites. The hydrated mineral deposits may reflect exposure of salty ocean water to the surface. On Mars, evaporate deposits may represent significant sinks of mobile anions and cations among the materials composing the Martian surface and upper crust. The nature of evaporate-precursor brines formed under Martian conditions is poorly understood at this time. Salts depress the freezing point of water significantly, so the presence of salts in the Martian soil could explain why water might be flowing in very high latitudes.

EVAPORITE MINERALOGY AND THE CONCEPT OF FACIES

Brines fall into three main types based on the predominating acid radical: chloride brines, sulfate brines, and alkali or volcanic brines. They include bitterns (natural brines) with other chlorides, bromides, iodides, and sulfates. The metallic ions in greatest abundance are sodium, magnesium, calcium, and potassium. Chloride type brines include many terrestrial brines as well as seawater. Terrestrial brines that contain chloride in excess of sodium are comparatively rare. Chloride type brines contain a higher proportion of sulfate than seawater. Seawater is an impure solution of sodium chloride and contains enough chloride to combine with all the sodium (the most abundant metallic ion) and part of the magnesium (the second most abundant metallic ion). The transition from chloride to sulfate type brines is gradational, whereby sulfate is the predominate acid radical. Alkali brines contain carbonate, sulfate, and borate; chloride is present in subordinate amounts.

Based on provenance, brines can be divided into marine brines that are concentrated from ocean water, continental brines concentrated from groundwater, and formation waters circulating in deeper bedrock horizons.

Evaporites are sedimentary deposits composed of minerals that have precipitated from brines concentrated during evaporation. These deposits are products of waters of inland desert basins, as well as interstitial waters of sediments located along ocean margins. Evaporites also occur from replacement of rocks that are not evaporites by evaporate minerals (4). Sedimentary processes vary significantly. Source fluids for evaporate precipitation can be classified by the degree of solute concentration of undersaturated brines. The three types distinguished include waters of low salinity or hypohaline waters, intermediate salinity or mesohaline waters, and high salinity or hypersaline brines.

Evaporites have a distinct and characteristic mineralogy. In the study of their geochemistry, origin, and geologic setting, mineralogy is the most important characteristic (2). Critical minerals derived from the evaporation of seawater are summarized in Table 1, along with the general facies sequence for marine evaporites. Facies in geological terms characterizes the critical variations or stages in the mineralogy of evaporite rocks during brine evaporation. Facies in this context essentially represent subdivisions of the evaporate process, recognizable through the appearance of new albeit critical minerals, regardless of proportion. For example, the mere presence of halite would characterize the assemblage as within the halite facies. The appearance of a potash-magnesia, halite, calcium sulfate, or calcium carbonate mineral is part of natural crystallization which occurs as water is removed during evaporation. This process is dependent on a balance between the proportions of various components in seawater and the corresponding mineral solubility in the brine. An extensive listing of the most common evaporate minerals is presented by Braitsch (5) and Sonnenfeld and Perthuisot (3).

Structurally, evaporates occur in two widely different structural forms: beds or lenses, and as salt structures which includes such features as bosses, plugs, ridges, and domes. Lenses and bed type deposits, such as the great Permian Basin, extend throughout parts of Kansas, Colorado, Oklahoma, Texas, and New Mexico. Nonbedded structures are common along or near the Gulf of Mexico. Bedded salt deposits vary in thickness but are typically of the order of 15 to 45 feet. The thickness of salt domes or diapirs remains uncertain.

BRINE RESOURCES

Known resources of evaporate and brine resources in the United States range from 100 years for potassium compound and iodine production, to unlimited, reflecting seawater as a source. The birthplace of subsurface brine production was in the Michigan Basin, an intracratonic basin that hosts thick successions of carbonates and evaporate-bearing strata.

Natural subsurface brines are the feedstock for a wide variety of industrial minerals and chemicals. For example, bromide is produced in Arkansas from the Upper Jurassic Smackover Formation, magnesium chloride and bromide are produced from the Devonian Detroit River Group in Michigan; lithium carbonate is produced in Chile and California from aquifers beneath playas and salares; iodide is produced from the Lower Pennsylvanian Morrow Formation in Oklahoma and coproduced in Japanese natural gas wells; and calcium chloride is produced near Slave Lake, Drumheller, and Brooks, Alberta.

Table 1. Summary of Evaporite Facies[a]

Facies	Subfacies	Mineralogy	Salinity, wt. %	Density, g/cm^3	Fraction Evaporated, wt. % H_2O	Concentration × Seawater, wt H_2O	Concentration × Seawater, Vol. of Brines
	Bittern subfacies	Bischoffite, tachyhydrite			99.2	120	
Potash-magnesia (supersaline)	Potash subfacies	Carnallite, sylvite, kainite, kieserite, halite, anhydrite or polyhalite	380	1.31	98.7	75	78.0
	$MgSO_4$ subfacies	Epsomite, bloedite, halite, polyhalite or anhydrite	375	1.29	98.4	65	68.0
Halite facies		Halite, anhydrite or gypsum	300	1.20	91.0	11.5	12.2
$CaSO_4$ facies		Gypsum or anhydrite, dolomite	150	1.10	72.0	3.5	3.6
Dolomite facies		Dolomite, calcite	35	1.02	0	1.0	1.0
$CaCO_3$ facies							
	(normal marine)	Calcite, aragonite	10	1.01	—		
	(brackish)		1	1.00	—		
	(terrestrial)		0	1.00	—		

[a] Modified after Reference 2.

BRINE PRODUCTION

Brines are extracted via several means, including underground mining, solar evaporation, and solution mining and mechanical evaporation. Underground halite deposits are conventionally mined by drilling and blasting. Vertical shafts are about 20 feet in diameter and extend to depths of 500 to more than 2000 feet below ground into the salt deposit. In the United States, 70% of the salt produced is extracted from natural or synthetic brines or seawater; the remaining is mined as a solid.

Products developed from brines include specialized industrial minerals used in the chemical industry for the manufacture of glass, fertilizers, pharmaceuticals, and batteries (6). Specialized industrial minerals produced include soda ash, potash, borax and boric acid, potassium chloride and sulfate, lithium, and nitrate and iodine. Salt produced from brine, and a small amount of dry salt, is used to produce chemicals such as chlorine gas and caustic soda (sodium hydroxide), among others. Deep unused brine-bearing aquifers are also used for to reduce greenhouse gas emissions via subsurface injection.

CONNATE WATER

Richard C. Brody
UC Berkeley
Berkeley, California

CHEMISTRY

Because of its long contact with rock material, connate water can change in chemical composition throughout the history of the rock and become highly mineralized (see Table 1). Connate water can be dense and saline compared with seawater; connate water salinities can range from 20 to more than 300 grams per liter. For comparison, seawater salinity is approximately 35 grams per liter total dissolved solids (1).

AGE

Some of the oldest connate water may stay beneath the land surface for millions of years, which is in contrast to the age of groundwater, which ranges from a few years or less to tens of thousands of years. Because of its long underground residence, connate water may move long distances, even though its velocity may be very low (3).

Table 1. Geochemical Composition of Connate Water Compared to Aquifer Water[a]

Chemical Component	Connate, mg/1	Aquifer, mg/1
Na^+	65,000	2,600
K^+	500	64
Mg^{2+}	28,000	210
Ca^{2+}	165,000	430
Ba^{2+}	0.1	0.1
Sr^{2+}	1,300	6.5
Fe^{2+}	0.1	0.1
Cl^-	138,360	5,100
Br^-	10	10
$SO_4{}^{2-}$	260	1,900
HCO_3	100	150
Organics	55	5
pH	5.8	7.65

[a] Ref. 2.

OIL RESERVOIR MONITORING

Crude oil is always produced with connate water, and the water-to-oil ratio is often greater than 10 to 1; therefore, the oil and gas exploration industry extensively monitors connate water (4). Connate water tends to rise toward the surface during oil and gas extraction, so resistivity logs track connate water movement to recognize and mitigate coning problems associated with excessive production yields (5). Distinguishing the difference between connate water and other types of underground water (e.g., meteoric water) through water analyses can aid in both oil and gas exploration. Variations in fluid composition can help to delimit reservoir boundaries and reveal the connectivity of different strata. Saline waters are generally more favorable for locating petroleum reservoirs. If the trapped fluid is saline, then there is less chance that any associated petroleum has been degraded by contact with meteoric water or flushed from the reservoir (1).

CONSOLIDATED WATER BEARING ROCKS

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

Consolidated rocks (otherwise known as bedrock) consist of rock and mineral particles of different sizes and shapes that have been welded together by heat and pressure or chemical reaction into a rock mass. Aquifers of this type are commonly composed of one or more of the following rocks: sandstone, limestone, granite, or lava. Water flows through these rocks through fractures, gas pores, and other openings in the rock.

CONSOLIDATED ROCKS

Consolidated rocks are usually classified according to their origin. There are three types: sedimentary, igneous, and metamorphic.

SEDIMENTARY ROCKS

Sedimentary rock is formed by the deposition of material suspended in water; the material may have been material weathered from older rocks, plant or animal remains, or precipitated chemicals. Important types of sedimentary rock aquifers include sandstone, carbonate rock, and conglomerate.

Sandstone

Sandstone is a cemented form of sand and gravel; the sand grains are cemented together when dissolved silica and calcium contained in the pore fluid precipitate. Sandstone shows great variation in water yielding capacity which is controlled chiefly by its texture and the nature of the cementing materials. Thus, whereas coarse-grained sandstone with rather imperfect cement may prove excellent aquifers, fine-grained varieties, especially those that are thoroughly cemented, may be the worst types from which no yield of water is possible (1).

Carbonate Rocks

Carbonate formations include limestone ($CaCO_3$) and dolomite (a mixture of $CaCO_3$ and $MgCO_3$). These deposits exhibit mostly secondary porosity due to fracturing and dissolution openings because $CaCO_3$ is soluble in rainwater. Limestones vary widely in density, porosity, and permeability, depending on the degree of consolidation and development of permeable zones after deposition. Openings in limestone may range from microscopic original pores to large solution caverns forming subterranean channels sufficiently large to carry the entire flow of a stream (2). Large springs are frequently found in limestone areas.

The dissolution of calcium carbonate by water causes prevailingly hard groundwater in limestone aquifers; by dissolving the rock, water, also tends to increase the pore space and permeability with time. Solution development of limestone forms a karst terrane, characterized by solution channels, closed depressions, subterranean drainage through sinkholes, and caves. Such regions normally contain large quantities of groundwater (3). Major limestone aquifers occur in the southeastern United States and in the Mediterranean area (4,5).

Conglomerates

Conglomerates like sandstone are cemented forms of sand gravel. As such, their porosity and yield have been reduced by the cement. Conglomerates have limited distribution and are unimportant as aquifers (6).

IGNEOUS ROCKS

Igneous rocks are formed from the cooling and solidification of molten magma originating in the earth's core. Important consolidated rock aquifers include basalts.

The important points in this context are as follows:

1. Basalts rocks are often vesicular. Vesicles, in them are of considerable size and number, and if they are interconnected (by fracture), they can serve as aquifers.
2. Contraction joints (like columnar joints) and other fractures, if present, also contribute to the porosity and permeability of basalts.
3. Basalts originate as lava flows, so sometimes, they may overlie buried valleys that offer good groundwater potential.

The Columbia River Plateau covering eastern Washington and Oregon, and Idaho, averages about 500 m in thickness and is one of the largest basalt deposits in the world. Basalt aquifers are critically important water sources for the Hawaiian Islands. Most of the largest springs in the United States are associated with basalt deposits.

Rhyolites are less permeable than basalt. Granites have very low porosity and permeability; what little exists is primarily due to fracturing. Although not important as aquifers, these materials are candidates for the host rock for high-level radioactive waste.

METAMORPHIC ROCKS

These are sedimentary or igneous rocks that have been altered by heat or pressure. They generally form poor aquifers.

SENSITIVITY OF GROUNDWATER TO CONTAMINATION

Michael D. Trojan
Minnesota Pollution Control Agency
St. Paul, Minnesota

For this discussion, groundwater sensitivity is defined as *the likelihood for contaminants to reach a specified position in the groundwater system after introduction at some location above the specified position* (1,2). Sensitivity is a widely applied concept that has several uses. Sensitivity analyses often lead to the development of maps showing the relative sensitivity of groundwater across a geographic area. These maps are used as a screening tool for land-use decisions and have increasingly been used in source water protection. Sensitivity analyses are also used in program development, such as identifying areas where groundwater monitoring will occur. The concept of groundwater sensitivity also has educational value because hydrogeologic concepts are easily expressed and the audience can visualize relationships between land use and aquifer protection.

WHAT MAKES AN AQUIFER SENSITIVE TO CONTAMINATION?

Groundwater sensitivity applies to a variety of situations; each requires a different level of analysis. Sensitivity, vulnerability, and susceptibility, which are often defined differently, are used interchangeably in this discussion. The simplest scenario involves transport of a conservative contaminant in water from the land surface to groundwater. This scenario can be modified to consider land use, account for attenuation or retardation of contaminants, consider a point below the top of the saturated zone, or consider risk to human or ecological receptors at some point within an aquifer.

Under the scenario where a conservative contaminant is transported from the land surface to groundwater, factors that affect sensitivity include the permeability of geologic materials, the thickness of the unsaturated zone, and recharge. Highly permeable geologic materials transmit water quickly and thus increase sensitivity (see Hydraulic Conductivity/Transmissibility). In heterogeneous deposits, the geologic material that has the lowest permeability typically has the greatest effect on the rate of water movement, provided the geologic material is sufficiently thick, laterally continuous, and does not have extensive macroporosity. As the thickness of the unsaturated zone increases, sensitivity decreases because water can be stored and has a farther distance to travel. Sensitivity increases as the quantity of recharge increases because contaminants are transported by recharge water. Recharge is often computed from a water budget by subtracting evaporation from precipitation and assuming no runoff or soil storage.

Even in sensitive hydrogeologic settings, groundwater will not become contaminated unless there is a source of contamination. We can generalize about how groundwater quality will be affected by land use (see Land Use Impacts on Groundwater Quality). Agriculture can contribute significant quantities of nitrates and pesticides to an aquifer, nonsewered residential areas can contribute large quantities of nitrates and chlorides (3), and industrial and older sewered residential areas can contribute large quantities of volatile organic chemicals (VOCs), chlorides, and some metals such as manganese. Within each of these land uses, specific management practices further affect contaminant volumes. Several studies show direct, although not necessarily linear relationships, between the quantity of chemical applied at or near the land surface and concentrations in sensitive aquifers. Thus, for example, groundwater is more sensitive in areas that use greater fertilizer application rates.

Nearly all contaminants attenuate to some extent within the unsaturated zone. The extent and rate of attenuation depend on the properties of the contaminant and on the chemical, physical, and biological properties of the geologic materials (Table 1). These properties are too numerous to discuss individually, but adsorption and degradation are the two primary attenuation processes that affect contaminants. Contaminants that are not readily adsorbed percolate to groundwater and result in increased sensitivity. Except in highly weathered, acidic soils, these are chemicals that have a negative charge, such as chloride, nitrate, and acid herbicides (2,4-D, Dicamba). Contaminants that are quickly degraded biologically or chemically represent a lower risk to groundwater than more persistent contaminants. In addition to the properties of a chemical, degradation is affected by factors such as temperature, the presence of oxygen, and pH. For example, most halogenated contaminants are persistent except under reducing conditions, nitrate is persistent in the presence of oxygen, and benzene is persistent in the absence of oxygen.

We are often interested in the sensitivity at some point below the top of the saturated zone, such as at a well. In addition to having a greater distance to travel, a contaminant may be affected by geochemical changes within the saturated zone. Trojan et al. (4), for example, showed that in the glacial aquifers of Minnesota, nitrate was quickly attenuated in the upper few meters of groundwater, even though these aquifers were mapped

Table 1. Characteristics of Different Classes of Contaminants. This Information is Generalized and Varies within Each Contaminant Class and Between Different Geologic Deposits and Hydrologic Environments

Contaminant Class	Examples	Adsorption	Persistence	Toxicity
Halogenated organics with one or more benzene rings	PCBs, dioxins, many pesticides, chlorobenzenes	High, increases with greater extent of halogenation	High, increases with greater extent of halogenation	High, increases with greater extent of halogenation
Polyhalogenated aliphatics	Industrial solvents (TCE, PCE), some pesticides	Low, increases with greater extent of halogenation	Moderate, increases with greater extent of halogenation	Moderate, increases with greater extent of halogenation
Nonhalogenated polynuclear aromatics	Pyrene, benzo(a)pyrene	Moderate but increases rapidly with increasing molecular weight	Moderate but increases rapidly with increasing molecular weight	Moderate but increases rapidly with increasing molecular weight
Other nonhalogenated aromatics	Benzene, toluene	Low	Low to high, depending on geochemical environment	Low except for some chemicals, such as benzene
Nonhalogenated aliphatics	Oil, alkanes,	Moderate to high	Low to high, depending on geochemical environment	Low
Metals	Lead, copper	Moderate to high	High	Moderate to high
Nonmetals	Arsenic, boron	Moderate but varies widely	High	Moderate to high
Anions	Chloride, nitrate	Low	High	Low
Radionuclides	Cesium-137, radon-222	High	High	High

as sensitive to contamination. In this case, denitrification was the most likely cause for disappearance of the nitrate. In other scenarios, contaminants may be adsorbed within an aquifer.

Few sensitivity methods consider the risk to receptors. Risk analysis does not consider whether a chemical will reach groundwater but whether it will pose a risk to receptors. Risk is a function of dose and toxicity. Thus, consumption of 1,1,2-trichloroethene (TCE) at a concentration of 5 μg/L poses a greater risk than consumption at 1 μg/L; consumption of TCE at 5 μg/L [maximum contaminant level (MCL) = 5 μg/L] poses a greater risk than consumption of xylene at 5000 μg/L (MCL = 10,000 μg/L). Because we have to consider specific exposure points (e.g., a well), the quantity of contaminant being transported, and the contaminant toxicity, estimates of sensitivity based on risk can be very complicated.

Table 2 provides a summary of factors that affect groundwater sensitivity to contamination. Figure 1 provides a schematic showing how different factors affect sensitivity. Figure 2 shows how sensitivity varies when different receptor points or contaminants are considered.

METHODS FOR ASSESSING SENSITIVITY

The Commission on Geosciences, Environment, and Resources (2) provides an excellent discussion of methods for assessing sensitivity. The most commonly employed methods are overlay and index methods. These involve combining various physical properties of the hydrogeologic system. Each property is assigned a score or other sensitivity value based on perceived sensitivity. Overlay and index methods use many of the factors in Table 2. DRASTIC (5) is a widely employed index and overlay method that uses seven factors in the sensitivity assessment. Overlay and index methods can be relatively simple and may require small amounts of information. Sensitivity analyses using these methods often result in plan view maps depicting relative groundwater sensitivity, usually through a color-coded scheme. These maps are useful interpretive and screening tools. The scale of these maps is usually not appropriate for site-specific decisions, although they have been used for this purpose.

Analytic or numeric methods predict the time it takes contaminants to reach groundwater. These methods typically consist of mathematical models. Attenuation of chemicals is often considered. Examples include PRZM (6), GLEAMS (7), and LEACHM (8). An advantage of analytic and numeric methods is that they quantify the processes that affect the movement of water and contaminant. The accuracy of these methods depends on the quality of data used in the model.

Statistical methods use statistical techniques, such as regression analysis, to predict the likelihood of contamination. These methods require data on contaminant concentrations and may require additional information to derive sensitivity estimates. For example, concentrations of nitrate may be correlated with depth to water and sand content in the vadose zone. Because they use actual data, statistical methods can provide accurate estimates of sensitivity, information on variability in a sensitivity analysis, and estimates of certainty. They are, however, data intensive.

LIMITATIONS OF THE SENSITIVITY CONCEPT

In 1993, the Commission on Geosciences, Environment, and Resources prepared a report on ground water vulnerability assessments (2). The Commission, “in struggling with the manifold technical and practical difficulties

Table 2. Summary of Factors that Affect Groundwater Sensitivity

Property	Effect on Sensitivity	Low Sensitivity	High Sensitivity
	Hydrologic Factors		
Aquifer material	Rate at which water moves within an aquifer	Shale, most hard rocks, clay, silt	Limestone, sandstone, sand, gravel
Depth to bedrock	Distance that water must travel to reach groundwater	Large distances (>50 feet)	Short distances (<10 feet)
Depth to water	Distance that water must travel to reach groundwater	Large distances (>50 feet)	Short distances (<10 feet)
Recharge	Amount of water reaching groundwater	Small quantities (<1 inch)	Large quantities (>10 inches)
Soil material	Rate at which water moves to or within groundwater	Clay, silt, organic soils	Sand, gravel
Thickness of confining layers	Rate at which water moves to or within groundwater	Large thickness (>20 feet)	Small thickness (<5 feet)
Topography	Amount of water reaching groundwater	Upland areas where water runs off	Lowland areas where water accumulates
Type of bedrock	Rate at which water moves to or within groundwater	Unfractured shale and hard rocks	Limestone, sandstone, fractured rock
	Other Factors		
Soil/aquifer material	Attenuation of chemical	High organic or clay content	Low organic or clay content
Contaminant	Persistence, mobility, toxicity	Rapidly degraded, low mobility, low toxicity	Persistent, highly mobile, highly toxic
Land use	Amount and type of chemical released	Low chemical inputs (forest, grassland)	Large chemical input (row crop agriculture, nonsewered communities)

affecting the performance of vulnerability assessments today, nearly concluded that their limitations are so great as to be of no use in management decision-making." Though the concept of sensitivity is applicable to land-use decisions, program development, or education, there are two important concerns over their use.

First, the analyses and resulting products, usually maps, are only as good as the data that go into them. Sensitivity analyses generally do not result in collection of new data and rely instead on existing information. Geologic maps, soil maps, and climate data are often available, but values for depth to water and hydraulic conductivity may be difficult to find. Data become more limiting when factors such as specific contaminants, land use, and risk are considered.

Second, maps or other products developed from sensitivity analyses can be misused. Many people who make land-use decisions rely on these maps. They often assume that sensitive areas will become contaminated and less sensitive areas will not, and they are often not aware of the way the maps were developed. Examples of misuse include

- using a 1:100,000 sensitivity map to site a landfill;
- assuming that all areas mapped as sensitive have equal sensitivity;
- assuming that the same data were available throughout a mapped area; and
- using a sensitivity analysis based on a conservative tracer to predict sensitivity to contamination with pesticides.

Researchers have increasingly modified existing methods to provide better tools to local users of sensitivity maps. Rupert (9) improved the effectiveness of a modified DRASTIC ground water vulnerability map by calibrating the point rating schemes to actual groundwater quality data by using nonparametric statistical techniques and a geographic information system. Snyder et al. (10) used a particle tracking model in conjunction with DRASTIC to evaluate groundwater vulnerability. Erwin and Tesoriero (11) related the occurrence of elevated nitrate concentrations in samples from public supply wells to natural factors to assess aquifer susceptibility using logistic regression. Holtschlag and Luukkonen (12) used a vulnerability model that incorporated several contaminant properties to predict atrazine leaching. Although researchers have generally focused on improving the accuracy of sensitivity estimates, the problems discussed before can also be overcome by improving data accessibility, providing information about the reliability

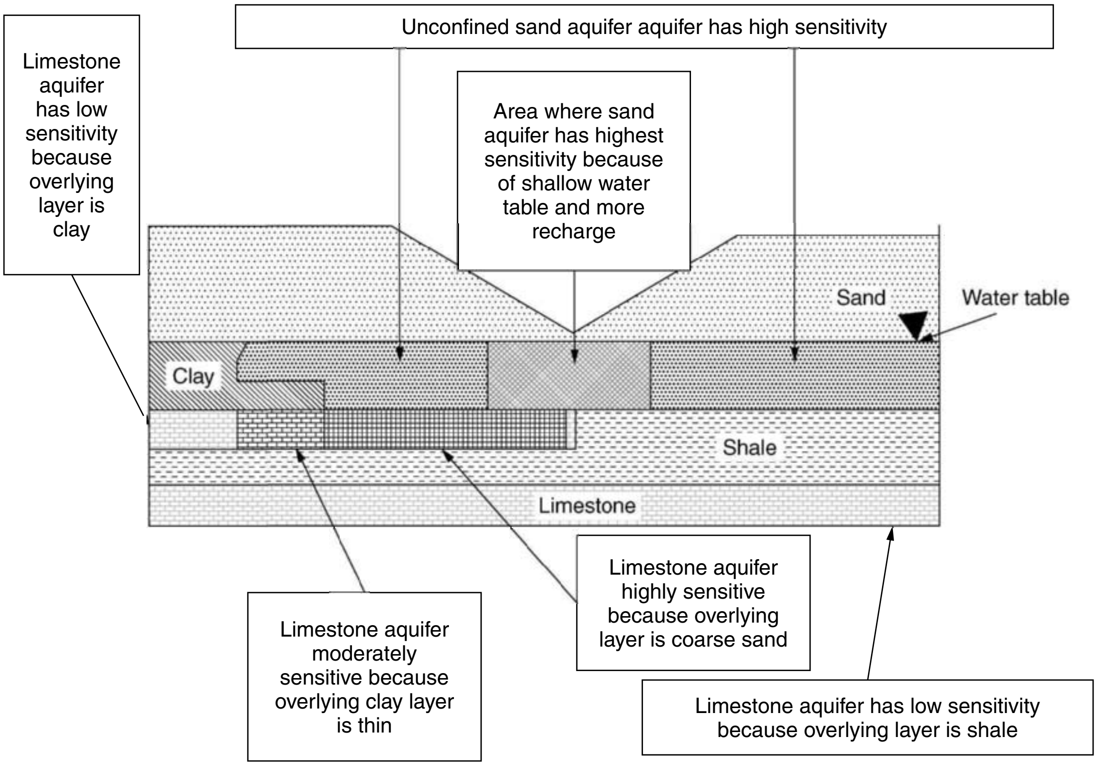

Figure 1. Schematic representation of geologic factors that affect groundwater sensitivity.

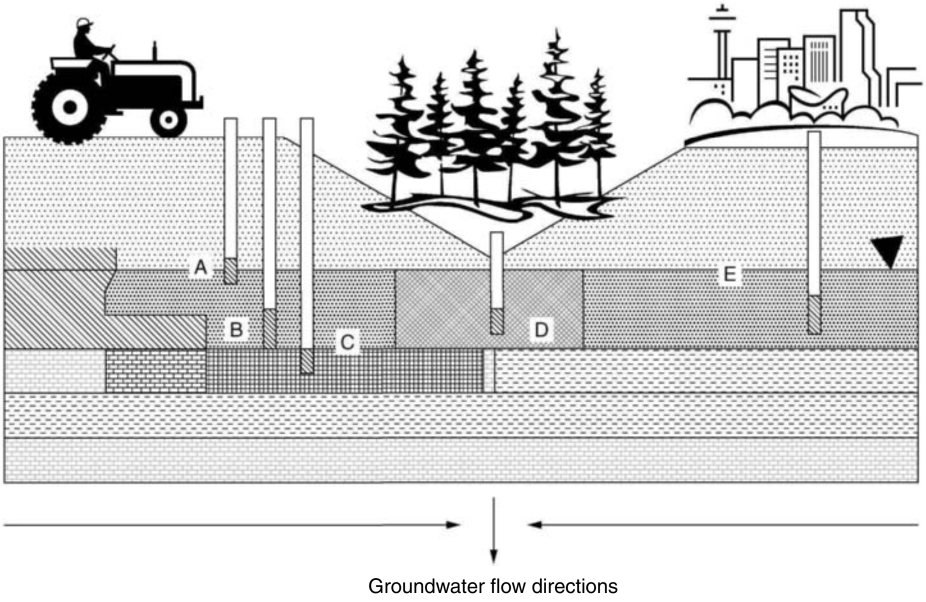

Figure 2. Schematic illustrating how a variety of factors affect groundwater sensitivity. Considering transport of a conservative chemical, the groundwater is considered sensitive at each of five well locations (A, B, C, D, E). At location A, the aquifer is most sensitive because the well is screened at the water table. The chemicals of concern are nitrate and pesticides from agriculture. At location B, the well may be less sensitive than at A because contaminants can be degraded or adsorbed within the aquifer. The chemicals of concern are nitrate and pesticides from agriculture. At location C, the well may be less sensitive than at B if the contaminant is degraded or adsorbed, but if the aquifer is fractured, sensitivity may be greater than at B. The chemicals of concern are nitrate and pesticides from agriculture. At location D, the well may be less sensitive than at all other well locations because the overlying land use does not contribute contaminants. Contaminants introduced at other locations may be degraded or adsorbed before reaching the well. At location E, sensitivity is similar to that at B but the contaminants of concern are VOCs and trace elements from commercial, industrial, and residential land use.

of data, providing estimates of variability or uncertainty, and training users.

SUMMARY

Understanding groundwater sensitivity and identifying areas where groundwater is sensitive to contamination is a potentially useful tool for managers, planners, and educators. Sensitivity analyses often lead to the production of maps showing relative sensitivity across a geographic area. Despite a potential for misuse, researchers have increasingly focused on improving the accuracy of these maps, including calibration, for local applications.

WATER CONTAMINATION BY LOW LEVEL ORGANIC WASTE COMPOUNDS IN THE HYDROLOGIC SYSTEM

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Timothy K. Parker
Groundwater Resources of
California
Sacramento, California

Laboratory methods have improved dramatically during the past decade with much lower detection levels enabling some interesting results of human impact on the condition of the hydrologic system. Low levels of organic contaminants are present in surface and groundwaters throughout the nation. Methyl tert butyl ether (MtBE) and some chlorinated solvents have been measured at low levels in public supply wells near rivers. Low levels of chloroform and other trihalomethanes produced as a result of the water disinfection process (also called disinfection byproducts) appear nearly ubiquitous in the urban environment. The source of disinfection byproducts is from the use and application of treated water in the urban environment for landscape irrigation, transport of household wastewater through leaky sewer systems, and also from leaky water pipe systems emanating form water treatment plants. An additional constituent which has low risk-based level, N-nitrosodimethylamine (NDMA), has also been found associated with water treatment plant disinfection byproducts.

A well-known nation wide study was conducted by the U.S. Geological Survey (USGS) in 1999 to 2000. The USGS collected surface water samples from 139 streams in 30 states across the lower 48 states (Fig. 1). The streams tended to be downstream of intense urban or livestock areas and consequently were suspected of contamination. The surface water samples were analyzed for organic wastewater contaminants (OWCs). The results of the surface water sample evaluation were published in Environmental Science & Technology (1) and in a USGS Open-File Report (2).

The USGS found that 80% of the streams sampled generally contained low concentrations of OWCs in the <1.0 μg/L range, impacted primarily by residential, industrial, and agricultural products. Seven chemical groups (steroids, nonprescription drugs, insect repellent, detergent metabolites, disinfectants, plasticizers, and fire retardants) were found in more than 60% of the stream samples, and three groups (detergent metabolites, steroids, and plasticizers) contributed to almost 80% of the total measured concentration. More than one-third (33 of 95 target OWCs) of the chemicals detected are known or are suspected of exhibiting at least weak hormonal activity and have the potential to disrupt normal endocrine function (Fig. 2).

One source of the chemicals identified is products and materials typically used in farming and industry. Additionally, a significant contribution was from residential

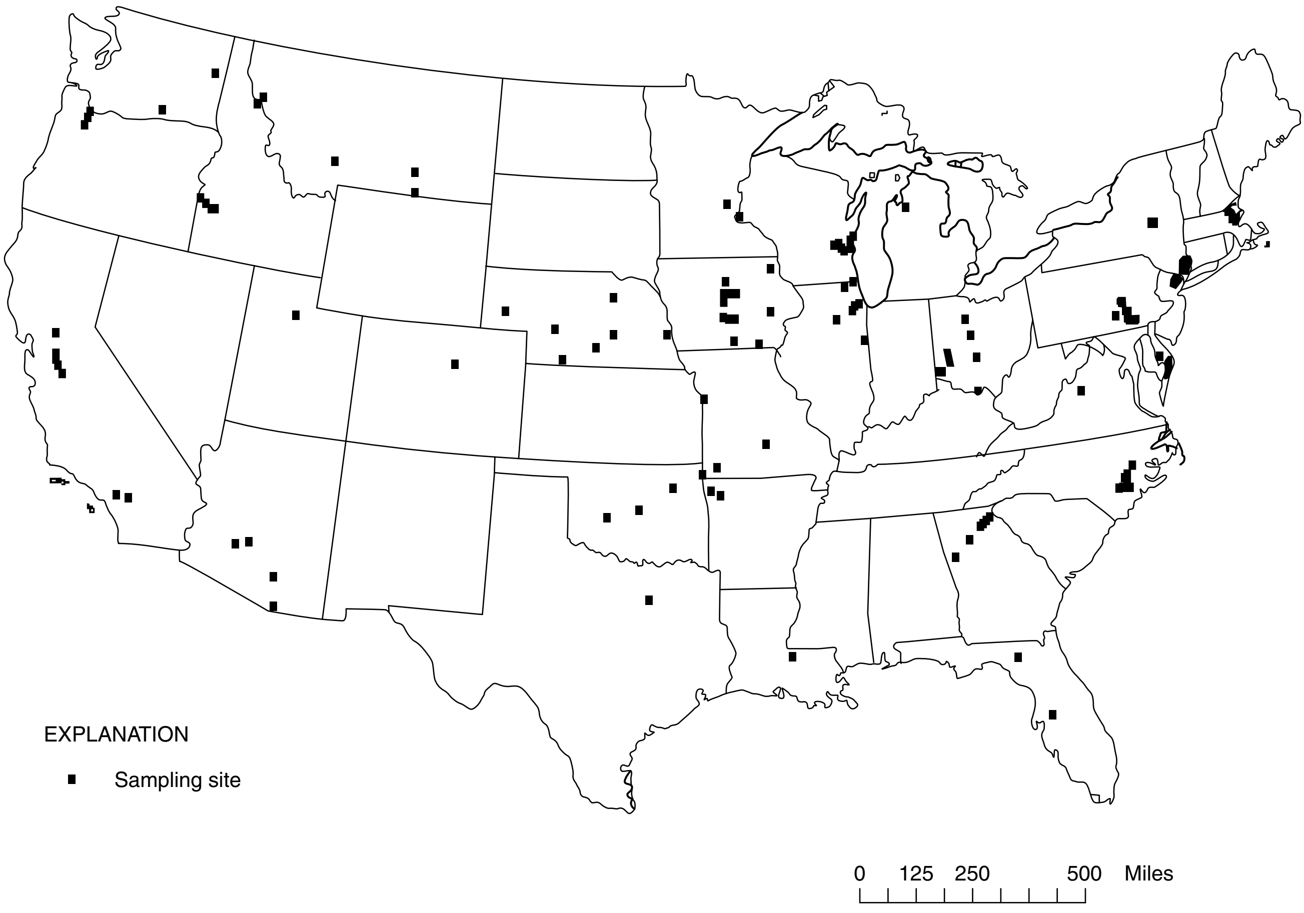

Figure 1. Sampling locations of USGS study (courtesy of USGS, Ref. 1).

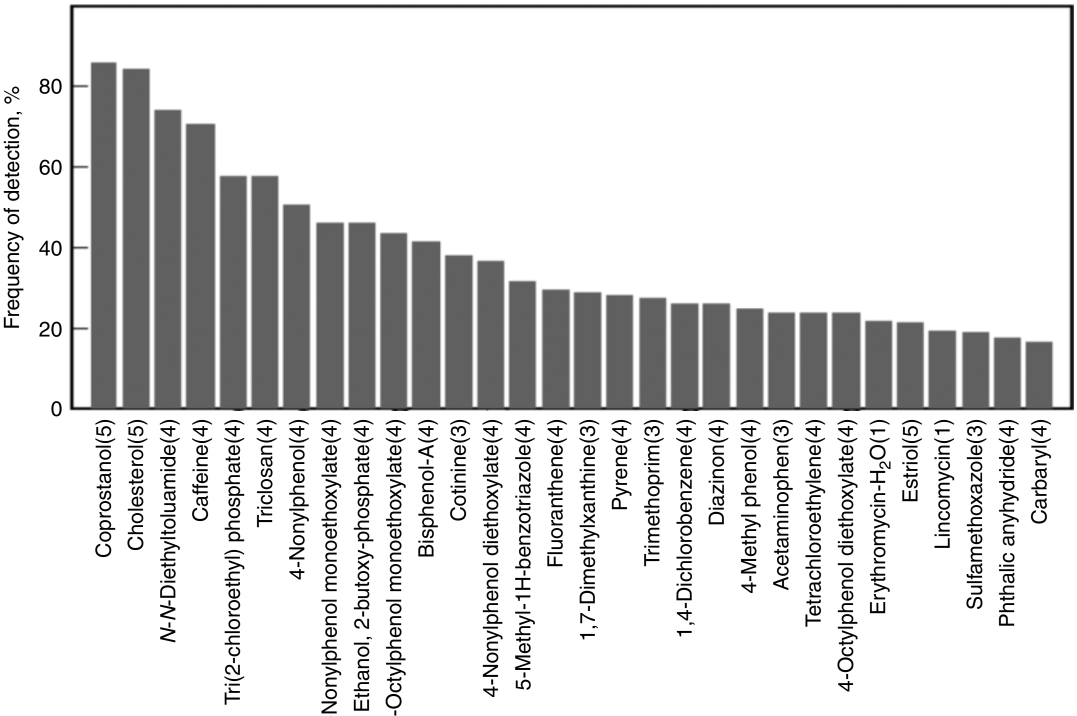

Figure 2. Most frequently detected compounds. The analytical method number is provided (in parentheses) at the end of each compound name (1).

use, drugs typically found in the medicine cabinet, and disposed of as is or as processed human waste in toilets and sinks. Some commonly detected constituents include caffeine in 70.6% of the samples at a maximum concentration of 5.7 μg/L, insect repellent *N*, *N*-diethyltoluamide in 74.1% of the samples at a maximum concentration of 1.1 μg/L, plant/animal steroid cholesterol in 84.3% of the samples at a maximum concentration of 60 μg/L, and fecal steroid coprostanol in 85.7% of the samples at a maximum concentration of 150 μg/L. The USGS study shows that many of the chemicals used in modern life survive human waste processing, current wastewater treatment plant processing, as well as biodegradation in the natural environment, and are detected as contaminants in potential water supplies.

A long list of contaminants have been documented in surface waters throughout the country partly due to the low laboratory detection levels. Considering the interconnection of surface water and groundwater, and the ability of these contaminants to move in the subsurface environment, our shallow groundwater resources are vulnerable to and likely impacted by contamination from these surface water sources. In California, the Ambient Groundwater Monitoring and Assessment Program (GAMA) implemented by the State Water Resources Control Board (SWRCB) is a program to assess the water quality and relative susceptibility of groundwater resources to contamination throughout the state. This assessment of relative contamination vulnerability is made based on the results of two types of analyses that are not routinely carried out at public water supply wells: ultra low-level measurement (part per trillion) of volatile organic compounds (VOCs), and groundwater age dating (using the tritium-helium-3 method). In addition, stable isotopes of oxygen are measured to help determine recharge water source location. Interpreted together with existing water quality and hydrogeologic data, these parameters assist in assessing the flow field of a groundwater basin, and indicate the degree of interconnection between near-surface sources (or potential sources) of contamination, and deeper groundwater pumped at high capacity production wells.

In GAMA studies that were conducted by the USGS and Lawrence Livermore National Laboratory under contract to SWRCB, the two most frequently detected volatile organic compounds were disinfection by products (trihalomethanes) dominantly chloroform, and methyl *tert* butyl ether (MtBE), which were found more frequently and at higher concentration in samples from rivers than in samples from nearby shallow public supply wells, suggesting the rivers may be the source of the groundwater occurrences (4,5). Additionally, chloroform was found associated with wellhead disinfection systems and may be present due to back-flushing of treated water (6). In one study of the Los Angeles Basin area, it was determined that the overall distribution of low level VOCs in groundwater was related to the hydrological and engineered recharge facilities (4). In a study of the Sacramento area, the frequent detection of one VOC (Perchloroethylene PCE) was believed to be due to mobilization of numerous point sources from spills or leaks at dry cleaners or other businesses, or possibly, from leaky sewer lines that hold small amounts of PCE (5).

Although these common chemicals are detected in very low or trace amounts, the possible cumulative or synergistic effects of these chemicals on plants, animals, and humans is currently unknown. Additional data from the USGS is forthcoming. There are no potential adverse health effects of these chemicals at such low documented concentrations.

If treatment or remediation is deemed appropriate, advanced oxidation, enhanced bioremediation, or improved water polishing/filtering could be added to existing wastewater treatment plants to reduce contaminants of these types from entering the environment. More limited pretreatment for septic systems could also help to reduce these chemicals in the environment. For individual water users, small point-of-use treatment systems could be used to remove trace amounts of contaminants (3).

This is a chemical society: Chemicals are widely used on a daily basis at a personal level in the household (personal care products, gasoline, solvents, pesticides, etc), and for a better quality of life in industry and agriculture (wide variety of chemicals). Anthropogenic impacts on the environment, which were largely uncontrolled until the last thirty years, are still unavoidable even with the current best standards of practice. Further, society is still continuing to understand the environmental impacts of past chemical handling and disposal practices as laboratory and investigative analytical tools improve. With population increasing at the current rate, projections are for increased demands on water supply, increased stress of the existing water supply and hydrologic systems, and shortages in dry years, unless steps are taken to increase water supplies and reliability through strategies including water conservation, recycling, desalination, conjunctive use, and artificial recharge. No doubt there will continue to be more “new” chemicals found to be present in our hydrologic system in the future that we did not know about before, but may have been present for some time. This will require planned adaptive management approaches and practices to assess the potential affects on humans and ecosystems, to develop alternative management strategies and remediation if appropriate, and to have on-going educational programs beginning at the elementary school level to edify society as to the information and risks so that society can make informed decisions as to how these challenges should be managed in the future.

DARCY'S LAW

Joseph Holden
University of Leeds
Leeds, United Kingdom

Darcy's law is a mathematical relationship originally determined by Henry Darcy in 1856 that permits quantification of fluid flow through porous media. Many sophisticated theoretical and practical derivations have been based on Darcy's law (1), and it has become the foundation for quantitative groundwater flow science and soil physics (2). In its most useful form, the formula can be used to calculate the amount of water (or other fluid) flowing through a given cross-sectional area of a porous substance and equates volumetric discharge per unit time (q) to the product of area (A), hydraulic gradient (I = change in head per unit length) and a coefficient (K = saturated hydraulic conductivity). In its simplest terms, the relationship may be expressed as $q = KIA$.

Figure 1 provides a schematic diagram for establishing the relationship in a laboratory soil column test for one-dimensional flow. Note that $\Delta h/L = I$. For a given porous media in a tube of cross-sectional area A, the hydraulic conductivity, K, can be determined as the only unknown in the equation. By changing the hydraulic head, it is also possible to confirm that the relationship between head and discharge is linear for most materials. It should also be possible to determine the head or discharge conditions for which the relationship deviates from the linear form and therefore the threshold beyond which Darcy's law is no longer applicable.

Since it was determined, Darcy's law has been found valid for any Newtonian fluid. It is important to note, however, that the relationship holds only for laminar (nonturbulent) flow of fluids in homogeneous porous media and that it was established under saturated flow conditions for one-dimensional flow. The Darcy equation is strictly applicable only when the cross section being considered is much greater than the dimensions of its microstructure, so that it can reasonably be regarded as uniform. Most groundwater movement takes place in small interstices, so that an aquifer provides considerable resistance to water movement, allowing laminar flow.

The determination of laminar flow depends upon the magnitude of the Reynold's number, a dimensionless ratio of inertial forces to viscous forces. At low Reynold's numbers, viscous forces dominate, and Darcy's law is valid. There follows a transition zone in which inertial forces become more important; Darcy's law cannot be accurately applied to the nonlinear laminar flow in this zone (3). Flow in the turbulent zone is both nonlinear and nonlaminar, and deviations from Darcy's Law can become very large. In many aquifer materials, however, the assumption of laminar water flow may not cause any inaccuracies.

Flow analysis predictions based upon Darcy's law in the presence of massively fissured rocks such as karstic limestones or highly fractured crystalline rocks can lead to large errors. Flow in such cases cannot be described adequately by a linear relationship such as Darcy's law, and a more detailed analysis is required. In very large interstices such as those found in many limestone and volcanic areas, groundwater flow is almost identical to the turbulent flow of surface water (1). Others have claimed that in clays that have very small pores and low hydraulic conductivities the very low flow rates are less than proportional to the hydraulic gradient (4,5). A possible explanation is that much of the water in such material is strongly held by absorptive forces and may be more rigid and less mobile than ordinary water (6). Similar processes may explain the large store of water held in peat soils that have very low hydraulic conductivities (7,8).

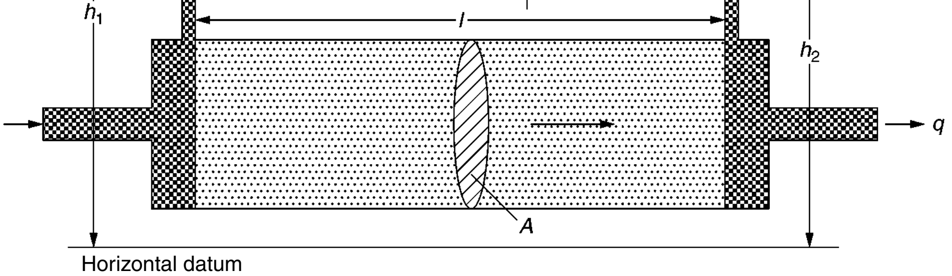

Figure 1. Schematic diagram of a soil column test for establishing components of Darcy's law.

As Hofmann and Hofmann (3) discuss, Darcy himself was careful not attribute too much to the specific magnitudes of individual data readings. Rather, he emphasized two aspects that his data supported, the proportionality of flow rate to total hydraulic head and the inverse proportionality of flow rate to column length (9). The limited experimental accuracy and scope were recognized by Darcy and have remained apparent to hydrologists ever since. By itself, Darcy's law suffices to describe only steady flow conditions, so that for most field applications it must be combined with mass conservation (or the continuity law) to obtain the general flow equation or, for saturated conditions, the Laplace equation. A direct solution of the latter for groundwater flow is generally not possible, and hence there is a need for various approximations or indirect methods of analysis. An important extension of Darcy's law to groundwater flow is its application in three-dimensions; see Childs (10) and Shaw (11) for more detail.

Fundamental to the application of Darcy's law is knowledge of the hydraulic conductivity of the saturated medium. The factors affecting hydraulic conductivity include those associated with the fluid and those associated with the aquifer, including temperature, salinity, pore space geometry, and soil or rock surface roughness (1). Hydraulic conductivity is often measured on a variety of scales ranging from a laboratory soil column, as shown in Fig. 1, to field-scale borehole tests and timed movement of tracers. As the scale of approach increases, often the estimation of hydraulic conductivity increases because of the incorporation of ever larger and more extensive fracture systems. A practical difficulty is that virtually any matrix considered, even on the laboratory scale, will be heterogeneous to some extent. Such heterogeneities do not theoretically prohibit the use of Darcy's law, but they lend uncertainty to generalizations on a large scale. It is for this reason that statistical models employing probabilistic parameter distributions are sometimes used to model the spatial variability of hydraulic conductivity (3).

However, particular problems emerge in assessing spatial variability in hydraulic conductivity and applying Darcy's law to groundwater flow when media are anisotropic, which is the case for highly layered soils such as peats where hydraulic conductivity may differ in the vertical direction by several orders of magnitude across just a few centimeters (8). Furthermore, full saturation of soils may be prevented by gases occupying pore spaces after entrapment upon rapid infiltration or gas production as a result of biogenic decomposition. This can lead to a reduction of hydraulic conductivity (12). Many wetland soils are compressible and so the field worker must be careful not to misapply rigid soil theories to these soils. Instead, compressible soil calculations have been developed but are not yet widely applied (8,13,14).

Despite concern about its strict validity, Darcy's law constitutes an adequate description of groundwater flow and fluid flow through porous media. It can be successfully applied to virtually all normal cases of groundwater flow and is equally applicable to confined and unconfined conditions (1).

GROUNDWATER DATING WITH RADIOCARBON

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

Groundwater age, based on measurement of the concentrations of chemical and isotopic substances in water, refers to the time elapsed since the introduction of the chemical or isotopic substance into the water, or to be more precise, the time elapsed since the chemical or isotopic substance was recharged and isolated from the modern reservoir. Although we often refer to dating of groundwater, we are actually dating a chemical substance that is dissolved in the groundwater, not the water itself. Unless we recognize and account for all the physical and chemical processes that affect the concentrations of tracers in an aquifer, the tracer-based age is not necessarily equal to the transit time of the water carrying the substance. Rather than referring to groundwater dating, it would probably be more correct to say we are interpreting temporal aspects of chemical and isotopic substances in groundwater.

For many applications in hydrology, we are interested in the travel time of water through an aquifer. The accuracy of the age determined depends in part on how perfectly the chemical and isotopic substances we are using as dating tools are transported in the aqueous phase. The concentrations of all tracers are, to some degree, affected by transport processes, and in the case of some tracers, such as chlorofluorocarbons, their concentrations can also be affected by chemical processes such as degradation and sorption during transit.

Various environmental isotopes and tracers are used to determine the age of groundwater. Carbon-14 is used to date ground waters older than 1000 years. Chloroflurocarbons (Freon) and tritium techniques are used to date groundwater that is less than 50 years old (Table 1).

The residence time of water underground has always been a topic of considerable speculation. But with the advent of radioisotopes, determination of the age of groundwater has become possible (1).

Carbon-14 (^{14}C), commonly referred to as radiocarbon, is continuously being produced in the atmosphere. This results from cosmic ray bombardment of nitrogen nuclei. Atmospheric testing of thermonuclear weapons doubled the ^{14}C concentration in the atmosphere. Carbon-14 is expressed in terms of percent of modern carbon (pmC). ^{14}C is useful when dating groundwaters that are between 1000 and 30,000 years old.

This isotope is present in groundwater as dissolved bicarbonate originating from the biologically active layers of the soil where CO_2 is generated by root respiration and the decay of humus (2).

Table 1. List of Environmental Tracers and Isotopes Used for Age Determination

Environmental Isotope/Tracer	Age Range, Years
Chloroflurocarbons (CFC-11, CFC-12, and CFC-113)	0 to 50
Tritium	0 to 50
Tritium/Helium-3	0 to 30
Carbon-14	1000 to 30,000

^{14}C

The ^{14}C generated in the atmosphere is carried down to the earth's surface by precipitation and becomes incorporated into the biomass or transported into waterbodies such as lakes, oceans, and groundwater. ^{14}C undergoes radioactive decay (to ^{14}N), so that once isolated from the atmosphere, the amount of ^{14}C decreases with time according to the equation

$$(^{14}\mathrm{C})_t = (^{14}\mathrm{C})_o e^{-kt}$$

where $(^{14}\mathrm{C})_t$ is the amount present at time t, $(^{14}\mathrm{C})_o$ is the amount present at $t = 0$, and k is the decay constant, which is related to the half-life $t_{1/2}$ by the equation

$$t_{1/2} = \ln 2/k$$

To determine the time since water lost contact with the atmosphere, it is necessary to know $(^{14}\mathrm{C})_o$. This is determined by tree rings for the most recent 7000 years; there is no accurate way to determine it prior to 7000 years ago, so it is generally assumed arbitrarily to have been constant. This gives rise to a timescale in "^{14}C years," which may be different from astronomical years (3).

There are some complications in the behavior of ^{14}C during recharge, so that the "absolute" age of a groundwater cannot be determined reliably. However, if the ^{14}C concentration is measured at several points along a flow line within an aquifer, the differences in age between the points and hence the flow velocity can be determined. One complication is that dissolution of carbonate minerals or oxidation of organic matter within the aquifer may add "old" or "dead" (no detectable ^{14}C) carbon to the water and give an erroneously old age. The contribution of carbon from these sources can sometimes be estimated from ^{13}C/^{12}C measurements and chemical arguments (4), so that corrections can be made. Another complication is mixing. A low ^{14}C concentration may mean that we are looking at relatively "old" water, or it may mean that we are looking at a mixture of relatively "young" water and "dead" water. ^{14}C measurements can be interpreted as ages only when mixing is insignificant.

Measurements of water samples taken from deep wells in deserts of the United Arab Republic and Saudi Arabia indicate ages of 20,000 to 30,000 years (5). This period is compatible with the Wisconsin Ice Age, when these desert areas last had high rainfall capable of recharging the underlying major aquifers.

GROUNDWATER DATING WITH H–HE

Craig E. Divine
John D. Humphrey
Colorado School of Mines
Golden, Colorado

PRODUCTION AND DECAY BEHAVIOR OF ATMOSPHERIC TRITIUM

Tritium (^{3}H) is a relatively short-lived radioactive isotope of hydrogen that is produced naturally in the atmosphere and enters the hydrologic cycle through meteoric precipitation. Natural atmospheric ^{3}H results from the interaction of nitrogen-14 (^{14}N) and cosmic-ray neutrons (n) by

$$^{14}\mathrm{N} + n \longrightarrow {}^3\mathrm{H} + {}^{12}\mathrm{C} \tag{1}$$

Tritium is then rapidly incorporated into water molecules. Tritium decays to helium-3 (^{3}He) by beta decay:

$$^3\mathrm{H} \longrightarrow {}^3\ \mathrm{He} + \beta^- \tag{2}$$

Tritium concentrations in water are typically reported as "tritium units" (TU), where 1 TU is equivalent to one ^{3}H atom per 10^{18} hydrogen atoms and 0.118 Bq kg^{-1} (1 Bq = 1 disintegration per second). Decay of 1 TU yields approximately 0.402 pcm^3 kg^{-1} of ^{3}He. The natural atmospheric production rate of ^{3}H is approximately 0.5 ± 0.3 atoms of ^{3}H cm^{-2} s^{-1} (1). The background ^{3}H concentration in meteoric precipitation before 1951 is estimated in the range between 0.5 and 20 TU, and most measurements are less than 10 TU (2) and (3, Fig. 7.2). The rate of ^{3}H decay and ^{3}He production follow these first-order rate laws:

$$^3\mathrm{H}_\mathrm{t} = {}^3\mathrm{H}_0 e^{-\lambda t} \tag{3a}$$

$$^3\mathrm{He}_\mathrm{t} = {}^3\mathrm{H}_0 e^{\lambda t} \tag{3b}$$

where $^3\mathrm{H}_\mathrm{t}$ and $^3\mathrm{He}_\mathrm{t}$ are the number of tritium and helium-3 atoms at time t, $^3\mathrm{H}_0$ is the initial number of tritium atoms, and λ is the tritium decay constant (0.05626 yr^{-1}). The tritium "half-life" ($t_{1/2}$), or time it takes for half of the starting tritium to decay to ^{3}He, is best estimated at 12.32 yr (4500 ± 8 day) (4). Figure 1 graphically shows the decay and generation behavior of ^{3}H and ^{3}He through time. The half-life is related to the decay constant by

$$\lambda = \frac{\ln 2}{t_{1/2}} \tag{4}$$

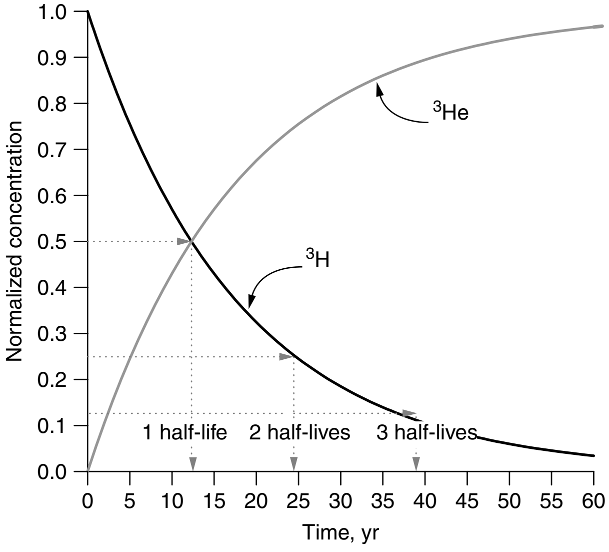

Figure 1. Tritium (^{3}H) decay and ^{3}He production through time. Values are normalized to the initial ^{3}H concentration ($^3\mathrm{H}_0$).

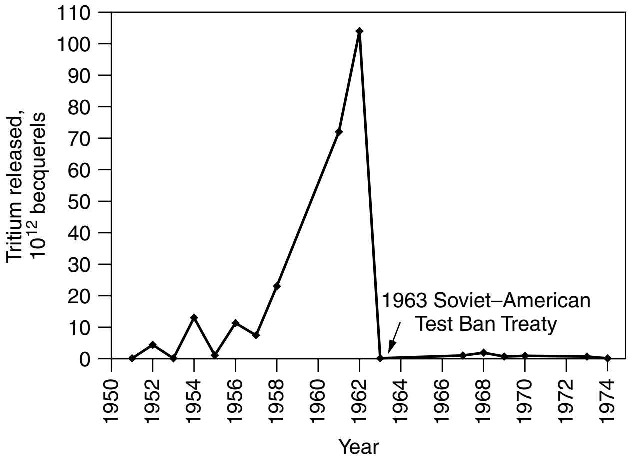

Figure 2. Anthropogenic ^{3}H released from atmospheric detonation of thermonuclear weapons testing (developed from data summarized by Reference 3).

During 1951, it was demonstrated that significant energy is released during hydrogen fusion to provide the basis for developing thermonuclear superbombs. Atmospheric testing (detonation) of these weapons during the next decade resulted in a dramatic increase in atmospheric ^{3}H concentration, until implementation of a Soviet–American atmospheric test ban treaty in 1963 (Fig. 2). Atmospheric thermonuclear weapons testing released vast quantities of high-energy neutrons that interacted with ^{14}N and led to the production of ^{3}H (Eq. 1). The incredible amount of ^{3}H produced in the atmosphere resulted in a distinct precipitation input signal of anthropogenic ^{3}H (Fig. 3), and a notable peak in 1963.

PRINCIPLES OF THE ^{3}H–^{3}HE DATING METHOD

The mid-1960s ^{3}H peak has been widely used as a direct time marker to determine groundwater ages. However, because of the relatively short half-life of ^{3}H, this peak has become difficult to differentiate in many systems. This is particularly true in the Southern Hemisphere where the anthropogenic ^{3}H in precipitation was notably lower than in the Northern Hemisphere. However, measurement of both parent ^{3}H and increases in its decay product, ^{3}He, can dramatically increase the sensitivity of the method. The "in-grown" ^{3}He (or ^{3}He produced by ^{3}H decay) can be equated to the initial $^3\mathrm{H}_0$ and $^3\mathrm{H}_\mathrm{t}$ by

$$^3\mathrm{He}_\mathrm{t} = {}^3\mathrm{H}_0(1 - e^{-\lambda t}) = {}^3\mathrm{H}_\mathrm{t}(e^{\lambda t} - 1) \tag{5}$$

Assuming that other ^{3}He sources are insignificant or can be accounted for and that there have been no systematic losses of tritiogenic ^{3}He, the relationships in Equation 5 can be rearranged, and the apparent age of the water (τ) can then be calculated from (Fig. 4)

$$\tau = \frac{t_{1/2}}{\ln 2} \ln\left(1 + \frac{^3\mathrm{He}_\mathrm{t}}{^3\mathrm{H}_\mathrm{t}}\right) \tag{6}$$

The ^{3}H–^{3}He method offers two significant advantages: (a) the method does not rely on accurate knowledge of the

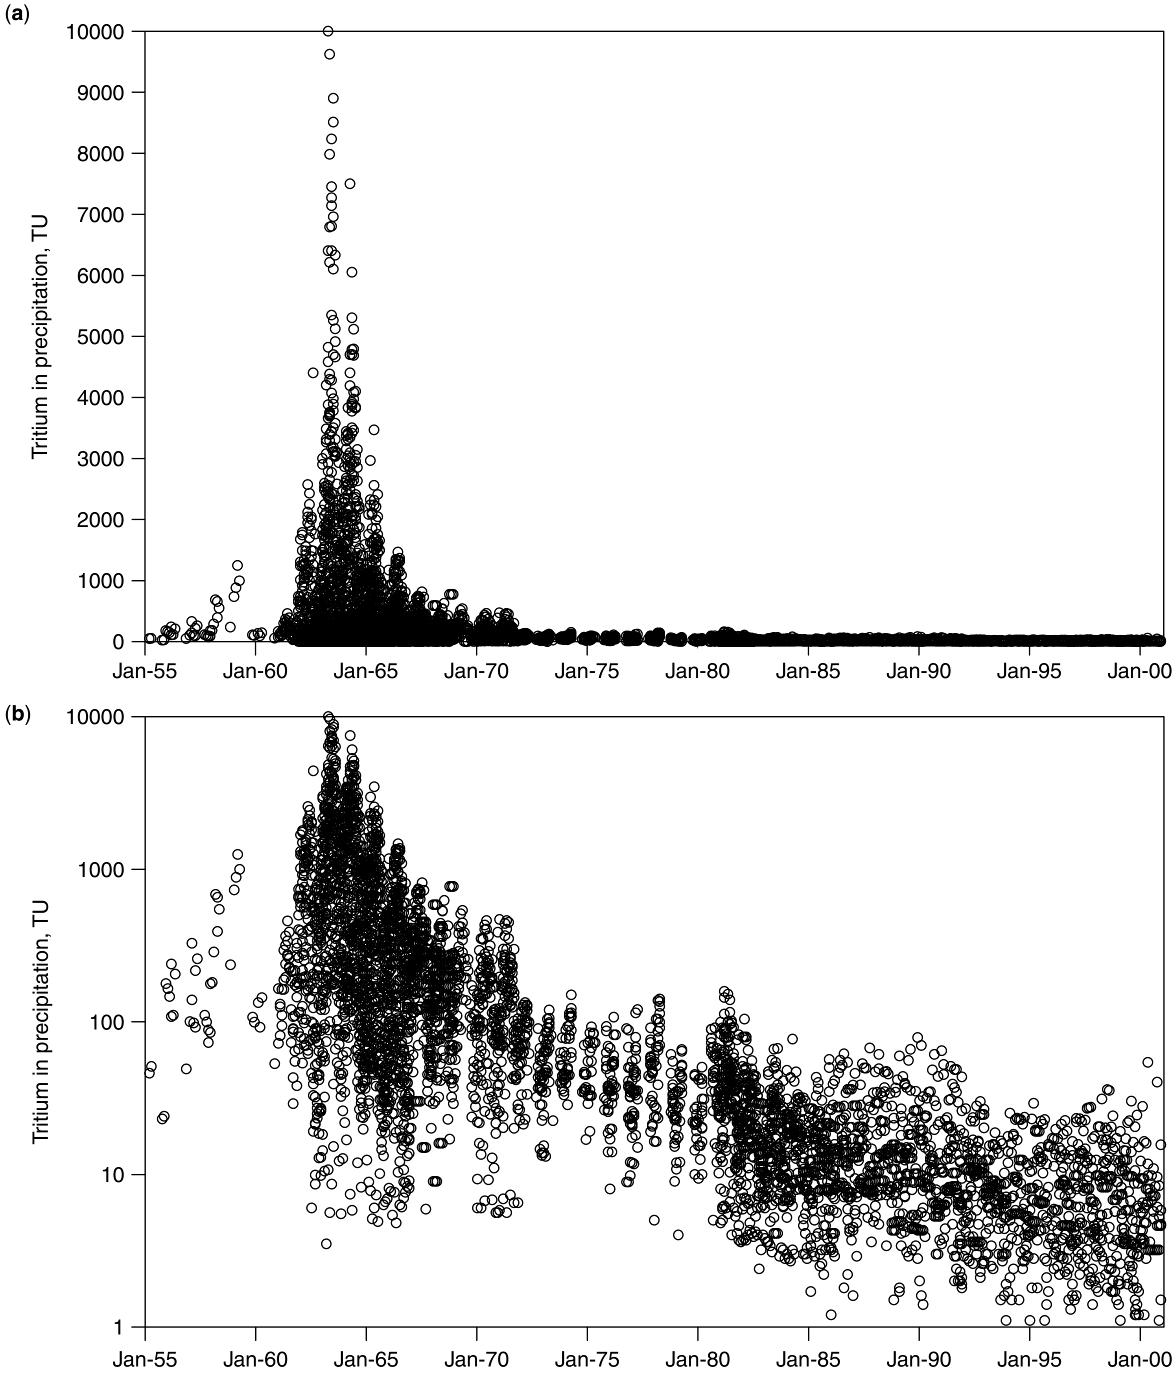

Figure 3. Tritium in precipitation (reported in tritium units, TU) measured at more than 50 locations in North America between 1955 and 2001 (top: arithmetic scale, bottom: logarithmic scale) (data obtained from Reference 5).

original ^{3}H input or identification of the mid-1960s peak, and (b) the method is generally less sensitive to analytical measurement errors (2).

The “clock” for the ^{3}H–^{3}He method begins at the seasonal water table low, where ^{3}He produced is no longer lost to the atmosphere and begins to accumulate in the groundwater. If the unsaturated zone is thick, the apparent ^{3}H–^{3}He age at the “bomb peak” signal may be significantly less than the actual time since the peak ^{3}H fallout. The difference in apparent ages can be used to estimate the travel time through the unsaturated zone. For example, Solomon et al. (6) determined an apparent ^{3}H–^{3}He age of 16 years for groundwater samples near the ^{3}H peak signal in a study at Cape Cod, Massachusetts. However, the samples were collected 30 years after the actual peak ^{3}H fallout in 1963. The difference in these age values resulted in an unsaturated zone travel time estimate of 14 years.

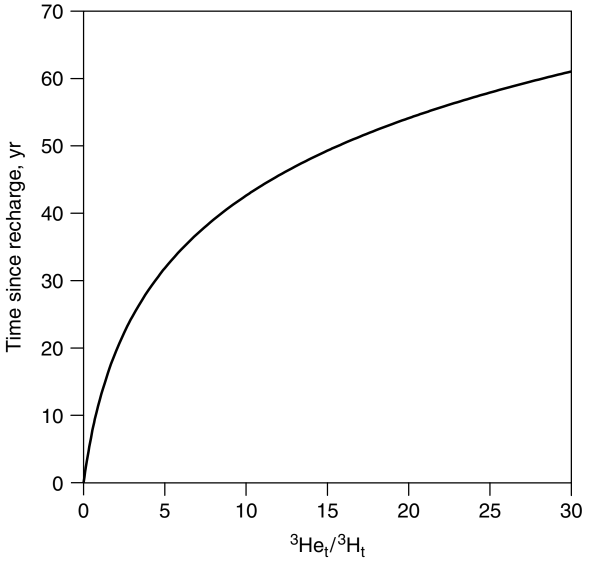

Figure 4. Calculated time since recharge from measured $^3He_t/^3H_t$ ratio (Eq. 6).

There are additional sources of ^{3}He in groundwater, and the measured ^{3}He value must be corrected for these sources before applying Eq. 6. Tritium-generated ^{3}He ($^3He_{trit}$) is determined from total measured tritium ($^3He_{total}$) by

$$^3He_{trit} = {}^3He_{total} - {}^3He_{atm} - {}^3He_{excess} - {}^3He_{crust} - {}^3He_{mantle} \quad (7)$$

where $^3He_{atm}$ is the ^{3}He concentration in solubility equilibrium with the atmosphere, $^3He_{excess}$ is the ^{3}He resulting from excess air, $^3He_{crust}$ is the ^{3}He produced in the crust, and $^3He_{mantle}$ is the ^{3}He produced in the mantle (also called primordial ^{3}He). Atmospheric ^{3}He dissolving in groundwater at the time of recharge is typically the most significant process resulting in excess ^{3}He. This process can be accounted for by considering the following (3):

- The atmospheric ^{4}He concentration is 5.24 parts per million (by volume), and the atmospheric $^3He/^4He$ ratio is 1.3×10^{-6}.
- The temperature-dependent aqueous solubility of helium (at 10 °C, the value is 4.75×10^{-8} cm^3 STP/cm^3 H_2O).
- ^{4}He is more soluble than ^{3}He in water and has a fractionation factor ($\alpha_{water-air}$) of 0.983.

Although the $^3H-^3He$ method is fairly insensitive to recharge temperatures, it is very sensitive to excess air, particularly for young groundwater (7). In some systems, ^{3}He from excess trapped air caused by a transient wetting front may be significant and can be identified by supersaturation of other gases, such as Ne and N_2. For most systems, subsurface generated ^{3}He ($^3He_{crust}$ and $^3He_{mantle}$) is insignificant; however, correction methods for these cases are discussed by Schlosser (8,9), Solomon et al. (2), and Cook and Solomon (7). Other potential errors in the $^3H-^3He$ method may be caused by diffusive loss and dispersion/mixing effects. ^{3}He diffusive loss to the atmosphere was greatest during the mid-1960 peak (due to the high concentration gradient), so this method may incorrectly calculate younger ages for groundwater below the mid-1960 peak (2). Because helium has a relatively high Henry's law constant (105.2 [dimensionless] at 25 °C) (10), care must be taken during sampling to prevent ^{3}He loss due to gas stripping.

ANALYTICAL MEASUREMENT METHODS

Tritium is typically measured by either low-level disintegration counting or by the more sensitive ^{3}He in growth method using mass spectrometry. Depending on the specific instruments and analytical procedures, ^{3}H detection limits of ~0.05–0.8 TU and analytical precision of ±2.5–5% can be achieved (9). For ^{3}He measurement, water samples are commonly collected in pinched-off copper tubes or gas-filled diffusion samplers. The helium is then isolated from all other dissolved gases and analyzed by a helium isotope mass spectrometer to resolve the $^3He/^4He$ isotopic ratio. Achievable measurement precision for the $^3He/^4He$ ratio is approximately 0.2% (9). Although approximately 40 years have passed since the mid-1960 ^{3}H "bomb peak," these analytical capabilities should permit identifying the peak signal in favorable hydrogeologic settings for several more decades (8). In most cases, analytical uncertainties result in calculated age uncertainties of less than approximately 10% (7).

CASE STUDY: COMPARISON OF THE $^3H-^3HE$ METHOD TO THE CFC AND ^{85}KR DATING METHODS

Ekwurzel et al. (11) compared calculated groundwater ages for three different dating methods, including the $^3H-^3He$ method, in a study on the Delmarva Peninsula (approximately 15,690 km^2) located on the east coast of the United States. The Delmarva Peninsula is characterized by low topographical relief and little urban development. The hydrogeology of the area is relatively simple, consisting of low hydraulic gradients, highly permeable surficial materials, and shallow water tables. Discrete groundwater samples were collected from approximately 30 wells throughout the Delmarva Peninsula (most wells were screened across less than 1 m of the aquifer). Additionally, age dating methods were compared for a single flow system on the peninsula at Locust Grove.

Most age values calculated from the three methods agreed within approximately 2 years, indicating conservative behavior of the various tracers and reliability of the dating methods. A few wells that produced large apparent age discrepancies were located in areas of significant mixing. Dissolved N_2 concentrations from several wells with large tracer age variations (>10 years) indicated that gas stripping may have occurred in these samples. A one-dimensional advection–dispersion model, applied to estimate the effect of dispersion on the age correlation, determined that hydrodynamic dispersion effects were negligible. As stated earlier, fairly close agreement was observed among the different dating methods for this study; however, the locations that produced significantly different tracer ages demonstrate that use of multiple methods for groundwater age dating is important because tracers are affected differently by diffusion, dispersion, sorption, degradation, gas entrapment, excess air, recharge temperature, and sampling errors. For additional case studies on the $^3H-^3He$ groundwater dating method, see Schlosser (9), Solomon et al. (6), Cook et al. (12), Cook and Solomon (7), and Vengosh et al. (13).

DATING GROUNDWATERS WITH TRITIUM

STEPHEN M. TESTA
Mokelumne Hill, California

INTRODUCTION

Tritium (^3H) is one of the most common radioisotopes used to identify the presence of modern groundwater recharge and estimate apparent groundwater ages (1). Tritium, a short-lived radioactive isotope of the element hydrogen, has one proton and two neutrons. Tritium emits only a very weak beta particle and has a half-life of 12.43 years. Although tritium can occur as a gas, its most common form is in water because, like nonradioactive hydrogen, radioactive tritium readily reacts with oxygen to form water, which allows groundwater to be dated. As tritium replaces one of the stable hydrogens in the water molecule, (H_2), it is referred to as the molecule HTO, or tritiated water (T_20). Similarly to water, tritium is colorless and odorless.

Tritium is produced naturally in both the atmosphere and hydrosphere of the earth when cosmic rays strike air molecules, notably by the interaction of ^{14}N with cosmic ray neutrons in accordance with the following reactions:

$$^{14}_{7}N + ^{1}_{0}n \rightarrow ^{3}_{1}H + ^{12}_{6}C$$

and

$$^2H + ^2H \rightarrow ^3H + ^1H$$

Cosmic rays interact with nitrogen (^{14}N) or with deuterium (^2H) and form tritium and carbon (^{12}C). The primary interactions occur within the upper atmosphere, and tritium falls to earth via meteoric precipitation. Atmospheric tritium is thus rapidly incorporated into water molecules allowing it to be removed from the atmosphere as rain.

The concentration of tritium in meteoric water is measured in "tritium units" (TU), where 1 TU is equal to an abundance of one atom of ^3H per 10^{18} atoms of hydrogen. This is equivalent to 7.1 disintegrations of ^3H per minute per liter of water.

ANTHROPOGENIC TRITIUM

The occurrence of tritium in the environment has been significantly changed over the years by anthropogenic influences. Tritium has several important uses; the most significant is its use as a component in the triggering mechanism in thermonuclear (fusion) weapons; very large quantities are required to maintain nuclear weapons capabilities. On May 9, 1951, the world's first thermonuclear flame reaction was ignited in a laboratory by a ^2H-^3H-^{235}U device code-named George. Following the birth of this concept, atmospheric detonation of these devices resulted in anthropogenic production of ^3H which raised concentrations in the stratosphere by several orders of magnitude. The proliferation of atmosphere testing continued throughout the mid-1950s, early 1960s, and into the 1970s. Tritium is also produced in accelerator cooling water systems or reactors, which are subjected to large proton or neutron fluxes via spallation reactions with oxygen, nitrogen, and carbon nuclei in the water systems and to a much smaller degree by radiative capture of neutrons by the deuterium nuclei in water. The tritium atom then combines with a hydrogen and oxygen atom to form tritiated water. Anthropogenic tritium has thus been formed by nuclear weapon explosions in the

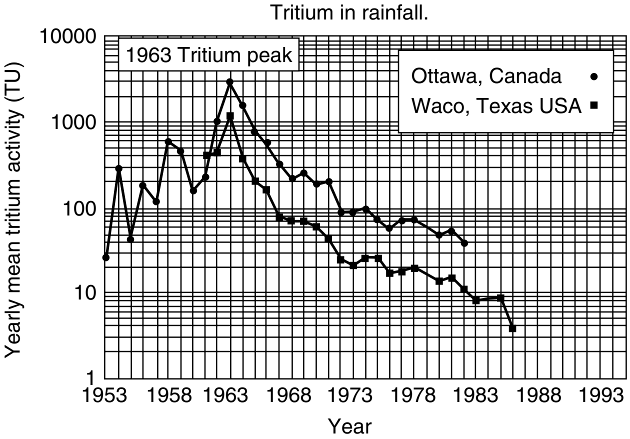

Figure 1. Tritium chart for Ottawa, Canada, and Waco, Texas, (2).

atmosphere and the operation of nuclear reactors and particle acceleration.

The longest record of atmospheric tritium measurements was initiated for precipitation in Ottawa, Canada, beginning in 1953. Atmospheric testing of nuclear devices commenced in 1952. After 1953–1954, the amount of tritium increased and reached a maximum in 1963–1964. Concentrations of ^{3}H in precipitation have decreased since the mid-1960 bomb peak, except for some small secondary peaks by China and France in 1973 and 1975. Tritium input to groundwater has subsequently occurred in a series of spikes following these periods of atmospheric testing (Fig. 1). The majority of tritium produced between the early 1950s through mid-1970s in the atmosphere has since been removed.

Other uses include various self-luminescent devices such as aircraft dials, gun sights, luminous paints, exit signs, and watches. Tritium is also used in life science research and in studies investigating the safety of new drugs.

DATING GROUNDWATER USING TRITIUM

The presence of tritium in the atmosphere from weapons testing has proved useful from several perspectives. The residual presence of nuclear-produced tritium has served as a tracer for atmospheric studies and the study of hydrologic and oceanographic processes. Tritium is considered a dating element for groundwater. By knowing the tritium concentration in precipitation and its distribution in groundwater, an apparent date for the age of the groundwater can be determined, which also allows evaluating aquifer water average transit time (T). This parameter is important because it can be used to address issues about evaluating, exploiting, and protecting water resources.

Dating groundwater can be used in ecologically sensitive coastal settings to understand the hydrogeologic setting and determine whether water is derived from surficial and/or subsurface groundwater. Oceanographers used the sharp spike in surface tritium levels over the years to measure the rate at which lower and upper ocean levels mixed. Tritium is a good marker for tracking ocean water.

Several factors affect tritium concentration in meteoric water. In the lower stratosphere, the residence time for tritium in water is between 1 and 10 years. When tritium water reaches the lower troposphere, residence time is 5 to 20 days (3). It is known that tritium concentration as meteoric precipitation in the Northern Hemisphere has fluctuated widely from less than 25 TU, prior to 1953, to more than 2200 TU in 1964 following extensive testing in the atmosphere (3). In the Southern Hemisphere, the level of bomb-produced tritium is much lower. Other factors to consider include

1. the natural production rate in the stratosphere which is estimated at 0.5 ± 0.3 atoms of ^{3}H/cm^2/s (4);
2. the decay of tritium by beta emission to stable $^{3/2}$He with a half-life of 12.26 y;
3. the seasonal injection of tritium from the stratosphere into the troposphere;
4. the presence of bomb-produced tritium; and
5. the presence of tritium produced locally by nuclear reactors and particle accelerators.

METHODOLOGY

Groundwater is dated by retrieving water samples from surface water bodies, ice or precipitation, or wells in the case of groundwater. By observing the spike in tritium levels, likely the result of atmospheric bomb testing, an age can be estimated. For example, if the spike in groundwater is determined to be 20 miles from its recharge or source area, then it could be deduced that the spike has moved 20 miles during the past 40 years, or an average rate of 0.5 miles per year.

Apparent groundwater age can be estimated directly from tritium precipitation records corrected for first-order decay. Groundwater is age dated by determining the early and late ratio of tritium in accordance with the following equation:

$$^{3}\mathrm{H}_{\text{early sample}} \times e^{\lambda\Delta t}/^{3}\mathrm{H}_{\text{later sample}}$$

where $\lambda = 0.0565\ \mathrm{yr}^{-t}$ (tritium decay constant)
$\Delta t =$ the time between samples in years

A ratio greater than 1 indicates that the tritium peak has passed, or in other words, the water is older 1963. Conversely, a ratio less than 1 indicates that the peak has not yet arrived, or the water is younger than 1963.

Some amount of hydrodynamic dispersion, however, is likely to occur, which explains why natural tritium levels in precipitation are very low and reflect a secular equilibrium between natural production and the combination of decay in the atmosphere in addition to losses in the hydrosphere and ocean. Advective dispersion and diffusion are typically addressed using a mixing model that more accurately estimates groundwater ages by accounting for attenuation of tritium levels due to these processes (5). Mixing models approximate dispersion and diffusion processes by assuming a Gaussian distribution of tritium activities.

Three kinds of models are commonly used:

1. the well-mixed or exponential model which assumes that water introduced into a system is completely and uniformly mixed with aquifer water. Thus, the water output from the system is actually representative of the aquifer waters.
2. the piston-flow model which assumes that the incoming water traverses the aquifer at constant velocity.
3. the dispersion model which assumes a dispersion phenomenon reflecting the heterogeneity of the aquifer material.

Different age waters can be distinguished. For example, tritium contents less than 2 TU typically characterize old groundwater, 2 to 10 TU may characterize mixing between old and recent water, 10 to 40 TU may characterize recent groundwater, and greater than 40 TU may characterize groundwater in close proximity to a nuclear station.

The main application of tritium is to differentiate pre-1952 water from younger water. Knowing the concentration of tritium in precipitation (the source) and its distribution in groundwater, an apparent date can be estimated.

The use of tritium to study the movement of water in the subsurface, evaluating source areas, and dating the last time subsurface water was last exposed to the atmosphere is hindered by several factors. The most important limitations are the continuing decay of nuclear-produced tritium, its unequal global distribution, and the local injection of anthropogenic tritium. For example, a tritium concentration of 30 TU may reflect late 1950s water that has decayed through three half-lives, or a 1970s water originally with 75 TU that has decayed through one half-life (6).

In many scenarios, locating the position of the mid-1960 peak is difficult due to the relatively high density of vertical sampling required, which can be expensive and impractical. Furthermore, although tritium can be used to locate the depth of the mid-1960s peak, many samples are required due to radioactive decay to locate its position. Furthermore, in waters younger than the mid-1960s, the bomb peak is not present.

DATING YOUNG GROUNDWATER USING TRITIUM/HELIUM RATIOS

Tritium is not useful for the dating relatively younger water. A way around this is the use of ^{3}H/^{3}He ratios. Radioactive decay of ^{3}H produces the noble gas helium-3 (^{3}He). First introduced by Tolstikhin and Kamenskiy (7), measurements of ^{3}H and tritiogenic ^{3}He define a quasi-stable tracer of initial ^{3}H input to groundwater and may be used to determine the position of the mid-1960s bomb peak in recharge areas and recharge rates (8–11).

Sources of helium are primarily atmospheric. Other sources include terrigenic He (R_{terr}), water in rocks that are enriched in certain elements such as thorium (Th) or Uranium (U), typically of crustal and mantle material, and samples representative of the mixing of relatively young water with old water containing R_{terr}.

Using tritium and helium concentrations, the tritium/helium age can be calculated as follows (12):

$$T_{\text{groundwater}} = t^{1/2}/\text{In } 2 \times \text{In } [1 + (^3\text{He}/^3\text{H})]$$

where $T = 12.3$ years (the half-life of tritium)
$^3\text{He}/^3\text{H} =$ helium/tritium concentration ratio (TU)

To convert the concentration units required to evaluate this equation:

$$1 \text{ cm}^3 \text{ STP g}^{-1} = 4.019 \times 10^{14} \text{ tritium units (for freshwater)}$$

This conversion can be used in conjunction with a correlation to the tritium peak method for verification.

Conditions for using this technique include the following:

1. Detectable tritium in the water sample needs to be greater than approximately 0.5 TU.
2. If R_{terr} terrigenic is present, then Ne data are also needed to define $^3\text{He}_{\text{tri}}$.
3. The ^{3}He/^{4}He ratio of R_{terr} must be known
4. If the amount of R_{terr} is small (i.e., <5% of the dissolved ^{4}He), the ^{3}H/^{3}He age may be insensitive to large uncertainties in R_{terr}.
5. R_{terr} must be known for samples with a large fraction of R_{terr} (i.e., within approximately 1% or better).
6. If R_{terr} cannot be defined with sufficient precision for age determination, a range in R_{terr} can be evaluated.

^{3}He/^{3}H allows dating groundwater of very young ages (approximately 1 year with an uncertainty in age of approximately 0.5 years due to analytic constraints) from a single water sample. This makes ^{3}He/^{3}H very attractive and complements other techniques for dating groundwater. ^{3}He/^{3}H can be applied to dating waters that have been recharged in the past approximately 30 years, so this technique can be used for interpreting ages of water from existing domestic, industrial, and municipal production supply wells and recharge operations. Water source(s) identification, flow paths, and flow rates for a variety of purposes and objectives can also be evaluated.

From an environmental perspective, it can also be used to monitor the use of certain chemicals released into the environment such as chlorofluorocarbons (CFCs) and sulfur hexafluoride. For example, for CFCs, the ^{3}H/^{3}He age is defined as the time elapsed since the water was isolated from the atmosphere following recharge.

Groundwater in aquifers is generally older than expected on the basis of flow velocity. Recent studies suggest that the rate of mass exchange between aquifers and aquitards or confining layers is assumed to be small (13). The effect on age, however, does not depend on mixing rates but rather on the ratio of fluid volume in aquitards to aquifers. This is important in understanding the relationship between groundwater flow and radiometric age distribution. It means that flow rates along an aquifer are higher than predicted by age measurements. Aquitard water is generally very old; thus, at high mixing rates, less-old water is supplied to the aquifer, and less-old water is being supplied to the aquifer because younger water is moving into the aquitard. Thus, mixing increases the age in an aquifer and also has a counterbalancing effect of decreasing the age in aquitards.

RECHARGE IN DESERT REGIONS AROUND THE WORLD

Kristine Uhlman
University of Arizona
Tucson, Arizona

INTRODUCTION

Arid regions are characterized by dryness, variously defined as rainfall insufficient for crops without irrigation, evaporation/evapotranspiration rates greater than precipitation, or less than 25 cm of annual rainfall. Most of the true deserts are found between 15 and 50° latitude north or south of the equator. Dry regions in the Arctic and Antarctic are not normally classified as deserts, although parts of northern Greenland and the McMurdo Sound area of Antarctica have closed basins and saline lakes and, except for temperature, would be hard to distinguish from deserts at lower latitudes (1). Middle latitude deserts in the basin interiors of the continents are characterized by scant rainfall and high summer temperatures. The trade-wind deserts, notably the Sahara of North Africa, exhibit negligible precipitation and large daily temperature ranges. Recharge rates in arid regions typically range between 3 to 4% of precipitation (2); however, a rate as low as 0.066 mm/yr or 0.033% has been measured in the Rio Grande Basin, New Mexico (3).

General

Approximately one-tenth of the land surface of the planet is arid, and an equal or slightly greater area is classified as semiarid. Arid climatic conditions profoundly affect landscape topography and depositional setting, which controls aquifer type in nonindurated deposits. Erosion and transport by wind and water result in fluvial and aeolian deposits ranging from sand dunes to valley fill deposits of stratified sand, gravel, silts, and clays. Some desert basins lack thick alluvial deposits, and groundwater is found in fractured consolidated bedrock. Carbonate aquifers exhibiting karstic features are found in some deserts and are likely vestiges of tropical climates predating current arid conditions. Regardless of the fabric of the aquifer material, it is generally true that average annual rainfall less than 12 to 25 cm may be insufficient to allow recharge to an arid region aquifer. For this reason, the sustainability of groundwater resources in arid regions is of serious concern and the focus of numerous investigations.

Historical Background

Several recharge investigations have been conducted in the southwestern United States related to water resource management and artificial recharge of arid region aquifers using waters imported from distant sources. With the construction of the California Aqueduct, the Columbia River Project (Eastern Washington State), and the Central Arizona Project, large tracts of land in the arid American west have been studied to design and engineer enhanced recharge and aquifer storage and recovery (water banking) projects (4–9).

Following environmental regulatory compliance actions in the mid 1980s, aquifer vulnerability to contamination due to agricultural and industrial practices has been the focus of several studies (3,10–12). The design of the low-level radioactive waste disposal facility in Nevada has been supported by the Amargosa Desert Research Site under the United States Geological Survey (USGS) Low-Level Radioactive Waste Program arid recharge investigations (10,13,14).

In response to recognized water resource issues related to drought, the National Science Foundation Sustainability of Semi-Arid Hydrology and Riparian Areas (SAHRA) program was initiated in 2000 to facilitate the transfer of knowledge to support the development of water resources policy. This multi-institutional/multidisciplinary program has conducted several studies on the Rio Grande and San Pedro/Gila River Basins (Arizona), including the Semi-Arid Land Surface Atmosphere (SALSA) project to investigate the watershed-basin-scale hydrologic water balance using remote sensing tools (15).

FUNDAMENTALS OF SUBSURFACE RECHARGE

Following Potter's (10) classification, arid and semiarid regions are those whose precipitation to evaporation (P/E) ratios are smaller than 0.5 and between 0.5 and 1.0, respectively. In addition to a lower net precipitation rate, rainfalls are typically infrequent and of short duration; high-intensity seasonal storms contribute a major portion of the annual rainfall over short periods of time. Under these conditions, the shallow soil surface layer infiltration capacity may be exceeded and excess overland flow propagates rapidly to flash flooding. Even low-intensity rainfalls, can lead to significant surface runoff when desert soil crusts have formed (16).

Water focused and concentrated by topography into ephemeral washes, wadis, sabkhas, and playas provides locations of enhanced recharge in arid areas. A significant component of recharge to arid basin aquifers occurs along mountain fronts. Important aspects along the mountain front include the partitioning of rainfall and snowmelt into surface runoff, deep infiltration along fractures and faults, and vegetation-controlled evapotranspiration (17). Focused flow along mountain stream channels into the major washes in the Tucson Basin (Arizona) visibly infiltrates flood-plain sediment, and surface water commonly does not leave the watershed (18). Half the annual recharge of 9 to 10 mm/year to the Ogallala Aquifer in the southern High Plains (Oklahoma and Texas) occurs through playa floors that cover only 6% of the aquifer land surface area (19).

Arid recharge requires the downward vertical flow of water in the unsaturated zone and an excess availability of water above the evapotranspiration demand. Once infiltrated, loss mechanisms in the unsaturated zone (uptake by plant roots, evaporation, and vertical vapor flow) increase the possibility that water never reaches an underlying deep aquifer (20). The measured ratio of groundwater recharge to precipitation ranges between 2 to 3% in most arid regions. An exception has been found, however, in the coastal sabkhas of Abu Dhabi, where measured recharge was approximately 90% of the mean annual precipitation of 70 mm. This high ratio is believed to be the result of several factors: the most important is the high water table, which allows infiltration to reach the saturated zone before evaporation within the vadose zone can occur (21). Fluid pathways in the unsaturated zone are inherently complex; transport distance and time of travel are significant factors that control arid region recharge rates. Because of this, unsaturated zone techniques are generally required to estimate recharge in arid regions (11).

Vadose Zone Capillary Flow

Capillary forces, together with gravity, determine fluid flow processes in unsaturated alluvium; finer grained materials respond like sponges so that there is no free drainage, even at high water content. Capillary rise causes water to move upward against the pull of gravity and takes place in small interstitial pores under negative soil water pressures that prevent free drainage. For example, it takes 1000 days for a water particle to travel though a 10 m deep vadose zone of fine sand whose volumetric soil water content is 0.15 and whose unsaturated hydraulic conductivity is 0.15 cm/day (the hydraulic gradient below the root zone equals unity, so water flux becomes equal to the hydraulic conductivity) (19). Capillary recharge through unsaturated fine-grained alluvium is unlikely in an arid setting.

In a study of recharge in the intermittent washes in the western Mojave Desert near Victorville, California, it was found that infiltration did not occur at control sites beyond the wash where water did not accumulate. Water did not pass the root zone, and the δ^{18}O and δ deuterium isotopic composition of water retained in the shallow coarse-grained soils were consistent with removal of water by vapor transport (9). Results from Southern Nevada research indicate that soil water may be as old as 120,000 years near the bottom of the deep (240–400 m) vadose zones, which shows there has been little or no infiltration of recent precipitation (14).

Vadose Zone Macropore Flow

"Macropore" is a common name for a wide range of large pores whose diameters are generally greater than 3 mm, such as cracks in clay soils, rock fractures, fissures in sediments, polygonal pressure cracks, pipes in the indurated calcic horizon, worm holes, and old root channels. Following precipitation that produces runoff and ponding, macropores that start at the soil surface quickly become conduits for recharge. The velocity of a water particle in a macropore in the soils from the previous example is approximately 30 cm/s, and it takes only 33 s for a water particle to travel 10 m from a ponded soil surface to the water table. Macropore transport reduces evaporation losses and results in a much larger recharge rate (19).

Techniques for quantifying macropore recharge were developed in the American southern high plains semiarid alluvial fan and dune aeolian deposits, where calculated recharge flux through macropores was between 60 and 80% of the total volume of recharge that reached the water table. Using a storm model to estimate rainfall-runoff with isotope geochemistry supporting the model simulations, 95% of the total recharge was found focused into 5% of the land area where water was focused into depressions and valleys (22).

In the southern high plains of Texas and New Mexico, recharge flux averages 9 mm/year regionally or approximately 2% of precipitation. Use of stable isotopes and tritium data indicate that approximately half of the recharge occurred in the floor of playa lakes that occupy 6% of the land area; much of the remaining recharge is believed to be from macropore flow (23).

MEASUREMENT TECHNIQUES

Approaches to quantify recharge vary depending on the climate, topography, and geology of the aquifer;

processes that control the spatial distribution and volume of infiltration that recharges arid aquifers are poorly understood. For these reasons, numerous techniques are typically used, and results are compared to calibrate the analyses.

Water Balance/Modeling

Rainfall/runoff modeling is widely used to estimate recharge where recharge is calculated as a residual of the water budget. This water budget approach assumes that deep drainage below the root zone will eventually reach the water table and become recharge, sometimes neglecting the potential for deep vapor fluxes to remove water from the system. When estimated as a residual in water balance models, recharge may be in error by an order of magnitude. In a study by Gee and Hillel (24), it was recommended that quantification of drainage by lysimetry and tracer tests should be used to calibrate qualitative model estimates. Modeling efforts that ignore seasonality or transient conditions cannot simulate recharge when average annual evapotranspiration exceeds precipitation (25,26). Arid site recharge studies found significant variability under similar climatic and soil conditions, but using different plant cover and topography, estimates of recharge based on fixed fractions of annual precipitation do not reflect the seasonal plant and soil factors that control recharge.

Chloride mass-balance methods that integrate temporal and aerial distribution of groundwater recharge have been found well suited to areas of large temporal and spatial variation in recharge. For small alluvial aquifers in the wadi systems of the A'Asir and A'Hijaz mountains of western Saudi Arabia, Bazuhair (2) found that recharge varied between 3% and 4% of precipitation using this technique.

Physical Measurement

Stream gaging, seepage meters, and lysimeters provide point estimates of recharge and discharge but are not representative of the entire system (24). Streamflow and groundwater data collected in the Rillito River in the Tucson Basin was compared to microgravity measurements that showed an increase in groundwater storage within the area of the floodplain. Coupled with neutron moisture readings and environmental tracer measurements, it was found that infiltration is controlled by geology and structure, where initial depths to groundwater were greatest (27–29).

Environmental Tracers—Recharge Sources

Many of the alluvial aquifers in the Basin and Range region of the American southwest were hydrologically closed during development, resulting in readily soluble evaporate material, such as gypsum and halite, interbedded with alluvial fill. The basin fill materials are typically of late Cenozoic age and consist of thousands of feet of coarse gravel to silt and clay derived primarily from igneous and metamorphic rocks eroded from the surrounding mountains. During precipitation that is intense enough to produce runoff in ephemeral streams, recharge to the aquifer occurs near the points where stream channels leave the mountains and flow across the alluvium. Recharge from ephemeral streams generally has low dissolved solids concentrations, but as water moves downward toward the zone of saturation and down-gradient, there is extensive opportunity for interaction between water and rock. This results in a regional geochemical pattern of groundwater chemistry where more dilute water occurs near recharge areas (4). High total dissolved solids (TDS), chloride, or boron concentrations indicate low water flux and concentration by evaporation within the vadose zone or long-term residence within the saturated zone (30). Mapping of geochemical tracers within the Middle Rio Grande Basin identified spatial patterns of recharge, and focused recharge was found beneath arroyos (13).

Other tracer methods include age-dating of groundwater with historical tracers such as bomb tritium, ^{36}Cl, carbon-14, and oxygen isotope/deuterium ratios (20). On the basis of carbon-14 data, most groundwater in the regional aquifer beneath Oro Grande Wash in the Mojave Desert was recharged between 5000 and 20,000 years ago (9). In the intensely arid region of the Western Desert of Egypt, deuterium data show that modern water cannot be the source of recharge for groundwater, and it is speculated that the waters derived either from distant recharge in Chad or the Sudan or are very old Pleistocene waters from a cooler glacial time (31). Oxygen isotope ratios can determine temperature and coincidental elevation of recharge waters, allowing for differentiation between winter storm/summer storm precipitation, mountain-front recharge, and snowmelt waters (18).

In the Trans-Pecos Texas, Chihuahuan Desert, ^{87}Sr/^{86}Sr ratios (in combination with other chemical and isotopic data) were used to infer flow paths and residence times of recharged water. Concentrated recharge was found within regional fracture trends in carbonate rocks in the highlands, losing streams on proximal portions of alluvial fans, and irrigation return flow along well casings (32).

Environmental Tracers—Recharge Rates

Mapping of environmental tracers allows the investigator to find recharge sources, but it is often more difficult to quantify recharge rates. Artificial tracer tests of soil moisture through unsaturated, poorly sorted, horizontally stratified alluvial deposits found that transport takes place along preferential flow paths. Bromide was used as a tracer to measure the velocity of soil moisture, which ranged from approximately 55 to 275 cm per day on a test plot where water was artificially applied to natural soils (6).

Because recharged water from desert washes also spreads laterally away from the wash as depth increases, the flux of water decreases with increasing depth. In addition, arid soils are less permeable beyond the channel due to deposition of soluble salts (9); therefore, quantifying recharge rates in these settings is difficult.

Studies from the Amargosa Desert in southern Nevada, the Middle Rio Grande Basin in north-central New Mexico, and the Palouse Catena of the Columbia River regional aquifer in southeastern Washington were used to compare tracer-based recharge estimates with water-balance models. Mean annual precipitation at the three study areas was approximately 0.1, 0.25, and 0.5 m per year, respectively. Estimates of groundwater recharge were derived from vadose zone profiling of chloride, stable isotopes, and tritium and compared. The geochemical chloride profiles suggested that recharge rates are in approximate equilibrium with current climatic conditions. This was corroborated by isotopic and hydraulic data; however, chloride profiles at the driest sites suggested features that could be interpreted as relicts of past wetter conditions (13,25,26,33).

Mapped geochemical and isotopic data reflect recharge from basin margins and from the Rio Grande River in the Middle Rio Grande Basin, New Mexico. Isotopically depleted waters were some of the oldest waters in the basin and represent water recharged in the area of the Jemez Mountains during the last glacial period about 20,000 years ago. Younger waters, about 7,000 years old, were also mapped along the basin margins. Radiocarbon ages were used to estimate modern and paleorecharge rates, and recharge rates during the last glacial period were estimated to be at least six times greater than the modern radiocarbon-based recharge (34).

INCIDENTAL RECHARGE

Arid land recharge may include incidental recharge due to environmental pollutant releases, irrigation return flow, canal seepage, sewage effluent seepage in dry washes, and seepage from surface impoundments such as stormwater retention ponds. The evidence for irrigation and industrial-related recharge includes the presence of pesticides, caffeine, pharmaceuticals, and other chemical pollutants in groundwater (20,35), although it should be recognized that some contaminant chemicals may be transported through the subsurface by nonaqueous means. Treated municipal wastewater released into ephemeral, effluent-dependent stream channels is an important source of recharge in some regions (36). The Santa Cruz River in south-central Arizona contributes 6.0 acre-feet/day/mile to the subsurface, or approximately 80% of the flow volume results in recharge (37).

SUMMARY

Hydrologic processes in arid or semiarid lands are distinctly different from those in humid climates and exhibit wide variation in magnitudes and type of recharge. Precipitation that results in focused flow and ponding allows macropore transport of recharge, whereas loss mechanisms in the unsaturated zone allow unsaturated water or vapor flux to occur in either vertical direction, depending on surface conditions. Recharge studies use a combination of approaches, such as thermal and geophysical techniques, geochemical tracers, radioisotopes, and unsaturated zone modeling calibrated against streamflow and groundwater level information to characterize this complex hydrologic process (28). Extremes in temperature and precipitation in arid regions necessitate focused consideration of the amount and distribution of recharge to the aquifers so as to manage limited water resources adequately.

HYDROLOGIC FEASIBILITY ASSESSMENT AND DESIGN IN PHYTOREMEDIATION

J.W. Weaver
S.C. Mccutcheon
S.L. Hutchinson
(from *Phytoremediation: Transformation and Control of Contaminants*, Wiley 2003)

SUMMARY OF PRACTICAL IMPLICATIONS

Several design considerations for phytoremediation are based on the capability of trees to remove contaminated water from aquifers. These capabilities depend upon the amount of water that can be withdrawn, the vertical distribution of contaminants, and flow patterns in the aquifer. For each of these, an example field site is given where methods were applied to quantify the characteristics. These include a model of forest evaporation for estimating the balance between precipitation and evapotranspiration, a simple model of recharge-driven plume diving, and the use of groundwater flow modeling for assessing various features of the groundwater flow.

ASSESSMENT AND CHARACTERIZATION OF PHYTOCONTAINMENT

To clean up a contaminated site, characterizing the type and extent of pollutants at the site and developing a conceptual remediation plan are essential. A proficient plan covers the expected effectiveness of the remedial technology, projection of the time required to achieve cleanup, and cost. The best way of assessing these factors is to use models to determine the capability of the existing or projected vegetation to contribute to the control and cleanup of the site. No other method has proven applicable and useful for projecting future scenarios, especially for selection and design.

Phytohydraulic containment (1) of contaminated groundwater depends on the evapotranspiration rate exceeding the flow rate of groundwater from the water table down to the lowest extent of the contaminated plume. Phytodegradation and phytotransformation require that the contaminants be in contact with the plants, rhizosphere microorganisms, and any associated exogenous enzymes, all of which can degrade or transform pollutants. Because roots grow from the surface downward to the water table and remain in the capillary zone in most cases, the main factor influencing the effectiveness of phytoremediation is the ability of the plants to draw contaminated water to the roots. Two critical elements are the rate and amount of water withdrawn directly from the aquifer (*versus* soil water from precipitation) and the vertical distribution of contaminants. In other cases to be illustrated in this chapter, plant control of infiltration will limit leaching from contaminated soil. Thus, the local water balance is the vital basis for the assessment and design of phytoremediation to control and remove soil and shallow groundwater contaminants.

The physiologies of vegetation at a site, local hydrology and geology, and the chemical characteristics of the contaminants control the leaching and uptake of contaminated water. The capabilities to transpire large amounts of water, to put roots into the capillary or phreatic zones, and to tolerate stress from other plants and wildlife, contaminants, disease, and occasional lack of nutrients and water are the vital plant attributes for phytocontainment and treatment. The local hydrology involves meteorology (precipitation, wind speed and direction, and air temperature); interception; surface conditions that control runoff *versus* infiltration; percolation through the vadose zone; quantity of flow and direction; and change in storage in the surficial aquifer. The local soil stratigraphy, porosity and hydraulic conductivity of different layers, and hydraulic gradient are the important hydrogeologic factors. The dominant chemical characteristic is the extent of sorption and uptake.

The art of using vadose and groundwater models and measurements to assess and design phytohydraulic control and treatment is progressing rapidly. Hong et al. (1) used modeling to guide the field design of a methyl *tertiary*-butyl ether (MTBE) phytoremediation application in Houston, Texas. They simulated the saturated and unsaturated zones and established that deep-planted (approximately 5 meters or 15 feet) hybrid poplar (*Populus deltoides* × *Populus nigra* 'DN-34' 'Imperial Carolina') trees could control this shallow methyl *tertiary*-butyl ether plume after full canopy development. Field studies are underway to confirm the projections. Quinn et al. (2) estimated the effects of hybrid poplars (*Populus trichocarpa* × *Populus deltoides*) planted to a depth greater than 8 meters (25 feet) into a confined aquifer at Argonne National Laboratory near Chicago, Illinois. Simulations with the U.S. Geological Survey standard groundwater model MODFLOW and the associated particle tracking code indicate that a high degree of containment should be achieved after tree canopy closure. Extensive parts of the trichloroethylene contaminated confined aquifer are expected to be dewatered, or nearly so, on a seasonal basis. Eberts et al. (this book) and Hirsch et al. (this book) along with this chapter, complete a summary of the pioneering work with vadose and phreatic zone modeling to assess and design phytocontainment and treatment systems based on evapotranspiration. Landmeyer (3) reviews some of the measurement techniques that may be useful in phytocontainment and treatment assessments. Ferro et al. (4) reviews measurement and assessment techniques (not involving modeling) applied at a petroleum hydrocarbon contaminated site in Ogden, Utah.

This chapter presents three field examples that illustrate important design considerations for the application of phytoremediation to shallow aquifer contamination. The first case presents a method for estimating the effective evapotranspiration rate for a site in Joliet, Illinois. The second case illustrates the need for vertical characterization of plumes in general by introducing a clear-cut example of a landscape feature that causes plume diving. Hydrogeologic features that cause plumes to migrate deeper into aquifers work against phytoremediation because of the increased evapotranspiration required to control the plume. The second case study also reveals that conventional monitoring approaches that use long-screened wells have a great potential for missing plumes or underestimating the length. The third case explores a proposed phytoremediation system at a site in Florida where a contaminant plume dived upon emerging from under a paved area. Methods to control the vertical location of the plume and potential application of phytoremediation are assessed using the U.S. Geological Survey modular groundwater flow model, MODFLOW (5).

AVERAGED TRANSPORT THROUGH THE VADOSE ZONE

Joliet Army Ammunition Plant

Trinitrotoluene (TNT) and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) plumes were found in the shallow aquifer at the Joliet Army Ammunition Plant. Figure 1 shows the area in a 1:7200 scale aerial photograph of the site. Of primary interest was a forested area along the banks of Prairie Creek. In this area of the site, there is a possibility either of naturally occurring phytoremediation by existing trees or of enhancing phytoremediation by planting new trees. Either option depends upon the capability of the trees to remove contaminants from the shallow aquifer. The objective of the work at the Joliet plant was to assess the potential for net withdrawal of water from the aquifer.

The photograph reveals some of the irregular nature of the forest cover in this area. A significant fraction of the forested area consists of a lower density of forest cover where lower evapotranspiration rates would be expected.

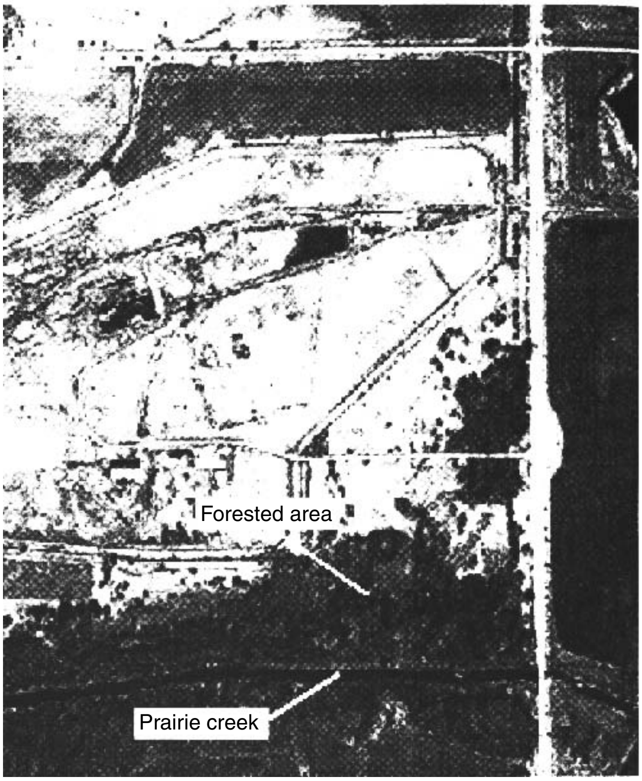

Figure 1. Aerial photograph (1:7200) of the Joliet Army Ammunition Plant site showing Prairie Creek and the forested area overlying the contaminated aquifer. Note that the side of the photograph is oriented north and south.

A vegetation survey conducted at the site showed that the lower density forests contained a number of dead or dying trees. Thus, the role of the existing vegetation in phytoremediation of the contaminant plume depends on the influence of the forest cover and the capability to continue extracting water in the future over this section of the groundwater flow path. Because of the relatively low quality of the existing vegetation, replanting with young trees [hybrid poplars (*Populus* spp.) or willows (*Salix* spp.)] or native prairie grasses might provide a more sustainable treatment system.

Evapotranspiration Estimates

Several equations have been developed for estimating evapotranspiration. The most applicable for this analysis is the Penman-Monteith equation (6). This equation is based on a site energy budget. The budget is based on (1) calculation of all the short- and long-wave energy available for evaporation at the plant canopy, and (2) water vapor diffusing out of the leaves, controlled by the surface or stomatal resistance, and then out into the atmosphere, controlled by aerodynamic resistance (7). The equation for evapotranspiration ET in millimeters per day is as follows

$$ET = \frac{1}{\lambda}\left[\frac{\Delta A + \rho_a c_p \dfrac{D}{r_a}}{\Delta + \gamma\left(1 + \dfrac{r_s}{r_a}\right)}\right] \tag{1}$$

where λ is the latent heat of vaporization equal to $2.501 + 0.002361\ T_w$ in million joules per kilogram, in which T_w is the water temperature at the interface with the air; Δ is the gradient of the saturated vapor pressure in kilopascals per °C; A is the available energy in million joules per square meter per day; ρ_a is the density of moist air in kilograms per cubic meter equal to $3.486P_a/(275 + T_a)$, in which P_a is atmospheric pressure in kilopascals and T_a is air temperature in °C; c_p is the specific heat of moist air equal to 1.013 kilojoules per kilogram per °C; D is the vapor pressure deficit in kilopascals at a reference height; r_a is the aerodynamic resistance in seconds per meter; γ is the psychrometric constant in kilopascals per °C equal to $c_pP_a/(1000\varepsilon\lambda)$, in which ε is the ratio of the molecular weight of water vapor to that of dry air or 0.622; and r_s is the surface resistance of the land cover in seconds per meter that also includes the effect of vegetation. [See Shuttleworth (7) for a description of the reference grass or crop method to estimate relative resistance of a different vegetative land cover.] Most of these variables are strongly related to the meteorological conditions of the site, affirming that the feasibility and success of phytocontainment is very site specific.

A practical approach (7) for estimating evapotranspiration, based on the energy balance and aerodynamic effects, uses generalized long-term climatic data to approximate evapotranspiration. For the evaluation at the Joliet site, existing climatic data were used to estimate evapotranspiration. In the U.S., the Solar and Meteorological Observation Network, SAMSON (8), provides hourly climate observations recorded for a 30-year period (1961 to 1990) from 239 stations located around the country. The data from SAMSON include (1) hourly precipitation (rainfall and snowfall) amounts, (2) air temperature, (3) percent cloud cover, (4) solar radiation, and (5) relative humidity. These data provide the means to estimate averaged hourly, daily, monthly, or annual evaporation amounts for locations in all parts of the U.S. For Joliet, the nearest SAMSON station is located at Chicago. The complete hourly SAMSON file for this station consists of approximately 38 megabytes of data. Practical use of these data in Equation (1) requires post processing to generate, in this case, monthly rainfall and climatic estimates from the 28-year-long record for the Chicago station.

Tables 1 and 2 give a summary of the processed SAMSON data for the Chicago station. These values were used in Equation (1) to generate the forest evapotranspiration estimates given in Table 3. The net extraction, defined here as the potential evapotranspiration less the rainfall, gives an estimate of the amount of water that the forested area near Prairie Creek can remove from the aquifer. For the months of December through March, the net extraction is assumed to be zero because average temperatures were less than 4.4 °C (40 °F). Thus, in the warmer months of the year, the estimated evapotranspiration exceeds the amount of water available from rainfall. Net extraction ranges from 222 to 348 millimeters per month. These correspond to 2.4×10^5 to 3.7×10^5 gallons per acre per month.

Table 1. Monthly Storm Statistics Determined from the SAMSON Database for the Chicago Station

Month	Average Interarrival Time (days)	Average Depth (Millimeters)	Average Storm Duration (hours)	Average Number of Storms
January	1.70	2	0.133	18.0
February	1.59	2	0.123	16.3
March	1.55	3	0.140	19.3
April	1.39	4	0.128	20.3
May	1.69	5	0.113	17.1
June	3.07	6	0.099	15.9

December	−2.66	−31.7	21.7	−6.74	0.76

Table 3. Monthly Estimated Evapotranspiration, Rainfall, and Net Extraction Estimates Determined from the SAMSON Database for the Chicago Station and the Forest Evapotranspiration Equation (1)

Month	Estimated Evapotranspiration (Millimeters Per Day)	Estimated Evapotranspiration (Millimeters)	Monthly Precipitation (Millimeters)	Net Extraction (Millimeters)	Net Extraction (Gallons Per Acre)
January	4.87	151	42.7		
February	6.21	174	34.7		
March	9.88	306	66.6		
April	11.34	352	92.3	259	2.8×10^5
May	12.22	379	86.4	293	3.1×10^5
June	14.80	444	95.7	348	3.7×10^5
July	13.85	429	99.0	330	3.5×10^5
August	12.27	380	118	262	2.8×10^5
September	10.42	313	90.6	222	2.4×10^5
October	8.62	267	63.1	204	2.1×10^5
November	5.75	173	77.7	95	0.4×10^5
December	5.50	171	65.2		

The estimated amount of water evaporated and transpired in excess of the rainfall amount was assumed to be drawn from the aquifer. This analysis assumed, however, that the trees can draw water from the aquifer without hydraulic limitation. The depth to the aquifer and the low hydraulic conductivity of the aquifer materials limit the actual rate of withdrawal. Another limitation was the variable density of vegetation in the forest. Dead or dying trees reduce the amount of water extracted from the aquifer. This analysis suggested that in the absence of site-specific evapotranspiration measurements, which would quantify how the existing vegetation actually draws water from the aquifer, there is the potential for the trees to create a net withdrawal of water from the Joliet surficial aquifer during the summer months. Nevertheless, additional site investigation and performance monitoring of any phytoremediation remedy is necessary. These feasibility and application procedures require collection of site-specific climatic and hydrogeologic data to verify and adjust the forecasts from Equation (1). Sap-flow measurements and sampling of tissues from trees are necessary to provide verification of remediation efficacy.

VERTICAL CHARACTERIZATION OF CONTAMINANT DISTRIBUTIONS

Typical Characteristics of Surficial Aquifers

With a positive potential for withdrawal of water from an aquifer, there are at least two important additional considerations. First is the vertical location of contaminants in the aquifer. Before being able to assess the prospects for removal, accurate delineation of contamination is required. The following example describes a case where accurate vertical delineation was used to reveal, in addition to the distribution of contaminants, landscape features that were responsible for diving of the plume (9). Because the contaminants move with the water, the location of aquifer recharge is also an important consideration for phytoremediation to be successful. This case indicates clearly that phytoremediation, which is dependent upon the capability of trees to remove water from the top of an aquifer, requires an understanding of the vertical distribution of the contaminants. The second consideration is the depth to which water is removed from the surficial aquifer. At each site, these recharge and discharge zones are important determinants of the groundwater flow. The importance of characterizing recharge, evapotranspiration, and discharge is illustrated in a second example where phytoremediation was considered to remediate a chlorinated solvent plume. See the section “Feasibility Investigation for Phytohydraulic Containment and Treatment.”

Vertical dimensions that are small relative to the length of the flow system characterize many aquifers. In order to better visualize the stratigraphy or vertical distribution of contaminants, however, commonly drawings are vertically exaggerated, which visually exaggerates the importance of vertical variations. Aquifers and some contaminant plumes can extend over distances of kilometers at least, whereas the thickness is of the order of meters. This results in ratios of length to thickness on the order of 100:1. For analysis of the flow at water tables or in surficial aquifers, the approach taken by Dupuit and Forchheimer (10) recognizes the two orders of magnitude difference in scale. The approach also uses the assumptions that the head in the aquifer is depth-independent (vertical potentials) and that the discharge is proportional to the slope of the water table (Darcy’s equation).

Two more observations are significant. First, because the hydraulic conductivity of a confining layer is orders-of-magnitude lower than that of an aquifer, flow in the confining layer tends to be almost vertical (11). Thus, because of the typical scale, the flow in the aquifer is nearly horizontal as a consequence of vertical potentials and nearly vertical in confining units as a consequence of permeability distributions. Conceptually, the three-dimensional character of flow has been reduced to aquifers with planar flow and confining units with vertical flow. The second important observation concerns the apparent dilution of contaminant plumes that is commonly characterized by aquifer dispersivity. In tabulating dispersivity, Gelhar et al. (12) stated that vertical dispersivities in aquifers were not often measured, but that available data suggested that the values of vertical dispersivity were two orders-of-magnitude lower than longitudinal dispersivity. Therefore, the dilution of plumes over the thickness of the aquifer is likely to be minimal when compared to longitudinal dispersion. The conventional explanation for the difference in dispersivities is that sediments resulting from depositional systems have a preferential orientation—that of the water that deposited the sediments. The practical implication is that transport of contaminants perpendicular to main direction of deposition is minimized.

The conclusions drawn from these observations are that water entering the aquifer vertically is turned so that flow is nearly horizontal. This follows from the Dupuit observations. As recharge accretes along the length of the flow path, more and more water is added to the aquifer. Because of continuity and limited vertical dispersivity, this water is added to the top of the aquifer and contaminant plumes appear to “dive” or move deeper into the aquifer. Likewise, when removed from a surficial aquifer due to evapotranspiration, water is removed from the top and a contaminant plume would appear to rise back to the water table. Such flow characteristics are similar in concept to the classic work of Toth (13) but consistent with the scaling observations of Dupuit and Forchheimer.

At some sites, unlined drainage ditches, leaking water mains and sewer pipes, irrigation, and the flow pattern in the aquifer can determine the vertical distribution of contaminants. Where recharge is the likely cause of diving, the amount of water that infiltrates into the area above the plume, and the amount that this recharge contributes to flow in the aquifer determine where and how much diving will take place.

Plume Diving: East Patchogue, New York

A gasoline release at an East Patchogue, New York, underground storage tank (*i.e.*, UST) facility created large benzene, toluene, ethylbenzene and xylene (BTEX), and methyl *tertiary*-butyl ether (MTBE) plumes. The plumes were detected because the contaminants showed up in a private water supply well, located 1200 meters (4000 feet) down gradient from the source. The well screen was about 15 meters (50 feet) below the water table, where much of the methyl *tertiary*-butyl ether mass was located. The site investigation started at this point and proceeded up gradient to identify the source.

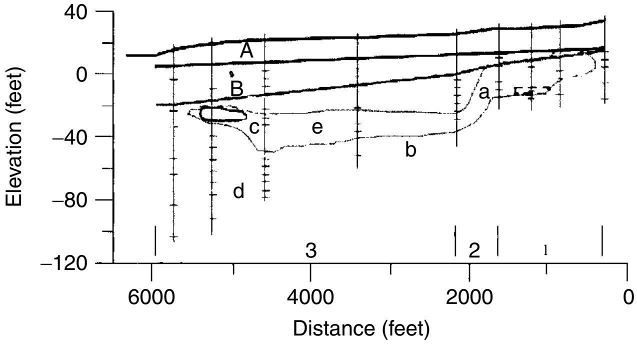

Figure 2. Vertical section through the xylene, benzene, and methyl *tertiary*-butyl ether plumes at East Patchogue, New York. A leaking tank was located at the right-hand edge of the drawing and the flow is to the left. The aquifer was divided into three recharge zones labeled 1, 2, and 3 below the plumes. In zones 1 and 3, the recharge was 559 millimeters per year (22 inches per year), whereas zone 2 recharge dominated by a gravel pit was 1120 millimeters per year (44 inches per year). The water table is marked "A" and the predicted top of the plumes by "B" (see www.epa.gov/athens/onsite for how the top of the plumes was derived). The plume labels are xylene: a—concentrations of 1000 micrograms per liter; benzene: b—100 micrograms per liter and c—1000 micrograms per liter; and methyl *tertiary*-butyl ether: d—100 micrograms per liter and e—1000 micrograms per liter. Note that 1 foot is equal to 0.3048 meter.

Because of the importance of the aquifer for drinking water supply, the State of New York undertook an extensive investigation of the site that included vertical characterization of the plumes. Multilevel samplers with 15-centimeter (6-inch) screens at 1.5-meter (5-foot) intervals were used. A resulting vertical section through the plume showed that BTEX and methyl *tertiary*-butyl ether tended to dive into the aquifer with distance from the source (Fig. 2). Furthermore, a significant amount of diving occurred as the benzene and xylene plumes passed under a gravel pit. At East Patchogue, the maximum depth of the hydrocarbon plumes reached 7.62 meters (25 feet) below the water table.

By studying the well logs and performing a detailed hydraulic characterization of the aquifer with a borehole flowmeter, vertical migration controlled by stratigraphy was ruled out because the hydraulic conductivities varied by less than a factor of two over the aquifer. Weaver et al. (14) present an Internet calculator for plume diving in simple aquifer systems (www.epa.gov/athens/learn2model) that is based on a mass balance and Dupuit-Forchheimer flows in aquifers (15). The calculator reproduces the upper bound on the contaminant distribution by accounting for enhanced recharge from the gravel pit (Fig. 2). Because of the lack of stratigraphic evidence for preferential flow paths and the ability of the model to reproduce the observed plume diving, recharge-driven plume diving is the likely reason for the observed vertical distribution of the contaminants at East Patchague (9).

This example sheds light not only on how recharge pushes the plume downward, but also what happens when water discharges from aquifers. Where water comes up at discharge points, so will the contaminants: along wetlands, streams, rivers, lakes, or the ocean. The ocean is the expected destination of the methyl *tertiary*-butyl ether plume at East Patchogue, where the groundwater discharges into Great South Bay, adjacent to the southern shore of Long Island. The groundwater and contaminants move upward as the plume approaches the discharge point at the bottom of the Bay.

Despite the low vertical dispersivity, contaminant distributions still, of course, vary over the vertical. This was seen in the East Patchogue plume where the maximum concentration at each sample location was higher than the average taken over the entire plume thickness. With conventional sampling techniques, there is effective averaging over the length of the well screens used. With no knowledge of the underlying vertical contaminant distribution, the well screen might be placed anywhere relative to the contaminant distribution. This could easily lead to well screens that sample part of the contaminant distribution and part clean water. The resulting concentrations will be between undetectable and the maximum for the location [(14); see the average borehole concentration calculator that is a part of the OnSite system at www.epa.gov/athens/onsite for a specific example]. Therefore, the same hydrologic characterization of a plume determines the feasibility for phytohydraulic containment and treatment, and also cost effectively dictates when and where the cleanup should be monitored.

FEASIBILITY INVESTIGATION FOR PHYTOHYDRAULIC CONTAINMENT AND TREATMENT

The Orlando Naval Training Center is one of thousands of U.S. Department of Defense facilities contaminated with chlorinated solvents. The plume is shallow and within the rooting depth of proven phytoremediation approaches using tree planting. The Training Center has been closed and the Navy is cleaning up and preparing the site to be turned over to the City of Orlando. As such the Naval Southern Command in Charleston, South Carolina has pilot tested a number of innovative remediation methods. One of the methods investigated was the use of phytoremediation to cost effectively clean up the plume. For this purpose, the EPA National Exposure Research Laboratory in Athens, Georgia was requested by the Navy to establish guidelines for determining the feasibility of applying phytocontainment and treatment and to apply those guidelines at the Orlando Naval Training Center.

The initial phase involved (1) designating appropriate characterization data for an assessment, (2) selecting the appropriate flow and transport models from a multimedia context, (3) vegetation surveys for indigenous phytoremediation potential (conducted by Navy forester), (4) pioneering sap-flow measurements of existing trees and extrapolation to stand-level estimates of existing evapotranspiration for assessments, (5) projecting improved evapotranspiration from replanting, and (6) assessing chlorinated solvent degradation rates in various media by vegetation and microorganisms. This section reports on the selection and application of appropriate models for assessment of the feasibility of phytocontainment and treatment. Existing stand assessments of evapotranspiration and projections were conducted by the U.S. Forest Service Coweeta Hydrologic Laboratory (16) based on sap-flow measurements and extrapolation and projection methods as described in Vose et al. (this book). Nzengung (17) collected vegetation from the site, soil and aquifer cores, and wetland and lake sediments to determine the level of ongoing attenuation. These laboratory incubations provide expected rates and kinetics of degradation and transformation of tetrachloroethylene and trichloroethylene that contaminate the site.

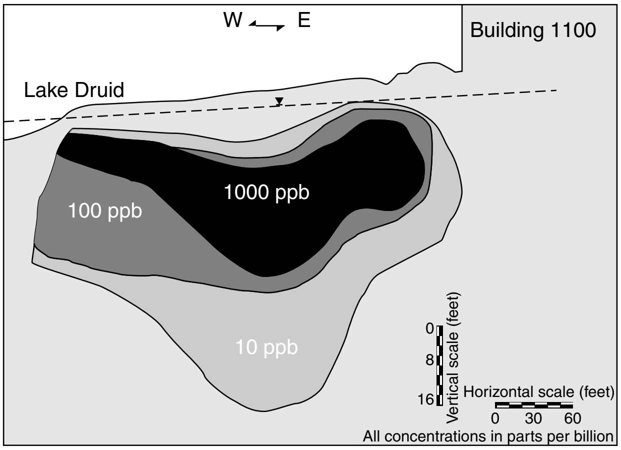
This section covers all other important components of a feasibility investigation—selecting and setting up a groundwater model, and parametrizing that model to simulate the effects of existing and projected vegetation, and runoff and infiltration control. Depth of the plume capture is used as the criteria for projecting the likelihood of using vegetation to capture and treat the plume. As a result, these projections are conservative because the transformation and degradation resulting from contaminant reactions in lake and wetland sediments and from plant enzymatic processes have not been fully assessed to date.

The Orlando Naval Training Center in Florida has a plume of chlorinated solvents that has resulted in detection of significant amounts of vinyl chloride in adjacent Lake Druid shown in Fig. 3. Lake Druid is also bordered by a number of residences and represents a valuable esthetic and recreational asset to adjoining residents.

Site Assessment and Apparent Plume Diving

A groundwater plume of chlorinated ethenes originated at the site of a laundry and dry cleaning facility. Prior to the closing in 1994, hazardous materials and water contaminated with chlorinated solvents were released to the groundwater from the surge tank beside Building 1100, and from spills of tetrachloroethylene and trichloroethylene in the facility. The contaminated groundwater plume flowed from the site of the former laundry underneath and into the nearby Lake Druid. The site plan shows that the source area is contained within an area of very high impervious cover. This consists of the buildings, paved driveways, and parking lots. Immediately down gradient from the parking lot is an unlined drainage ditch. The ditch that receives runoff from the parking lot and buildings on the site runs perpendicular to and crosses the plume that emerges from beneath the pavement. Beyond a narrow grassy area lies a densely wooded area that borders Lake Druid, where the plume discharges. Located nearly over the top of the plume is a creek that feeds the lake. Much of the wooded area is a seepage wetland.

Figure 4 shows the distribution of the chlorinated ethene contaminants taken over a vertical section of the



All concentrations in parts per billion

Figure 4. Vertical section of chlorinated ethene plume at Orlando Naval Training Center. Lake Druid is on the left and the contaminant source on the right. Note that 1 foot = 0.3048 meter and ppb is the concentration in micrograms per liter.

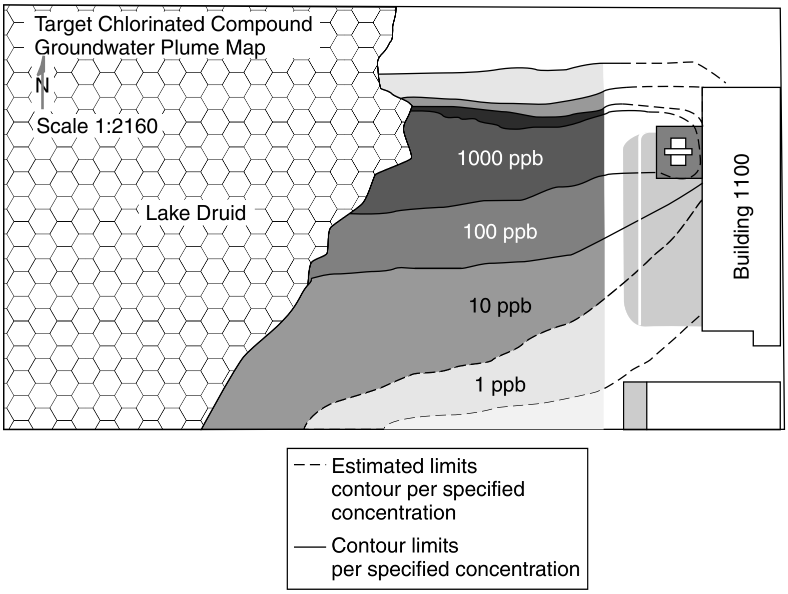


Figure 3. Site map of the Orlando Naval Training Center showing the Building 1100 source area and the shoreline of Lake Druid. The light shading surrounding Building 1100 delineates impervious parking lots and roads. Note that ppb is the concentration in micrograms per liter.

aquifer spanning the distance from the former laundry to the lakeshore. The data were obtained using a direct push probe operated on a 0.6-meter (2-foot) interval. These results show that the concentrations are low in the upper part of the aquifer, once the plume is down gradient of the ditch. In these locations the depth of uncontaminated water having undetectable amounts of chlorinated ethenes ranges up to 2.4 meters (7 feet) below the water table. The horizontal distance spanned by the diving portion of the plume is approximately 67 meters (220 feet). Thus the plume moves deeper into the aquifer upon emergence from the paved area and upon passing under the unlined ditch.

Model Application for Orlando Naval Training Center

The effects of recharge and discharge on the groundwater flow at Building 1100 were simulated with two models. First, the simple screening model for plume diving was applied (14). The model assumes that flow occurs between two points with fixed heads, the aquifer is a single uniform layer, and the flow system can be described by a set of one-dimensional segments. These assumptions are satisfied for a screening analysis of the Orlando Naval Training Center plume, although other details of the flow system require the use of a numerical model. This consideration led to the application of MODFLOW with particle tracking for a more detailed evaluation.

The screening-level plume diving calculation allows determination of the vertical displacement of the plume generated by the supply and withdrawal of water from the aquifer. The simple model was used to assess the amount of diving that would occur as the plume passed under the unlined ditch. With an estimated average annual rainfall of 1400 milliliters (55 inches) at Orlando, the amount of water that could run off into the ditch is very large. Estimates based on the area of the pavement surrounding the source ranged up to the equivalent of 38000 millimeters per year (1500 inches per year) concentrated in the ditch. The actual amount of infiltration through the ditch was not determined for this study. However, the leakage through the ditch would be a function of the transient depth of water, soil properties, soil antecedent moisture content, and the vegetation in the ditch. The online calculator (www.epa.gov/athens/onsite) was used to determine how much water would be required to infiltrate through the ditch to cause the observed diving of the plume. The purpose of this exercise was to determine if the observed plume diving could be attributed to reasonable recharge amounts ranging from the rainfall rate of 1400 milliliters (55 inches) to the estimated runoff amount of 38000 millimeters per year (1500 inches per year). Figure 5 shows the results from infiltration amounts of 1400 milliliters per year (55 inches per year) and 2800 millimeters per year (110 inches per year). Thus, if the ditch recharges double the average annual precipitation to the aquifer from the impervious area, this amount can account for the observed plume diving. This amount of water 2800 millimeters per year (110 inches per year) is less than 10 percent of the maximum estimated flow in the ditch and thus forms a plausible explanation for the vertical distribution of the contamination observed at the site. In the upper portion of the aquifer, there is no evidence for stratigraphic preferential flow paths and density-driven plume diving is not evident because the plume dives only after emerging from below the pavement.

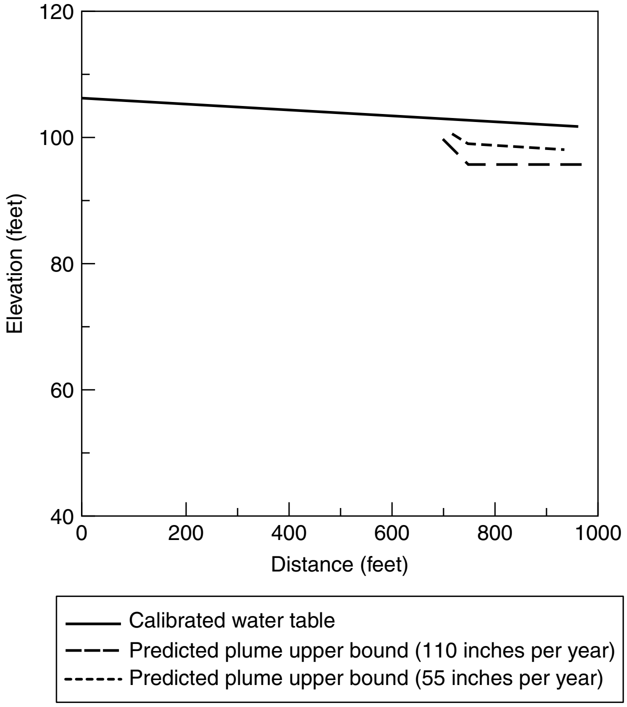

Figure 5. Predicted plume diving using the OnSite plume diving calculator (www.epa.gov/athens/onsite) and two estimates of infiltration through the unlined ditch. Note that 1 foot is 0.3048 meter and 1 inch is 25.4 millimeters.

Numerical Modeling

The U.S. Geological Survey modular groundwater flow (MODFLOW) code with particle tracking was used to perform more detailed simulations of the site. These simulations provided a more precise determination of the vertical and horizontal distribution of flow and a tool with which to evaluate the various design alternatives. Some of the parameters used in the model were taken from a previous modeling study (18) that was not focused on the plume and Lake Druid. Halford (18) calibrated the model to regional flow conditions. Calibrated parameters for hydraulic conductivity, porosity, and aquifer and layer thicknesses from Halford (18) were used in the current model. Boundary conditions were taken to match observed water levels collected around the site and consistent with the large-scale flows simulated by Halford (18). The need for site-scale water levels constrained the modeled flow domain to the area immediately surrounding Lake Druid. For an adequate assessment of the potential effects of vegetation, the area around Lake Druid and Building 1100 was modeled in more detail, both horizontally and vertically. To provide sufficient vertical delineation of the plume, the model simulations were based on 12 layers to adequately resolve the lake bathymetry. The refinements provided sufficient resolution to explore the factors that control the vertical movement of the contaminants moving from Building 1100 to Lake Druid.

The amount of transpiration from either the existing vegetation or by any proposed plantings was difficult to estimate. A generalized estimate of 1300 millimeters per year (51 inches per year) was available from the Florida Agricultural Extension Service for central Florida. An estimate of 500 millimeters per year (20 inches per year) was determined for nearby orange groves (19). Finally, a site-specific estimate of 200 to 300 millimeters per year (8 to 12 inches per year) was made by Vose and Elliot (16) for the existing mature trees over the down gradient end of the plume. The estimate was made by measuring the sapflow rate in nine trees in spring, summer, and fall. The estimate included only mature trees and did not account for the understory vegetation. Vose and Elliot (16) believed that this might not be too severe a limitation because the understory may be cycling shallow soil moisture, and they cite studies that show that understory transpiration can offset reduced overstory transpiration in open stands. The potential evapotranspiration at full stocking of the stand was 600 to 900 millimeters per year (24 to 35 inches per year), a higher value because of the relatively sparse distribution of the existing mature trees (also see Vose et al. this book). With the estimated precipitation of 1400 millimeters per year (55 inches per year) in central Florida, the estimated evapotranspiration ranges from 14 to 93 percent of that value. The lower values reflected the site-specific measurements.

These values suggested that in any case there was no strong driving force for removal of water from the aquifer by the vegetation. The generalized or regional estimate of evapotranspiration of 1300 millimeters per year (51 inches per year) came close to balancing precipitation. With the site-specific estimate of 200 to 300 millimeters per year (8 to 12 inches per year) accounting for some of the precipitation, the remainder would evaporate, contribute to soil moisture, or run off.

The MODFLOW results reproduced the presumed flow pattern in the cross section of the aquifer (Fig. 6). The simulated downward flow just down gradient of the paved area accurately reflects the observed plume (Fig. 4). The 12-layer representation of the aquifer allows adequate representation of the bathymetry of the lake in order to properly resolve the pattern of groundwater flow to the bottom of the lake. The discharge pattern was consistent with measurements of the attenuated plume emerging into the lake (data not shown in this chapter). The significance of these simulations was that the recharge and discharge patterns of the aquifer alone, can explain the vertical distribution of the contaminants (Fig. 4). Furthermore, the use of 12 thin layers to represent the surficial aquifer is unusual [see for example (18)] but necessary to represent a plume in this hydrogeologic setting.

These observations lead to the following strategies for phytoremediation at the site. First, the prospects for the trees transpiring sufficient water to pull the contaminant plume up to the root zone for treatment is too unlikely for phytoremediation alone to be considered as an adequate

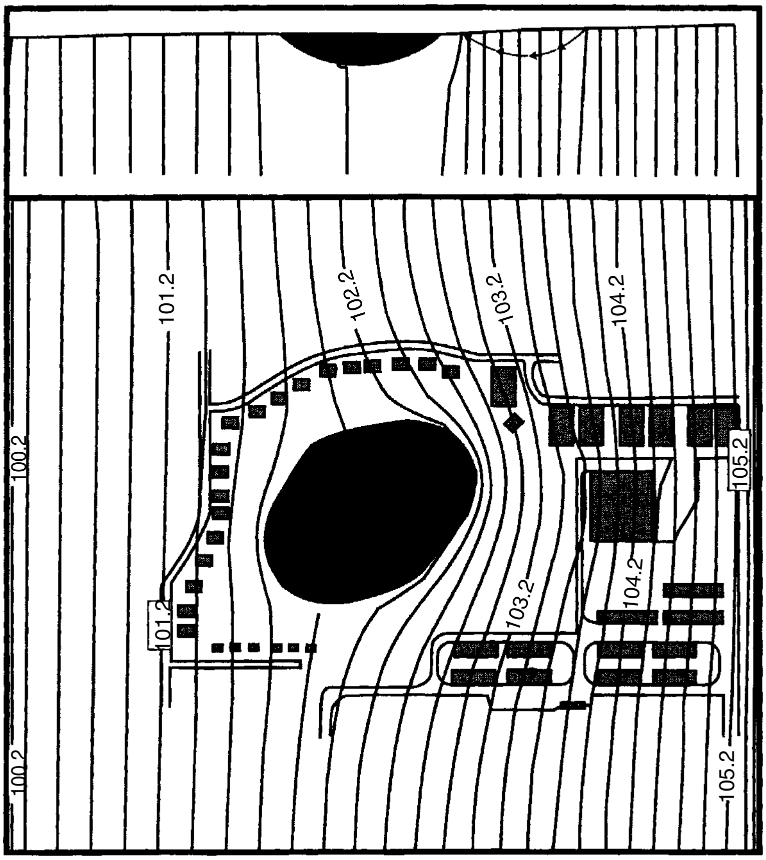

Figure 6. MODFLOW simulation of part of the Orlando, Florida U.S. Naval Training Center showing the effects of infiltration through the unlined ditch and upwelling at the shoreline. The upper panel represents a vertical section through the source and Lake Druid. The nearly vertical lines represent constant head contours, which correspond to the contours (labeled in feet above mean sea level; note that 1 foot is 0.3048 meter) on the plan view shown in the lower panel. The arrows in the upper panel represent a flow path from the unlined ditch to a discharge point along the shoreline. The scale is approximately 1:8280. The sides of the lower panel are vertically oriented north (top) to south (bottom).

cleanup remedy. This follows from the fact that the existing vegetation, extracting at least of 200 millimeters per year (8 inches per year), has not contained the existing contaminant plume.

Because the transpiration of trees alone cannot contain the plume, clearly the combined effects of replanted trees and natural attenuation in the seepage wetland and lake sediments needed to be investigated next. Nzengung (17) found significant potential for microbial and enzymatic degradation of chlorinated solvents in the wetland and lake sediments, thus requiring a refined hydraulic analysis. The refined analysis established that enhanced evapotranspiration would pull some of the plume upward into the seepage wetland and probably achieve better attenuation. This next investigation established more contact with a wider range of shallow rooted aquatic and wetland plants at the lakeshore without threatening the health of the existing wetland (Medina et al. this book). Nevertheless, the quantification of attenuation rates (17) was deemed too uncertain to forecast whether this enhanced natural attenuation would be sufficient without a field pilot investigation. These pilot investigations are currently (2003) underway. Because forecasting was not possible for the enhanced natural attenuation option, other supplemental design scenarios were also investigated. These included diversion of the surface runoff (from the impervious parking lots and roofs) from the unlined ditch to alleviate some plume diving, and planting more trees through the parking lot cover and over the source to contain the plume. Because of the ecological sensitivity of the seepage wetlands, an investigation of alternative planting was useful to avoid any temporary disruption of the wetland with supplemental planting if possible, especially to avoid planting alien species that are of regulatory concern to the State of Florida.

Simulations of eliminating the localized recharge to the aquifer at the edge of the parking lot established that most but not all of the downward movement of plume below the water table would be eliminated. However, some infiltration through the down gradient tree and shrub cover would continue because rainfall in this humid area exceeds potential evapotranspiration (Vose et al. this book). In addition, this sandy aquifer has high conductivity that limits contact of the plume with roots, wetland soils, and lake sediments, even under the best of conditions.

Finally, if trees were planted over the source zone, the simulations demonstrate that transpiration could remove water from the upper part of the aquifer despite the hydraulic conductivity. With the proper selection of trees that transform and degrade chlorinated solvents, some of the contaminated water could be treated, leaving less for natural attenuation. This could have the effect of removing contaminants from the aquifer, before the plume enters wetland soil and lake sediments. The MODFLOW results show that upward gradients would be established through the upper 7 meters (23 feet) of the aquifer if the evapotranspiration rate was 800 millimeters per year and through the upper 10 meters (30 feet) of the aquifer if the evapotranspiration was 1300 millimeters per year. These amounts exceed the site specific measured values of 200 to 300 millimeters per year (16) because the observed values were net values that integrated the effect of the trees working against infiltration. The higher values used in the model were selected because recharge was assumed to be zero due to the presence of the pavement. Forcing the trees to draw water from the aquifer exclusively over the source area maximized the impact on the contaminated portion of the aquifer by maximizing the withdrawal of water from the source zone. Overall, runoff diversion, tree planting over the source, and enhanced natural attenuation in the seepage wetland and nearer the lakeshore have the potential to manage contamination at this site but the uncertainty in enhanced attenuation requires a field pilot test to be sure this is the best remedy for this particular plume.

FEASIBILITY AND DESIGN IMPLICATIONS

Design of phytoremediation systems requires delineation of contaminant plumes and the parameters governing flow and transport in shallow aquifers. Because trees remove water and contaminants from the aquifer, estimates of evapotranspiration are needed to design phytocontainment systems. For the Joliet Army Ammunition Plant, the estimates were based on a forest evaporation model (7) using the Penman-Monteith equation (6) with climate data from the U.S. SAMSON database. From these readily available data, the feasibility of phytoremediation can be assessed.

Vertical delineation of contaminant plumes is best accomplished with short-screened or point sampling that eliminates (1) mixing of clean and contaminated water caused by screen placement that is only partly contained within the plume, and (2) averaging of concentration over long well screens. Both of these sampling effects or artifacts cause contaminant concentrations to be underestimated. Further, if the horizontal and vertical boundaries of the plume are not accurately defined, then transport processes are not correctly determined and phytoremediation potential can not be accurately assessed.

Sampling at the Orlando Naval Training Center revealed that the chlorinated solvent plume was depressed once the plume emerged from below the paved parking lot located adjacent to the source. Because of the presence of an unlined ditch adjacent to the parking lot, the plume dived due to localized recharge from the bottom of the unlined ditch. This plume characteristic was quantified with two models. These models included a simplified analytical solution of flow and a three dimensional numerical model of the site (MODFLOW) to simulate groundwater flow. Like the field data, the numerical model needed to be sufficiently resolved in the vertical to simulate the vertical distribution of flow and the bathymetry of the lake. Thus, a greater-than-usual number of layers were required for this phytocontainment assessment.

Both of these models showed that with reasonable rates of recharge and evapotranspiration and using some regional scale MODFLOW parameters, the observed plume diving could be accounted for just from the hydraulics of flow in the aquifer. Thus, the application of phytoremediation to this site was established as critically dependent upon the localized pattern of flow in the aquifer.

The analysis of the Naval Training Center site shows that the localized plume characteristics must be known to plan the locations for tree planting or design other remedial options for the site.

At the Naval Training Center, observations and simulations show that the contaminated water discharges to Lake Druid. Thus, the shoreline vegetation has the potential to intercept and treat the contaminated aquifer water. This interception of the groundwater flow is dependent upon evapotranspiration and all other characteristics of flow in the aquifer. Other elements of a remedy at this site include plume control by eliminating runoff from the parking lot to the unlined ditch. This would have the effect of preventing some of the downward migration of the contaminants. The depth of contamination at the source, however, is approximately 10 meters (34 feet). The depth of contamination is due to the location of the sump and the denser-than-water nature of the contaminants. If trees were planted and successfully grown at the source, then some of the contaminated water would migrate upward. The effectiveness of this source control depends upon the evapotranspiration rate that could be achieved by the trees and by the continued prevention of recharge in the parking lot.

Overall, runoff diversion, source phytocontainment, and phyto-enhancement of natural attenuation may be sufficient to remediate this site over a long period (until the nonaqueous phase is completely dissolved). However, due to the uncertainty in extrapolating treatment and attinuation kinetics, field pilot studies are necessary. These pilot investigations are underway at the Orlando site and other source removal remedies have been tested.

Acknowledgments

Dan Reible and John Quinn provided insightful and through peer reviews used in the evaluation of this chapter. Jerry Schnoor accepted a revised version of the chapter for this book. Support for the work came from the U.S. Environmental Protection Agency Office of Research and Development Contaminated Sites Program and a cooperative interagency research agreement with the U.S. Navy Southern Command. Cliff Casey of the U.S. Navy was instrumental in conceiving of and pursuing the work at the Orlando Naval Training Center. This chapter has been reviewed in accordance with the U.S. Environmental Protection Agency peer and administrative review policies and approved for publication. WELL DESIGN AND CONSTRUCTION

Nikolay Voutchkov
Poseidon Resources Corporation
Stamford, Connecticut

INTRODUCTION

Wells are used to collect groundwater from alluvial fresh water aquifers, saline water from brackish water aquifers, and seawater from beach shore aquifers. Wells are relatively simple to build, and the source water they collect is pretreated via slow filtration through the subsurface granular geologic formations in the area of source water extraction. Therefore, source water from wells is usually of better quality in terms of solids, silt, oil and grease, natural organic contamination, and pathogen content compared to source water collected from open surface water (i.e., river, lake, or ocean) intakes.

Key well performance characteristics are yield, static and pumping water levels, and cone of depression. Well yield indicates how much water can be withdrawn from a given well for a preset period of time. Well yield is typically measured in cubic meters per second (m^3/s) or cubic feet per second (cfs) for large wells and in liters per second (lps) or gallons per hour (gph) for small wells. Pumping and static water levels are the groundwater levels in the well when pumping from the well is on and off, respectively. When a well is operational, the surface of the groundwater level in the aquifer takes an inverted cone shape due to directional water flow toward the well. This inverted shape is called a cone of depression (Fig. 1).

Well type, size, and capacity are determined by a hydrogeologic investigation which typically includes the following key steps:

1. Complete a preliminary geologic survey to identify if the selected site is generally suitable for constructing of subsurface water intake.
2. Drill-test to collect samples of the aquifer formation deposits for visual classification and grain-size distribution analysis.
3. Install one or more test wells and observation wells, and conduct a pumping test to determine the site-specific hydraulic characteristics of the aquifer for subsurface system design and determination of the intake system yield.
4. Collect an adequate amount of samples of the source water and analyze sample water quality, with special emphasis on the content of iron, manganese, barium, strontium, silica, radon, carbon dioxide, arsenic, and hydrogen sulfide in the source water. If the aquifer water quality is under the influence of a surface water source (i.e., river, lake, ocean) whose quality and quantity vary seasonally, then complete year-round intake water quality sampling to determine seasonal fluctuations of source water quality.
5. If the subsurface intake system requires multiple collection facilities (wells, or infiltration galleries/river bank filtration facilities), then complete a computer model analysis to establish the response of the production aquifer to pumping and the potential impact of groundwater collection on adjacent fresh or saline water aquifers, which could interact with the water supply aquifer.

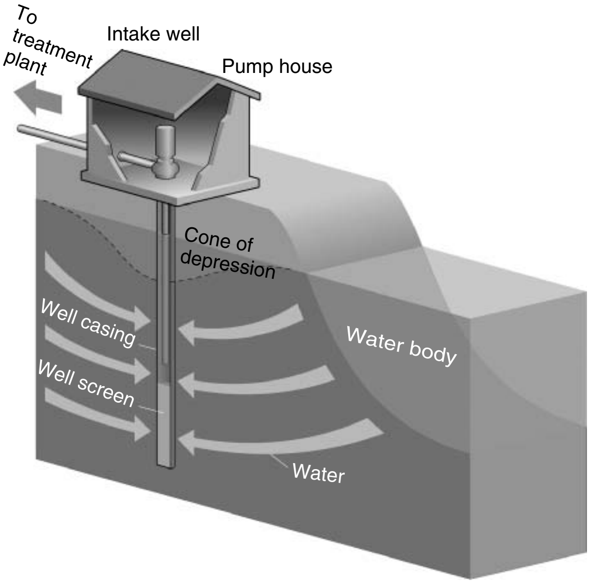

Figure 1. Vertical intake well.

The key factors that determine if the use of subsurface intake is practical or/and economical are the type of the water source aquifer (confined vs. unconfined); the aquifer permeability (hydraulic conductivity), which is a measure of the velocity of water movement through the ground (typically measured in m/s); the average specific yield (productivity) of the aquifer (in m^3/day per linear meter of riverbank or seashore along which the collector wells are located); the thickness of the production aquifer deposits; and the existence of nearby fresh or brackish water aquifers, which could be negatively impacted by the intake well operations or may have a measurable effect on intake well water quality. A confined aquifer (also often referred to as an artesian aquifer) is a water saturated geologic formation between two layers of low permeability (i.e., bedrock) that restrict the vertical movement of the groundwater in or out of the aquifer. Confined aquifers are often contained by the surrounding geologic formations and are pressurized therefore, collecting water from such aquifers may not require pumping. Unconfined aquifers are groundwater saturated formations whose upper surface (commonly referred to as the water table) fluctuates over time. Aquifer water table fluctuation is driven by recharge from surface runoff (rain or snowmelt)

INTRODUCTION

Wells are used to collect groundwater from alluvial fresh water aquifers, saline water from brackish water aquifers, and seawater from beach shore aquifers. Wells are relatively simple to build, and the source water they collect is pretreated via slow filtration through the subsurface granular geologic formations in the area of source water extraction. Therefore, source water from wells is usually of better quality in terms of solids, silt, oil and grease, natural organic contamination, and pathogen content compared to source water collected from open surface water (i.e., river, lake, or ocean) intakes.

Key well performance characteristics are yield, static and pumping water levels, and cone of depression. Well yield indicates how much water can be withdrawn from a given well for a preset period of time. Well yield is typically measured in cubic meters per second (m^3/s) or cubic feet per second (cfs) for large wells and in liters per second (lps) or gallons per hour (gph) for small wells. Pumping and static water levels are the groundwater levels in the well when pumping from the well is on and off, respectively. When a well is operational, the surface of the groundwater level in the aquifer takes an inverted cone shape due to directional water flow toward the well. This inverted shape is called a cone of depression (Fig. 1).

Well type, size, and capacity are determined by a hydrogeologic investigation which typically includes the following key steps:

1. Complete a preliminary geologic survey to identify if the selected site is generally suitable for constructing of subsurface water intake.
2. Drill-test to collect samples of the aquifer formation deposits for visual classification and grain-size distribution analysis.
3. Install one or more test wells and observation wells, and conduct a pumping test to determine the site-specific hydraulic characteristics of the aquifer for subsurface system design and determination of the intake system yield.
4. Collect an adequate amount of samples of the source water and analyze sample water quality, with special emphasis on the content of iron, manganese, barium, strontium, silica, radon, carbon dioxide, arsenic, and hydrogen sulfide in the source water. If the aquifer water quality is under the influence of a surface water source (i.e., river, lake, ocean) whose quality and quantity vary seasonally, then complete year-round intake water quality sampling to determine seasonal fluctuations of source water quality.

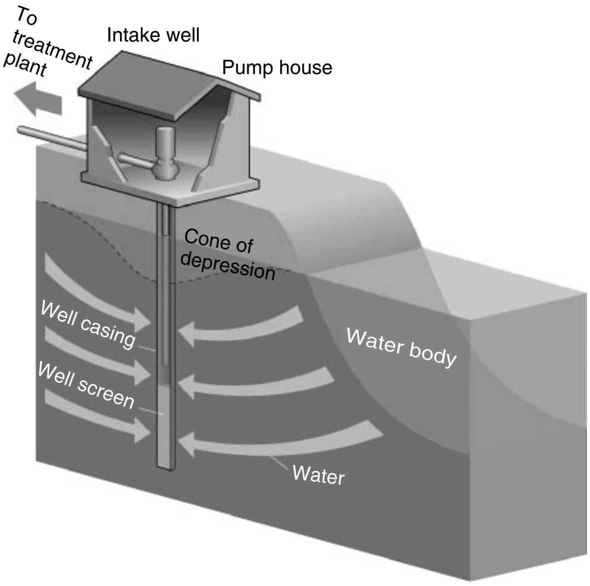

Figure 1. Vertical intake well.

5. If the subsurface intake system requires multiple collection facilities (wells, or infiltration galleries/river bank filtration facilities), then complete a computer model analysis to establish the response of the production aquifer to pumping and the potential impact of groundwater collection on adjacent fresh or saline water aquifers, which could interact with the water supply aquifer.

The key factors that determine if the use of subsurface intake is practical or/and economical are the type of the water source aquifer (confined vs. unconfined); the aquifer permeability (hydraulic conductivity), which is a measure of the velocity of water movement through the ground (typically measured in m/s); the average specific yield (productivity) of the aquifer (in m^3/day per linear meter of riverbank or seashore along which the collector wells are located); the thickness of the production aquifer deposits; and the existence of nearby fresh or brackish water aquifers, which could be negatively impacted by the intake well operations or may have a measurable effect on intake well water quality. A confined aquifer (also often referred to as an artesian aquifer) is a water saturated geologic formation between two layers of low permeability (i.e., bedrock) that restrict the vertical movement of the groundwater in or out of the aquifer. Confined aquifers are often contained by the surrounding geologic formations and are pressurized therefore, collecting water from such aquifers may not require pumping. Unconfined aquifers are groundwater saturated formations whose upper surface (commonly referred to as the water table) fluctuates over time. Aquifer water table fluctuation is driven by recharge from surface runoff (rain or snowmelt) or fluctuation of the water table of the surface waterbody (river, lake, etc.) connected to the aquifer.

Unconfined alluvial aquifers located along riverbanks are commonly used for freshwater supplies. Confined or semiconfined aquifers yield the most suitable source of water for brackish water desalination systems (1). Aquifers that favor the construction of wells are coarse-grained, porous, and highly permeable geologic formations (i.e., sand, gravel, and limestone) connected to a riverbed (for freshwater intakes) or the ocean floor (for seawater intakes) whose specific yield (transmissivity) exceeds 1,500 m^3/day/m and whose water carrying zone is at least 6 meters (20 feet) deep (2). The higher the aquifer permeability, transmissivity, and thickness, the larger the well yield the aquifer can support.

WELL SITE SELECTION

Once an aquifer of suitable yield has been identified, the location of the actual field is to be selected. Whenever possible, the well field should be located perpendicularly to the main direction of groundwater flow (i.e., along the banks of a nearby river). The most suitable location for collecting a large amount of river water is on a river island or within a meander. If significant clogging of the riverbed is expected, then the wells should be located closer to the riverbanks.

In addition, a potable water well field has to be sited away and uphill from potential contamination sources such as septic tanks, landfills, industrial plants, and underground fuel storage tanks. Most states regulate the location of private potable water wells and require locating wells at least 15 to 30 meters (50 to 100 feet) away from septic systems.

INTAKE WELL TYPES AND KEY DESIGN CRITERIA

Intake wells are typically vertical or horizontal water collectors drilled into the source water aquifer. Vertical intake wells are usually less costly than horizontal wells, but their yield is relatively small, typically, 0.004 to 0.044 m^3/s (0.1 to 1.0 MGD). Therefore, vertical wells are typically used for supplying relatively small quantities of water usually less than 20,000 m^3/day (5 MGD).

Vertical Intake Wells

Vertical intake wells consist of the following key elements: a casing, well screen, filter pack, well seal, and surface seal. Many wells have submersible or vertical turbine pumps installed inside the well casing (Fig. 1). A well casing is a steel or nonmetallic (typically, fiberglass) pipe which lines the well borehole to protect the well from caving in. Most state standards require steel casings for freshwater supply wells and specify the thickness of the casing. The diameter of the casing has to house the well intake pump and provide ample room for pump service. The diameter of the well casing is determined mainly by the well screen size and yield, but the well borehole diameter has to be at least 0.1 meters (4 in.) larger than the well casing to accommodate the installation of the well seal. Usually, the well casing diameter is between 200 and 1200 mm (8 and 48 in.), and the well depth is typically less than 75 meters (250 feet).

The well screen is the intake portion of the well and is a sieve-like structure that has slotted or perforated openings. The well screen is located at a depth corresponding to the water carrying zone of the aquifer. Screen depth, size of openings, diameter, and length are key well performance design criteria. These well parameters are selected to maximize a well's safe yield; control well entrance velocity; and to avoid excessive entrance of sand and other particulates, which have a negative impact on well useful life and water quality. The performance of the well screen is enhanced by a gravel (filter) pack, which consists of clean, uniform, and well rounded gravel and sand placed between the borehole wall and the well screen to prefilter the groundwater entering the well. Typically, the gravel pack depth extends at least 1 meter (3 feet) above the well screen. A well seal is installed above the filter pack to prevent soil and contaminants from entering the well screen area. The well seal is a cylindrical layer of cement, bentonite, or clay placed in the annulus of the well between the well casting and the borehole. Typically, the well seal extends at least 0.6 meters (2 feet) above the top of the gravel pack and usually through the elevation of the soil frost zone. The aboveground portion of the well is finished with a concrete surface seal. The surface and well seals protect the well from surface runoff contamination and support the casing.

A detailed methodology for sizing well screen diameter, length, openings and capacity, and for selecting the grain size of the material for the gravel pack is presented elsewhere (3). This source also provides information on determining the thickness of the gravel pack around the well screen, the permissible approach velocity of the water stream converging to the well, and ultimately the design capacity of a new well or the maximum capacity of an existing well.

Once constructed, vertical well performance has to be monitored frequently to secure long-term performance and identify early signs of potential malfunction and failure. The most common causes of well failure are borehole collapse, corrosion of the casing, improper or defective construction techniques, growth of organisms within the well borehole, and formation of mineral concentrations or crusts in the open-hole or screened section of the well borehole.

Horizontal Collector Wells

Horizontal (Ranney) collector wells consist of a caisson that extends below the ground surface and has water well collector screens (laterals) projected horizontally from inside the caisson into the surrounding aquifer (Fig. 2). The well screens in the collector wells are placed horizontally, but a higher rate of source water collection is possible than that of vertical wells, which allows, collecting the same intake water quantity with fewer wells.

Individual horizontal intake wells are typically designed to collect from 0.0044 to 1.75 m^3/s (0.1 to 40.0 MGD) of source water per well. The largest 1.75 m^3/s (40 MGD) horizontal collector wells in the United States were installed on the banks of the Platte River in 1990

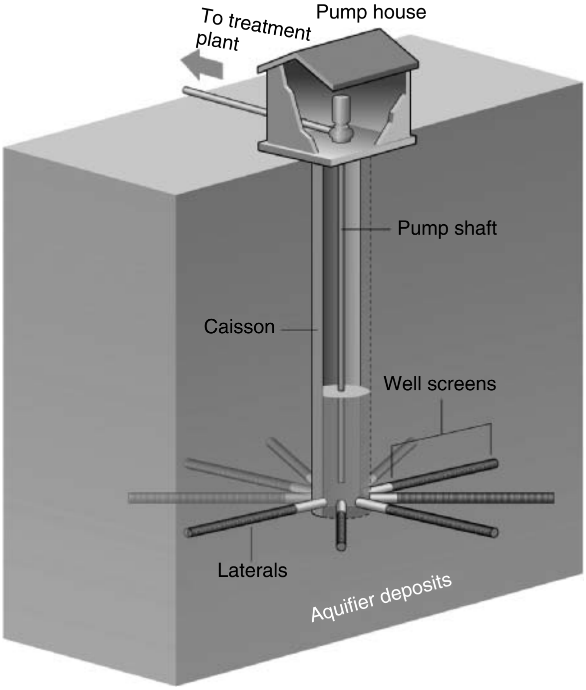

Figure 2. Horizontal collector well.

for water supply to the City of Lincoln, Nebraska. In the United States, utilities use horizontal collector wells whose laterals are located directly under the riverbed.

The caisson of the horizontal collector well is constructed of reinforced concrete of 2.7 to 6.0 m (9 feet to 20 feet) inside diameter and a wall thickness of approximately 0.5 to 1.0 meters (1.5 to 3.0 feet). The caisson depth varies according to site-specific geologic conditions, ranging from approximately 10 meters to over 45 meters (30 to 150 feet).

The number, length, and location of the horizontal laterals are determined by a detailed hydrogeologic investigation. Typically, the diameter of the laterals ranges from 0.2 to 0.3 meters (8 to 12 inches) and their length extends up to 60 meters (200 feet). The size of the lateral screens is selected to accommodate the grain size of the underground soil formation. If necessary, an artificial gravel-pack filter can be installed around the screens to suit finer grained deposits. Usually, one well has 2 to 14 laterals.

When horizontal wells are used for fresh or brackish groundwater intake, the caisson is extended above the floodplain elevation for this location to protect the pumping equipment, electrical, and instrumentation and control equipment from flooding. When used as seawater beach wells, especially for smaller size applications, Ranney-type wells can be constructed watertight at or below grade to minimize their visual impact on the shoreline. In large intake capacity applications, horizontal beach wells are typically coupled so that the intake pump station is installed above the well caisson. The well intake pump station can be designed with submersible pumps to minimize noise. However, for medium and larger size wells, most frequently vertical turbine pumps are used because these pumps usually have higher energy efficiency and require less power. A more detailed description of horizontal collector well design and construction is presented elsewhere (4).

Infiltration Galleries

Infiltration galleries are riverbank or seashore filtration systems that are typically implemented when conventional horizontal or vertical intake wells cannot be used because of unfavorable hydrogeologic conditions. For example, they are suitable for intakes where the permeability of the underground soil formation is relatively low, or for river or seashore filtration, where the thickness of the beach or the onshore sediments is insufficient to develop conventional intake wells.

Infiltration galleries consist of an excavation trench which is filled with filtration media of size and depth similar to that of the granular media filters used for conventional water treatment plants. Vertical or horizontal collector wells are installed at equal distances (usually 30 to 60 meters) inside the filter media. Typically the capacity of a single collection well is 0.009 to 0.09 m^3/s (0.2 to 2.0 MGD).

A common type of infiltration gallery is a horizontal well collection system that has a single trench (Fig. 3). The media in the wells are configured in three distinctive layers: a bottom layer of sand of approximately 2 to 3.5 meters (6 to 10 feet), followed by a 1.2 to 2 meter (4 to 6 feet) layer of graded gravel pack surrounding the horizontal well collector screens, topped by a (6 to 9 meter) (20- to 30-foot) layer of sand. Horizontal well collector screens are typically designed for an inflow velocity of 3 cm/s (0.1 ft/s) or less.

Infiltration galleries can be designed either similarly to conventional rapid sand filters (if the natural source water movement, such as river flow or ocean water wave motion, can provide adequate flushing of the infiltration gallery media contact surface with the waterbody) or can be constructed as slow sand filtration systems, which have at least a 9-meter (30-feet) layer of sand overlying the collection well screens. Infiltration galleries are usually 15 to 20% more costly to construct than conventional vertical or horizontal intake wells, and therefore, their use is warranted only when the hyrogeologic conditions of the intake site are not suitable for conventional intake wells.

Riverbed/Seabed Filtration Intake Systems

These intake systems consist of a submerged, slow sand medium filtration system (filtration bed) located in a riverbed or in the near-shore surf zone of the ocean floor (Fig. 4). The filtration bed is connected to a series of intake wells located on the shore via tunnels or horizontal collector pipes.

The filtration bed is sized and configured using design criteria similar to those for slow sand water treatment plant filters. The filter bed depth is typically between 0.9 m and 1.2 m (3 to 4 ft). The gravel supporting the filter bed's sand is 0.15 to 0.5 m (0.5 to 1.5 ft) deep. The design surface loading rate of the filter medium is typically between 0.05 and 0.2 m^3/m^2h (0.2 and 0.8 gpm/sq ft). Similar to slow sand filters, a mat of natural organic materials is formed on the surface of the filtration bed. This mat enhances removal of organics and fine particles from the source

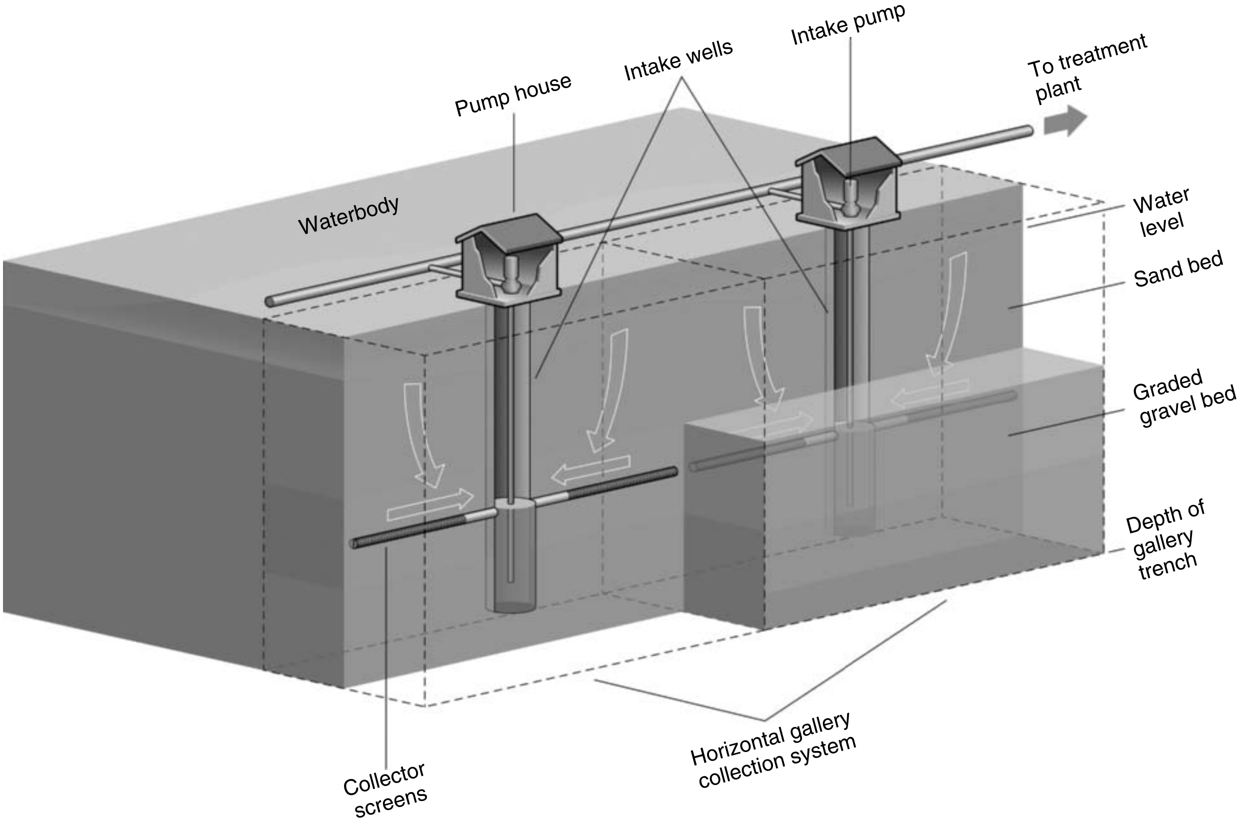

Figure 3. Infiltration gallery.

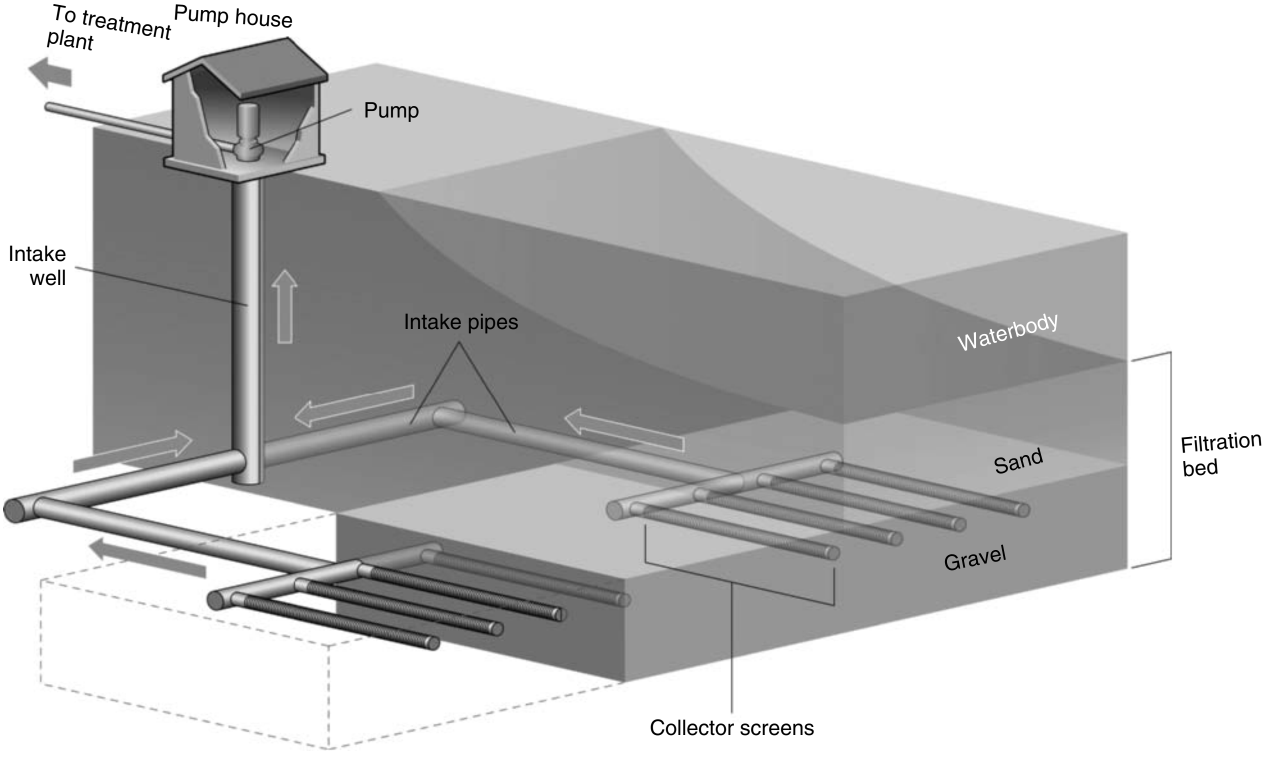

Figure 4. Riverbed/seabed filtration intake system.

water. The surface filtration mat is often removed from the surface of the filtration bed by naturally occurring seasonal scouring, such as river flooding or storms. When the mat is removed and some of the filtration bed sand is lost over time, the sand medium has to be replaced to its original depth to maintain filtration bed efficiency.

An alternative riverbed filtration system, which consists of a soft-soil tunnel constructed in the sand and gravel aquifer, whose well screens extend horizontally from the tunnel under the river, has been designed on the Ohio River for the Louisville Water Company in Kentucky (2). The riverbed filtration system consists of twenty-three 61-meter (200-ft) long laterals located at an equidistance of 79.3 meters (260 ft) in the riverbed, connected to the collection tunnel of a total length of 1830 meters (6000 ft). The laterals are 0.3 m in diameter, and the riverbed serves as a natural slow sand filtration system. The experience gained at Louisville indicates that the maximum water yield of this system is 0.22 to 0.31 m^3/s (5 to 7 MGD) per 305 m (1000 feet) of riverbank length.

The largest seawater desalination plant with a seabed intake system currently under construction is the 0.58 m^3/s (13.2 MGD) Fukuoka District RO facility in Japan. This plant is planned to be operational in late 2005. The Fukuoka seawater desalination plant seabed intake area is 30,000 m^2 (312,000 sq ft).

Typically, riverbed and seabed filtration intakes are the costliest well intake systems. Their construction costs are approximately 1.2 to 2.3 times higher than those of conventional intake wells (5).

PHYSICAL PROPERTIES OF DNAPLs AND GROUNDWATER CONTAMINATION

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

The physical behavior of dense nonaqueous phase liquids (DNAPLs) can broadly be divided between two classes based on melting point. Polynuclear aromatic hydrocarbons (PAHs) have melting points that are at the lowest, 80 °C (for naphthalene). Consequently, PAHs are solids at the temperatures typical in the subsurface; thus, the potential for migration through the soil column or groundwater systems is limited. Cosolvents can make PAHs soluble and mobile; however, the PAH solutions (when dissolved by petroleum hydrocarbons) are typically lighter than water and do not behave as DNAPLs. The second class of DNAPLs are chlorinated solvents. These compounds are liquids at normal subsurface temperatures, making them extremely mobile in unsaturated and saturated zone soils. Here we discuss those and other properties that make contamination by chlorinated solvents one of the most ubiquitous and recalcitrant of groundwater problems. A good overview of chlorinated solvent characteristics and remediation is included in Pankow and Cherry (1).

The introduction of chlorinated solvents was perceived as a great innovation for safety and an improvement in the quality of the degreasers. Prior to that introduction, distilled mineral spirits were the only available solvents. Explosions and fires from mineral spirits were a constant threat and occurrence causing death and injury. In today's climate where risk is evaluated in terms of one event in a million cancer risk, there are numerous lives saved through the use of chlorinated solvents. One of the most common chlorinated solvents is tetrachloroethene, also called perchloroethene (PCE) or "perc." This solvent is mostly associated with dry cleaner leaks. Another commonly used industrial degreaser, trichloroethene (TCE), has been found at many industrial facilities.

The properties that make chlorinated solvents so problematic with regard to groundwater contamination include density, solubility, viscosity, surface tension, and dehydration.

Chlorinated solvents are significantly denser than water. The density values in g/cm^3 (water is 1.00) are:

1,1-Dichloroethane (1,1-DCA)	1.18
1,1-Dichloroethene (1,1-DCE)	1.22
Trichloroethane (TCA)	1.34
Trichloroethene (TCE)	1.46
Tetrachloroethene or perchloroethylene (PCE)	1.62

Upon release into the environment, DNAPLs sink through the vadose zone, through the water table, and, over the long-term, through aquitards. A release of chlorinated solvents will travel downward or laterally until it has been exposed to a volume of soil sufficient to retain the released DNAPLs in pore spaces within the soil matrix.

Due to high density, chlorinated solvents can flow upgradient to the groundwater flow along the down dip surface of an aquitard. The most problematic phenomenon caused by high density chlorinated solvents is the dimple effect. Upon release, chlorinated solvents will travel to an aquitard and seek the lowest point on the surface of that aquitard. It is unlikely that any given stratigraphic unit acting as an aquitard is perfectly planar; it will have small to large dips, depressions, and dimples. Each of these can act as a reservoir for DNAPLs. These reservoirs will be outside an advective flow regime set up by a "pump and treat" groundwater system. The only means of transport from these reservoirs is through diffusion, which is effective enough to cause significant dissolved phase contamination, but not effective enough to offer timely remediation.

Chlorinated solvents are soluble in water. Values in mg/L are:

1,1-DCA	5100
1,1-DCE	400
TCA	700
TCE	1100
PCE	200

These levels of solubility represent significant potential for groundwater transport of released chlorinated solvents in the dissolved phase.

Most chlorinated solvents are less viscous than water. Values in centiposes (water is 1.00) are:

1,1-DCA	0.51
1,1-DCE	0.36
TCA	0.90
TCE	0.57
PCE	0.93

The low viscosity makes chlorinated solvents extremely mobile in the vadose zone; they can readily flow through flow channels that may be as small as a human hair.

The surface tension of chlorinated solvents with respect to water has significant impact on the manner in which chlorinated solvents penetrate the capillary fringe zone and then migrate through the saturated zone. Water has a high surface tension of 73 dyn/cm; chlorinated solvents have surface tensions in the range of 20–40 dyn/cm. When free phase chlorinated solvents migrate to the capillary fringe, they will be held up until a head is built up sufficient to overcome the capillary retention of the water. The capillary retention is directly proportional to the interfacial tension and inversely proportional to the pore throat radius and liquid density. The smaller the pore size, the greater the head required to displace entrained water. This can result in significant lateral spreading of a DNAPLs release above the capillary fringe in fine grained soils.

Another effect of surface tension forces involves how surfaces in larger pore spaces are wetted. The tendency of one fluid to replace another on a surface is termed wettability.

As broad rules, the following apply:

In soil, water is the wettting fluid with respect to solvents or air.

Solvents are wetting fluids in air, but not in the presence of water.

With respect to carbonaceous soil components, solvents are wetting in the presence of air or water.

Free phase chlorinated solvents have the capacity to dehydrate clays, causing cracking and further migration through what at first analysis appears to be impermeable layers. Bentonite pellets used to seal wells in areas contaminated with DNAPLs may not work, due the failure of the bentonite to swell in those conditions. DNAPLs can also migrate through previously installed and sealed wells via the same mechanism.

All of the above phenomena impact the fate and transport of DNAPLs to and through groundwater systems. Those physical properties also manifest themselves by the nature of a given release. The release of a large volume of DNAPLs in a short period of time causes rapid migration laterally as well as downward through the vadose and saturated zone that overcomes any small permeability differences. This leaves a significant volume of residual contamination entrained in the zone of passage. Conversely, DNAPLs release that occurs slowly over a long period of time will travel through narrow channels representing the most permeable path through the subsurface. Small differences in permeability will be exploited under these conditions. Under slow release conditions, less of the DNAPLs is entrained within the soil matrix: the overall potential for vertical migration is greater, more DNAPLs will penetrate to a greater depth, and the potential to impact groundwater is also greater.

Subsurface “dimples”—slight depressions or irregularities at the top of an underlying aquitard where DNAPLs may collect—have been observed. These features are difficult to locate.

The overall effect of the physical properties described above, particularly where the “dimple” effect is manifest, may make timely remediation of groundwater contaminated with DNAPLs impossible. In those instances, the most economic method of protecting health will lie in municipal or point of use treatment systems for the recovered groundwater.

WATER DOWSING (WITCHING)

David P. Commander
Water and Rivers Commission
East Perth, Australia

‘Water dowsing’ is the supposed ability to locate underground water using a simple handheld device such as a forked stick, bent wires, or a plumb bob. ‘Dowsing’ is the general term applied to ‘divining’ for objects or materials concealed beneath the ground. Divining, or divination, implies a supernatural intervention and has been practiced for at least 2000 years for a variety of purposes. Water dowsing is also known as water witching.

To dowse for water, the ‘diviner’ walks along the ground holding the device, which then ‘responds’ to the presence of an ‘underground stream.’ The traditional European divining rod is a forked hazel twig, which is grasped in both hands and bent under tension; the ends held horizontal and point, forward. Only a slight involuntary movement on the part of the operator is then needed to make the twig jerk downward. Other such methods in use are two pieces of bent wire, one in each hand, which then cross to indicate the 'underground stream,' or a plumb bob, which begins to rotate.

The concept relies on the hypothesis that groundwater occurs in streams, similar to surface water. A diviner can then trace the path of an 'underground stream' from the surface. He may pick up several streams and indicate where they cross. A successful bore or well must be sunk exactly on the stream, or failure will be justified by having missed the 'stream.' Some diviners also claim to be able to detect the salinity of the underground water, or the depth of the water table, water-bearing strata or fracture, and the likely well yield.

There is vast literature on dowsing, and modern texts can be found in 'New Age' bookshops. Water witching is carried out in all hydrogeologic environments, ranging from extensive shallow aquifers, where success is assured, to fractured rock terrains in which success rates are poor. However, scientifically constructed tests always produce statistically random results, often to the chagrin of the diviner, who may have a real belief in his ability to dowse for underground water. Water witchers often have experience and local knowledge that aids them in selecting of favorable areas before actually applying the technique to locate an exact drilling site.

Dowsing with a forked twig was first mentioned in 1556 by Georgius Agricola in his descriptions of mining practices in the Harz Mountains of central Germany where the diving rod was being used supposedly to locate mineral veins (Fig. 1). Agricola mentions that the material for the twig was selected for different minerals, for instance, hazel for silver and ash for copper. Agricola is scathing about the practice, referring to dowsers as cunning manipulators and to the faith among common miners 1.

The practice of water dowsing spread through Europe in the seventeenth century, and then to North America and Australasia, where it is a widely held belief among farmers. The first mention of divining applied to water was apparently to locate a well for a convent in Spain (from a life of Saint Theresa, in Ref. 2, p. 171) in 1568. However, Arthur J. Ellis (3), who comprehensively reviewed the history of water witching, suggested that the practice gained wider credence from the activities of Baron and Baroness de Beausoleil in the early 1600s. The Beausoleils traveled through mining areas, even visiting

Figure 1. Use of divining rods in prospecting for ore 1. (From Agricola, De re metallica, German edition, 1580).

America, and the Baroness apparently used divining to discover the Chateau Thierry mineral water in France. After this, the divining rod seems to have been exclusively applied to locating groundwater, no doubt because of the interest in mineral water at the time and the high success rate of water wells in northern Europe. Connection with witchcraft led to the name water witching, which is used exclusively in North America.

SUBSURFACE DRAINAGE

Harendra S. Chauhan
G.B. Pant University of
Agriculture and Technology
Uttar Pradesh, India

The basic reason for agricultural lands to be affected by waterlogging and salinity is the inadequacy of the natural drainage system to handle the water that reaches the land either by natural or artificial means. Under such situations, an artificial drainage system has to be provided. The meaning of land drainage varies in different regions and contexts. A geographer or a surface hydrologist may use it to mean the pattern of natural watercourses in a hilly area. A pedologist may think in terms of the permeability of a poorly drained or well-drained soil. In Peru, engineers interpret drainage as reconstruction of natural waterways rather than removal of water. In Canada, it may mean reclamation of marshland for agricultural or urban development. In Holland, a Dutch farmer may use it for the installation of drainpipe in the soil. Thus, in different areas, this term implies different meanings and objectives. If the land use is primarily agricultural then land drainage could be defined as the establishment and operation of a system by which the flow of water from the soil is enhanced, so that agriculture can benefit from the subsequently reduced or controlled water level in the soil. Agricultural land drainage aims at reclaiming and conserving land for agriculture, to increase crop yields, to permit cultivating more than one crop in an area, and to reduce the cost of production

INTRODUCTION

There are no hard and fast lines between the objectives of different kinds of agricultural drainage, but broadly there are two types of drainage, surface drainage and subsurface drainage. Surface drainage is the removal of excess water from the land surface to create more favorable conditions for plant growth. Subsurface drainage is the removal or control of groundwater and/or removal or control of salts using water as the vehicle. The excess water may be from precipitation, water applied in irrigation, losses from conveyance channels and storage systems, and water that has seeped from groundwater in upper reaches. It is the drainage of excess water from the land surface at a rate that will prevent long periods of ponding without excessive erosion, so that crops would have favorable moisture conditions. Any drain or well-designed system to control or lower the groundwater is considered subsurface drainage. It can be broadly classified in two categories as (1) horizontal drainage and (2) vertical drainage. The other category of drainage frequently referred to nowadays is biodrainage. The objective of this article is to discuss various aspects of subsurface drainage. The main focus will be on horizontal drainage hereafter referred to as subsurface drainage. Vertical drainage and biodrainage will also be discussed briefly later.

HISTORICAL PERSPECTIVE

Agricultural drainage to improve crop production is an age-old concept that has been used with profitable results for quite some time in the past with different orientations and variations. Even though agricultural drainage is discussed in ancient Greek history, its development in different parts of the world is not very well known. In Greek civilization, some areas were reclaimed by systems of ditches. Drainage of humid and semi-humid areas started in the tenth century and extended to different parts of Europe in the sixteenth and seventeenth centuries. Herodotus has referred to the oldest instance of drainage in 400 B.C. by the Egyptians in the Nile Valley. In the United Kingdom, the earliest work is traced to the thirteenth century when Romney marsh was reclaimed, but the major work was carried out about 250 years before. In the United States, the first tile drains were laid by John Johnson of New York for a total length of 56 km. Due to the import of tiling machines in 1848 more than 100 tile factories existed in Illinois, Indiana, and Ohio. By 1882, about 43,230 km of tile drains were installed in Indiana alone. The Bureau of Reclamation had constructed about 4990 km of drains in 1931. By this time, subsurface drains had been installed extensively in most of the states in the United States.

In India, the problem of waterlogging and soil salinity were observed in village Munak in the former Punjab as early as 1855. Due to the construction of large canal systems, salinity was observed in several areas. In the Ganges canal, salinity was observed in 1876, and in lower Chenab canals, it was observed after these canals opened in 1892. The first subsurface drainage experiment was laid out in India in 1873, although it was not considered successful. In Punjab, a Waterlogging Board was constituted in 1925. In 1928, Inglis and Gokhale established that subsurface drainage is effective in lowering the water table at the Baramati farm.

The earliest drainage method consisted of making drains from stones. With the use of stones, the old method of drainage by open trenches was abandoned. Another method of draining permanent pastures was through turf drains the remains of which can still be seen in many fields in the mid lands in the United Kingdom. Some of these even had useful lives of 100 years. Besides turf drains, other varieties of drains were plug drains principally used in arable lands, straw drains used extensively in the heavy land districts, and brushwood drains made from fagots or bundles of brushwood, which were placed at in the bottom of deep trenches. Then, came brick drains followed by U-tiles or horseshoe drains. The last to come were cylindrical brick tiles or clay tiles, which have now been replaced by PVC perforated/corrugated pipes.

HORIZONTAL SUBSURFACE DRAINAGE

Buried pipes, pipeless drains, or deep open ditches are commonly used to drain lands in this kind of drainage. Pipe drains consist of a system of tiles or pipes such that excess water enters in lateral lines through the joints between two tiles or perforations in the pipes and flows towards collector/main drains. Pipeless drains, called mole drains, are cylindrical channels artificially made in the subsoil by a mole plow. When the cost of regular pipe drains becomes too high due to close spacing, mole drains are used. The principles and hydraulics of mole drains are similar to those of pipe drains. It is a temporary method of drainage because moles deteriorate in a few years and have to be remade frequently. Deep open ditches, if constructed close enough, can work similarly to pipe drains or mole drains to lower the water table and remove excess water. Practically, open ditches are difficult to maintain and cause a lot of inconvenience to men, animals, and farm equipment that cross them.

SUBSURFACE DRAINAGE THEORIES

A number of mathematical solutions have been proposed to describe water table behavior and to evolve drainage criteria for appropriate design of drainage systems, using steady-state or transient flow conditions in horizontal or sloping aquifers. The solutions have been obtained by employing experimental, analytical, or numerical approaches. These solutions help to evolve drainage criteria that help in determining the drainage rate and spacing for a preselected suitable depth of drains, depending on soil characteristics and water table height midway between drains. The basic objective of evolving drainage criteria is to attain and maintain an optimum or a reasonably permissible value of average water table depth and root zone that is either free from salts or has electrical conductivity below the tolerance limit of the plants to get the maximum net benefit. Some of the theories are presented here.

Steady State

In this situation, recharge due to rainfall or irrigation is assumed constant and equal to the discharge from drains, such that water table does not change with time. This criterion describes the quantity of water to be removed in a given period of time under conditions of given water table height above the drain level. This criterion is generally applicable in flat areas of a humid region, where low intensity, long duration rainfall occurs in winter and spring. By selecting appropriate soil water hydrologic parameters, it can also be used for arid salt-affected lands. Based on this theory, Colding (1), Rothe (2), Kozeny (3), and Hooghoudt (4) obtained the same relationship independently. Hooghoudt (5), based on the Dupuit–Forchheimer assumptions, proposed an equation for computing of drain spacing as

$$L^2 = \frac{4Kh_0(2d + h_0)}{q} \tag{1}$$

where L is the drain spacing, K is the hydraulic conductivity of the soil, d is the depth to an impermeable layer below the drain axis, q is the rate of recharge, and h_0 is the height of the water table above the drain axis at the midpoint between the drains. It is more appropriately applicable only when the depth to impermeable layer d is relatively small compared to h. For comparatively large values of d, the flow to drains will tend to be radial. To account for the extra resistance caused by radial flow, Hooghoudt introduced the concept of equivalent depth (d_e), such that d is replaced by d_e. In such cases, Equation 1 may be written as

$$L^2 = \frac{8K_b d_e h_0 + 4K_a h_0^2}{q} \tag{2}$$

In this equation, K_a and K_b are the hydraulic conductivities of the soil above and below the drain, levels. The first term pertains to flow below the drains and the second term indicates flow above the drains.

Ernst (6) extended Hooghoudt's approach to make it applicable to stratified soils that have a slowly permeable top layer. He assumed horizontal and radial flow resistance in his analysis. His solution is simple, but the presence of the geometry factor in the solution makes it slightly cumbersome for practical applicability. Nomographs developed by Van Beers (7) made Ernst's solution simpler for practical purposes.

Kirkham (8) obtained an analytical solution for a problem similar to Hooghoudt's, using potential theory and ignoring the flow above the drains. Later on Kirkham (9) reported that, if vertical flow in the upper region is also taken into account, the solution becomes

$$h = \frac{qL}{K}\left(\frac{1}{1 - q/K}\right)F_k \tag{3}$$

where

$$F_k = \frac{(L - d\sqrt{2})^2}{8dL} + \frac{1}{\pi}\ln\left(\frac{d}{r\sqrt{2}}\right) + f(d, L)$$

r is the radius of the subsurface drain, and $f(d, L)$ is a function of d and L, which was evaluated from an infinite series, which introduced a reduction in flow depth. The new reduced depth, d_e, was called equivalent depth and was defined as $L/8F_k$.

Wessling (10) analyzed the solution given by Hooghoudt (5) and Kirkham (9) and concluded that both solutions gave almost identical results within a 5% variation. Lovell and Youngs (11) calculated water table heights above drains using a number of steady-state equations and found that it could be computed with sufficient accuracy for smaller as well as for larger depths of the impermeable barrier. At intermediate depths, the solutions led to large uncertainties in the estimates. It was also noticed that among all drainage equations, Hooghoudt's equivalent depth equation, when used with an optimum drain radius obtained by a hodographic analysis for finite soil depths, gave reasonable values of lateral drain spacing which were within the known limits of uncertainty.

Unsteady State

This theory is generally used in areas that have a high intensity of rainfall or in arid lands where the rise in the water table due to frequent irrigation needs to be lowered by drainage. It describes the fall of the water table required within a certain period after the water table has risen near the land surface due to instantaneous recharge. Most of the unsteady-state theories relate to the study of groundwater flow in a homogeneous, isotropic, unconfined aquifer lying over a horizontal impermeable layer and are characterized by Dupuit–Forchheimer assumptions based on the Boussinesq (12) partial differential equation, which is

$$h\frac{\partial^2 h}{\partial x^2} + \left(\frac{\partial h}{\partial x}\right)^2 = \frac{f}{K}\frac{\partial h}{\partial t} \tag{4}$$

where K is the hydraulic conductivity of the aquifer, h is the height of the phreatic surface above the impermeable layer, and f is the drainable porosity (dimensionless). Equation 4 is a nonlinear second-order partial differential equation. Solutions of nonlinear or linearized forms of this equation for appropriate boundary conditions representing different physical flow conditions have been obtained in the past by a number of researchers. There are three physically identified commonly occurring flow situations: (1) a falling water table between two level drains, (2) a falling water table between two bilevel drains, and (3) a water table between two drains/canals fluctuating due to recharge or evapotranspiration.

Falling Water Table between Two Level Drains. Boussinesq (13) obtained an exact analytical solution of Eq. 4 with initial conditions $h(L/2, 0) = h_0$ and boundary conditions $h(0, t) = h(L, t) = 0$, assuming drains located at the impervious layer. His solution, which describes the temporal and spatial variation of a falling water table in nondimensional form, can be written as:

$$\frac{h}{h_0} = \frac{1}{\left(\dfrac{9Kh_0 t}{fL^2} - 1\right)} \tag{5}$$

where h_0 is the initial midpoint of the water table height, h is the water table height after lowering it from an initial value of h_0 in time t, and L is the spacing between two drains.

Glover (14) also obtained the same solution for Eq. 4 as given by Boussinesq (13). Dumm (14) assumed an initially horizontal groundwater table at a certain height above the drain level because of instantaneous recharge due to rainfall or irrigation. Equation 4 was linearized by assuming that the free water surface has a small slope enabling h, associated with $(\partial^2 h/\partial x^2)$, to be replaced by D, average depth of flow, and neglecting $(\partial h/\partial x)^2$ by considering that it is very small. Equation 4 is thus reduced to

$$\frac{\partial^2 h}{\partial x^2} = \frac{f}{KD}\frac{\partial h}{\partial t} \tag{6}$$

Assuming that the initial water table is horizontal and zero end conditions, a Fourier series solution for falling water table heights midway between the drains was obtained as

$$h\left(\frac{L}{2}, t\right) = \frac{4h_0}{\pi}\sum_{n=1,-3,5}^{\infty}\frac{1}{n}e^{-\frac{n^2\pi^2 KDt}{fL^2}} \tag{7}$$

Dumm (15) assumed that the initial water table was a fourth-degree parabola and obtained the solution for the boundary conditions used by Glover (14). The only difference between Eq. 8 and his solution was the shape factor which was replaced by 1.16 instead of a value of $4/\pi$.

Brooks (16) presented a solution to the nonlinear Boussinesq equation describing unsteady flow toward equally spaced drains above a horizontal impermeable barrier in the form of a perturbation series. Van Schilfgaarde (17, 18) derived an exact solution to Boussinesq's Equation 4 for the boundary conditions when drains did not reach the impermeable layer. He also applied a convergence correction to the solution of the drainage problem and finally obtained an equation for drain spacing as

$$L = 3A\left[\frac{K(d_e + h)(d_e + h_m)t}{2f(h_m - h)}\right]^{\frac{1}{2}} \tag{8}$$

where

$$A = \left[1 - \left(\frac{d_e}{d_e + h_m}\right)^2\right]^{\frac{1}{2}}$$

d_e is the equivalent depth of an impervious layer below the drain, and h_m is the maximum water table height above the drain level. The results of this solution compared with those obtained from the Glover–Dumm (14) solution differed by the order of 10 to 40%.

Role of Evapotranspiration in Drainage Design

Work was also carried out by Brooks (16), Moody (19), Pandey and Gupta (20), Singh et al. (21, 22), and Nikam et al. (23) to include the contribution of other processes, mainly evapotranspiration, in lowering the water table. Both steady and nonsteady approaches have been used.

Falling Water Table Between Two Bilevel Drains. De Boer and Chu (24) developed an unsteady-state theory for a bilevel drainage system using the Bouwer and Van Schilfgaarde (25) approach. They suggested using a bilevel drainage system because by having deep and shallow drain lines on an alternate basis, the excavation and digging cost would be reduced substantially and thus a bilevel drainage system would be economical compared to a conventional level drainage system. Studies were also carried out by Chu and De Boer (26), Sabti (27), Verma et al. (28), and Upadhyaya and Chauhan (29).

Fluctuating Water Table. Kraijenhoff van de Leur (30) studied the effect of constant steady-state recharge during the drainage process instead of an instantaneous recharge, as assumed by Dumm. The governing equation and initial and boundary conditions are written as

$$\frac{\partial^2 h}{\partial x^2} + \frac{R}{Kd} = \frac{f}{KD}\frac{\partial h}{\partial t}$$

$$h(x,0) = 0, \qquad 0 < x < L$$

$$h(0,t) = h(L,t) = 0, \quad t > 0$$

where R is the recharge rate per unit area. The height of the water table midway between parallel drains at any time t is given as

$$h(L/2,t) = h_t = \frac{4}{\pi}\frac{R}{f}J\sum_{n=1,3,5}^{\infty}\frac{1}{n^3}(1 - e^{-\frac{n^2 t}{J}})$$

where $J = fL^2/\pi^2 KD$.

This equation is not used for routine drain spacing computations; however, it is useful for hydrologic studies such as estimating water table fluctuation or drain discharge variation with time for a given recharge pattern.

Maasland (31) also analyzed the problem of water table fluctuations in response to constant recharge, intermittent constant recharge, and intermittent instantaneous recharge independently and almost at the same time as Kraijenhoff van de Leur (1958) using similar and a few different boundary conditions.

NUMERICAL SOLUTIONS

Dass and Morel-Seytoux (32) solved the one-dimensional nonlinear Boussinesq equation by Galerkin's finite element technique for three initial water table conditions. They observed that Galerkin's method was applicable to any initial water table profile. Studies were also carried out by Marino (33), Singh and Jacob (34), Singh and Rai (35), Skaggs (36), Pandey et al. (37,38), and Sewa Ram et al. (39).

Drainage of Sloping Lands

When wetness is prolonged, subsurface drainage and hillside seeps are an acute problem in many parts of the world such as the pre-Alps in Switzerland and adjacent countries and the tea gardens of Assam, India, where drainage of sloping lands is considered quite an important problem.

Because of saturation of the soil, the growth of plantations and trees is retarded, and there is difficulty in new afforestations and plantations. In the southern Appalachian Mountains, such problems were experienced for which elaborate experimental studies were carried out to study storm flow response on sloping forested watersheds. The theoretical analysis of this problem has also been difficult and is a classical hydrologic issue. Some notable works may be mentioned as those of Werner (40), Schmid and Luthin (41), Wooding and Chapman (42), Luthin and Guitjens (43), Chauhan et al. (44), Childs (45), Jaiswal and Chauhan (46), Sewa Ram and Chauhan (47), and Upadhyaya and Chauhan (48).

DESIGN CRITERIA FOR HORIZONTAL DRAINS

Steady-State Criteria

This criterion is generally applicable in flat areas of humid regions, where low intensity, long duration rainfall occurs in winter and spring. In this situation, recharge due to rainfall or irrigation is assumed constant and equal to the discharge from drains such that the water table height does not change with time. This criterion describes the quantity of water to be removed in a given period of time under conditions of given water table heights above the drain level. In this criterion, drain discharge is matched to provide a clear root-zone depth above the midpoint of the water table. Such a criterion can be expressed as for example, a drain discharge of 7 mm per day when the water table depth is at the midpoint of two drains at 50 cm below the ground level. Hooghoudt's equation has generally been recommended for designing drain spacing in homogeneous soils because of its simplicity and ease of use. For layered soil or for soil that has a slowly permeable top layer, the Ernst equation (6) has been recommended because it takes radial flow into account in the total flow.

Unsteady-State Criteria

This criterion is generally used in areas of high intensity storms that occur quite commonly or in irrigated lands which requires establishing a rate of fall of the midpoint of the water table between two horizontal drains to match the sensitivity of a selected crop that can sustain a high water table for a limited period. The Glover–Dumm equation is recommended for use by the United States Bureau of Reclamation. According to this criterion, the water table should drop from the ground surface to at least 30 cm below in 24 hrs and to 50 cm below in 48 hrs (49). When the water table rises to some 15 cm below the ground surface, it should drop to 35–40 cm below in 1 day (50).

Equivalence Between Steady-state and Nonsteady State Criteria. Steady-state criteria are comparable to the falling water table criteria. For the drainage criterion consisting of a discharge rate of 0.007 m/day, when the water table depth is 0.50 m, the hydraulic head (h) will be 50 cm if the drain depth is 1 m. If the water table rises to the surface, both the discharge rates and hydraulic head will increase by two times and become 0.014 m/day and 100 cm, respectively. For a clay soil whose drainable porosity is 4 to 5%, this would result in a drop of the water table from the ground surface to about 30 cm below in 1 day which corresponds to the U.S. standard.

Vertical Drainage

Vertical drainage and conjunctive use of canals and groundwater is another good way of lowering the water table and providing subsurface drainage. With good quality groundwater, it is an excellent practice. On one hand, it lowers the water table and, on the other hand, through the same process, it also provides irrigation for increasing the production of agricultural crops. However, it is important to understand the different issues involved. Sometimes, the objective of vertical drainage is steady-state lowering of water tables in the root zone for growing crops due to overlapping of drawdown caused by pumping closely spaced wells. In other words, it is similar to the well-known well point system. Such a system is used for building foundations or other structures in high water table areas where rapid lowering of water tables is required for short periods. Such a system would not only be structurally costly but would also involve high recurring energy costs. Such a system does not seem to be practicable for growing agricultural crops. Thus, lowering of water tables should be considered in terms of total withdrawal on a long-term basis instead of transient lowering in a short period for growing crops that require lowering of 0.3–0.5 m in 1 to 2 days, as for maize or soybean.

De Ridder (51) and Attia and Twinhof (52) recommend the technical feasibility of tube well drainage only based on the geometry of the aquifer, hydraulic parameters, the thickness and hydraulic resistance of the clay cap, the groundwater quality, and the rate of recharge. According to them, well drainage enables lowering the groundwater to a much greater depth than gravity drainage. Where deeper layers of substrata are more pervious than layers near the surface, pumping from these layers may reduce the artesian pressure that is often present, and create a vertical downward flow through the upper layers. If the pervious strata are found at a depth of 5 m or more, well drainage can be applied successfully, if the transmissivity of the aquifer is fairly high. If the aquifer is semiconfined, an additional criterion would be the value of the hydraulic resistance of the upper clay layer. The energy requirement is another consideration that should be looked into for well drainage. Unlike gravity drainage, well drainage is not economically feasible in small areas because too large a portion of the water drained consists of foreign water. Well drainage may also not be feasible in areas where artesian pressure is too high.

In a case study of SCARPS in Pakistan by Awan (53), tube wells were installed to lower the water table and provide more water for intensive agriculture and to reduce salinity. Large capacity tube wells were installed near the outlets to feed one or two watercourses. A large number of problems were faced from vertical drainage. The operational and maintenance costs were quite heavy. There were problems of spares making tube wells remain idle. Eighty percent of the total budget went to electricity bills leaving little money for maintenance. Several disputes cropped up among the farmers who were supplied water from the same watercourse. The authorities were forced to shift the policy in the sweet water zone from large public tube wells to the private sector. In a later study, Smedema and Zimmer (54) also favored private investments in the freshwater zone, which seemed quite successful. It was also observed that providing horizontal drainage instead of tube well drainage could have reduced the salinity of the drainage effluent.

Even in the Australian Wakool drainage project of about 57,000 ha, affected lands had water tables within 2 to 3 m of the surface. An attempt to lower the water table by using 52 tube wells faced similar problems, as in SCARPS in Pakistan. The high capital and growing operating and maintenance costs affected the economic value of the scheme, and it seemed unlikely that a scheme of such a magnitude could ever be built again for Australian agriculture.

Biodrainage

Biodrainage is being propagated as a method of subsurface drainage. It is an economical method of drainage, it improves the ecology of the area, and it is environmentally friendly. It provides costly wood and biomass useful for many purposes. It can transpire water from the groundwater table in good amounts. A large range of plants tolerant to salinity can be grown in waterlogged, salt-affected lands. However, it is important to identify appropriate situations where this method can be effective and useful. It is unfair to assign it an objective, which it cannot achieve, and then misinterpret the approach. The issue to be examined is whether meeting the shortage of food production is a pressing need now or in the future in developing countries and, if so, how can biodrainage be used to reclaim waterlogged and salt-affected lands for food production. If there is no immediate necessity to increase food production, then it could be a good alternative to put all such areas under trees. However, if the priority favors food production, then it has to be seen whether forest or tree crops can lower water tables at a fast enough rate to grow maize/soybean or other crops without the ill effects of waterlogging. Even if plants can lower the water table at a fast rate, one would have to look for a proper cropping system. It needs to be seen whether one can grow food crops simultaneously with tree crops and maintain a deep enough water table. Alternatively, one will be required to grow tree crops for a few years, and, after the water table has been lowered, then one can grow grain crops; this has to be properly understood and practically planned. Similarly, it is understandable that many agricultural, horticultural, and other tree crops can tolerate salinity of different levels. But, whether it is practicable to reclaim a saline soil whose electrical conductivity is more than 50 dS/m, through tree crops, so as to make it suitable for growing agricultural crops, needs to be explored.

According to Smedema (55) there are three situations for biodrainage: waterlogged landscape depressions, areas along a canal to intercept canal seepage, and growing plants to act as parallel field drainage. In the first, instead of installing a pumped well for drawing down the water table, the drainage improvement could be done by planting trees, shrubs, or other vegetation. In the second, in place of an interceptor drain practised in the past at the toe of the embankment of a canal, drainage conditions could be improved by planting a strip of suitable vegetation. In the third, biological line sinks (strips of planted trees/shrubs) can be used instead of conventional parallel field drainage systems such as ditches or pipe drains. Such a system could also work as a typical windbreak for a more favorable microclimatic environment. According to Smedema (55) this is generally not a realistic option, when common crops are facing severely waterlogged conditions. However, biodrainage under certain conditions has merit according to which it may be confined to growing tolerant species under not too extreme waterlogging conditions. The scope of biodrainage seems to be more favorable in an arid zone where drainage surpluses are small in relation to evapotranspiration rates (1 to 2 mm/day vs. 10 mm/day). The claims of using biodrainage to cope with salinity do not seem to be supported by experimental evidence from Australia and California. Biodrainage without any physical drainage is more likely in the long run to lead to a harmful buildup of root-zone salinity.

PRESENT STATUS AND SCOPE OF DRAINAGE

Land drainage in the past has played an important role in the modernization of rain-fed and irrigated agriculture throughout the world. Drainage of European agricultural lands, where improved drainage was needed in as much as 25% of agricultural land, helped Europe to attain self-sufficiency in food production. Nearly 70% of this land has been put under subsurface drainage during the last 30 years. Drainage development in the United States, helped by other technologies, created one of the most efficient production systems. As half of wetlands were converted into cropped land, drainage developments since 1960 are being influenced by changing environmental ethics because there is more emphasis on protecting wetlands. In spite of this, even in the United States, about 10 to 20 mha of cropland still need drainage. Out of a total agricultural area of 18.65 mha in the United Kingdom, besides presently drained lands, a further 3.5 mha still require drainage. Considerable experience in design and construction of drainage systems has been gained in Russia. The total area of drained land exceeds 1 mha. More than half of the land is under subsurface drainage.

According to Smedema, the world's total cropped land area stands at 1450–1500 mha of which 250 mha (70%) is provided with irrigation facilities. Of this cropland, 150–200 mha (10–15%) have drainage facilities. Of this about a 50 mha area is irrigated, and the remaining 100–150 mha are rain fed. All of the latter are in Europe and North America. It is estimated that 250–300 mha of rain-fed cropland still needs drainage of which 25–30 mha would be a reasonable medium-term program to cover the humid tropic lands of Southeast Asia. The current rate of drainage development is estimated at 0.5–1.09 mha/year.

Drainage, it is predicted, will increase food production in the irrigated area by 1–1.5% and in the rain-fed area by 0.5–1%. The global average will be about 1%. The need for drainage of irrigated lands consists of surface drainage and subsurface drainage to combat waterlogging and salinity. A medium-term (25 years) drainage plan would cover 10–15 mha surface drainage and 2–3 mha of subsurface drainage. All of this is located in developing countries.

DRAWDOWN

John E. Moore
USGS (Retired)
Denver, Colorado

According to Wilson and Moore (1), drawdown is the lowering of the water level in a well as a result of withdrawal. Drawdown data are collected to evaluate the performance of the well and to determine the aquifer's hydraulic character (transmissivity). Drawdown measurements also provide information on the well efficiency and performance. For example, measurements can be used with well discharge data to detect deterioration of the well screen.

The drawdown in a pumping well is the sum of head loss factors (2). Some of the factors are natural processes, head loss in the aquifer, loss in the damage zone (well drilling), well development, and turbulent loss in the filter zone. The damage zone consists of drilling debris, filter cake, and drilling fluid.

When water is withdrawn from a well, the initial discharge is from casing storage and from aquifer storage near the well bore. As withdrawal continues, water is withdrawn at greater distances from the well. The cone depression or drawdown expands and deepens more slowly with time because an increasing amount of stored water is available from each foot of expansion of the cone (3). The cone of depression will continue to enlarge until the following conditions are met (4):

1. It intercepts a body of water (stream, lake, or wetland) that supplies enough water to equal the pumping rate.
2. Enough recharge from precipitation occurs within the cone of depression's influence to equal the pumping rate.
3. Leakage occurs from overlying or underlying aquifers to equal the pumping rate.

The cone of depression around a well is controlled by the transmissivity of the aquifer. In aquifers of a low transmissivity (10,000 gpd/ft_2), the cone is deep and has steep sides and a small radius. In aquifers of high transmissivity (100,000 gpd/ft_2), the cone is shallow and has a large radius

Slichter in 1899, Thiem in 1906, and Theis in 1935 (5) introduced the equations to predict drawdown. The transmissivity of the aquifer determines the shape of the drawdown curve.

The following is a list of key terms associated with well drawdown (6):

Static level— water level of a well that is not affected by the withdrawal of ground water.

Pumping level— the level of water in the well during pumping.

Well yield— the discharge of a well or rate at which a well yields water either by pumping or free flow.

Specific capacity— an expression of the productivity of a well obtained by dividing the rate of discharge by the drawdown in the well. It should be described on the basis of the number of hours of pumping prior to the time the measurement is made because it generally decreases with time as drawdown increases.

Well efficiency (well hydraulics)— defined as the ratio of actual specific capacity to theoretical specific capacity. Actual specific capacity is related to drawdown in the well and theoretical specific capacity. Well efficiency is determined by a step drawdown test.

Step drawdown test— In this test, the well is pumped at several (three or more) successively higher pumping rates, and the drawdown at each rate is recorded. The test is usually conducted during 1 day. The discharge is kept constant through each step.

Getting access to the well to take drawdown measurements is sometimes difficult. Ideally, you can gain access through a pipe intended for measurements. Measurements of drawdown in wells can be obtained by one of the following methods (7):

1. wetted steel tape
2. air-line submergence method
3. electrical tape
4. pressure transducer

Wetted Steel Tape

Before the 1960s, most water level measurements were made with a steel tape (most likely a 100- or 200-foot Lufkin tape). It is typically used for depths up to 90 feet. Electrical methods and pressure transducers in part have replaced tapes. However, the steel tape still has applications today, for example, to calibrate pressure transducers. To use the wetted tape method, the hydrologist will need a steel measuring tape, a weight, and carpenter's chalk. Before the tape is lowered down the well, the lower 1 to 2 feet or so of the tape is coated with carpenter's chalk. Problems that may be encountered using this method are moisture on the well casing, cascading water, and oil (leaking from pump lubrication). In some cases, this method can be very inaccurate. For example, if the water level is below the well screen, water flowing into the well can wash the chalk off the tape.

Electrical Tape

Most electrical tapes are marked every one-tenth foot. An electrical probe is lowered into the water, which completes an electrical circuit, and this sounds a buzzer or light.

Pressure Transducer

The transducer probe measures the column of water above the probe. It is very useful in aquifer tests where the water level changes rapidly with time.

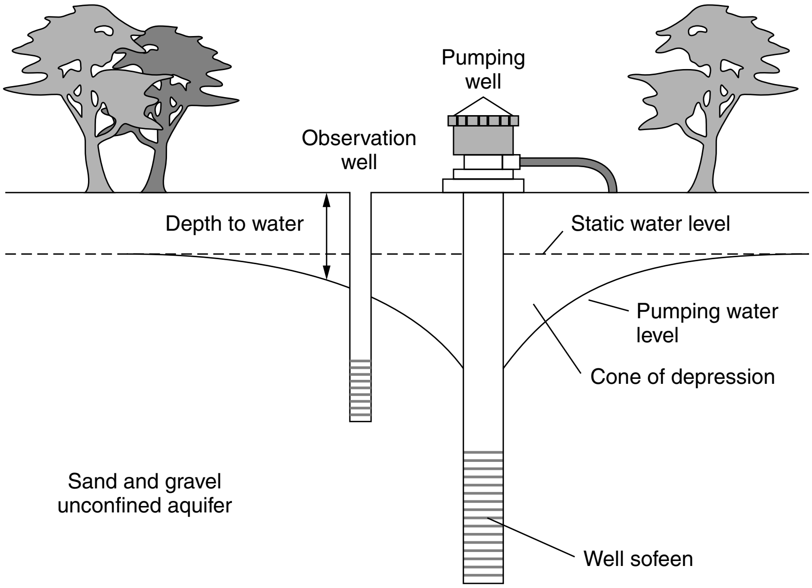

Figure 1. Diagram of a well (6).

Specific capacity tests can be used to determine the amount of water a well will yield. In this test, the pumping rate and drawdown (water-level changes) are monitored for a set period of time. The first step is to measure the initial water level in the well. Commonly, a well is pumped at several successively increasing rates for uniform periods (typically 1 hour) to establish a rate that can be maintained for long-term pumping. The well is then pumped at a steady rate and the water-level changes are monitored at the pumped well. Water levels should also be monitored in at least one observation well 2 to 20 meters (6 to 65 feet) from the pumped well. The water level will decline quickly at first as water is removed from the well, then more slowly as the rate of flow into the well approaches the pumping rate. The ratio of the discharge rate (Q) to the water-level change (drawdown, dd) gives the well's specific capacity, or $\mathrm{Sc} = Q/\mathrm{dd}$. For example, if the discharge rate is 6 liters per second (L/s) [100 gallons per minute] and drawdown is 3 meters (10 feet), the specific capacity of the well is 2 L/s per meter (10 gpm/ft) of drawdown. Once the specific capacity and the available amount of drawdown are known, the yield of the well can be determined from the formula $Q = \mathrm{Sc} \times \mathrm{dd}$. An estimate of the transmissibility in an unconfined aquifer can be obtained by multiplying the specific capacity by 2000.

A step-drawdown test evaluates the performance of the well. Well performance can be affected by resistance to flow in the aquifer itself; partial penetration of the well screen, incomplete removal of mud from the gravel envelope, or invasion of fines into the envelope; and blockage of part of the screen area. The well should be developed prior to the test by using a surge block and/or pumping until the well discharge is clear. In this test, the well is pumped at several (three or more) successively higher pumping rates, and the drawdown for each rate is recorded. The test is usually conducted during 1 day. The discharge is kept constant through each step. The test measures the change in specific capacity. The data provide a basis to choose the pump size and rate for the aquifer test and for long-term production.

WATER LEVEL DRAWDOWN

Mark D. Steele
MDC Systems, Inc.
Berwyn, Pennsylvania

INTRODUCTION AND DEFINITIONS

Contrary to the popular image of caverns and underground rivers, ground water is the water that fills or saturates the soil in a specific location. *Water level drawdown* describes the effect on the actual or potential water surface of removing water from a well, trench, or sump. The water table is the interface between this saturated water/soil zone (or aquifer) and an unsaturated water/soil zone. The concept of an aquifer can be easily seen by filling a jar with rocks. Water can then be poured into the jar to fill up the empty spaces between the rocks. The level of the water in the jar is analogous to the subsurface water table, and the volume saturated with water is the aquifer. If one then placed a straw in the middle of the jar and began to pull out water, the water table would become depressed in a cone shape around the straw similar to the depression in the water level of a sink as the water goes down the drain. This depression in the water table is known as the cone of depression. The vertical difference, at any given point, between the original (or static) water level and the water surface formed by the cone of depression is called the *drawdown*.

The goal of this article is to provide an understanding of the key terms and concepts associated with drawdown and an introduction to the uses of drawdown in groundwater hydrology. The meaning of drawdown varies slightly between unconfined and confined (artesian) aquifers.

DRAWDOWN IN UNCONFINED AND CONFINED AQUIFERS

Depending upon whether an aquifer is unconfined or confined, drawdown is discussed in terms of either the water table or the piezometric surface, respectively (Fig. 1).

Unconfined aquifers have no impermeable layer between the water table and the ground surface. They can also be called “free” or “water table” aquifers. The water table in these aquifers is in direct contact with the atmosphere through the pores of the unsaturated soil above, and the water table is in balance with the air pressure. These aquifers are influenced by the infiltration of storm water and are also more easily contaminated through the infiltration of chemicals from surface spills.

For unconfined aquifers, the static water level is the height of the water in the well before pumping (Fig. 2). This is often calculated by measuring the depth to the water

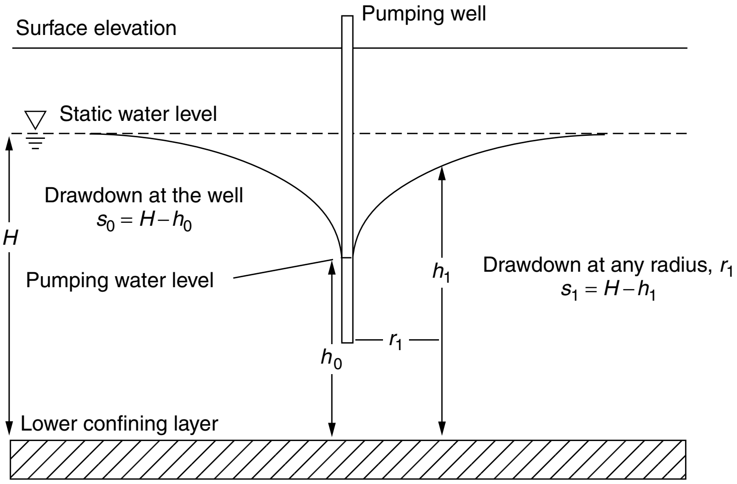

Figure 1. Drawdown in an unconfined aquifer.

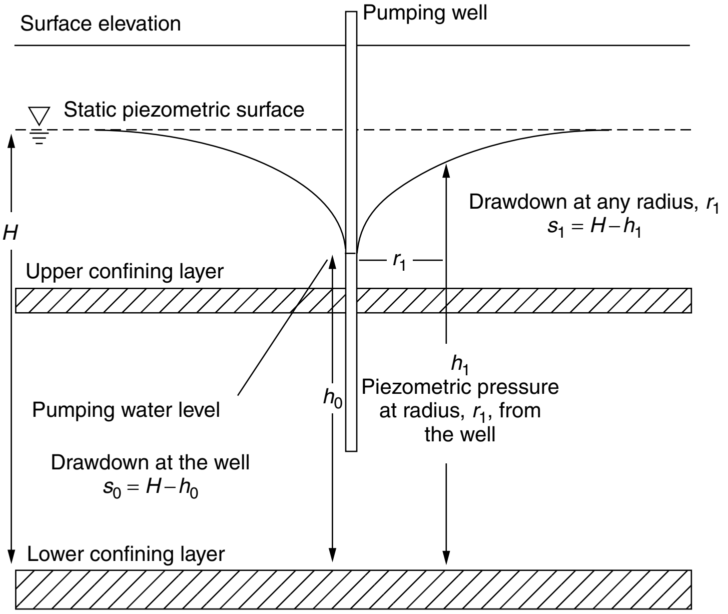

Figure 2. Drawdown in a confined (artesian) aquifer.

from the surface elevation. It can be given as "depth-to-water" or, sometimes, can be given as an elevation compared to mean sea level (MSL). In groundwater equations, it is expressed by a capital "H" and is measured, not from the surface down, but from the lower confining layer up. It is a measurement of pressure or head. So, if the depth to water is 26 feet and the surface elevation is 686 feet above MSL, the static water level is at 660 feet above MSL. If boring logs show that the lower confining level is at an elevation of 585 feet, then $H = 75$ feet ($660 - 585 = 75$).

Confined (or artesian) aquifers have a confining layer, an impermeable bed, between the aquifer and the ground surface. As a result, the water in confined aquifers is often under pressure. Artesian springs are one result of this phenomenon. If a well is drilled into a confined aquifer, the water level in the well will rise to the height of the pressure in the aquifer. Artesian springs occur when the water pressure is such that the water rises to the surface through a fracture in the confining layer. This height, or head, is the *piezometric* level at the well. A combination of all piezometric or *potentiometric* heights throughout a confined aquifer is the *piezometric surface*. The piezometric surface is what the water table would be if there were no upper confining layer.

In confined aquifers, the static piezometric surface is the piezometric surface measured before pumping begins. It is expressed in the same terms as the static water level and is also measured as a pressure, or head, from the lower confining layer.

The pumping water level in a well is a water level in the well during pumping. Like the static water level or static piezometric surface, the pumping water level is measured from the lower confining bed and is a pressure or head in feet or meters. It is usually designated by a lower case "h."

The difference between the static level and pumping level at the well is the *drawdown* at the well. It is usually designated by s_0. Observation wells can be placed at various distances or radii from the pumping well to observe the drawdown at these locations. The difference between the static level and the pumping level at any radius, r_1, from the well is the drawdown, s_1, and it is the difference between H and the pumping water level, h_1, at that radius.

If all the pumping levels could be viewed in cross section, they would form a curve, the *drawdown curve* similar to these shown in the two figures. Drawdown in three dimensions is an inverted cone known as the *cone of depression*. The cone of depression defines the distance at which drawdown occurs as a result of the pumping of the well in question. This distance is known as the *radius of influence* of the well, and the area circumscribed by this radius is known as the *area of influence*.

IMPORTANCE AND USE OF DRAWDOWN INFORMATION

The measurement of drawdown is very useful to the study of the hydraulic characteristics of an aquifer. To understand this importance, it is first necessary to review the basic equilibrium equations for both unconfined and confined aquifers. The equation for an unconfined aquifer is

$$Q = \frac{\pi K(H^2 - h^2)}{\ln\left(\frac{r_i}{r_w}\right)} \tag{1}$$

where

Q = pumping rate

K = coefficient of permeability

H = saturated thickness at the radius of influence (static water level)

h = saturated thickness at the well

r_i = radius of influence

r_w = radius of the well

The equation for a confined aquifer is

$$Q = \frac{2\pi KM(H - h)}{\ln\left(\frac{r_i}{r_w}\right)} \tag{2}$$

where

M = thickness of confined aquifer

H = piezometric pressure at the radius of influence (static piezometric)

h = piezometric pressure at the well

r_i = radius of influence

r_w = radius of the well

When these equations are adjusted to solve for K at any two radii, r_1 and r_2, using drawdown at those two radii, s_1 and s_2, then the equations become
for an unconfined aquifer

$$K = \frac{Q \ln\left(\frac{r_2}{r_1}\right)}{\pi(s_1 - s_2)} \tag{3}$$

and for a confined aquifer

$$K = \frac{Q \ln\left(\frac{r_2}{r_1}\right)}{2\pi M({h_2}^2 - {h_1}^2)} \tag{4}$$

These equations can be used as part of a pump test to determine the permeability of an aquifer. The distances to the various confining layers and the thickness of the aquifers (as well as the static levels) should have been determined by soil borings. So, H and M are known. A pumping well is drilled along with one or more observation wells set at known radii from the pumping well. The well is then pumped at a known rate, Q, and time–drawdown data are recorded for each of the wells. From this information, the coefficient of permeability for the aquifer can be developed. This coefficient can then be applied to design other wells in this aquifer or for modeling the aquifer.

WATER WELL DRILLING TECHNIQUES

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Water well installation, for groundwater monitoring projects or for water supply wells for irrigation or human consumption involves a variety of drilling techniques. Rig selection is related to accessibility, time and cost of project, sediment type (consolidated rock or unconsolidated soils), sample type (undisturbed vs. disturbed), and sample integrity. For environmental projects, designing wells and evaluating groundwater also involves assessing the soil, sediments, or rocks above and below the water table.

The vadose zone includes the zone immediately above the water table to the surface. The lower vadose zone includes the capillary fringe, the zone where water is drawn upward by capillary force. The water table is the top of the saturated or phreatic zone within the aquifer.

More detail regarding water wells, aquifers, and drilling techniques is provided in Driscoll (1), Testa (2), Sisk (3), and DWR (4,5). There are numerous differences in drilling techniques, methods and equipment, many regional variations, and specific local requirements. A generalized summary of selected water well drilling techniques follows.

ROTARY DRILLING

Rotary drilling techniques include direct mud rotary, air rotary, air rotary with a casing driver, and dual-wall reverse circulation. Rotary drilling techniques are commonly used for deep water supply wells. Direct mud rotary drilling uses fluid, which is pumped down through the bit at the end of the drill rods and is circulated up the annular space back to the surface. The fluid at the surface is routed via a pipe or ditch to a sedimentation tank or pit, then to a suction pit where the fluid is recirculated back through the drill rods. Air rotary drilling uses air as a circulation medium instead of water. In unconsolidated deposits, direct mud or air rotary can be used, providing that a casing is driven as the drill bit is advanced. In dual-wall reverse circulation, the circulating medium (mud or air) is pumped downward between the outer casing and inner drill pipe, out through the drill bit, then up the inside of the drill pipe.

Figure 1. Rotary drilling rig used to assess shallow spillage from train derailment area at mile 262 (Photo P045; EPA).

Rotary drilling techniques are commonly limited to consolidated deposits of rocks (Fig. 1). In mud rotary, a mud filter cake develops along the borehole wall, potentially reducing aquifer permeability. Where a resistant layer such as overlying basalt flows or conglomerate strata exists at shallow levels within the vadose zone and above the target depth, an air rotary rig can be used to drill to a predetermined depth followed by another more suitable drilling method (2).

CABLE-TOOL DRILLING

Cable-tool drilling is the oldest drilling technique available and is for installing water supply wells in selected locations. It is not used often in the environmental field, as the technique is slow, noisy, and dusty. The exception is the use of cable-tool drilling in glacial environments containing large cobbles in the Pacific Northwest portion of the United States or in young volcanics such as in Hawaii. Cable-tool rigs, called percussion or spudder rigs, operate by repeatedly lifting and dropping the heavy string of drilling tools in the borehole, crushing larger cobbles and rocks into smaller fragments. During cable-tool drilling, the hole is continuously cased by an unperforated steel casing with a drive shoe. The casing is attached on top by a rope socket to a cable that is suspended through a pulley from the mast of the drill rig. The process of driving the casing downward a few feet is followed by periodically bailing the borehole of the broken rocks and accumulated soils from the bottom of the borehole. Formation water or added water is used to create a slurry at the bottom of the borehole.

WIRE LINE CORING

Coring is the drilling method that produces cylindrically shaped cores. A rotary rig is used in conjunction with water, drilling mud, or air. Cutting is accomplished by drill bits located at the end of the rotating barrel or tube. The barrel gradually slides down into the annular opening. The core is then separated from the rest of the formation mass, and the barrel containing the core is retrieved.

HOLLOW-STEM AUGER DRILLING

Hollow-stem continuous flight auger drilling techniques are commonly used for subsurface environmental projects (Fig. 2). Hollow stems consist of a series of continuous, interconnected hollow auger flights. The hollow-stem flight augers are hydraulically pressed downward and rotated to start drilling. Soil cuttings are rotated up the outside of the continuous flighting in the borehole annulus. A center rod with plug and pilot bit are mounted at the bottom. The plug is designed to keep soil from entering the mouth of the lead auger while drilling. Upon reaching the sampling depth, the center rod string with plug and pilot bit attached is removed from the mouth of the auger and replaced by a soil sampler.

The soil sampler is lowered into the borehole through the hollow stem of the auger (the center tube), and sampling is started. Samples can be continuously retrieved but are typically collected at 5-foot intervals, at hydrologic or lithologic changes, or at intervals of obvious contamination.

HORIZONTAL DRILLING

Horizontal or lateral radial wells are used more in subsurface environmental remediation although they have been used by the oil industry for decades. Based on the configuration in map view, horizontal water wells emanate from a center hub well. The most obvious application is where the area of concern, such as a contaminant plume, is inaccessible due to aboveground structures, tankage, roads, or subsurface structures such as landfills, lagoons, pits, pipelines, or wells.

Figure 2. Close-up of a hollow-stem auger rig (Courtesy of Joe Ryan, University of Colorado).

Figure 3. Direct push technology rig (Courtesy FAST-TEK).

DIRECT PUSH DRILLING

Direct push technology (DPT) rigs are used almost exclusively in the environmental field (Fig. 3). DPT rigs rely on the static weight of the vehicle, typically a pick-up truck or van, combined with the percussion of the onboard industrial jackhammer as the energy for advancing the soil and groundwater samplers. DPT rigs are designed for easier accessibility than larger more conventional drilling rigs. DPT rigs can install small-diameter driven well points or piezometers. Unlike rotary auger rigs, DPT rigs do not generate large amounts of drilling derived wastes. DPT rigs, including cone penetrometer technology (CPT) rigs, can also drive various sensors tools to obtain data about subsurface conditions (6).

WELL INSTALLATION

Well materials for water supply wells and monitoring wells must be chemically compatible with potential contaminants as well as water geochemistry, such as pH, iron content, turbidity, alkalinity, and other parameters (Fig. 4). Casing, both blank and screen sections, can be constructed of fiberglass-reinforced plastic, stainless steel, concrete, or thermoplastic which include polyvinyl chloride (PVC), acrylonitrile butadiene styrene (ABS), and styrene rubber (SR). Based on cost, availability, and chemical compatibility, the most common casings and screens used for shallow drilling projects in the environmental field are made of PVC. Deeper wells are typically constructed of either thicker gauge PVC or steel. Well screen openings are commonly slotted, lowered, or created through a wire wrapping process. Slot sizes can be determined by previous well installations in the area or by a grain size sieve analysis. Centering devices may be fastened to the casing to assure even distribution of filter material and grout within the borehole annulus.

GROUNDWATER DYE TRACING IN KARST

David M. Bednar, Jr.
Michael Baker Jr., Inc.
Shreveport, Louisiana

Groundwater dye tracing has proven to be an effective tool for aquifer characterization, protection, and to provide remediation strategies in karst areas. Tracing groundwater flow routes with fluorescent dyes is highly successful because they are water soluble and inexpensive. Fluorescent dyes are usually the best tracers to use in karst because they are easily detected in concentrations that are one to three orders of magnitude less than those at which nonfluorescent dyes can be measured spectrometrically (1). Additionally, they are safe to use, work effectively in different hydrogeologic settings, and can be used effectively to trace water from subsurface to surface water bodies. Dye tracing in karst has been used successfully to (1) delineate spring recharge areas and subsurface basins, (2) determine site-specific hydrology, (3) estimate groundwater flow velocities, (4) trace groundwater flow from areas of recharge to discharge, (5) delineate wellhead protection areas, (6) map and characterize conduit flow routes, (7) detect leakage from residential sewage disposal systems, (8) identify sources of potential pollution from hazardous waste sites, (9) detect leakage from dam sites, and (10) characterize groundwater flow routes to important springs and cave streams along highway corridors.

WHAT IS KARST?

To understand why groundwater dye tracing is an effective tool for characterizing karst groundwater resources, one must have a basic understanding of karst and the unique hydrologic characteristics of its landscape. Karst refers to lands primarily underlain by limestone and dolomite where surface water is integrally connected to the groundwater system through preferential flow routes, which results in the formation of distinctive surface landforms and hydrologic features as well as subsurface features. Lack of these landforms and features does not mean that karst is not present.

A characteristic feature of karst areas is the sometimes rapid interconnection of surface water with the groundwater flow system. Even in the absence of surface streams, a karst region is a zone of drainage into the aquifer; the entire area can be a recharge zone (21). In most karst areas, two general types of recharge have been recognized: discrete and diffuse recharge. Discrete recharge, also known as concentrated recharge, is characterized by relatively rapid movement of water through localized areas (such as through sinkholes, losing streams, or other areas) toward the groundwater flow system. Areas of discrete recharge transport much of the water through preferential flow routes that commonly transport water at rates several orders of magnitude greater than those encountered on nonkarst groundwater systems, support turbulent flow, are too large to provide effective filtration for most pathogens, and provide minimal adsorption or other natural cleansing processes (4). Substantially greater quantities of water per unit area enter the groundwater system through discrete recharge areas than through diffuse recharge (5). For this reason, the groundwater system is highly vulnerable to contamination from accidental spills and poor land use practices. Groundwater flow velocities in many karst areas vary as much as 10 to 1500 ft per hour between the same two points—the latter, in response to storms—and are tens of thousands to several million times faster than those characteristic of many granular aquifers (1).

Diffuse recharge refers to the general and relatively slow seepage and percolation of recharge toward the groundwater system.

THE EPIKARST

The epikarst is the uppermost portion of the bedrock that consists of fissures and cavities formed by dissolution. The dissolution features in the epikarstic zone are organized to move infiltrating water laterally to downgradient seeps and springs or to collector structures such as shafts that conduct the water farther into the subsurface (6). The epikarst can vary from essentially zero to 30 meters or more (4) and is controlled by such factors as climate, depth of groundwater circulation, and bedrock structure.

Aley (7) summarized general dye recovery results for karst aquifers where dye was introduced directly into locations of discrete recharge that ultimately discharged to springs that passed through the epikarst. Aley recognized three hydrologically distinctive epikarstic zones in karst areas; rapid draining epikarsts, seasonally saturated epikarsts, and perennially saturated epikarsts. Rapid draining epikarsts commonly occur in areas of high topographic relief in bedrock of high solubility and negligible sediment infiltration. Rapidly draining epikarsts are saturated with water for short periods of time, especially after storms, and have little water storage or detainment. Seasonally saturated epikarsts occur in areas of moderate relief where the solubility of the bedrock has resulted in the development of soil and residuum thickness and at elevations greater than local perennial streams. Water is typically stored seasonally and after major storms lasting periods of weeks to months. Perennially saturated epikarsts occur in areas of low to moderate relief along perennial streams and are mostly saturated with water.

Groundwater dye tracing in the epikarst is more complex than that reported in most karst groundwater tracing reports. Aley (7) stressed that dye tracing in the epikarst requires extensive sampling and quantitative analysis, more detailed and quantitative analysis of background fluorescence characteristics, and simultaneous use of multiple dyes with dye quantities and analytical approaches selected to minimize the chance that small dye recoveries are obscured by another dye.

Fluorescent Dyes

Many fluorescent dyes have been used in groundwater dye tracing to characterize flow routes in karst areas. For general problem solving in karst areas, eosine, fluorescein, pyranine, rhodamine WT, and sulforhodamine B are the most useful fluorescent dyes (8). The characteristics of these dyes are well documented in Aley (9), Smart and Laidlaw (10), and Kass (11). The selection of dyes to be used, the location of dye introduction points, the manner in which the dyes are introduced, the sampling strategy employed, and the analytical approach used must be tailored to the hydrogeologic setting, the issues of concern, and the quality and credibility of the data needed for the study (12).

Sampling Locations

In karst landscapes, water that goes down into the subsurface eventually comes up at a spring or a series of springs. Springs represent the final terminus or discharge points of groundwater flow in karst areas and serve as excellent sampling locations to monitor for dye introduced into the groundwater system (surface streams, pumping wells, and monitoring wells can also be used).

It is equally important to know where the dye does not go as where the dye does go. All possible discharge points should be sampled. All springs within a radius of perhaps 5 to 15 miles from a facility, especially those within ±90° of the vector of the hydraulic gradient from it, should be monitored during dye traces (13). For maximum results, dye tracing should be conducted during low and high flow conditions. Groundwater movement during periods of high flow may be diverted to higher preferential flow routes that may discharge at springs in adjacent groundwater basins. For this reason, it may be necessary to monitor 10 to 40 sites during a single trace to ensure that dye is detected. However, due to time and budget constraints, dye trace tests are often designed to maximize current hydrologic conditions.

GROUNDWATER TRACING METHODS

Activated carbon samplers are often used to recover dyes. Activated carbon samplers (also called charcoal samplers or passive detectors) consist of a few grains of activated coconut charcoal placed in heat-sealed packets of fiberglass screening. They are placed at sampling locations to adsorb continuously and thus accumulate specific fluorescent dyes (Figs. 1 and 2). As an illustration, a charcoal sampler in place in flowing water containing fluorescein or rhodamine WT for a week will typically contain about 400 times more dye upon analysis than the mean dye concentration in the water being sampled (14).

The sampling interval is based on site-specific conditions and the questions that need to be answered by the study. Weekly sampling intervals are appropriate for most studies. Once dye introduction points and sampling locations have been identified, Aley (7) recommends one or more rounds of sampling at most (and preferably all) of the sampling locations to characterize background fluorescence before the final selection of dye types and quantities are determined. The amount of dye used for tracing studies is typically based on professional experience, as there is no credible standard equation for estimating dye quantities needed for groundwater tracing work (8).

Figure 1. Activated charcoal packet placed at Big Spring, Hardy County, West Virginia. Spring discharges near red house located in the upper left corner of photo.

Figure 2. Activated charcoal packet attached to rock prior to placement in Waites Run, Hardy County, West Virginia.

SELECTION OF DYE INTRODUCTION POINTS

In karst areas, sinking streams (Fig. 3) and sinkholes (Fig. 4) are commonly used as dye introduction points. However, the selection of appropriate dye introduction points depends on the type of study being performed. On some occasions, it is often difficult to encounter overland flow at ideal introduction points. This problem can be resolved by using “dry sets.” A dry set involves the placement of a dye so that it will be flushed into a surface drainageway, sinkhole, culvert, or roadside ditch by the first storm flow (8).

Additional successful techniques used for introducing dye, especially at hazardous waste sites, include epikarstic dye introduction points (EDIPs) and dye introduction trenches (DITs). EDIPs are vertical boreholes that enter the top of the bedrock. DITs are constructed with a backhoe, typically 17 to 33 feet long, and extend into the epikarst. The construction and use of EDIPs and DITs, in addition to determining water quantities used to flush dye into the subsurface, are described in Aley (7,8).

Groundwater monitoring wells are typically poorly suited for use as dye introduction points primarily because they often fail to intersect the preferential flow openings that transmit water flow.

ANALYTICAL STRATEGIES

Quinlan (13) identified three analytical strategies used during dye trace studies. Qualitative tracing involves introducing dye at some discrete recharge point or zone and either visually observing the dye plume or

Figure 3. Fluorescein dye introduced into a sinking stream that flows across recharge units of the Capon Warm Springs Complex in Hampshire County, West Virginia.

visually observing dye removed from passive detectors. This method can be somewhat problematic especially when the dye arrives at a monitoring station at night. Qualitative dye tracing can be used to delineate boundaries of groundwater basins and identify point-to-point connections between input and recovery points, allowing special attention to be given to those points that have the highest potential for contaminating the groundwater system (15). Time of travel and flow velocity may generally be determined through qualitative dye tracing. Semiquantitative tracing uses passive detectors at sampling points followed by analysis with an instrument such as a scanning spectrofluorometer. Quantitative tracing includes instrumental analysis of water samples collected at sampling stations. Passive detectors are often used in concert with collection of water samples. The result of quantitative dye tracing is a set of measured dye concentrations, each sampled at a specific place and time. This method makes it possible to determine, with greater precision, groundwater flow velocities within preferential flow routes from points of recharge to discharge. Quantitative tracing provides a measure for determining the effectiveness of the monitoring system by estimating the tracer loss involved. Inadequate tracer recoveries are an indication that losses other than sorption or decay may be significant (16).

DYE TRACING AT WASTE DISPOSAL SITES

Figure 4. Fluorescein dye introduced into a perennial stream that flows into a sinkhole near Greenland Gap, Grant County, West Virginia.

Groundwater dye tracing in karst is used for a wide variety of purposes, however, one of the most important uses of dye tracing is for investigations at waste disposal sites. Investigations at waste sites in mature karst should include, locating all springs, streams in sinkhole bottoms, and major streams in caves; dye tracing to establish connections between the disposal site, springs, and underground streams; monitoring connected points; monitoring at least one spring shown by dye tracing not connected to the site, as a control; and, dye tracing to delineate boundaries of groundwater basins (17).

Groundwater monitoring at facilities regulated under the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Conservation, and Liability Act (CERCLA, more commonly known as Superfund sites) require the installation of groundwater wells to monitor the potential leakage of contaminants from the site. The problem with using groundwater monitoring wells in karst areas is that they often fail to intercept the conduits through which pollutants move. In many karst settings, most groundwater flow occurs in discrete conduits that are dendritic or trellised and terminates at springs whose water quality is representative of the mean of the ground water basin (17). Monitoring wells located on the basis of fracture trace and lineament analysis often fail to intercept major conduits in karst areas (18).

EARTHQUAKES—RATTLING THE EARTH'S PLUMBING SYSTEM

Michelle Sneed
Devin L. Galloway
William L. Cunningham
U.S. Geological Survey
Denver, Colorado

Hydrogeologic responses to earthquakes have been known for decades, and have occurred both close to, and thousands of miles from earthquake epicenters. Water wells have become turbid, dry or begun flowing, discharge of springs and ground water to streams has increased and new springs have formed, and well and surface-water quality have become degraded as a result of earthquakes. Earthquakes affect our Earth's intricate plumbing system—whether you live near the notoriously active San Andreas Fault in California, or far from active faults in Florida, an earthquake near or far can affect you and the water resources you depend on.

RESPONSES IN WATER WELLS

Water-level fluctuations caused by the 1964 magnitude(M) 8.5 Alaska earthquake were recorded in 716 wells in the United States (1); the earthquake also was registered on water-level recorders in many other countries. Responses of water levels in wells to earthquakes are influenced by such factors as the magnitude and depth of the earthquake, distance from the epicenter, and the hydrogeologic environment, which may be consolidated rock, unconsolidated sediment, karst, or hydrothermally altered. The depth of the well, whether the aquifer is confined or unconfined, and well construction also influence the degree of water-level fluctuations in wells in response to seismic waves. Some aquifers may act as resonators, which may amplify the response.

The most common type of observed ground-water response is an instantaneous water-level offset, or step, which may be either an increase or a decrease and may occur near or far from the epicenter. Recovery to the pre-earthquake water level can be so rapid that no change will be detected if the water level is measured

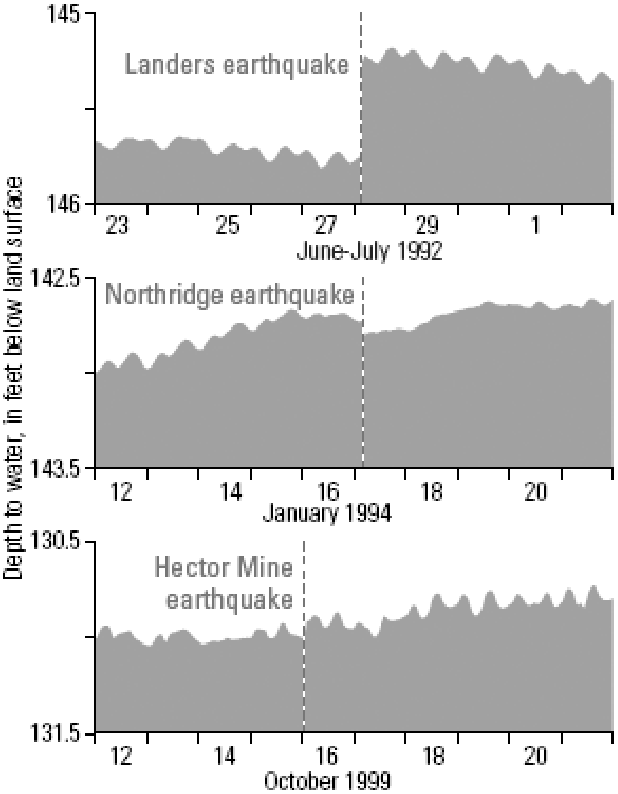
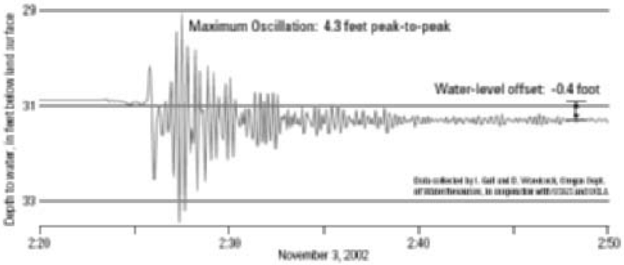
This petroleum seep in the Ojai Valley, California developed as a direct result of the 1994 Northridge earthquake in southern California. Notice the oil has not yet spread far and grass blades can be seen standing through the crude oil. The photo was taken a few days after the earthquake.



Well MO-18/02W/29-0017 in Wisconsin responded to the distant Denali Fault earthquake in Alaska.



Hydroseismogram recorded in a well near Grants Pass, Oregon, shows water-level oscillations and a small offset relative to pre-earthquake water level in response to the Denali Fault earthquake.

infrequently, or it may take as long as days or months. Steps can be large enough to make a well flow at land surface, or render it dry. The 1998 M5.2 Pymatuning earthquake in northwestern Pennsylvania caused about 120 local household-supply wells to go dry within 3 months after the earthquake (2). The 2002 M7.9 Denali Fault earthquake in Alaska caused a 2-foot water-level rise in a well in Wisconsin, more than a thousand miles from the epicenter.

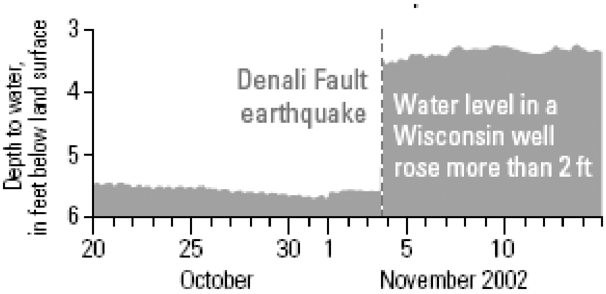
The other type of ground-water response is a water-level oscillation, which occurs more often, but is less commonly recorded. In the few cases where oscillations have been recorded, they resemble long-period seismograms, known as hydroseismograms. A well in Grants Pass, Oregon, is instrumented to record water levels at 1-second intervals, and the record from the Denali Fault earthquake shows peak-to-peak seismic oscillations of more than 4 feet and a permanent offset of 0.4 feet.

RESPONSES IN STREAMS, SPRINGS, SEEPS, AND LAKES

Well 8N/10W-1Q1 in the western Mojave Desert, California responded to several southern California earthquakes.

Surface-water responses to earthquakes include changes in chemistry, seiches (wave oscillations) in lakes and other open water bodies, increases in stream, spring, and seep discharge, some instances of springs going dry or the appearance of new springs, and a very few examples of decreases in stream discharge. After the Denali Fault earthquake, many eyewitnesses throughout the contiguous United States reported water "sloshing" back and forth in lakes, bayous, ponds, and pools. Seiches lasted as long as half an hour, resulting in broken moorings in Lake Pontchartrain, Louisiana (Seth Moran, U.S. Geological Survey, written commun., 2002).

Streamflow may continue to increase for a few days and then gradually decline toward the pre-earthquake baseline condition for several months. Water flowing in a stream can come from overland flow or from ground water discharging into the streambed (baseflow). An abrupt increase in streamflow without precipitation or upstream reservoir release indicates increased contributions from the ground-water system. A coseismic (at the time



the seismic wave train arrives) discharge increase of approximately 40 percent was recorded in Santa Paula Creek, California, 35 miles WNW., of the 1994 M6.7 Northridge, California earthquake epicenter (3), and increased discharges were measured at numerous sites in the California Coast Range in response to the 1989 M7.1 Loma Prieta, California earthquake (4). The appearance of new seeps and springs and turbidity in streams also are common. Following the Northridge earthquake, a new oil seep began flowing in the Northern Ojai Valley (Stephen P. Mulqueen, Department of Conservation, Division of Oil, Gas, and Geothermal Resources, oral commun., 2003).

PRECURSORY RESPONSES

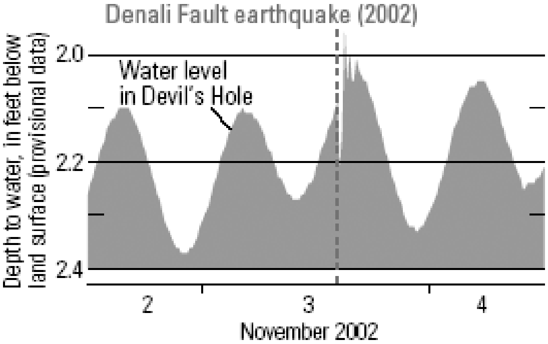
Many preseismic or precursory hydrogeologic responses have been reported, but in most cases, documentation has not been sufficient to convince the scientific community of their predictive value or to rule out explanations unrelated to earthquakes. Some investigators believe earthquakes cannot be predicted (5), whereas others believe that while earthquake prediction is difficult because of the youthfulness of seismic research and the limited number of case studies to investigate, prediction will not forever be impossible (6). Roeloffs (7) states "The documentation of a few of these reports [of precursory hydrogeologic changes] is now approaching levels that require them to be given scientific credibility." Water levels and chemical data seem to be the best documented precursory signals to date, and are monitored in several countries as potential indicators of an impending earthquake.

Japan has some of the best documented occurrences of precursory hydrogeological changes, preceding both the 1978 M6.8 Izu-Oshima earthquake (8,9), and the more recent, disastrous 1995 M7.2 Kobe earthquake (10). Before either or both of these events, water-level changes occurred in many wells, and there appeared to have been precursory changes in ground-water temperature, radon, chloride, and sulfate concentrations, as well as dissolved gas ratios in mineral springs (11,12). The preseismic changes in chloride and sulfate content of the Kobe event were reconstructed by analyzing dated, bottled ground water that is distributed in the domestic market.

The well-documented and similar hydrogeologic precursors at Izu-Oshima and Kobe have motivated the Japanese government to continue water-level monitoring at more than 30 wells in seismically active areas (13). The suggestion of precursory hydrogeologic changes is tantalizing, because the ultimate goal of most earthquake research is to reduce the hazard posed by major events, and providing some warning of impending activity would be very useful in that regard.

HAZARDS RELATED TO HYDROGEOLOGIC RESPONSES

Hydrogeologic responses to earthquakes can create a variety of hazards. Water supply may be disrupted if wells go dry or become too turbid to pump, and infrastructure damage may result from ground motion. After the 1992 M7.3 Landers, California, earthquake, bubbles of gas (carbon dioxide-enriched air) appeared in water from several San Bernardino, California, supply wells, clogging and disabling the filtration system (14). Hydrogeologic responses that cause wells to flow or streamflow to increase may cause flooding, landslides, erosion, and other related problems. Water quality also may be adversely affected



This pristine spring in the unique environment of Ash Meadows in Nevada is hydrologically connected to Devil's Hole, which is a nearly vertical cavern below the water table in southern Nevada. An endangered species, Devil's Hole pupfish, has lived in Devil's Hole pool for thousands of years. The water level in Devil's Hole oscillated in response to the Denali Fault earthquake, which disrupted the spawning areas of the pupfish near the surface of the pool.

by increased discharge, turbidity, or hydrogeochemical changes. Following the Landers earthquake, a pre-existing oil and natural gas seep in Tapo Canyon became more active, eventually flowing into and polluting the Santa Clara River (14).

Water-quantity and quality changes following an earthquake can adversely affect sensitive ecosystems, harming the plants and animals that live there. The endangered Devil's Hole pupfish (Cyprinodon diabolis) has lived for thousands of years in only one pool in Ash Meadows, Nevada, spawning on a single 6 × 13 foot shelf just below the water surface. In 1978, an earthquake in Mexico caused such violent water-level oscillations in Devil's Hole that algae was scoured from the shallow shelf (15), and the 2002 Denali Fault earthquake also apparently caused oscillations of 5–6 feet (Jim Roche, National Park Service, written commun., 2002). A persistent drop of water level below the shelf could extinguish the pupfish, whose life span is only a few years. Although court orders and careful management have led to population stability, the existence of the Devil's Hole pupfish remains precarious.

Ground-water systems are mechanically coupled to the rocks and sediments in which they exist. In addition to hydrogeologic responses to earthquakes, hydrogeologic changes may cause earthquakes or volcanic events. Earthquakes can be induced by the filling of surface reservoirs, or by annual or shorter-term fluctuations in reservoir levels, as is the case in most shallow earthquakes in the Aswan, Egypt area (16). Earthquakes also can be induced by the injection or withdrawal of fluids through wells, as was illustrated by the earthquakes caused by injection of waste fluid from munitions production at the Rocky Mountain Arsenal in the 1960s (17). More speculatively, the observation that large earthquakes can cause distant hydrogeologic changes may help explain how the 1992 M7.3 Landers, California earthquake triggered microearthquakes at a number of locations many hundreds of miles from the epicenter (18).

MECHANISMS FOR HYDROGEOLOGIC RESPONSES TO EARTHQUAKES

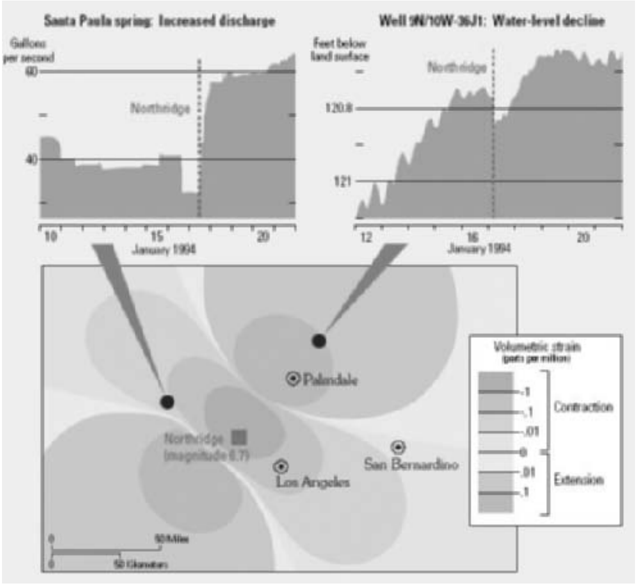
Known hydrogeologic responses most often occur as the seismic wave train arrives (coseismic) or sometime thereafter (postseismic); evidence of precursory (preseismic) hydrogeologic changes is becoming more compelling, but additional scientific investigation is needed to explain these phenomena.

Water levels in wells respond to the seismic-wave induced expansion and contraction of the aquifer tapped by the well, in turn causing step or oscillatory fluid-pressure changes. If flow in the well-aquifer system is fast enough, then these pressure changes cause flow into and out of the well, which sets up resonant motion of the water column, and the result is the seldom-recorded water-level oscillation. The more commonly recorded water-level offsets have been measured both near and far from earthquake epicenters. Offsets are expected in the 'near field', or static strain field, of an earthquake because the earthquake subjects the earth's crust, including its aquifer systems, to stress and permanent strain (deformation). This deformation process results in altered fluid pressure within the aquifer systems, and consequently, a steplike change in water level would be expected (3,14). The earthquake-induced water-level decline in well 9N/10 W-36J1 is the expected response for an extensionally strained region (14). Providing that the water-level response to strain is known, this relation allows scientists to use the earthquake response of water levels in favorably located and designed wells to measure strain, and also to calculate otherwise difficult-to-measure hydrologic properties of the aquifer. At distances of hundreds or thousands of miles, the offset can often be directly related to the amount of deformation produced by movement on the earthquake fault (19).

Possible mechanisms for responses are variable. For upward steps in shallow wells, compaction of overlying alluvium such as occurs during liquefaction may be the mechanism producing the offset (19). Fluid-pressure declines also can be caused by the escape of small amounts of exsolved gas from pore spaces in response to seismic waves. In a fractured rock environment such as northwestern Pennsylvania where the Pymatuning earthquake occurred, permeability may be altered due to the unclogging, widening, or narrowing of a fracture, or the creation of new fractures (2). Similarly, an increase in co- and post-seismic ground-water discharge at the surface through a spring, seep, or stream, can be caused by an increase in vent or fracture conductance (20), or an increase in the subsurface fluid pressure or permeability in the formation (4,14). The earthquake-induced increased discharge in Santa Paula spring is the expected response for a contractionally strained region (14). For a brief review of streamflow and water well responses to earthquakes and discussion of potential mechanisms see Montgomery and Manga (21).

RECORDING ACCURATE HYDROGEOLOGIC RESPONSES

Measurement techniques often do not adequately reflect hydrogeologic responses to earthquakes. In the recent past, water levels and discharge were recorded continuously using a drum recorder, similar to the method in which earthquakes are recorded on a seismograph. More recently, scientists have migrated to more cost-effective digital measurements that are recorded on an electronic datalogger. Ground-water levels typically change slowly, and dataloggers have limited storage capacity, such that data are recorded at 15-minute intervals, or more often, at 30- or 60-minute intervals. With a recording interval on this order, a water-level response from an earthquake may not be adequately defined by the periodic data; the recovery to the pre-earthquake water level can occur so



quickly that no change will be detected. In some cases, the water-level response is not in the expected direction because the initial response was not recorded, or because the response is affected by the particular well construction (the well-bore storage effect). Although stream or spring discharge may change as a result of a change in the ground-water contribution to the baseflow of the stream, surface-water discharge measurements often are not accurate enough to reliably detect small changes in flow. Additionally, flow is often controlled artificially, either partially or completely, preventing the detection of earthquake-induced changes.

CONCLUSIONS

Hydrogeologic responses to large distant earthquakes have important scientific implications with regard to our earth's intricate plumbing system. The exact mechanism linking hydrogeologic changes and earthquakes is not fully understood, but monitoring these changes improves our insights into the responsible mechanisms, and may improve our frustratingly imprecise ability to forecast the timing, magnitude, and impact of earthquakes.

IN SITU ELECTROKINETIC TREATMENT OF MtBE, BENZENE, AND CHLORINATED SOLVENTS

Walter W. Loo
Environmental & Technology Services
Oakland, California

INTRODUCTION

The practice of soil and groundwater cleanup should follow the intent of the U.S. EPA laws and regulations such as the Safe Drinking Water Act (SDWA), the Resources Conservation and Recovery Act (RCRA) and the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA). Any environmental treatment process must be able to, or must be engineered to protect and conserve our resources (air, water, soil, and human) and not create undesirable side effects. Many of the conventional waste treatment technologies cannot meet these objectives and simply involve transferring the waste from one location or phase to another. This is true for waste excavation, landfill disposal, incineration, pump and treat, thermal desorption, and soil vapor extraction. Sound waste treatment technologies must be able to transform toxic and hazardous chemicals into harmless chemicals or render them harmless with the least energy consumption to achieve a good economic balance. To the extent possible, all treated soil and groundwater should be recycled for beneficial use. Most organic chemicals can be oxidized to harmless carbon dioxide, water, and inorganic chloride with existing and available innovative waste treatment technologies. The most difficult media for most waste treatment processes are relatively impermeable clayey media and fracture media. These media often absorb/adsorb the toxic and hazardous wastes spilled below the ground surface. Often, more than 90% of the waste spilled is attracted to these media. It is most fortunate that electrokinetic treatment processes can overcome the difficulties of relatively impermeable media and achieve or enhance the oxidation of many toxic and hazardous wastes at relatively low energy consumption.

The following sections discuss the *in situ* treatment processes, tests and design parameters, achievable cleanup levels, and case histories of successful treatment.

ENGINEERED ELECTROBIOCHEMICAL PROCESSES

Most petroleum hydrocarbons, including gasoline, diesel, jet fuel, kerosene, aviation fuel, motor oil, benzene, toluene, ethylbenzene, and xylenes are biodegradable. There has been some concern over the bioremediation of MtBE. However, electrokinetically enhanced cometabolic biotreatment of MtBE has been demonstrated in the field with repeated success (1).

Most chlorinated solvents are biodegradable through the application of the cometabolic biotreatment processes. However, because of the earlier publication of laboratory successes by the U.S. EPA in the 1980s, many scientists and engineers began to apply flammable methane and butane blindly into the vadose zone without questioning the side effects for health and safety (2–4). The same applies to the addition of toxic phenol, dichlorobenzene, and toluene into the groundwater as cosubstrates for bioremediation, which violates the underground injection control regulation established by the U.S. EPA. However, electrokinetically enhanced cometabolic biotreatment of chlorinated solvents using glucose sugar has been demonstrated in the field with repeated success (1).

Biochemical Processes

Bioremediation can be defined as the use of naturally occurring microorganisms to detoxify hazardous wastes (1), which is particularly true for hazardous organic wastes. The basic mechanism of bioremediation is promotion of the growth of microorganisms that are adapted to the organic wastes spilled in soil and groundwater. Stimulation of the growth of the microorganisms is controlled by proper temperature, oxygen, moisture, nutrients, and distribution of such in the impacted media. During growth, the microorganism will secrete enzymes and biosurfactants to break down the hazardous organic molecules (detoxification) and make them available for cellar absorption. Subsequently, the microorganism will grow and multiply, and the process will repeat itself. The end result is mineralization of the carbon source (from spilled hazardous organic wastes) aerobically into carbon dioxide, water, and biomass without undesirable side effects.

The application of bioremediation in hazardous waste management began in the early 1980s. The basic principles of biotreatment in the environment are described by Gaudy and Gaudy (5), who emphasized the enhancement factors, or engineering, in applying the bioremediation technology in the field. The biotreatment of excavated soil in engineered biopiles began to gain recognition in the late 1980s. In the 1990s, engineered bioremediation took such forms as soil bioventing, *in situ* aqueous phase biotreatment of soil and groundwater, and bioreactors to treat water, sludge, and organic vapor. In the mid-1990s, the evaluation of intrinsic or natural attenuative bioremediation prior to an engineering feasibility study became popular. The application of cometabolic bioremediaion treatment processes also flourished for chlorinated solvents to petroleum hydrocarbons.

The bioremediation professional must follow the basic fundamental science and engineering to complete a bioremediation project successfully. The following sections cover the science and engineering of bioremediation processes, microbial ecology, bioenhancement, soil microbes and pathogens, the aerobic process, the anaerobic processes, and the cometabolic process.

To carry out a bioremediation process properly, the living environment favorable for the microorganism must be understood. Microorganisms used in bioremediation are generally classified as mesophiles or the warm temperature type. The optimum range of temperature in which they thrive is from 80–100 °F. When the temperature of the bioremediation system drops below 40 °F, the microorganism goes into hibernation. Microorganisms must also have optimal moisture to grow and to survive. Dry conditions are not favorable for bacterial growth. All microorganisms require an available carbon source and nutrients for growth. An adapted indigenous microorganism in a hazardous waste environment relies on the carbons in organic chemicals as a food source (substrate). The nutrient requirements include sources of phosphorus, nitrogen, and iron. The microorganism also relies on the availability of oxygen in the environment to mineralize the hazardous chemicals into carbon dioxide and water under aerobic conditions.

Bioenhancement Methods. It is evident that when hazardous wastes spill into soil and groundwater, it is not an optimized microbial ecology for bioremediation. Therefore, we must engineer a favorable microbial ecology for optimal bioremediation to take place. The following sections cover an optimal microbial ecology that can be engineered or enhanced for all situations.

Oxygen Enhancement. If oxygen is not available in soil (vadose soil) or in groundwater (aquifer), this anaerobic condition is prone to create hydrogen sulfide (toxic gas) and methane gases (flammable gas). The quantity of oxygen required must satisfy the chemical oxygen demand (COD) of the soil and groundwater media. It is important to point out that in fully saturated media, both the COD of the soil and the groundwater must be satisfied. The objective is to supply enough oxygen to satisfy the COD of the impacted media. Oxygen can be enhanced by injecting air or oxygen into the pore space of the vadose soil. Dissolved oxygen in groundwater can be enhanced by adding oxidants, by *in situ* electrolytic (electric current) generation of water in the impacted media, or by creating of hydroxyl radicals (a strong oxidant) at the initial stage of the electrolysis of water. Another source of oxygen is through introducing carbohydrates, which will biodegrade and provide enough oxygen to mineralize the hazardous organic compound into carbon dioxide, water, and biomass.

Heat Enhancement. To achieve an optimal growth temperature (80–100 °F) for mesophilic microorganisms, the vadose zone soil can be heated by circulating warm air into the pore space in the soil. It may not be necessary to heat up the entire solid matrix of the mass because most of the hazardous waste tends to adhere to the surface of the solid matrix. Passive solar panel air heating can provide an economical means of heat delivery. Recirculation of heated air in the subsurface will also save energy cost because the soil mass itself acts like a heat sink that has very good insulating value. The same applies to heating groundwater by a passive solar water heater. The heating requirements (in BTUs) must be estimated based on the weight of the impacted media. The weight of the impacted media can be calculated as the volume of the soil or groundwater plumes. A swimming pool passive solar heating panel can supply more than adequate heating value in less than 30 days for most bioremediation projects.

Nutrient Enhancement. Sometimes, there are insufficient nutrients in the form of nitrogen, phosphorus, and iron in the soil and groundwater plumes. Nutrient enhancement applies only when there is a deficiency. For proper bioremediation, a carbon (C) to nitrogen (N) to phosphorus (P) weight ratio of 100:10:1 should be followed. The weight of carbon in the plume is determined by the total organic carbon (TOC) concentration times the weight of the plume that requires cleanup.

Moisture Enhancement. If warm air (80° to 100 °F) is being recirculated within the soil plume for soil remediation, the moisture in the warm air (humidity) should be adequate enhancement. No need exists for moisture enhancement in saturated media.

Nutrient Distribution. The most difficult media for hazardous waste treatment processes to work in are a relatively low-permeability clayey medium and a fracture medium. These media often absorb/adsorb the toxic and hazardous waste spilled below the ground surface. Often, more than 90% of the waste spilled is attracted to these media. It is most fortunate that the electrokinetic treatment process (electro-osmosis and electromigration of water) can overcome the difficulties of relatively low-permeability media, achieve or enhance the aerobic biochemical oxidation of the human toxic and hazardous wastes, and consume relatively little energy (see ELECTROKINETIC PROCESSES).

CoMetabolic Processes With Glucose and Sugar. The basic mechanism of bioremediation is triggering the growth of microorganisms that are adapted to organic wastes spilled in the soil and groundwater. Stimulation of the growth of the microorganism is controlled by proper temperature, oxygen, moisture, nutrients, and cosubstrates, and distribution of such in the impacted media. During growth, the microorganism will secrete enzymes and biosurfactants to break down the hazardous organic molecules (detoxification) and to make them available through cellular absorption. Subsequently, the microorganism will grow and multiply, and the process repeats until the food source is depleted. The end result is mineralization of the carbon source (from spilled hazardous organic wastes) aerobically into carbon dioxide, water, and biomass without undesirable side effects. The cometabolic processes for bioremediation of chlorinated solvents and petroleum hydrocarbons are the most promising trouble-free biotreatment processes and are very efficient. The cometabolic process can be defined as the introduction of an easily biodegradable substrate into the environment, which triggers the secretion of enzymes from microorganisms that are adapted to the spilled hazardous organic waste.

The biotreatment of chlorinated solvents is a highly sought after solution to widespread soil and groundwater contamination problems. However, most of the knowledge of biotreatment of chlorinated solvents is found only in research laboratories. A successful laboratory demonstration of the cometabolic biotreatment of trichloroethene (TCE) by methanotrophic bacteria columns was achieved by the EPA Ada Laboratory in 1985 (6). In 1987, the EPA Gulf Breeze Laboratory successfully demonstrated the cometabolic biotreatment of TCE by *Pseudomonas putida* through an aromatic pathway (7). In 1989, Loo, (8) successfully demonstrated the first field closure of the cometabolic biotreatment of TCE and trichloroethane (TCA) together with toluene in soil through heat and nutrient enhancement by the growth of indigenous bacteria *Bacilli* and *Pseudomonas fluorescens*. In 1991, Stanford University demonstrated partial success of the cometabolic biotreatment of chlorinated solvents in groundwater by methanotrophic bacteria at Moffet Field, California. Loo et al. (9) demonstrated the bio-treatment of TCE in the laboratory, field pilot, and in field application using glucose, which is nontoxic and nonhazardous, as a co-substrate. Loo et al. (9) developed and successfully applied the cometabolic biotreatment of petroleum hydrocarbons using glucose and sucrose as a co-substrate in both soil and groundwater Subsequently, many other site closures were achieved through the application of the cometabolic bioremediation of petroleum hydrocarbons.

Electrokinetic Processes

Direct current (DC) electricity is a widely used technology in industrial, commercial, and military applications. Direct current from solar panels is also used in space age technology for the electrolysis of water to produce hydrogen as fuel and oxygen for breathing. For environmental protection, direct current is used in the cathodic protection of steel underground storage tanks and pipelines from corrosion and leaks. Electrokinetic (EK) processes involve the application of DC electricity to soil and groundwater in the subsurface (1). EK processes originated or based their work on the geotechnical dewatering of clayey material by Casagrande (10–12). Other significant pioneering EK applications in oil and gas recovery were developed by Chilingar et al. (13–16).

The application of EK technology in the environmental field was first reported in the literature in the 1980s (17), most of the applications were for the isolation or recovery of metals. Van Doren and Bruell (18) first reported that the EK process destroyed benzene in wet clay in a laboratory bench scale test. Loo (8) and Loo and Wang (33) first reported the successful commercial application of the EK process as the primary enhancement process for removing or desorbing chlorinated solvents from a thick clayey soil layer at a defense contractor site closure located in Anaheim, California. The U.S. Army Corp of Engineers (19) listed EK treatment as a viable remedial process for treating hazardous wastes. In 1995 at the HAZMACON Conference, Santa Clara, California, the best paper award was given to the paper entitled “Elecrokinetic Treatment of Hazardous Wastes in Soil and Groundwater” (20). In 1995, the U.S. EPA (21) summarized the application and development of electrokinetic (EK) treatment processes by various private companies, the U.S. Department of Defense, the U.S. Department of Energy, and various universities as a potential cost-effective treatment for hazardous wastes. In 1997, the U.S. EPA (17) summarized and updated various EK applications in research, development, and commercial treatment of hazardous and radioactive wastes.

The EK processes works effectively for both permeable and relatively impermeable media. For relatively impermeable porous media like clay and silt, direct current conducts well in the media. The electrical conductivity of clay is often 1000 times greater than that of sand, sandstone, limestone, and igneous and metamorphic rocks. The same applies to fractured media where the fractures are often filled with highly conductive clayey and fine grain minerals. For porous media like sand, the flow of electricity is most likely through water that has naturally occurring electrolytic ions such as chloride, bicarbonate, nitrate, potassium, and sodium. The water molecules and positively charged ions (cations) will also be “dragged” by the electron flow from the anode toward the cathode and create a hydraulic mound (high) around the cathode by the induced electrokinetic gradient (Fig. 1). The EK processes works for both the vadose zone and the saturated zone in the subsurface, as long as there is adequate moisture in the medium. A dry medium does not conduct electricity very well.

As mentioned in the previous section, electrolysis of the water molecule will produce dissolved hydrogen around the anode and dissolved oxygen around the cathode. Therefore, higher dissolved oxygen around the cathode will help and encourage aerobic biotreatment of organic compounds. Electromigration will also help to bring the desorbed organic compounds to places enriched with oxygen and nutrients.

Regulatory And Permitting Requirements. No regulation or permitting requirement apply directly to the use of direct current in the subsurface. When the EK process is applied as an enhancement process for bioventing in the vadose zone, the extracted volatile organic vapor can be recirculated back into the center of the soil plume to avoid an air emission permit.

The EK process can make the groundwater migrate back and forth within the groundwater (thorough *in situ* mixing), so there is no need to pump and treat and thus no discharge permit. Also, when electrolytes and nutrients are added into the subsurface for EK processes, no underground injection control permit is required as long as all electrolytes and nutrients added are nontoxic and nonhazardous.

EK application in the subsurface is similar to cathodic protection with an impressed current and to the function of electrical grounding devices, which require no permit to construct and operate.

IN SITU FIELD FEASIBILITY CHARACTERIZATION

Before implementing a full-scale bioremediation project, one should conduct a field pilot confirmation test for mineralization products. The purpose of the field pilot test is to determine if the indigenous microorganism responds to the various enhancement elements. A simple oxygen slug injection into a vadose zone well while monitoring the respiration of the metabolic function of the indigenous microorganism will suffice. The simple oxygen enhancement field test should show a favorable increase in carbon dioxide and a reduction in oxygen in the well.

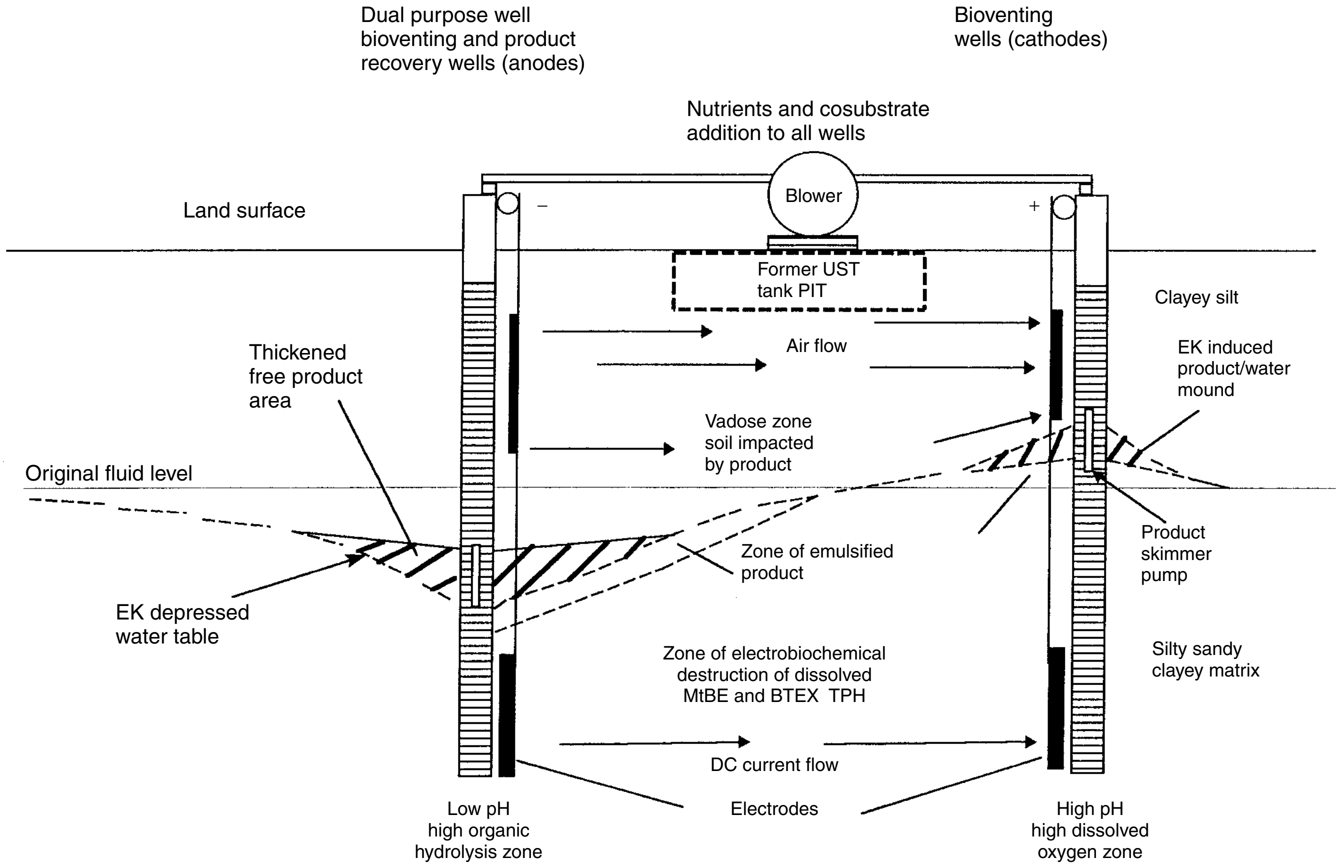

Figure 1. Generalized *in situ* electrobiochemical remedial cross section.

This whole field test involves only one vadose well in the middle of the impacted soil plume, one compressed oxygen bottle, and an oxygen/carbon dioxide field.

Biochemical Field Survey

The initial distribution of the organic hazardous waste in the soil and groundwater is the starting point for the design of a bioremediation project. For the baseline condition of a soil plume, a statistically significant soil sampling plan will be required because of the heterogeneous nature of the distribution of organic hazardous wastes in the soil. The plan should follow the requirements of the EPA SW-846 sampling procedure for the lateral extent of a soil plume to ensure statistical significance. For the vertical extent, one should add randomness by staggering depths instead of using a regular depth interval to ensure even distribution and to eliminate any significant lithologic layering effects. It is fairly easy to establish a baseline for dissolved constituents in the groundwater because of the slow dilution resulting from the influx of clean groundwater from upgradient. The only requirement is an adequate number of monitoring wells. The key sample analysis parameters required for bioremediation design and engineering are as follows:

weight of the soil and groundwater plumes
concentration of wastes in soil and water
total heterotroph plate count
chemical oxygen demand (COD)
total organic carbons (TOC)
total Kjeldahl nitrogen (TKN)
nitrate
total phosphorus
iron
temperature within the soil and groundwater plume
dissolved oxygen and pH in groundwater
moisture content in soil
concentration of oxygen and carbon dioxide in soil pores

When the soil and groundwater plumes are fully characterized in weight, chemical requirement, engineering, installation, equipment, delivering lines, monitoring, and analysis, operating and maintenance costs can then be estimated for economic feasibility. The ultimate cost should be presented in dollars per ton of soil or groundwater plume that requires biotreatment.

Electrokinetic Field Surveys

The main purpose of the *in situ* direct current survey is to detect any anisotropic (uneven and bias) flow directions. The survey also may provide clues to unidentified buried metallic lines and structures that may require cathodic protection. Field DC flow should be conducted with combinations in pairs of all available wells located inside and outside of the plume. For example, for four wells there should be six survey measurements. For six wells, there should be 15 survey measurements. The survey should be conducted at fixed voltage (electrical potential) and measure the direct current flow in amperes. The DC flow survey requires 110 volt AC power with a DC converter rated for 50 to 100 DC volts (range) and a maximum of 10 DC amperes. Wires must be insulated to prevent short circuits.

IN SITU ELECTROBIOCHEMICAL TREATMENT DESIGN

The economical alternative to digging, hauling, and disposing or *ex situ* treatment of contaminated soil is bioventing in the subsurface. The economical alternative to pumping, treating, and discharging of contaminated water is *in situ* groundwater biotreatment.

Soil Bioventing

Bioventing is a method of treating petroleum hydrocarbon contaminated soil in the vadose zone by circulating air through the pores of the soil matrix. It is particularly effective when the moisture content and nutrient level in the soil can be amended to prime enhancement conditions for bio treatment. Bioventing can treat both volatile and nonvolatile organic hydrocarbons. Hinchee et al. (22,23) and Miller et al. (24) developed the bioventing concept for bioremediating petroleum hydrocarbons at many U.S. Air Force sites. However, only oxygen enhancement was adopted for soil cleanup at many of these sites. The process involved injecting air at one well into the contaminated soil plume, with little evaluation of the engineering feasibility. Little engineering consideration was given to the migration of organic vapor that was pushed out of the soil plume and formed condensates, which further spreads the groundwater contamination. This may be the most economic means of treating petroleum hydrocarbons in soil for the U.S. Air Force, but it may face the side effects of uncontrolled spreading of the dissolved groundwater plume.

The first fully enhanced bioventing system for treating gasoline was applied in the clayey marine conglomerate at the PepBoys site, San Diego, California (25). The electroosmosis process desorbed or squeezed out the gasoline in the clayey soil and made the gasoline available for bioventing. The extracted air was heated and reinjected into the vadose zone soil for heat enhanced biotreatment. The heated air also carried the water squeezed from the clay layer as humidity for moisture enhancement. Pure oxygen gas was injected into the middle of the soil plume to replenish the oxygen used during aerobic bioventing. Nitrogen-based nutrient gas was also injected into the middle of the soil plume for nutrient enhancement. Nitrogen-based nutrient gas injection into soil is widely used in large-scale agricultural farming practices.

Groundwater Biotreatment

The aqueous phase biotreatment discussed in this section does not involve pumping out any water from the ground. The most challenging aspect of *in situ* aqueous biotreatment is the distribution or penetration of nutrient, oxygen, and heat into the clayey or less permeable areas within the saturated media. Electrokinetic processes can overcome these conditions.

Passive Biotreatment. Passive biotreatment involves oxygen, nutrient, heat, and electrokinetic enhancement to biodegrade toxic organic chemicals into harmless carbon dioxide, water, and biomass. Oxygen can be enhanced by creating dissolved oxygen through electrolysis of groundwater or by using the oxygen in food additive cosubstrates dissolved in the groundwater. Nutrients can be enhanced by adding ammonium-based food additive chemicals into the groundwater. Heat can be enhanced economically by infiltrating solar heated water into the groundwater through an infiltration gallery or through injection into a remedial well. Electrokinetic enhancement or mixing can be achieved by electromigration of nutrient/electrolyte through permeable and impermeable water saturated media.

Loo (26) demonstrated that benzene can be biotreated to a nondetectable level in groundwater. Loo (27) also demonstrated that MtBE can be electrobiochemically treated to a nondetectable level in groundwater. Finally, Loo et al. (28) and ETS showed that chlorinated solvents can be biotreated to nondetectable levels in groundwater.

The following sections provide the requirements for EK design and implementation. The basic electrokinetic feasibility test parameters are as follows:

field pH, conductivity, and dissolved oxygen of water
laboratory pH and conductivity of soil
chemical oxygen demand (COD)
contaminant concentration in soil above and below the water table
contaminant concentration in groundwater
selective anion and cation analysis

Representative samples must be obtained at the center of the plume where the concentration of the contamination is the highest. Representative samples must also be obtained at the peripheral monitoring wells upgradient, downgradient and cross gradient.

Electrokinetic System Components

Electrokinetic system components may include but are not limited to electrodes, electrolytes, wiring, and power supply. The description and selection of these components are described in the following sections.

An electrode can be made of any good conductor. All electrodes for environmental cleanup must be relatively inert and should not contain hazardous or toxic chemicals. Typically, copper and stainless steel electrodes should be avoided. The most common electrodes are made of iron, black steel, carbon, and graphite. More exotic electrodes used are made of gold, platinum, and titanium. The electrodes can be ordered in any shape and form to fit the particular application. The most common form is a round solid rod or a tube from 1 to 10 feet long.

The use of food additive chemicals as an electrolyte is preferred to increase the flow of direct current in the ground. Note that the electrolyte should be applied on an as needed basis. Soil and groundwater may contain enough electrolyte minerals to provide adequate direct current flow. The application of electrolyte sometimes is necessary for maintenance of electrodes to prevent corrosion at the anode and mineral scaling at the cathode. Potassium and sodium chlorides are not considered environmentally friendly electrolytes electrolysis of potassium and sodium chlorides will yield toxic chlorine gas, which may create unsafe and unhealthy conditions.

All electrical wiring must be insulated and rated for at least 30 amperes. The length of wires to cathodes and anodes need not be equal, but multiple wires to either cathode or anode must be equal in length and size to prevent short circuits. It is often very common for each circuit wire to carry less than 2 amperes of DC current.

Direct current power supplies often draw from 110 Volt AC or 220 Volt AC power sources. Same of the common names for the DC power converter are DC testing power supply, DC welding units, an automobile battery with a proper recharging source, and electrical solar panels. It is advised that no more than 10 DC amperes be drawn from any converters to prevent overheating.

ACHIEVABLE CLEANUP LEVELS

EK processes can achieve the very low levels of concentrations of various hazardous wastes in soil and groundwater listed here as examples:

	In Soil	In groundwater
Petroleum hydrocarbon (gasoline)	Less than 50 ppm	Nondetectable (less than 1 ppm)
Petroleum hydrocarbon (diesel kerosene, jet fuel, motor oil, etc.)	Less than 100 ppm	Nondetectable (less than 1 ppm)
Benzene	Less than 100 ppb	Nondetectable (less than 1 ppb)
Methyl tertiary-butyl ether (MtBE)	Less than 1 ppm	Nondetectable (less than 5 ppb)
Chlorinated solvents (PCE, TCE)	Less than 100 ppb	Nondetectable (less than 5 ppb)

ECONOMICS OF *INSITU* ELECTROBIOCHEMICAL TREATMENT

For a typical small-scale project, assuming less than 3,500 tons of contaminated soil and groundwater, the following is a breakdown of the in-situ electrobiochemical treatment project cost estimate in 2002 US dollars:

Planning and preliminary design	$3,000
Field feasibility testing	$20,000
Detailed engineering design	$5,000
Remedial system installation (six remedial wells)	$40,000
Startup remedial testing	$13,000
Operation and maintenance (6 months)	$18,000
Remedial monitoring	$6,000
Closure confirmation sampling	$5,000

The unit price remedial cost estimate is about $30 per ton. For medium size remedial projects of more than 10,000 tons, it is not unusual to complete the project at less than $20 per ton. For larger size remedial projects of 50,000 tons or more, it is not unusual to complete the project at less than $15 per ton.

The economics of power consumption can be measured in kilowatt hours (kwh) and each kwh costs US $0.10 to $0.20 or less than $2 per ton depending on the cost of power at the location. Each watt of energy is equal to the product of voltage (1 volt) and amperage (1 ampere). Normally, the cost of electricity is insignificant compared to the overall remedial project cost.

CASE HISTORIES

There are many documented examples of field pilot-scale EK remediation of toxic/radioactive metals and hazardous organic chemicals. The individual project descriptions are included in the publicly available reference documents listed below:

U.S. ARMY CORP OF ENGINEERS 1992
Installation Restoration and Hazardous Control Technologies

Electrokinetic Laboratory and Field Processes Applicable to Radioactive and Hazardous Mixed Waste in Soil and Groundwater

Electrokinetic Enhanced Soil Bioventing

The conventional application of soil vapor extraction of volatile organic chemicals (VOCs) cannot overcome low permeability soil media to render the successful completion of a project. The electrokinetic process can enhance the desorption of water and contaminants from clay by breaking down the clay layer's electrically charged bonds. This will make the VOCs available for contact and treatment. The major drawback of soil vapor extraction is air emission which is a physical phase transfer process instead of destruction. The EK enhanced closed loop bioventing process was applied to destroy the VOCs without air emission at sites with clayey soil. The following is a list of sites where EK enhanced bioventing processes were successfully implemented:

PepBoys Site, San Diego, California (25)
Bioventing of gasoline in clayey soil

Bat Rentals Site, Las Vegas, Nevada (29)
Bioventing of gasoline, diesel and kerosene in clayey caliche soil

Evergreen Site, Los Angeles, California (30)
Bioventing of gasoline in clayey soil

DBM Oil Site, Long Beach, California (30)
Bioventing of diesel and waste oil in clayey soil

Cadillac Site, Northridge, California (27)
Bioventing of gasoline in clayey soil

Former Texaco Site, Long Beach, California (27)
Bioventing of gasoline in silty/clayey soil

Former ARCO Site, Monterey Park, California (27)
Bioventing of gasoline in clayey soil

Electrochemical Oxidation

It is difficult to distinguish which electrokinetic process is responsible for destroying petroleum hydrocarbons. The bench test on a soil sample from the PepBoys Site indicated that electrochemical oxidation is responsible for destroying petroleum hydrocarbons.

For all the bioventing projects described in the previous section, the electrochemical oxidation process is responsible for a portion of the destruction of the petroleum hydrocarbons rather than bioventing alone.

Electrobiochemical Oxidation

Electrobiochemical oxidation applies to the aqueous phase biotreatment of petroleum hydrocarbons in soil and groundwater. Electrokinetic processes are responsible for distributing nutrients and oxidants in impacted soil and groundwater. It can be used together with bioventing in the vadose zone. The following is a list of sites where EK enhanced aqueous phase biotreatment processes were successfully implemented:

Westland Site, Hayward, California (26)
Electrobiochemical of gasoline and diesel in Bay Mud clay and water

Bat Rentals Site, Las Vegas, Nevada (29)
Bioventing(wet) of gasoline, diesel and kerosene in clayey caliche soil and shallow groundwater

Cadillac Site, Northridge, California (27)
Bioventing(wet) of gasoline in clayey soil and groundwater

Former Texaco Site, Long Beach, California (27)
Bioventing(wet) of gasoline in silty/clayey soil and groundwater

Former ARCO Site, Monterey Park, California (27)
Bioventing(wet) of gasoline in clayey soil

At all these sites, food additive nutrients and oxidants were introduced as electrolytes by electrokinetically induced migration through wells (horizontal migration) and infiltration galleries (vertical migration) to penetrate into the clayey matrix of soil and groundwater. Additions of nontoxic and nonhazardous food additives, nutrients, and oxidants into the subsurface are not regulated by underground injection control regulations. Petroleum hydrocarbons like BTEX in soil and groundwater were treated to nondetectable levels at most sites.

Electrolysis of MtBE and Benzene

The two most resistant dissolved petroleum hydrocarbons in the environment are MtBE and benzene due to their higher solubility in water and low cleanup levels which most often cannot be achieved by conventional remedial treatment technologies.

The gasoline additive MtBE is highly soluble in water and usually migrates furthest away downgradient from the spill location. Air stripping of MtBE is not an effective treatment option. There are reports that MtBE in the air were solublized into air-stripper blowdown water. Plus, MtBE is not readily biodegradable in the subsurface. The following is a list of sites where EK induced electrolysis processes were successfully implemented:

Cadillac Site, Northridge, California (27)
Bioventing(wet) of gasoline in clayey soil and groundwater

Former Texaco Site, Long Beach, California (27)
Bioventing(wet) of gasoline in silty/clayey soil and groundwater

MtBE was first treated in groundwater, accidentally (not by design), in 1997 at the Cadillac Site, Northridge, California, while treating dissolved BTEX using the electrobiochemical aqueous phase treatment. It was discovered that MtBE soon “disappeared” after the start-up of the electrokinetic enhanced biotreatment. The MtBE in groundwater was treated to nondetectable levels in less than 3 months of treatment. It also appeared that benzene concentration was decreasing at a slower rate at various monitoring wells. The electrolysis of MtBE and benzene cannot actually be confirmed. It was a surprise to document the MtBE disappearance at the Cadillac Site while at the time the oil company sponsored numerous seminars that pointed to no effective remedy for MtBE in the environment.

The same electrobiochemical treatment technique was applied to MtBE and BTEX at the former Texaco Site in Long Beach, California, in 1997. The dissolved benzene and MtBE in groundwater were treated to nondetectable levels in two monitoring wells outside of the zone of influence of the electrobiochemical treatment area which was focused on the former underground storage tank pit area. This indicated that the only thing that can influence these peripheral monitoring wells is the DC flow field. This is the first confirmation of the electrolytic breakdown of dissolved MtBE and benzene in groundwater. The nondetectable MtBE and benzene performance in the vadose zone soil in the tank pit area is also a first.

Chlorinated Solvents

The conventional remedial treatment technology of chlorinated solvent in soil is soil vapor extraction. The newer and innovative remedial treatment of chlorinated solvents in groundwater is cometabolic biotreatment. None of the above will be effective when treating clayey material. Electrokinetic processes excel in desorbing the contaminants from clay and distributing nutrient, oxidants and cosubstrates in the soil and groundwater.

The following is a list of sites where the EK enhanced chlorinated solvent treatment processes were successfully implemented:

Northrop ESD Site, Anaheim, California (31)
EK enhanced soil vapor extraction of chlorinated solvents in clayey soil

The Good Guys Site, Emeryville, California (8,20,28, 30,32) EK enhanced cometabolic biotreatment of chlorinated solvents in clayey soil and groundwater

FIELD CAPACITY

Joseph Skopp
University of Nebraska
Lincoln, Nebraska

Storage of soil water is important to soil flora and fauna, to hydrologic processes, and to a variety of soil physical properties. One element of soil water storage is an upper limit on water that is available for plant use, referred to as "field capacity." This entry provides a history of the concept, its relation to soil water holding properties, predictive techniques for field capacity, applications, and failures of the field capacity concept.

HISTORY OF THE CONCEPT

Plant Available Water

Early researchers of plant water relations quickly realized that in water limited regions, the ultimate crop yield depended not only on the amount of rainfall received but on what portion of that rainfall was usable. Three key factors could reduce the usefulness of rainfall: runoff, drainage below the root zone, and evaporation. The net effect of rainfall, runoff, and drainage results in retention of water in the root zone. Evaporation and transpiration reduce this retained water. This retention was studied by Veihmeyer and Hendrickson (1). The concepts developed by Veihmeyer and Hendrickson provide a means to evaluate whether a soil retains sufficient water to support a particular crop. Veihmeyer and Hendrickson (2) redefined their original definition of field capacity to "the amount of water held in soil after excess water has drained away and the rate of downward movement has materially decreased, which usually takes place within 2–3 days after a rainfall event or irrigation in pervious soils of uniform structure and texture."

Field studies focused on measuring the soil water content following a heavy rainfall (that penetrated deeply into the soil). It was observed that the water content would change after the rain stopped. This change gradually slowed such that after 3 days it was difficult to observe additional changes. The inaccurate concept took hold: that after 1–3 days, drainage stopped, and the water retained in the soil at that time would then be available for transpiration. The choice of 2–3 days was partially the result of limited means to measure soil water content. However, the concept took hold that the soil stored water and an upper limit on stored water (available for plant use) could be defined. This upper limit is called "field capacity."

Correspondingly, there is a lower limit to the soil's ability to store water that plants can use. This lower limit is called the "wilting point" or "permanent wilting point." This also has a historical basis, usually limited to a particular plant but more typically taken as the volumetric water content at a matric potential of −1.5 MPa (−15 bars). The difference between field capacity and the permanent wilting point is called the "available water capacity" or the potential "plant available water." Figure 1 shows how the soil porosity (or void space) might be divided into these components. For dryland agriculture, the "available water capacity" approximates the soil's water storage ability. For irrigated agriculture, the field capacity is combined with a lower limit of water content usually set at a point where irrigation is started.

A related interpretation of the field capacity is the water held against gravity. Early attempts to transfer these ideas to the lab depended on a centrifuge to remove

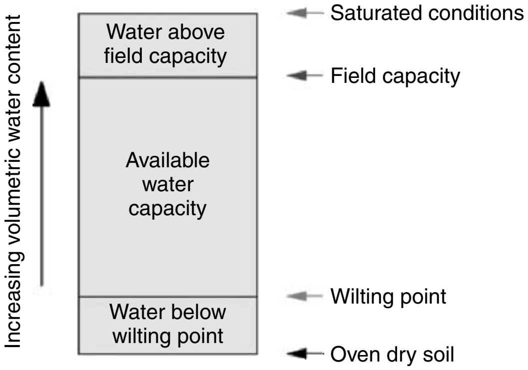

Figure 1. Naive concept of water filled soil porosity.

soil water (3–5). Some workers attempted to relate field capacity to these soil water contents (measured under specific centrifuge conditions, e.g., moisture equivalent) with limited success. Many of these early researchers were limited by their understanding of water movement.

There are several concerns in regard to the definition of field capacity proposed by Veihmeyer and Hendrickson. These include identifying when water movement ceases and the rarity of "soils of uniform structure and texture." The following section addresses the first issue, and the second is postponed to a later section.

Does Drainage Cease?

Later research into the process of drainage showed variation across soil types. Typically, sandier soils drain faster before a noticeable drop-off in water movement. More finely textured soils show a much longer decay process for changes in water content. Thus, at least sands appeared to conform to the Veihmeyer and Hendrickson concept. However, Gardner et al. (6) and Hillel et al. (7) clearly showed that water content does not approach equilibrium up to 30 days after infiltration even on a uniform sandy soil. Figure 2 shows an example of this drainage process for a sandy soil. Thus, for many soil environments, the concept of field capacity is an oversimplification and invalid (i.e., there is no well-defined drainage-induced upper limit to soil water content).

Infiltration Storage Capacity and Runoff

As indicated earlier, not all rainfall enters the soil. Depending on the infiltration characteristics of the soil and the rainfall (intensity and duration), water may pond and runoff. The ability of soils to accept rainfall (i.e., infiltration) depends on a number of soil hydraulic properties (most directly hydraulic conductivity and the soil water characteristic) as well as surface roughness. These infiltration properties may in turn correlate with properties such as field capacity. Thus, some hydrologic runoff models may require soil hydraulic properties as input parameters, which provides an indirect linkage of soil properties such as field capacity to runoff. It also creates a demand for estimates of field capacity, no matter how poorly defined it may be.

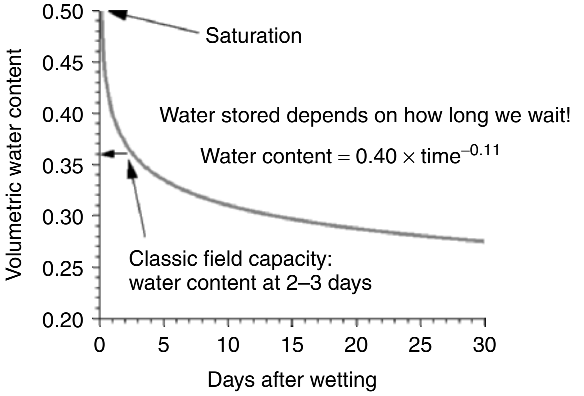

Figure 2. Example of a drainage curve for a sandy soil.

Erosion

When runoff occurs, the potential for water erosion and transport of eroded material also arises. Ponding and runoff contribute separately to the detachment of soil material (the initial process in soil erosion). Subsequent to detachment, runoff can remove the suspended material and transport it off-field or downstream. Runoff also contributes with greater velocities resulting in greater detachment. Finally, the ability of runoff to transport eroded material is also proportional to its velocity.

Field capacity influences the water erosion process through its indirect effect on infiltration. Typically, a larger field capacity results in greater infiltration rates and lower runoff velocities compared to a similar soil with smaller field capacity. These effects may be masked if the storm is very small or very large.

Wind erosion is also influenced indirectly by field capacity. The ability of wind to detach and suspend particles depends on the water content and vegetation (or plant residue) near the soil surface. The linkage between field capacity and some of these variables is weak, but some modeling efforts still rely on inputs of field capacity in their prediction algorithms.

RELATION TO WATER HOLDING PROPERTIES

The original experiments by Veihmeyer and Hendrickson (1,2) were time-consuming, labor-intensive, and not always readily adaptable to all soils and soil environments. A number of researchers looked for alternative means of estimating soil water content (or another property) that would relate to the concept of field capacity (i.e., the water content of a soil following a heavy rain and after 2–3 days of drainage). Several methods have been proposed; the most widely adopted is the use of volumetric water content at a specified matric potential. The water content is usually reported with units of $m^3\ m^{-3}$ to remove confusion with gravimetric water content. We describe three approaches to determining this water content, based on matric potential, unsaturated hydraulic conductivity, or soil water flux.

Matric Potential: The 1/10 and 1/3 Bar Criteria

A variety of workers (8,9) have examined the behavior of soil water content from field experiments meant to simulate field capacity. A broad pattern emerged suggesting that soil matric potential (a measure of the energy with which water is held by soil) provides an indicator independent of soil texture. An initial examination suggests that a range of values from −5 to −50 kPa might be reasonable; values closer to zero are used for coarse textured soils, and the more negative values are for more finely textured soils. Some researchers suggested that −10 kPa (or 1/10 bar in older units) was appropriate for sands and −33 kPa (or 1/3 bar) for all other soils. Thus, the volumetric water content at either −10 kPa or −33 kPa is commonly reported as the field capacity. The relative simplicity of this concept resulted in the adoption of these values as standard measurements by the USDA Natural Resources Conservation Service and by most introductory textbooks. However, not all researchers have adopted these values, and for individual soils, a different matric potential may be more appropriate. Below (under the section titled Deficiencies), we mention some of the profound limitations and errors that can be introduced when using the concept of field capacity as the volumetric water content at 1/10 or 1/3 bar.

Unsaturated Hydraulic Conductivity Concept

A second approach to field capacity looks for a soil property that describes water movement. In particular, a property is desired that characterizes the point where water movement slows to an imperceptible level. Unsaturated water movement is described by a Buckingham–Darcy law where the “unsaturated hydraulic conductivity function” controls water movement. In this approach, the appropriate water content (or matric potential) is the value where the unsaturated hydraulic conductivity is reduced to some fraction of its saturated value. A variety of fractions have been proposed (0.1 or 1/e). This method is rarely used because of the difficulty currently associated with measuring unsaturated hydraulic conductivity.

Flux Concept

A third concept looks directly at water movement. The Buckingham–Darcy law can be used to predict the flux of water. The concept of field capacity is interpreted to mean the point where the flux is close to zero (10). Like the hydraulic conductivity method, just described, it relies on basic concepts of water movement, and it may set up a criterion relative to saturated flow. Unlike the hydraulic conductivity method, it uses a directly measured water movement (the flux), rather than an indirect physical property, and may provide an absolute criterion for zero flux, rather than a relative one. Meyer and Gee (10) suggest that a drainage flux of 3×10^{-7} cm/s represents field capacity.

PREDICTIONS OF WATER CONTENT AT 1/10 AND 1/3 BAR

The lack of a valid laboratory method combined with the time and expense of field methods has not reduced the desire for information about field capacity. Instead, many researchers have adopted the most convenient measurement (i.e., the volumetric water content at 1/10 bar or 1/3 bar). A number of laboratories will perform this analysis. However, water content measurements at these matric potentials is extremely sensitive to sample disturbance. This requires collecting and transporting undisturbed samples to laboratories for measurement. Handling of undisturbed samples is costly and requires special training that many laboratories do not have. The coefficient of variation for undisturbed samples has been reported as between 20 and 50% (11). Thus, laboratory measurements have clear advantages over field methods, but they are not without their own set of difficulties.

One solution to the problems just described is to develop regression or physical models to predict the water content at a specified matric potential. A variety of regression models have been proposed. Some of them are described by Acutis and Donatelli (12), Baumer and Brasher (13), Cassel et al. (14), Ritchie et al. (15), and Rawls et al. (16). More recently, Gijsman et al. (17) compared a variety of predictive techniques and found a great deal of variation among the models they tested. These authors recommend the method described by Saxton et al. (18) based on their independently obtained data set. Note that use of any of these relations does not remove the concerns expressed later in this article.

APPLICATIONS

The use of field capacity (usually as 1/10 or 1/3 bar water content) has grown beyond the original goal of understanding crop yields. In this section, we briefly look at current applications for crop yield prediction as well as a surrogate for other soil hydraulic properties that are more difficult to measure.

Agronomic/Ecological Models

Advances in computational power allow researchers to describe water movement in soils after rainfall and during plant growth by using physical transport principles. One common application of such models is the prediction of plant growth and crop yield (17,19). These models typically require the input of soil physical properties, possibly including field capacity. Input to these models is the laboratory measured water content at 1/10 or 1/3 bar as one point on a soil water retention curve that is used to predict other hydraulic properties. In other words, these models tend to be dynamic and allow soil water content to change continuously beyond the 2- or 3-day period despite the input of a so-called field capacity. In addition to crop yield/plant growth, these models may be used to develop irrigation timing strategies.

Hydrologic Models

Another area where field capacity estimates are used is in watershed modeling (20,21). These hydrologic models provide a means to describe the response of a watershed to a rainfall. A key component of these models is the infiltration process. In some cases, empirical infiltration models are used. Otherwise, physical soil water transport models (similar to agronomic models) are used. In either case, parameter inputs are typically needed either as an explicit parameter or to calculate the needed parameter (e.g., to estimate unsaturated hydraulic conductivity).

Other Applications

Field capacity (or at least the volumetric water content at 1/10 or 1/3 bar) can frequently act as a surrogate for other (less readily measured) soil properties, which, combined with its ready availability in a variety of databases, has led to its appearance in a variety of publications that are not directly tied to water movement or plant growth. In this case the use of the phrase “field capacity” refers only to a specific laboratory measured water content and has lost any “field” significance.

Examples of this use of field capacity include observations of microbial occurrence and activity (22), solute transport (23), soil strength (24,25), and soil erodibility (26).

DEFICIENCIES IN MEASUREMENTS

A variety of criticisms have been directed toward the field capacity concept by Richards (27), Baver et al. (28), Hillel (7) and Cassel and Nielsen (29). In addition to questions regarding the time when drainage ceases (mentioned earlier), there are three basic areas of concern with field capacity as a widely used concept describing water movement in field soils. The importance of changes in soil structure, soil layering, and initial conditions. We briefly discuss these issues as presented by the previously cited researchers.

Dependence on Structure and Disturbance

Field capacity measurements in the field and laboratory measurements (for matric potentials between 0 and 100 kP) are sensitive to changes in soil structure or aggregation. Changes in soil structure due to tillage, root growth, faunal activity, or freeze/thaw cycles are expected to alter soil hydraulic properties and the movement of water. Water quality (e.g., sodium or total salts) is also expected to influence aggregation and ultimately water movement.

Dependence on Soil Morphology and Internal Drainage

Soils are rarely uniform. Layers that have different hydraulic properties are typical. These layers may result in perched water tables or hindered drainage, which can be expected to extend drainage times. Equally important, drainage will not be uniform throughout the soil profile, so there will not be a single water content at a point of restricted water movement.

This existence of soil layers plays particular havoc with the use of laboratory determined values based on a specific matric potential. It may be possible to measure each soil layer independently, but the sequence of layers may be more important in controlling drainage patterns.

Dependence on Initial Conditions

The soil conditions prior to wetting (required in the basic definition of field capacity) are assumed to be unimportant. In fact, initial soil water content can influence the uniformity of wetting (30). It is not possible to measure field capacity under all possible scenarios of initial water content distribution or wetting history. Also of importance, the existence and position of the water table will influence both wetting and the drainage process. The presence of a shallow water table may act to reduce drainage. The use of laboratory methods to estimate field capacity cannot account for these conditions.

SUMMARY

The field capacity concept has been used to approximate the ability of soils to store water and to calculate an "available water capacity." However, soil water is not a static reservoir, and such a picture oversimplifies soil water movement and availability. Field representations of soil water storage require field measurements. Laboratory measurements (particularly water content at 1/10 and 1/3 bar) are popular because of their availability and seeming simplicity. Laboratory measurements can be useful for describing soils or estimating other soil hydraulic properties; however, their use as a reflection of water storage may be misleading and should be used with extreme caution. Any representation of soil water storage must be site specific and must take antecedent conditions into account.

GROUNDWATER FLOW PROPERTIES

Mukand Singh Babel
Asian Institute of Technology
Pathumthani, Thailand

Groundwater constitutes a large component of the freshwater cycle. It moves more or less continuously from areas of recharge to areas of discharge through interconnected void spaces in porous media, fractured media, and large passages. Groundwater flow results mainly from precipitation that infiltrates into the soil; it also originates from influent streams, seepage from reservoirs, artificial recharge, seepage from oceans, etc. It often augments streamflow, eventually moving through the soil to the stream channel, also referred to as baseflow, or dry-weather flow.

The driving force for groundwater movement is measured in terms of hydraulic head, which represents the fluid pressure potential and elevation potential. It is also referred to as the piezometric or potentiometric head. Contour maps of hydraulic head (piezometric or potentiometric maps), which can be constructed from water-table elevations, can be used to infer directions of groundwater flow.

The hydraulic and physical properties of a porous medium influence groundwater flow. They are porosity, hydraulic conductivity and permeability, specific storage, transmissivity and storage coefficient. A hydrologic unit (aquifer) is homogenous if its hydraulic properties are the same at every location. However, owing to the spatial and temporal variability in the geologic processes that create and modify rocks and sediments, no unit is truly homogenous.

HYDRAULIC CONDUCTIVITY

Hydraulic conductivity (K) is a measure of the ability of a fluid to move through interconnected void spaces in a sediment or rock. It is a function of both the medium and the fluid properties. A medium has a unit hydraulic conductivity if it transmits in unit time a unit volume of groundwater at the prevailing kinematic viscosity through a unit cross-sectional area, measured at right angle to the direction of flow, under a unit hydraulic gradient. The SI unit is

$$K = -\frac{q}{dh/dl} = -\frac{\text{m/day}}{\text{m/m}} = \text{m/day} \tag{1}$$

Several factors affect hydraulic conductivity—those that pertain to the water-bearing material itself and those related to the groundwater as a fluid. The geometry of the pore spaces through which groundwater movement occurs, the grain size distribution, the surface roughness of the particles, and other secondary geologic processes such as faulting and folding, secondary deposition, and secondary solution in rock (such as limestone) are the major factors pertaining to the porous medium. The fluid characteristics that affect hydraulic conductivity are density, viscosity, and salinity. Temperature, by inversely affecting viscosity, has a direct influence on groundwater flow. The effect of salinity, on the other hand, is brought about by changes in the ionic concentrations of the groundwater and also due to the chemical effect of the saline water on the aquifer material. However, the effects of fluid characteristics on hydraulic conductivity tend to be rather less important than the effects of the aquifer characteristics.

PERMEABILITY

The term permeability (k), used synonymously with intrinsic permeability, of a porous medium defines its ability to transmit a fluid, which is a property only of the medium and is independent of fluid properties. Permeability (k) is defined as

$$K = \frac{k\rho g}{\mu} \tag{2}$$

Table 1. Representative Values of Hydraulic Conductivity and Permeability[a]

Sediment or Rock Type	Hydraulic Conductivity (m/day)	Permeability (m^2)
Clays	10^{-7}–10^{-3}	10^{-19}–10^{-15}
Silts	10^{-4}–10^{0}	10^{-16}–10^{-12}
Fine to coarse sands	10^{-2}–10^{+3}	10^{-14}–10^{-9}
Gravels	10^{+2}–10^{+5}	10^{-10}–10^{-7}
Shales (matrix)	10^{-8}–10^{-4}	10^{-20}–10^{-16}
Shales (fractured and weathered)	10^{-4}–10^{0}	10^{-16}–10^{-12}
Sandstones (well-cemented)	10^{-5}–10^{-2}	10^{-17}–10^{-14}
Sandstones (friable)	10^{-3}–10^{0}	10^{-15}–10^{-12}
Salt	10^{-10}–10^{-8}	10^{-22}–10^{-20}
Anhydrite	10^{-7}–10^{-6}	10^{-19}–10^{-18}
Unfractured igneous and metamorphic rocks	10^{-9}–10^{-5}	10^{-21}–10^{-17}
Fractured igneous and metamorphic rocks	10^{-5}–10^{-1}	10^{-17}–10^{-13}

[a] Reference 1.

where K = hydraulic conductivity, k = permeability, ρ = fluid density, g = acceleration due to gravity, and μ = dynamic viscosity of the fluid. Table 1 presents representative values of hydraulic conductivity and permeability for a variety of sediment and rock types.

Owing to the spatial and temporal variability in the geologic processes that create and modify rocks and sediments, heterogeneity occurs in a range of spatial scales. In a porous multilayer medium, the variation in hydraulic conductivity among the depositional units can amount to five or six orders of magnitude. The groundwater analyst has to decide whether or not the homogeneity approximations are adequate, and if not, at what scale the heterogeneity should be specified. Some averaging rules can be applied to average a set of measurements to a single value of effective hydraulic conductivity (K_e) when using a homogenous medium approximation.

The effective hydraulic conductivity (K_e) depends upon the properties of the porous medium and the pattern of fluid flow. For steady-state flow, with a spatially uniform hydraulic gradient, the following averaging rules apply:

1. For a perfectly stratified medium, n layers of layer thickness d_i, and hydraulic conductivity K_i:
   (a) When flow is parallel to the layering, K_e is given by applying the arithmetic mean as

$$K_e = K_A = \sum_{i=1}^{n} \frac{d_i K_i}{\sum_{i=1}^{n} d_i} \qquad (3)$$

   (b) When flow is perpendicular to the layering, K_e is given by applying the harmonic mean as

$$K_e = K_H = \sum_{i=1}^{n} \frac{d_i}{\sum_{i=1}^{n} \frac{d_i}{K_i}} \qquad (4)$$

2. For a heterogeneous medium, nonstratified, and m measurements
   (a) For two-dimensional models, K_e is given by applying the geometric mean as

$$K_e = K_G = (K_1 K_2 \cdots\cdots K_m)^{1/m} \qquad (5)$$

   (b) For three-dimensional models, K_e is given as,

$$K_e = (1 + \sigma^2{}_y/6) \qquad (6)$$

where $\sigma^2{}_y$ is the variance of the natural logarithms of the hydraulic conductivity measurements.

TRANSMISSIVITY

Transmissivity (T) is defined as the amount of water that can be transmitted horizontally through a unit width by a fully saturated thickness of an aquifer under a unit hydraulic gradient. The transmissivity of an aquifer is equal to the hydraulic conductivity of the aquifer multiplied by the saturated thickness of the aquifer. Thus,

$$T = Kb \qquad (7)$$

where T = transmissivity, K = hydraulic conductivity, and b = saturated thickness of the aquifer.

STORAGE COEFFICIENT

Specific storage (S_s) is defined as the volume of water that a unit volume of aquifer releases from storage under a unit decline in hydraulic head. Storage coefficient or storativity (S) is the product of specific storage (S_s) and aquifer thickness. It is defined as the volume of water that a permeable unit will absorb or expel from storage per unit surface area per unit change in head. It is a dimensionless quantity, and this property becomes important when an aquifer loses or gains water. Storativity is due to porosity in the aquifer and is different for confined and unconfined aquifers. For a unit decline in hydraulic head, the volume of water released from a confined aquifer is substantially less than that for an unconfined aquifer, indicating a comparative low value of the storage coefficient for a confined aquifer.

SPECIFIC YIELD (S_Y)

The storativity of an unconfined aquifer termed specific yield, is defined as the volume of water that an unconfined aquifer releases from storage per unit surface area of aquifer per unit decline in the water table, as shown in Fig. 1. Table 2 gives representative values of the specific yield for different aquifer materials.

STORATIVITY IN CONFINED AND UNCONFINED AQUIFERS

The storativity in unconfined aquifers is higher than that in confined aquifers. The higher values of storativity for unconfined aquifers (specific yield), as shown in Table 2, reflect the fact that releases from storage in unconfined aquifers represent an actual dewatering of the soil pores, whereas releases from storage in confined aquifers

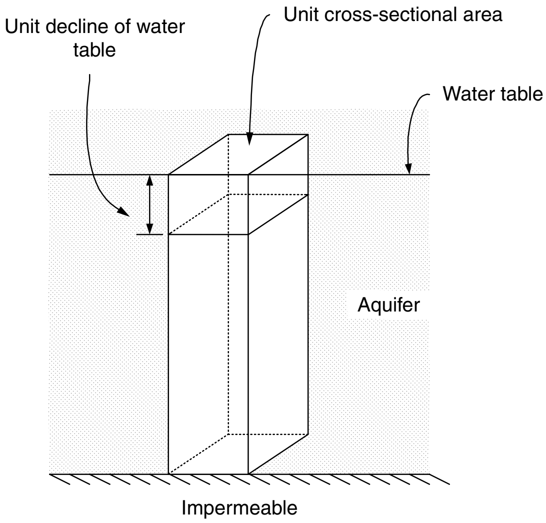

Figure 1. Schematic representation of storativity in unconfined aquifers.

Table 2. Representative Values of Specific Yield[a]

Material	Specific Yield, %
Clays	1–5
Silts	10–20
Fine sands	10–30
Sands and gravels	20–30
Sandstone	5–20
Shale	0.5–5
Limestone	0.5–20

[a] Reference 1.

represent only the secondary effects of water expansion and aquifer compaction brought about by changes in fluid pressure. In most confined aquifers, the storativity values fall in the range 0.00005 to 0.005 (2), indicating that large pressure changes over extensive areas are required to produce substantial water yields. Thus, the same yield can be realized with smaller head changes over less extensive areas in unconfined aquifers compared to confined aquifers, making them more efficient for exploitation by wells.

FLUORIDE CONTAMINATION IN GROUND WATER

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

Fluoride occurrence in ground water is a natural phenomenon, influenced by the local and regional geological setting and hydrogeological conditions of the region. Fluoride content much higher than the maximum permissible limit has been found in many regions throughout the world. The problem assumes more significance in India and other developing countries because a major portion of the population that lives in rural as well as urban areas have to depend on available groundwater resources for their day-to-day requirements. An estimated 62 million people in 17 out of 32 states are affected with dental, skeletal, and/or nonskeletal fluorosis in India. The extent of fluoride contamination varies from 1.0 to 48.0 mg/L.

INTRODUCTION

One of the serious health problems facing India today is the prevalence of a disease known as fluorosis. It involves millions of people and arises primarily due to an excess of fluoride in drinking waters. Fluorosis was first detected in India among cattle (bullocks used for ploughing land) by the farmers of Andhra Pradesh during early 1930s. The farmers noticed the inability of the bullocks to walk due to painful and stiff joints. During later years, the same disease was detected in human beings. Shortt et al. (1) published the first report on endemic fluorosis in India, when the disease was prevalent in four states, Andhra Pradesh, Tamil Nadu, Punjab, and Uttar Pradesh (2). During the period 1960–1986, nine more states have been identified as endemic for fluorosis. During 1990–1992, two more states, Kerala and Jammu and Kashmir have also been identified as endemic for the disease. As per the report published by Rajiv Gandhi National Drinking Water Mission (3), fourteen states and Delhi have been identified as endemic for fluorosis. Datta (4) has also reported fluoride contamination in the ground water of the National Capital Territory of Delhi. Recently, elevated levels of fluoride have been reported from the Birhum district of West Bengal and Karbi-Anglong and Nagaon districts of Assam (5–8). Thus, the total number of states endemic for fluorosis at present is seventeen: Andhra Pradesh, Assam, Bihar, Delhi, Gujarat, Haryana, Jammu and Kashmir, Karnataka, Kerala, Madhya Pradesh, Maharashtra, Orissa, Punjab, Rajasthan, Tamil Nadu, Uttar Pradesh, and West Bengal.

Fluoride is essential for normal mineralization of bones and formation of dental enamel. About 96% of the fluoride in the body is found in bones and teeth. Calcium-rich constituents of teeth, enamel and dentine, have a strong affinity for fluoride during the formation of teeth. Fluoride combines with calcium to form calcium fluoroapatite crystals during the mineralization of teeth. The principal sources of fluoride for human physiology are water and food. At the same time, fluoride also has considerable physiological importance for humans and animals. If one is exposed to fluoride for long durations, it may pose serious health hazards. The major health problems caused by fluoride are dental caries, teeth mottling, skeletal fluorosis, and deformation of bones in children as well as in adults (9).

The Geological Survey of India has brought out considerable data that reveal that fluorite, topaz, apatite, rock phosphate, phosphatic nodules, and phosphorites are wide-spread in India and contain high percentages of fluoride (10). As a result of rich mineral content, fluoride leaches out and contaminates water and soil, thereby contaminating agricultural crops as well. Several natural fluoride-bearing minerals identified in India include fluorides, fluorites, and cryolite; phosphates, fluorapatite, and wagnerite; silicates and topaz; and the mica group, magnesium mica and lithium mica.

The permissible limits for fluoride in drinking water have been defined by various agencies. In view of the health problems, the Bureau of Indian Standards, formerly known as Indian Standards Institution (ISI), has laid down the Indian standard of 1.0 mg/L as the desirable limit (11). The Indian Council of Medical Research (ICMR) has recommended a desirable level of 1.0 mg/L and the maximum permissible limit of 1.5 mg/L, which means that the body may tolerate fluoride up to the limit of 1.5 mg/L depending on the nutritional standards and body physiology. The World Health Organization (12) has recommended 0.5 mg/L as the maximum limit for fluoride.

In India, more than 76% of the population lives in rural areas. The problem of endemic fluorosis occurs with varying intensity in different parts of the country. An extensive survey of community water supplies has shown that around 25 million people in rural areas consume water whose fluoride content is more than the maximum permissible concentration of 1.5 mg F/L (13). According to a Sub-mission set up by the Government of India under a Technical Mission, about 25 million people are suffering from fluorosis at various stages, and another 25 million are reported to be prone to it (14,15). Jain et al. (16) have reviewed the status of fluoride contamination in groundwater and Susheela (7) reported the overall status of fluoride contamination and the suffering of the people in India. It is stated that an estimated 62 million people in 17 states out of 32 states are affected with dental, skeletal, and/or nonskeletal fluorosis.

Rajasthan is one of the states where fluorides at high levels in all 31 districts and the problem of dental and skeletal fluorosis is widespread (17). The studies carried out by the Rajasthan Voluntary Health Association (RVHA) noticed that the total number of problem villages that have high fluoride content in groundwater is 2702. About three million people are consuming water with excess fluoride, out of which one-fifth of the affected population are children below the age of 7 years, and about 35,000 people are consuming water that has more than 10 mg/L of fluoride.

As much as 90 mg/L of fluoride was found in groundwater in western Rajasthan (18). High fluoride content is attributed to the circulation of groundwater through fluorite-bearing granites and acid volcanics and basic dykes (that act as barriers and result in ample contact time for circulating water to dissolve fluorite). High fluoride content is always associated with a lower Ca/F ratio. It is an established fact that waters high in calcium are low in fluoride content, and therefore the low fluoride concentration in the eastern region can possibly be explained by the presence of high calcium in the water due to the movement of groundwater through carbonate rocks and a higher recharge from surface water to the Sukri River that possibly dilutes the fluoride content further.

The fluoride concentration in the Nagpur district of Maharashtra state varies from 0 to 44 mg/L (19). The fluoride content increases with an increase in salinity. High bicarbonate and sodium content were observed in groundwater rich in fluoride. High values of phosphorous were also observed in association with high fluoride content indicating its possible occurrence due to mineral weathering and local pollution.

Wodeyar and Sreenivasan (20) reported the occurrence of fluoride in the Bellary district in the state of Karnataka. Deeper aquifers have shown higher fluoride concentrations than shallow aquifers. A high degree of weathering and easy accessibility of circulating water to the weathered rocks due to intensive and long-term irrigation are responsible for leaching of fluoride from parent minerals in soil and rocks. Further concentration has been brought about by the arid climate of the region and the long residence time of groundwater in the aquifer. The influence of local lithology and soil, aided by other factors like very low freshwater exchange due to the arid climate of the region, is also responsible for higher concentrations of fluoride in groundwater.

Shukla et al. (21) studied the fluoride level in human teeth obtained from two different regions, Bhilai and Shillong in the state of Madhya Pradesh. They reported that the Bhilai region is fluoridated and have an average fluoride level of 1.3 ppm, whereas the Shillong region is nonfluoridated and has an average fluoride level of 0.02 ppm. The fluoride content of the teeth, it was found, increases with age, and therefore, the duration of exposure to fluoride has a significant effect on its accumulation in the dental structure. The biologically active age group of 10–30 years incorporates fluoride in teeth more rapidly compared to the passive age group of 50–70 years in both regions.

Apparao and Karthikeyan (22) reported a fluoride content of less than 1 mg/L in the drinking water of seven fluorosis-affected villages of the Nilakottai and Dindigul blocks in the state of Tamil Nadu. The poor socioeconomic groups of these villages are affected much by dental as well as skeletal fluorosis. The general nutritional status of their diet is poor, and specifically, the calcium and vitamin C intake are very low. It is surprising that people exposed to 0.51 mg/L F water are affected, and such reports are scanty in India. However, analysis of food grains grown in these areas indicated 4.0 to 4.6 mg/kg of fluoride which is a significant amount of the total fluoride intake and hence the prevalence of fluorosis in these areas. Other fluoride-affected districts include Vellore, Dharmapuri, Trichy, Karur, Salem, Namakkal, Erode, Coimbatore, and Virudhunagar (23–28). Agricultural practices and the depth to the groundwater table, it has been found, have an important impact on fluoride concentration.

Malhotra et al. (29,30) studied fluoride contamination in the groundwater of the Allahabad, Pratapgarh, Gonda, Ballia, Bareilly, and Fatehpur districts in the state of Uttar Pradesh and reported apparently high levels of fluoride. The maximum fluoride content of 6.5 mg/L was found in rural areas of Phulpur in the Allahabad district. The extent of fluoride increases in summer months, apparently because of a drop in the water level. The evidence suggests that due to a gradual drop in the water level below the earth's crust a greater concentration of fluoride is found in the water because of greater dissolution of fluoride from rocks and soil.

Gupta et al. (31,32) and Shrivastav and Choudhary (33) reported fluoride contamination in the Agra district the highest concentration of 22 mg/L was in Bainkhera village. A significant positive correlation of fluoride with pH and negative correlation with hardness and magnesium was observed. Dental fluorosis was observed among school children in most of the villages, even where water had a fluoride concentration well within permissible limits. These observations clearly indicate the need for redefining the permissible levels of fluoride in drinking water and an exhaustive assessment of fluoride levels in foods.

Swamy (13) presented an interdisciplinary approach to understanding the problem of fluorosis against the background of present day development. Sudarshan and Reddy (2) described the pollution of fluoride in groundwater and its impact on the environment and on the socioeconomic status of the people. Mariappan et al. (28) described the occurrence and method of removing fluoride.

SOURCES OF FLUORIDE CONTAMINATION

Geological Sources

Fluoride occurrence in groundwater is a natural phenomenon, influenced by the local and regional geologic setting and hydrogeological conditions of the region. Fluoride occurs abundantly in the earth's crust as a component of rocks and minerals. The dissolution of fluoride from geologic formations occurs through the rainwater and repeated irrigation of agricultural lands. As rain water percolates through the soil, it comes in contact with the rocks and minerals in the aquifer materials. Due to the acid in the soil, dissolution of fluoride from the country rocks occurs.

The main sources of fluoride in natural water are fluorite (CaF_2), fluorapatite [$3Ca_3(PO_4)_2{-}CaF_2$], cryolite (Na_3AlF_6), magnesium fluoride (MgF_2), and as a replacement of, ions in the crystal lattice of mica and many other minerals (34,35). The other important fluoride-bearing minerals are biotite, muscovite, lepidolite, tourmaline, hornblende series minerals, glucophane riebeckite, asbestos (chrysolite, actinolite, anthophyllite), sphene, apophyllite, zinnwaldite, etc.

Dissolution of fluoride in groundwater itself may also contribute to the fluoride contamination phenomenon. The fluoride content in groundwater becomes higher in summer season due to a drop in the water level. The higher concentration of fluoride in the summer may be further attributed to the higher dissolution of fluoride, which may be due to the presence of air in the minerals/rocks cavities, which indicates that oxygen in the cavities of the geologic formation catalyzes the fluoride dissolution process. The evidence suggests that, as the ground water level gradually drops below the earth's crust, a greater concentration of fluoride is found in the water because of greater dissolution of fluoride from rocks and soil.

Industrial Sources

Industries are also a very important source of groundwater contamination. The effluents and other by-products of industries often constitute sources of groundwater pollution. Industries that release significant quantities of fluorides in process waste streams include fluorosilicone acid and fluorocarbon polymer synthesis, gasoline production; and manufacture's of coke, ceramic, cement, enamel, fiberglass, electronics, pesticides and fertilizers, surface heating operations, metal etching (with hydrofluoric acid), and wood preservatives (36).

Fluoride discharged from fertilizer manufacturing processes is typically in the form of silicon tetrafluoride, as a result of processing of phosphate rock. Power plant boiler cleaning wastes may contain fluoride due to its presence in the cleaning formulation. Both fluorspar and limestone are among the basic fluxing materials used in steelmaking. Air pollution control scrubbers water from steel manufacturing in basic oxygen, open hearth, and electric arc furnaces as well as in the sintering plant is the principal source of fluoride-containing wastewater from this industry. The primary aluminum processing industry uses the fluoride compound cryolite as a catalyst in bauxite ore reduction, The gaseous fluorides resulting from this process are discharged directly into the atmosphere or the fluorides into aqueous waste streams from wet scrubbing of the process fumes (37). Average fluoride values for aluminum reduction plants are reported as 107–145 ppm in wastewater streams. It has been observed that the number of echinocytes increases, depending on the duration of fluoride exposure among the workers in aluminum smelters (38). Fluoride concentrations ranging from 1,000–3,000 ppm have been reported for a glass manufacturing process. Glass and plating wastes typically contain fluoride in the form of hydrogen fluoride or fluoride ion, depending on the pH of the waste.

A high amount of fluoride has been reported in the groundwater in the vicinity of the aluminum industry (34,39). The main sources of fluoride in brick works are local clay and burning of coal. Malhotra et al. (30) have reported the fluoride content in groundwater in the vicinities of brickworks in Pratapgarh, Mirapur, Kechavpur, Mander, and Ahmedpur. Clarke et al. (40) have also reported fluoride contamination in groundwater due to by-products of brick kilns. Fluoride has also been detected in groundwater and air near Agra due to the 16 brick industries in the area (36).

Nonpoint Sources

Nonpoint sources of groundwater pollution also contribute fluoride to ground water to some extent. Modern agricultural practices that involve the application of fertilizers coupled with pesticides which contain about 1–3% fluoride also contribute fluoride to groundwater (41). The use of phosphatic fertilizers might also be one of the factors contributing to high fluoride concentration, which is being leached down to the groundwater by irrigation return flow (2,36). Irrigation with water containing small amounts of fluoride ion would tend to concentrate these ions in the soil. If the calcium ions are removed as calcite, fluoride ions will either be absorbed or coprecipitated with calcite. If the carbonate concentration is high enough to precipitate calcium as calcite without concomitant removal of fluoride ions, these ions may move down to the water front and ultimately join the main groundwater body (42). The U.S. Environmental Protection Agency (43) has recommended 1 mg/L of fluoride in irrigation water for continuous use but up to 15 mg/L of fluoride for short term use (20 years) on fine soils.

The production of fly ash is another important nonpoint source of fluoride contamination. More than 150 million tonnes of fly ash one produced annually worldwide from the combustion of coal in power plants (44). At least half of this amount is disposed of by landfill, thus contributing to environmental pollution due to leaching of fluoride. In addition to this, smoke particles from the aluminum industry, brickworks, and volcanoes also contain traces of fluroride (37,39,40). Fluoride in the atmosphere has been detected near Agra, India, due to the presence of about 16 brickworks in this area (36). A possibility of groundwater contamination may exist due to traces of fluoride in the atmosphere during the rainy season. The Geological Survey of India has also brought out considerable data which reveal that fluorite, topaz, apatite, rock phosphates, phosphatic nodules and phosphorites are widespread in India and contain high percentages of fluoride. As a result of their rich mineral content, fluoride leaches out and contaminates not only the groundwater but the soil as well, thereby contaminating agricultural crops also.

Other Miscellaneous Sources

Besides water, fluoride is also found in agricultural crops and other edible items. It is well recognized that fluoride enters the human body through various foods, though the data available in India are rather scanty. The information that is available is based on the analysis of food or agricultural crops in certain regions. Thus, data, from a specific location may not be applicable to other regions due to the varying concentration of fluoride in water and soil. Chary et al. (45) and Lakdawala and Punekar (46) reported the fluoride content in some commonly used foods in the Prakasam district and Bombay (India). Nanda and Kapoor (47) found the fluoride content in pine and betel. Sengupta and Pal (48) also reported the fluoride contents of different foodstuffs. Gradien (49) reported that fluoride content generally decreased in the order: tea> cereals> vegetables> pulses> fish> meat> fruits.

In addition to foodstuffs, fluoride has also been reported in cosmetics and drugs. The use of drugs containing sodium fluoride for osteoporosis, otosteosclerosis, and dental caries is very common. Different brands of toothpaste contain excessive amounts of fluoride. Fluoride enters into the circulation directly from the oral cavity through the fine blood vessels of the mouth. Fluoride is a persistent bioaccumulator; even small amounts that enter through fluoride toothpaste one guaranteed entry in children as well as adults, and the cumulative effects of fluoride are a matter of serious concern.

CONTROLLING FACTORS AND MECHANISM

Controlling Factors

Fluoride contamination in ground water is controlled by a number of parameters. The most important are

- distribution of easily weathered fluoride-bearing minerals
- the accessibility of circulating water to these minerals
- pH of the percolating water
- calcium content of the leaching water
- temperature of the percolating water and the soil
- exchangeable ions in the percolating water
- extent of fresh water exchange in an aquifer
- evaporation and evapotranspiration
- complexing of fluoride ions with other ions
- presence of CO_2 and other chemicals in draining water
- residence time of the percolating water in soil

The pH of circulating water is an important factor that controls leaching of fluoride from fluoride-bearing minerals. Wodeyar and Sreenivasan (20) have indicated that higher alkalinity of waters promotes leaching of fluoride and thus affects the concentration of fluoride in groundwater. Alkaline water dissolves fluoride-bearing minerals under simultaneous precipitation of calcium carbonate (50). It has been reported that the degree of weathering and easy accessibility of circulating waters from weathered rocks, due to intensive and long term irrigation, are responsible for leaching fluoride from the parent minerals in soil and rocks. A high content of fluoride has been reported in black cotton soil due to excessive canal irrigation (20). Further, concentration of fluoride has been brought about by the arid climate of the region and the long residence time of groundwater in the aquifer (20,50). Very low fresh water exchange due to the arid climate of the region is also responsible for higher concentration of fluoride in groundwater (20).

The fluoride concentration in groundwater, it was found, is positively correlated with calcium content but with a very low degree of validity (14,15). This observation is similar to that reported by Somani et al. (51), but there is no agreement to that report by Gupta et al. (31,32). This departure from the normal trend may be due to an irregular distribution of fluoride-bearing minerals in the soil, their solubilization characteristics, the nature of the product with soil, and other environmental conditions (51). Generally, waters of high calcium contents are low in fluoride content (52). The presence of carbon dioxide also affects the fluoride dissolution process in rocks.

Fluoride in soil and ground water is also concentrated by evaporation and evapotranspiration due to arid and semiarid atmospheric conditions following scanty rainfall. The overwithdrawal of groundwater may also have favorable effects on fluoride concentration in groundwater. The combined effect of evapotranspiration and long-term contact of the water in the aquifer (due to low hydraulic conductivity of the weathered zone) activates the process of dissolution (50). Ion exchange of the different elements in the soil and circulating water during the weathering process help in dissolving of fluoride from rocks and minerals (17,50). Besides, the formation of ion pairs such as $CaSO_4$, $CaHCO_3$ and complexing of fluoride with aluminium, beryllium, ferric ions, and series of mixed fluoride hydroxide complexes with boron affect fluoride contamination (35). The temperature also plays a crucial role in the fluoride content of groundwater because the amount of fluoride ingested by living beings is influenced primarily by air temperature (20). Besides, the dissolution of fluoride from minerals/rocks is a physicochemical process that is also controlled by the temperature of the water and the soil itself. Chand (36) presented a correlation of ambient temperature with fluoride content.

Mechanism

During the process of chemical weathering, dissolution of fluoride species in natural water is controlled by calcium ions and governed by thermodynamic principles. The $CaCO_3$ equilibrium in groundwater plays an important role in this process. The equilibrium constant of calcite can be evaluated from the following reactions (53).

$$\mathrm{CaCO_3} + \mathrm{H^-} \Longleftrightarrow \mathrm{Ca^{2+}} + \mathrm{HCO_3}^-$$

$$K_{\mathrm{CaCO3}} = [\mathrm{Ca^{2+}}][\mathrm{HCO_3}^-]/[\mathrm{H^+}] = 97 \text{at } 25\,^\circ\mathrm{C} \qquad (1)$$

$(CaCO_3$ is constant)

The fluoride equilibrium is given by (54):

$$\mathrm{CaF_2} \Longleftrightarrow \mathrm{Ca^{2+}} + 2\mathrm{F^-}$$

$$K_{\mathrm{CaF2}} = [\mathrm{Ca^{2+}}][\mathrm{F^-}]^2 = 10^{-10.58} \text{ at } 25\,^\circ\mathrm{C} \qquad (2)$$

(CaF is constant)

Dividing the first equation by the second, the solubility of calcite and fluorite can be represented by a third constant K:

$$K = \frac{[\mathrm{HCO_3}^-]}{[\mathrm{H^+}][\mathrm{F^-}]^2}$$

$$\text{or} \quad [\mathrm{F^-}]^2 = \mathrm{K'}\frac{[\mathrm{HCO_3}^-]}{[\mathrm{H^+}]} \text{ (where } \mathrm{K'} = 1/\mathrm{K})$$

$$\text{or} \quad [\mathrm{F^-}] \propto [\mathrm{HCO_3}^-]/[\mathrm{H^-}]$$

It is evident that the activity of fluoride is directly proportional to the bicarbonate ion at constant pH. Thus, according to the principle of ionic product, if the concentration of calcium and fluoride in water exceeds the solubility product of fluorite ($10^{-10.58}$ at 25 °C), CaF_2 precipitates. Before reaching saturation the calcium ion has a positive correlation with fluoride ion, and after this stage, there will be a negative correlation between calcium and fluoride ions. In fact, the total concentration of fluoride in a solution will be somewhat greater due to the presence of other electrolytes (ionic strength and complexing effects). But it appears that a high fluoride concentration is more likely to occur in water of low calcium concentration. Handa (55), Das (56), and Gupta et al. (57) summed up the characteristics of ground water whose fluoride content is from dissolved minerals, as follows:

- negative correlation of calcium and fluoride ions
- positive correlation of bicarbonate and fluoride ions
- close of saturation with respect to calcium fluoride
- saturated with calcium carbonate

Thus, the dissolution mechanism of fluoride from its minerals and rocks can be explained on the basis of the solubility product. The dissolution mechanism is physicochemical and, therefore, is governed by thermodynamic parameters, too. The important parameters are temperature, pH, ionic strength, and pressure.

REMEDIAL MEASURES

There are two types of remedial measures to control fluoride contamination. The first is to control fluoride contamination in groundwater, and the second includes removal of fluoride from fluoride-containing water. The control of fluoride contamination in groundwater is very difficult because the contamination of fluoride in groundwater is controlled by a number of hydrogeologic and physicochemical parameters. However, various artificial recharge techniques, including the aquifer storage recovery (ASR) technique may be applied to improve the quality of water by dilution.

The ASR technique is being followed in many parts of the world. In this technique, water is stored underground in wells when it is available, and this water is recovered from the same wells when needed to meet peak, long-term, and emergency water needs. The technique is being applied in United States, Canada, England, Australia, Israel, and other countries. The technique has proved to be a viable, cost-effective option for storing large volumes of fresh water not only in fresh, but also in brackish and other nonpotable aquifers at depths as low as 900 m. Most ASR sites store drinking water in confined aquifers containing water that is brackish or contains constituents such as nitrates, fluorides, iron, manganese, and hydrogen sulfide, all unsuitable for drinking purposes except following treatment. Mixing between the drinking water and the native water in the aquifer can be controlled in most situations by the proper design and operation of ASR wells, so that recovered water has acceptable quality. The operation includes development of a buffer zone surrounding the ASR well to contain the stored water and development of a target storage volume for each well so that recovered water will meet flow, volume, and water quality criteria with acceptability. This technique, however, still remains to be tried in India.

Excess withdrawal of groundwater should be avoided to the extent possible. Aquifers should be recharged periodically so that air cannot enter the aquifer. In addition, only those types of raw materials should be used in industries, which do not release fluoride into the environment. In addition to this, contamination through nonpoint sources should also be minimized by checking man-made activities and the use of fluoride-containing fertilizers and pesticides.

The second type of remedial measure includes removal of fluoride from fluoride-containing water (28,58). There are several methods that have been advocated for defluoridation of drinking water. These methods can be broadly divided into two categories, those based upon the addition of some chemical to the water during the softening or coagulation processes and those based upon ion exchange or adsorption processes. Adsorption or ion exchange processes are recommended for treating low concentrations. These processes are performed by using lime and alum, bone char and synthetic bone, activated carbon and bauxite, ion exchange, activated alumina, and reverse osmosis.

CONCLUSION

The problem of high fluoride concentration in groundwater resources has now become one of the most important health-related geoenvironmental issues in India influenced by the regional and local geological and hydrological conditions of the region. It is high time that an affordable solution is found to minimize fluoride contamination to maintain the health of the large population of the country. There is an immediate need to defluoride the water system either by community or by domestic defluoridation techniques. Demonstration-cum-awareness camps for the purpose should be arranged in fluorosis endemic areas. There is a need to carry out detailed fluoride mapping, hydrological studies for existing water sources to show flow lines, and hydrogeochemical surveys where fluorosis is endemic. In the affected areas, the government should apply firm guidelines for using groundwater, so that tube wells and/or hand pumps in high fluoride zones can be discouraged. Short-term solutions to minimize the fluoride level in drinking water could be using domestic defluoridation equipment or filters.

ROCK FRACTURE

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

INTRODUCTION

From their origin, rocks are more or less disturbed by forces acting within the lithosphere. When a mass of rock is not strong enough to resist forces that are tending either to compress it or to stretch it, the rock is deformed. The change of form is brought about by flow in the deeper parts of the lithosphere and fractures in the upper parts (1). Fractures in rocks are either joints or faults.

JOINTS

The term joint is most commonly used in reference to relatively continuous and through-going fractures that are reasonably planar and along which there has been imperceptible movement. Joints may form as a result of either diastrophism or contraction.

Classification of Joints

Theoretically, joints may be classified according to whether they have been formed by compression or tension. Joints due to compression are (1) diagonal joints, (2) irregular cracks induced by the expansion of rocks consequent upon chemical alteration, and (3) probably a majority of the regular joint system in stratified rocks. Tension joints include (1) irregular cracks formed in the shrinkage accompanying certain kinds of rock alteration; (2) cross-joints in igneous rocks; (3) hexagonal columnar structures and associated fractures due to cooling; (4) small local fractures; (5) fractures clearly associated with tension faulting; and (6) cracks due to drying of muds, clays, and argillaceous limestones.

Description of Joints

1. A series of parallel joints is called a "joint set."
2. Two or more joints intersecting each other produce a "joint system."
3. A persistent joint or set that may be horizontal or vertical is called a "master joint."

Probably all consolidated rocks and a good share of unconsolidated deposits contain joints. Although not well recognized by most individuals involved in groundwater problems, joints exert a major control on water movement and chemical quantity. Characteristically, joints are open and serve as major conduits or pipes. Water can move through them quickly, perhaps carrying contaminants, and, being open, the filtration effect is lost. It is a good possibility that the outbreak of many waterborne diseases that can be traced to groundwater supplies result from the transmission of infectious agents through fractures to wells and springs.

Most joints, at least initially, are tight fractures, but because of weathering, the joint may be enlarged into an open fissure; this is especially common in limestone regions.

Effect of Joints

Knowledge of joints is important in many kinds of geologic studies. Quarry operations, especially those involved in obtaining blocks of certain dimensions and sizes, are obviously greatly influenced by joints. Closely spaced horizontal joints are obviously of great concern in tunneling. A large joint dipping into a highway cut is the site of a potential landslide. Wells drilled in granites for water supply are more productive in highly jointed rocks than in less jointed rocks (2).

If joints are too numerous (i.e., more sets), closely spaced, and of great magnitude, then such a fractured site will be physically too weak to withstand the stresses of dams and bridges. Saturation with water along with the accompanying decay of rocks will make the site more unsuitable for foundations.

Value of Joints

Although joints are often difficult to interpret, they are nonetheless very important structures. For ages, quarry workers have taken advantage of joint-controlled planes of weakness in removing building blocks of granite and limestones from bedrock. These fracture weaknesses exert profound control on weathering and erosion and, thus, on fashioning landscape. Many scenic attractions owe much of their uniqueness to weathering and erosion of horizontal layers of systematically broken up, steeply dipping joints.

Beyond their scenic value, joints constitute structures, of indisputable geologic and economic significance. Joints invite circulation of fluids, including rain and groundwater, hydrothermal mineralizing solutions, and oil and gas. As cracks in rocks, joints can be thought of as structures that significantly contribute to the bulk porosity and permeability of rocks.

Explorers appreciate the benefits of the circulation of fluids through jointed rocks. Petroleum geologists evaluate the nature and degree of development of joints as one guide to the reservoir quality of sedimentary formations. To increase the yield of reservoir rocks in oil and gas fields where production is waning, it is common practice to "crack" the rocks artificially, either by explosives or by high-pressure pumping of fluids into wells.

Joints can serve as sites of deposition of metallic and nonmetallic minerals. In almost all hydrothermal deposits, a part of the mineralization is localized in and around joints. The minerals are deposited either through open-space filling of joints or through selective replacement of chemically favorable rocks adjacent to the joint surfaces along which hydrothermal fluids once circulated.

FAULTS

A fault may be defined as a fracture along which there has been slipping of contiguous masses against one another. Points formerly in contact have been dislocated or displaced along the fracture. Solid rocks or unconsolidated sands, gravel, etc. may be dislocated in this way. Faulting may result from compression, tension, or torsion. Some faults in loose or weakly consolidated clays, sands, and gravels are produced by the removal of a support.

Faults are most common in the deformed rocks of mountain ranges, suggesting either lengthening or shortening of the crust. Movement along a fault may be horizontal, vertical, or a combination. The most common types of faults are called normal, reverse, and lateral (Fig.1). A normal fault, which indicates stretching of the crust, is one in which the upper or hanging wall has moved down relative to the lower or foot wall. The Red Sea, Dead Sea, and the large lake basins in the East African highlands, among many others, lie in a graben, which is a block bounded by normal faults. A reverse or thrust fault implies compression and shortening of the crust. It is distinguished by the fact that the hanging wall has moved up relative to the foot wall. A lateral fault is one in which the movement has been largely horizontal. The San Andreas Fault, extending some 600 miles from San Francisco Bay to the Gulf of California, is the most notable lateral fault in the United States. Movement along this fault produced the 1906 San Francisco earthquakes.

Recognition of Faults in the Field

To recognize faults in the field, a number of criteria are used. The faults may be directly seen in the field, particularly in artificial exposures such as river cuttings and road cuttings. In most of cases, faults are recognized by stratigraphic and physiographic evidence such as (2)

1. repetition or omission of strata,
2. discontinuity of structures,
3. features characteristic of fault planes,
4. silicification and mineralization,

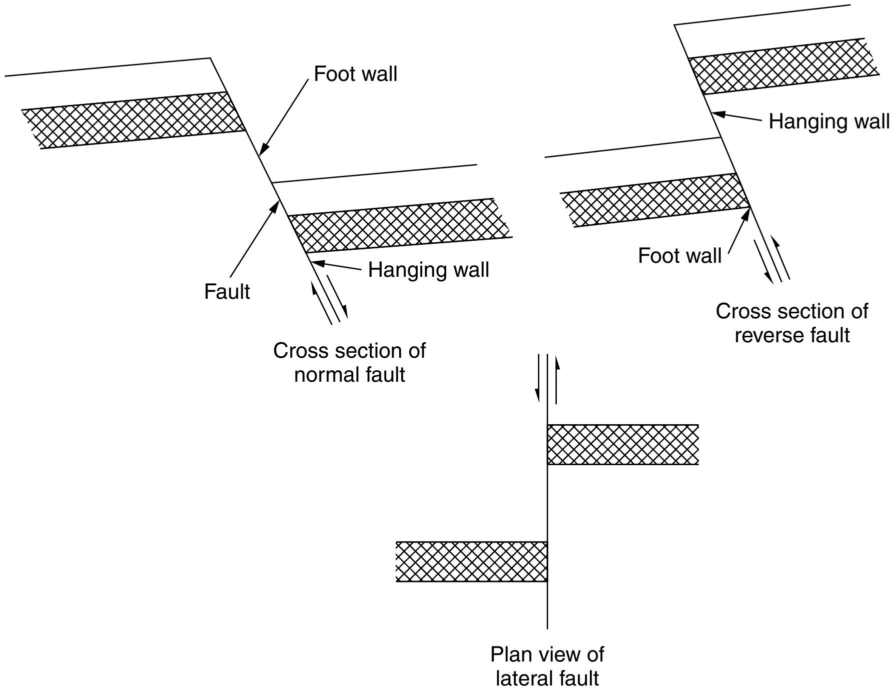

Figure 1. Cross sections of normal, reverse, and lateral faults.

5. sudden changes in sedimentary facies, and
6. physiographic data.

Effects of Faulting

Faulted areas are neither safe nor stable for the foundation of civil engineering works because of the various harmful effects produced by faults. Some important effects of faulting follow (3):

1. Faults cause considerable fracturing and shattering of rocks along fault zones, which means that they are not compact, massive, or strong. Such places are reduced to physically very weak grounds and hence are unfit as foundation sites to withstand heavy loads of structures such as dams.
2. When such porous and fractured zones are saturated with water, their strength is reduced further.
3. The same fractures act as channels for movement of groundwater, which may cause severe groundwater problems in tunnels and leakage problems in reservoirs.
4. The most dangerous features of faulting are its possible recurrence at the same place, which means that the faulted ground is unstable as long as faulting remains active there. Vertical, lateral, or rotational movements are likely to take place at the time of renewed faulting. Naturally, under such conditions, any civil engineering structure cannot have a safe or stable foundation. And if constructions are made, they are likely to collapse when renewed ground movements occur.
5. The fault plane itself is a very prominent fracture plane in the fault zone and therefore may act as a severe source of water leakage. When such percolated water reaches underground, it decomposes the shear zone or fault zones. Such weathering further reduces the competence of rocks.

GEOCHEMICAL MODELS

Mário Abel Gonçalves
Faculdade de Ciências da
Universidade de Lisoba
Lisbon, Portugal

INTRODUCTION

A geochemical model, like any other model, is an abstract representation of a given reality, normally reduced to a set of master variables and described by mathematical equations, which aim at representing natural processes that occur in a system. The output data of these models are a quantitative representation of an outcome that can be observable in the natural system or subject to experimental validation. This operational definition of a geochemical model suggests that a model is nothing more than a set of mathematical equations, which is not strictly true. Any set of equations representing a process must be bounded within limits imposed by nature; otherwise the outcome of these models may be totally unrealistic. Thus, the modeler is called to set proper initial and boundary conditions such that the natural system is correctly represented, and to feed the model with the correct parameters, most of them previously determined experimentally. The quality and self-consistency of the thermodynamic data used, as well as other parameters, such as kinetic ones, are of fundamental importance for the outcome of geochemical models. This issue is considered one of the most critical in any geochemical model. When using any of the available computer programs for geochemical modeling, the choice of the thermodynamic database is left to the modeler. Several compiled thermodynamic databases are available, but this does not mean that all data is internally self-consistent. It is, however, possible to find some databases that are self-consistent relative to some set of chemical species.

Geochemical models have been extensively reviewed in the literature, such as Yeh and Tripathi (1), Mangold and Tsang (2), Appelo and Postma (3), Nordstrom and Munoz (4), and Nordstrom (5). Some textbooks on aqueous geochemistry or geochemical modeling also discuss and include several examples and case studies where specific geochemical computer models have been used (6–8). Of relevance is also the book of Albarède (9), which provides a wealth of mathematical methods and extensive examples on how to build and develop geochemical models in a truly wide range of applications.

COMPONENTS OF GEOCHEMICAL MODELS

Geochemical models may have several components that can be combined in different configurations. These components may be coupled within the model or may imply certain feedback loops.

An essential component of these models is chemical reactions, and these determine, for example, the chemical speciation in solution or the saturation states relative to solid phases. Within these reactions, biological processes may be involved, which take active part in certain reactions, boosting their kinetics (catalysts), hindering the formation of certain compounds (inhibitors), or just transforming chemical compounds (such as the biodegradation of organic pollutants).

Chemical species and compounds in solution are carried away with the water by advection and disperse through the medium by molecular diffusion. These are the components of transport of chemical elements in solution, which determine their spreading in the system.

Transport of chemical elements are thus a function of water velocity and, consequently, of fluid flow in the system. Physical parameters of the system, such as porosity and permeability, determine the patterns of fluid flow and velocity variations in space and time. In the coupled reactive transport models, precipitation/dissolution of mineral phases can reduce/increase the porosity and permeability of the medium and change fluid flow patterns.

In certain systems, such as large-scale sedimentary basins, it is necessary to consider heat transport. Heat can increase the kinetics of several chemical reactions and induce fluid flow along thermal gradients.

TYPES OF GEOCHEMICAL MODELS

The description of the different types of geochemical models is not extensive and outlines only their main characteristics, as presented by Zhu and Anderson (8). Geochemical models are generally grouped according to their level of complexity. The simplest ones are the speciation-solubility models. These models are meant to compute the thermodynamic equilibrium of species in a system at a given temperature and pressure. Therefore, the output comprises the concentration and activity of the various ionic and molecular species in a solution. It also includes the saturation state of the solution relative to several minerals and the distribution of stable species on surfaces or ion-exchange sites in equilibrium with the aqueous solution.

Reaction-path models calculate the sequence of equilibrium states of a system in response to incremental additions (or subtractions) of mass to the system, change in temperature and/or pressure, and mass transfer between phases in the system. The configuration of these models can be diverse and includes the addition of a reactant (such as a titration), fixation of the activity of a chemical species modeling a buffered system, incremental feeding of a reactant solution (as in a continuous stirred tank reactor), and kinetic controls of heterogeneous reactions.

Another group of models corresponds to inverse mass balance models. These specialized models derive the initial composition of a water solution from its actual final composition, which takes into account the reactions and mass transfer between water and solid and/or gas phases, in agreement with the available data of a system. Thus, the initial composition of the water is determined by subtracting the amount of dissolved species caused by reaction with minerals and other phases in the system from its final composition. Inverse mass balance calculations may also involve the determination of the fractions of different waters that have, at some given time, mixed completely.

Finally, coupled reaction-transport models are the most complex. In these models, both the partial differential equations describing the advection-dispersion transport and the set of algebraic equations describing the chemical equilibrium are solved. These models can also include heat transfer and fluid flow, thus increasing the number of equations to be solved. The level of complexity depends also on the details of chemical reactions considered. These details can include multicomponent reactive transport, which accounts for the kinetics of mineral dissolution and precipitation; adsorption onto mineral surfaces; and radioactive decay, to name but a few.

FINAL REMARKS: MODEL VALIDATION AND USEFULNESS

The outcome of geochemical models can be either observable in nature or subject to experimental testing. Both processes are fundamental for model validation, and they are surely the ultimate test that a model must face. However, the process is not as simple as it may seem. Usually, geochemical models may adequately describe several processes and mechanisms in nature, but nature's inherent complexity puts a limit to model precision and accuracy, which limits considerably its proper validation. Normally, the number of variables assumed within a model is limited and corresponds to a fraction of the ones found in nature. In such complex models, slight variations in parameters may induce diverse outcomes, such as in climate modeling. Thus, models are not only helpful tools to gain insight into the workings of nature, but they also must have some sort of predictive power. A model outcome may not be accurate enough to make a prediction relative to contaminant dispersion in a groundwater system, for example. However, it may give enough confidence to help make decisions on regulatory issues.

GEOCHEMICAL MODELING-COMPUTER CODES

Mário Abel Gonçalves
Faculdade de Ciências da
Universidade de Lisoba
Lisoba, Portugal

An important share of geochemical studies increasingly relies on the use of computer programs[1] to model diverse geochemical systems. Most of these programs are freely available to the general public, or at a symbolic cost for educational and research purposes. Although developing open source and/or precompiled codes is markedly important, their regular maintenance should not be dismissed. Programming languages evolve, as well as operating systems and computer hardware, which means that codes without regular revision become outdated and eventually useless as their compiled versions may stop working properly under new operating systems.

All geochemical models rely very much on the availability of good quality, self-consistent thermodynamic data. This data is stored in database files that are accessed by the program while it is executed, making it one of its core elements. In the absence of specific data in the database for the problem to be modeled, some programs allow the incorporation of the data in simulations or, alternatively, the database can be modified by incorporation of new data. As new and improved experimental thermodynamic measurements are continuously being made, thermodynamic databases should also be regularly revised and updated.

The description that follows is meant to address mainly those computer programs most readily accessible and does not pretend to be an exhaustive list of all available programs. Although presenting the address of websites where these programs and codes are stored and may be obtained, one should be aware that this information will potentially become out of date rather quickly.

USGS CODES

The USGS supports various projects for developing software, including aqueous geochemistry computer programs, which include the chemical speciation program WATEQ4F (1), well suited for processing large numbers of water analyses. The most recent upgrades include the revision of the thermodynamic data on uranium and arsenic species. The most complete computer programs available are the ones from the PHREEQC (2) family (http://wwwbrr.cr.usgs.gov/projects/GWC_coupled/).
PHREEQC is a program that performs chemical speciation calculations, reaction-path modeling, one-dimensional transport, and inverse geochemical calculations. Currently, it contains a basic interpreter allowing a very flexible use of the program, meeting each one's needs, especially for modeling kinetic data. The latest revisions (February–April 2003) include isotope fractionation modeling (3). PHREEQC uses its own thermodynamic database, and also the LLNL and WATEQ4F databases, which are still updated and corrected regularly. Two graphical user interfaces (GUI) were developed: PHREEQCI by USGS and PHREEQC for Windows by Vincent Post from the Vrije Universiteit Amsterdam (http://www.geo.vu.nl/users/posv/phreeqc). The latter allows the graphical display of the output, which is unavailable in the original program, which is rather achieved by using the PHRQCGRF program. PHAST is a three-dimensional multicomponent reaction-transport model that simulates transient groundwater flow, that may or may not include geochemical reactions. PHAST combines the HST3D simulator (4) for the transport calculations with PHREEQC for geochemical calculations. PHRQPITZ is specially designed to use with brines, as it implements Pitzer's equation for the calculation of activity coefficients.

---

[1] We will use the term "computer code" as a set of written instructions aiming at solving a set of specific problems, and computer program to a compiled code to be executed as a standalone application under a given operating system.

Other computer programs include OTIS (5), used for the geochemical modeling solute transport in streams and rivers. Recently, Bowser and Jones (6) presented a Microsoft® Excel spreadsheet for a mineral-solute mass-balance model in order to study and understand the mineralogical controls on water composition in surface and groundwater systems dominated by silicate lithologies. All of these programs, and others, are available from USGS webpages at http://water.usgs.gov/software/geochemical.html.

USEPA CODES

The USEPA has a series of supported computer codes, the most popular of which is the MINTEQA2/PRODEFA2 (last release in 1999 is version 4.0), widely used in environmental geochemistry problems (7), which is a chemical equilibrium computer model that is able to calculate chemical speciation, solubility equilibrium, titration, and surface complexation modeling. It also includes the Gaussian model for the interaction of dissolved organic matter (DOM) with cations. However, it lacks database maintenance. Gustafsson (8) has been developing VisualMINTEQ, a GUI version of this program that also presents other improvements, such as the NIST database, adsorption with five surface complexation models, ion-exchange, and inclusion of both the Stockholm Humic Model and the NICA-Donnan model for metal-DOM complexation to name only a few.

The program BIOPLUME III (9) is a 2-D finite difference model that accounts for advection, diffusion, adsorption, and biodegradation in groundwater systems to model natural attenuation of organic contaminants. BIOCHLOR (10) and BIOSCREEN (11) are both Microsoft® Excel spreadsheet-based codes that model natural attenuation of chlorinated solvents and petroleum-derived hydrocarbons in water systems, respectively.

CHEMFLO-2000 (12) is a model that simulates water flow and chemical transport and fate in the vadose zone. CHEMFLO-2000 is a program that is written in Java®, which makes it platform-independent. All of these programs can be obtained from http://www.epa.gov/ada/csmos/models.

OTHER CODES

The set of computer codes known as EQ3/6 (13) supported by Lawrence Livermore National Laboratory (LLNL) was originally developed to model water-rock interactions in hydrothermal systems. It is currently one of the most complete programs applied to several problems, including municipal and industrial waste situations, and has been used to assess natural and engineered remediation processes. Unlike the programs presented until now, it must be purchased from LLNL. Closely related but mostly used for a range of high temperature and pressure is SUPCRT92 (14). This program has been discontinued, but still available on request to the authors.

The Geochemist Workbench® (15) is a commercial software with a range of capabilities similar to EQ3/6 and PHREEQC. It is available for Windows® only, but taking advantage of this environment makes it user friendly, with graphical capabilities included that are normally absent from most of these programs.

The Windermere Humic Aqueous Model (WHAM) version 6 (16) models the ion–humic substances interaction in surface waters using surface complexation. It also incorporates cation exchange on clays. However, precipitation and dissolution of solids as well as oxidation-reduction reactions cannot be simulated. This program must also be purchased for use. Alternatively, WinHumicV is a freely available GUI version of WHAM with model V implemented (17).

Steefel and Yabusaki (18) developed the GIMRT/OS3D codes for 2-D and 3-D multicomponent coupled reactive-transport modeling for flow in porous media. Both of these programs were superseded by the program CRUNCH (http://www.csteefel.com/CrunchPublic/WebCrunch.html), which can be obtained from the developer (C. I. Steefel) on request.

ORCHESTRA (19) (http://www.meeussen.nl/orchestra/) represents a new class of computer programs for use in geochemical reactive-transport modeling. This program is actually a framework where chemical speciation models can be implemented by the user and combine them with kinetic and transport processes. It is written in Java® and takes advantage of object-oriented programming. In the same class of programs is MEDIA (http://www.nioo.knaw.nl/homepages/meysman/), to simulate the biogeochemistry of marine and estuarine sediments.

GEOCHEMICAL MODELING—COMPUTER CODE CONCEPTS

Geoffrey Thyne
Colorado School of Mines
Golden, Colorado

INTRODUCTION

This article is focused on geochemical models in aqueous systems. The applications for these models have grown over the last 20 years as the capabilities and flexibility of the codes has increased in conjunction with the increased speed of personal computers. Many earlier computer models were designed for specific questions related to aqueous speciation (1,2). Many earlier models have been discontinued or superseded by newer programs that incorporate new features and capabilities, increased flexibility, and improved input and output options. This change has been driven by the wider use of geochemical modeling and the increase in modeling as a component of environmental studies. Some more important recent applications include modeling high-level radioactive waste disposal, environmental issues associated with mining, landfill leachate, injection of hazardous wastes into deep wells, water resources issues, and artificial recharge to aquifers (3).

All available models use the same basic approach, that of calculating the thermodynamic equilibrium state of a specified system that can include water, solutes, surfaces, and solid and gas phases. These models comprise four major components. They are as follows:

1. Input: specific information that defines the system of interest such as concentrations of solutes, temperature, partial pressure of gases, and composition of solid phases.
2. Equations that are solved by the model.
3. Equilibrium and kinetic formulations between solutes of interest.
4. Output: in tabular or graphic form.

CAPABILITIES AND METHODS

The computer codes require initial input constraints that generally consist of water chemistry analyses, units of the measurement, temperature, dissolved gas content, pH, and redox potential (Eh). The models work by converting the chemical concentrations, usually reported in wt./wt. or wt./volume terms such as mg/kg or mg/L, to moles, and then solving a series of simultaneous nonlinear algebraic equations (chemical reaction, charge balance, and mass balance equations) to determine the activity-concentration relationship for all chemical species in the specified system. The models usually require electrical balance and will force charge balance with one of the components (can be designated), as they solve the matrix of nonlinear equations. The capabilities of modern codes include calculation of pH and Eh, speciation of aqueous species, equilibrium with gases and minerals, oxidation and reduction reactions (redox), kinetic reactions, and reactions with surfaces.

The nonlinear algebraic equations are solved with an iterative approach by the Newton–Raphson method (4). The equations to be solved are drawn from a database that contains equations in the standard chemical mass action form. In theory, any reaction such as sorption of solute to surface that can be represented in this form can be incorporated into the model. These equations represent chemical interactions with reactants on the right and products on the left. Reactions are assumed to reach equilibrium (the point of lowest free energy in the system) when there is no change in concentration on either side.

$$\mathrm{CaCO_3} \leftrightarrow \mathrm{Ca^{2+}} + \mathrm{CO_3{}^{2-}}$$

Note that the arrow in the calcite dissolution example above goes in both ways; that is, the reaction as written is reversible. Once a mineral reaches equilibrium with a solution, adding more mineral will not increase the dissolved concentration because we have already saturated the solution. But removing ions from the right side (e.g., lowering the concentration by dilution with distilled water) will cause more solid to dissolve.

We express this in a mathematical form where, at equilibrium, the ratio of the concentration of reactants (on the bottom) and products (on the top) is equal to K, known as the proportionality constant or distribution coefficient or equilibrium constant.

$$\mathrm{K_{calcite}} = \frac{[\mathrm{Ca^{2+}}][\mathrm{CO_3{}^{2-}}]}{[\mathrm{CaCO_3}]}$$

Kinetic reactions, those involving time, are included by assuming that the chemical reaction will proceed to equilibrium, but at a specified rate. The available kinetic reactions include mineral dissolution and precipitation, redox reactions and microbial growth, and metabolism of solutes. The rate laws used in the codes vary, but all codes with kinetic capabilities include simple first-order rate laws, and they may include more complex rate formulations such as cross-affinity, Michaelis–Menten, and Monod formulations (5).

THERMODYNAMIC BACKGROUND

The formalism that allows us to relate mass actions equations (balanced chemical reactions) to actual solutions is called chemical thermodynamics or, more precisely, equilibrium thermodynamics. The basic idea is that elements, molecules, and compounds all contain some internal energy and that all systems try to reach a state where that energy is minimized (equilibrium). Natural systems, particularly low-temperature systems, do not always reach equilibrium, but they do move in that direction. The internal energy of an element, molecule, or compound is expressed as its enthalpy or internal heat. The free energy of an element is an element, molecule or compound is the sum of its internal heat and its internal tendency toward disorder (entropy).

$$G = H - TS$$

Assuming constant T and P, we get

$$\Delta G = \Delta H - T\Delta S$$

The total free energy of a component in the system is dependent on this inherent energy of an element, molecule, or compound and the amount (concentration). When two or more elements, molecules, and compounds are combined, the result is a reaction that minimizes the energy of the new system, lowering the ΔG. The free energy of a reaction is calculated by

$$\Delta G^0 \text{ rxn.} = \sum \Delta G^0 \text{ products} - \sum \Delta G^0 \text{ reactants}$$

The ΔG^0 values (standard free energy) for many compounds can be found in the back of textbooks such as Drever (6). This way we can calculate a ΔG value for any reaction that for which we can write a balanced chemical equation. The minimum energy state (equilibrium) between the reactants and products is related to the ΔG value by

$$\log K_{\text{rxn.}} = \frac{-\Delta G^0 \text{ rxn}}{2.303\, RT}$$

where R is the universal gas constant in kJ/mole; T is the temperature in Kelvin; and K is the equilibrium constant for the reaction.

COMPUTER MODELS

The computer models are divided into two basic types, speciation models and reaction-path models. In both cases, the models are fundamentally static; that is, no explicit transport function exists; however, some forms of transport can be simulated by manipulation of the models. More complex reaction-transport models that explicitly incorporate transport are briefly described below.

The equilibrium models are speciation models in that they can calculate the speciation (distribution) of aqueous species for any element or compound included in the database. Speciation models calculate activities (chemically reactive concentration), species distribution for elements in the database, saturation indices, and ion ratios at the specified conditions of pH and redox potential (ORP or Eh). Most models allow selection of method of activity calculation (Davies, Debye-Huckel, extended Debye-Huckel, Pitzer). Some models incorporate adsorption, solid phase solutions, and kinetics. Only one model, PHREEQC, has the inverse modeling option. This features uses mass balance constraints to calculate the mass transfer of minerals and gases that would produce an ending water composition given a specified starting water composition (7). This method does not model mass transport; it only calculates and provides statistical measures of fit for possible solutions to the mass balance between starting and ending water compositions.

The next step in complexity is the reaction path (mass transfer) models. The reaction path models use speciation calculation as a starting point and then make forward predictions of changes along the specified reaction path (specified change in T, P, pH, addition of new reactants such as another fluid or solid). The program makes small incremental steps with stepwise addition or removal of mass (dissolution or precipitation), and it can include changes in temperature or pressure along the reaction path. Typical questions posed by modelers include:

- If I change a variable (pH, pe, P_{CO2}), how does system change?
- What happens if I mix water A with water B?
- What is concentration of A^+ in water saturated with mineral AB?

- What happens to the water chemistry *A* if I react the water with mineral *B*?

Limitations exist with any model. The field input data may be corrupt with bad analysis, missing parameter, or electrical imbalance. Speciation models assume equilibrium conditions, which may not be the case. The databases are also a source of uncertainty. They do not always contain all elements or species of interest; the data have some uncertainty, and some data may be inaccurate data (6). Some available codes try and minimize this problem by including several of the most popular databases such as the MINTEQ database (EPA-approved database specializing in metals), WATEQ (USGS database specializing in minerals), and the LLNL database (the most complete database available that is compiled and maintained by Lawrence Livermore National Laboratory). For environmental applications, the limited data for organic compounds remain a concern.

Other limitations include the redox reactions that are of particular importance in metal transport. These reactions are difficult to model correctly because redox reactions may have different rates producing natural systems that are not in redox equilibrium (8). This problem can be addressed by modeling redox reactions as rate-limited (kinetic) formulations if the data are available.

The most complex models explicitly incorporate transport and reaction. The codes couple and solve both the partial differential equations of flow using the advective-dispersion equation and the nonlinear algebraic equations of chemical equilibrium. The general approach is to solve for the reaction term in each cell with the chemical module of the code, and then separately solve for the effects of transport (split-operator approach). The effects of adsorption are solved in the transport module with the retardation portion of the equation (3,8,10). These models are much more complex than are the reaction path models. Presently, only three commonly used models have transport capabilities, HYDROGEOCHEM2, PHREEQC (1D) and the related PHAST (3D) code, and Geochemist's Workbench.

Table 1 lists the most common programs, their sources, and some of the most useful capabilities. The list is not meant to be exhaustive; rather, it offers an overview to serve as a starting point for further investigation. Details of the capabilities of each program can be found on the listed websites or in the manuals. More detailed comparison of these and other models are available in related publications (1,11,12).

GEOLOGICAL OCCURRENCE OF GROUNDWATER

JOHN E. MOORE
USGS (Retired)
Denver, Colorado

The occurrence, movement, and storage of groundwater are controlled by geology. The geologic factors that control groundwater are petrography, stratigraphy, structure, geomorphology, lithology, and thickness (1). The petrography of a given rock type controls the porosity and permeability. Porosity defines the storage capacity of an aquifer. There are two types of porosity: primary and secondary. Primary porosity, such as pores between sand grains, is created when rocks are formed. The shape, sorting, and packing of grains determine primary porosity. Sedimentary rocks are poorly sorted when the grains are not the same size creating spaces between the larger grains that are filled by smaller grains. Secondary porosity such as joints, fractures, and solution opening, is formed after the rock has been deposited. The number and arrangement of fracture openings and the degree to which they are filled with fine-grained material control secondary porosity.

Aquifers (1) are classified as unconfined and confined. An unconfined aquifer has the water table as its upper boundary (2). Recharge to unconfined aquifers is primarily by downward seepage through the unsaturated zone. The water table in an unconfined aquifer rises or declines in response to rainfall and changes in stream stage. When a well that tap an unconfined aquifer is pumped, the water level is lowered, gravity causes water to flow to the well, and sediments near the well are dewatered. Unconfined aquifers are usually the uppermost aquifers and, therefore, are more susceptible to contamination from activities at the land surface.

A confined (artesian aquifer) contains water under pressure greater than that of atmospheric. Rocks of permeability lower than the aquifer overlie a confined aquifer. The low-permeability layer that adjoins a confined aquifer is called a confining bed. A confining bed has very low permeability that restricts the movement of groundwater either into or out of the aquifer. Confining beds are thus poorly transmissive to groundwater flow. Because the water is under pressure, water levels in wells rise above the base of the confining bed. If the water level in a well that taps a confined aquifer stands above the land surface, the well is called a flowing artesian well. In some cases, a fault (fractures along which rocks have moved) will allow the passage of water from a confined aquifer to the surface, resulting in a spring.

Sand and gravel aquifers are the source of most of the groundwater pumped in many parts of the world, including North America, The Netherlands, France, Spain, and China. Sand and gravel aquifers are common near large to moderately sized streams. Rivers or the meltwater from glaciers formed these aquifers.

Limestone aquifers are the sources of some of the largest well and spring yields because limestone is soluble in water. Openings that existed when the rocks were formed are frequently enlarged by solution (dissolved by water), providing highly permeable flow paths for groundwater (3).

Basalt and other volcanic rocks are some of the most productive aquifers. Basalt aquifers contain water-bearing spaces in the form of shrinkage cracks, joints, and lava caves. Lava tubes are formed when tunneling lava ceases to flow and drains out, leaving a long, cavernous formation.

Fractured igneous and metamorphic rock aquifers are the principal sources of groundwater for people who live in mountainous areas. Where fractures are numerous and interconnected, these rocks can supply water to wells and can be classified as aquifers. Wells are commonly 50 to 100 feet deep (15 to 30 meters). Granite and metamorphic rocks have not been extensively developed as aquifers. Groundwater movement in these rocks is irregular, which makes exploration for a water supply difficult (4).

Sandstone aquifers are formed by the cementation of sand. Their porosity ranges from 5–30%. Their permeability is largely a function of the amount of cement (clay, calcite, and quartz). Sandstone is an important source of groundwater in Libya, Egypt (Nubian), Britain (the Permo-Triassic sandstones), the north central United States (St. Peter-Mount Simon Sandstone), and in the west central United States (the Dakota Sandstone).

GEOPHYSICS AND REMOTE SENSING

JOHN R. JANSEN
Aquifer Science & Technology
Waukesha, Wisconsin

When data cannot be gathered by direct observation, such as observing an outcrop or taking a physical sample, information can often be obtained by using remote sensing techniques. Remote sensing methods measure physical properties of materials by measuring changes in the flux of various forms of energy using natural or transmitted fields. The science of applying these methods to earth materials is called geophysics

Geophysics is commonly used to obtain subsurface information for a variety of resource development and engineering applications. A partial list of applications for which geophysical methods can be used includes mapping aquifers, mapping water quality, mapping geologic structure, measuring flowing fluids, finding buried objects for engineering and archeological purposes, and measuring *in situ* soil and rock properties. The major energy fields used include magnetic fields (magnetometry), electrical fields (electrical resistivity and spontaneous potential), electromagnetic fields (electromagnetic induction and ground-penetrating radar), propagation of seismic waves (seismic reflection, seismic refraction, passive acoustic emission monitoring, and spectral analysis of surface waves), the gravitational field (gravimetry), gamma-ray radiation (gamma-ray spectroscopy), and heat transfer (geothermal). Other physical properties can be measured by bombarding the material with gamma rays (electron density) or high-energy neutrons (hydrogen content). Less commonly, properties such as thermal conductivity, electrical chargeability, or magnetic resonance are also measured.

The methods can be broadly classified in several ways. Most commonly, methods are classified by their mode of deployment. Surface methods are commonly applied from the ground surface. Borehole methods are used within boreholes or wells. Several techniques can also be applied using airborne or marine systems. Methods can also be classified as active or passive measurement. Methods that measure variations in natural fields, such as gravimetry or magnetometry, are called passive methods because they use natural fields propagating through the earth. Other methods are called active methods because the measurement is based on the response of earth material to some form of transmitted energy. Active methods include most seismic methods and most electrical methods.

There are many types of geophysical methods; each has specific advantages and limitations. The choice of the proper method requires understanding the target body, the matrix material, and the environment in which the survey is to be conducted. The following is a brief outline of the most common geophysical methods with a summary of the characteristics of each method. The list is by no means complete.

SURFACE METHODS

Electrical Methods

Electrical Resistivity. The electrical resistivity method uses two electrodes planted at the surface to pass an electric current through the ground. A second pair of electrodes is used to measure the potential difference between two points. The measured potential and the applied current are used to calculate the electrical resistance per unit length (resistivity) of the subsurface. The depth of measurement is changed by changing the relative position and spacing of the electrodes. Several newer systems use cables with multiple electrodes connected to a switching system to select the electrode pairs. The field data produce an apparent resistivity value, which is a function of all materials penetrated by the current. The data must be modeled to obtain the unique resistivity and thickness of each layer for a nonuniform subsurface.

Applications

Can distinguish saturated from unsaturated materials.
Can distinguish sandy material from clay-rich material.
Can distinguish high-conductivity groundwater (inorganic contaminants) from low-conductivity groundwater.
Less susceptible to cultural interference than electromagnetic (EM) methods.
Better vertical resolution for resistive targets than EM methods.

Limitations

Requires electrical coupling with the surface, which can be difficult in dry soils.
Generally requires three to five times the surface array length to the depth of investigation.
Field acquisition generally slower than EM methods.
Poorer lateral resolution than EM methods at depths of more than a few meters.
Relatively insensitive to changes in the resistivity of highly conductive bodies.
Highly resistive near-surface material can mask conductive bodies at depth.
Can be affected by strong EM fields such as from high-voltage power lines.
Interpretation of field data produces nonunique solutions (i.e., many possible solutions can fit data nearly as well as actual conditions).

Spontaneous Potential. The SP method uses two nonpolarizing electrodes and a high-impedance voltmeter to measure natural voltages between two points generated by several natural processes. Anomalies can be due to variations in the geochemical properties of soils, fluids, or moving groundwater. Although its origins are in the mining industry for finding sulfide ore bodies, the method is principally a profiling technique to find seepage pathways such as for a dam investigation.

Applications

Relatively fast and simple data acquisition and interpretation.
Can detect zones of high groundwater flow.
Can detect oxidizing metal bodies.

Limitations

Requires special nonpolarizing electrodes for accurate voltage measurements.

Susceptible to interference from near-surface soil conditions.
Interpretation is qualitative and can be ambiguous.

Induced Polarization. The IP method measures a property known as chargeability, which is the ability of subsurface materials to hold a charge after an electrical current is shut off. It is basically a modification of the electrical resistivity method that measures induced electrical polarization between two electrodes caused by an applied low-frequency alternating current. Measurements are typically made by measuring the decay of voltage with time after the applied current is shut off, called the time domain method, or by measuring the suppression of voltage relative to the frequency of the applied external current, called the complex resistivity method. IP surveys have been used to determine the clay content of the subsurface or the geochemical properties of several minerals in the subsurface. The surveys can be conducted as profiles or as depth soundings.

Applications

Can be used to estimate the clay content of the subsurface and thereby infer hydraulic conductivity.
Can be acquired simultaneously with electrical resistivity data.
Can be used to detect organic contamination of soils under certain conditions, primarily sites that have 6% to 12% clay content.
Can be used to measure the *in situ* oxidation state of some inorganic compounds.

Limitations

Requires surface electrodes and better electrode coupling than standard resistivity surveys.
Requires higher currents than electrical resistivity—potentially dangerous.
Ability to convert IP soundings to depth sections is limited.
IP response is relatively insensitive to increases in clay content above 7% to 10%.
Interpretation is qualitative and can be ambiguous.

Azimuthal Resistivity. The azimuthal resistivity method is a modification of the standard electrical resistivity method that measures electrical resistivity versus azimuthal orientation at one location. The method is used to identify areas of fractured till or bedrock and determine the orientation of the principal fracture set. Several specialized electrode arrays have been developed to reduce the number of readings required, including the tripotential array and the square array.

Applications

Can determine the fracture orientation and fracture porosity from the surface.
Uses standard resistivity equipment.

Limitations

Data acquisition can be relatively slow and require a relatively large area of open land.
Limited ability to determine location of individual fractures.
Steeply dipping or irregular bedrock surfaces can skew data.
Cannot distinguish clay-filled from fluid-filled fractures.
Interpretation is quantitative for uniformly fractured materials with no overburden; quantitative interpretation is more limited for more common cases such as discrete fracture zones with overburden.

Seismic Methods

Seismic Refraction. The seismic refraction method uses the principle of refraction (bending) of sound energy across a boundary between two materials that have different sound velocities. The travel time of sound energy from a seismic source, such as a hammer blow or explosive, to a line of ground motion detectors, called geophones, is measured by a device called a seismograph. The travel time versus distance between the source and the geophones is used to calculate the thickness and depth of the geologic layers present. The method can resolve only layered systems in which each layer has a higher sound velocity than the layer above it. A layer that is too thin or whose velocity is lower than the layer above it cannot be detected and will introduce an error in the depth calculation of deeper layers. The shape of dipping or undulating surfaces can be resolved if several source locations are used in different positions relative to the geophone string.

Applications

Relatively simple and fast.
Requires less interpretation than other seismic methods.
Directly measures the seismic velocity of the materials present.
Measured velocities can be used to determine the type of bedrock or soil.
Can provide information on depth to bedrock to within about 10%.
Can determine the slope and shape of a bedrock surface.
Can map dense till sheets beneath softer sediments.
Can identify larger faults under the right conditions.

Limitations

Typically requires three to five times the surface array length to the depth of penetration.
Practical depth limit approximately 150 to 200 feet without a strong seismic source such as explosives.
Cannot detect low velocity layers beneath high velocity layers (i.e., sand beneath clay).
Limited ability to measure changes in velocity along a layer.
Cannot resolve steep dips.
Water table mapping only possible in coarse, sandy soils.
Sensitive to vibrations from cultural features such as highways.

Seismic Reflection. The reflection methods uses a string of geophones connected to a seismograph to measure direct reflections of sound energy from geologic boundaries between layers with contrasting acoustic impedance values (density times sound velocity). After significant processing, the data are typically plotted as a time section that shows the two-way travel time to major reflectors that is analogous to a geologic cross section, except that the depth axis is presented in travel time, which is not linear with depth. The method is typically used for deeper, more detailed studies than the refraction method, and the limitation of increasing velocity with depth does not apply. Faults, geologic structure, and dipping or truncating beds are commonly mapped by reflection.

Applications

The depth of penetration can be several times the surface array length.

More sophisticated interpretation and processing techniques are available.

Produces a continuous image of the subsurface that provides a time cross section that can be converted into a depth cross section.

Lateral resolution is much better than refraction.

Can tolerate steeper dips than refraction.

Can accurately map small faults.

Can be used onshore or offshore.

Can handle low velocity layers beneath high velocity layers.

Limitations

Requires more sophisticated field equipment, processing, and field procedures.

Data acquisition and processing are more intensive than refraction.

Requires sophisticated analysis and accurate seismic velocity data from an independent source to convert from time to depth cross section.

Difficult to apply to shallow exploration targets (i.e., above approximately 50 to 100 feet).

Interpretation of data subjective and requires experienced interpreter.

Sensitive to vibrations from cultural sources such as highways.

Gravitational Methods

Gravimeter Surveys. The gravitational method uses a sensitive balance, called a gravimeter, to measure variations in the force of gravity at the surface caused by variations in the density of the subsurface. A common modification of the method is called the microgravity method. Microgravity uses a more sensitive gravimeter to detect small near-surface features, such as voids or cavities.

Applications

Can be used to detect buried bodies of contrasting density.

Can be used to detect bedrock valleys, faults, cavities, and other geologic structures.

Data acquisition relatively simple.

Forward modeling can easily be used to predict the success of the method for a given target.

Limitations

Requires a series of complex data corrections requiring precise locations and elevations at points of measurement and surrounding topography.

Materials of similar density do not produce a measurable anomaly (e.g., granite and quartzite)

Large anomalies at depth can mask shallow, smaller anomalies.

Interpretation of data produces a nonunique solution.

Can be difficult to collect accurate data around buildings or in areas of highly irregular topography.

Magnetic Methods

The magnetic method measures variations in the intensity of the earth's magnetic field caused by material of high magnetic susceptibility such as ferrous iron. Measurements can be made with single sensor units, so-called total field magnetometers, that measure the total magnitude of the magnetic field at a given point. Other types of magnetometers make simultaneous measurements at two elevations and compute the vertical gradient of the magnetic field, which increases the sensitivity to shallow targets and decreases the interference from adjacent objects. Some magnetometers measure only the vertical component of the magnetic field, which also reduces interference from adjacent objects. Three types of magnetometers are currently available: (1) Proton precession instruments measure the total field and commonly use two sensors to measure the vertical gradient. Proton precession magnetometers are commonly available and relatively inexpensive, but they are sensitive to steep magnetic gradients from cultural sources, such as power lines and large metal bodies, and do not provide reliable data in many highly developed sites. (2) Flux gate magnetometers measure only a single (usually vertical) component of the magnetic field. The readings are slower, and the sensor must be properly oriented, making data acquisition slower; but the sensor functions well in the presence of steep vertical gradients and is less sensitive to horizontal fields from adjacent objects. The units are less common and more expensive, but they work on sites where proton procession units do not. (3) Cesium magnetometers make fast, very accurate total field measurements, and two sensors are commonly used to make vertical gradient measurements. The sensors can handle steep magnetic gradients and operate at a higher data acquisition rate than other magnetometers. The sensor has an axial blind spot of about 30° that may produce erroneously low readings if the sensor is not properly aligned with the target bodies. The units are more common than flux gate systems but more expensive than proton systems.

Applications

Field acquisition is fast and relatively easy.

Can readily detect buried ferrous objects (e.g., buried drums, tanks, and pipelines).

Can be used to detect geologic structures where materials of contrasting magnetic susceptibility are present (e.g., igneous vs. sedimentary rock).

Limitations

Large masses of ferrous objects can have coalescing anomalies that prevent precise location of individual targets.

Susceptible to interference from surface metallic objects such as fences or strong electromagnetic fields from power lines.

Does not detect material of low magnetic susceptibility (e.g., nonferrous objects such as aluminum or fiber barrels).

Interpretation of data produces nonunique results.

Electromagnetic Methods

Frequency Domain Electromagnetic Induction. Frequency domain EM systems use a two-coil system to transmit an electromagnetic field to induce "eddy" currents in the subsurface and measure the resultant magnetic field, which is a product of the primary field and the induced fields. In some systems, the receiver coil is coincident with the transmitter coil. Systems typically operate at a single frequency that can be selected by the operator. Some systems use a sweep across a range of frequencies. The depth of investigation is controlled by changing the separation between the coils or the frequency of the transmitted field. Two components of the magnetic field are measured, the in-phase or quadrature component and the out of phase component. Some units are designed to operate in low-conductivity soils and use the quadrature term to set the coil spacing. These units are called low induction number systems and generally provide a direct reading of subsurface conductivity. They are easier to use in the field but do not make accurate measurements in soils above a few hundred millimhos per meter. Other systems require measuring the coil spacing independently. These systems make an accurate measurement of subsurface conductivity over a broader range of conditions, but the data must be processed to provide a conductivity measurement. The in-phase component of these units can be used as a direct indicator of high induction number material, such as metal, in the subsurface. Both types of systems produce an apparent conductivity measurement that must be modeled to obtain individual layer conductivity and thickness for a nonuniform subsurface.

Applications

No electrodes required; can be used on surfaces where electrode plants would be impossible.

Data acquisition is fast and efficient.

Can be conducted through freshwater.

Different coil orientations and intercoil spacing can be used to accommodate different depths of investigation.

Lateral resolution much better than electrical resistivity techniques.

Can be used to detect buried metal.

Detects nonferrous metal (e.g., copper, aluminum, brass, bronze).

Sensitive to inclined conductive sheets such as faults or fracture zones.

Can be used for azimuthal surveys to map fracture density and orientation.

Simple profiling instruments can be used by relatively inexperienced operator (e.g., Geonics EM34 or EM31).

Multiple-frequency systems can make vertical depth soundings.

Limitations

Depth interpretation of sounding data requires an experienced interpreter.

Vertical resolution generally poorer than with electrical resistivity.

More sensitive to cultural interference (pipelines, metal fences, power lines, etc.) than electrical resistivity.

Relatively insensitive to changes in the conductivity of highly resistive targets.

Highly conductive surface material limits depth of penetration.

Cannot be used through reinforced concrete.

Problem of nonunique interpretation greater than with resistivity method.

Very Low Frequency Induction. The VLF method uses low-frequency radio waves from one of several military transmitters as a plane wave source. The instrument measures the magnetic field generated by induced eddy currents. Some instruments use a pair of electrodes to measure the phase shift of the electric field. The depth of penetration of the system is limited by the frequency of the military transmitter and the conductivity of the subsurface. Penetration may be limited in areas of clay-rich soils, and the method is generally incapable of detecting features that are aligned perpendicularly to the direction of propagation of the plane wave. The method is generally used for profiling to detect fractures in bedrock, although it does have some limited depth sounding capabilities.

Applications

Simple instrumentation and operation.

Very rapid and efficient.

Sensitive to inclined conductive sheets such as faults or fracture zones.

Can map lateral variations in conductivity such as conductive plumes, changes in soil type, or landfill boundaries.

Limitations

Limited range in transmitted frequencies available that limits choices of the depth of investigation.

Certain transmitters are out of service periodically.

Relatively insensitive to changes in conductivity in highly resistive targets.

Highly conductive surface materials limit the depth of penetration.

Location of transmitters makes it difficult to detect linear conductive bodies oriented approximately perpendicularly to the direction of propagation of the plane wave.
Long, narrow, near-surface conductors (such as pipelines, fences, or groundwater-filled bedrock depressions) produce strong anomalies that can mimic or mask deeper anomalies.
Depth of investigation is totally dependent on subsurface conductivity for a given transmitter frequency.
Interpretation is largely qualitative and nonunique.

Magnetotellurics. The magnetotelluric (MT) method uses plane waves from natural electromagnetic fields generated by oscillations in the earth's ionosphere as transmitter signals or from transmitters positioned remote from the area of investigation. The magnetic and electric fields are measured in two horizontal components using two orthogonal electrode dipoles and two orthogonal magnetometers. The intensity and phase of electric and magnetic fields are used to determine the conductivity of the subsurface. The method is commonly used to map conductive targets at depths of hundreds or thousands of meters, where other EM methods are impractical. The magnitude and frequency range of the natural EM signals are variable, and data collection often is limited to the later afternoon or evenings. Deep studies require very low source frequencies that can require hours of data collection to record a single sounding. Shallower studies frequently require a remote transmitter to provide enough EM energy in the audio-frequency range, known as a controlled source audio-frequency magnetotelluric (CSAMT) survey. Interference from power lines and other utilities is common in developed areas. Modern MT systems generally can collect both natural source MT and CSAMT data in a single sounding to provide a broader spectrum of frequencies.

Applications

Can find conductive anomalies at depths of a few hundred to a few thousand meters.
A large area can be surveyed with a single transmitter setup (CSAMT) or with no transmitter (MT).

Limitations

The natural source is often biased toward low frequency, which seriously limits the sensitivity of the method to shallow features without a CSAMT transmitter.
Relatively insensitive to small, near-surface targets.
Relatively insensitive to highly resistive targets.
Sensitive to interference from cultural features such as power lines and buried utilities.
Interpretation is nonunique

Time Domain Electromagnetic Induction. The TEM (or TDEM) method uses a loop of wire to pass a current of several amps. The current is shut off almost instantaneously to create a broad-frequency-pulsed EM source. Typical transmitter loops are square or rectangular and a few meters to a few hundred meters on a side. The receiver uses a small magnetic coil to measure the magnetic field over a series of time windows following the shutoff of the current in the transmitter coil. The magnetic field measured at the receiver is a function of the induced eddy currents, which are a function of the conductivity of the subsurface. The data produce a sounding that can be modeled to determine the change in electrical conductivity versus depth. Several systems are available that cover a range in exploration depths of a few tens of meters to a few hundred meters.

Applications

Well suited to map conductive bodies at depths of a few tens of meters to a few hundred meters.
Often used to map zones of saline groundwater.
Vertical resolution significantly better than most multiple-frequency FDEM methods.
Can be used to find resistive targets under favorable circumstances.

Limitations

Practical upper limit of method is approximately 10 to 20 meters, depending on near-surface conductivity.
Interpretation produces nonunique results.
Sensitive to interference from linear conductors such as power lines, fences, or pipelines within distances of one or two times the depth of investigation from the transmitter loop.

Metal Detectors. Metal detectors are essentially specialized FDEM or TEM devices designed to find buried metal objects. The FDEM instruments use the high response of metal objects to distinguish them from natural materials. TEM instruments take advantage of the relatively long duration of the eddy currents induced in metal bodies. In most instruments, the depth of penetration is related to the coil size, transmitter frequency, and the surface area and shape of the metal target. The depth of penetration is generally unaffected by soil type over the conductivity range of typical soils. The instruments have high lateral resolution, but the vertical resolution of the depth of the target is generally limited.

Applications

Ease of use.
Very portable.
High lateral resolution.

Limitations

Limited depth of investigation.
Response of target related to the surface area of the target rather than the volume of metal.

Ground Penetrating Radar. GPR uses a high-frequency pulse of EM energy to probe the subsurface. The EM energy is reflected off boundaries of contrasting dielectric constant (the ability of a material to separate an electric charge), so the instrument can find nonmetallic or metallic targets. The output is a time versus amplitude plot that is generally displayed as a series of plots along a transect line. The field plots are analogous to cross sections, except that the vertical access is in two-way travel time, not depth. The data can be processed similarly to seismic reflection data to produce depth sections. The instruments are configured with single transmitter/receiver antennas or with separate transmitter and receiver antennas that can be offset to collect data at different separations to increase the data processing that can be conducted. Under ideal conditions, the GPR method provides very high-resolution images of buried bodies, stratigraphic structure, or areas of disrupted soils.

The penetration of the method is determined by the conductivity of the subsurface and the degree of scattering from rubble or other small targets. Penetration is severely limited in highly conductive soils or in areas with lots of buried rubble or other discontinuous reflectors. The depth of penetration can be increased to some degree by using a lower frequency antenna but at the cost of resolution of the target.

Applications

Resolution can be of the order of a few centimeters.
Provides a cross section of subsurface in the field.
Can detect buried, ferrous or nonferrous targets.
Can detect disturbed soil zones.
Sophisticated data processing techniques available (similar to seismic reflection processing).

Limitations

Equipment is somewhat cumbersome; usually requires a relatively flat surface.
Depth of penetration is seriously limited by conductive material such as clay or water. Penetration through moist clay can be less than 1 foot.
Decreasing transmitter frequency to increase penetration decreases resolution.
Penetration and resolution limited by scattering effects at sites with buried cobbles or rubble.

Geothermal Techniques

The geothermal method uses soil temperature measurements to detect zones of anomalous flow at depth. Soil temperature is measured by using a shallow probe driven a few feet below the surface or a dedicated monitoring probe installed in a shallow borehole. Surface temperature variations diminish with depth below the surface. Daily temperature variations penetrate less than 1 or 2 meters, whereas seasonal temperature variations generally penetrate only about 10 meters. Below a depth of a few meters, soil temperature variations are largely a function of heat flow from within the earth. On a local scale, variations in heat flux often indicate zones of anomalous groundwater flow. Geothermal methods have been used to find permeable zones at depths of a few meters to over 100 meters using probes at depths of less than 1 meter to approximately 15 meters. A principal advantage of the method is that it detects anomalous flow instead of some other less directly related property, such as electrical resistivity. The method is susceptible to thermal interference by infiltration from shallow sources or from small features near the probes.

Applications

Identifies areas of high groundwater flow such as bedrock fractures or clean sand and gravel deposits.
One of the few methods that can directly detect moving groundwater from the surface.
Can pinpoint location of maximum permeability.
Can detect permeable features at depths of more than 100 feet beneath probes.

Limitations

Requires relatively uniform soils above target interval.
Small sand lenses near probes can create false anomalies or mask deeper anomalies.
Interpretation is qualitative.
Probe installation is relatively labor-intensive.

GROUNDWATER GEOPHYSICS—BOREHOLE METHODS

Most of the geophysical measurements made at the surface can also be made in a borehole using sensors lowered down the hole on a cable connected to up-hole recording equipment. Borehole measurements tend to be more accurate and precise because the borehole environment tends to be more predictable and less prone to noise. The field of measurement is typically only a few inches to a few feet around the borehole. Due to the small scale of the measurement, borehole methods tend to produce excellent vertical resolution. The combination of high resolution and greater accuracy make most borehole methods suitable for quantitative measurements and small-scale correlation of stratigraphic properties.

Borehole measurements are commonly used to determine the physical properties of the formation and formation fluids. The measurements can be used to measure directly or interpret several properties such as lithology, porosity, water quality, borehole diameter or alignment, borehole flow, formation or fluid temperature, mineralogy, and other properties of interest.

A variety of logging tools are available. Each tool has specific requirements for the borehole environment. Some tools can measure through casing; most cannot. Some tools require a fluid-filled hole; others operate in air, water, or drilling mud.

Electrical Logs

Spontaneous Potential Log. The SP log measures the electrical potential between a surface reference electrode and an exposed electrode that is raised up or down the borehole. The SP response is caused by a difference in resistivity between the borehole fluid and the formation fluid.

Applications

Quick and inexpensive.
Can be a good sand versus shale indicator.
Can be used to estimate total dissolved solids (TDS) of formation fluid.

Limitations

If borehole fluid and formation fluid have similar resistivity (typical for a water well), there is no SP response.
Works only in uncased fluid-filled boreholes.

Single Point Resistance Log. The SPR log measures the resistance between a grounded surface electrode and an electrode that is moved up or down the borehole. The tool measures the resistance of the total thickness of the formation between two electrodes. As a result, the measurement is in units of resistance, which is not a material property. The log is used primarily to detect changes in the formation but is not appropriate for quantitative analysis of the physical properties of the formation or the formation fluid.

Applications

Quick and inexpensive.
Good indicator of formation contacts.

Limitations

Measures resistance, not resistivity.
Works only in uncased fluid-filled boreholes.

Resistivity Log. Resistivity logs use two or more potential electrodes in the borehole to measure the change in potential difference along the borehole across a fixed electrode separation. Both current electrodes can be located on the down-hole sonde, or more commonly, one current electrode is on the sonde, and the other is planted at the surface. The depth of penetration of the current can be controlled by using different electrode spacings. Typically, a short electrode spacing is used to provide a high-resolution measurement of formation changes, and one or more longer electrode spacings are used for more accurate measurements of the bulk formation resistivity. Some sondes use additional current electrodes to focus the electrical field into the formation. The data can be corrected for borehole effects to provide a quantitative measurement of the bulk formation resistivity which is a function of the resistivity of the formation and formation fluid.

Applications

Measures bulk resistivity of formation.
Can be used to determine the formation lithology, porosity, and fluid resistivity.

Limitations

Works only in uncased fluid-filled boreholes.

Induction Log. Induction logs use a frequency domain electromagnetic (EM) sonde to measure the conductivity of the formation around the borehole. Some tools include a short spacing electrode tool to measure the conductivity of the borehole fluid independently.

Applications

Can be run in fluid-filled or air-filled borehole.
Can be run in open hole or through PVC casing.
Can be run with shallow or deep depths of investigation (dual induction) to determine the invasive effects of borehole fluids.

Limitations

More expensive than electrode logs.
Response of highly resistive materials (freshwater aquifers) is small, so the sensitivity of the tool is reduced.
Cannot be run in highly conductive borehole fluids.

Passive Radioactivity Log

Natural Gamma Log. Natural gamma logs use a sensor that measures the gamma-ray energy emitted by the formation. In most formations, gamma-ray emissions are almost entirely produced by shale minerals. As a result, the gamma-ray response is a good indicator of the concentration of clay in the formation.

Applications

Good clay indicator
Can be run in cased or uncased, fluid-filled or air-filled boreholes.

Limitations

Gamma-ray units (API units or counts per second) are arbitrary units and do not relate directly to clay mineral content.
Raw data must be corrected for borehole diameter effects before making direct comparisons.

Spectral Gamma Log. A spectral gamma log separates gamma-ray energy by frequency to measure the spectrum of gamma rays emitted by the formation. The frequency spectrum of gamma rays emitted by the formation is diagnostic of the radioactive isotopes in the formation.

The gamma-ray spectrum is commonly used to determine the concentrations of potassium, uranium, and thorium in the formation (KUT logs), but full spectrum tools are available that allow identifying additional elements.

Applications

Can be used to perform “complex formation analysis,” where the mineral content and groundwater flow history of formation are estimated.
Can be used to detect uranium or radium-enriched zones of sandstone aquifers.
May have application to radioactive contamination problems.

Limitations

Equipment is significantly more expensive than natural gamma tools.

Porosity Log

Several logging tools have been developed to measure the porosity of a formation. Porosity is a useful property to measure, but it does not always relate directly to permeability, which is generally the property of greatest interest. If more than one porosity tool is used, the data can be cross-plotted to identify formation type directly and correct the porosity measurement for lithologic effects. Most porosity tools require the use of a radioactive source in the tool. The use of radioactive sources requires special licensing and is prohibited in water wells in some states. The following sections describe the most common types of porosity tools.

Neutron Density Log. Neutron density logs use a radioactive source to bombard a formation with high-energy neutrons and records gamma-ray energy "bounced back" from the formation. The tool measures the hydrogen content of a formation, which is equivalent to the water content of the formation if no hydrocarbons are present. The water content of the formation is equivalent to the porosity below the water table and the soil moisture content above the water table. Some tools do not compensate for changes in borehole diameter and produce erroneously high estimates of porosity in washouts in the borehole. Compensated tools can accommodate some degree of variation in borehole diameter, but erroneous data can be recorded in zones with rough borehole walls. Bound water in shale zones produces erroneously high values of measured porosity.

Applications

Directly measures water content of formation. Can be related to porosity of nonshale units.
Measures porosity below water table and moisture content above water table.
Can be run in a cased or uncased hole.

Limitations

Sensitive to variations in borehole diameter.
Will see "bound water" in shale zones as porosity and give unrealistically high values.
Presence of hydrocarbons (pure product) erroneously suppresses calculated porosity.
Stringent licensing requirements to make a log due to the radioactive source.
Application to cased holes is limited.

Gamma Density Log. Gamma density tools use a radioactive source to bombard a formation with high-energy gamma rays. The tool has a sensor that records gamma rays "scattered" back to the detector. The magnitude of the backscattered gamma rays is a measurement of the electron density of formation that is related directly to bulk density. Given a bulk density measurement, the formation porosity is calculated for an assumed rock matrix (sandstone or limestone).

Applications

Will record accurate porosity values in shale zones.
Can be run in cased or uncased boreholes.

Limitations

Sensitive to variations in borehole diameter.
Presence of hydrocarbons causes erroneously high porosity values.
Stringent licensing requirements to make a log due to the radioactive source.

Sonic Log. Sonic logs use a source of high-frequency sound and one or more detectors on the down-hole sonde to measure the transit time of sound across a known distance of the formation. By comparing the measured velocity of sound in the formation to the known sound velocity for the rock type, the percentage of void space (porosity) can be calculated. Sonic tools do not require a radioactive source. The measurement is sensitive to irregular hole conditions. Specialized versions of the tool record the full waveform of the sound energy transmitted and can be used to detect poor bonds between the casing and grout or find voids behind the casing.

Applications

Porosity can be calculated for a given matrix (sandstone or limestone).
Modified sonic log can be used to inspect the bond of the cement grout to the casing (cement bond log).
Full waveform sonic logs can be run to measure the engineering properties of the formation.

Limitations

Sensitive to borehole diameter and roughness of borehole wall.
Works only in a fluid-filled uncased hole (except the cement bond log).

Borehole Condition Log

Several types of logs have been developed to measure the physical condition of the borehole, rather than measuring the properties of the surrounding formation. These tools can be used to determine the integrity of a borehole, determine if the hole is straight, or determine if flow is occurring between different zones. The following section describes several of the more common logs.

Down-Hole Televising Log. Down-hole televising logs use a down-hole video camera to inspect a borehole visually. Most cameras provide a fish-eye, forward-looking view with a depth reading on the image. Some cameras offer a side-looking view that looks directly at the borehole wall and can be rotated 360°.

Applications

Produces a visual record of a well bore on VCR tape or DVD.
Can be used to inspect borehole irregularities or obstructions.
Can be used to inspect the casing.
Can be used to detect fractures or solution cavities.
Shows small-scale stratigraphic layering with more resolution than other logs.

Valuable tool in assessing options to recover lost logging tools or drilling equipment.

Limitations

Requires clear borehole fluid. May have to add clear water to flush the hole if the water is cloudy.
Produces a qualitative record. Does not measure any physical property in calibrated units.
Most tools do not provide an oriented image.

Caliper Log. Caliper tools use spring-loaded arms that scrape along the borehole wall to record the variation in diameter. Simple tools that use two arms tend to turn so that the tool always measures the maximum hole diameter. Three-arm tools average the diameter at three points and provide better measurements of the average hole diameter. Four-arm caliper tools are available that provide oriented independent measurements in two coordinates in the horizontal plane that provide additional information on the shape of the hole.

Applications

Can identify ledges or washouts that can identify incompetent zones or fractures.
Can be used to calculate volumes of grout or backfill.
Can be measured in x and y planes (four-arm caliper) to estimate the shape of the borehole.

Limitations

Two-arm caliper measures only maximum hole diameter. Can be misleading in elliptical boreholes.
Does not measure alignment of borehole.

Alignment Log. Alignment tools measure the deviation of the center of the borehole from vertical. Simple alignment tools use a weighted plumb bob suspended from a tripod. The deflection of the plumb bob is measured by crosshairs at the surface. More sophisticated alignment tools use cameras with targets mounted on a system of gimbals or gyroscopes and magnetometers to measure the deviation of the borehole.

Applications

Can identify deviations in a borehole that can limit the size of the casing or pump that can be installed.
Can be used to calculate actual well depth and actual lateral position of a borehole.

Limitations

Must be combined with a caliper log to determine the shape of the hole accurately.
Large washouts can cause erroneous alignment readings unless the diameter of the hole is taken into account.
Sharp doglegs or extreme deviations can cause a surface line to “hold up” on the side of a borehole for simple tripod and crosshair systems and make measurements from below impossible.
Alignment tools that use magnetometers do not work inside a metal casing.

Acoustic Televiewer. Produces a high-resolution image of a borehole wall using a high-frequency sonic tool that is rotated to scan the hole. The log produces an image that shows relief on the borehole wall as shading or color patterns. Standard log formats show the borehole wall from 0 to 360° on the horizontal axis and depth on the vertical axis. The tools are generally oriented with respect to true directions. Televiewer logs are often used to map fractures and plot their strike and dip. The tool requires a fluid-filled hole, but water can be added to raise the water level artificially for logging.

Applications

Can measure the aperture, strike, and dip of fractures.
Can operate in either mud- or water-filled boreholes.

Limitations

Does not operate in air-filled holes.
Measures only the surface of the borehole; does not penetrate scale or casing.
The resolution of the tool is limited to several millimeters by the wavelength of the sonic source.
Scrapes or washouts from the drilling process can obscure true fractures.

Optical Televiewer. Produces a high-resolution image of the borehole wall using an optical scanning tool that is rotated to scan the hole. The log produces an image of the borehole wall in true color. Standard log formats show the borehole wall from 0 to 360° on the horizontal axis and depth on the vertical axis. The tools are generally oriented with respect to true directions. Optical televiewer logs are often used to map fractures, plot their strike and dip, and image small-scale stratigraphic features. The tool requires a clear borehole, either air or clear water.

Applications

Can measure the aperture, strike, and dip of fractures.
Can image individual grains and other fine stratigraphic features.

Limitations

Does not operate in mud-filled holes, cloudy water, or dusty air-filled holes.
Measures only the surface of the borehole; does not penetrate scale or casing.
Scrapes or washouts from the drilling process can obscure true fractures.

Flowmeter Log. Flowmeter tools are used to measure the flow within a borehole that develops from head differences between different zones or while pumping. Spinner tools are simple flowmeters that use small impellers to measure the flow past the tube. The tools are usually trolled up or down the borehole to overcome the frictional resistance of the impeller and its bearings.

For stronger flows, the tool can be held stationary to measure the absolute flow velocity past the tool without correcting for the speed of the tool in the borehole. Heat pulse tools can be used to measure lower flow rates. Heat pulse tools use a heating element to create a small pulse of heated water, and temperature sensors are placed at known distances above and below the heating element. The tool measures the time required for the pulse of heated water to move upward or downward to the sensor and calculates the flow velocity and direction. A modification of the heat pulse flowmeter has been used to measure horizontal flow in boreholes. The diameter of the hole must be known before the flow velocity can be converted into a volumetric flow rate. Specialized tools have been developed to detect flow behind a casing.

Applications

Can measure the flow up or down a borehole.
Can be used to estimate the head difference and transmissivity of different zones of a borehole.

Limitations

The friction of the bearings and inertial mass of the impeller impose a lower limit of flow that can be measured by a spinner tool.
Heat pulse tools have an upper limit of flow rate that can be accurately measured.

Temperature Logs

Down-Hole Temperature Log. Temperature logs use down-hole thermistors or thermocouples to measure the variation in the temperature of the borehole fluid with depth. Temperature variations in the hole can be used as indicators of flow. The data can be plotted as absolute temperature or as a differential temperature that removes the effect of the geothermal gradient from the plot.

Applications

Provides direct measurement of fluid temperature.
Can be used to detect zones of increased fluid flow within a borehole or between two boreholes.
Directly measures the geothermal gradient.

Limitations

Geothermal gradient causes a continuous drift in borehole temperatures that can mask thermal variations within the borehole.
Requires temperature and head variations between units to create a thermal anomaly to detect permeable zones within a borehole.
Flow within a borehole during or after drilling can mask geothermal gradient measurements.

GEOPHYSICAL SURVEY DESIGN

When designing a geophysical survey, several factors must be considered, including the physical properties of the target, the desired resolution, the physical properties of the matrix around the target, the ambient noise in the survey area, and the physical access at the site. To be detected, the feature you are trying to find must have some physical property that has sufficient contrast with the surrounding matrix. A variety of physical properties can be remotely sensed by geophysical methods. Some targets, such as buried pipes in sand, present obvious contrasts of a number of properties. Some targets, such as excavations backfilled with native soils, present less obvious contrasts or can be identified only by contrasts of related features, such as disruption of macropore drainage structures causing perched soil moisture over old graves.

Geophysical methods each have characteristic resolution limits that are a function of the wavelength of the fields used for measurement and the limitations of the equipment. The resolution of the various geophysical methods varies from several tens of feet for deep studies using electromagnetic induction methods to fractions of an inch using ground penetrating radar with high-frequency antennas. The resolution of the geophysical method used must match the physical dimensions of the target body if the target is to be detected. The magnitude and size of the anomaly must be predicted with reasonable accuracy, typically by forward modeling, to determine the minimum grid size that can be used for a reasonable probability of detection.

Site conditions also play an important role in determining the ultimate success of the survey. Surface and subsurface conditions can create a noisy environment that can easily obscure the signal from the target body. Noise sources are different for each method. For instance, ground vibrations from traffic or machinery can be a major source of noise for seismic or gravity methods but do not affect other methods such as electromagnetic induction or magnetics.

Physical conditions at a site also affect the utility of geophysical methods. Major obstructions such as buildings or developed land often limit the area where data can be gathered and create inherent limitations on the geophysical survey. Buildings, parked cars, dumpsters, overhead power lines, buried utilities, fences, buried rubble, and other cultural features are not often considered when designing a geophysical survey. In addition, subsurface conditions such as soil type, uniformity, and other factors affect the propagation of energy and can limit the performance of most methods. Surface conditions, such as paved surfaces, heavy vegetation, frozen ground, rough topography, and surface debris, must be considered when designing a survey.

Assuming that the site conditions are acceptable, it is still necessary to select a method that can detect the target body. The following is a partial list of typical survey objectives with some suggestions of methods to consider.

1. Locating optimal well locations (bedrock fractures or sand and gravel deposits)
    a. EM
    b. Electrical resistivity

   - c. Azimuthal EM
   - d. Azimuthal resistivity
   - e. Geothermal
2. Determining depth to bedrock and mapping bedrock surface
   - a. Seismic refraction
   - b. Gravity
   - c. Seismic reflection
   - d. GPR
3. Locating preferred pathways for groundwater flow (bedrock fractures, voids, seepage paths, or sand and gravel lenses)
   - a. EM
   - b. Electrical resistivity
   - c. Azimuthal EM
   - d. Azimuthal resistivity
   - e. Geothermal
   - f. SP
   - g. GPR
4. Finding buried metal bodies (tanks, drums, Buicks, etc.)
   - a. Magnetometer
   - b. Electromagnetic induction (EM)
   - c. Ground penetrating radar (GPR)

GEOTHERMAL WATER

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

Geothermal water has a temperature appreciably higher than that of the local average annual air temperature. However, in general, a spring is considered hot when its temperature is about 12.2 °C higher than mean annual ambient temperature (1). The relative terms geothermal water, warm springs, and hot springs are common.

From earliest times, hot geothermal water or geothermal springs have been used for bathing and cooking. The first technological success in using geothermal energy was in Italy in 1904 where the worlds first geothermally driven electrical plant was opened and operated. Today, applications of low- and moderate-temperature (100 to 300 °F) geothermal waters have expanded enormously to include heating large tracts of homes and buildings (district heating), heating greenhouses for growing vegetables and flowers, fish farming (aquaculture), drying foods and lumber, and many other uses. In the United States alone, there are 17 district heating systems, 38 greenhouse complexes, 28 fish farms, 12 industrial plants, and 218 spas that use geothermal waters to provide heat. The district heating system in Boise, Idaho, has been operating since the 1890s and continues to provide heat today. In Iceland, most of the homes and other buildings are connected to geothermal district heating systems, and in the Paris basin in France, many homes are heated by bringing geothermal water to the surface. Geothermal greenhouses are prominent in Italy and in the western United States.

Worldwide, there are about 12,000 thermal megawatts of installed direct uses of geothermal fluids in nearly 30 countries, replacing the combustion of fossil fuels equivalent to burning 830 million gallons of oil or 4.4 million tons of coal per year. This illustrates the trend of countries switching to alternative energy sources such as geothermal energy.

Geothermal water discharges from numerous springs located mostly in mountainous or plateau areas. The springs are connected by faults to deeply buried reservoirs that contain geothermal water, which moves upward along the fault zones to discharge at the land surface. Much geothermal water discharges as hot springs that flow steadily instead of erupting at intervals.

Hydrothermal phenomena involving the release of water and steam are nearly always associated with volcanic rocks and tend to be concentrated in regions where large geothermal gradients occur. By implication, aquifers must also be present that permit water to percolate to great depths—often 1500 to 3000 m (2). One theory used to explain how geothermal water becomes heated in areas that are underlain by complex geologic structures is that when precipitation falls in highland areas, it recharges the aquifer system. Some of the water moves downward along faults and fracture zones to great depths. As the water descends, it becomes heated because of the geothermal gradient. At some depth, the heated water becomes lighter than the overlying water and then moves upward along faults to discharge as spring flow.

Deeply circulating groundwater can also become heated by cooling magma (molten igneous rock) at great depths in the crust of the earth. The water warms as it descends, possibly along fault zones that overlie the magma chamber, until it absorbs enough heat to become lighter than overlying water. The warm water then rises to the surface. The mechanism for circulating the water is the same, regardless of whether the water becomes heated by the geothermal gradient or by the buried cooling magma. It can also be heated through mantle decay of radioactive elements such as U, Th, and Ra, tectonic activity, metamorphic processes, and exothermic reactions of minerals.

More than 10,000 individual thermal features, including geysers, hot springs, mud pots, and fumaroles (steam vents), have been identified. Geysers are the best known and certainly the most spectacular features. They are a type of hot spring that periodically emits sudden, violent eruptions of stream and hot water. Water from surface sources and/or shallow aquifers drains downward into a deep vertical tube where it is heated above the boiling point. As the pressure increases, the steam pushes upward; this releases some water at the surface, which reduces the hydrostatic pressure and causes the deeper superheated water to accelerate upward and to flash into stream. The geyser then surges into full eruption for a short interval until the pressure is dissipated; thereafter, the filling begins, and the cycle is repeated (2). The explosive release of pressure can cause a column of steam and hot water to rise 200 feet or more into air. The period between eruptions depends on several factors, including the volume of steam and water that is ejected and how rapidly ground water refills the tubes and chambers. A mud pot, results when only a limited supply of water is available. Here, water mixes with clay and undissolved particles brought to the surface, forming a muddy suspension from the small amount of water and steam that continues to bubble to the surface. A fumarole, meaning smoke, is an opening through which only steam and other gases such as hydrogen sulfide and carbon dioxide discharge. These features are normally found on hillsides above the level of flowing thermal springs; water can often be heard boiling underground (3).

Excessive concentration of certain dissolved minerals in geothermal water poses water quality problems. The most common of these minerals are dissolved fluoride, arsenic, and iron. Concentration of dissolved fluoride in excess of 4 milligrams per liter can cause mottling of teeth, especially children's, and can cause bones to become brittle. Dissolved iron is not detrimental to human health, but concentrations in excess of 200 micrograms per liter can cause staining of kitchen and bathroom fixtures and can cause clogging of well-screen openings and pumps. Concentrations of dissolved arsenic in excess of 30 micrograms per liter are toxic to humans. Sodium, calcium, magnesium, and their salts are nontoxic to human beings. Chloride salts of these metals in higher concentrations may be toxic to plants because of their chloride ions rather than the metals. A chloride ion concentration of >300 mg/L is in general toxic to vegetation and results in defoliation, chlorosis, bronzing, and burning of plants (4). Boron in trace quantities is necessary for plants, but it is toxic to certain plants in concentrations as low as 1 to 2 mg/L.

Natural steam that always contains some noncondensable gases, such as hydrogen sulphide, and ammonia, presents the greatest potential hazard. Ammonia affects primarily the upper respiratory tract and causes coughing, vomiting, and redness of the mucus membranes of the mouth, nose, lips, and pharynx (4). In geothermal operations, ammonia is not likely to present a direct toxic hazard except possibly in the immediate vicinity of the power plant. Hydrogen sulphide, which is a noticeable geothermal effluent, is much more toxic than commonly realized. A concentration of more than 600 ppm hydrogen sulfide can cause death within 1 hour. It can also paralyze the respiratory center.

High values of total dissolved solids in geothermal water sometimes interfere with the usefulness of water as a source of energy. Rain, the prime source of meteoric water, which feeds the geothermal reservoir, is practically devoid of chemical ingredients. But after entering the atmosphere, it picks up gases such as CO_2, O_2, SO_2, and dust particles. As it falls to the ground, its concentration of chemical constituents may be up to 40 mg/L (5). Other important factors are climatic conditions and the state of weathering of rocks and their mineralogical compositions. Thus, even before entering the geothermal reservoir, water is considerably rich, chemically. Groundwaters whose salt content is around 1000 mg/L are not uncommon. The major cations in groundwater are Ca, Mg, Na, and the anions are HCO_3, SO_4 and Cl. Geothermal water commonly contains large concentrations of silica (if the water has moved through limestone or other calcite-rich rocks).

Along with these radicals, gases dissolved in meteoric water such as CO_2, O_2, He, and Ar also enter the reservoir. The chemistry of meteoric water is modified in the geothermal reservoir due to rock–water interaction under the influence of temperature, contributions from magmatic sources, mixing of different types of waters, and decay of U, Th, and Ra. Closer to the surface, within the zone of oxidation, air can also enter thermal waters. In that case, the nitrogen and oxygen content will be high, and their mutual ratio may also match that of the atmosphere. Some geothermal waters may be brines, for example, the Salton Sea area, California, whose salinity is 30% (6); others may be as pure as distilled water, for example, the Rajgir thermal spring of Bihar, India (7).

Microorganisms can thrive in geothermal waters, even at boiling temperature (8). Extremely thermophilic bacteria that survive at 350 °C have also been found (9). Fortunately, these microorganisms do not survive in animal systems. Pathogenic organisms can enter thermal waters through soil and air and also through contamination by animal/man in thermal water pools. Thermal springs of various kinds are found throughout the world. Notable areas exist in the United States, Iceland, New Zealand, the Kamchatka Peninsula of the former Soviet Union, Brazil, Argentina, Ethiopia, Zambia, China, Tibet, India, Thailand, Taiwan, and Japan. Yellowstone National Park in Wyoming, United States, that contains literally thousands of hydrothermal features possesses the greatest concentration of thermal springs in the world (10). This area marks the site of an enormous volcanic eruption 600,000 years ago. Today, a temperature of 240 °C exists only 300 m below the ground surface.

As economies expand and population grows, energy demand worldwide is increasing rapidly. If we are to increase our energy consumption while simultaneously reducing environmental pollution, we must change our fuel mix, which today relies heavily on fossil and nuclear fuels. The use of geothermal energy has enormous environmental advantages over the use of fossil or nuclear fuels. Among these advantages are far fewer and more easily controlled atmospheric emissions, maintenance of groundwater quality, and much smaller dedicated land requirements. The small quantities of gases emitted from geothermal power plants are naturally occurring and result from geologic processes. Because the earth is porous and permeable, these gases would eventually find their way to the surface, even in the absence of geothermal power development.

GHIJBEN–HERZBERG EQUILIBRIUM

Ekkehard Holzbecher
Humboldt Universität Berlin
Berlin, Germany

THE ORIGINAL PAPERS

In 1889 a note was published in The Hague (The Netherlands), which dealt with a suitable location for a new borehole for the pumping of drinking water for the city of Amsterdam. The authors, Drabbe and Badon Ghijben (1), outline in length the different geological formations, their extension and their connection with each other, and especially their connection with various saline surface water bodies in that region. In the final part, salinity becomes the subject of their consideration. The authors describe that saltwater is found in the subsurface, when there is a hydraulic gradient from the surface water into the aquifer and contrast this to the situation in the dunes at the North Sea coast. There, a freshwater lens can be observed on top of the salt water. In one sentence, the topic of this contribution can be summarized: If the height of the groundwater table above the mean sea level is denoted by a, the equilibrium between saltwater and freshwater is reached at a depth of $a/0.0238 = 42a$, when the seawater weight exceeds the freshwater weight by a factor of 1.0238. A simple calculation example follows using the given formula and a reference to an even earlier communication of Conrad in 1881, who is cited to have used factors between 40 and 50 in analogy to the proposed 42.

Twelve years later, the other note (2) appeared, in which the Ghijben–Herzberg equilibrium (GHE) is named. Herzberg, an engineer from Berlin (Germany), in a talk in Vienna on behalf of the annual meeting of the German Association of Gas- and Water-Specialists, was concerned with the water supply of villages on the German North Sea coast. More specifically, he was interested in the water supply on the North Sea islands, which, due to a rise in tourism, had an increasing demand for drinking water in the summer season. Compared with his Dutch counterpart, Herzberg provided a much more detailed derivation of the equilibrium rule. In order to illustrate his arguments, Herzberg presented a figure, which is reproduced in Fig. 1.

In Herzberg's version, t denotes the elevation of the groundwater table above mean sea level and is thus identical to Badon Ghijben's a; h is the depth of the freshwater boundary below mean sea level. A saltwater column of length h has the same weight as a freshwater column of length $H = t + h$, when the condition

$$h \cdot 1.027 = h + t \tag{1}$$

is fulfilled, and when it is taken into account that the specific weight of saltwater exceeds that of freshwater by a factor of 1.027. Solving Eq. 1 for h delivers

$$h = 37t \tag{2}$$

In both studies it is shown that a wide freshwater lens is to be expected in coastal regions. The extension of this length is roughly 40 times the elevation of the groundwater table above the seawater level. For practical purposes—the authors' main concern was water supply—one conclusion is that quite a large amount of fresh groundwater is available, as the lens extends much deeper into the subsurface than above the seawater horizon. Another conclusion is that the occurrence of freshwater at greater depth does not rely on the existence of an additional freshwater source in deeper horizons.

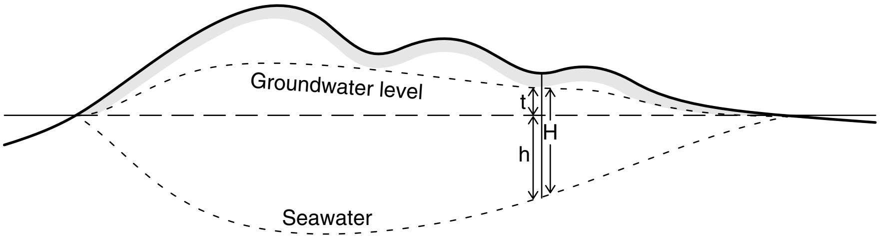

Figure 1. Illustration concerning the freshwater–saltwater equilibrium. Adapted from Reference 2.

Following the Ghijben note, a strong dispute took place in the beginning of the twentieth century in The Netherlands with respect to the maximum amount of pumping by the water works, as reported by de Vries (3). Proponents of the GHE argued in favor of such a regulated maximum.

In both publications the density difference is recognized as the major factor concerning the conditions of subsurface water near the sea coast. Freshwater is lighter than saltwater, and in order to reach an equilibrium (i.e., equal pressure), the freshwater column must extend further into the subsurface. The general situation with freshwater salinity ρ_f and water of elevated salinity ρ_s in the deeper subsurface, in current formulation, would be written as

$$h_f = -\frac{\rho_s - \rho_f}{\rho_f} z \tag{3}$$

where h_f denotes the elevation of freshwater above sea level, while z measures the depth of the interface below that level. As both extend in different directions from the zero sea level, they have different signs.

The equilibrium formulas given above can be taken as rule of a thumb. In most textbooks the formula is used with a factor of 40. The deviation of the factor in the formulation of Badon Ghijben (42) from the one given by Herzberg (37) stems from different assumptions concerning the relative weight of saltwater in relation to the freshwater. According to current knowledge, the density of seawater ρ_s lies between 1.02 and 1.029 g/m^3, depending on salinity and temperature. For a mean salinity of 35 ppt and a temperature of 10 °C (typical for subsurface water), the density is 1.027 g/m^3 (4), which is the value used by Herzberg. In real situations, it has to be taken into account that, due to mixing, dissolution, or precipitation, the subsurface saltwater may have a different salinity than seawater and that freshwater may have a slightly elevated density too.

CONDITIONS

The Ghijben–Herzberg equilibrium (GHE) has proved to be valid in several coastal systems all around the world. In both original publications, correspondence with observations is stressed. Herzberg describes that he already used the equilibrium formula for predictions concerning the depth of the saltwater in the sandy subsurface of several North Sea islands and that he obtained a good confirmation of the rule by measurements in boreholes. De Vries (3) lists field measurements and laboratory experiments, performed by Pennink in The Netherlands at the beginning of the twentieth century. However, the formula is linked to several conditions.

In the derivation it is assumed that the transition from the fresh to saline water appears quite rapidly. When the scale of the transition zone is very small in relation to the scale of the depth of the aquifer, one speaks of a *sharp interface*, which is a common term in the current literature; see, for example, Reference 5. One condition for a sharp interface is small dispersion, more specifically small transverse dispersion, as the flow direction coincides more or less with the interface (see below). But the tides and seasonal fluctuations in groundwater recharge and/or in the amount of groundwater being withdrawn also have an influence on the width of the transition zone. Extended descriptions have been derived nowadays, which are valid for situations with transition zones (see below).

Herzberg demanded caution concerning the transfer of his results obtained for the islands to cities near the coast, pinpointing the different scale, especially concerning the water supply. In a remark to Herzberg in Vienna, Halbertsma, another Dutchman, stated that the situation along the Dutch coast is quite different from one place to the other, but in some parts it is very similar to the situation described by Herzberg. As a counterexample he reports a situation where a confining impermeable clay layer can be found near the surface, which separates the freshwater on top from the saline water.

Custodio (6) illustrates several different situations, concerning the position of one or more clay layers, which disturb the ideal situation assumed for the GHE, showing that the GHE may over- or underestimate the position of the interface depending on local circumstances. In atoll islands a permeable layer below the upper strata of low hydraulic conductivity also results in a different situation, and the GHE can surely not be applied on coastlines of volcanic rock.

In the very vicinity of the coastline the GHE is mostly not valid. The GHE predicts that both fresh and saltwater heads (see below) should approach zero. But at many locations submarine groundwater discharge of freshwater has been observed (see Fig. 2). Kooi and Groen (7) provide an overview of the phenomenon and interpretations using different sharp-interface approaches.

The original formulation is given for phreatic aquifers and for the hydrostatic situation, that is, where flow in the freshwater zone as well as in the saltwater zone is neglected. Various different extensions have been made since the first formulations. Thus it is possible to use the generalizations of the Ghijben–Herzberg relation in situations for which the simple formula was not stated originally. In that sense, it is possible to use GHE as a

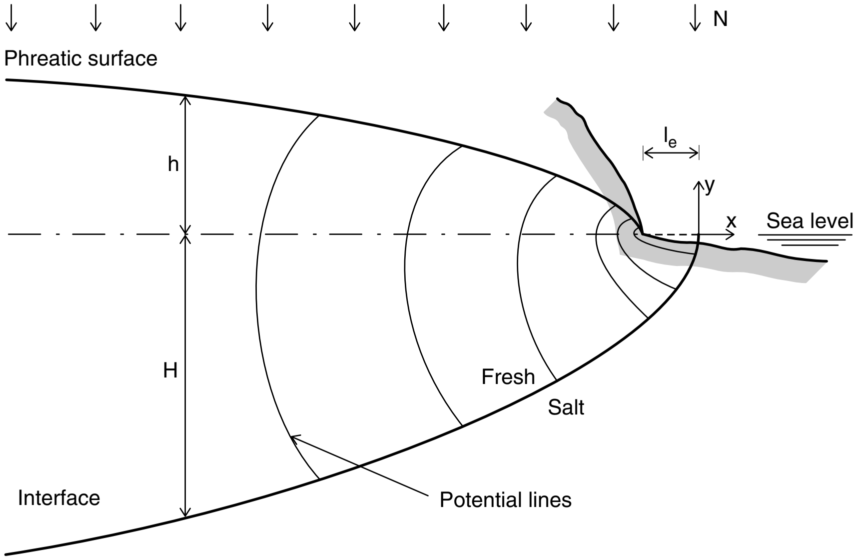

Figure 2. Schematic view of flow in an unconfined aquifer near the coast, describing submarine groundwater discharge. Adapted from Reference 12.

principle for confined aquifers, for dynamic situations, and for a dispersed transition zone, as described in the following.

When the amount of water withdrawal becomes a significant part of the entire water budget of a coastal system, the Ghijben–Herzberg formula should be questioned. Hydrostatics then has to be replaced by a quantification of the hydrological balance of the system.

GENERALIZATIONS

The original derivation assumes hydrostatic conditions, while the real situation is hydrodynamic in all cases. The authors were aware of that: in the report Badon Ghijben describes that under the North Sea dunes there is a relatively strong freshwater flow, recharged by infiltrating rainwater in the upper part, directed toward the sea, while there is a very weak flow of saltwater in the opposite direction in the lower part. In-between there is a transition from inflow to outflow.

However, the hydrostatic state can be taken as a limiting case from which the dynamic situation deviates only slightly as long as the groundwater velocities are small. The GHE idea of an equilibrium between freshwater and saltwater can then be transferred to dynamic situations. Hubbert (8) introduced the variable of *freshwater head*, defined as

$$h_f = \frac{\rho}{\rho_f}h - \frac{\rho - \rho_f}{\rho_f}z \tag{4}$$

where ρ and h denote density and head, measured at depth z. As outlined in the overview papers by Reilly and Goodman (9) and Cheng and Quazar (10), the freshwater head was used also by Muskat (11) in a description of the interface between oil and water in the subsurface. For $h = 0$ (stagnant saltwater) and $\rho = \rho_s$, the Ghijben–Herzberg formula (Equation 3) results for the interface position at depth z.

With the help of the freshwater head h_f, descriptions of situations with an interface can be simplified. A solution for freshwater head distribution is determined first; the location of the interface is calculated on the basis of the GHE afterward. This procedure is followed in many publications concerning different situations with fluids of different densities.

van der Veer (12) presents a simple formula for the one-dimensional flow in a coastal aquifer and a complex solution for flow in a vertical cross section, both based on the GHE. It is shown that distant from the shore both solutions coincide; that is, the use of the simpler solution is justified. But when the coastline is approached, the differences between both solutions increase. With the two-dimensional solution, it is possible to describe the submarine groundwater discharge into the sea.

Strack (13,14) uses the GHE and freshwater head to construct analytical solutions for shallow interface flow in confined and unconfined situations. In the case of the confined situation, the piezometric head h is the relevant variable, not the water table in the confined layer. Using these solutions the regional flow in coastal aquifers toward wells can be calculated in a two-dimensional horizontal domain.

The cross-sectional view, given in Fig. 3, depicting schematically the flow in the confined situation, is adapted from Strack (14). Due to pumping of freshwater in the upper part of the aquifer, the interface between saltwater and freshwater rises. Such an upconing may lead to severe problems, when the interface comes close to the well filter, as the salinity of the pumped water may increase above limits, which makes the water unsuitable for the drinking water supply, irrigation, or other purposes.

According to the static GHE, the interface rise exceeds the water table decline by a factor of 40 in coastal aquifers. Recent experience in Sweden shows that the GHE overestimates the rise of the interface (15). Dynamic approaches using well-known formulas for single wells were combined with the GHE by Wang (16) and by Motz (17). In regard to saltwater upconing, the GHE today

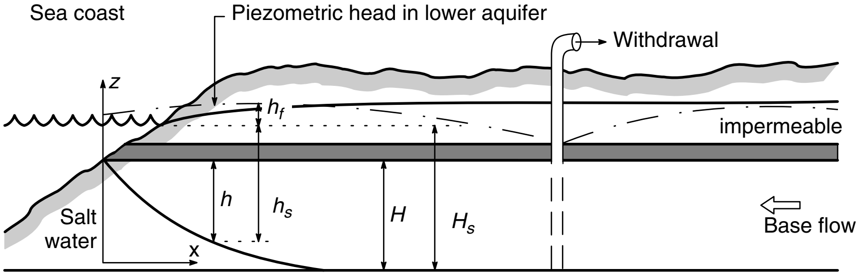

Figure 3. Schematic view of flow in a confined coastal aquifer with groundwater withdrawal. Adapted from Reference 14.

is often applied in combination with finite differences or finite elements (18,19).

The mentioned analytical solutions are valid for horizontal flow in an aquifer with a sharp interface, but vertical fluxes cannot be treated correctly by freshwater heads. As a further generalization of the GHE, Lusczynski (20) showed that for the general three-dimensional case in variable density flow, the gradients of freshwater head are responsible for horizontal groundwater flow, while for flow in the vertical direction the so-called environmental water head h_e is responsible. h_e is a generalization of Eq. 3:

$$h_e = \frac{\rho}{\rho_f}h - \frac{\rho - \rho_a}{\rho_f}z \qquad (5)$$

where ρ_a denotes the average density in the column between position z and sea level.

Note that for the latter extensions of the GHE the condition of a sharp interface has been dropped. But with ρ_a another parameter is introduced, which cannot be estimated easily without any knowledge of the mean position of the interface: remember that the principal purpose of the Ghijben–Herzberg formula was to deliver an estimate for that position.

In fact, saltwater intrusion is a problem of density-driven flow (21), in which flow and transport processes are coupled and cannot be calculated independently. Naturally, the flow in the aquifer determines the salt distribution, but on the other hand the salinity influences the flow via density and possibly via viscosity.

In order to treat such complex interactions, computer models are often used today. An overview on numerical approaches, codes, and applications, concerning saltwater intrusion, is given by Sorek and Pinder (22). Henry (23) presented a widely discussed solution for the miscible displacement in a confined aquifer, which has been used by numerous modelers as a test case. Figure 4 represents the solution in a vertical cross section, calculated with the new FEMLAB code (24) for multiphysics simulations. Depicted are streamlines extending from the left freshwater boundary to the seawater boundary on the right-hand side. On the seaside, streamlines enter in the lower part and return to the seaside after a u-turn. Along the paths salinity changes due to dispersion and diffusion. The grey pattern visualizes salinity, which is high in the lower right corner.

The Henry solution and with it the penetration of the saltwater wedge and its dispersion depends on various flow and transport parameters: the ambient freshwater flow and the dispersivities—dependencies that cannot be predicted by the GHE, which is based on water densities only.

CONCLUSION

The history of the GHE offers some more peculiarities. According to Carlston (25), the static equilibrium condition

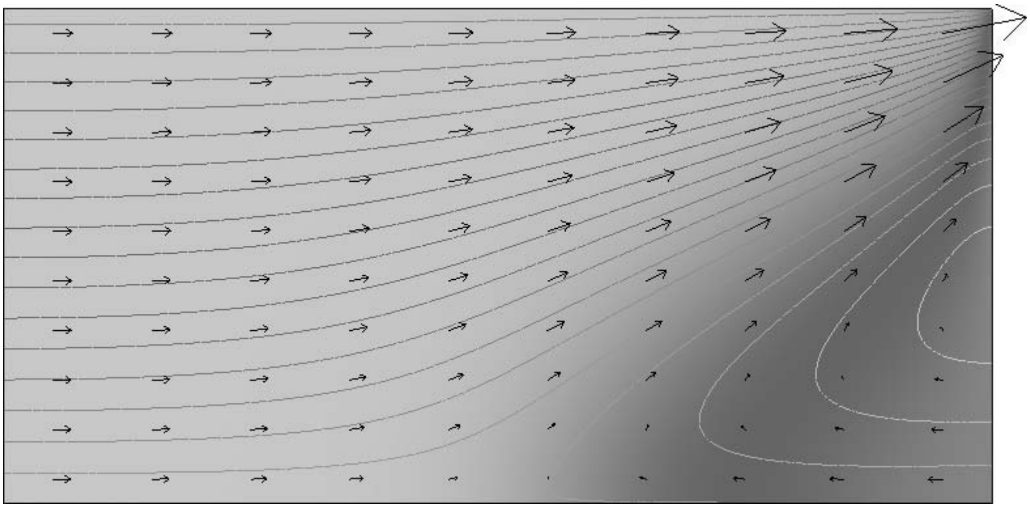

Figure 4. The solution for saltwater intrusion presented by Henry (23).

for saltwater and freshwater was formulated long before the referenced authors. Du Commun (26) already envisaged a U-tube that is filled with fluids of different density on both sides. The equilibrium in that tube was characterized by different fluid levels in both ends of the tube, and the height difference could be calculated from the density difference between the fluids. Du Commun did not provide a formula (like Badon Ghijben) but illustrated the calculation by an example. The background for his derivations was a practical problem: on the ground of a distillery in New Brunswick (New Jersey) a water well had been drilled. At that time, where not much was known about groundwater, the water level in the well and its fluctuations with the tide became the subject of a newspaper dispute (25).

GROUNDWATER BALANCE

C.P. Kumar
National Institute of Hydrology
Roorkee, India

INTRODUCTION

Rapid industrial development, urbanization, and increase in agricultural production have led to freshwater shortages in many parts of the world. In view of increasing demand of water for various purposes like agricultural, domestic, and industrial, a greater emphasis is being placed on a planned and optimal utilization of water resources. The water resources of the basins remain almost constant while the demand for water continues to increase.

As a result of uneven distribution of rainfall both in time and space, the surface water resources are unevenly distributed. Also, increasing intensities of irrigation from surface water alone may result in an alarming rise of the water table, creating problems of waterlogging and salinization, affecting crop growth adversely and rendering large areas unproductive, which has resulted in increased emphasis on development of groundwater resources. The simultaneous development of groundwater, especially through dug wells and shallow tubewells, will lower the water table and provide vertical drainage, which can prevent waterlogging and salinization. Areas that are already waterlogged can also be reclaimed.

On the other hand, continually increased withdrawals from a groundwater reservoir in excess of replenishable recharge may result in regular lowering of the water table. In such a situation, a serious problem is created resulting in drying of shallow wells and increasing pumping head for deeper wells and tubewells, which has led to an emphasis on planned and optimal development of water resources. An appropriate strategy will be to develop water resources with planning based on conjunctive use of surface water and groundwater.

For a sustainable development of water resources, it is imperative to make a quantitative estimation of the available water resources. For this, the first task would be to make a realistic assessment of the surface water and groundwater resources and then plan their use in such a way that full crop water requirements are met and neither waterlogging nor excessive lowering of the groundwater table occurs. It is necessary to maintain the groundwater reservoir in a state of dynamic equilibrium over a period of a time, and the water level fluctuations have to be kept within a particular range over the monsoon and nonmonsoon seasons.

A complexity of factors, hydrogeological, hydrological, and climatological, control the groundwater occurrence and movement. The precise assessment of recharge and discharge is rather difficult, as no techniques are currently available for their direct measurements. Hence, the methods employed for groundwater resource estimation are all indirect. Groundwater, being a dynamic and replenishable resource, is generally estimated based on the component of annual recharge, which could be subjected to development by means of suitable groundwater structures.

For quantification of groundwater resources, proper understanding of the behavior and characteristics of the water-bearing rock formation, known as an aquifer, is essential. An aquifer has two main functions: (a) to transit water (conduit function) and (b) to store water (storage function). The groundwater resources in unconfined aquifers can be classified as static and dynamic. The static resources can be defined as the amount of groundwater available in the permeable portion of the aquifer below the zone of water level fluctuation. The dynamic resources can be defined as the amount of groundwater available in the zone of water level fluctuation. The replenishable groundwater resource is essentially a dynamic resource that is replenished annually or periodically by precipitation, irrigation return flow, canal seepage, tank seepage, influent seepage, etc.

The methodologies adopted for computing groundwater resources are generally based on the hydrologic budget techniques. The hydrologic equation for groundwater regime is a specialized form of water balance equation that requires quantification of the components of inflow to and outflow from a groundwater reservoir, as well as changes in storage therein. Some of these are directly measurable, few may be determined by differences between measured volumes or rates of flow of surface water, and some require indirect methods of estimation.

Water balance techniques have been extensively used to make quantitative estimates of water resources and the impact of man's activities on the hydrological cycle. The study of water balance requires the systematic presentation of data on the water supply and its use within a given study area for a specific period. The water balance of an area is defined by the hydrologic equation, which is basically a statement of the law of conservation of mass as applied to the hydrological cycle. With the water balance approach, it is possible to quantitatively evaluate individual contribution of sources of water in the system over different time periods and to establish the degree of variation in water regime because of changes in components of the system.

A basinwise approach yields the best results where the groundwater basin can be characterized by prominent drainages. A thorough study of the topography, geology, and aquifer conditions should be employed. The limit of the groundwater basin is controlled not only by topography but also by the disposition, structure and permeability of rocks and the configuration of the water table. Generally, in igneous and metamorphic rocks, the surface water and groundwater basins are coincident for all practical purposes, but marked differences may be encountered in stratified sedimentary formations. Therefore, the study area for groundwater balance study is preferably taken as a doab, which is bounded on two sides by two streams and on the other two sides by other aquifers or extension of the same aquifer. Once the study area is identified, comprehensive studies can be undertaken to estimate for selected period of time, the input and output of water, and change in storage to draw up the water balance of the basin.

The estimation of groundwater balance of a region requires quantification of all individual inflows to or outflows from a groundwater system and change in groundwater storage over a given time period. The basic concept of water balance is:

Input to the system − outflow from the system = change in storage of the system (over a period of time)

The general methodology of computing groundwater balance consists of the following:

- Identification of significant components,
- Evaluating and quantifying individual components, and
- Presentation in the form of water balance equation.

The groundwater balance study of an area may serve the following purposes:

- As a check on whether all flow components involved in the system have been quantitatively accounted for, and what components have the greatest bearing on the problem under study.

- To calculate one unknown component of the groundwater balance equation, provided all other components are quantitatively known with sufficient accuracy.
- As a model of the hydrological processes under study, which can be used to predict the effect that changes imposed on certain components will have on the other components of groundwater system.

GROUNDWATER BALANCE EQUATION

Considering the various inflow and outflow components in a given study area, the groundwater balance equation can be written as:

$$R_{\mathrm{r}} + R_{\mathrm{c}} + R_{\mathrm{i}} + R_{\mathrm{t}} + S_{\mathrm{i}} + I_{\mathrm{g}} = E_{\mathrm{t}} + T_{\mathrm{p}} + S_{\mathrm{e}} + O_{\mathrm{g}} + \Delta S \tag{1}$$

where R_{r} = recharge from rainfall
R_{c} = recharge from canal seepage
R_{i} = recharge from field irrigation
R_{t} = recharge from tanks
S_{i} = influent seepage from rivers
I_{g} = inflow from other basins
E_{t} = evapotranspiration from groundwater
T_{p} = draft from groundwater
S_{e} = effluent seepage to rivers
O_{g} = outflow to other basins
ΔS = change in groundwater storage

Preferably, all elements of the groundwater balance equation should be computed using independent methods. However, it is not always possible to compute all individual components of the groundwater balance equation separately. Sometimes, depending on the problem, some components can be lumped and account only for their net value in the equation.

Computations of various components usually involve errors, because of shortcomings in the estimation techniques. The groundwater balance equation, therefore, generally does not balance, even if all its components are computed by independent methods. The resultant discrepancy in groundwater balance is defined as a residual term in the balance equation, which includes errors in the quantitative determination of various components as well as values of the components that have not been accounted in the equation.

The water balance may be computed for any time interval. The complexity of the computation of the water balance tends to increase with increase in area. This is because of a related increase in the technical difficulty of accurately computing the numerous important water balance components.

DATA REQUIREMENTS FOR A GROUNDWATER BALANCE STUDY

For carrying out a groundwater balance study, the following data may be required over a given time period:

Rainfall Data

Monthly rainfall data of sufficient number of rainguage stations lying within or around the study area, along with their locations, should be available.

Land Use Data and Cropping Patterns

Land use data are required for estimating the evapotranspiration losses from the water table through forested area. Cropping pattern data are necessary for estimating the spatial and temporal distributions of groundwater withdrawals, if required. Monthly pan evaporation rates should also be available at a few locations for estimation of consumptive use requirements of different crops.

River Data

Monthly river stage and discharge data along with river cross sections are required at a few locations for estimating the river-aquifer interflows.

Canal Data

Monthly water releases into the canal and its distributories along with running days during each month are required. To account for the seepage losses through the canal system, the seepage loss test data are required in different canal reaches and distributories.

Tank Data

Monthly tank gauges and water releases should be available. In addition, depth vs. area and depth vs. capacity curves should also be available for computing the evaporation and seepage losses from tanks. Field test data are required for computing infiltration capacity to be used to evaluate the recharge from depression storage.

Water Table Data

Monthly water table data (or at least premonsoon and postmonsoon data) from a sufficient number of well-distributed observation wells along with their locations are required. The available data should comprise reduced level (RL) of water table and depth to water table.

Groundwater Draft

For estimating groundwater withdrawals, the number of each type of well operating in the area, their corresponding running hours each month, and discharge are required. If a complete inventory of wells is not available, then this can be obtained by carrying out sample surveys.

Aquifer Parameters

Data regarding the storage coefficient and transmissivity are required at a sufficient number of locations in the study area.

ESTIMATION OF GROUNDWATER BALANCE COMPONENTS

The various inflow/outflow components of the groundwater balance equation may be estimated through appropriate field experiments or other methods, as discussed below.

Recharge from Rainfall (R_r)

Rainfall is the major source of recharge to groundwater. Part of the rain water that falls on the ground is infiltrated into the soil. A part of this infiltrated water is used in filling the soil moisture deficiency, whereas the remaining portion percolates down to reach the water table, which is termed as *rainfall recharge* to the aquifer. The amount of rainfall recharge depends on various hydrometeorological and topographic factors, soil characteristics, and depth to water table. The methods for estimation of rainfall recharge involve the empirical relationships established between recharge and rainfall developed for different regions, groundwater balance approach, and soil moisture data-based methods.

Empirical Relationships. Several empirical formulae have been worked out for various regions on the basis of detailed studies. For example, Kumar and Seethapathi (1) conducted a detailed seasonal groundwater balance study in Upper Ganga Canal command area (India) for the period 1972–1973 to 1983–1984 to determine groundwater recharge from rainfall. It was observed that as the rainfall increases, the quantity of recharge also increases, but the increase is not linearly proportional. The recharge coefficient (based on the rainfall in monsoon season) was found to vary between 0.05 to 0.19 for the study area. The following empirical relationship was derived by fitting the estimated values of rainfall recharge and the corresponding values of rainfall in the monsoon season through the nonlinear regression technique.

$$R_r = 0.63\ (P - 15.28)^{0.76} \qquad (2)$$

where R_r = Groundwater recharge from rainfall in monsoon season (inch)
P = Mean rainfall in monsoon season (inch)

The relative errors (%) in the estimation of rainfall recharge computed from the proposed empirical relationship was compared with groundwater balance study. In almost every years, the relative error was found to be less than 8%. Therefore, Eq. (2) can conveniently be used for better and quick assessment of natural groundwater recharge in Upper Ganga Canal command area.

It is to be noted that the relationships, tentatively proposed for specific hydrogeological conditions, have to be examined and established or suitably altered for application to other areas. If adequate data of groundwater levels are not available, rainfall recharge may be estimated using the rainfall infiltration method. The same recharge factor may be used for both monsoon and nonmonsoon rainfall, with the condition that the recharge because of nonmonsoon rainfall may be taken as zero, if the rainfall during nonmonsoon season is less than 10% of annual rainfall. An additional 2% of rainfall recharge factor may be used in areas where watershed development with associated soil conservation measures are implemented. This additional factor is separate from contribution because of water conservation structures, such as check dams, nalla bunds, percolation tanks, etc., for which the norms are defined separately.

Groundwater Balance Approach. In this method, all components of the groundwater balance Eq. (1), except the rainfall recharge, are estimated individually. The algebraic sum of all input and output components is equated to the change in groundwater storage, as reflected by the water table fluctuation, which in turn yields the single unknown in the equation, namely, the rainfall recharge. A prerequisite for successful application of this technique is the availability of very extensive and accurate hydrological and meteorological data. The groundwater balance approach is valid for the areas where the year can be divided into monsoon and nonmonsoon seasons, with the bulk of rainfall occurring in former.

Groundwater balance study for monsoon and nonmonsoon periods is carried out separately. The former yields an estimate of recharge coefficient and the latter determines the degree of accuracy with which the components of water balance equation have been estimated. Alternatively, the average specific yield in the zone of fluctuation can be determined from a groundwater balance study for the nonmonsoon period, and using this specific yield, the recharge because of rainfall can be determined using the groundwater balance components for the monsoon period.

Soil Moisture Data-Based Methods. Soil moisture data-based methods are the lumped and distributed model and the nuclear methods. In the lumped model, the variation of soil moisture content in the vertical direction is ignored and any effective input into the soil is assumed to increase the soil moisture content uniformly. Recharge is calculated as the remainder when losses, identified in the form of runoff and evapotranspiration, have been deducted from the precipitation with proper accounting of soil moisture deficit. In the distributed model, variation of soil moisture content in the vertical direction is accounted for, and the method involves the numerical solution of partial differential equation (Richards equation) governing one-dimensional flow through unsaturated medium, with appropriate initial and boundary conditions.

Soil Water Balance Method. Water balance models were developed in the 1940s by Thornthwaite (2) and revised by Thornthwaite and Mather (3). The method is essentially a bookkeeping procedure that estimates the balance between the inflow and outflow of water. When applying this method to estimate the recharge for a catchment area, the calculation should be repeated for areas with different precipitation, evapotranspiration, crop type, and soil type. The soil water balance method is of limited practical value, because evapotranspiration is not directly measurable. Moreover, storage of moisture in the unsaturated zone and the rates of infiltration along the various possible routes to the aquifer form important and uncertain factors. Another aspect that deserves attention is the depth of the root zone, which may vary in semiarid regions between 1 and 30 meters. Results from this model are of very limited value without calibration and validation, because of the substantial uncertainty in input data.

Nuclear Methods. Nuclear techniques can be used for the determination of recharge by measuring the travel of moisture through a soil column. The technique is based on the existence of a linear relation between neutron count rate and moisture content (% by volume) for the range of moisture contents generally occurring in the unsaturated soil zone. The mixture of Beryllium (Be) and Radium (Ra) is taken as the source of neutrons. Another method is the gamma ray transmission method based on the attenuation of gamma rays in a medium through which it passes. The extent of attenuation is closely linked with moisture content of the soil medium.

Recharge from Canal Seepage (R_c)

Seepage refers to the process of water movement from a canal into and through the bed and wall material. Seepage losses from irrigation canals often constitute a significant part of the total recharge to groundwater system. Hence, it is important to properly estimate these losses for recharge assessment to groundwater system. Recharge by seepage from canals depends on the size and cross section of the canal, depth of flow, characteristics of soils in the bed and sides, and location as well as level of drains on either side of the canal. A number of empirical formulae and formulae based on theoretical considerations have been proposed to estimate the seepage losses from canals.

Recharge from canals that are in direct hydraulic connection with a phreatic aquifer, underlaid by a horizontal impermeable layer at shallow depth, can be determined by Darcy's equation, provided the flow satisfies Dupuit assumptions.

$$R_c = K\frac{h_s - h_l}{L}A \tag{3}$$

where, h_s and h_l are water-level elevations above the impermeable base, at the canal, respectively, and at distance L from it. For calculating the area of flow cross section, the average of the saturated thickness $(h_s + h_l)/2$ is taken. The crux of computation of seepage depends on correct assessment of the hydraulic conductivity, K. Knowing the percentage of sand, silt, and clay, the hydraulic conductivity of undisturbed soil can be approximately determined using the soil classification triangle showing relation of hydraulic conductivity to texture for undisturbed sample (4).

A number of investigations have been carried out to study the seepage losses from canals. United States Bureau of Reclamation (USBR) recommended the channel losses based on the channel bed material as given below:

Material	Seepage Losses (Cumec Per Million Square Meter of Wetted Area)
Clay and clay loam:	1.50
Sandy loam:	2.40
Sandy and gravely soil:	8.03
Concrete lining:	1.20

These values are valid if the water table is relatively deep. In shallow water table and waterlogged areas, the recharge from canal seepage may be suitably reduced. Specific results from case studies may be used, if available. The above norms take into consideration the type of soil in which the canal runs while computing seepage. However, the actual seepage will also be controlled by the width of canal (B), depth of flow (D), hydraulic conductivity of the bed material (K), and depth to water table. Knowing the values of B and D, the range of seepage losses (R_{c_max} and R_{c_min}) from the canal may be obtained as

$$R_{c\_max} = K(B + 2D) \quad \text{(in case of deeper water table)} \tag{4a}$$

$$R_{c\_min} = K(B - 2D) \quad \text{(in case of water table at the level of channel bed)} \tag{4b}$$

However, the various guidelines for estimating losses in the canal system are only approximate. The seepage losses may best be estimated by conducting actual tests in the field. The methods most commonly adopted are:

Inflow-Outflow Method. In this method, the water that flows into and out of the section of canal under study is measured using current meter or Parshall flume method. The difference between the quantities of water flowing into and out of the canal reach is attributed to seepage. This method is advantageous when seepage losses are to be measured in long canal reaches with few diversions.

Ponding Method. In this method, bunds are constructed in the canal at two locations, one upstream and the other downstream of the reach of canal with water filled in it. The total change in storage in the reach is measured over a period of time by measuring the rate of drop of water surface elevation in the canal reach. Alternatively, water may be added to maintain a constant water surface elevation. In this case, the volume of water added is measured along with the elapsed time to compute the rate of seepage loss. The ponding method provides an accurate means of measuring seepage losses and is especially suitable when they are small (e.g., in lined canals).

Seepage Meter Method. The seepage meter is a modified version of permeameter developed for use under water. Various types of seepage meters have been developed. The two most important are seepage meter with submerged flexible water bag and falling head seepage meter. Seepage meters are suitable for measuring local seepage rates in canals or ponds and used only in unlined or earth-lined canals. They are quickly and easily installed and give reasonably satisfactory results for the conditions at the test site, but it is difficult to obtain accurate results when seepage losses are low.

The total losses from the canal system generally consist of the evaporation losses (E_c) and the seepage losses (R_c). The evaporation losses are generally 10–15% of the total losses. Thus, the R_c value is 85–90% of the losses from the canal system.

Recharge from Field Irrigation (R_i)

Water requirements of crops are met, in parts, by rainfall, contribution of moisture from the soil profile, and applied irrigation water. A part of the water applied to irrigated field crops is lost in consumptive use and the balance infiltrates to recharge the groundwater. The process of re-entry of a part of the water used for irrigation is called return flow. Percolation from applied irrigation water, derived both from surface water and groundwater sources, constitutes one of the major components of groundwater recharge. The irrigation return flow depends on the soil type, irrigation practice, and type of crop. Therefore, irrigation return flows are site specific and will vary from one region to another.

The recharge because of irrigation return flow may be estimated, based on the source of irrigation (groundwater or surface water), the type of crop (paddy, nonpaddy), and the depth of water table below ground surface. For surface water, the recharge is to be estimated based on water released at the outlet from the canal/distribution system. For groundwater, the recharge is to be estimated based on gross draft. Where continuous supply is used instead of rotational supply, an additional recharge of 5% of application may be used. Specific results from case studies may be used, if available.

For a correct assessment of the quantum of recharge by applied irrigation, studies are required to be carried out on experimental plots under different crops in different seasonal conditions. The method of estimation comprises application of the water balance equation involving input and output of water in experimental fields.

Recharge from Tanks (R_t)

Studies have indicated that seepage from tanks varies from 9–20% of their live storage capacity. However, as data on live storage capacity of large number of tanks may not be available, seepage from the tanks may be taken as 44–60 cm per year over the total water spread, taking into account the agroclimatic conditions in the area. The seepage from percolation tanks is higher and may be taken as 50% of its gross storage. In the case of seepage from ponds and lakes, the norms as applied to tanks may be taken. Groundwater Resource Estimation Committee (5) has recommended that, based on the average area of water spread, the recharge from storage tanks and ponds may be taken as 1.4 mm/day for the period in which the tank has water. If data on the average area of water spread is not available, 60% of the maximum water spread area may be used instead of the average area of water spread.

In the case of percolation tanks, recharge may be taken as 50% of gross storage, considering the number of fillings, with half of this recharge occurring in monsoon season and the balance in nonmonsoon season. Recharge because of check dams and nala bunds may be taken as 50% of gross storage (assuming annual desilting maintenance exists), with half of this recharge occurring in the monsoon season and the balance in the nonmonsoon season.

Influent and Effluent Seepage (S_i & S_e)

The river-aquifer interaction depends on the transmissivity of the aquifer system and the gradient of the water table in respect to the river stage. Depending on the water level in the river and in the aquifer (in the vicinity of river), the river may recharge the aquifer (influent) or the aquifer may contribute to the river flow (effluent). The effluent or influent character of the river may vary from season to season and from reach to reach. The seepage from/to the river can be determined by dividing the river reach into small sub-reaches and observing the discharges at the two ends of the sub-reach along with the discharges of its tributaries and diversions, if any. The discharge at the downstream end is expressed as:

$$Q_{\mathrm{d}}.\Delta t = Q_{\mathrm{u}}.\Delta t + Q_{\mathrm{g}}.\Delta t + Q_{t}.\Delta t - Q_{\mathrm{o}}.\Delta t - E.\Delta t \pm S_{\mathrm{rb}} \quad (5)$$

where Q_{d} = discharge at the downstream section
Q_{u} = discharge at the upstream section
Q_{g} = groundwater contribution (unknown quantity; −ve computed value indicates influent conditions)
Q_{t} = discharge of tributaries
Q_{o} = discharge diverted from the river
E = rate of evaporation from river water surface and flood plain (for extensive bodies of surface water and for long time periods, evaporation from open water surfaces cannot be neglected)
S_{rb} = change in bank storage (+ for decrease and − for increase)
Δt = time period

The change in bank storage can be determined by monitoring the water table along the cross section normal to the river. Thus, using the above equation, seepage from/to the river over a certain period of time, Δt, can be computed. However, this would be the contribution from aquifers on both sides of the stream. The contribution from each side can be separated by the following method:

$$\textit{Contribution from left bank} = \frac{I_{\mathrm{L}}T_{\mathrm{L}}}{I_{\mathrm{L}}T_{\mathrm{L}} + I_{\mathrm{R}}T_{\mathrm{R}}} \cdot Q_{\mathrm{g}} \quad (6a)$$

$$\textit{Contribution from right bank} = \frac{I_{\mathrm{R}}T_{\mathrm{R}}}{I_{\mathrm{L}}T_{\mathrm{L}} + I_{\mathrm{R}}T_{\mathrm{R}}} \cdot Q_{\mathrm{g}} \quad (6b)$$

where I_{L} and T_{L} are gradient and transmissivity, respectively, on the left side and I_{R} and T_{R} are those on the right.

Inflow from and Outflow to Other Basins (I_g and O_g)

For the estimation of groundwater inflow/outflow from/to other basins, regional water table contour maps are drawn based on the observed water level data from wells located within and outside the study area. The flows into and out of a region are governed mainly by the hydraulic gradient and transmissivity of the aquifer. The gradient can be determined by taking the slope of the water table normal to water table contour. The length of the section, across which groundwater inflow/outflow occurs, is determined from contour maps, the length being measured parallel to the contour. The inflow/outflow is determined as follows:

$$I_{\mathrm{g}} \; or \; O_{\mathrm{g}} = \sum^{\mathrm{L}} T \, I \, \Delta L \quad (7)$$

where T is the transmissivity and I is the hydraulic gradient averaged over a length, ΔL, of contour line.

Evapotranspiration from Groundwater (E_t)

Evapotranspiration is the combined process of transpiration from vegetation and evaporation from both soil and free water surfaces. Potential evapotranspiration is the maximum loss of water through evapotranspiration. Evapotranspiration from groundwater occurs in waterlogged areas or in forested areas with roots extending to the water table. From the land use data, area under forests is available whereas the waterlogged areas may be demarcated from depth to water table maps. The potential evapotranspiration from such areas can be computed using standard methods.

Depth to water table maps may be prepared based on well inventory data to bring into focus the extensiveness of shallow water table areas. During well inventory, investigation should be specifically oriented toward accurately delineating water table depth for depths less than 2 meters. The evapotranspiration can be estimated based on the following equations:

$$E_t = PE_t * A \qquad \text{if } h > h_s \qquad (8a)$$

$$E_t = 0 \qquad \text{if } h < (h_s - d) \qquad (8b)$$

$$E_t = PE_t * A(h - (h_s - d))/d \qquad \text{if } (h_s - d) \le h \le h_s \qquad (8c)$$

where E_t = evapotranspiration in volume of water per unit time$[L^3T^{-1}]$
PE_t = maximum rate of evapotranspiration in volume of water per unit area per unit time $[L^3L^{-2}T^{-1}]$
A = surface area $[L^2]$
h = water table elevation $[L]$
h_s = water table elevation at which the evapotranspiration loss reaches the maximum value
d = extinction depth; when the distance between h_s and h exceeds d, evapotranspiration from groundwater ceases $[L]$

Draft from Groundwater (T_p)

Draft is the amount of water lifted from the aquifer by means of various lifting devices. To estimate groundwater draft, an inventory of wells and a sample survey of groundwater draft from various types of wells (state tubewells, private tubewells, and open wells) are required. For state tubewells, information about their number, running hours per day, discharge, and number of days of operation in a season is generally available in the concerned departments. To compute the draft from private tubewells, pumping sets, rahats, etc., sample surveys have to be conducted regarding their number, discharge, and withdrawals over the season.

In areas where wells are energized, the draft may be computed using power consumption data. By conducting tests on wells, the average draft per unit of electricity consumed can be determined for different ranges in depth to water levels. By noting the depth to water level at each distribution point and multiplying the average draft value with the number of units of electricity consumed, the draft at each point can be computed for every month.

Change in Groundwater Storage (ΔS)

To estimate the change in groundwater storage, the water levels are observed through a network of observation wells spread over the area. The water levels are highest immediately after monsoon, in the month of October or November, and lowest just before rainfall, in the month of May or June. During the monsoon season, the recharge is more than the extraction; therefore, the change in groundwater storage between the beginning and end of monsoon season indicates the total volume of water added to the groundwater reservoir, whereas the change in groundwater storage between the beginning and end of the nonmonsoon season indicates the total quantity of water withdrawn from groundwater storage. The change in storage (ΔS) is computed as follows:

$$\Delta S = \sum \Delta h\, A\, S_y \qquad (9)$$

where Δh = change in water table elevation during the given time period
A = area influenced by the well
S_y = specific yield

Groundwater Resource Estimation Committee (5) recommended that the size of the watershed as a hydrological unit could be of about 100 to 300 sq. km area, and there should be at least three spatially well-distributed observation wells in the unit, or one observation well per 100 sq. km, whichever is more. However, as per IILRI (6), the following specification may serve as a rough guide:

Size of the Area (ha)	Number of Observation Points	Number of Observation Points per 100 Hectares
100	20	20
1,000	40	4
10,000	100	1
1,00,000	300	0.3

The specific yield may be computed from pumping tests. The values of specific yield in the zone of fluctuation of water table in different parts of the basin can also be approximately determined from the soil classification triangle showing relation between particle size and specific yield (7).

ESTABLISHMENT OF RECHARGE COEFFICIENT

Groundwater balance study is a convenient way of establishing the rainfall recharge coefficient, as well as to cross check the accuracy of the various prevalent methods for the estimation of groundwater losses and recharge from other sources. The steps to be followed are:

1. Divide the year into monsoon and nonmonsoon periods.
2. Estimate all the components of the water balance equation other than rainfall recharge for monsoon period using the available hydrological and meteorological information and employing the prevalent methods for estimation.
3. Substitute these estimates in the water balance equation and thus calculate the rainfall recharge and, hence, recharge coefficient (recharge/rainfall ratio). Compare this estimate with those given by various empirical relations valid for the area of study.
4. For nonmonsoon season, estimate all the components of water balance equation including the rainfall recharge, which is calculated using recharge coefficient value obtained through the water balance of monsoon period. The rainfall recharge (R_r) will be of very small order in this case. A close balance between the left and right sides of the equation will indicate that the net recharge from all the sources of recharge and discharge has been quantified with a good degree of accuracy.

By quantifying all the inflow/outflow components of a groundwater system, one can determine which particular component has the most significant effect on the groundwater flow regime. Alternatively, a groundwater balance study may be used to compute one unknown component (e.g., the rainfall recharge) of the groundwater balance equation when all other components are known. The balance study may also serve as a model of the area under study, whereby the effect of change in one component can be used to predict the effect of changes in other components of the groundwater system. In this manner, the study of groundwater balance has a significant role in planning a rational groundwater development of a region.

CONCLUDING REMARKS

- Water balance approach, essentially a lumped model study, is a viable method of establishing the rainfall recharge coefficient and for evaluating the methods adopted for the quantification of discharge and recharge from other sources. For proper assessment of potential, present use, and additional exploitability of water resources at optimal level, a water balance study is necessary.
- Groundwater exploitation should be such that protection from depletion is provided, protection from pollution is provided, negative ecological effects are reduced to a minimum, and economic efficiency of exploitation is attained. Determination of exploitable resources should be based on hydrological investigations. These investigations logically necessitate use of a mathematical model of groundwater system for analyzing and solving the problems. The study of water balance is a prerequisite for groundwater modeling.
- A need exists for studying unsaturated and saturated flow through weathered and fractured rocks for finding the recharge components from rainfall and from percolation tanks in hard rock groundwater basins. The irrigation return flow under different soils, crops, and irrigation practices needs to be quantified. Assessment of groundwater quality in many groundwater basins is a task yet to be performed. A hydrological database for groundwater assessment should be established. Also, user-friendly software should be developed for quick assessment of regional groundwater resources.
- Nonconventional methods for utilization of water, such as through interbasin transfers, artificial recharge of groundwater, and desalination of brackish or seawater as well as traditional water conservation practices like rainwater harvesting, including rooftop rainwater harvesting, need to be practiced to further increase the usable water resources.

HYDRAULIC HEAD

MATTHEW M. ULIANA
Texas State University—San Marcos
San Marcos, Texas

Hydraulic head is defined as the fluid energy per unit weight at a given point in a fluid system (like a pipe filled with flowing water or an aquifer). In simple, everyday terms, we can conceptualize (and measure) hydraulic head as an elevation—more specifically, the elevation to which water rises in a manometer, in a pressurized water pipe or in a piezometer.

Water elevations is a manifestation of the fluid energy in a groundwater system, and measuring a water elevation in a piezometer is really a measurement of the energy in the fluid at a certain point in a groundwater system.

WHAT DO WE MEAN BY "ENERGY"?

Everything in the universe has some amount of energy associated with it, and that energy is present in various forms. Energy drives every natural process, and the key to understanding physical processes is understanding how energy is distributed in a system.

There are two basic types of energy:

Potential Energy: energy stored in a piece of matter or at a point in a system, generally associated with position or with the thermodynamics of the system (elevation, pressure, chemical, thermal).

Kinetic: energy of motion (velocity).

At every point in an aquifer, the fluid possesses some total amount of energy. That energy is the *sum* of all the potential and kinetic energy in the fluid associated with the velocity of the fluid, pressure of the fluid, temperature of the fluid, chemical bonds in the fluid, etc.

As previously stated, the fluid energy at a point in an aquifer manifests itself as the water level in a piezometer. So we could also say that the water level, or hydraulic head, represents the total energy in the aquifer at a given point, and we can use the various energy components of the hydraulic head (elevation, pressure, velocity, etc.) to understand the driving forces behind fluid motion in the subsurface.

THE BERNOULLI EQUATION

As previously stated, fluid energies (and, subsequently, water levels) vary from one point in an aquifer to the next (Figs. 1 and 2). Now, if we recall the first and second laws of thermodynamics:

First law of thermodynamics: Energy is conserved.

$$\text{Energy added} - \text{energy subtracted}$$
$$= \text{change in total energy}$$

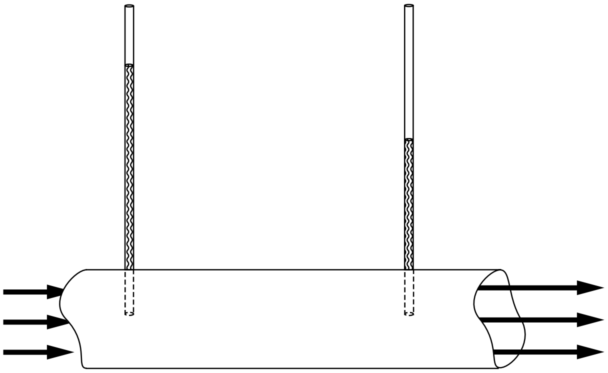

Figure 1. Pipe of flowing water with manometers showing the loss of head along the flow path.

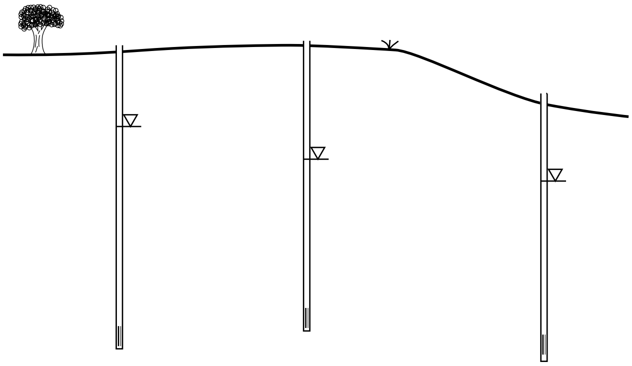

Figure 2. Cross section of aquifer showing hydraulic heads in three wells.

We could also express the first law in terms of the difference in energy at two points in a dynamic system:

$$\text{Total energy}_{(\text{atpoint1})} + \text{energy added/lost}_{(\text{betweenpoint1and2})}$$
$$= \text{total energy}_{(\text{atpoint2})}$$

Second law of thermodynamics: Closed systems move toward increasing entropy.

— In a dynamic system like an aquifer, water will move from a point of higher energy (i.e., lower entropy) to a point of lower energy (higher entropy).

— In other words, groundwater moves in the direction of decreasing hydraulic head.

The *Bernoulli equation*, which describes the total energy of a fluid at all positions along a flow path in a closed system, is basically an expression of the first and second laws of thermodynamics:

$$z_1 + \frac{p_1}{\rho_w g} + \frac{v_1^2}{2g} + H_a = z_2 + \frac{p_2}{\rho_w g} + \frac{v_2^2}{2g} + H_L + H_E \tag{1}$$

where z = elevation (L)
p = pressure ($\mathrm{M{\cdot}L^{-1}{\cdot}t^{-2}}$)
ρ_w = fluid density ($\mathrm{M{\cdot}L^{-3}}$)
g = gravitational acceleration ($\mathrm{L{\cdot}t^{-2}}$)
v = velocity ($\mathrm{L{\cdot}t^{-1}}$)
H_a = heat energy added (L)
H_L = mechanical energy lost (L)
H_E = heat energy extracted (L)

and the numerical subscripts represent two different positions along the flow path.

Let's assume that we don't add or subtract any heat energy from the system and the only change is the loss of mechanical energy from one point to the next; then we can rewrite the equation as

$$z_1 + \frac{p_1}{\rho_w g} + \frac{v_1^2}{2g} + I_1 = z_2 + \frac{p_2}{\rho_w g} + \frac{v_2^2}{2g} + I_2 \tag{2}$$

where **I** is the internal energy at each point (i.e., the rest of the potential energy not described by the other terms) and $\mathbf{I}_2\mathbf{I}_1$ is equal to $\mathbf{H}_L$ in Eq. 1.

We can understand this equation by considering that each term in the equation represents a specific component of energy with units of length. The terms of the equation represent, (respectively),

— elevation
— pressure
— kinetic (velocity)
— other internal energies (thermal, chemical)

This equation describes the change in energy from one point along a flow path to the next point. This equation expresses all the components of energy in the same units (i.e., length), so we can use it to compare the relative magnitude of the individual components. When we do that, we see that for most groundwater situations, the internal and kinetic components of the total energy are so small that we can ignore them. The result is that we can describe fluid energy in a groundwater system by only the elevation and pressure components.

HYDRAULIC HEAD AND HYDRAULIC POTENTIAL

If we assume that we can ignore velocity and internal energy components when dealing with groundwater, we can drop all that out of the equation and express the fluid energy as the sum of the elevation and pressure components. That sum is what we call *hydraulic head*; in physical terms, it is the fluid energy per unit weight, and in mathematical terms, it is

$$h = z + p/\rho_w g \tag{3}$$

where h = hydraulic head (L)
z = elevation (L)
p = pressure ($\mathrm{M{\cdot}L^{-1}{\cdot}t^{-2}}$)
ρw = fluid density ($\mathrm{M{\cdot}L^{-3}}$)
g = gravitational acceleration ($\mathrm{L{\cdot}t^{-2}}$)

If we multiply both sides of the equation by the gravitational constant, g, we get a quantity called *hydraulic potential* (Φ), which is the fluid energy per unit *mass*, or

$$\Phi = gz + p/\rho_w \tag{4}$$

such that

$$\Phi = gh \tag{5}$$

The hydraulic potential is simply a way of expressing the same fluid energy, so that it is independent of gravity.

PHYSICAL DESCRIPTION OF THE COMPONENTS OF HEAD

From Eq. 3, we can see that hydraulic head is the sum of the elevation component (or *elevation head*) and the pressure component (or *pressure head*). The physical meaning of pressure head and elevation head are defined and described in Fig. 3a–c. These figures show an idealized cross section of a piezometer that has a screened interval at the bottom. Figure 3a shows the depths and elevations measured in the field (relative to some datum, like mean sea level). Figure 3b shows the pressure, elevation, and total heads, and Fig. 3c is a combination of the other two figures.

From Fig. 3b, we see that the elevation head is the height of the screened interval above the datum. Keep in mind that the datum is arbitrarily chosen—if we wanted, we could choose the bottom of the well as the datum, and the elevation head would be zero. However, it is important to realize that the head is really only important to us when we are looking at multiple wells in the same aquifer, and we need to have a constant datum for all those wells make the comparison meaningful. Sea level is usually chosen, but it is not the necessary datum.

We also see that the pressure head is the length of the column of water in the well above the screened interval. Keep in mind that *pressure* and *pressure head* are two different things; the *pressure* at the screened interval is the force per unit area of the column of fluid above that point; the *pressure head* is the pressure divided by the product of the density of the fluid and gravitational acceleration and is manifest as the length of the column of water above the screen. If we know the density of the fluid and the length of the column of water in the well, we can calculate the pressure at the well screen.

Finally, we see that the total head is just the sum of the other two heads, or more generally, the height of the water level in the well above the datum, this brings us full circle to the concept of water levels reflecting fluid energy.

DISTRIBUTION OF HEADS (I.E., FLUID ENERGY) IN A 3-D AQUIFER

An aquifer is a dynamic system of flowing water. The fluid energy varies throughout the system and is different from one point to the next. The result is

— different water levels throughout the aquifer
— hydraulic gradients
— movement of water driven by those gradients

Head is a scalar quantity; it is measured at a point, and it has a single magnitude that doesn't vary with respect to direction. So, when we talk about heads, from a theoretical standpoint, we are talking about the energy at an infinitesimal point in an aquifer. However, that aquifer exists in three dimensions, contains an infinite number of points, and the head varies from point to point.

The trends in that variation control the directions and magnitudes of flow. We call this variation the *hydraulic gradient*. The hydraulic gradient is defined as the change in hydraulic head over the change in length, and it is directly analogous to other physical gradients (topographic slope, thermal gradient, concentration gradients, etc.)

Hydraulic heads exist in three dimensions, so hydraulic gradients are not necessarily horizontal. In reality, most groundwater flow is generally in a horizontal direction, and it is often a realistic assumption to ignore fluid movement in a vertical dimension. However, there are many situations where vertical gradients (and, subsequently, vertical flow) are significant.

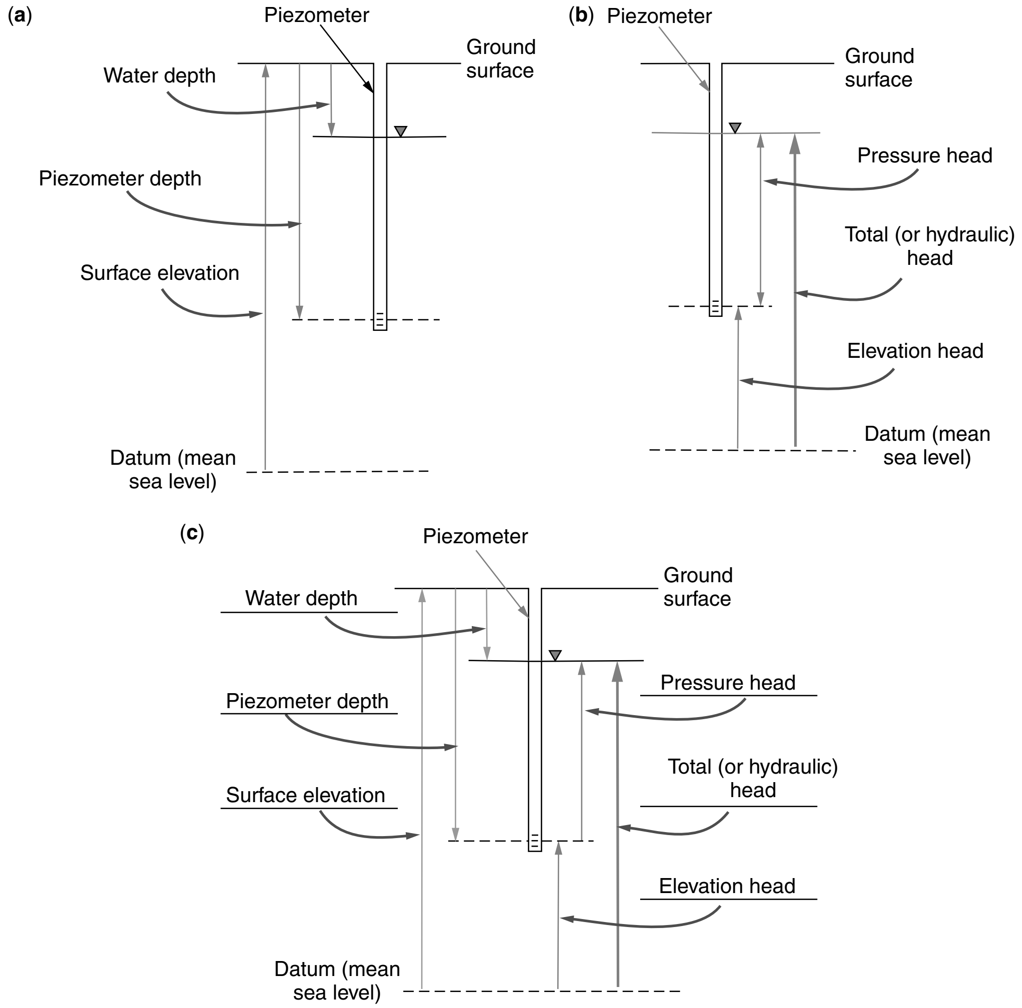

Figure 3. Hypothetical well showing depths, elevations, and heads.

THE ROLE OF HEAT IN GROUNDWATER SYSTEMS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

The role of heat in the subsurface includes the study of the overall transport of heat in saturated groundwater systems. Once site specific dynamics of heat transport are understood the effects of temperature on physical, chemical, and biological processes that govern the transport and degradation of contaminants in an aquifer can be evaluated.

FUNDAMENTALS

Of the many parameters that are monitored in association with the assessment and remediation of contaminated groundwater, temperature is typically regarded as a background condition that must be accepted for a given site. In the northern tier of states, it is customary that in the winter months remediation processes will be slowed or stopped depending on the depth of groundwater.

DEFINITIONS

Heat is an added or external energy that causes a rise in temperature, physical expansion, evaporation or other physical change. The rise or drop of temperature in an aquifer is the result of the transport of heat into or away from the aquifer. The key measure of the relationship between heat flow and resulting temperature is heat capacity, Cp. Heat capacity is used as specific heat in English units, which is the number of BTUs required to raise one pound of aquifer matrix by one degree Fahrenheit.

There are two primary materials through which heat is transported in an aquifer, the mineral matrix and the entrained groundwater. Density of the mineral matrix and water, porosity, and heat capacity combine to govern the temperature response of an aquifer to heat flow. The specific heat Cp (as BTU/lb °F), dry density (rho, as lbs/ft^3) and percent porosity (phi) of some soils and minerals are as follows:

	Specific Heat	CpDensity (rho) lbs/ft^3	% Porosity (phi)
Water	1.00	62.4	NA
Clay	0.27	65.0	75
Sand	0.19	110.0	35
Granite	0.20	165.0	1
Limestone	0.22	155	4
Organic Fraction	0.30	55	65

The thermal energy capacity per unit volume per degree of temperature change is called the aquifer thermal capacity (q). With the above information, it is possible to calculate the thermal capacity (q) of an aquifer:

$$\mathbf{q} = (\mathrm{Cp} \times \mathrm{rho})_{\mathrm{rock}}(1 - \mathrm{phi}) + (\mathrm{Cp} \times \mathrm{rho})_{\mathrm{water}} \times \mathrm{phi}$$

Assuming a sandy aquifer with a specific heat of 0.19 for the mineral matrix, a density of 110 lb/ft^3, and a porosity of 0.35, the specific thermal capacity per cubic foot of aquifer is

$$\begin{aligned}\mathbf{q} &= (0.19 \times 110)_{\mathrm{rock}} \times (1 - 0.35) \\ &\quad + (1.0 \times 62.4)_{\mathrm{water}} \times 0.35 \\ \mathbf{q} &= 13.59_{\mathrm{rock}} + 21.84_{\mathrm{water}} \\ &= 35.4 \text{ BTU per cubic foot per 1 degree Fahrenheit}\end{aligned}$$

EXAMPLE

Given a volume in an aquifer 100 feet by 100 feet by 20 feet in depth, it would require 7,080,000 Btu to raise the temperature 1 °F. Converting Btu to kilowatt hours gives 2073 KW hours. At 6 cents per Kilowatt, that is equal to $125 in electrical cost. That estimate does not take into account the efficiency of the heat generation system, transfer of that heat into the aquifer, and effects of heat transport away from the zone undergoing heating.

Three physical processes are responsible for heat transfer in groundwater systems:

1. Conduction—heat flows from hotter regions to cooler regions through the molecular transfer of kinetic energy.
2. Convection—heat is transported along with overall mass transport of groundwater.
3. Radiation—the transference of heat through space via electromagnetic radiation.

The dominant mechanisms in groundwater systems are convection and conduction.

Thermal conductivity (k) is the amount of heat that will flow through a unit area in a unit time with a unit temperature difference. Under saturated conditions, the value of thermal conductivity is primarily governed by the texture, degree of compaction, and mineralogical composition of the aquifer matrix. Thermal conductivity decreases with the reduction of particle size. The units of thermal conductivity are Btu per hour per foot per degree Fahrenheit. Typical values are as follows:

Water	0.346
Air	0.0145
Wet Sand	0.95
Dry Sand	0.157
Wet Clay	0.87
Dry Clay	0.138

Notice that the thermal conductivity of water is about 23 times that of air. In the past, the use of heat as an augmentation to remediation has been applied to the vadose zone through the application of steam. For heat transport efficiency, that is probably not the most efficient application of a subsurface heating process.

Heat flow through a mass (qx) is calculated by the equation:

$$\mathrm{qx} = Ak(dT/dX)$$

where A is the cross-sectional area normal to the heat flow,
k is the thermal conductivity,
T is temperature in Fahrenheit,
X is the distance over which the heat must flow.

The solution to the above function requires substitution of an equation describing the system geometry for the dX term followed by integration. That is beyond the scope of this article.

Thermal diffusivity (in units of square feet per hour) is equal to the thermal conductivity (k) divided by the thermal capacity (q) of the aquifer; it measures the rate at which temperature changes occur in the soil mass. Higher values of thermal diffusivity result in more rapid changes in temperature and deeper penetration of heat into the soil.

Ratio of Thermal Velocity to Groundwater Velocity Versus Porosity

Lastly, as heated groundwater moves through an aquifer, thermal energy is transferred to the mineral matrix. As a consequence the thermal front associated with the advective flow of heated groundwater will move at a lower velocity than the groundwater. Aquifer porosity is the dominant element in this dynamic. The ratio of the velocity of the migration of the thermal front versus the groundwater velocity is affected by aquifer porosity. The smaller the ratio, the slower the thermal front velocity compared with the overall groundwater velocity.

EFFECT ON PHYSICAL PROPERTIES AND REACTION KINETICS

The two dominant physical characteristics of groundwater that change with temperature are viscosity and density. Their relationship is not linear. In the temperature range of 0 °C to 30 °C, the viscosity decreases by over 50%. This change improves the efficiency of both advective fluid flow and diffusional transport. In contrast, water density decreases significantly at temperatures over 60 °C.

Next, chemical reactions should be considered. Most salts increase in solubility as the temperature increases, the common exception to this general rule being carbonates in which solubility decreases as temperature increases. As temperature increases, the solubility of gases in groundwater decreases. The solubility (in milligrams/liter) of environmentally important gases over the temperature range of 5 °C to 35 °C is as follows:

Oxygen with air as the source	12.7 to 7.1
Carbon Dioxide	2774 to 1105
Methane	34.1 to 17.3

The relationship between temperature and the kinetics of chemical reactions is expressed by the Arrhenius equation:

$$\ln k = \ln A - E_a/RT$$

where k is the rate constant,
A is an integration constant,
E_a is the energy of activation,
R is the universal gas constant, and
T is the temperature in Kelvin.

Commonly, this relationship is graphed as ln k versus $1/T$, which results in a straight line in which k increases exponentially as T increases. Under proper circumstances, small increases in temperature can have large effects on kinetic rates.

In addition to reaction rates, temperature also affects equilibrium constants, particularly those that involve reactions with noncovalent bonds. Covalent bonds are relatively resistant to thermal perturbation. However, van der Waals interactions, hydrogen bonds, weak ionic bonds, and hydrophobic interactions are disrupted by relatively small temperature changes.

Hydrogen bonds, ionic bonds, and van der Waals interactions all form with the release of heat, and hydrophobic interactions form with heat consumption.

Increases in temperature will destabilize the first three, whereas it will stabilize the hydrophobic interactions.

As temperature increases, the solubility of hydrocarbons increases, not uncommonly two to three times in the temperature range of 5 °C to 30 °C. Through this and the bonding reactions mentioned above, the forces responsible for the retardation of hydrocarbons within the soil matrix are reduced as temperature increases, improving the flushing action of groundwater flow induced by pump and treat recovery systems.

Vapor pressure also increases with temperature, and increased vapor pressure results in increased mass transport rates in soil vapor extraction systems, which is where many of the prior applications of external heat to subsurface remediation have been used. Examples of the percent increase in vapor pressure as a result of a temperature increase from 5 °C to 35 °C are as follows:

Benzene	417%
Ethylbenzene	638%
Toluene	513%
TCE	476%
Tetrachloroethylene	545%

With regard to free product recovery, an increase in temperature will reduce the hydrocarbon viscosity and increase the recovery of free product from the surface of a water table. A temperature increase from 10 °C to 50 °C can increase the recoverable amount of middle distillates by 10%.

Molecular diffusion is driven by the presence of a chemical concentration gradient between adjacent zones in the subsurface. The presence of a temperature gradient will also set up the diffusion of dissolved components in a fluid. The phenomena is called the Soret Effect and is known generally as thermal diffusion. Mass transport rates under thermal diffusion are described by the equation:

$$N_{\mathrm{AT}} = D_{\mathrm{T}}(\mathrm{Rho})d\ln\,(T/dz)$$

where N_{AT} is the mass transport rate as number of moles/cm2/second, D_{T} is the coefficient of thermal diffusion in centimeters squared/second, T is temperature in kelvins, z is the distance in the direction of diffusion in centimeters, and Rho is the fluid density in g-moles/centimeters cubed.

The magnitude of thermal diffusion is dependent on the size and chemistry of the molecules involved as well as on the temperature. At maximum, it may reach a diffusional mass transport rate of 30% that is seen for molecular diffusion driven by chemical concentration gradients, and it is typically significantly less than that.

Lastly, a brief discussion on temperature and biological systems. Bacteria typically have a relatively narrow temperature range (about 10 °C) in which they experience maximum growth and metabolic activity. As groundwater temperatures increase, the dominant bacterial consortia will change in response. This is true with increases of temperature up to about 35 °C; temperatures of 50 °C or above will cause traumatization and partially kill many bacterial species indigenous to the subsurface. It is common for the rates of physiological and biochemical processes to undergo a two-fold increase because of a temperature change of only about 10 °C. This change is caused by the nature of the Arrhenius equation previously discussed as applied to biological systems.

A practical note with regard to bench scale studies of soil bacteria: Incubation of bacteria in the laboratory ideally should be conducted in a temperature range that is from 5 °C below the in situ groundwater temperature to 10 °C above. On average, the groundwater temperature in the United States is approximately 10 °C. Most bench scale laboratory testing is done at room temperature (about 25 °C).

In conclusion, many of the processes exploited in aid of subsurface remediation are impacted by temperature. The overall compounded physical/chemical/biological effects that can be anticipated within a relatively normal temperature range (5 °C to 35 °C) could on an additive basis make a three- to five-fold increase in remediation rates, which is not insignificant. The issue is then site specific, i.e., shallow versus deep contamination. Passive heating systems using modification of the ground surface to improve heat adsorption or low-intensity intrusive systems such as those associated with heat pump systems could offer remediation actions with possible economic benefits.

GROUNDWATER FLOW IN HETEROGENETIC SEDIMENTS AND FRACTURED ROCK SYSTEMS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

Groundwater flow in heterogenetic sediments and fractured rock systems is highly complex. Contaminants within these types of subsurface conditions are relatively common. Similarities and differences exist in flow characteristics of heterogenetic sediments and fractured rock systems, which influence contaminant fate and transport and subsequent remediation efforts at environmentally impacted properties.

FLOW IN HETEROGENETIC SEDIMENTS

Heterogeneity in granular aquifers is common and is caused by the large variability in water flow regimes in various depositional environments. The vertical and lateral variability in granular aquifers can occur on a scale of centimeters or less.

Anisotropic advective flow, dispersion, diffusional transport, contaminant adsorption, and other physical/chemical processes taking place in these systems is complicated. Complete evaluation and understanding of these processes at any given site is impractical, and attempting to gather comprehensive data in support of that understanding is prohibitively expensive. Anisotropic advective groundwater flow dominates the heterogenetic sedimentary systems.

Heterogeneity and subsequent anisotropic groundwater flow conditions are considered normal at most contaminated sites. Near-surface granular aquifers that are impacted by the release of contaminants are usually poorly indurated and can be classified according to the depositional regime as follows:

- Fluvial that includes rivers, streams, and alluvial fans
- Glacial such as tills
- Lacustrine lake deposits
- Eolian sand dune systems

In these depositional systems (particularly fluvial and glacial), it is common to have granular deposits of high permeability contrast juxtaposed to each other, and therein lies the source of great complexity.

Granular media advective flow regimes can be classified into three broad types:

- Uniform, medium-to-coarse granular soils capable of supporting significant intergranular advective flow
- Low permeability silts, clays, and tills in which any advective flow actually occurs in secondary permeable channels such as fractures or joints
- Complex interbedded soils with zones of high permeability contrast resulting in anisotropic advective flow

Sediment source and energy of transport are the primary controllers of the characteristics of water-deposited materials. A rain storm, rising tide, or flood waters carry an initial high-energy load of coarser material (that may be mixed with finer grained silts and clays). As a given deposition event begins to subside, the denser and typically larger size grains settle first, followed by granular materials of decreasingly less dense and smaller sizes. The last stage may involve quiescent waters from which the finest clay and silt particles will settle over a significant period of time. The result of a given episode is a layer stratified by size within the overall soil mass.

Scale is important when evaluating water flow characteristics. The smallest scale heterogeneity is expressed by variations in pore size and shape. Slightly larger, bench scale heterogeneity is expressed by variance in the particle size; on the larger scale of a road cut, heterogeneity is seen as the layering of individual bedding planes; and on larger scales, as changes in size of the layers occurs, pinch outs and facies change. In layered sediments of this type, horizontal flow is dominated by the most permeable units in the sequence and vertical flow by the least permeable. Mega scale depositional heterogeneity can also be created by processes such as braided stream sediments or glacial till systems, where lenticular pods of sand may be deposited in a matrix of lower permeability silts and clays.

Material that is two or three orders of magnitude higher in permeability than the bulk soil matrix will totally govern the groundwater flow system. For example, 1 in. of sand can dominate the flow through tens of feet of silt or clay. The practical problem this presents is the determination of the spatial configuration of the physically small but hydraulically dominant units in the soil matrix. Because of this significant problem, continuous soil coring is recommended during subsurface investigations of soils with mixed sands and clay or silts, where practical.

One potentially most damaging situation includes conditions in which the permeable channels or layers are preferentially exposed to the surface. These zones are susceptible to contaminant impact followed by surface recharge, which can act as a hydraulic driver of contaminants within a matrix that overall does not support high rates of advective groundwater flow, even in the more permeable (but unexposed) portions of the coarser soil units.

The testing and analysis of these anisotropic heterogenetic flow systems is potentially extremely complex. As a matter of practicality, a significant number of assumptions must be made in the analysis of these aquifers. As readily available computing power has increased over the past decades, the number and degree of required assumptions have declined in the more sophisticated applications. Irrespective, two prime assumptions are that at some scale the heterogenetic soil can be treated as a homogenous block and that the spatial configuration of the heterogeneity has been defined. Increasing computational power typically allows for a finer mesh of blocks, but it has not addressed the issue of spatial configuration.

A significant new tool that is beginning to be put to use is the employment of fractal concepts to study the hydrology of heterogenetic soils. This approach points to a serious flaw in the value of using finer blocks in the modeling matrix. If the geometry of the heterogeneity is fractal in the soil matrix (which evidence increasingly indicates it often is), the assumption that the matrix can be represented by averaging is false. A fractal matrix will not become homogenous with averaging irrespective of block size. With further use of the concepts of fractal analysis, it is possible to model general features and hydraulic behavior and interpolate hydraulic dynamics from sparse data, an ability of potentially great value in these complex groundwater flow systems. With this approach, water level, flow, and soil data can be used from an operating groundwater recovery system to fine tune understanding of the site. Through an iterative process, the fractal model resolves hydrogeological attractors in the flow system. Known hydraulic properties model drawdown in the forward iteration, and observed drawdown and flow rates model hydraulic properties in the inverse iteration. This process has the potential to be a powerful tool for defining heterogenetic anisotropic groundwater systems.

At this juncture, computer capacity allows for primitive two-dimensional modeling in this manner. With improvements, it will soon be possible to robustly model three-dimensional systems. This technology will spatially identify which portions of the soil matrix have the greatest impact on the groundwater flow regime. It can also subtly determine areas where data gaps of high impact exist and that require additional testing wells.

FLOW IN FRACTURED ROCK SYSTEMS

Usually shallow water-bearing zones underlying a site are in shallow unconsolidated sediments. However, in some cases where bedrock outcrops or lies just meters below the surface, fractured rock hydrogeologic systems occur. In the latter case, any significant groundwater flow occurs in fracture systems within the bedrock. If soils are fine grained (i.e., tills or clays), fractures may also play a dominant role in advective flow.

The study of fluid flow through porous media was first established by Henri Darcy in 1857. Much of the science of hydrogeology was developed with and was designed for use in granular porous media because of the incentive to find and produce aquifers for large-scale groundwater consumption. It took almost 100 years before fractured flow was studied in great detail. The study of fluid flow through fractured rock was first developed by the petroleum industry in the 1950s (1). These petroleum studies resulted from observations that oil and gas production could be significantly increased by fracturing the oil-producing formations near the well bore (2). Fractured media in most instances will not produce groundwater on the same scale as homogeneous granular aquifers. Fracture flow systems are also more complex to analyze and hydraulically respond differently than do those in porous granular matrices. A good overview of contaminant transport in fractured media is presented in Schmelling and Ross (3).

To compare groundwater flow in fractured rock systems with granular media, under identical hydraulic gradients, one square meter of granular material with a hydraulic conductivity of 8.1×10^{-2} cm/s has the equivalent water-conducting capacity of one fracture in one square meter of rock with an aperture of 1 mm. In granular media, grain size, shape, and degree of sorting are the prime microscale parameters that determine hydraulic character. Fracture density, orientation, aperture, and type of rock matrix are the major parameters affecting groundwater flow in fractured media. The typical range for fracture aperture is from 0.2 to 25 mm, and fracture spacing is from 2 mm to 3 m.

Individual fractures are not infinite in extent. Therefore, where flow is supported, fracture density must be high enough to ensure connectivity through the system. The fracture density required to sustain advective flow is termed the “percolation threshold.” Below that threshold, fractures may be connected, but only in small localized regions. Above, localized regions become interconnected, and flow over significant distances can take place. With an increase in fracture density, the system becomes increasingly previous.

An expression of the parameter that determines the percolation through fracture is $N(L_F)^2$, where N is fracture density and L_F is equal to fracture length times pi/2. The percolation threshold has been found to fall around 0.3.

As an example, in an area underlain by metamorphic rocks with discrete water-producing fracture systems:

- Fractures were approximately 0.5 m in length
- Rocks with a fracture density of 50 to 200 per 0.5 m

This process gave values of NL_F^2 of 30 to 120, well above the percolation threshold of 0.3.

Given adequate connectivity, the flow an individual fracture can support is proportional to the cube of the fracture aperture. This cube rule means that a few fractures with preferentially higher apertures can dominate the flow system, and those are the ones most important to delineate. Typically, fracture aperture will decrease with depth. Usually the highest flow rates occur in the upper 9 m of a fracture system, with flow decreasing to near zero below depths of 30 m.

To some degree, all rocks or soils are reactive. In most igneous, metamorphic, or fine-grained sedimentary rocks, geochemical reactions tend to seal a given fracture over time. In carbonates, the opposite can be true, with the fracture aperture increasing with time (and the potential flow rate increasing with the cube of that aperture). The hydrodynamics of fracture flow systems will approach those in porous media in systems where fractures are randomly oriented and density is high. These systems can be analyzed with conventional granular media methodologies. To use those methods on other fracture systems is an error with potentially significant consequences.

Characterization of a fracture flow system is potentially an expensive process. Ideally, data should be gathered on fracture length, orientation, aperture, and density. Additionally, information on hydraulic head, the porosity and hydraulic characteristics of the bulk matrix, the type of contaminants, and the potential interactions between contaminants and the matrix are also important. Hydrogeologic characterization of fracture systems can be accomplished through coring, complex pumping tests, tracer tests, geophysical evaluation, or bore hole flow meters. In addition, evaluation of the hydrodynamics of a fracture system that has been defined with multiple orientations is mathematically extremely complex.

However, some level of useful knowledge can be inferred based on the structural setting of a site. The tectonic and depositional history of a given site is generally available in the geologic literature. The removal of overburden introduces stresses caused by reduction of overburden pressure, uplift of the region, and thermal stresses caused by cooling; the net stress is extensional.

Fractures that form in the tensile stress field can be placed into two classes:

- Unloading fractures, which include vertical fractures, indicating response to tensile stress in the horizontal plane and fractures horizontal or parallel to the topographic surface
- Release fractures that are fabric controlled in their orientation.

If a site has undergone even a mild degree of tectonic deformation, structural analysis can be a powerful predictive tool for the orientation of the dominant fracture sets at a site. Several points are important to use this concept:

- The deformational pattern observed in the large scale is replicated at medium, small, and microscopic scales. For example, the NE trend of the Appalachians is generally reflected as an NE-oriented fabric at all scales.
- Deformation imparts a fabric to the impacted rocks. This fabric imparts anisotropicity, which in turn will control subsequent fracture generation. For example, fractures will tend to propagate perpendicular to a strong linear fabric element.
- The stronger the degree of imprinted fabric, the greater the density of fractures in the controlled orientations.
- Depositional features such as bedding planes also impart anisotropic fabric.

Important differences exist between fractured and porous media with regard to contaminant fate and transport. Rapid transport in preferred directions can occur through rocks that normally would be thought impervious, such as bedrock fractured flow systems. Because of the general lack of organics in fractured rock systems, the flow of organic chemicals traveling through fractured rock systems is generally not retarded as much as in organic-rich granular sediments. Retardation is a function of matrix and contaminant chemistry and surface area. As an estimate, a block of granular media, such as well-sorted sand or gravel, will have a surface area 1000 to 100,000 times greater than a similar block of fractured media, such as fractured limestones or granites. Contaminant retardation will be roughly proportional. Contaminants in fractures can be mobile over long distances or until they are transported into a granular media.

Fractured rock systems create interesting challenges as well as opportunities. When drilling contaminant recovery wells in fractured terrain, it is suggested to orient the well bore such that it is perpendicular to the major water-bearing fracture set. The resulting well may not necessarily be vertical, but it will maximize the potential to intersect flow-bearing fractures, which allows for more complete contaminant removal.

HORIZONTAL WELLS

Milovan Beljin
Cincinnati, Ohio

Horizontal wells are a new technology for solving problems in the environmental industry. Due to interest in horizontal wells for oil production, a large number of technical papers have been published regarding the reservoir engineering aspects of horizontal drilling and reservoir simulation. In the groundwater supply industry, the first theoretical analysis of groundwater flow to horizontal drains (collector wells) can be traced back to the early 1960s. In recent years, however, there has been renewed interest in horizontal wells for subsurface remediation. Horizontal wells offer significant advantages over vertical wells in environmental remediation and protection in many hydrogeologic scenarios. Horizontal well-screen orientation complements common site logistics, typical aquifer geometry, and groundwater flow patterns. A single horizontal well can replace many closely spaced vertical wells.

The logistical advantages of horizontal wells are obvious. Horizontal wells avoid the need for installing wellheads inside buildings or in the midst of complex manufacturing or process facilities. Landfills, spoil mounds, and landfill liners need not be penetrated to extract leachate or other underlying contaminants. In addition, contaminant concentrations are often highest directly beneath buildings, landfills, and other obstacles to remedial operations, so that treatment facilities are constructed tens or hundreds of feet away from the target zone of remediation.

Soils are naturally stratified and individual aquifers or water-bearing zones are much wider than they are thick. Despite the dominance of the horizontal direction in aquifer shapes and groundwater flow, the dominant tool for extracting contamination from subsurface sources is a vertical well. However, in many environmental remediation scenarios, a horizontal well offers a better match of form and function than a vertical well. The tabular geometry of many aquifer zones renders horizontal wells more productive than vertical wells. The flow characteristics of many aquifers create elongate contaminant plumes, and extracting contaminated groundwater is often more efficient using horizontal wells. A horizontal well placed through the core of a plume can recover higher concentrations of contaminants at a given flow rate than a vertical well.

Horizontal wells also offer many advantageous over vertical wells in fractured aquifers. Fractures in an aquifer are commonly vertical. Because fluid or vapor recovery from fractured zones requires penetration of numerous fractures, a horizontal well oriented normally to vertical fractures is the optimal tool for pump-and-treat or soil vapor extraction systems in vertically fractured zones. By analogy, vertical wells are efficient in highly stratified soils that have little vertical communication between strata, where fluid or vapor recovery from many thin layers through a single wellbore is required.

Injection of groundwater is part of some remediation systems, either to create a water table mound or to reinject treated effluent from a manufacturing plant into the subsurface. Water table mounds can help control flow of contaminants toward recovery wells or trenches, or they can serve as hydraulic barriers. Manufacturing plants can avoid high sewer discharge costs if their treated plant effluent can be reinjected into a nondrinking water aquifer. Reinjection can cause mounding, but the mounding can be minimized by using horizontal wells. Hydraulic barriers are most efficiently created using horizontal wells oriented perpendicularly to the groundwater flow direction.

Various drilling technologies are capable of installing horizontal wells for subsurface pollution control. Such wells are typically installed in unconsolidated soils, 10 to 200 feet deep. Selection of drilling technique depends on surface access, well placement and completion requirements, and subsurface hydrogeology. During drilling of a well, drilling mud can invade the aquifer and change its permeability in the vicinity of the well and cause formation damage or a “skin effect.” The thickness of the skin zone depends on drilling technology and also on the permeability of the aquifer. The additional drawdown due to the change in permeability and the turbulent flow around the well is called “well losses.” Because of lower flow rate per unit screen length, horizontal wells show smaller well losses due to drilling mud invasion than vertical wells.

The current high installation cost of a horizontal well compared to that of a vertical well is offset by operating and maintenance cost savings. New developments in horizontal drilling technology will further reduce the cost of installing horizontal wells, and subsurface pollution control using horizontal wells should become as common as using vertical wells.

HORIZONTAL WELLS IN GROUNDWATER REMEDIATION

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

Horizontal wells have been used in an increasing number of remediation projects. In addition to chemical and biological reactive barriers, horizontal borings can be used for groundwater extraction and control, air sparging, bioremediation, groundwater injection, for vadose zone soil vapor extraction or bioventing systems, and free product recovery. Although, in areas where there is a great deal of fluctuation in the groundwater table, use for free product recovery can be problematic.

Horizontal well technology was first used in the late 1920s by the petroleum industry to increase oil reservoir thickness per well and greatly increase oil production. In the 1970s, the technology was applied by utility companies to cross rivers and other natural or manmade barriers such as highways. The use of horizontal drilling technology for environmental applications began in the late 1980s and has escalated ever since.

Horizontal wells offer distinct advantages over trenching or vertical wells. Trenching produces massive quantities of excavation spoils and is economically limited in depth of application. In addition, horizontal wells can be installed beneath structures and other surface obstructions that would be impossible to access using trenches or vertical wells.

Horizontal wells have a unique advantage that originates in the geometry of the typical contaminated groundwater system. Horizontal permeability is on the order of ten times greater than vertical, because of the stratigraphic layering of near-surface soil horizons. The effect of increased horizontal permeability enhances the spread of contaminant plumes horizontally. Horizontal wells can be installed through contaminated zones, along their leading edges, or along a property line. All active groundwater remediation systems rely on the mass transport of water, air, or other chemicals. Mass transport is induced through the interface offered by the screened sections of a well that are exposed to the contaminated strata. Compared with vertical wells, horizontal wells can increase well screen interface by an order of magnitude or more.

Various drilling heads and cutting removal technologies have been applied to horizontal drilling. Fluid-cutting systems, mechanical cutting, augers, percussion drilling, and sonic methods are all available. The selection of which is dependent on the geology and competency of the subsurface (and the selected technology vendor). With appropriate techniques, bore holes may be extended through difficult conditions such as gravel formations, coral reefs, and even boulders or bedrock.

The removal of cuttings is usually based on mud slurry systems for installation beneath the groundwater table and air systems for installation in the vadose zone. The formulation and engineering of a mud slurry system takes great care; historically this has been one of the most common points for the failure of an installation. The mixture must be capable of holding the hole open, removing the cuttings without erosion of the walls of the well bore, and it must be capable of decomposing with time to restore the well bore to permeable operation.

Inherent with the horizontal drilling process is the ability to accurately direct the placement of the horizontal well bore. Two dominant methods of achieving directional control of the drill head are available: magnetometer/accelerometer and radio beacon. A magnetometer/accelerometer array is expensive, and the long configuration of an array makes it prohibitive for short radius bends. It is also subject to magnetic interference, which can be a serious issue around tanks or other surface or near-surface structures (i.e., buildings, piers and piles, pipelines, or utility runs). Radio beacons previously have been limited to a depth of 25 feet or less, although there have been instances where down hole wirelines have increased accessible depth. Well casings for horizontal wells must be more highly engineered than for vertical wells. They must have great tensile strength to withstand the significant forces associated with installation. Compressive strength is required to resist the overburden load as the horizontal well bore collapses with time. The screen pack is also a critical issue with regard to installation and subsequent operational efficiency. Conventional sand packs can be installed, but they require great care. Many vendors now use prepacked screens. These are nested screens, an exterior screen (typically HDPE), a packing system (sand, filter cloth, or other filter media or mixtures of media), and an internal screen typically constructed of stainless steel. These prepacked screens are stiffer and subject to larger turn radii, but they obviate the difficulties associated with installing a conventional sand pack in a horizontal boring.

Horizontal drilling is a relatively costly process to use. It is driven by necessity, or the economic advantages of scale. Necessity drivers are generally the need for the installation of a remediation system underneath a structure or facility that cannot be disturbed. Economics of scale come in to play with regard to large contaminant plumes. A single horizontal boring can replace 10 to 30 vertical wells in a plume of large aerial extent. The break-even point for the choice between horizontal or vertical wells occurs around the need for four to five vertical wells. Installations requiring more than five vertical wells along a linear trend can often be more cost effectively addressed with horizontal wells.

Two basic methods of horizontal well installation are available. The simplest involves two ends, boring downward to near the desired depth at one end, curving the boring to the horizontal, traversing the required path and distance horizontally, and then recurving to the surface at the other end. The casing is then pulled back through the boring from the distal end. A more sophisticated approach is to use a single end, through which the boring is advanced, followed by the casing being pushed through the boring, a more difficult, risky, and time-consuming process. Horizontal drilling using the two-end approach can cost as little as \$30 to \$40 per linear foot; the cost for single-ended systems start at \$80 to \$90 per linear foot.

As with many other technologies applied to the environmental industry, developers over the last decade have focused on the creation of a "just good enough" technology. Placement accuracy is sufficient, boring sizes are minimal, and construction materials are designed for the limited life of the project. Successful installation of horizontal wells depend on the selection of a vendor who is flexible enough to use an approach that is appropriate for the subsurface condition of your site; who is experienced in the use of the specialized drilling equipment and screens; who can engineer the application as well as the installation procedures; and who is experienced enough to be quick. Aside from failure caused by inadequate mud engineering, taking too long is another key source of failure; the well bores simply cave in before installation is complete.

Horizontal wells have been adapted for use in many soil and groundwater projects. The use includes groundwater extraction, air sparging, free product recovery, in situ bioremediation and bioenhancement, soil vapor extraction, in situ soil flushing, in situ radio-frequency heating, treatment walls, hydraulic and pneumatic fracturing, and leachate containment and collection (1). The overall performance of horizontal wells used for air sparging and vacuum extraction at the Savannah River Site in South Carolina (2) shows the following:

- A five-time increase in chlorinated solvent removal as compared with conventional vertical wells.
- Eight tons of chlorinated solvents were removed over a 20-week period. The equivalent would have been 11 vertical wells at a pump and treat system, each extracting at a rate of 500 gallons per minute;

The Savannah River Site project managers estimate that a 40% cost savings was predicted when compared with the use of conventional pump and treat technologies.

In the six years between 1987 and 1993, over 100 horizontal wells were drilled in the United States as part of environmental remediation projects. One quarter of them were used for groundwater extraction, one quarter of them were used for soil vapor extraction, and one half of them were used for other technologies (air injection, bioventing, and free product recovery). Eighty percent of the horizontal wells were installed at depths of 25 feet or less (2).

The advantages of horizontal wells are well known: Horizontal well screens contact a larger surface area of contaminated aquifer than do conventional vertical wells; the cost of horizontal wells, although more than vertical wells, is less expensive when comparing the fewer number of wells required for a particular remediation project; and finally because horizontal transmissivity generally exceeds vertical transmissivity in most aquifers, horizontal wells can deliver and recover more fluids, gases, and groundwater than can vertical wells (1). With these advantages and the improvements in directional drilling and global positioning systems (GPS), it is likely that horizontal wells will become more common in future remediation projects.

HEAD

TODD RASMUSSEN
The University of Georgia
Athens, Georgia

Water moves from zones of higher energy to zones of lower energy. For example, gravity causes water to move from higher to lower elevations. Water also moves from higher to lower pressures. The total energy is the sum of the all forces acting on water. This total energy is referred to as the *head*, which can determine the direction and rate of water movement.

Bernoulli's equation commonly combines the dominant forces that cause water to move:

$$H = z + \frac{P}{\gamma} + \frac{v^2}{2g} \tag{1}$$

where H is the total head, z is the elevation of the point where the head is measured, P is the fluid pressure at the point of measurement, $\gamma = \rho g$ is the fluid specific weight, ρ is the fluid density, g is the gravitational constant, and v is the fluid velocity.

The velocity component can be omitted if the flow is slow, $v \approx 0$, which is generally true in groundwater systems. When the velocity is neglected, the total head is

$$H = z + p \tag{2}$$

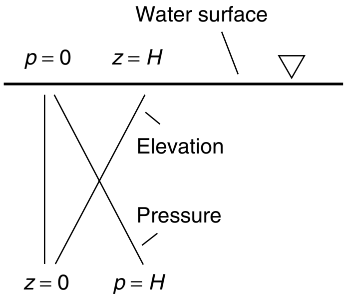

Figure 1. Total head is the sum of the elevation and pressure heads. For example, the elevation decreases and the pressure increases when moving downward from the water surface in a column of still water.

where $p = P/\gamma$ is the fluid pressure head. Figure 1 shows how the pressure head and elevation head compensate in a column of still water.

The pressure term is omitted when the water surface elevation is measured, because the fluid pressure is zero, $p = 0$, at this point. This simplification yields the equation, $H = z$, where z is the elevation of the water surface.

Important assumptions required for the use of water levels to determine the head include (1) hydrostatic conditions exist with no vertical water movement; (2) the water velocity within the aquifer is sufficiently small; (3) water within the monitoring borehole or piezometer is pure water at a standard temperature and density; and (4) the air pressure on the water surface equals the mean barometric pressure.

CAPILLARY AND OSMOTIC FORCES

Capillary and osmotic forces also affect the total head. Failure to account for these forces may result in incorrect predictions of water flow and transport.

Capillary forces develop because of the tendency of soil surfaces to attract water. Water held on soil surfaces resists the downward force of gravity, and it does not readily drain from the soil. The head must consider the negative fluid pressure that develops because of capillary forces. A measure of the force by which water is held is the *matric tension*, which can be measured with *tensiometers*.

Water may move upward above the regional water table because of capillary forces. The height of the saturated zone formed above the water table (i.e., the capillary fringe) is largely determined by the magnitude of capillary forces, which is a function of the pore surface area. Finer grained media have greater capillary forces, which result in higher capillary fringes.

Capillary forces generally increase with decreasing pore size, as shown in Fig. 2. The *capillary rise equation* relates the pore size to the height of rise:

$$\psi = \frac{2\sigma \cos \alpha}{\gamma r} \tag{3}$$

where ψ is the capillary height of rise, σ is the surface tension of water, α is the solid−liquid contact angle, and r is the pore radius (1).

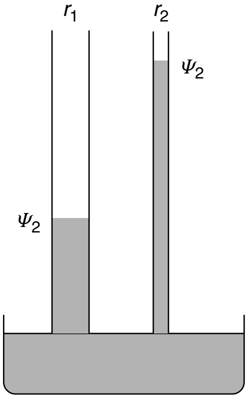

Figure 2. Height of rise of water in capillary tubes. Note that the height of rise increases as the radius of the tube decreases. Equivalently, small pores hold water to greater tensions than do large pores.

An additional force that induces fluid movement is a change in solute concentration. The *osmotic potential* decreases the head of water, which causes water to flow from areas of low solute concentrations to areas where solute concentrations are higher. In arid areas with high soil solute concentrations, salts may become concentrated as water evaporates at the soil surface, which causes an increase in the salt concentration. This increase in salt concentration induces an additional force that causes water to move upward from less saline groundwater to the surface.

Thus, evaporation can increase the height of the capillary fringe by augmenting the capillary force with osmotic forces. The osmotic height of rise in dilute solutions is

$$\phi = \frac{kTC}{\gamma} \tag{4}$$

where ϕ is the osmotic height of rise, k is the Boltzmann constant, T is the absolute temperature, and C is the solute concentration (2).

FLUID DENSITY

Water levels can be affected by the density of the fluid within the borehole. For example, water levels in a well monitoring a deep aquifer may be affected by the temperature of the water in the borehole.

Warmer water is less dense than is colder water (except below 4 °C) and so a column of warm water will display a higher water level than will a column of colder water for the same pressure at the bottom of the borehole. Because of the *geothermal gradient* (the tendency of temperature to increase with depth below the surface), deeper water within the borehole is warmer and slightly less dense than is water near the surface.

Other factors besides temperature affect the water density in a well. The dissolved solids concentration (salinity) causes the water density to increase. Suspended sediments also increase the weight of the fluid, whereas air bubbles rising to the surface lower the density of the water column. Small changes in density over a long water column cause an appreciable difference in observed water levels.

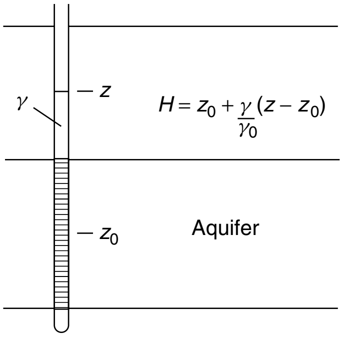

Figure 3. Total head, H, adjustment for conditions when the borehole specific weight, γ, is different from the freshwater weight, γ_o. The effect is greater for larger differences in elevation between the water level, z, and the screened zone, z_o.

To account for the variation in fluid density, observed water levels should be adjusted with a standard water density, called the *freshwater density*. The corrected head is called the *freshwater head*, which accounts for the fluid density within the borehole:

$$H = z_o + \frac{\gamma}{\gamma_o}(z - z_o) \tag{5}$$

where H is the freshwater head, z_o is the elevation of the screened interval, z is the observed water level elevation in the well, $\gamma = \rho g$ is the average fluid specific weight in the well, and $\gamma_o = \rho_o g$ is the standard freshwater specific weight. Figure 3 illustrates the geometry of this problem.

The freshwater head equation can also be written as

$$H = z_o + \varrho\,\Delta z \tag{6}$$

where $\varrho = \gamma/\gamma_o$ is the specific gravity of the fluid within the well and $\Delta z = z - z_o$ is the height of the column of water within the monitoring well above the screened zone.

These equations show that the freshwater head correction is larger for longer water columns and for water with a density that is substantially different from the freshwater density.

SPATIAL AND TEMPORAL VARIATION

Head is often observed to vary over both space and time. These variations are particularly important when mapping the regional potentiometric surface, because long-term averages may not accurately reflect the surface dynamics over time.

Temporal variations result from barometric (atmospheric pressure) influences, tidal effects, fluid density (sediment, salinity) changes, and vertical flow (nonhydrostatic conditions) within the water column (2). Spatial variations are a function of aquifer properties as well as of the regional hydrogeologic flow environment.

Heads within a specific hydrogeologic unit generally vary smoothly over space, unless some kind of intervening boundary causes a jump in the head within the formation. For example, water levels may decline smoothly, only to change abruptly when a fault displaces one side of an aquifer relative to the other, which causes a sharp change in the head across the boundary.

Also, heads in different hydrogeologic units may be different because the recharge and discharge patterns for each aquifer are different. A unit that outcrops in one area may have a different head than one that outcrops at a higher elevation. Wells that tap different aquifers are commonly observed by scientists to have different water levels, even when the wells are situated next to each other. This variation of head by aquifer is a result of the regional hydrogeologic setting, which must be considered when trying to evaluate water head data.

Spatial variations are plotted on maps with *equipotentials*, which are lines of constant head within a hydrogeologic unit. Each aquifer generally has a unique set of equipotentials that can also vary over time. In *isotropic* media (i.e., aquifers with no preferential flow direction), the direction of fluid flow is shown by placing lines, called *streamlines*, on the map that are perpendicular to the equipotentials.

Water levels in wells can also vary over time. Water levels in wells are commonly affected by barometric pressure—they fall as barometric pressure rises, and they rise as the pressure falls—because the total head in the aquifer is the sum of the water level elevation plus the atmospheric pressure on the water surface in the borehole.

Although the influence of barometric pressure is commonly neglected when monitoring water levels in wells, large changes in barometric pressure (such as when large storms pass overhead) can occasionally cause large errors in the determination of the total head.

To correct for the effects of barometric pressure, observed water levels, W, can be adjusted by the variation in pressure about the mean, $\Delta B = B - \overline{B}$:

$$H = W + \Delta B \tag{7}$$

The mean pressure, $\overline{B}$, can be taken as the average global sea-level barometric pressure, $\overline{B} = 1013.25\ hPa \approx 33.9$ ft, or, alternatively, equal to the local average barometric pressure, which varies with elevation and local weather conditions. Air pressure variations can be neglected by sealing the well, or by measuring absolute pressure instead of the gauge pressure within the monitored interval.

Barometric pressure changes cause many wells to fluctuate over short time periods (e.g., from day to day), whereas precipitation, evapotranspiration, and pumping patterns often cause longer term variations. Climatic variation over time also can have a large influence on observed head. In trying to establish a long-term average head for a well, one must consider all possible sources of short- and long-term variation.

WELL HYDRAULICS AND AQUIFER TESTS

John E. Moore
USGS (Retired)
Denver, Colorado

The objectives of an aquifer test are to identify the performance of a well (to estimate the yield capability) and to estimate aquifer properties. Accurate estimates of the hydraulic characteristics of aquifers depend on reliable aquifer test data. The tests are done on existing wells or a well drilled specifically for that purpose. An aquifer test is a controlled, field site experiment to determine hydraulic conductivity and aquifer storage. The test consists of measuring groundwater discharge and observing water level changes in the pumped well.

These are the hydrologic and geologic conditions needed for a successful aquifer test:

- Hydrogeologic conditions should not change over short distances.
- No discharging well or stream nearby.
- Discharge water should not return to the aquifer.
- The pumped well should be completed to the bottom of the aquifer and should be screened or perforated through the entire thickness of the aquifer.
- Observation wells (at least three) should be screened at the middle point in the aquifer. One observation should be located outside the area of influence of the pumping well drawdown.
- Location of observation wells should be based on the aquifer character.
- Determination of prepumping water-level trend.

The following conditions and field measurements are needed for an aquifer test:

- Accurate water-level measurements during pumping and recovery
- Pumped well developed prior to test (several hours of pumping and surging)
- Dependable power source to provide a constant pumping rate
- A flow meter that can read instantaneous and cumulative discharge
- Electrical conductance, Eh, pH, DO, and temperature measurements
- Water levels measured several hours before the test begins
- Pumping rate maintained at 5% tolerance. An optimal rate is 50% of maximum yield
- Water level is measured with an electric sounder or pressure transducer
- Remove the discharge water from the site

- Observation wells should be tested by injecting a known volume of water and measuring the recovery response
- Establish baseline trends of regional water level changes and barometric pressure changes
- Pumping well lithology and construction data

TYPES OF TESTS

Specific Capacity Test

The amount of water that a well will yield can be determined by a specific-capacity test, in which the pumping rate and water-level changes are monitored for a set period of time. The first step is to measure the initial water level in the well. Commonly, a well is pumped at several successively increasing rates for uniform periods (typically 1 hour) to establish a rate that can be maintained for long-term pumping. The well is then pumped at a steady rate and the water-level changes are monitored at the pumped well. Water levels should also be monitored in at least one observation well 2 to 20 meters (6 to 65 feet) from the pumped well. The water level will decline quickly at first, as water is removed from the well, then more slowly as the rate of flow into the well approaches the pumping rate. The ratio of the discharge rate (Q) to water-level change (drawdown, dd) gives the well's specific capacity, or $\mathrm{Sc} = Q/\mathrm{dd}$. For example, if the discharge rate is 6 liters per second (L/s) (100 gallons per minute) and the drawdown is 3 meters (10 feet), the specific capacity of the well is 2 L/s per meter (10 gpm/ft) of drawdown. Once the specific capacity and the available amount of drawdown are known, the yield of the well can be determined from the formula $Q = \mathrm{Sc} \times \mathrm{dd}$. The pump should be deep enough that the water level does not go below the pump intake. The pump depth should also be sufficient to allow drawdown caused by pumping and natural declines in water level during periods of drought

Step-Drawdown Test

The step-drawdown test evaluates the performance of a well. Well performance can be affected by resistance to flow in the aquifer itself; partial penetration of the well screen, incomplete removal of mud from the gravel envelope, or invasion of fines into the envelope; and blockage of part of the screen area. The well should be developed prior to the test using a surge block and/or pumping until the well discharge is clear In this test, the well is pumped at several (three or more) successively higher pumping rates, and the drawdown for each rate is recorded. The test is usually conducted for 1 day. The discharge is kept constant through each step. The test measures the change in specific capacity. The data provide a basis to choose the pump size and discharge rate for the aquifer test and for long-term production.

Slug Test

In this test, a small volume of water is removed from a well, or a small volume is added and the recovery of the water level is measured. The aquifer transmissivity can be determined from the time–drawdown or recovery data. The disadvantages of the test are that a data logger is needed to measure water-level changes and water removed represents only a small volume of the aquifer. Slug test data are evaluated by the Bower and Rice (1) method for unconfined aquifers and the Cooper, Bredehoeft, and Papadopulos (2) method for confined conditions. The advantages of these tests, compared to those of full aquifer tests with observation wells, are reduced cost and time. The disadvantage is that a storage coefficient is not determined and only a small volume of the aquifer is sampled. Many factors contribute to error in slug tests as follows: entrapped air, partial penetration, leaky joints, and the radius of influence of the test.

ANALYSIS OF AQUIFER TEST DATA USING THE THEIS EQUATION

The Theis equation (3) is used to determine the hydraulic characteristics of an aquifer. In this test, a well is pumped, and the rate of decline of the water level in nearby observation wells (two or more) is noted. The time drawdown is then interpreted to yield the aquifer parameters. In 1935, C.V. Theis (3) developed the first equation to include pumping time as a factor (4). The following are assumed:

1. The pumping well is screened only in the aquifer being tested.
2. The transmissibility of the aquifer is constant during the test to the limits of the cone of depression.
3. The discharging well penetrates the entire thickness of the aquifer, and its diameter is small compared to the pumping rate.

These assumptions are most nearly met by confined aquifers at sites far from the aquifer boundaries. However, if certain precautions are observed, this equation can also be used to analyze tests of unconfined aquifers (5).

HYDRAULIC PROPERTIES CHARACTERIZATION

WALTER W. LOO
Environmental & Technology Services
Oakland, California

Groundwater is becoming an important issue as a source of fresh water. The groundwater that exists at the subsurface is called an aquifer. An aquifer is a geologic unit that can store and transmit water at rates fast enough to supply reasonable amounts to wells. Thus, understanding a groundwater body is an essential factor in groundwater development and protection.

The geohydrologic properties of a groundwater body consist of physical, chemical, and biological parameters of the solid matrix and liquid within its pore space. These parameters determine the quantitative, qualitative, and interpretive aspects of the groundwater body. The solid matrix may consist of various sedimentary deposits or rock types. The liquid within the pore space of the groundwater body consists of water, dissolved minerals and gases, microorganisms, and colloidal material.

INTRODUCTION

Many groundwater professionals define a groundwater body by its flow property, such as aquifer, aquitard, and aquiclude (1), which is only good in defining the rate of water yield from a groundwater body. When dealing with water quality and environmental issues, we need better definition of the other properties and characteristics, not just dissolved chemicals, hydraulic conductivity, and effective porosity.

The following parameters characterize groundwater body properties:

Geophysical parameters: electrical conductivity, hydraulic conductivity, storativity, effective porosity, temperature, media thickness, pressure or hydrostatic level, adsorption, absorption, radioactivity, electrical charge, electrokinetic flow, porous or fracture media, recharge, discharge

Biochemical parameters: pH, bacteria counts, inorganic chemicals, organic chemicals, oxidation/reduction, ion exchange potential

Most of these parameters are not required for site characterization by natural resources agencies and the U.S. EPA (2,3). It is very clear that most groundwater bodies are poorly characterized because there is no incentive or pressure to understand these parameters, as long as the groundwater is fit for use. Most textbooks define only some of the parameters but without standardized procedures. The following sections provide typical definitions of the parameters, analytical methods, use, interpretation, limitations, and the necessity for future improvement in characterization.

PARAMETER DEFINITIONS

The definitions of the following parameters are provided in Driscoll (4), Freeze and Cherry (1), Todd (5), Lohman (6), and Batu (7), Ferris et al. (8) Loo et al. (9) unless otherwise noted.

Geophysical Parameters

Electrical conductivity is the ability of a medium to conduct electricity measured in μmho/cm. Resistivity is the inverse of electrical conductivity measured in ohm-meters.

Hydraulic conductivity is the measurement of the ease of water flowing through a medium or water permeability. It is often expressed as cm/s or gpd/ft^2.

Storativity of a saturated aquifer is the volume of water release from storage per unit surface area per unit decline of hydraulic head.

Effective porosity or flow porosity is the interconnected pore space available for water to flow through (10).

Media thickness is defined as the aquifer thickness or productive water-bearing zone.

Potentiometric surface is expressed as the pressure in the water head in a confined aquifer. It is called the groundwater table when the aquifer is unconfined.

Adsorption/Absorption is the process by which molecules of dissolved chemicals in a fluid attach to solid surfaces (11–13).

Radioactivity is the radiation emitted by natural elements or radioactive wastes. Radon and tritium are commonly occurring radioisotopes of uranium or other radioactive elements (14).

Electrical charge is measured as the electrical potential difference (in millivolts) between layers of different materials. Fine-grain material such as clay and silt are slightly positively charged whereas sand and gravel are slightly negatively charged.

An **electrokinetic gradient** occurs when a flow of water is created by dc electricity flow from an anode to a cathode (1,15). It is common to create several feet of water head at the cathode when the applied direct current potential difference is 50 volts over a short distance of 40 to 50 feet between electrodes.

Recharge/Discharge Boundaries can be detected during a pump test when the drawdown curve becomes flat, recharge condition and change (steepened) slope, negative or discharge condition (16). Pumping near a surface stream can often detect a recharge condition. Pumping near a fault or lithologic discontinuity can often detect a negative boundary condition.

Biochemical Parameters

pH is an indication of the acidity or alkalinity of soil or water.

Bacteria count is the enumeration of the population of indigenous bacteria in soil or water which often is expressed in colony forming units, CFU (17).

Inorganic Chemicals are any chemicals not based on carbon such as any salts of major cations and anions and trace metals.

Organic Chemicals are carbon based compounds and can be naturally occurring or occurring as spilled chemicals.

Oxidation/Reduction Potential redox potential in short as is the state of electrochemical reaction which is measured in millivolts.

Ion exchange potential is related to the electrical charge measured in millivolts of colloidal particles which carry relatively large surface area. Colloidal particles have diameters in the range of 10^{-3} to 10^{-6} millimeters. Clayey material has very high cation exchange potential.

FIELD TESTING AND ANALYSIS OF PARAMETERS

Geophysical Parameters

Many of the following physical parameters can be defined by field pump tests:

electrical conductivity
hydraulic conductivity
storativity
effective porosity or flow porosity
temperature
radioactivity
media thickness
pressure or hydrostatic level or potentiometric surface
porous or fracture media
recharge/discharge boundaries

Pumping Test. Before a pumping test is conducted, geological and hydrological information such as the geological characteristics of the subsurface, the type of aquifer and confining bed; the thickness and lateral extent of the aquifer and confining beds, including boundary conditions, is obtained, preferably by surface resistivity and electric logs. Also, data on the groundwater flow system, including the hydraulic gradient and regional groundwater flow and existing wells in the area, should be collected. Then, the site for the well is selected considering the area representative of hydrological conditions, not near railroads and motorways, not in the vicinity of an existing discharge well, or a low water level gradient. After the well site has been chosen, the drilling operation can begin. The pumping well should be drilled to the bottom of the aquifer. Then the pump size and pump type are planned. Besides the well diameter and well depth, the location of the well screen is to be determined. The length of the well screen will largely be decided by the depth at which coarse materials are found. A general rule is to screen the well 100% of the aquifer thickness or full penetration. Partially penetrated observation wells can be used if the distance of the observation is more than 2.5 times the thickness of the aquifer tested, which is true for isotropic and anisotropic aquifer pump tests.

With regard to a pumping rate, too low or too high a pumping rate is not desirable. Too high a rate can produce water loss, and too low a rate may make too gentle a drawdown curve. The water levels measured in observation wells represent the average head at the screen of the observation wells. The measured drawdown responses to be taken during a pumping test are of two kinds, measurements of the water levels in the well and the observation wells and measurements of the discharge rate of the well.

To be practical, each pump test should last no more than one day (1440 minutes), which is enough to cover more than three time log cycles; 10, 100 and 1000 minutes, respectively. Measurements should also be made of the atmospheric pressure, temperature, the levels of nearby surface water, if present, and any precipitation. A longer duration pump test is good only for the analysis of boundary conditions (16). Drawdown data for the time period to overcome well bore storage should not be plotted for analysis.

A step drawdown test should not be conducted because it is a test for well yield and well efficiency for well drillers' use and not for the analysis of geohydrologic parameters (18).

Single Dimensional Pump Test Analysis. The data analysis for the result of the pumping test is dependent on the aquifer conditions such as isotropic or anisotropic aquifer, homogeneous or non-homogenous aquifer, non-leaky or leaky aquifer, confined or unconfined aquifer, confining aquitard, etc. Data analysis also depends on the drawdown condition such as steady state or transient conditions. Before interpreting the pumping test result, conversion of the data into appropriate units and correction of the data for external influences are necessary. The interpretation of the pumping test data is primarily a matter of identifying an unknown system. Theoretical models comprise the type of aquifer and the initial and boundary conditions, which, in a pumping test, affect the drawdown behavior of the system in their own individual ways.

Old fashioned curve matching techniques and computer fitting analysis all have inherent errors such as matching inaccuracy and oversimplified statistical assumptions. Therefore, curve matched analysis results may not be very accurate.

It is more practical to do a pump test analysis on semilog paper using the straight line plot interpretations established by Cooper and Jacob (19) for hydraulic conductivity, storativity, and radius of influence from drawdown versus time and drawdown versus distance semilog plots. The scatter of the data points is also an indication of whether anisotropic or heterogeneous conditions are encountered. An isotropic and homogeneous aquifer will be reflected by subparallel slopes on the drawdown versus time plots for observation wells, and all points on the drawdown versus distance plot will fall on a straight line (only isotropic). If the slopes of the drawdown versus time plots are not subparallel, the aquifer is heterogeneous. If the points on the drawdown versus distance do not fall or fit onto a straight line (scattered), the aquifer is anisotropic or shows a potential preferential flow direction such as channel flow, fracture media, or artificial conduits of migration (20,21).

For aquifer test analysis in unconfined aquifers, the Boulton analytical method will apply for determining hydraulic conductivity and specific yield or storativity (22). New analytical solutions for evaluating the drawdown near horizontal and slanted wells with finite length screens in water table aquifers are presented in Zhan et al. (23). These fully three-dimensional solutions consider instantaneous drainage or delayed yield and aquifer anisotropy.

For the analysis of the leakage property of the confining layers of the aquifer, Hantush (24) developed a semilog straight line analytical method, known as the 'inflection point' method.

Multidimensional Pump Test and Analysis. Two-dimensional horizontal hydraulic conductivity anisotropic tests (major and minor tensor) require three or more observation wells at different distances and orientations from the fully penetrating pumping well (25,26). The Hantush and Thomas analytical method is a hand contouring method which is not very accurate and may require many observation wells. The Papadopulos method requires drawdown data from three or more observation wells at the same elapsed time and a least squares or equivalent numerical fitting technique for an elliptical fit. The fitted ellipse orientation and axes thus define the horizontal anisotropic hydraulic conductivity tensors (20,21) Loo (27).

For the analysis of vertical hydraulic conductivity (not leakage from confining layers), the pump test requires nonoverlapping partially penetrated wells, one pumping well and one or more observation well, located within 2.5 times the aquifer's thickness from the pumping well (28). The pump test procedure for multi dimensional hydraulic conductivity tensors was first conducted in an alluvial deposit at Christensen Ranch in Powder River Basin, Wyoming, at an *in situ* uranium mining test site. Loo et al. (29) conducted a similar test at the Equity/DOE BX *in situ* oil shale project.

All pump test and analysis procedures described were documented in the manual written by Loo (20), Loo (30) and Loo (27).

Effective Porosity Testing and Analysis. No pump test can analyze effective porosity. The specific yield value from pump test analysis provides only a partial characterization because the specific retention is not defined.

Freeze and Cherry (1) described the tracer test analysis for dispersivity and effective porosity. However, the tracer test procedures have not considered retardation of the sorption properties of the solid matrix. The selection of different tracers for different media is an art more than a science because there is no perfect tracer. Therefore, a tracer test for determining effective porosity is not very practical.

The analysis of effective porosity can actually be easily determined (though seldom used) from stressing or loading an aquifer. This can be done by tidal efficiency or barometric efficiency tests or simply by sucking a vacuum on the pump test well. The effective porosity can then be calculated once the storativity is defined by the pump test analysis. Jacob (31) provides an analytical solution for a confined aquifer. Hantush (32) provides an analytical solution for an unconfined aquifer.

Radioactivity can be mapped by a natural gamma ray borehole geophysical log. If an abnormal level of radiation is mapped, then it may be necessary to test for radioisotopes of uranium, radon, and tritium and the level of their radioactivity (14).

Electrokinetic Parameter Testing and Analysis. A resistivity survey can be conducted in boreholes to distinguish the lithologic layering sequence. A surface resistivity survey can define lateral continuity or discontinuity or boundaries (33,34). These geophysical surveying methods provide large areal extent and vertical definition or three-dimensional mapping of the groundwater body.

The electrokinetic gradient was mentioned in only one paragraph in Freeze and Cherry (1). The electrokinetic gradient can be tested between monitoring wells by impressing a dc voltage across the wells (15). The response of the water level rise in the cathode well can be quite large (some times more than 10 feet) between wells 50 feet apart at a modest 50 volts potential difference and 10 amperes of dc flow. However, there is no standard test procedure at this time. This is an evolving field testing technology which may ultimately partly replace the standard pumping test. It may also provide artificially induced desorption and oxidation/reduction environments for contaminant treatment.

Elemental adsorption can be tested for cation and anion exchange capacity on soil samples in the laboratory (35). The amount of adsorbed chemical can be estimated from the Freundlich and Langmuir approximations (11). There is no standardized laboratory test for adsorption/absorption parameters of on organic compounds a fine-grain solid matrix at this time. But these are important properties because for most contaminant mass migration (mostly not very soluble), more than 90% by weight is adsorbed/absorbed by the solid matrix.

Biochemical Parameters

pH
bacteria count (17)
inorganic chemicals
organic chemicals
oxidation/reduction
ion exchange potential

All these parameters can be determined by standardized U.S. EPA laboratory analytical methods for water and wastewater. The redox potential of groundwater was required only recently for evaluating natural attenuation or intrinsic bioremediation.

However, there is very little emphasis on the test procedures for a solid matrix below the groundwater level. Most people treat soil as soil in the vadose zone. There is no requirement for characterizing soil or rock properties underneath the water table (2,3). It is important to understand that the weight of solid matrix underneath the groundwater table represents more than 90% of the total weight. The laboratory procedures can easily be changed to accommodate the characterization of these properties in a solid matrix submerged under groundwater.

USE, INTERPRETATION, AND LIMITATIONS

After the aquifer system's properties are properly characterized, then groundwater use planning and management can be implemented.

Groundwater Resources Use

Groundwater is a limited resource, and it is very easy to overdraw a groundwater system. The result is water shortages, coastal saline water intrusion, and land subsidence. The remedy for the situation is to ensure that the design of the groundwater withdrawal system is within safe yield limits that is, using groundwater at less than the natural recharge rate. Groundwater recharge usually can be expressed as 1 to 10% of natural precipitation. The rate of recharge is dependent on the evapotranspiration rate of the area.

The remedy for saline water intrusion or upwelling is either to pump less or design a water mound or recharge mound near the coastal area (5). It is most unfortunate that, once the aquifer is intruded by saline water, the aquifer will be difficult to clean up by natural dilution.

The remedy for land subsidence is to use surface water to recharge the groundwater during the wet season. This is cyclic recharge and pumping management of a groundwater basin.

Groundwater Pollution, Prevention, and Remediation

Since the U.S. EPA was formed about 30 years ago, groundwater pollution has not stopped. Nitrate pollution due to overfertilization and from feed lots, dairy farms, pig farms, and chicken farms continues unabated. This has resulted in the 'dead zone' at the estuary of the Mississippi River in the Gulf of Mexico. Inland, the Salton Sea and the Kesterson Reservoir in California here become irrigation drainage wastewater catch basins. Farmers and agricultural business are often exempted from environmental protection regulations. Most shallow groundwater in these areas is heavily polluted.

Organic solvents such as PCE and TCE exist at almost all Superfund sites, electroplating shops, dry cleaners, and electronic manufacturing sites. Fuel hydrocarbons containing benzene, MTBE, and PAHs (such as naphthalene in diesel) have reached the groundwater at many groundwater supply sources. Chromium and naturally occurring arsenic are also reaching groundwater supplies. Fortunately, there are cost-effective technologies for cleanup at the source (15).

FUTURE IMPROVEMENTS

As mentioned in the previous sections, there is much room for improvement in geohydrologic characterization. Characterization efforts need large-scale representation area. This will lead to large-scale geohydraulic tests, geophysical surveys, and more in-depth characterization of the solid matrix submerged under groundwater.

New Test Methods

Future geohydraulic tests will most likely replace the aquifer pump test by stressing the aquifer by seismic or electrokinetic methods, so that it is more cost-effective. The mapping of anisotropic flow can be done better by horizontal and vertical resistivity profiling to map these geohydrologic anomalies. Electrokinetic surveys may in the future characterize adsorption, ion exchange, electrical charge properties in situ and have a large areal representation.

Interpretive Techniques

When all is said and done, then it's time to do some real groundwater modeling using real data. There is no doubt that the theory and modeling effort have advanced much further than parameter characterization methods.

After trying for more than 20 years, leaders in geohydrology admitted in the early 1990s that groundwater modeling does not work because of the general lack of real geohydrologic data. Hopefully, groundwater modeling will work in the next decade with real data on hand.

MOBILITY OF HUMIC SUBSTANCES IN GROUNDWATER

Gunnar Buckau
Institut für Nukleare
Entsorgung
Karlsruhe, Germany

INTRODUCTION

Humic substances are a relatively stable part of the global carbon inventory. They are found mainly in solid sources, in both seabed and land sediments. High concentrations are found especially in lignite and peat. The most obvious source is the organic/humus inventory in soil. Humic substances are also found in natural water. The dissolved inventory is relatively small compared to that found in sediments. Nevertheless, this inventory is a key in the mobilization of numerous trace elements and pollutants, which includes the key influence in determining the stability of and interface reactions with minerals.

Some key information on the origin, stability, and mobility of dissolved aquatic humic substances is presented here. Also described are the experimental methods required, the approach for derivation of conclusions from experimental results, and background information. The focus is on the hydrophilic part of the total humic substance inventory. The hydrophilic aquatic humic substances originate from the same source as the stationary less hydrophilic ones, including partial oxidation from this stationary inventory. The hydrophilic nature is given by oxygen-containing functional groups. Some of these, especially carboxylic acids, may change the degree of hydrophilicity depending on physicochemical conditions, that is protonation, metal ion complexation and localization of counterions, pH, metal ion concentration, and ionic strength. Consequently, the whole inventory and changes in physicochemical conditions must be kept in mind when discussing the behavior of the hydrophilic aquatic part.

Humic acid is used both as a collective term for humic substances with a sufficiently high content of hydrophilic groups to dissolve in pH neutral range or specifically for the fraction that is dissolved in pH neutral range and flocculates in the acidic range with the complementary fraction of fulvic acid, soluble also under acidic conditions. Furthermore, a fraction of organic carbon found in soil not soluble in aqueous media (humin) but with some properties common with humic and fulvic acids is also frequently considered part of the overall term. This term may also be considered for rather hydrophobic humic material or humic acid precursor material also in sediments, including peat, lignite, and mineral-bound natural organic substances, such as clay organic matter. Below, humic and fulvic acids are used for the aquatic hydrophilic part of the overall inventory unless otherwise specified.

First, some basic relevant properties of humic substances are discussed. In order to study the origin, stability, and mobility of aquatic humic substances they must be isolated and purified. In order to ensure the quality of results, the success of isolation and purification must be verified by adequate characterization of the sampled humic material. Therefore, isolation, purification, and verification methods of aquatic humic substances are described as a prerequisite for interpretation of experimental results. Also discussed are the origin, stability, and mobility of aquatic humic acid followed by a summary.

BASIC RELEVANT PROPERTIES OF HUMIC ACID

The composition, mass distribution, and functional group content vary within limits, reflecting different origins and histories. Disregarding sulfur and nitrogen (present in varying low concentrations generally on the order of up to around 1% by weight), the atomic composition is dominated by carbon, oxygen, and hydrogen. The contributions of these substances vary around $CO_{0.5}H$; that is, the formal oxidation state of carbon is around zero. With respect to aquatic humic and fulvic acids, the mass distribution centers around approximately 500 mass units. In dissolved form, the molecules are highly hydrated and possibly form associates. The size distribution is generally determined to center slightly above 1 nm diameter.

Oxygen-containing functional groups and structural entities are abundant, as seen from the elemental composition. These oxygen-containing structural elements are of key importance for the hydrophilic character of humic substances. The oxygen to carbon ratio of aquatic humic and fulvic acids is somewhat higher than for the bulk sedimentary hydrophobic humic matter. The proton exchange capacity is on the order of 7 meq/g, where protonation/deprotonation takes place from about pH 10 down into the acidic range (below pH 3 a considerable number of the groups are still ionized). There is clear spectroscopic evidence for both carboxylic and phenolic types of proton exchanging groups. Carboxylic types of groups are normally quantified with about two-thirds of the total capacity. The hydrophilic character and thus the stability in aqueous solution, of humic and fulvic acids, vary with pH, ionic strength, and metal ion complexation.

ISOLATION AND PURIFICATION METHODS

Isolation

Isolation of humic and fulvic acids from natural water, including groundwater, is based on sorption chromatography. For this purpose, the XAD-8 resin is used where humic and fulvic acids sorb at low pH. Depending on the humic substance concentrations in the water sample, a pH of typically 1 or 2 will be used, the latter especially in order to limit the total amount of acid where the sample volumes are very large. Elution of both humic and fulvic acids is achieved by desorption at high pH. Typically, HCl and NaOH are used for adjustment of pH. In order to remove salt from the original sample, the column should be washed with HCl solution (pH not higher than that of the acidified water sample) prior to alkaline humic and fulvic acid elution. Where the humic acid concentration is sufficiently high, it, or at least a large part of it, will flocculate at low pH and thus is separated prior to sorption chromatography treatment.

The alkaline elute solution should be taken to pH neutral range within a relatively short time (ideally after not more than around 10 min) in order to prevent alkaline hydrolysis and sample oxidation. If desired, the humic and fulvic acid fractions are separated from each other from this concentrate by acidification, where the humic acid fraction flocculates and may be separated by centrifugation. The so obtained humic and fulvic acid concentrates are then further processed and purified. In many cases, however, preconcentration is desired, especially directly in the field.

The application of RO to humic and fulvic acid preconcentration makes use of the retention of these substances over the RO membrane. The retentate, containing salts, particles, and the humic and fulvic acids, is recirculated as long as practical with the clean water from penetration of the membrane being discarded. With increasing retentate salt concentration, the permeation of clean water through the RO membrane is decreased and finally ceases for all practical purposes (pressure buildup). Therefore, the level of preconcentration that can be obtained by RO depends on the salt content of the original water sample. Furthermore, where Ca ions and carbonate are present, calcite will precipitate unless the sample is slightly acidified and carbonic acid released. The concentrate obtained by RO is then treated by XAD-8 chromatography as described above, resulting in further sample concentration and removal of salt.

Purification

Purification has a number of objectives, including removal of organic and inorganic contaminants such as salt, complexed metal ions, and inorganic mineral constituents. For the purpose of dissolving Si-based minerals, NaF is added and the samples are left for typically 24 h. With respect to humic acid, subsequent purification is relatively simple. Humic acid is flocculated in HCl (pH 1) and centrifuged, and the supernatant is discarded, followed by dissolution in weak NaOH. The cycle is repeated until the flocculate is finally washed with HCl until no Na (from NaOH) is found. The sample is then in its protonated form and is brought to the final product by freeze-drying.

The fulvic acid does not flocculate at low pH and thus the procedure is more tedious. The fulvic acid is sorbed/desorbed on XAD-8 in a number of cycles. Finally, the slightly alkaline solution is acidified and protonated by cation exchange chromatography. The protonated fulvic acid in its final form is then obtained by freeze-drying of this solution.

The method described has successfully been applied for isolation of about 200 mg fulvic acid from about 10 m^3 of groundwater. Subsequent analysis was successfully used for ^{14}C dating and determination of general characteristic properties (1). Details on the isolation and purification of humic and fulvic acids, including description of the RO technique, can be found in Artinger et al. (2).

Verification

Verification of the purity of humic and fulvic acids is done by characterization of the final products. It should also be borne in mind that trust in published results on the mobility of humic and fulvic acids requires evidence for successful separation and purification from the source. Characterization of humic and fulvic acids can be done by a broad spectrum of methods. For the purpose of study concerning the present topic, the quality of the samples needs to be demonstrated by a minimum of characterization methods. The elemental composition, the concentrations of inorganic constituents, and UV/Vis and IR spectra should be compared with expectation values from the literature.

Inorganic constituents will be exhibited if inorganic minerals and complexed metal ions are removed to an acceptable level. The UV/Vis absorption increases uniformly with decreasing wavelength and the logarithm of the absorption should be close to linear with the wavelength. For fulvic acids the absorption ratio of 300–400 nm is expected to fall in the range between about 5 and 8 (abs. units/g and cm), whereas the values for humic acids are lower and are expected to fall around 2.5–4. These indicators show whether the UV/Vis absorbing carbon inventory is in agreement with humic and fulvic acids.

IR spectroscopy shows a number of characteristic bands. Comparison to published spectra will reveal if there are considerable amounts of non-UV/Vis absorbing organic contaminants. Presence of such contaminants may also be identified by strong deviation from an atomic ratio around $CO_{0.5}H$.

For the purpose of determining the origin and age of humic and fulvic acids, the ^{14}C concentration is essential. In this context the ^{13}C concentration is a good indicator for possible contaminants. The ^{13}C concentration should be close to −27‰ (rel. PDB) for C-3 plant cycle origin and around −13‰ for C-4 plant cycle origin.

Again, only if a sufficient purity of the isolated substances is demonstrated can the results be considered trustworthy.

ORIGIN, STABILITY, AND MOBILITY OF AQUATIC HUMIC ACID

Determination of the origin, stability (with respect to decomposition and sorption), and mobility of aquatic humic and fulvic acids in groundwater is based on several indicators. The origin can be determined based on ^{14}C content, functional entity distribution, and general information on climatic conditions, vegetation history for soil recharge, and sedimentary and groundwater composition. Another important indicator is the cogeneration with dissolved inorganic carbon (DIC) of biogenic origin, where deviations from such a correlation show that either the DIC or the humic and fulvic acid inventory deviates from ideal tracer transport and stability behavior.

Origin

The principal origin of humic and fulvic acids is plant material. In sea sediments, marine organisms may also play a role. From the viewpoint of aquatic humic and fulvic acids in a groundwater, two principal sources may be distinguished. These are introduction from the soil zone with recharge groundwater and *in situ* generation by conversion of organic sediment material. In the former case, the source term will depend on climatic conditions and the type of vegetation, including extensive vegetation versus, for example, intense modern agriculture and land conditions such as wetland and peat deposits. In the case of *in situ* generation, an oxidizing agent and partial oxidation of the hydrophobic source material by microbial activity are required (3,4).

The different origin can be distinguished by some characteristic properties and especially the ^{14}C content (5). In aquifer systems where the groundwater residence time is sufficiently low, compared to the half-life of ^{14}C (57,300 years), the ^{14}C content of recharge humic and fulvic acids is that of the soil recharge source. Numbers deduced for fulvic acid for conditions prior to nuclear atmospheric testing are around 55 pmc (percent modern carbon) (5), basically the same as for the cogenerated dissolved inorganic carbon of biogenic origin (6). Depending on local conditions, however, this value may vary. One example is modern agriculture, where the turnover of the organic soil inventory may be higher and thus the ^{14}C concentration is higher, reflecting the lower average residence time. The ^{14}C concentration of fulvic acid and cogenerated DIC from *in situ* generation is basically zero. The relative fractions of *in situ* generated and recharge originating fulvic acid can be deduced by the overall ^{14}C concentration (5).

Another important indicator for the origin of aquatic humic and fulvic acids is the concentration varying with recharge conditions. Drainage of wetland results in a decrease in the inflow of both aquatic humic and fulvic acids and the cogenerated dissolved inorganic carbon of biogenic origin (7), which is an indicator of changes in the land use and also of changes in climatic conditions with a drastic impact on land structure and vegetation. Recharge humic and fulvic acids can only be found in water originating from areas with vegetation. For this reason, the absence of humic and fulvic acids is an indicator for vegetation free recharge conditions, also indicative of climatic changes.

In one study ^{14}C groundwater dating on the DIC indicated ages well beyond 15,000 years for the most distant part of the groundwater flow system (1). Not only did the ^{14}C concentration of fulvic acid show that these age determinations were wrong, but also the pure presence of fulvic acid showed that the groundwater at the end of the flow path could not be older than 15,000 years. The reason is that, in this area, vegetation started to develop around 15,000 years ago at the decline of the Pleistocene conditions.

Some characteristic properties of aquatic humic and fulvic acids reflect their origin. Both spectroscopic properties and basic functional entity distribution are sufficiently insensitive to the physicochemical environment to retain origin-related properties, which is especially true for the ^{14}C content, which solely depends on the concentration upon their generation and subsequent decay with a half-life of approximately 5730 years. Extraction of hydrophilic humic and fulvic acids from clay sediments revealed that the distribution of functional entities and photodynamic behavior vary with marine and terrestrial origin of the clay sediments (8,9). Other characteristic properties reflect chemical reactions of functional groups, especially redox reactions. It should thus be kept in mind that not all characteristic properties can be used as indicators for the origin of aquatic humic or fulvic acid. The content and redox state of sulfur functional entities partly reflect the redox conditions and presumably also the microbial sulfate reduction as part of the in situ generation process (5).

Stability and Mobility

In groundwater systems where the in situ generation is negligible, the fulvic acid inventory is given solely by recharge and possible follow-up geochemical reactions. Where the residence time is considerable compared to the half-life of ^{14}C, the age of the fulvic acid can be determined. A linear increase in ^{14}C age of fulvic acid with flow distance from recharge was found, with the maximum age of fulvic acid of about 15,000 years (cf. above and Ref. 1). The agreement with groundwater flow velocity calculations and the age of fulvic acid shows that the fulvic acid has an ideal tracer transport behavior over this time period, which is direct evidence for the stability and mobility with an ideal tracer behavior of aquatic fulvic acid over 15,000 years.

In the case of *in situ* generation of fulvic acid, the quantification of the recharge originating inventory by ^{14}C content and supporting spectroscopic and composition information is required. The outcome of one study is that in situ generated fulvic acid is flocculated in deeper brines, whereas the recharge originating fulvic acid remains stable in the brines. Both the conserved ^{14}C concentration and structural entity content by C-XANES show that the fulvic acid in the deeper brines (200–250 m depth) originates from recharge. The flocculation of in situ generated fulvic acid in the high ionic strength brines is shown to be the result of their less hydrophilic nature compared to the recharge fulvic acid. The similar concentrations in recharge and in the deep brines show the stability and mobility of these fulvic acids over at least several hundreds years and, furthermore, that the recharge conditions have not changed dramatically within this time period. In addition, the close correlation between the DIC of biogenic origin and humic and fulvic acids in the broad spectrum of groundwater samples shows that there is no considerable decomposition or retention of fulvic acid from either recharge or in situ generation. This correlation is also found for deep groundwater from a former wetland. This shows also that the elevated concentration from this previous source is not subject to sorption or decomposition but the dissolved humic and fulvic acids remain stable and mobile over long time periods (7).

Studies on clay organic matter show that the organic matter sorbed on the sediments are mainly of hydrophobic character and are strongly bound to mineral surfaces. Studies where humic or fulvic acid is in contact with fresh mineral surfaces frequently show strong sorption. The natural situation, however, is that active sites on sediments are coated with organic substances and subsequent introduction of hydrophilic aquatic humic and fulvic acids will behave differently and remain in solution rather than competing with sorbed hydrophobic/sediment bound organic material. Care must therefore be taken when analyzing experimental data that the real situation is reflected. Strong sorption may be expected where a recent increase in the inflow of humic acid/fulvic acid is given, such as a deposit leaking organic material into sediment previously in contact with very low organic carbon concentrations. Under stable groundwater conditions, no indication is given for retention or decomposition of humic and fulvic acids from recharge.

CONCLUSION

With respect to the origin of aquatic humic and fulvic acids, a large number of studies have shown that they are cogenerated with inorganic carbon of biogenic origin from microbial processes and that there is a strong variation in the concentration of humic and fulvic acids in natural groundwater—an indicator for recharge conditions, including climatic changes. With respect to the stability and mobility, there is no indication for decomposition of aquatic humic and fulvic acids under natural groundwater conditions for as long as 15,000 years and no indication for their retardation. An exception is the selective flocculation of less hydrophilic in situ generated fulvic acid in high ionic strength brines.

ASSESSMENT OF GROUNDWATER QUALITY IN DISTRICT HARDWAR, UTTARANCHAL, INDIA

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

The groundwater quality of District Hardwar in the state of Uttaranchal (India) has been assessed to see the suitability of groundwater for domestic use. Forty-eight groundwater samples from shallow and deep aquifers were collected each during pre- and postmonsoon seasons during the year 2002. Various water quality constituents, pH, conductance, total dissolved solids, alkalinity, hardness, sodium, potassium, calcium, magnesium, chloride, sulphate, phosphate, fluoride, total coliforms, and fecal coliforms were determined. The data were analyzed with reference to BIS and WHO standards, and hydrochemical facies were determined. The concentration of total dissolved solids exceeded the desirable limit of 500 mg/L in about 25% of the samples analyzed, but the values were well within the maximum permissible limit of 2000 mg/L. The alkalinity exceeded the desirable limit of 200 mg/L in about 50% of the samples, but these were also within the maximum permissible limit of 600 mg/L. From the hardness viewpoint, about 80–85% of the samples were within the desirable limits. One sample of the study area exceeded the maximum permissible limit of 100 mg/L for nitrate. Other constituents such as chloride, sulphate, and fluoride were within the desirable limits. The bacteriological analysis of the groundwater samples indicated bacterial contamination in about 40% of the samples analyzed. Inadequate maintenance of hand pumps, improper sanitation, and unhygienic conditions around the structure may be responsible for bacterial contamination in groundwater of the region and is a cause of concern. It is recommended that the water drawn from such sources be properly disinfected before being used for drinking and other domestic purposes. The grouping of samples according to their hydrochemical facies indicates that all the samples of the study area fall under $Ca-Mg-HCO_3$ hydrochemical facies.

INTRODUCTION

Water is an essential and vital component of our life support system. In tropical regions, groundwater plays an important role in the context of fluctuating and increasing contamination of water resources. Groundwater has unique features, which render it particularly suitable for public water supply. It has excellent natural quality; is usually free from pathogens, color and turbidity; and can be consumed directly without treatment. Groundwater is widely distributed and can be frequently developed incrementally at points near water demand, thus avoiding the need for large-scale storage, treatment, and distribution systems. It is particularly important because it accounts for about 88% of safe drinking water in rural areas, where the population is widely dispersed and the infrastructure for treating and transporting surface water does not exist.

Unfortunately, the availability of groundwater is not unlimited, nor it is protected from deterioration. In most instances, extracting excessive quantities of groundwater has resulted in drying of wells, damaged ecosystems, land subsidence, saltwater intrusion, and depletion of the resource. It has been estimated that once pollution enters the subsurface environment, it may remain concealed for many years, becoming dispersed over wide areas of groundwater aquifer and rendering groundwater supplies unsuitable for consumption and other uses. The rate of depletion of groundwater levels and deterioration of groundwater quality are of immediate concern in major cities and towns of the country.

The creation of the new state of Uttaranchal has posed many challenges for planners and policy makers. Problems such as drinking water, transportation, power, housing and construction, and safety against natural hazards are very serious and require immediate attention. For sustainable development of a society, it is essential that the natural resources are used judiciously for the benefit of the existing population and also to meet the needs and aspirations of future generations. Drinking water is one such precious commodity for which a planned strategy is needed for immediate demands and also for sustainability for future needs. A large part of the state of Uttaranchal lies in the hills, where distribution of drinking water supply and its quality is a major problem that needs immediate attention. About 90% of the rural population of this region depends on natural springs for their daily water. However, due to population pressure, unplanned construction, garbage disposal, and changes in land use patterns, the water of these springs is becoming contaminated, and the discharge of these springs is declining.

A wide number of activities are associated with, the human introduction of foreign chemical and biological materials into the subsurface environment. In the long run, the most potentially hazardous of these may be the chemical fertilizers and pesticides used in agriculture. But it is possible that tremendous use of chemical fertilizers as plant nutrients may be a more significant problem, causing an increasing buildup of nutrients in some groundwaters. Bacteriological parameters are of great importance from the human point of view. It is essential to examine the presence of toxic substances and pathogenic organisms in potable water. Experience has established the significance of coliform group density as a criterion of the degree of pollution and thus of sanitary quality. The significance of the various tests and the interpretation of results are well authenticated and have been used as a basis for standards of the chemical and bacteriological quality of water supplies. In this article, the groundwater quality of District Hardwar has been assessed to see the suitability of groundwater for drinking, which will provide a proper basis for judicial management of drinking water supplies in the state.

STUDY AREA

District Hardwar, part of the Indo-Gangetic plains, lies between latitude 29°30′ and 30°20′ N and longitude 77°40′ to 78°25′ E in the state of Uttaranchal (Fig. 1). It is the largest district (in population) of Uttaranchal State and occupies an area of about 2360 km^2. Per the 2001 census, the population of District Hardwar is 14,44,213, a population density of 612 per km^2.

Physiographically, the area is generally flat except for the Siwalik Hills in the north and northeast. The area is devoid of relief features of any prominence except for deep gorges cut by gullies and rivers flowing through the area. The area is bounded by River Yamuna in the west and River Ganga in the east. The climate of the area is characterized by moderate subtropical monsoons. The average annual rainfall in the region is about 1000 mm; the major part is received during the monsoon period. The major land use is agriculture, and there is no effective forest cover. The soils of the area are loam to silty loam and are free from carbonates. The most common groundwater use is achieved by hand pumps and tube wells. Based on the lithologic logs and water table fluctuation data,

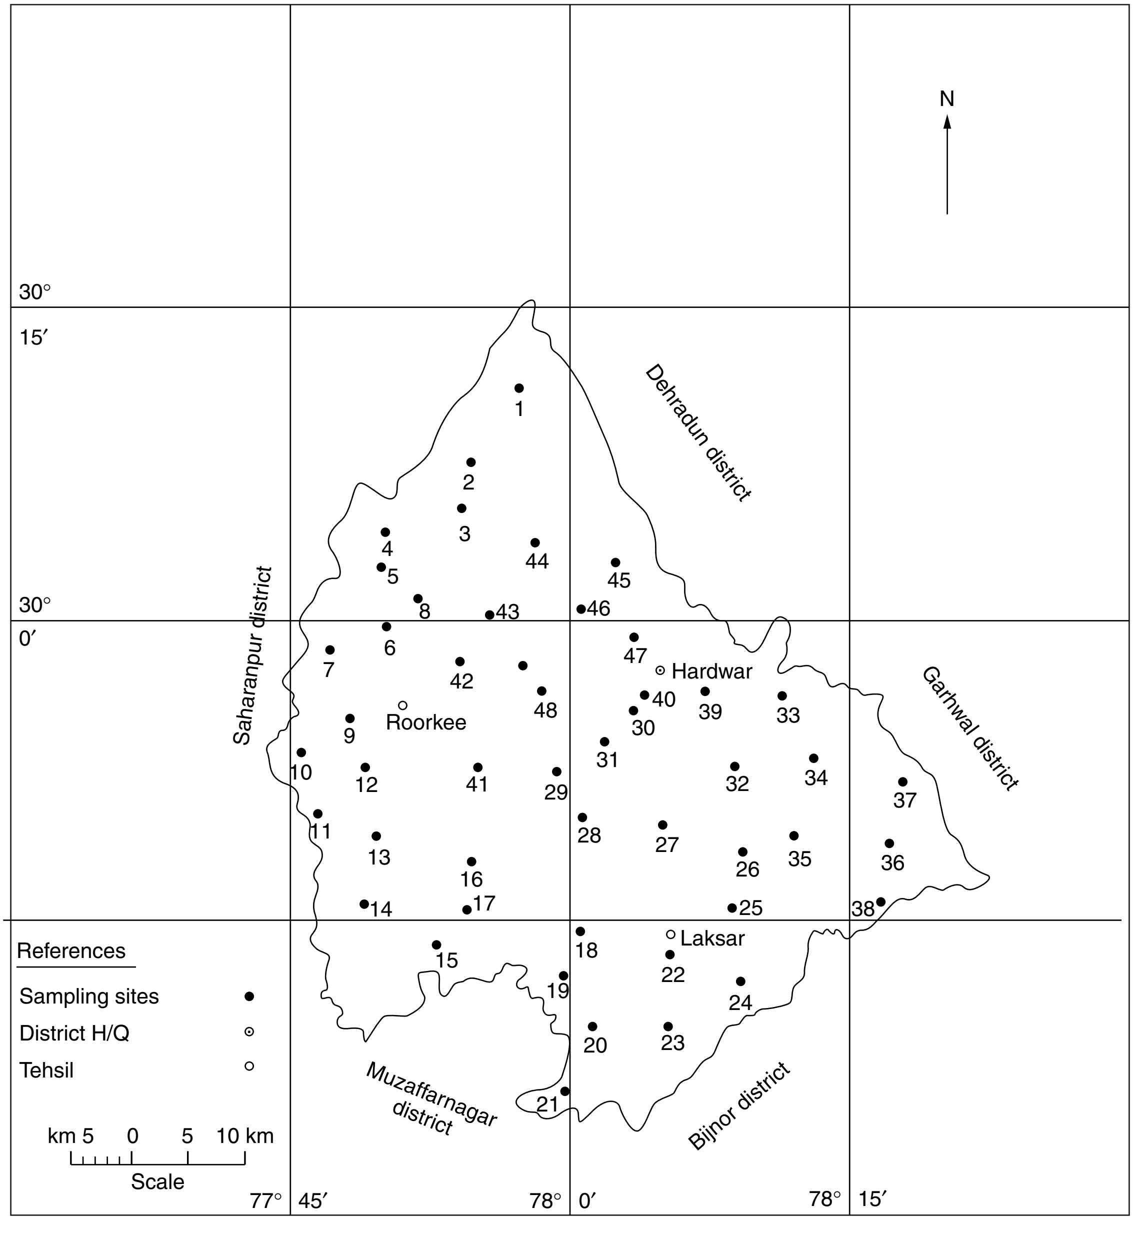

Figure 1. Study area showing location of sampling sites, District Hardwar.

two types of aquifers have been delineated in the area. The upper one is the shallow unconfined aquifer which generally extends to depths of around 25 m. The deeper one consists of semiconfined aquifers located at a depth of about 25 to 150 m below ground level separated by three to four aquifers at average depths of 25 to 55, 65 to 90, and 120 to 150 m. Water table contours in the area indicate a southward trend of groundwater flow in both unconfined and confined aquifers.

EXPERIMENTAL METHODOLOGY

Forty-eight groundwater samples from District Hardwar were collected each during pre- (June 2002) and post-monsoon (October 2002) seasons from various abstraction sources at various depths covering extensively populated area, commercial, industrial, agricultural, and residential colonies so as to obtain a good areal and vertical representation. The samples were preserved by adding an appropriate reagent (1,2). The hand pumps and tube wells were continuously pumped prior to sampling to ensure that the groundwater to be sampled was representative of the groundwater aquifer. The water samples for bacteriological analysis were collected in sterilized high-density polypropylene bottles covered with aluminum foil. All samples were stored in sampling kits maintained at 4 °C and brought to the laboratory for detailed chemical and bacteriological analysis. The details of sampling locations and source and depthwise distribution are given in Tables 1 and 2, respectively.

The physicochemical analysis was performed following standard methods (1,2). The total coliforms and fecal coliforms were determined by the multiple tube fermentation technique using MacConkey broth and EC medium, respectively.

RESULTS AND DISCUSSION

During 1983, the Bureau of Indian Standards (BIS), earlier known as Indian Standards Institution (ISI), laid down standard specifications for drinking water which have been revised and updated from time to time. To enable the users to exercise their discretion toward water quality criteria, the maximum permissible limit was prescribed especially where no alternate source was available. The national water quality standards describe the essential and desirable characteristics that must be evaluated to assess the suitability of water for drinking (3). The hydrochemical data for the two sets of samples collected from District Hardwar during pre- and postmonsoon seasons are presented in Table 3.

General Characteristics

The pH of the groundwater of District Hardwar is mostly confined within the range 6.22 to 7.58 during the premonsoon season and 6.70 to 7.70 during the postmonsoon season. The pH values of all samples are well within the limits prescribed by the BIS (3) and the WHO (4) for various uses, including drinking and other domestic supplies.

The measurement of electrical conductivity is directly related to the concentration of ionized substances in water and may also be related to excessive hardness and/or other mineral contamination. The conductivity values in the groundwater samples of District Hardwar vary from 233–1440 μS/cm during the premonsoon season and from 221–1442 μS/cm during the postmonsoon season; about 10% of the samples had conductivity values above 1000 μS/cm during both pre- and postmonsoon seasons. The maximum conductivity of 1440 and 1442 μS/cm was observed at village Manubas (hand pump, 10 m depth) during pre- and postmonsoon season, respectively.

In natural waters, dissolved solids consists mainly of inorganic salts such as carbonates, bicarbonates, chlorides, sulfates, phosphates, and nitrates of calcium, magnesium, sodium, potassium, iron, etc. and small amounts of organic matter and dissolved gases. In the present study, the values of total dissolved solids (TDS) in the groundwater varied from 149–922 mg/L during the premonsoon season and from 141–923 mg/L during the postmonsoon season, indicating low mineralization in the area. More than 75% of the samples analyzed were within the desirable limit of 500 mg/L, and about 25% of the samples were above the desirable limit but within the maximum permissible limit of 2000 mg/L. An almost similar trend was observed during the postmonsoon season. The TDS content at deeper levels (>40 m depth) is comparatively low and lies well within the desirable limit of 500 mg/L. The TDS distribution maps for the pre- and postmonsoon seasons are shown in Fig. 2a,b. Water containing more than 500 mg/L of TDS is not considered desirable for drinking water, though more highly mineralized water is also used where better water is not available. For this reason, 500 mg/L as the desirable limit and 2000 mg/L as the maximum permissible limit have been suggested for drinking water (3). Water containing more than 500 mg/L TDS causes gastrointestinal irritation (3). No sample of District Hardwar exceeded the maximum permissible limit of 2000 mg/L.

Table 3. Hydrochemical Data for Groundwater Samples from District Hardwar[a]

Characteristics	Min	Max	Average
pH	6.22 (6.70)	7.58 (7.70)	6.87 (7.10)
Conductivity, μS/cm	233 (221)	1440 (1442)	642 (647)
TDS, mg/L	149 (141)	922 (923)	411 (414)
Alkalinity, mg/L	78 (71)	460 (482)	213 (215)
Hardness, mg/L	81 (80)	464 (427)	209 (212)
Chloride, mg/L	0.1 (1.2)	32 (35)	9.0 (9.0)
Sulphate, mg/L	0.5 (0.7)	72 (62)	22 (21)
Nitrate, mg/L	0.1 (0.1)	140 (130)	13 (13)
Phosphate, mg/L	0.01 (0.02)	0.41 (1.60)	0.03 (0.25)
Fluoride, mg/L	0.01 (0.01)	0.94 (0.88)	0.36 (0.42)
Sodium, mg/L	5.0 (4.5)	69 (71)	26 (25)
Potassium, mg/L	0.8 (0.2)	42 (32)	7.0 (7.4)
Calcium, mg/L	22 (24)	140 (135)	55 (56)
Magnesium, mg/L	5.0 (5.0)	36 (38)	18 (17)
Boron, mg/L	0.12 (0.12)	0.92 (0.87)	0.50 (0.49)

[a] Values given in parenthesis represent postmonsoon data.

Carbonates, bicarbonates, and hydroxides are the main cause of alkalinity in natural waters. Bicarbonates represent the major form because they are formed in considerable amounts by the action of carbonates upon the basic materials in the soil. The alkalinity in the groundwater varies from 78–460 mg/L during the premonsoon season and from 71–482 mg/L during the postmonsoon season. About 50% of the samples of the study area fall within the desirable limit of 200 mg/L both during the pre- and postmonsoon seasons, and the remaining 50% of the samples exceeds the desirable limit but are within the maximum permissible limit of 600 mg/L. No sample of the study area exceeded the maximum permissible limit of 600 mg/L. The high alkalinity may be due to the action of carbonates upon the basic materials in the soil.

Calcium and magnesium along with their carbonates, sulfates, and chlorides make the water hard. A limit of 300 mg/L has been recommended for potable water (3). The total hardness values in the study area range from 81–464 mg/L during the premonsoon season and from 80–427 mg/L during the postmonsoon season. About 80% of the samples of the study area fall within the desirable limit of 300 mg/L and the remaining samples exceed the desirable limit but are well within the maximum permissible limit of 600 mg/L. From the point of view of hardness all samples of District Hardwar were within the permissible limit of 600 mg/L.

The desirable limits for calcium and magnesium for drinking water are 75 and 30 mg/L, respectively (3). In the groundwater of the study area, the values for calcium and magnesium range from 22–140 mg/L and 5.0–36 mg/L, respectively, during the premonsoon season. An almost similar trend was observed during the postmonsoon season. In groundwater, the calcium content generally exceeds the magnesium content in accordance with their relative abundance in rocks. The increase in magnesium is proportionate to calcium in both seasons. All the

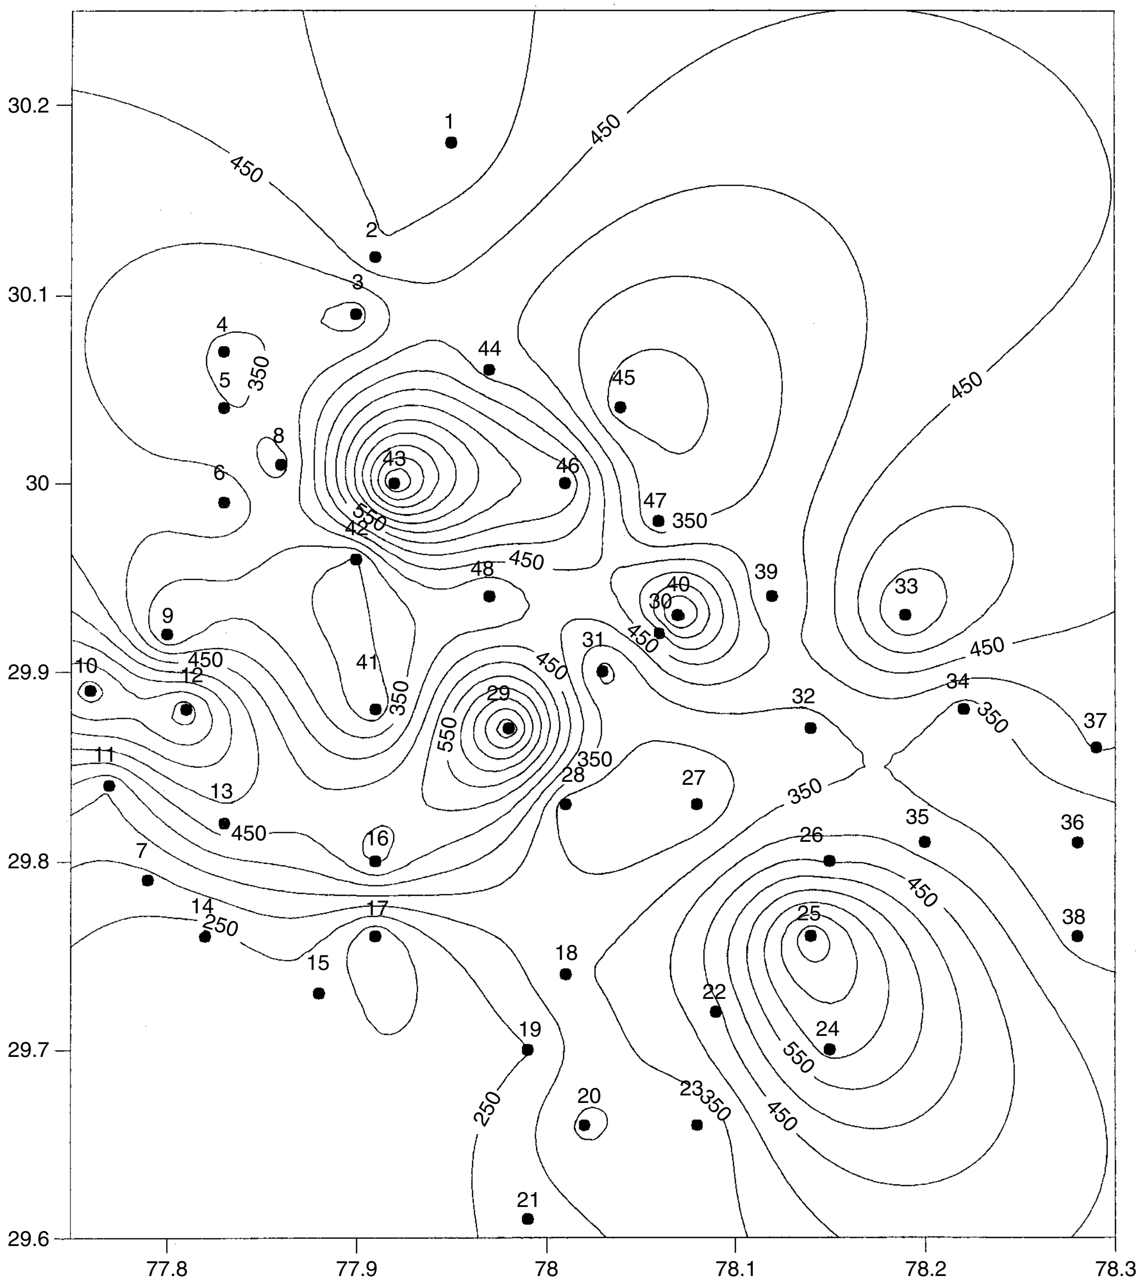

Figure 2. (**a**) Distribution of TDS in groundwater from District Hardwar (premonsoon 2002). (**b**) Distribution of TDS in groundwater from District Hardwar (postmonsoon 2002).

samples of the study area fall within the desirable limit at most places.

The concentration of sodium in the study area varied from 5.0–69 mg/L during the premonsoon season and from 4.5–71 mg/L during the postmonsoon season. The violation of BIS limits could not be ascertained for sodium as no permissible limit of sodium has been prescribed in BIS drinking water specifications. Groundwater high in sodium is not suitable for irrigation due to the sodium sensitivity of crops/plants.

The concentration of potassium in the groundwater of District Hardwar varied from 0.8–42 mg/L during the premonsoon season and from 0.2–32 mg/L during the postmonsoon season. Potassium, an essential element for humans, plants, and animals, is derived in the food chain mainly from vegetation and soil. The main sources of potassium in groundwater include rainwater, weathering of potash silicate minerals, use of potash fertilizers, and use of surface water for irrigation. It is more abundant in sedimentary rocks and commonly present in feldspar, mica, and other clay minerals. The Bureau of Indian Standards has not included potassium in drinking water standards. However, the European Economic Community has prescribed a guideline level of 10 mg/L potassium in drinking water. Per EEC criteria, about 10–15% of the samples of the study area exceeded the 10 mg/L

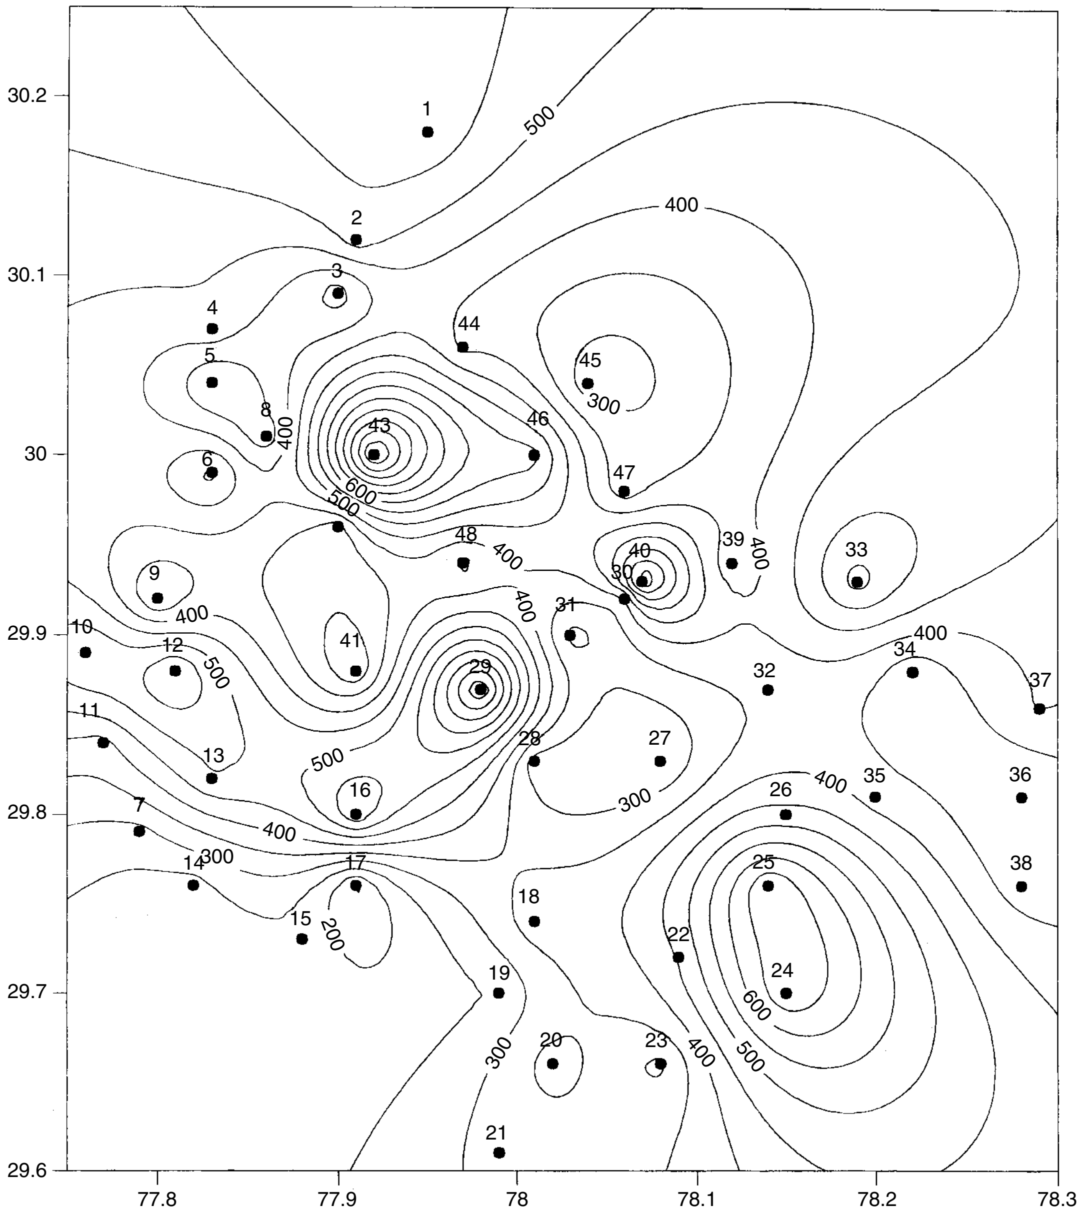

Figure 2. (*Continued*)

guideline level. Though potassium is found extensively in some igneous and sedimentary rocks, its concentration in natural waters is usually quite low because potassium minerals offer resistance to weathering and dissolution. A higher potassium content in groundwater is indicative of groundwater pollution.

The concentration of chloride in the study area is quite low and varies from 0.1–32 mg/L during the premonsoon season. An almost similar trend was observed during the postmonsoon season. The limits of chloride have been laid down primarily from taste considerations. A limit of 250 mg/L chloride has been recommended as a desirable limit for drinking water supplies (3,4). However, no adverse health effects on humans have been reported from intake of waters containing an even higher chloride content. No sample in the study area exceeded the desirable limit of 250 mg/L.

The sulfate content of groundwater generally occurs as soluble salts of calcium, magnesium, and sodium. The sulfate content changes significantly with time during infiltration of rainfall and groundwater recharge, which takes place mostly from stagnant water pools and surface runoff water collected in low-lying areas. The concentration of sulfate in the study area varied from 0.5–72 mg/L during the premonsoon season and from 0.7–62 mg/L during the postmonsoon season. It is clearly evident from the distribution maps that all the samples from District Hardwar fall within the desirable limit of 200 mg/L prescribed for drinking water supplies.

Excess nitrate content in drinking water is considered dangerous for its adverse health effects. The occurrence of high levels of nitrate in groundwater is a prominent problem in many parts of the country. The nitrate content in District Hardwar varies from 0.1–140 mg/L during the premonsoon season and from 0.1–130 mg/L during the postmonsoon season. About 95% of the samples shows nitrate content less than the desirable limit of 45 mg/L. Only one sample from Jwalapur exceeded the maximum permissible limit of 100 mg/L during both pre- and postmonsoon seasons. The nitrate distribution maps for the pre- and postmonsoon seasons are shown in Fig. 3a,b. The higher level of nitrate at Jwalapur may be attributed to improper sanitation and unhygienic conditions around the structure.

Nitrate is an effective and moderately toxic plant nutrient. A limit of 45 mg/L has been prescribed by the WHO (4) and the BIS (3) for drinking water. Its

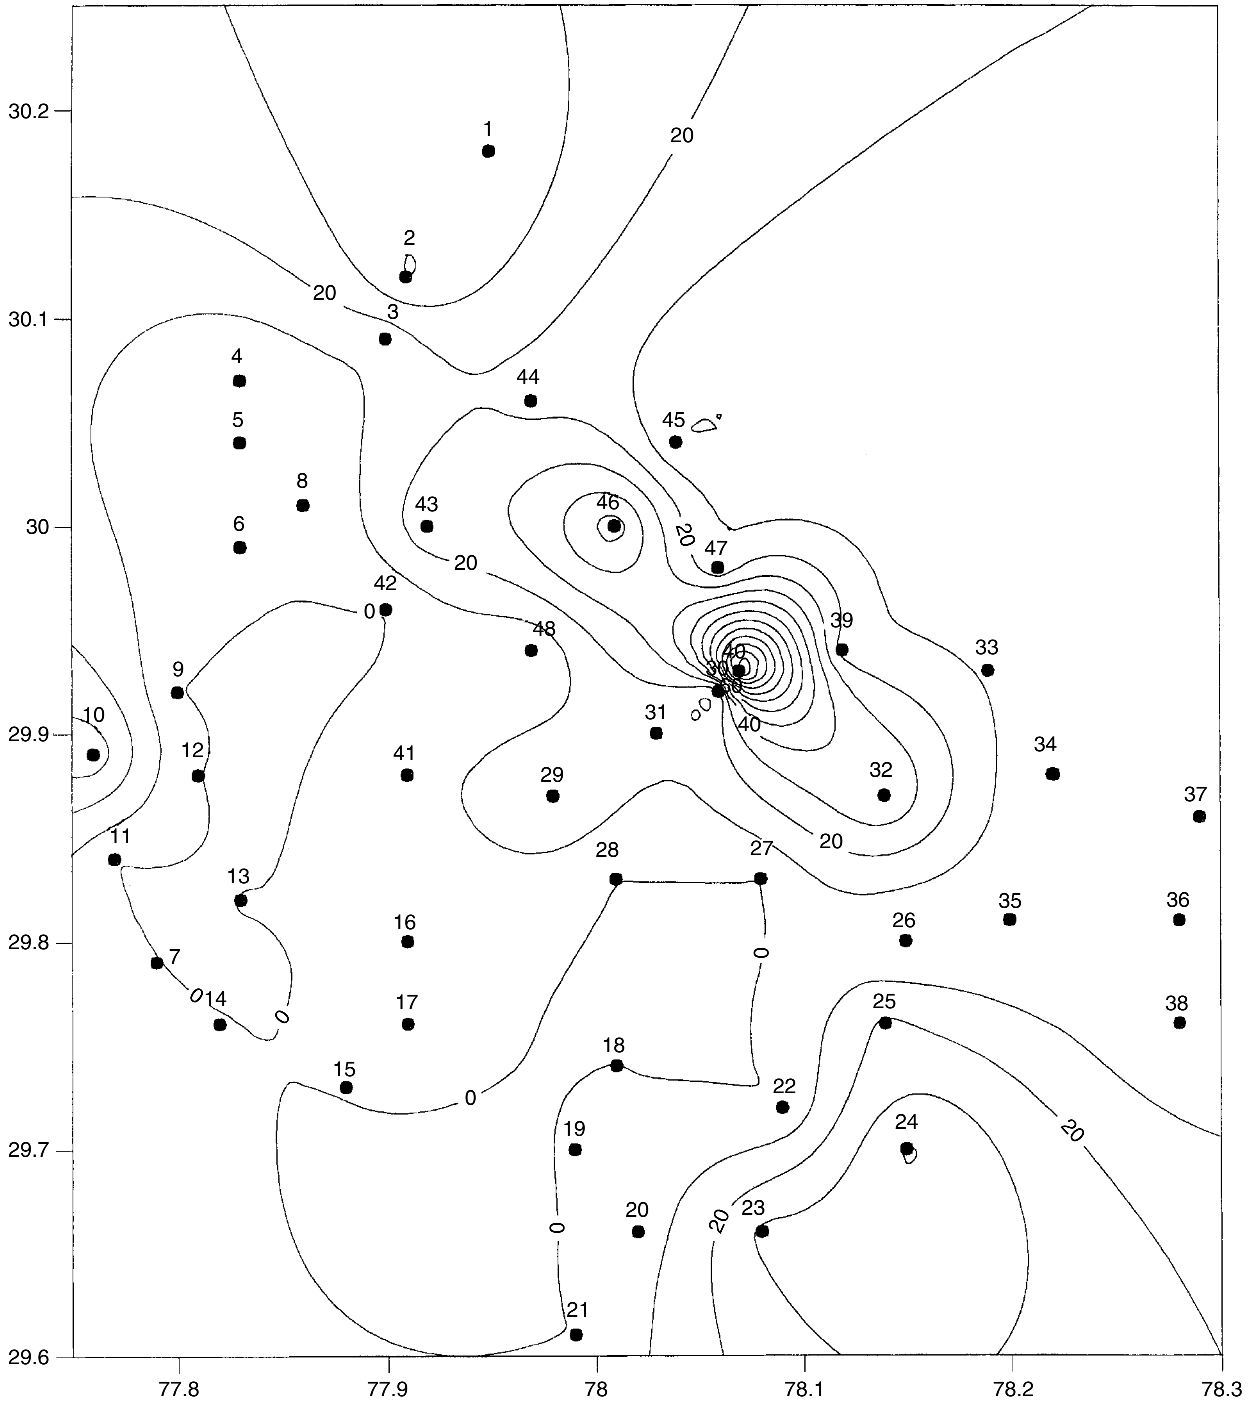

Figure 3. (**a**) Distribution of nitrate in groundwater from District Hardwar (premonsoon 2002). (**b**) Distribution of nitrate in groundwater from District Hardwar (postmonsoon 2002).

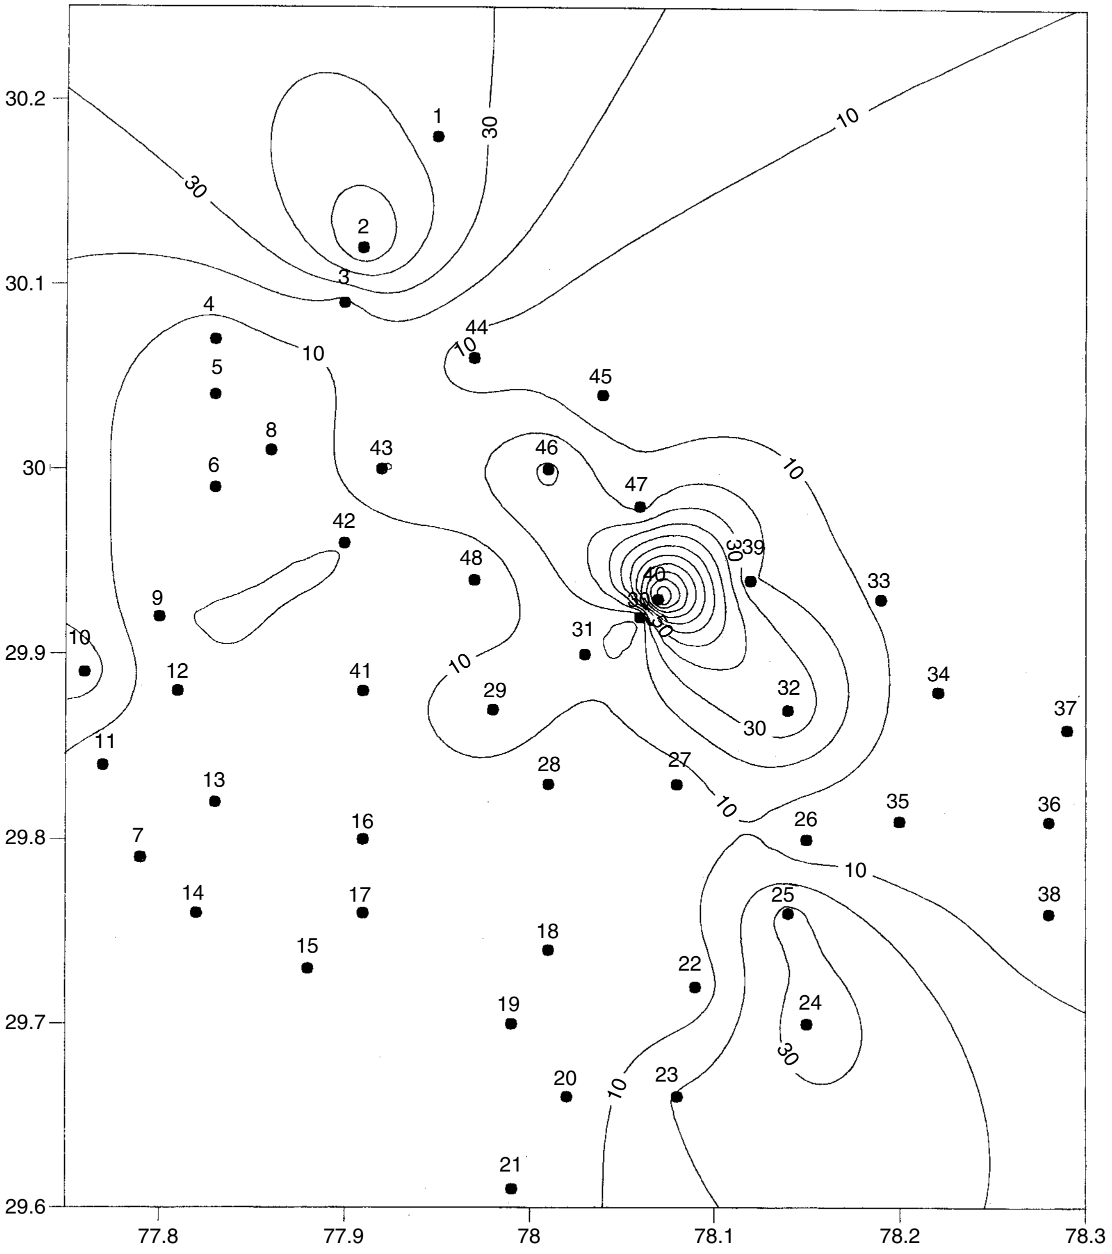

Figure 3. (*Continued*)

concentration above 45 mg/L may prove detrimented to human health. In higher concentrations, nitrate may produce a disease known as methemoglobinemia (blue babies) which generally affects bottle-fed infants. Repeated heavy doses of nitrates by ingestion may also cause cancer.

The concentration of phosphate in the study area is generally low at all locations. Phosphorous is an essential plant nutrient that is used extensively as a fertilizer. Phosphate is adsorbed or fixed as aluminium or iron phosphate in acidic soils or as calcium phosphate in alkaline or neutral soils; as a result, the concentration of phosphate in groundwater is usually low, but various chemical processes in soil strata may induce the mobility of phosphate in sub-soil and groundwater.

The fluoride content in the groundwater of District Hardwar varies from 0.01–0.94 mg/L during the premonsoon season and from 0.01–0.88 mg/L during the postmonsoon season; it lies well below the desirable limit of 1.0 mg/L in all samples. The fluoride distribution maps for pre- and postmonsoon seasons are shown in Fig. 4a,b.

The presence of fluoride in groundwater may be attributed to the localized effects of natural sources. Fluoride present in soil strata is from geological formations, such as fluorspar, and fluorapatite, and amphiboles, such as hornblende, tremolite, and mica. Weathering of igneous and sedimentary alkali silicate rocks, especially shales, contribute a major portion of fluorides to groundwaters. In addition to natural sources, considerable amounts of fluoride may be contributed by human activities. Fluoride

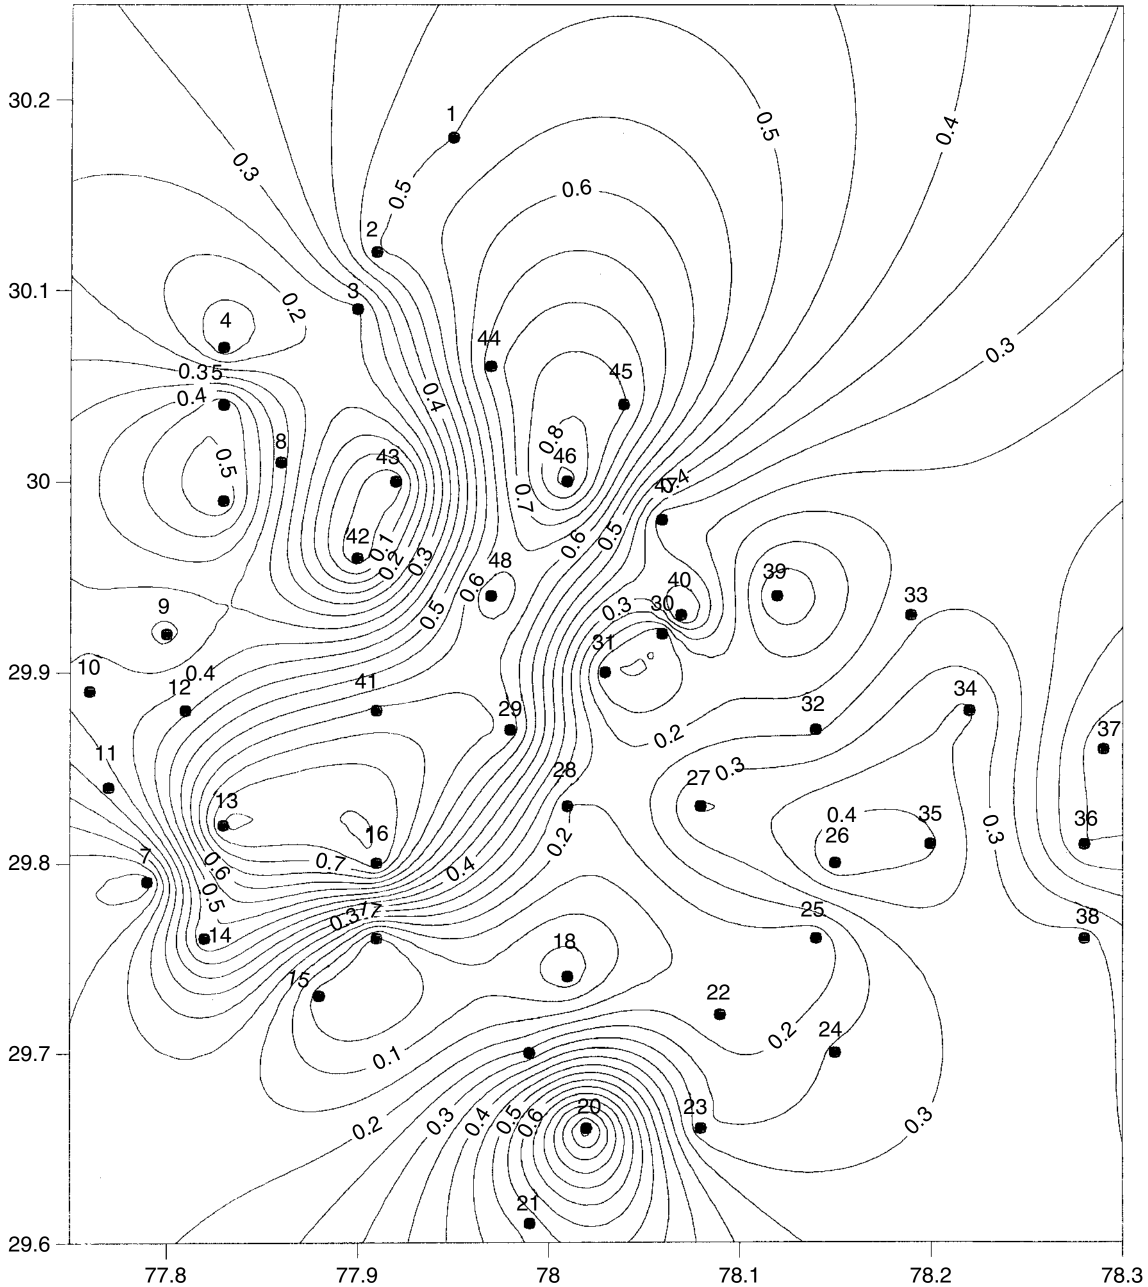

Figure 4. (**a**) Distribution of fluoride in groundwater from District Hardwar (premonsoon 2002). (**b**) Distribution of fluoride in groundwater from District Hardwar (postmonsoon 2002).

salts are commonly used in the steel, aluminum, brick, and tile industries. Fluoride containing insecticides and herbicides may be contributed through agricultural runoff. Phosphatic fertilizers, which are extensively used, often contain fluorides as impurities, and these may increase the levels of fluoride in soil. The accumulation of fluoride in soil eventually results in leaching it by percolating water, thus increasing the fluoride concentration in groundwater.

The study has clearly indicated that the concentration of total dissolved solids exceeds the desirable limit of 500 mg/L in about 25% of the samples analyzed, but the values are well within the maximum permissible limit of 2000 mg/L in all samples. The alkalinity exceeds the desirable limit of 200 mg/L in about 50% of the samples, but the levels are well within the maximum permissible limit of 600 mg/L. Total hardness exceeds the desirable limit of 300 mg/L in about 15% of the samples. The nitrate content exceeds the maximum permissible limit of 100 mg/L in only one sample (Jwalapur) of the study area. The fluoride content is well within the desirable limit in all samples analyzed.

Bacteriological Parameters

The coliform group of bacteria is the principal indicator of the suitability of water for domestic, industrial, and other uses. The density of the coliform group is the criterion for

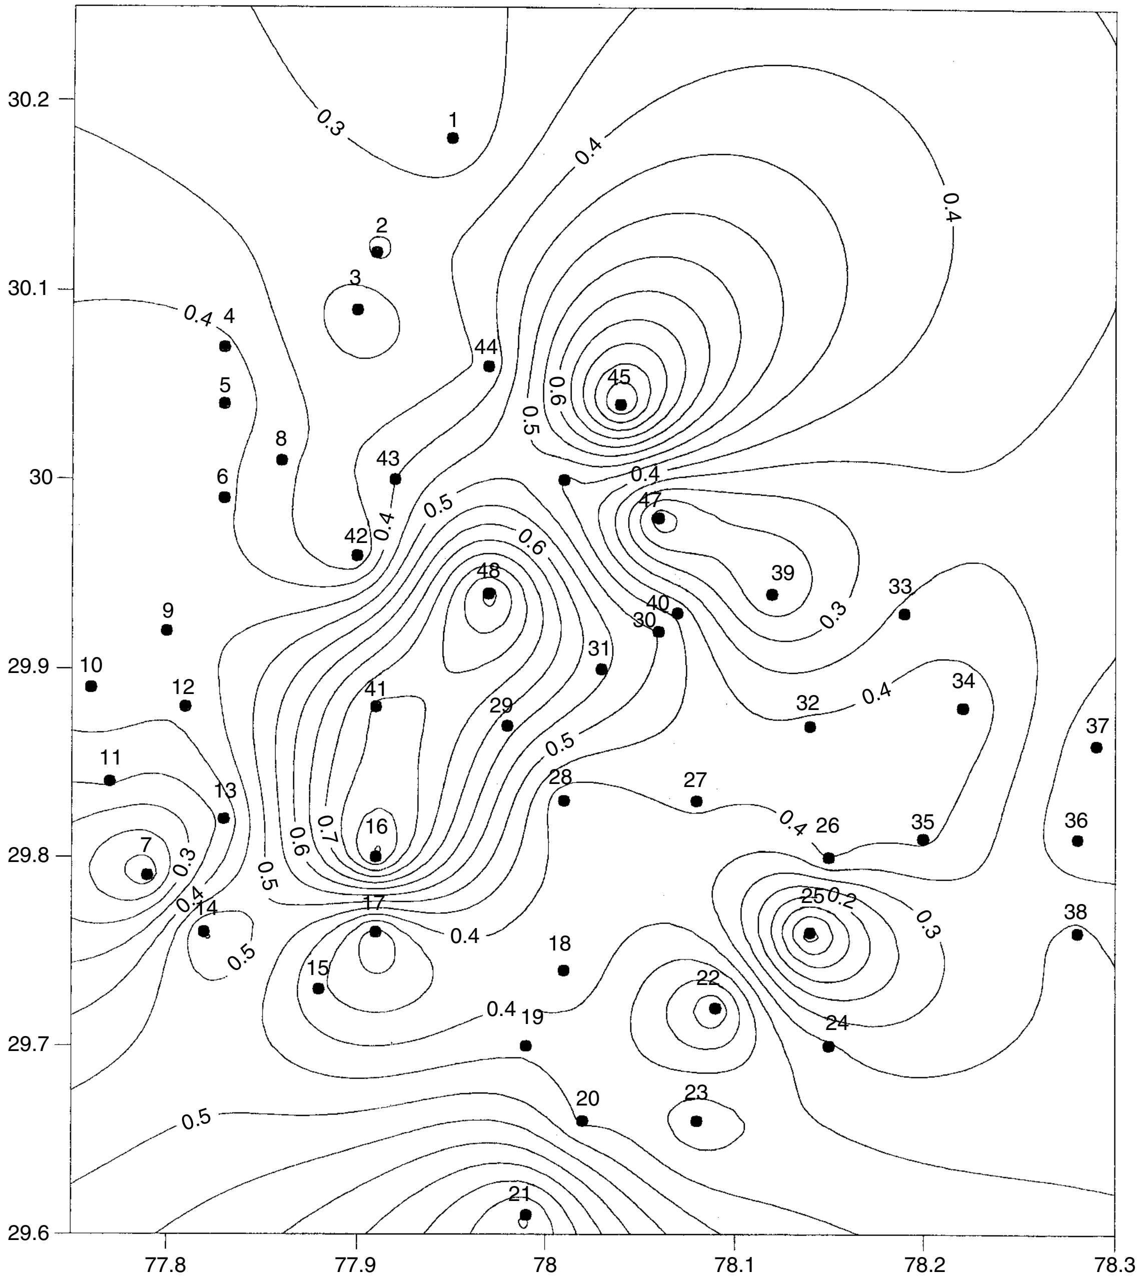

Figure 4. *(Continued)*

the degree of contamination and has been the basis for the bacteriological water quality standard. In ideal conditions, all samples taken from the distribution system should be free from coliform organisms, but in practice, this is not always attainable, and therefore, the following standard for water has been recommended (4):

— 95% of water samples should not contain any coliform organisms in 100 mL throughout the year.

— No water sample should contain *E. coli* in 100 mL water.

— No water sample should contain more than 10 coliform organisms per 100 mL.

— Coliform organisms should not be detected in 100 mL of any two consecutive water samples.

However, from bacteriological considerations, the objectives should be to reduce the coliform count to less than 10 per 100 mL, and more importantly, the absence of fecal coliform should be ensured. The presence of coliforms in water is an indicator of contamination by human or animal excrement. The presence of fecal colifirms in groundwater indicates a potential public health problem because fecal matter is a source of pathogenic bacteria and viruses. Groundwater contamination from fecal coliform bacteria is generally caused by percolation from sources of contamination (domestic sewage and septic tanks) into the aquifers and also from poor sanitation. Shallow wells are particularly susceptible to such contamination. Indiscriminate land disposal of domestic waste on the surface and improper disposal of solid waste, and leaching of wastewater from landfill areas further increase the chances of bacterial contamination in groundwater. The results of the bacteriological analysis of groundwater samples from District Hardwar are given in Table 4.

Bacteriological analysis of the groundwater samples collected from District Hardwar indicates bacterial contamination in about 40% of the samples analyzed. About 20% of the samples even exceed the permissible limit of 10 coliforms per 100 mL of sample. Inadequate maintenance of hand pumps, improper sanitation, and unhygienic conditions around structures may be responsible for bacterial contamination in the groundwater of the region and is a cause of concern. The water from such sources should be

Classification of Ground Water

The groundwater of District Hardwar has been classified per Chadha's diagram (5). The diagram is a somewhat modified version of the Piper trilinear diagram (6). In the Piper diagram, the milliequivalent percentages of the major cations and anions are plotted in two base triangles, and the type of water is determined on the basis of the position of the data in the respective cationic and anionic triangular fields. The plottings from the triangular fields are projected further into the central diamond field, which represents the overall character of the water. A Piper diagram allow comparisons among numerous analyses, but this type of diagram has a drawback, as all trilinear diagrams do, in that it does not portray actual ion concentration. The distribution of ions within the main field is unsystematic in hydrochemical process terms, so the diagram lacks a certain logic. This method is not very convenient when plotting a large volume of data. Nevertheless, this shortcoming does not lessen the usefulness of the Piper diagram in representing some geochemical processes.

In contrast, in Chadha's diagram, the difference in milliequivalent percentage between alkaline earths

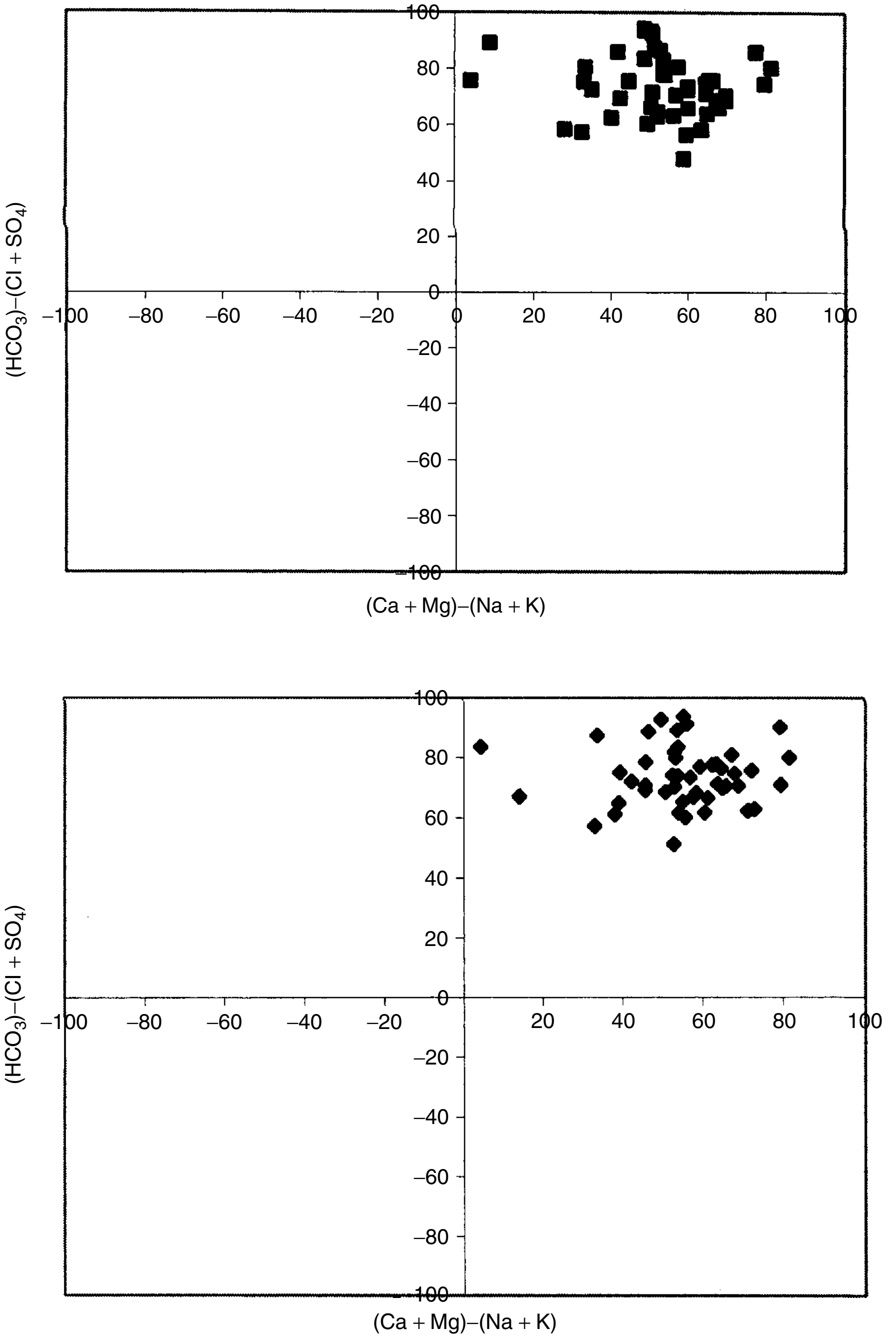

Figure 5. (**a**) Chadha's diagram showing the chemical character of groundwater in District Hardwar, Uttaranchal (premonsoon 2002). (**b**) Chadha's diagram showing the chemical character of groundwater in District Hardwar, Uttaranchal (postmonsoon 2002).

(calcium plus magnesium) and alkali metals (sodium plus potassium), expressed as a percentage of reacting values, is plotted on the x-axis, and the difference in milliequivalent percentage between weak acidic anions (carbonate plus bicarbonate) and strong acidic anions (chloride plus sulfate) is plotted on the y-axis. The resulting field of study is a square or rectangle depending upon the size of the scales chosen for the x and y coordinates. The milliequivalent percentage differences between alkaline earth and alkali metals and between weak acidic anions and strong acidic anions would plot in one of the four possible subfields of the diagram. The main advantage of this diagram is that it can be produced easily on most spreadsheet software packages.

The square or rectangular field describes the overall character of the water. The diagram has all the advantages of the diamond-shaped field of the Piper trilinear diagram and can be used to study various hydrochemical processes, such as base cation exchange, cement pollution, mixing of natural waters, sulfate reduction, saline water (end product water), and other related hydrochemical problems (5). The chemical analysis data of all samples collected from District Hardwar have been plotted on Chadha's diagram (Fig. 5a,b).

It is evident from the results that all samples of the study area fall in Group 5 ($Ca-Mg-HCO_3$ type) during both pre- and postmonsoon seasons. Chadha's diagram has all the advantages of the diamond-shaped field of the Piper trilinear diagram and can be conveniently used to study various hydrochemical processes. Another main advantage of this diagram is that it can be produced easily on most spreadsheet software packages.

CONCLUSIONS AND RECOMMENDATIONS

The groundwater quality in District Hardwar varies from place to place and with the depth of the water table. The water drawn for domestic use should be tested and analyzed to ensure the suitability of groundwater for human consumption. The groundwater abstraction sources and their surroundings should be properly maintained to ensure hygienic conditions; no sewage or polluted water should be allowed to percolate directly to a groundwater aquifer. Proper cement platforms should be constructed surrounding the ground water abstraction sources to avoid direct wellhead pollution, and the surrounding surface area should be frequently chlorinated by using bleaching powder. The hand pumps and wells, which have been identified as of suspect water quality, should be painted red to indicate and warn the public that the water drawn from the source is not fit for human consumption. In the absence of an alternate safe source of water, the water with excessive undesirable constituents must be treated by a specific treatment process before it is used for human consumption. The untreated sewage and sewerage flowing in various open drains are one of the causes of groundwater quality deterioration. A proper underground sewage system must be laid in inhabited areas, and the untreated sewage should not be allowed to flow in open drains. A proper system of collection and transportation of domestic waste should be developed. Landfill site(s) should be identified and must be scientifically designed. A mass awareness should be generated about water quality, its effect on human health, and the responsibilities of the public to safeguard water resources.

IRRIGATION WATER QUALITY IN DISTRICT HARDWAR, UTTARANCHAL, INDIA

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

The groundwater quality of District Hardwar in the state of Uttaranchal (India) was assessed to determine the suitability of groundwater for irrigation. Two sets of 48 groundwater samples from shallow and deep aquifers were collected during pre- and postmonsoon seasons in the year 2002, and the suitability of the groundwater for irrigation was evaluated based on salinity, sodium adsorption ration (SAR), residual sodium carbonate (RSC), and boron content. The values of SAR ranged from 0.24–1.75 during the premonsoon season and from 0.22–1.92 during the postmonsoon season, respectively. Values of the SAR indicate that the majority of samples of the study area falls under the category of low sodium hazard, indicating no risk of sodification. In general, the groundwater of District Hardwar is safe for irrigation. According to the U.S. Salinity Laboratory classification of irrigation water, the majority of the samples (70%) falls under water type C2-S1 followed by the C3-S1 type.

INTRODUCTION

IRRIGATION WATER QUALITY IN DISTRICT HARDWAR, UTTARANCHAL, INDIA

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

The groundwater quality of District Hardwar in the state of Uttaranchal (India) was assessed to determine the suitability of groundwater for irrigation. Two sets of 48 groundwater samples from shallow and deep aquifers were collected during pre- and postmonsoon seasons in the year 2002, and the suitability of the groundwater for irrigation was evaluated based on salinity, sodium adsorption ration (SAR), residual sodium carbonate (RSC), and boron content. The values of SAR ranged from 0.24–1.75 during the premonsoon season and from 0.22–1.92 during the postmonsoon season, respectively. Values of the SAR indicate that the majority of samples of the study area falls under the category of low sodium hazard, indicating no risk of sodification. In general, the groundwater of District Hardwar is safe for irrigation. According to the U.S. Salinity Laboratory classification of irrigation water, the majority of the samples (70%) falls under water type C2-S1 followed by the C3-S1 type.

INTRODUCTION

The intensive use of natural resources and the large production of wastes in modern society often pose a threat to groundwater quality and have already resulted in many incidents of groundwater contamination. Pollutants are being added to groundwater systems by human activities and natural processes. Solid waste from industrial units is being dumped near factories, is subjected to reaction with percolating rainwater, and reaches the groundwater level. The percolating water picks up a large amount of dissolved constituents, reaches the aquifer system, and contaminates the groundwater.

Groundwater plays an important role in agriculture for both watering crops and for irrigating dry season crops. It is estimated that about 45% of the irrigation water requirement is met from groundwater sources. Indiscriminate use of fertilizers and pesticides in agricultural fields has become common practice in India and has already resulted in very high concentrations of these constituents in groundwater, which in the long term, may create the greatest hazard to groundwater.

Many problems originate from inefficient management of water for agricultural use, especially when it carries high salts. The problem of groundwater contamination in several parts of the country has become so acute that unless urgent steps for detailed identification and abatement are taken, extensive groundwater resources may be damaged. Keeping in view the severity of the problem, the groundwater quality of District Hardwar in the newly created state of Uttaranchal (India) was studied to examine the suitability of groundwater for irrigation.

STUDY AREA

District Hardwar is part of the Indo-Gangetic plains and lies between latitude 29°30′ to 30°20′ N and longitude 77°40′ to 78°25′ E in the state of Uttaranchal (Fig. 1). It is the largest district (populationwise) of Uttaranchal State and occupies an area of about 2,360 km^2. Per the 2001 census, the population of the District Hardwar is 14,44,213, and the population density is 612 per km^2.

Physiographically, the area is generally flat except for the Siwalik Hills in the north and north east. The area is devoid of relief features of any prominence except for deep gorges cut by drains and rivers flowing through the area. The area is bounded by River Yamuna in the west and River Ganga in the east. The climate of the area is characterized by a moderate type of subtropical monsoon. The average annual rainfall in the region is about 1000 mm; the major part is received during the monsoon period. The major land use is for agriculture, and there is no effective forest cover. The soils of the area are loam to silty loam and are free from carbonates. The most common groundwater use is achieved by hand pumps and tube wells. Based on lithologic logs and water table fluctuation data, two types of aquifers have been delineated in the area. The upper is the shallow unconfined aquifer which generally extends to depths around 25m. The deeper one is confined to semiconfined and located at

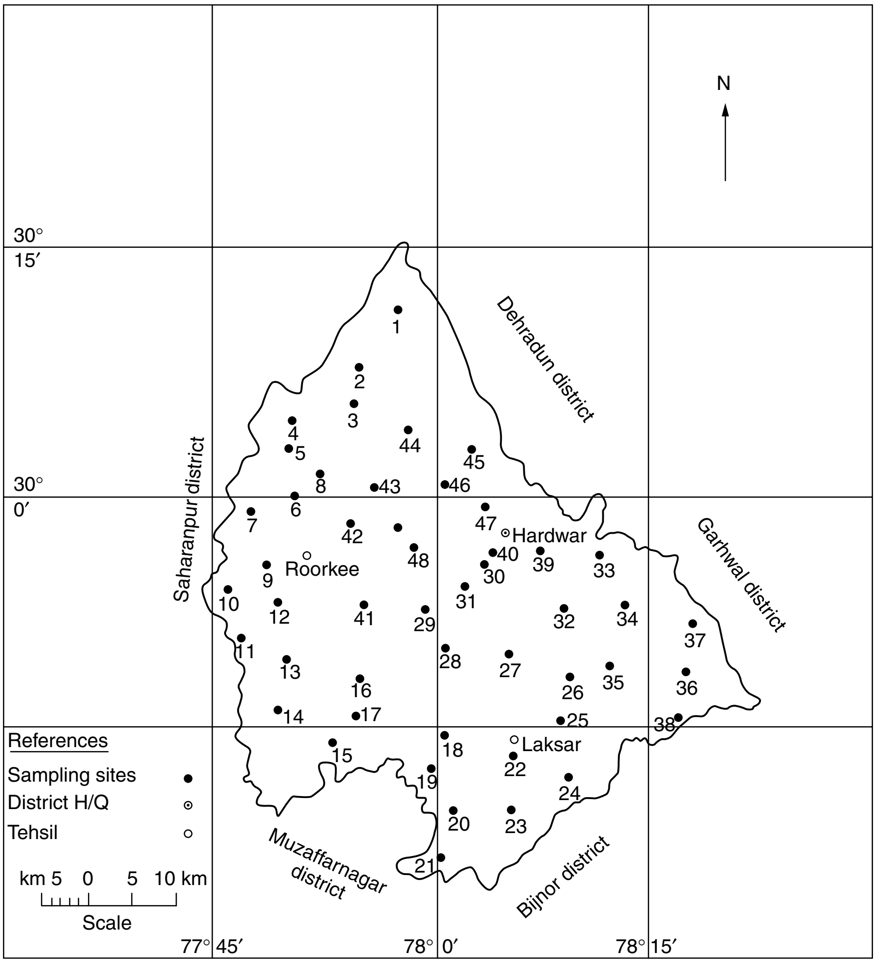

Figure 1. Study area showing location of sampling sites in District Hardwar.

a depth about 25 to 150m below ground level, separated by three to four aquifers at average depths of 25–55, 65–90, and 120–150m. Water table contours in the area indicate a southward trend of groundwater flow in both unconfined and confined aquifers.

EXPERIMENTAL METHODOLOGY

Two sets of 48 groundwater samples from District Hardwar were collected during pre- and postmonsoon seasons in the year 2002 from various abstraction sources at various depths. They were preserved by adding an appropriate reagent (1,2). The hand pumps and tube wells were continuously pumped prior to sampling to ensure that groundwater sampled was representative of the groundwater aquifer. The details of sampling locations and source and depth distribution are given in Tables 1 and 2, respectively. The physicochemical analysis was performed following standard methods (1,2).

RESULTS AND DISCUSSION

The hydrochemical data for the two sets of samples collected during pre- and postmonsoon seasons are presented in Table 3. The suitability of groundwater for domestic use was discussed in an earlier report (3). The quality of water plays an important role in irrigated agriculture. Many problems originate from inefficient management of water for agricultural use, especially when it carries high salts. The concentration and composition of dissolved constituents in water determine its quality for irrigation. The quality of water is an important consideration in any appraisal of salinity or alkaline conditions in an irrigated area. Good quality water has can provide maximum yield under good soil and water management practices. The most important characteristics of water which determine suitability of ground water for irrigation are

1. Salinity
2. Relative proportion of sodium to other cations (SAR)
3. Residual sodium carbonate (RSC)
4. Boron content

The safe limits of electrical conductivity for crops of different degrees of salt tolerance under varying soil textures and drainage conditions are given in Table 4.

[a] Values in parentheses represent postmonsoon data.

The quality of water is commonly expressed by classes of relative suitability for irrigation with reference to salinity levels. The recommended classification with respect to electrical conductivity, sodium content, sodium absorption ratio (SAR), and residual sodium carbonate (RSC) are given in Table 5. The values of sodium percentage (% Na), SAR, and RSC in the groundwater of District Hardwar are given in Table 6.

Salinity

Salinity is broadly related to total dissolved solids (TDS) and electrical conductivity (EC). High concentrations of TDS and electrical conductivity in irrigation water may increase the soil salinity, which affects the salt intake of a plant. The salts in the water affect the growth of plants directly and also affect the soil structure, permeability, and aeration, which indirectly affect plant growth. Soil water passes into a plant through the root zone by osmotic pressure. As the dissolved solid content of the soil water in the root zone increases, it is difficult for the plant to overcome the osmotic pressure and the plant root membranes are able to assimilate water and nutrients. Thus, the dissolved solids content of the residual water in the root zone also has to be maintained within limits by proper leaching. Negative effects are visible in plants by stunted growth, low yield, discoloration, and even leaf burns at margin or top. The electrical conductivity values for water in District Hardwar are well within the prescribed limits of 1500 μS/cm and are therefore safe for irrigation.

Relative Proportion of Sodium to Other Cations

A high salt concentration in water leads to saline soil, and high sodium leads to development of an alkaline soil. The sodium or alkaline hazard in using water for irrigation is determined by the absolute and relative concentration of cations, expressed in terms of the sodium adsorption ratio (SAR). If the proportion of sodium is high, the alkaline hazard is high, and conversely, if calcium and magnesium predominate, the hazard is less. There is a significant relationship between SAR values of irrigation water and the extent to which sodium is absorbed by the soil. If water used for irrigation is high in sodium and low in calcium, the cation-exchange complex may become saturated with sodium. This can destroy the soil structure owing to dispersion of the clay particles. A simple method of evaluating the danger of high-sodium water is the sodium adsorption ratio (SAR) (4):

$$\mathrm{SAR} = \frac{\mathrm{Na}^+}{\sqrt{(\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+})/2}}$$

The sodium percentage is calculated from

$$\%\mathrm{Na} = \frac{\mathrm{Na}^+ + \mathrm{K}^+}{\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+} + \mathrm{Na}^+ + \mathrm{K}^+} \times 100$$

where all ionic concentrations are expressed in milliequivalents per liter.

Table 5. Guidelines for Evaluation of Irrigation Water Quality

Water Class	Sodium (Na), %	Electrical Conductivity, μS/cm	SAR	RSC, meq/L
Excellent	<20	<250	<10	<1.25
Good	20–40	250–750	10–18	1.25–2.0
Medium	40–60	750–2250	18–26	2.0–2.5
Bad	60–80	2250–4000	>26	2.5–3.0
Very bad	>80	>4000	>26	>3.0

Table 4. Safe Limits of Electrical Conductivity for Irrigation Water

S. No.	Nature of Soil	Crop Growth	Upper Permissible Safe Limit of EC in Water, μS/cm
1.	Deep black soil and alluvial soil whose clay content is more than 30% in soils that are fairly to moderately well drained	Semitolerant	1500
		Tolerant	2000
2.	Textured soil of clay content of 20–30% in soils that are well drained internally and have a good surface drainage system	Semitolerant	2000
		Tolerant	4000
3.	Medium textured soils whose clay is 10–20% internally very well drained and has a good surface drainage system	Semitolerant	4000
		Tolerant	6000
4.	Lightly textured soils whose clay is less than 10% of soil that has an excellent internal and surface drainage system	Semitolerant	6000
		Tolerant	8000

Calculation of SAR for a given water provides a useful index of the sodium hazard of that water for soils and crops. A low SAR (2 to 10) indicates little danger from sodium; medium hazards are between 7 and 18, high hazards between 11 and 26, and very high hazards above that. The lower the ionic strength of the solution, the greater the sodium hazards for a given SAR (4).

The values of SAR in the groundwater of District Hardwar vary from 0.24–1.75 during the premonsoon season and from 0.22–1.92 during the postmonsoon season. As evident from the SAR values, the groundwater of the study area falls under the category of low sodium hazard, which reveals that the groundwater of the study area is free from any sodium hazard. The sodium percentage in the study area varies from 9.1–47.9% during the premonsoon season and from 9.2–47.8% during the postmonsoon season. All samples are well within the permissible limit for irrigation water and are free of any sodium hazard.

Residual Sodium Carbonate

In addition to total dissolved solids, the relative abundance of sodium with respect to alkaline earths and boron and the quantity of bicarbonate and carbonate in excess of alkaline earths also influence the suitability of water for irrigation. This excess is denoted residual sodium carbonate (RSC) and is determined by the following formula:

$$\mathrm{RSC} = (\mathrm{HCO_3}^- + \mathrm{CO_3}^{2-}) - (\mathrm{Ca}^{2+} + \mathrm{Mg}^{2+})$$

where all ionic concentrations are expressed in meq/L. Groundwater containing high concentrations of carbonate and bicarbonate ions tends to precipitate calcium and magnesium as carbonate. As a result, the relative proportion of sodium increases and is fixed in the soil thereby decreasing soil permeability. If the RSC exceeds 2.5 meq/L, the water is generally unsuitable for irrigation. Excessive RSC causes the soil structure to deteriorate, as it restricts the water and air movement through soil. If the value is between 1.25 and 2.5, the water is of marginal quality; values less than 1.25 meq/L indicate that the water is safe for irrigation. During the present study, the RSC values clearly indicate that the groundwater of District Hardwar does not have any residual sodium carbonate hazard.

Boron

Boron is essential to the normal growth of all plants, but the concentration required is very small and if exceeded may cause injury. Plant species vary in boron requirement and in tolerance to excess boron, so that concentrations necessary for the growth of plants that have high boron requirements may be toxic to plants sensitive to boron. Although boron is an essential nutrient for plant growth, generally it becomes toxic beyond 2 mg/L in irrigation water for most field crops. It does not affect the physical and chemical properties of the soil, but at high concentrations, it affects the metabolic activities of the plant. During the present study, the boron content in the groundwater clearly indicates that the groundwater is safe for irrigation.

U.S. Salinity Laboratory Classification

The U.S. Salinity Laboratory classification (5) is used to study the suitability of groundwater for irrigation. In classifying irrigation waters, it is assumed that the water will be used under average conditions with respect to soil texture, infiltration rate, drainage, quantity of water used, climate, and salt tolerance of the crop. Sodium concentration is an important criterion in irrigation-water

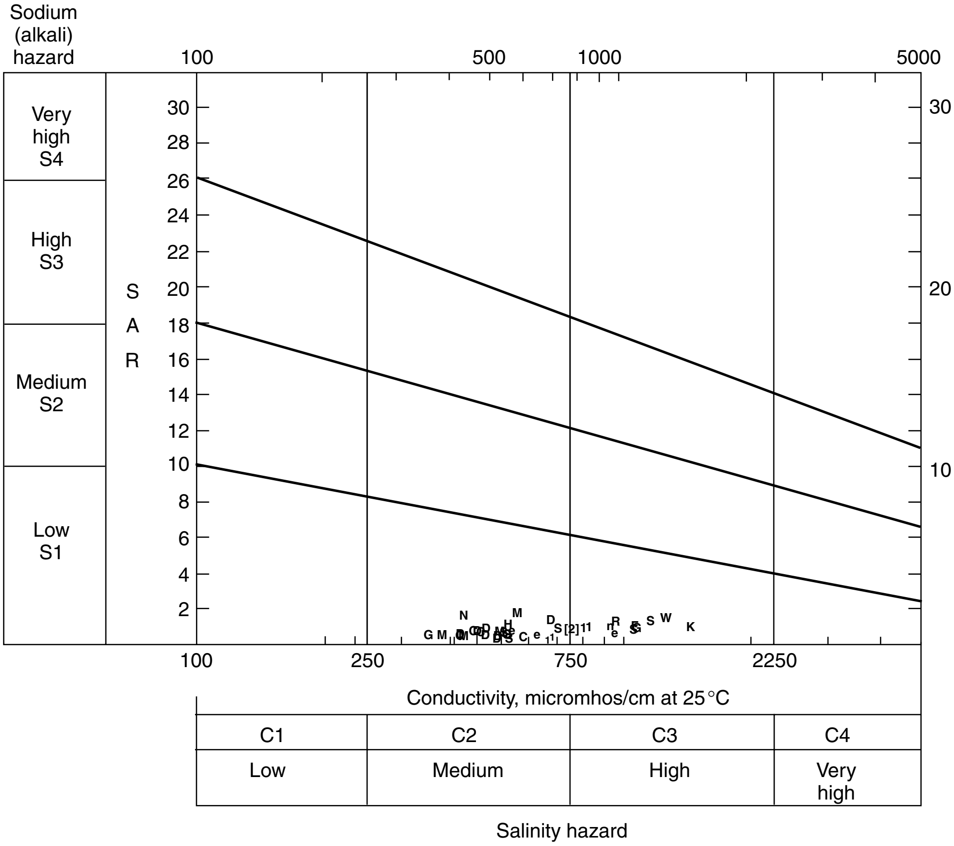

Figure 2. U.S. Salinity Laboratory classification, District Hardwar (pre-monsoon 2002).

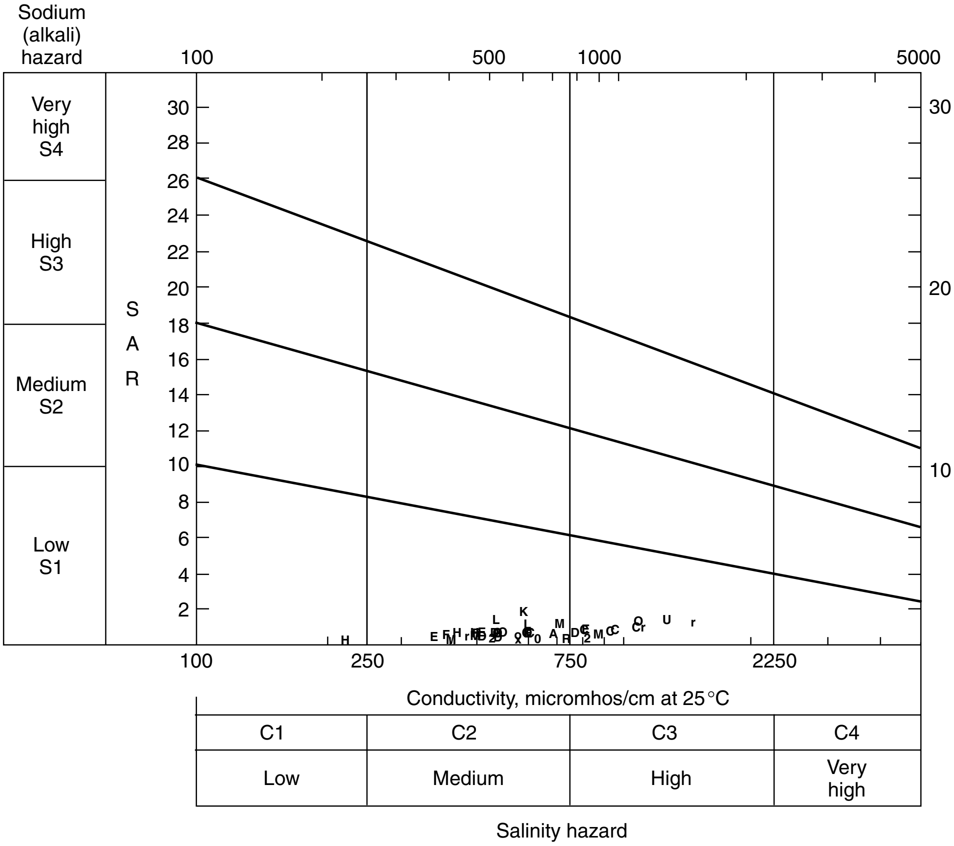

Figure 3. U.S. Salinity Laboratory classification, District Hardwar (postmonsoon 2002).

Table 7. Summarized Results of U.S. Salinity Laboratory Classification

	Sample Numbers	
Classification/Type	Premonsoon 2002	Postmonsoon 2002
C1-S1	17	17
C2-S1	3, 4, 5, 6, 7, 8, 9, 11, 14, 15, 18, 19, 20, 21, 22, 23, 26, 27, 28, 31, 32, 34, 35, 36, 37, 39, 40, 41, 42, 44, 45, 47, 48	3, 4, 5, 7, 8, 9, 11, 14, 15, 18, 19, 20, 21, 22, 23, 26, 27, 28, 30, 31, 32, 34, 35, 36, 37, 38, 39, 41, 42, 44, 45, 47, 48
C3-S1	1, 2, 10, 12, 13, 16, 24, 25, 29, 30, 33, 38, 43, 46	1, 2, 6, 10, 12, 13, 16, 24, 25, 29, 33, 40, 43, 46

classification because sodium reacts with the soil to create sodium hazards by replacing other cations. The extent of this replacement is estimated by the sodium adsorption ratio (SAR). A diagram for use in studying the suitability of groundwater for irrigation is based on the sodium adsorption ratio (SAR) and the electrical conductivity of water expressed in μS/cm. The chemical analytical data on groundwater samples from District Hardwar were processed as per the U.S. Salinity Laboratory classification for the two sets of data (Figs. 2 and 3), and the results are summarized in Table 7.

It is evident from the results that majority of the samples (about 70% of total samples) falls under water type C2-S1 (medium salinity and low SAR); such water can be used if a moderate amount of leaching occurs, and plants with moderate salt tolerance can be grown in most cases without special practices for salinity control. About 30% of the samples falls under water type C3-S1 (high salinity and low SAR); such water cannot be used on soils where drainage is restricted. Even with adequate drainage, special management for salinity control may be required, and plants with good tolerance should be selected. An almost similar trend was observed during the postmonsoon season.

CONCLUSIONS

Groundwater quality varies from place to place and with the depth of the water table. The SAR values indicate that the majority of samples from the study area falls under the category of low sodium hazard indicating no risk for sodification. In general, the groundwater of District Hardwar is safe for irrigation. According to the U.S. Salinity Laboratory classification of irrigation water, the majority of the samples (70%) falls under water type C2-S1 followed by the C3-S1 type.

INFILTRATION AND SOIL WATER PROCESSES

Joseph Holden
University of Leeds
Leeds, United Kingdom

Water at the soil surface is drawn into the soil pores under the influence of both suction and gravity. Suction (or tension/capillary) forces are largest in the small pore spaces between soil particles. Therefore, small pores fill first, and large pores empty first. As a soil becomes saturated, suction forces approach zero. As a soil dries, suction forces dominate, and there is little or no gravitational flow. For a dry soil during the early stages of wetting, the effect of soil pore suction is predominant. However, as the depth of wet soil increases, the suction gradient decreases (the same difference in suction is spread over an ever increasing depth interval) and the gravitational head gradient becomes the main driving force (1).

Infiltration processes cannot easily be separated from the processes involved in movement of water within soil because the rate of infiltration is partly controlled by the rate of soil water movement below the surface. Soil water movement continues after an infiltration, as the infiltrated water is redistributed. Infiltration and soil water processes play a key role in surface runoff, groundwater recharge, ecology, evapotranspiration, soil erosion, and transport of nutrients and other solutes in surface and subsurface waters.

Bodman and Colman (2) suggested that for a uniform soil, there would be a series of zones in the wetting part of the soil profile during an infiltration. The zone nearest the surface is a saturated zone (typically in the upper centimeter of the soil profile). As water penetrates more deeply, a zone of uniform water content, the transmission zone, develops behind a well-defined wetting front (Fig. 1).

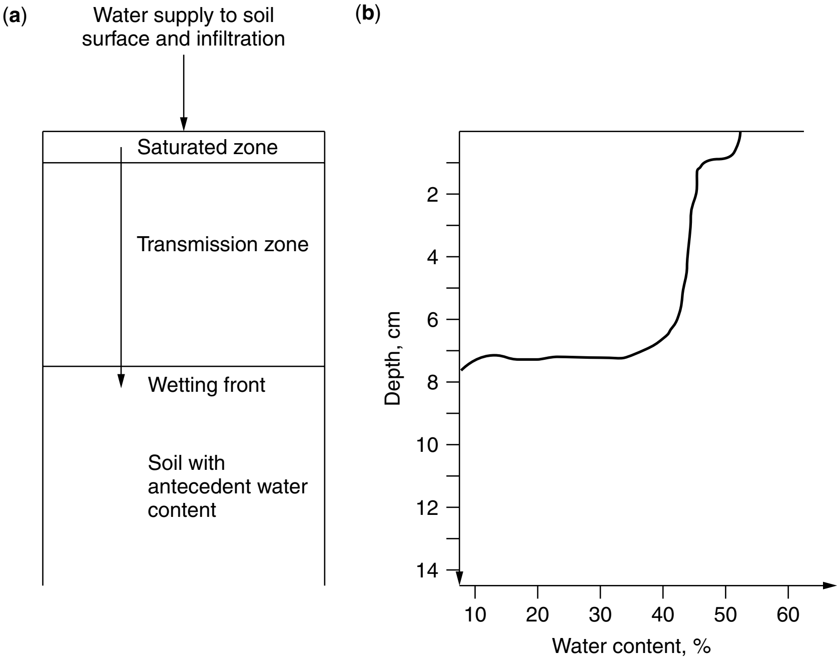

Figure 1. Soil water zones during infiltration: (**a**) theoretical zonation, (**b**) measured water content for a sandy soil 4 minutes after ponded infiltration commenced.

There is a sharp change in water content at the wetting front because the water at the boundary takes up a preferred position of minimum potential energy in the narrowest pores, for which the hydraulic conductivity is very low, and does not move at an appreciable rate until the large pores begin to fill. Figure 1 shows the water content versus depth for a sandy soil 4 minutes after ponded infiltration at the surface. The sharp transition in water content can be seen at the wetting front. Note that the soil below the wetting front still has some pre-event moisture. There is also a sharp transition in the moisture profile between the upper saturated zone and the transmission zone, sometimes called the transition zone (1).

Gravitational and suction gradients result in continued downward movement of water within the soil profile which may occur long after infiltration at the surface has ceased. As a result, the transmission zone which existed during infiltration becomes a draining zone that releases water from the wetter upper layers of the soil to deeper drier layers. As the draining zone becomes drier, the hydraulic conductivity reduces, and so the rate of soil water redistribution slows down. The suction gradient also weakens as the soil water content becomes more uniform. While the wetting front continues to advance into deeper soil layers, its movement is reduced over time until eventually the water content changes only very slowly and the soil is said to be at field capacity (1). In some soils, this may take several days (2). Theoretically, soil water redistribution following rainfall would continue until gravity and soil suction forces were in balance (4,5). At this stage and at all depths, there would be equal soil water potential. Therefore, without a hydraulic gradient, there would be no soil water movement, which is rarely observed in the field because soils are highly heterogeneous, rainfall itself is rarely an on–off uniform event (a theoretical model examining this issue was applied to a range of soil types by Ref. 6), and because evaporation from soil and plants can result in drying of surface soil layers.

Evaporation at the soil surface encourages upward movement of soil water, which therefore reduces downward movement of water over time. There is probably a two-way effect whereby drainage reduces the amount of evaporation and evaporation reduces the amount of drainage (3). During water redistribution following infiltration, the upper part of the soil profile may be drying through drainage and evaporation while the lower part is still becoming wetter, which complicates the water content–soil moisture tension (suction) relationship within the soil because it will depend on the history of wetting and drying in any given part of the soil profile (soil water hysteresis; 4,7,8).

Often, the soil water redistribution that follows an infiltration is complicated by the nonuniform nature of most soils. In addition to the effects of soil layering, many studies, for example, often assume that the water table has little impact on postinfiltration water redistribution. However, in many soils, the water table may be shallow (e.g., peats), and this may exert considerable influence on the distribution of water in a soil profile (9). Trapped soil gases may also affect water redistribution by blocking pores and preventing water entry (10). Furthermore, noncapillary macropores or voids such as decayed root channels, worm holes, and structural cracks that are open at the soil surface can capture the free water available at the surface during rainfall and overland flow. This causes the water flowing through the macropores to bypass the soil matrix. Often, water and solutes (e.g., fertilizer applications) can infiltrate into the soil via macropores but then are quickly transferred to much deeper parts of the soil profile where the water and nutrients are not readily available to plants (11,12). Bypassing flow also causes some parts of the soil profile at any given depth to wet well before other parts of the soil that are at the same depth.

INFILTRATION/CAPACITY/RATES

JOSEPH HOLDEN
University of Leeds
Leeds, United Kingdom

Infiltration is the process of water entry into the surface of a soil. It involves surface water entry, transmission through the soil, and depletion of the soil water storage capacity. Surface water entry is influenced by surface vegetation cover, soil texture, soil porosity, soil structure (e.g., cracks, surface crusting), and compaction. Land management can influence all of these parameters and therefore influence infiltration.

The infiltration rate is the volume of water passing into the soil per unit area per unit time and therefore has dimensions of velocity (e.g., m s^{-1}; mm h^{-1}). The infiltration rate is often measured using an infiltrometer (INFILTROMETERS) and is one of the most easily and frequently measured soil water processes. Despite the units of velocity, the values of infiltration rate are actually volume fluxes expressed as volume flux density and therefore do not indicate the effective velocity of vertical water movement in the soil (1).

The maximum rate at which water soaks into or is absorbed by the soil is the infiltration capacity. Infiltration capacity may be very important in determining the proportion of incoming rainfall that runs off as infiltration-excess overland flow and the proportion that moves into the soil. The infiltration capacity is different from the infiltration rate. Infiltration may be limited by the rate of supply of rainfall (or other water supply) or the capacity of the soil to absorb water. In the former case, infiltration is limited by the water supply to the soil surface, and in the latter case, infiltration is restricted by the infiltration capacity of the soil. Use of the term infiltration rate therefore indicates that infiltration is proceeding at less than the infiltration capacity (2). If infiltration is occurring at less than the infiltration capacity, then all rain reaching the soil surface that is not held as surface storage will infiltrate into the soil. Thus, there will be a direct relationship between infiltration rate and rainfall intensity. However, when rainfall intensity exceeds the infiltration capacity of the soil surface, this relationship breaks down and may be inverted, as infiltration capacity declines through a storm as the soil wets (2). Excess rainwater that cannot infiltrate into the soil because the surface water supply is greater than the infiltration capacity will pond on the soil surface and eventually run over the surface as infiltration-excess overland flow.

The infiltration capacity of a soil generally decreases during rainfall, rapidly at first and then more slowly, until a more or less stable value has been attained (Fig. 1). Water initially crosses the soil surface interface at an initial rate (f_0), depending on existing soil moisture content. As the rainfall or other water supply to the soil surface continues, the rate of infiltration decreases (because it is limited by decreasing infiltration capacity) as the soil becomes wetter and less able to take up water. Philip (3) put forward the theory that the infiltration capacity of a soil declines over time in a manner described by the equation,

$$f = A + Bt^{-0.5}$$

where $f =$ infiltration capacity at time t, and A and B are constants. This equation may be solved using simultaneous equations, allowing constants A and B to be evaluated:

$$B = (f_1 - f_0)/(t_1^{-0.5} - t_0^{-0.5})$$

$$A = (f_0 t_1^{-0.5} - f_1 t_0^{-0.5})/(t_1^{-0.5} - t_0^{-0.5})$$

The curve of infiltration rate over time shown in Fig. 1 reduces to a constant value f_c, which is the infiltration capacity at time t_c. The Philip model is useful for short infiltration events, but other models (e.g., those based on the Richards equation) are more reliable for longer periods (4,5).

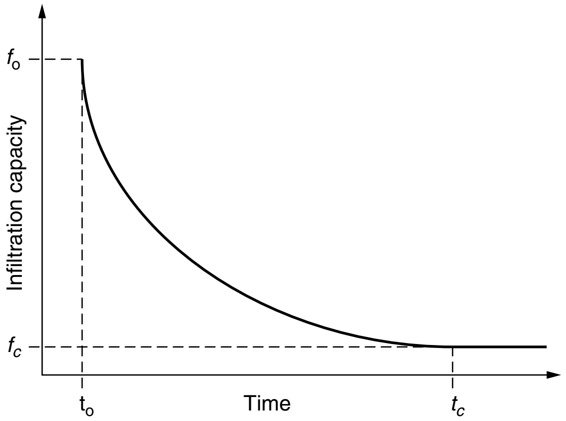

Figure 1. The decline of infiltration capacity during a rainfall.

Soil surface conditions may impose an upper limit on the rate at which water can be absorbed, despite a large available capacity of the lower soil layers to receive and to store additional infiltrating water. Often, the infiltration capacity is reduced by surface sealing resulting from compaction, washing of fine particles into surface pores, and by frost (6,7). Frozen moisture will block soil pores, and the greater the frozen moisture content, the lower the infiltration rate upon melt, as the larger pores remain blocked for longest. Holden and Burt (8) noted that infiltration capacity increases with the depth of standing water on the surface because of increased water head (9,10) and unblocking of pores due to flotation of fines (11). The number of cracks and fissures at the surface and the ground slope also influences infiltration capacity. Cultivation techniques may either increase or decrease infiltration capacity (12). Field plowing can increase soil infiltration capacity, whereas raindrop compaction subsequent to field plowing can reduce infiltration capacities when splashed silt and clay soil particles clog soil pores as the aggregates break down. Organic matter also binds aggregates together. New vegetation, however, tends to increase the infiltration capacity of a soil by retarding surface water movement, stabilizing loose particles, reducing raindrop compaction, and improving soil structure. Soils with well developed humus and litter layers tend to have high infiltration capacities. Most forest floors that have a litter layer tend, for example, to have higher infiltration than that beneath grass (2).

The infiltration capacity of a soil is dependent on surface properties and also on transmission through the soil below the surface and the storage capacity of the soil. Water cannot be absorbed by the soil surface unless the underlying soil profile can conduct the infiltrated water away. Transmission rates depend on soil texture, porosity, pore size distribution, soil stratification, antecedent soil moisture content, initial gradient of soil water potential, salinity, and biotic activity. Storage capacity depends on pore size distribution, porosity, and antecedent moisture conditions. Where the soil profile contains a relatively impermeable layer at some distance below the surface, the curve of infiltration capacity against time may display a sudden reduction of infiltration capacity because when available storage in the surface soil horizons has been filled, infiltration will be governed by the rate at which water can pass through the underlying impeding layer.

Soil properties are highly heterogeneous. Infiltration capacities and infiltration rates vary greatly even within a small area and in a short time. The effect of spatial variability on infiltration produces a difference between point infiltration values and apparent infiltration rates associated with measurements from large plots, composite areas, and estimates from watershed calculations, which may provide a reason that mean infiltration capacity across a plot increases with rainfall intensity (13,14; see also RAIN SIMULATORS). In other words, the nonuniform nature of soil across a large plot may cause in the surface of one part of the plot to have a higher infiltration capacity than the rest of the plot. Therefore, as Hawkins (13) demonstrated numerically, the mean infiltration rate across a plot will increase with rainfall intensity simply because a greater flux of water is occurring through the parts of the plot surface that have higher relative infiltration capacities. It must be acknowledged, therefore, that only a fraction of the area within a plot or hillslope need contribute to overland flow, even when the rainfall rate exceeds the mean infiltration capacity across the plot or hillslope, which also suggests that the spatial variability in infiltration parameters has more effect at lower rainfall rates, closer to the saturated hydraulic conductivity of the soil (5).

INFILTROMETERS

Joseph Holden
University of Leeds
Leeds, United Kingdom

Infiltrometers allow measuring of the rate of infiltration of water into a given medium. Rain simulators, a particular type of infiltrometer, are discussed elsewhere (see entry Rain Simulators). Unlike rain simulators, other infiltrometers do not simulate raindrop activity but measure the rate of infiltration from a reservoir of water at the ground surface. Their main advantage is their simplicity and ease of use. There are two main types of infiltrometer, a ponded ring infiltrometer and a disk infiltrometer.

PONDED RING INFILTROMETER

A ponded ring infiltrometer is the most common type of infiltrometer used. It is inexpensive to construct or operate and requires relatively little water for measurements. One person can set up and run several tests simultaneously. A cylindrical ring of stainless steel or plastic pipe is used, and the ring is pushed a few centimeters into the ground (Fig. 1). Care is taken to minimize disturbing the soil surface and soil structure during installation. Water is then flooded into the ring. The water inside the ring gradually infiltrates the soil, so measurements of the depth of water in the ring over time can be used to provide an infiltration rate usually in units of length per unit time (e.g., mm hr^{-1}) allowing easy comparison with rainfall intensity data. If the ring empties, it can be easily refilled.

There are two main problems in this method: (1) lateral flow below the ring; (2) changing pressure of water in the ring as the water level decreases in the ring during infiltration. To get around the lateral flow problem, it is advisable to use two concentric rings; the larger ring forms a buffer compartment around the inner ring (Fig. 2). While water is topped up in the outer ring, measurements are taken only of infiltration from the inner ring. It is preferable that a constant head of water is maintained within the rings to avoid changing pressures. The head of water should also be less than 5 cm deep. The constant head can be supplied by a Mariotte bottle placed above the rings, and readings of water usage can be made from the Mariotte bottle (Fig. 2). Thus the optimum design for a ring infiltrometer is a constant-head, double-ring device whose rings have large diameters, so that they can represent the soil surface more readily. A plot of water uptake against time should show a leveling off as the infiltration capacity is reached. It often takes several hours before a constant rate of infiltration is achieved from the infiltrometer, depending on soil type, texture, and antecedent soil moisture.

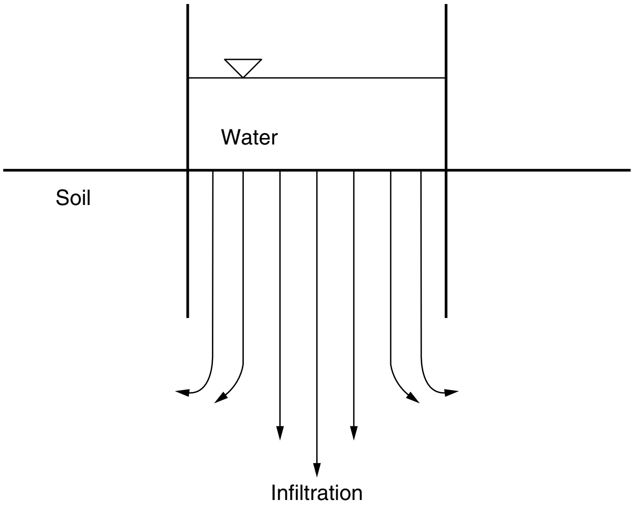

Figure 1. Infiltration from a single ring infiltrometer.

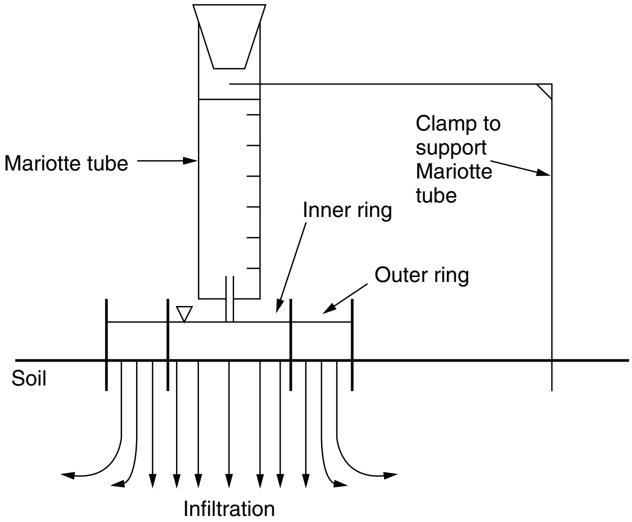

Figure 2. Double-ring infiltrometer with constant-head supply.

The method of placement is serious limitation to the use of ring infiltrometers. Knocking rings into the ground can result in destruction of the soil structure or compression. If a soil is shattered, it can disturb the contact between the ring edge and the soil, resulting in leakage and high infiltration rates. Research has demonstrated that ring infiltrometers give higher infiltration rates than rain simulators because of the effect of a pond on the soil surface, lateral seepage, and soil cracking.

DISK INFILTROMETER

Tension disk infiltrometers are a standard tool for in situ determination of saturated and near-saturated soil hydraulic properties. These infiltrometers have a porous membrane disk at their base which rests on the soil surface of interest. To assess the role of matrix and macropore flow, a tension infiltrometer allows infiltration of water into the soil matrix, while preventing flow into larger pores that may otherwise dominate the infiltration process. The infiltrometer provides a source of water at a small negative pore water pressure at the surface. The supply pressure head is controlled with a Mariotte bottle. A schematic diagram of a tension disk infiltrometer is given in Fig. 3. As for a ring infiltrometer, infiltration rates can be measured manually by observing the volume of water lost from the Mariotte bottle over time. The negative pressure prevents the larger pores that fill at greater pore water pressures from wetting and short-circuiting the flow. Hence, by subtraction, the hydrological role of larger pores during the infiltration process can be evaluated. Further details on designs for these infiltrometers are given in Ankeny et al. (1) and Zhang et al. (2). Most studies using tension disk infiltrometers have been conducted at the soil surface, although Azevedo et al. (3) looked at infiltration properties of an Iowa loamy soil at 0.15 m depth, and Logsdon et al. (4), and Messing and Jarvis (5) conducted measurements at different depths under different agricultural tillages.

Careful preparation of the soil surface is required to use a disk infiltrometer, which is to ensure even and sound contact of the disk with the soil surface. At each location, vegetation must be cut back to the soil surface, and a fine layer of moist fine sand of the same diameter as the circular base of the infiltrometer should be applied, which must be smoothed out to remove any irregularities at the soil surface and improve contact between the disk and soil surface. Moist sand is essential as air-dry sand may readily fall down into surface-vented macropores, forming ‘wicks’ (5). The infiltrometer is then placed on the sand. The weight of the infiltrometer must not be too great so as compress the soil surface significantly, as this will restrict the water flux. Therefore, it is usual to make the water supply reservoir narrow so that the total volume of water held in the infiltrometer is low, resulting in reduced weight and also aiding accurate measurements of discharge.

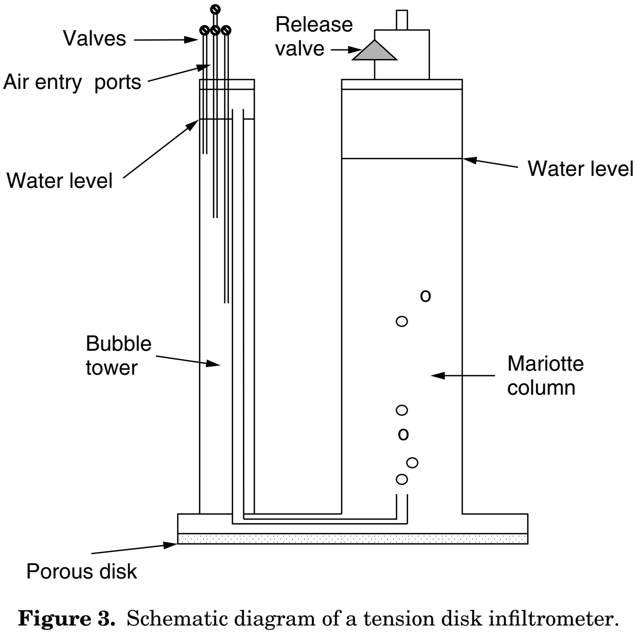

Figure 3. Schematic diagram of a tension disk infiltrometer.

If a range of supply heads is to be used, then infiltration tests are normally conducted with the lowest supply head first. Reversal of this may lead to hysteresis where drainage occurs close to the disk while wetting continues near and at the infiltration front (6). Infiltration measurements should proceed until a steady state is achieved. Users should be careful to ensure that sunlight does not heat the supply reservoir significantly: this can be reduced by shading.

Methods for analyzing the data from disk infiltrometers (e.g., hydraulic conductivity values and macropore contribution to infiltration) are given in Reynolds and Elrick (6). Typically, Wooding’s (7) solution for infiltration from a shallow pond is combined with Gardner’s (8) unsaturated hydraulic conductivity function. A range of assumptions is involved in using of these techniques, including that the hydraulic conductivity before the test is much less than that imposed under the infiltration experiment and that the soil below the tension disk is homogeneous, isotropic, and uniformly saturated, which are unlikely to be satisfied fully in most soils, and so it is necessary to evaluate the potential errors involved (9).

Water levels in supply bottles for both the ring and disk infiltrometers can be measured automatically by using electronic pressure sensors with data recorders, thus allowing an experiment to continue unattended for several hours if the infiltration rates are very low.

SUMMARY OF ISOTOPES IN CONTAMINANT HYDROGEOLOGY

Segun Adelana
University of Ilorin
Ilorin, Nigeria

INTRODUCTION

The word contaminant is a general term to describe dissolved constituents, nonaqueous phase liquids (NAPLs), or industrial solvents which, when added to water as a result of human activities, impair groundwater quality. To an important extent, the complexity of a groundwater contamination problem can be determined by whether or not NAPLs are present (1). Obviously, contaminants related to anthropogenic activities are one of the major threats facing groundwater resources today. Groundwater contamination can have a significant impact on the present and future use of groundwater resources as a source of drinking water for an increasing population living in cities and rural areas (2).

In the investigation of problems posed by contaminants in the hydrologic environment, the modern approach is to use a combination of tracers. These tracers include radioactive isotopes (such as ^{3}H, ^{13}C, ^{14}C,), stable isotopes (^{18}O, ^{2}H), and dissolved geochemical constituents (Cl^{-}, $SO_4{}^{2-}$, $NO_3{}^{-}$ and some cations). An important facet of contaminant hydrogeology is the movement of liquids that are immiscible with water through the vadose zone as well as below the water table. Such liquids are usually called nonaqueous phase liquids. There are numerous cases of groundwater contamination involving organic liquids that are either insoluble or partially soluble in water. When the densities of these liquids are greater than that of water, they are called dense nonaqueous phase liquids (DNAPLs). Those whose densities are less than that of water are light nonaqueous phase liquids (LNAPLs). They could also be partially soluble in water, such that both dissolved and nonaqueous phases may be present (3–7).

The major groups of contaminants in hydrogeology include radionuclides, trace metals, and nutrients. They could also be classified as inorganic and organic contaminants. These include synthetic organic compounds, hydrocarbons, and pathogens (7). Some types of these contaminants are inorganic chemicals that are either metallic or nonmetallic (1,8). Included in the group of organic contaminants are NAPLs, which naturally subdivide into LNAPLs and DNAPLs (7).

A wide variety of materials have been identified as contaminants found in groundwater. An extensive listing of these compounds is tabulated in (Reference 7, pp. 3–10). Many of these materials will dissolve in water to different degrees. Some of the organic compounds are only slightly soluble and will exist in both dissolved form and as an insoluble phase, which can also migrate through the ground (7). According to (2), the main relevant organic compounds of the LNAPLs are benzene, toluene, ethylbenzene, and xylenes (BTEX) from spills at gas stations and industrial facilities. The most common compounds of the group found in groundwater are perchloroethene (PCE), trichloroethene (TCE), *cis*-1,2-dichloroethene (*cis*-1,2-DCE), and dichloroethane (DCA) (9). In terms of environmental contamination, the major concern is focused on those organic compounds that are not readily degraded by bacteria, either in the soil zone or in sewage treatment facilities. The presence of these substances in the surface environment is becoming increasingly pervasive (8).

The sources that contribute to groundwater contamination are varied. Among these are land disposal of solid wastes, inorganic substances, metal and nonmetal trace elements. Other sources of groundwater contamination are from introducing of salts on roads to combat ice in winter, the infiltration of leachate from tailings in the mining industry, seepage from industrial water lagoons and septic tanks of urban waste disposal systems, wastewater discharge into rivers and lakes, agricultural wastes and fertilizers, saline or geogenic polluted water attracted by overexploitation of groundwater, and fossil fuels (1,7,8,10,11). Inorganic cations and anions occur in nature and may come from natural as well as anthropogenic sources. Some of the radionuclides are naturally occurring; others are man-made and come from the production and testing of nuclear weapons.

There are three important attributes that distinguish sources of groundwater contamination: (1) their degree of localization, (2) their loading history, and (3) the kinds of contaminants emanating from them (1). From the work of Domenico and Schwartz (1) contaminants are organized by groups according to reaction type and mode of occurrence. Six categories have been tabulated:

Category 1—Sources designed to discharge substances, for example, subsurface percolation (from septic tanks and cesspools), injection wells (hazardous and nonhazardous wastes), and land application.

Category 2—Sources designed to store, treat, and/or dispose of substances; discharge through unplanned release, for example, landfills, open dumps (including illegal dumping waste), residential or local disposal wastes, waste tailings, material stockpiles (nonwaste), graveyards, animal burial, surface and underground storage tanks, and containers.

Category 3—Sources designed to retain substances during transport or transmission, for example, pipelines and materials transport and transfer operations.

Category 4—Sources discharging substances as a consequence of other planned activities, for example, irrigation practices, pesticide applications, fertilizer applications, animal feeding operations, deicing salt applications, urban runoff, percolation of atmospheric pollutants, and mining and mining drainage.

Category 5—Sources providing conduits or inducing discharge through altered flow patterns, for example, production wells (oil/gas wells, geothermal and heat recovery wells, water supply wells), other nonwaste wells (monitoring and exploration wells), and construction excavation.

Category 6—Naturally occurring sources whose discharge is created and/or exacerbated by human activity, for example, groundwater–surface water interactions, natural leaching, saltwater intrusions and brackish water upconing, or intrusion of other poor-quality natural water.

For details of sources and background concentrations of contaminants in groundwater, refer to Forstner and Wittman (10). More information on inorganic contaminants is available in Reference 7 (Chapter 6), Reference 1 (Chapter 17); methods of detecting groundwater contamination are fully discussed in Domenico and Schwartz (1), and the sources and hydrochemical behavior of contaminants are described in Chapter 9 of Reference 8 as well as Chapter 1 of Reference 11. As a general introduction to groundwater contamination and related literature, the following are suggested for further reading: Baetsle (12), Fuhriman and Barton (13), Hall (14), Scalf et al. (15), Miller et al. (16), Summers and Spiegal (17), Cherry et al. (18), Back and Cherry (19), Fried (20), Todd and McNulty (21), Wilson et al. (22), Freeze and Cherry (8), IAEA (23, 24), Pearson et al. (25), Fetter (7), Pankow and Cherry (9), Domenico and Schwartz (1), and Seiler (11).

ENVIRONMENTAL ISOTOPES IN CONTAMINANT HYDROGEOLOGY

Introduction

For many years, environmental isotopes have been used in hydrogeology to address a range of issues such as evaluation of recharge areas, determination of groundwater residence time, and evaluation of surface water–groundwater interactions. Isotope studies applied to a wide spectrum of hydrologic problems related to both surface and groundwater resources as well as environmental studies in hydro-ecological systems are presently an established scientific discipline, called “Isotope Hydrology.” However, it is now becoming increasingly popular to use environmental isotopes as tracers to provide information about sources of contaminants and processes that affect these compounds in the groundwater flow system (2).

In essence, isotope techniques are becoming an integral part of many hydrologic investigations and sometimes a unique tool in studies related to groundwater contamination. Stable and radioactive environmental isotopes have now been used for more than four decades to study hydrologic systems, particularly in determining the hydrodynamics of aquifers, and have proved useful for understanding groundwater systems. The applications of isotopes in hydrogeology are based on the general concept of “tracing,” in which either intentionally introduced isotopes or naturally occurring (environmental) isotopes are employed.

Environmental isotopes (either radioactive or stable) have the distinct advantage over injected (artificial) tracers in that they facilitate the study of various hydrologic processes on a much larger temporal and spatial scale through their natural distribution in a hydrologic system. Thus, environmental isotope methodologies are unique in regional studies of water resources to obtain the time and space integrated characteristics of groundwater systems. The use of artificial tracers generally is effective for site-specific, local applications (26,27). Environmental isotopes can now be used to trace the pathways as well as spatial distribution and temporal changes in pollution patterns for assessing pollution migration scenarios and planning for aquifer remediation (27,28).

Recent research and the development of new analytical methods have led to fast expansion of the application of isotopes in hydrogeology. In particular is the introduction of techniques that make it possible to measure isotopic ratios of individual compounds at low concentrations (29). These have opened new and exciting possibilities for using isotopes in organic contaminant studies in groundwater. For example, nitrogen and carbon isotopes can now provide information regarding such attenuation processes as the denitrification and biodegradation of halogenated solvents, respectively (28).

Environmental isotopes have, therefore, become useful tools in differentiating between different sources of organic contaminants or in assessing biotic and abiotic transformation processes associated with natural attenuation or engineered groundwater remediation techniques (30–32). The isotope method used to evaluate the degradation of organic contaminants relies on the frequent occurrence of small differences in the degradation rate between molecules of the same contaminant that contain different isotopes. Usually, the rate is slightly faster for molecules that contain light isotopes (e.g., ^{12}C) compared to those that contain heavy isotopes (e.g., ^{13}C) because bonds between light isotopes are weaker. As a result, degrading contaminants should contain increasingly more of the heavier isotope (^{13}C) as degradation proceeds, and thus the ratio between heavy and light isotopes ($^{13}C/^{12}C$) is expected to increase (2). Oxygen-18 in dissolved oxygen also has a significant potential as a tracer to evaluate the fate of oxygen in contaminated plumes.

The sequel to these environmental isotope studies has focused on the light elements and their isotopes: hydrogen (^{1}H, ^{2}H, ^{3}H), carbon (^{12}C, ^{13}C, ^{14}C), nitrogen (^{14}N, ^{15}N), oxygen (^{16}O, ^{18}O), and sulfur (^{32}S, ^{34}S). These are the most important elements in biological systems that occur in relatively great abundance and also participate in most geochemical reactions (33). Other less important and less abundant isotopes (^{17}O, ^{33}S, ^{36}S) are not often employed in environmental studies but have significance in very specific studies. Table 1 lists the isotopes of major elements used in environmental studies and their average abundances in natural compounds.

Table 1. Isotopes of Major Elements Used in Environmental Studies[a]

Element	Isotopes	Average Terrestrial Abundance, (%)	Comments[b]
Hydrogen	^{1}H	99.984	
	^{2}H	0.015	
	^{3}H	10^{-14} to 10^{-16}	Radioactive, $t_{1/2} = 12.35$ years
Carbon	^{12}C	98.89	
	^{13}C	1.11	
	^{14}C	$\sim 10^{-10}$	Radioactive, $t_{1/2} = 5730$ years
Oxygen	^{16}O	99.76	
	$^{17}O^{c}$	0.037	
	^{18}O	0.1	
Nitrogen	^{14}N	99.34	
	^{15}N	0.366	
Sulphur	^{32}S	95.02	
	$^{33}S^{c}$	0.75	
	^{34}S	4.21	
	$^{36}S^{c}$	0.02	
Strontium	$^{84}Sr^{c}$	0.56	
	^{86}Sr	9.86	
	^{87}Sr	~7.02	
	$^{88}Sr^{c}$	82.56	
Uranium	^{234}U	~0.0056	Radioactive, $t_{1/2} = 2.47\times10^{5}$ years
	$^{235}U^{c}$	0.7205	Radioactive, $t_{1/2} = 7.13\times10^{8}$ years
	^{238}U	99.274	Radioactive, $t_{1/2} = 4.51\times10^{9}$ years

[b] $t_{1/2}$ = half-life.

[c] These isotopes are not presently used in environmental studies.

Uses of Isotopes in Contaminant Hydrogeology

General uses of environmental isotopes in contaminant studies are often based on evaluating the various sources of contaminants in both surface and groundwater. The isotope approach to evaluating these sources relies mostly on the distinct isotope composition, that can characterize the different sources of contaminant (2,34). Environmental isotopes have found good use as tracers both artificially and naturally (26,35–38). For general review of the use of environmental isotopes in contaminant hydrogeology and potential future use of these tracers in vulnerability studies in groundwater, see References 2,27 and 28.

Environmental isotopes have been found widely applicable, especially in identifying the origin of water that is infiltrating an aquifer (28). Obviously, there is a relationship between recharge and the vulnerability of groundwater to contamination because the transport of many contaminants to the saturated zone of the aquifer occurs in the dissolved phase as part of the recharge process (39). Generally, ^{18}O and ^{2}H, among the various environmental isotopes, are most widely used in defining groundwater recharge areas as well as their origins. Changes in the isotopic relationships between $^{18}O/^{16}O$ and $^{2}H/^{1}H$, during the evaporation and condensation of water allow defining its origin (28).

New isotope applications are being developed in organic contaminant studies of groundwater. These studies have shown that carbon isotopes allow very sensitive evaluation of the fate of precursors and by-products of the biodegradation of chlorinated compounds, which are the most common organic contaminants found in groundwater. Potentially new applications include ^{18}O to evaluate the fate of oxygen in contaminant plumes and ^{11}B in salinization and nitrate studies of groundwater (2). Table 2 shows the potential/common applications of isotopes in groundwater pollution studies.

Boron-11, a stable isotope of boron, has also been used to differentiate nitrate from sewage and fertilizers as well as to trace the sources of salinity in groundwater. This approach was used to differentiate isotopic composition of injected treated wastewater and irrigation-affected water ($\delta^{11}B > 40‰$) distinctly and to trace the effect of injection into an alluvial aquifer near El Paso, Texas (40).

It has also been possible to approach the tracing of various organic pollutants (chlorinated hydrocarbons) in groundwater by using a combination of the isotopes $^{13}C/^{12}C$, $^{2}H/^{1}H$, and $^{37}Cl/^{35}Cl$. For example, the isotopic ratios $^{37}Cl/^{35}Cl$ and $^{10}B/^{11}B$ have been used recently in pollution studies of groundwater (41,42). The strontium isotopic ratio ($^{87}Sr/^{86}Sr$) is also a valuable tracer for studies related to the mixing and origin of mineralized groundwater. It is a tracer for the origin of salinity, groundwater movement, and water–rock interactions (43,44). In the past, a combination of stable and radioactive isotopes that has dissolved geochemical constituents has been used in tracing the migration of contaminants in groundwater (45–47).

According to Hirata and Varnier (28), isotope techniques are useful in determining groundwater pollution vulnerability, to the extent that they allow for better understanding of the degree of access provided for penetration of contaminants and the attenuative capacity offered by the geologic medium (Table 3).

The most frequently used environmental isotopes in contaminant hydrogeology include nitrogen isotopes ($^{14}N/^{15}N$), chlorine - 37, the sulphur isotope (^{34}S), carbon

Table 2. Common/Potential Isotopes Used in Groundwater Pollution Studies[a]

Isotope(s)	Potential/Common Applications
^{13}C in HCO_3^- and CH_4	Identifying of methane sources Monitoring CO_2 and CH_4 production in biodegradation studies
^{34}S and ^{18}O in SO_4^{2-}	Identifying of sources of pollution Acidification and acid mine drainage
^{15}N and ^{18}O in NO_3^-, NH_4^-, N_2	Origin of nitrates Sources of pollution Microbial denitrification processes
^{11}B in B $(OH)_4^-$ and B $(OH)_3^-$	Identifying of pollution sources Characteristics of brines, source of salinity
Chlorine-37 (^{37}Cl)	Identifying pollution sources Characteristics of brines, sources of salinity
Tritium (^3H)	Indicators of recent pollution/recharge Water transport in the unsaturated zone
Strontium isotope ratio ($^{87}Sr/^{86}Sr$)	Tracer for the origin of salinity, mixing, and origin of mineralized groundwater, groundwater movement, and water–rock interactions.
Uranium isotopes (^{234}U, ^{238}U)	Sensitive indicators of radioactive pollution in natural waters, Rock–water interaction, dating of old groundwater

[a] Modified from Reference 27.

Table 3. The Use of the Isotope Technique for Groundwater Pollution Vulnerability Characterization[a]

Component of Aquifer Pollution Vulnerability	Information Related to	Isotope Technique
Hydraulic accessibility of the saturated aquifer to penetration of pollutants	Identification of recharge/discharge areas Degree of aquifer confinement Definition of period of recharge Identification of paleowaters Interconnection of surface and groundwater	^{18}O in H_2O ^2H in H_2O ^{85}Kr flow through fissured rock ^3H in H_2O (environmental and applied tracer) ^{51}Cr, ^{58}Co, ^{60}Co, ^{131}I (applied tracers)
Attenuative capacity of strata overlying the saturated zone, resulting from the physicochemical retention or reaction of pollutants	Determination of transit time of water through the saturated and unsaturated zones (advective flow)	Dating young water ^3H ^3He Dating midage water ^{39}Ar ^{14}C, correction with ^{13}C in HCO_3^- ^{81}Kr Dating old water ^{81}Kr ^{234}U
	Identification of physico chemical reactions of pollutants (degradation)	^{15}N and ^{18}O in NO_3^-, NH_4^+, N_2, microbial denitrification processes ^{13}C, biodegradation of synthetic solvents and fuel ^{34}S, oxidation/reduction of sulfur
Pollution hazard factors	*Information related to*	*Isotope technique*
Definition of pollutant origin	Identification of source of pollution	^{34}S and ^{18}O in SO_4^{2-}, acidification and acid mine drainage ^{37}Cl, ^{11}B, in $B(OH)_4^-$ and $B(OH)_3^-$ characteristics of brines; sources of salinity ^{15}N and ^{18}O in NO_3^-, NH_4^+, N_2 ^{18}O, ^2H in H_2O, salinization mechanisms, recycling of irrigation water ^{14}C and ^{13}C for origin of sources of organic compounds

[a] After Reference 28.

isotopes (^{13}C, ^{14}C), and the boron isotope (^{11}B). Those of the water molecules (^{18}O, ^2H) are also sometimes used with some of these isotopes in groundwater contamination studies. Following are brief descriptions of the isotopes commonly employed in contaminant hydrogeologic studies.

Nitrogen Isotopes ($^{14}N/^{15}N$). The most common contaminant identified in groundwater is dissolved nitrogen in the form of nitrate (NO_3^-). Other forms of inorganic nitrogen are nitrite (NO_2^-), nitrogen gas (N_2), ammonia (NH_4^+), and cyanide (CN^-). Nitrogen is also a major constituent of organic matter as amino acids (7). These contaminants are becoming widespread due to increased agricultural activities worldwide and disposal of sewage on or beneath the land surface.

Nitrogen occurs as two isotopes in nature: ^{14}N(≈99.6%) and ^{15}N(≈0.36%). ^{14}N is more abundant in the atmosphere than ^{15}N. Hence, the ^{15}N/^{14}N ratio in nitrate can be used to distinguish the origin of nitrates either from animal/human wastes or from the application of chemical fertilizers (48,49). The origin of contamination by nitrates can be determined through the relationship between ^{15}N/^{14}N and standard values (δ^{15}N). Combined isotope analyses of nitrogen and oxygen in NO_3^- leave fingerprints on natural and anthropogenic sources of nitrate; on microbial denitrification, nitrification and biological fixation processes; and on the nitrogen budget in groundwater (50–53).

Therefore, the δ^{15}N values of dissolved nitrates, ammonium, and organic nitrogen in soil water are well distinguished from one region to another. The δ^{15}N of animal waste is between +5 to 15‰, and fertilizers have a δ^{15}N of about 0‰. However, for nitrogenous fertilizers, these values lie between −4‰ and +4‰ (50,54).

For more information and related nitrogenous inputs in groundwater, refer to Foster and Crease (55), Kreitler and Jones (56), Létolle (57), Kreitler and Browning (58), White (59), Flipse et al. (60), Heaton (60), Mariotti (61), Flipse and Bonner (62), Tessendorff (63), Hübner (64), Mariotti (65), Böttcher et al. (51), Exner and Spalding (66), Aravena et al. (52), Buzek (67), Révész et al. (68), Pauwels et al. (69), Tore et al. (70), and Anwar and Ghosh (71).

Chlorine-37. Naturally, chlorine exists with two common stable isotopes: ^{35}Cl (≈75.7%) and ^{37}Cl (≈24.2%). Chloride ions are generally not reactive and as such, do not participate in redox reactions, are not sorbed onto mineral or organic surfaces, and do not form insoluble precipitates. As a result, ^{37}Cl is sometimes used as a conservative tracer in groundwater studies. Data are expressed as δ^{37}Cl with respect to the standard mean oceanic chloride (SMOC). The ratio ^{37}Cl/^{35}Cl is measured by isotope ratio mass spectrometry (IRMS). Precision must be better than ± 0.1‰ (72). δ^{37}Cl values contain information on the origin of chloride ions in fresh and polluted groundwater as well as in subsurface brines (30,41,42).

In geochemical studies generally, chlorine isotopes are not highly fractionated, but research has shown that measurable fractionations can be used to distinguish sources of groundwater mixing (73). The ^{37}Cl content of chloro contaminants in groundwater can fingerprint the sources of contaminants and salinity. It is therefore a potential tool in contaminant hydrogeology (27,43).

Sulphur Isotope (^{34}S). Sulphur has four stable isotopes: ^{32}S (95.02%), ^{33}S (0.75%), ^{34}S (4.21%), and ^{36}S (0.02%). The abundance ratio of ^{34}S and ^{32}S is generally given as a δ^{34}S value. Iron sulfide from the troilite phase of the Diablo Canyon iron meteorite (DCT) (that has a ^{32}S/^{34}S ratio of 22.220) is conventionally used as a standard (72). ^{34}S is one of the distinct isotopes that can be used to characterize different sources of sulfate contamination. For example, high sulfate in aquifers in areas close to mine tailings could be associated with the oxidation of sulfide minerals in the tailings. However, other sources of sulfate in aquifers such as gypsum of marine origin, input from volcanic sources, or sulfate from recirculated water from agriculture have been identified (2). Generally, sulfate produced from sulfide minerals is much more depleted in ^{34}S and ^{18}O than marine sulfate (74,75).

Moreover, owing to isotope fractionation during sulfate reduction, ^{34}S and ^{18}O in sulfate can also be used to evaluate the fate of sulfate in groundwater flow systems (76). The isotopic composition of sulfate can also be an indicator of anthropogenic pollution of groundwater (75).

Carbon Isotopes (^{13}C, ^{14}C). Carbon has three isotopes in nature: ^{12}C, ^{13}C, and ^{14}C. The heavy carbon isotope, ^{14}C, is unstable and decays radioactively into ^{14}N. The stable isotopes of carbon, ^{13}C and ^{12}C, have an average ratio of about 1:100 (72). The isotopic composition of carbon in the dissolved carbon constituents of groundwater is very variable. The sources of carbon dissolved in groundwater are soil CO_2, CO_2 of geogenic origin or from magmatic CO_2 (from deep crustal or mantle sources) or in fluid inclusions, living and dead organic matter in soils and rocks, methane, and carbonate minerals (53). Each of these sources has a different carbon isotopic composition and contributes to total dissolved carbon in various proportions. Therefore, the isotopic composition of dissolved inorganic carbon compounds in groundwater has a wide range of δ^{13}C values.

Carbon isotopes (^{13}C, ^{14}C) can be used to evaluate the origin of methane in landfills (2). The origin of methane is a common problem in landfills located in old quarries. Methane in this type of environment can be thermocatalytic in origin, associated with gases present in the bedrock or/and originating in the landfill itself (2). According to Schoell (77), gases of thermocatalytic origin are generally more enriched in carbon-13 ($\delta^{13}C > -50$‰) than methane of biogenic origin ($\delta^{13}C < -50$‰). In addition, Hackley et al. (78) proved that catalytic gases are devoid of carbon-14, whereas methane in landfills has a ^{14}C content higher than 100% modern carbon (pmc). Obviously, due to carbon-14 from thermonuclear explosions, any carbon in domestic waste that was deposited in a landfill after 1950 is usually characterized by a ^{14}C content higher than 100 pmc (2). Furthermore, carbon isotopes have also been employed in monitoring CO_2 and CH_4 production in biodegration studies in unsaturated areas impacted by organic contamination (79,80).

Boron Isotope (^{11}B). Natural boron has two stable isotopes, ^{11}B (≈80%) and ^{10}B (≈20%). The variation in the ratio of these two isotopes is expressed in δ^{11}B (‰) with respect to SRM-951 NBS standard (81). Generally, boron is present in groundwater mainly as trigonal undissociated boric acid, $B\ (OH)_3{}^0$, and its conjugate base, tetrahedral borate, $B\ (OH)_4{}^-$. Tetrahedrally coordinated boron is more isotopically depleted (i.e., lower in δ^{11}B) relative to trigonally coordinated boron; thus the δ^{11}B of dissolved boron in groundwater is usually higher than that in aquifer rocks (81).

Boron is used as tracer in groundwater because of its high solubility in aqueous solution, natural abundance in all waters, and the lack of effects from evaporation, volatilization, and oxidation–reduction reactions. The concentrations of boron in pristine groundwaters are generally low (<0.05 mg/L), and contaminant sources are usually enriched in boron (e.g., sea water: 4.6 mg/L; domestic wastewater: 1 mg/L; flyash leachate: 14 mg/L; landfill leachate: 6 mg/L), so the δ^{11}B of groundwater is highly sensitive to the impact of contamination (81). The large isotopic variation of the potential sources can be used to trace the origin of contamination. Vengosh (81) reported that coastal aquifers affected by seawater intrusion and marine-derived fossil brines are characterized by high δ^{11}B values (up to 60‰). In contrast, domestic wastewater that has relatively high boron concentrations and a high B/Cl ratio has δ^{11}B values of 0‰ to 12.9‰. Boron stable isotope ratios have a potential to play a role in pollution studies (82). They also have applications in the characterization of brines and geothermal waters (83).

It will suffice at this point to say that some of these environmental isotopes are in themselves a source of groundwater contamination, especially radioactive isotopes. Radioactive isotopes, also known as radionuclides, are therefore discussed in the following section in relation to groundwater contamination.

Radioactive Contaminants

It is now well known that numerous human activities have created nuclear isotopes by detonating nuclear weapons and constructing nuclear reactors. A number of radionuclides are produced in the earth's atmosphere by nuclear reactions caused by cosmic rays. Cationic radionuclides may be subjected to ion exchange and other processes that sorb the radionuclides onto mineral organic surfaces in the soil (7). Examples of transition metals that have large distribution coefficients and hence low mobilities in waters are listed in References 7 and 84. ^{90}Sr, ^{137}Cs, and ^{226}Ra are involved in cation exchange similar to other exchangeable cations, for example, Ca^{2+} and Mg^{2+} (84).

Many of these radionuclides are frequently produced as fission products from the decay of ^{235}U and ^{239} Pu and from neutron activation of stable isotopes. These processes result in the production of more than 75 radionuclides such as ^{137}Cs, ^{134}Cs, ^{58}Co, ^{51}Cr, ^{54}Mn, ^{55}Fe, ^{3}H, and ^{131}I (1). Table 4 lists the various sources of environmentally important radioactive isotopes. These are elements that undergo spontaneous decay resulting in the release of energy as well as energetic particles and consequent formation of different isotopes. They occur either naturally or are created by bombardment of the earth by cosmic radiation (7) and undergo spontaneous decay resulting in the release of energy as well as energetic particles and consequent formation of different isotopes.

The nuclear industry has been the main generator of radioactive contaminants. However, potential sources occur throughout the nuclear fuel cycle, which involves mining and milling uranium, uranium enrichment and fuel fabrication, power plant operation, fuel reprocessing, and waste disposal (1). In the examples presented by Domenico and Schwartz, the United States, Japan, France, and Germany have large numbers of light-water reactors that use enriched uranium (^{235}U) as the predominant fuel source and possibly ^{239} Pu and ^{238}U. The process of enrichment and fuel fabrication is also accompanied by generation of the following radionuclides: ^{238}U, ^{235}U, ^{137}Cs, and ^{90}Sr, which are common contaminants.

Furthermore, there are potential radionuclide contaminants that result from the processing of raw uranium ore (during mining operation) alongside other nonradioactive pollutants, which include ^{238}U, ^{230}Th, ^{226}Ra, and ^{222}Rn. Examples of locations where this type of contamination occurs are Colorado, New Mexico, Texas, Utah, Wyoming, northern Saskatchewan, and Ontario (1).

PRACTICAL APPLICATIONS OF ENVIRONMENTAL ISOTOPES IN SOLVING GROUNDWATER CONTAMINATION PROBLEMS

Many examples exist in the literature on the use of environmental isotopes in solving groundwater contamination problems. There are also case studies in publications, which have addressed the applications of isotopes in contaminant hydrogeology. In this section, the results of the application of isotopes in groundwater contamination studies, particularly in solving specific problems are summarized. The case studies cut across continents and varied hydrogeologic settings. Some of these applications are based on single isotopes, and others combine several isotopes, particularly oxygen with nitrogen and sulfur to understand the origin and migration of contaminants in groundwater. However, some case studies applied an integrated approach (using isotope techniques and conventional hydrochemistry) to interpret contaminant sources and pathways. This is not an exhaustive listing but rather selected to demonstrate the applications of environmental isotopes in solving specific hydrogeologic problems.

Table 4. Various Sources of Environmentally Important Radioactive Isotopes[a]

Source	Radionuclides
Naturally occurring	^{40}K, ^{222}Rn, ^{226}Ra, ^{230,232}Th, ^{235,238}U
Cosmic irradiation	^{3}H, ^{7}Be, ^{14}C, ^{22}Na
Nuclear weapon tests	^{3}H, ^{90}Sr, ^{137}Cs, ^{239,240} Pu
Mining wastes—uranium, phosphate, coal	^{222}Rn, ^{226}Ra, ^{230,232}Th, ^{235,238}U
Industrial wastes—nuclear power plants, weapons manufacturing, research and medical waste	^{59,63}Ni, ^{60}Co, ^{90}Sr, ^{93,99}Zr, ^{99}Tc, ^{107}Pd, ^{129}I, ^{137}Cs, ^{144}Ce, ^{151}Sm, ^{152,154} Eu, ^{237}Np, ^{239,240,242} Pu, ^{241,243}Am

Fritz et al. (45) studied the possible movement of leachate from a sanitary landfill in Frankfurt am Main, Germany. Interpretation of results of both isotopic and chemical data in the pollution monitoring showed that $\delta^{2}H$ and $\delta^{18}O$ are most useful in tracing the leachate and mapping the pollution plume. Three groups were identified from $\delta^{18}O$ data: The first group (−8.6‰ to −8.0‰) is of uncontaminated groundwater; the second group (−6.7‰ to −6.3‰) is polluted groundwater, and the third group (−3.0‰ to −2.0‰) reflects recharge from lake water. The same $\delta^{18}O$ data have also been used (by these researchers) to calculate the percentage of leachate water in each well, and this was helpful in producing a map of the pollution plume at the landfill site.

Mazor et al. (85) conducted a study of groundwater contamination by a slaughterhouse at Lobatse, Botswana. The results of this study revealed that tritium and chloride were the most conservative tracers in this case. The slaughterhouse used water from a dam, and this water (when sampled and analyzed) had tritium concentrations that were significantly higher than those in the local groundwater. High tritium concentrations/contamination were observed in wells near the slaughterhouse and along the Peleng riverbed into which the effluent was released. Other wells (according to the researchers) showed low tritium and chlorine values, indicating that they were not contaminated.

Egboka (46), in the investigation of problems posed by contaminants in the hydrologic environment, used a combination of tracers: (radioisotopes, such as bomb tritium), stable isotopes (^{18}O and ^{2}H), and dissolved geochemical constituents (Cl, SO_4, NO_3 and some major cations). These isotopes, in combination with the dissolved geochemical constituents, have been used to delineate the aerial extent of spread of leachate plumes in landfills and spillage zones and around sewage lagoons. He presented two case studies where this multitechnique approach was used successfully to investigate environmental pollution and contamination. These include using bomb tritium, ^{18}O, ^{2}H, Cl^{-}, and $SO_4{}^{2-}$ to investigate the leachate migration in an aquifer beneath an abandoned landfill at CFB Borden, Ontario (Canada) and the Lake Chad drainage basin (NE Nigeria), where ^{3}H, ^{18}O, ^{2}H, ^{14}C, and ^{13}C were extensively analyzed.

Song et al. (86) used ^{34}S in 66 water samples and 30 rock (anhydrite) samples to determine the origin of sulfate in the stable isotopic composition and geochemistry of fresh water and brine in Sichuan Basin, China. The results indicate that $\delta^{34}S$ values of saline waters are similar to those in the samples collected from different sections of the same sequence and differ from different strata. These authors considered that the evaporate of the early Triassic was formed in an enclosed and reductive beach and the facies belongs to the beach salt-lake in the environment of a supratidal zone and that of the middle Triassic belongs to lagoon-salt-lakes in the intertidal environment. The consistency of $\delta^{34}S$ in water and rock implies that they have a common source of sulphur.

Wassenaar (87) carried out a representative study in Abbotsford aquifer (a regional aquifer in Canada characterized by nitrate concentrations between 80 and 160 mg/L) using the isotopes of ^{15}N and ^{18}O. In this case, it was well documented that the main sources of nitrate were manure produced in the poultry industry and inorganic fertilizers used in cultivated fields. Based on the ^{15}N data, it was shown that most of the nitrate in the contaminated groundwater has $\delta^{15}N$ values greater than +8‰. Wassenaar (87) demonstrated that the main source of this nitrate was the manure piles that were deposited on top of the aquifer.

Similarly, a nitrate study carried out by Auge and Nagy (88) in the city of La Plata (Argentina) illustrates one of the applications of nitrogen isotopes in Latin America. The isotope study, which was part of a comprehensive hydrogeologic study of this aquifer, aimed to provide information about the sources of high nitrate observed in production wells in the city of La Plata. According to these researchers, the main potential sources of nitrate in this area are fertilizers and manure from agricultural and pasture areas located upgradient of the city of La Plata and leakage from the sewage system and possibly landfills located downgradient of the center of the city. A regional nitrate study showed a plume that had high nitrate concentration below the city. From the result, the nitrogen isotope pattern showed a clear trend toward enriched $\delta^{15}N$ values correlated with an increase in nitrate concentration. The high nitrate concentration (80–120 mg/L as nitrate) and enriched $\delta^{15}N$ values (14–15‰) correspond to groundwater located below the city. The low nitrate concentration (15–40 mg/L) and depleted $\delta^{15}N$ values (7–11‰) correspond to groundwater representing the agricultural areas and wells located upgradient on the high nitrate concentration plume. The enriched $\delta^{15}N$ values indicated input of nitrate from an enriched ^{15}N source associated with domestic wastes.

Aravena and Robertson (38) used multiple isotope tracers to evaluate denitrification in groundwater and documented that septic systems are point sources of nitrate in groundwater, which was documented in a nitrate plume generated in a large communal septic system operating at a campsite. As a result of oxygen consumption by the oxidation of pyrite and organic carbon in the unsaturated zone, the groundwater became anaerobic in the shallow part of the flow system. A steady decrease in nitrate concentrations from values around 80 mg N/L at the water table to nondetectable was observed versus depth along the groundwater system. A trend toward enriched $\delta^{15}N$ values accompanied these concentration changes, reaching values as high as +58‰, demonstrated that nitrate attenuation was controlled by denitrification. A linear correlation between $\delta^{15}N$ and $\delta^{18}O$ values in nitrate also supported denitrification as the mechanism for nitrate attenuation in the aquifer.

Tandia et al. (89), in the investigation of the origin, process, and migration of nitrate compounds in the aquifers of the Dakar region, Senegal, used environmental isotopes (^{18}O, ^{2}H, ^{3}H, ^{13}C, ^{14}C) along with major inorganic constituents and fecal coliform on yearly water samples. The samples were taken from piezometers, hand-pumped wells, and dug wells in different areas of the Peninsula from 1987 to 1997. Results showed that only a limited area is affected by nitrate pollution in the confined layer. Stable isotopes, tritium and ^{14}C, gave a better understanding of nitrate contamination of groundwater in this region; tritium in groundwater indicates that nitrate concentration is recent. This has been confirmed by the presence of high activities of ^{14}C (80‰), in good agreement with recent analyses of recharge groundwater.

The distribution of the values of ^{18}O and ^{2}H (89) around the World Meteoric Water Line indicate that the recharge of the Dakar aquifer system originates from the monsoon rainfall after it has been exposed to evaporation. However, the cluster of points relating to ^{18}O and ^{2}H were also interpreted as contributions of nitrate contamination along the flow path from east to west.

Buzek et al. (67) investigated the nitrate pollution of a karstic groundwater system in Svaty Jan Pod Skalou in the Czech Republic using $\delta^{18}O$ in water and $\delta^{15}N$ in nitrate. Increasing agricultural activity in the republic after the 1960s resulted in contaminating both shallow and deep-water resources. Therefore, to identify the sources of nitrate contamination and evaluate the parameters of the karstic system, the stable isotopes $\delta^{15}N$ and $\delta^{18}O$ were used together with monitoring of the flow dynamics, water chemistry, and soil composition. The results of the isotopic investigation revealed the sources of nitrate contamination from $\delta^{15}N$ in soil solutes at sites that had different agronomic records (sequential use of organic and inorganic fertilizers). They further showed that spring-discharge nitrate is formed from an atmospheric source (an average nitrate content of 8 mg/L and $\delta^{15}N$ of −6‰) and two groundwater components that had nitrate content of 50 to 60 mg/L and $\delta^{15}N$ values from 2 to 7‰. However, the contribution of groundwater components varied in time more frequently than can be described by the model developed for flow dynamics and ^{18}O. From this case study, data from the flow dynamics, ^{18}O, and tritium gave sufficient information to estimate the volume of the karstic system and the residence times of the three contributions (direct infiltration, fast, and old components) to spring discharge. The estimated turnover time of the old component (about 22 years) could be used for calculating the spring nitrate content in the future.

Aggarwal et al. (90) initiated a study using a suite of different isotopes to fingerprint and determine the source of contaminants in groundwater systems in New Zealand. Four different isotope systems were examined: boron isotopes, oxygen and nitrogen isotopes in nitrates, oxygen isotopes in sulfates, and oxygen and sulfur isotopes in sulfates. In a case study of the semirural Manakau area as well as the South and North Islands (all in New Zealand) conducted to investigate the possibility of using nitrate isotopes to detect the source of nitrate contamination, results showed nitrogen isotope (+4 to +12‰) coupled with oxygen isotope measurements (+5 to +9‰) and demonstrated that nitrogen is not sourced from fertilizers but from some combination of septic and animal waste. However, for the case study of sulfate isotope used, sulfur and oxygen isotopic compositions of sulfate in river and lake water from seven major catchments of the North and South Islands of New Zealand were determined. The results of the isotope analyses allowed distinguishing between natural (geologic, geothermal, and volcanic) and anthropogenic (fertilizer) sulfur sources. Boron (B) isotope measurements were also carried out in the Bartholomew (Manawatu) and Petone waters in New Zealand. Results showed that the Cl/B ratio and the $\delta^{11}B$ of the water from Bartholomew may be interpreted as a consequence of mixing between saline water and freshwater. Seawater (included for comparison) showed a distinctly heavy B isotopic composition, relatively high B concentrations, and a high Cl/B ratio, whereas these two freshwaters contain a variable B isotope ratio that has a low B concentration and a much lower Cl/B ratio than that in the seawater.

Groundwater contamination in coastal aquifers of Israel, Italy, and the United States was determined by boron isotope systematics (81). This work reports isotopic results of contaminated groundwater from the coastal aquifers of the Mediterranean in Israel, the Cornia River in northwestern Italy, and the Salinas Valley in California. The interpretation of the results revealed different contamination sources; underlying saline water of a marine origin in saline plumes in the Mediterranean coastal aquifer of Israel ($\delta^{11}B = 31.7$ to 49.9‰; B/Cl ratio $\sim 1.5 \times 10^{-3}$), mixing of fresh and sea water ($\delta^{11}B = 25$ to 38‰; B/Cl ratio7×10^{-3}) in saline water associated with a saltwater intrusion into the Salinas Valley, California, and a hydrothermal contribution (high B/Cl of ~ 0.03; $\delta^{11}B = 2.4$ to 9.3‰) in groundwater from the Cornia River, Italy. Vengosh et al. (81) observed that the boron concentrations in pristine groundwaters are generally low (<0.05 mg/L), whereas contaminant sources (e.g., domestic wastewater) are enriched in boron; hence, boron isotopes can be used to evaluate the impact of anthropogenic boron on the environment. Moreover, the isotopic composition of contaminated groundwater has revealed the sources of pollution because different sources are characterized by distinguishable isotopic ratios. For example, seawater ($\delta^{11}B = 39$‰), saltwater intrusion, and marine-derived brines (40 to 60‰) sharply differ from hydrothermal fluids ($\delta^{11}B = -10$‰ to 10‰) and anthropogenic sources (sewage effluent: $\delta^{11}B = 0$‰ to 10‰; boron-fertilizer: $\delta^{11}B = -15$‰ to 7‰). This research further showed that some differences (up to 15‰) might exist between domestic wastewater and boron fertilizer.

Shivanna et al. (91) used environmental isotopes (^{18}O, ^{2}H, ^{3}H, ^{14}C, and ^{34}S) along with hydrogeology and hydrochemistry to investigate (1) the source of salinity and the origin of sulfate in the groundwater of coastal Orissa, Orissa state (India) and (2) to study the source of salinity in deep and saline groundwaters of charnockite terrain at Kokkilimedu, south of Chennai, India. The results of the first case indicate that the shallow groundwater (depth <50 m) is fresh and modern. Groundwater salinity in the intermediate aquifer (50−100 m) is due to the Flandrian transgression during the Holocene period. The saline groundwater found below the fresh deep aquifer has marine water entrapped during the late Pleistocene. The source of high sulfate in the groundwater (as identified by the researchers) is of marine origin. In most of the deep aquifers, saline samples showed enriched $\delta^{34}S$ values

(+20.8‰ to +43.8‰) compared with the seawater value, and radiocarbon ages are in the range of 12, 000 to 24, 000 years BP with negligible tritium.

However, in the second case, the results of isotope investigation showed that there are two different sources of salinity in this area: one, the salinity attributed to infiltration of seawater together with the contribution of solute from pseudotachylites observed along the fractures and shear zones in the host rock; second, salinity attributed to solutes mostly from sheared and fractured charnockite rock. The high tritium content observed in this case was interpreted as due mainly to effluent from the nuclear power plant located 0.5 km west of the site and partly due to mixing of surface water with groundwater.

Halas and Trembaczowski (92) applied stable isotopic analysis of oxygen and sulfur in sulfate to trace the sources of groundwater pollutants in the industrial area of Belchatow, central Poland, where a large brown coal deposit is exploited and the coal is burned in an electric power plant. The interpretation of isotope ratios allowed recognizing three groups of sulfates:

1. from the leaching of a Permian salt dome,
2. produced by the leaching of soluble sulfates from an ash pool, and
3. produced by the oxidation of natural sulfides in water-bearing rocks.

It was obvious from the data presented in this work that the oxygen and sulfur isotopic ratios of the dissolved sulfates are informative of their origin.

Liu et al. (93) carried out an investigation of groundwater contamination due to uranium deposits in the Zhoujiashan district of the Xiangshan uranium ore field, China. Samples of groundwater collected from five completed exploration boreholes in the area revealed the pollution source. It was traced and analyzed by using isotope as well as radiohydrochemical techniques. The researchers experimentally proved that the uranium concentration and uranium isotope ratio $^{234}U/^{238}U$ in natural waters are two sensitive indicators of radioactive pollution in natural waters. It was concluded that, under present conditions, exploration of uranium deposits might not cause serious groundwater contamination by radioactive elements (U, Ra, Rn, and Tn). Activity ratios $^{226}Ra/^{228}Ra$ and $^{230}Th/^{232}Th$ in water can be used only as supplementary indicators.

Qureshi et al. (94) used stable carbon isotope ratios as water quality indicators in the coastal areas of Karachi, Pakistan. Stable carbon isotope ratios ($\delta^{13}C$) of total dissolved inorganic carbon (TDIC), total organic and inorganic carbon in bottom sediments, as well as sea plants in polluted water sources, nonpolluted Karachi seawater, and pollution recipients were used to elaborate the pollution scenario of the shallow marine environment (off the Karachi coast). Groundwater pollution in the coastal areas of Karachi is also reflected in the stable isotope composition of carbon ($\delta^{13}C$) in the TDIC pool of organic carbon in bottom sediments, mangrove leaves, and seaweed. These results were supplemented with stable isotope analysis of nitrogen ($\delta^{15}N$) in seaweed and mangroves. Isotopic data revealed that the mangrove ecosystem and its tidal fluctuations play a key role in controlling contamination inventories in the shallow seawater off the Karachi coast, specifically the Manora Channel. The Karachi harbor zone was reportedly the most heavily polluted marine site in Manora Channel during high as well as low tide.

De Vito et al. (95) carried out a study in a 200 meter long wetland located between agricultural fields and the Boyne River in southern Ontario (Canada) using ^{15}N and ^{18}O (in nitrate) to evaluate the role of denitrification as an attenuative mechanism in nitrate. Results showed that nitrate levels of 30 and 40 mg N/L characterize the groundwater impacting the wetland. A significant change in nitrate concentration was observed by the researchers along the groundwater flow system that reached values as low as 1 mg N/L in areas close to the river. This pattern is accompanied by an isotope trend toward enriched ^{15}N and ^{18}O. The isotopic data and the dissolved organic carbon that increases along the groundwater flow system were interpreted as demonstrating that denitrification is the main process responsible for nitrate attenuation in the area.

According to Aravena (2), applications of isotopes in organic contaminants have focused on evaluating carbon and hydrogen isotope fractionation in biological and physical processes that can affect organic contaminant concentration in groundwater. The results of these studies have shown that very little isotopic fractionation occurred during physical processes (96,97). However, recent analytical developments in stable isotope research have shown that carbon isotopes are very sensitive tracers for evaluating the biodegradation of chlorinated compounds in groundwater (31,32). However, they are not sensitive enough to document biodegradation of petroleum hydrocarbons in groundwater (98,99).

ENVIRONMENTAL ISOTOPES IN HYDROGEOLOGY

Segun Adelana
University of Ilorin
Ilorin, Nigeria

In the last three to four decades, environmental isotopes have contributed immensely to studies and investigations in hydrogeology, complementing physical and chemical hydrogeology. Many hydrogeologic studies use stable isotopes of the water molecule to determine groundwater quality, origin, recharge mechanism, and rock–water interaction. A good number of the applications of environmental isotopes in hydrogeology have been in the arid and semiarid areas of the world, where water scarcity is most acute and poses constraints on economic development. A substantial amount of basic data (1–3) and results of applied field investigations have already been published (4–15) on applications of different isotopes for hydrologic purposes.

Environmental isotopes provide indications of groundwater age and serve as natural tracers for groundwater provenance. Stable isotopes of carbon, boron, nitrogen, and sulphur (i.e., $^{13}C/^{12}C$, $^{11}B/^{10}B$, $^{15}N/^{14}N$, and $^{34}S/^{32}S$) can give valuable information about reactions involving these elements and can also serve as pollution tracers. On the other hand, radioactive isotopes of some of these elements decay, providing us with a measure of the circulation time and, invariably, groundwater renewability. The most common of the radioisotopes, carbon-14, is used to estimate groundwater residence time. Isotopes of the uranium series (^{234}U, ^{238}U, ^{226}Ra, and ^{222}Rn) are also useful tracers in isotope hydrogeology but are often not precise enough to establish the age of groundwater due to mineral–water interactions

HISTORICAL BACKGROUND

The history of isotopes dates back to the formation of matter by nucleosynthesis during the birth of our solar system more than 5 billion years ago. This process produced most of the stable and unstable (radioactive) isotopes that naturally exist today (16).

The term “isotope” was first used in 1913 by Soddy Frederick to describe nuclides that occupy the same position in the periodic table but differ in their nuclear properties. Thomson (1913) later showed that the element neon is made up of more than one isotope. In 1919, Francis Aston constructed a mass spectrograph that could be used in discovering virtually all elements. But it was not until 1925 that the existence of oxygen of mass 17 was first observed (32). Later on, oxygen-18 and 17 were discovered in natural material (18). In 1931, Urey discovered the hydrogen isotope of mass 2 (called deuterium) and estimated its natural concentration (19 a, b).

This achievement made it obvious that the isotopic compositions of oxygen and hydrogen were highly variable. As more precise measurements of isotopic ratios continued, it became evident that almost all D_2O and H_2O depleted in deuterium could be prepared by electrolytic decomposition of water. Much later, the concentration of pure ^{18}O was achieved in Switzerland using a thermal diffusion method (20). The work of Urey in 1946 formed the basis of isotopic fractionation (21).

Significant achievement in measuring of natural isotope abundances came with the advent of the Nier/McKinney mass spectrometer (22,23) designed for measuring small differences in isotopic abundance. The discovery of isotopes of water molecules stirred up the several earlier investigations on isotopic hydrology, as reviewed in the work of Rankama (24). Ever since then, investigations using the natural isotopic abundances of all lighter elements have continued to increase and many of them have been published in several texts, journals, and edited specialist volumes (16,25–33).

FUNDAMENTALS OF ISOTOPES IN HYDROGEOLOGY

Isotope derived its name from the Greek word, “*isos*,” meaning equal, and “*topos*,” which means place (referring to the place in the periodic table). Generally, isotopes of an element are atoms or nuclides that have the same number of protons in the nucleus and thus the same atomic number but differ in the number of neutrons and hence in their atomic mass. There are 92 naturally occurring elements comprising more than 1000 isotopes. Most of these occur in terrestrial compounds in trace amounts, but some are sufficiently abundant to be determined quantitatively through routine analysis. Hydrogen, for example, is known to have three isotopes with the following names and symbols:

1. H—common hydrogen (one proton)
2. D—deuterium, heavy and stable Hydrogen (two protons + one neutron)
3. T—tritium, radioactive hydrogen (one proton + two neutrons).

These isotopes can also be described by adding the number of particles in the nucleus of each (i.e., proton + neutron) and placing this at the upper left corner of the symbol for the element. In this way the hydrogen isotopes above may be written as ^1H, ^2H, and ^3H, respectively. For details on elements, nuclei, and valences, see Ref. 30.

There are two classes of isotopes:

(1) Stable isotopes, that do not change with time, even though their concentrations are affected by other physicochemical processes (such as evaporation or condensation).

(2) Unstable isotopes, that decay with time. The products of this decay are said to be radiogenic if they do not themselves decay. An alternative grouping of isotopes exists: (a) environmental isotopes and (b) artificial isotopes.

Environmental isotopes occur naturally, and investigators have no direct control on the variations of their concentrations: artificial isotopes are those whose variations in the environment are created by humans.

The environmental isotopes most commonly used in hydrogeology are the stable isotopes deuterium (^2H) and oxygen-18 (^{18}O) as well as the radioisotopic molecules tritium (^2H), carbon-14 (^{14}C) (see Tables 1 and 2).

The characteristics of isotopes useful to hydrogeologists are isotopic ‘signature’ and ‘decay.’ Once water reaches

the water table, it retains its isotopic content, as long as isotopic exchange with the reservoir at high temperature does not occur (34).

THE ISOTOPES: ^{2}H, ^{18}O, ^{3}H, ^{13}C AND ^{14}C

Stable Isotopes of the Water Molecule (^{2}H, ^{18}O)

Water is composed of hydrogen and oxygen and therefore occurs with different isotopic combinations in its molecules. As discussed in the previous section, the isotopes of hydrogen are ^{1}H, ^{2}H, ^{3}H, and those of oxygen are ^{16}O, ^{17}O, ^{18}O. Therefore, the possible stable isotopes of water species are $H_2^{16}O$, $HD^{16}O$, $D_2^{16}O$, $H_2^{17}O$, $HD^{17}O$, $D_2^{17}O$, $H_2^{18}O$, $HD^{18}O$, and $D_2^{18}O$.

Significant among these in geochemistry (based on the natural abundance of the isotopes) are $^{1}H_2^{16}O$, $HD^{16}O$, $H_2^{17}O$, and $H_2^{18}O$. The slight variations in their abundance are caused by small differences in the reactivity of the isotopes due to mass differences. Usually, $H_2^{16}O$ is about 10% lighter than $H_2^{18}O$ and therefore more reactive. Under closed conditions and without further reactions, the concentrations of isotopes of the water molecule remain stable over time.

Generally, stable environmental isotopes are measured as ratios of the two most abundant isotopes of a given element. The absolute abundance ratio of isotopes is not usually measured in natural waters because it requires a sophisticated mass spectrometric technique. Due to the low differences, the ratio of the stable isotopes R is given in a delta notation (in per mil units, i.e., parts per thousand) as a deviation from a standard. The mean isotopic composition of seawater, generally known as "SMOW" (Standard mean ocean water), is used for reference (35). However, the reference now commonly adopted for stable oxygen and hydrogen isotopic variation in natural water is V-SMOW (Vienna standard mean ocean water), which is isotopically identical to SMOW (9,36). This difference between samples and the reference standard is expressed in the following relation:

$$\text{Delta}(\delta) = (R_{\text{sample}} - R_{\text{standard}})/R_{\text{standard}} \times 1000 \quad \text{(per mil or ‰)} \tag{1}$$

(R = ratio of the heavy isotope to the light one, for example, $[^{1}H^{2}H^{16}O]/[^{1}H_2{}^{16}O]$).

By definition, the seawater standard has δ^{2}H and δ^{18}O values equal to 0‰. Negative values characterize water isotopically depleted ("lighter"), whereas positive values correspond to water samples isotopically enriched ("heavier") with respect to the standard. The measuring accuracy is 0.15‰ for δ^{18}O and 1‰ for delta δ^{2}H (37). For details of the measuring technique, refer to IAEA (9,29).

Isotopic Fractionation. Environmental isotopes of the same element can be partitioned or separated in a thermodynamic reaction due to differences in the rates of reaction of different molecular species. Fractionation is a fundamental process common to stable isotopes of H, B, C, O, N, S, and Cl and can occur under equilibrium or nonequilibrium (kinetic) conditions. Fractionation can also result from molecular diffusion. The different isotopic water molecules have various vapor pressures and freezing points. The changes in the isotopic ratio during evaporation, condensation, and chemical and biological processes—caused by these differences—are termed "isotopic fractionation."

Vapor derived from seawater is isotopically depleted compared to SMOW. One of the reasons for the depletion is the lower vapor pressure of the heavy water (e.g., $^{2}H_2^{18}O$). The fractionation or separation occurs at the transition between gaseous, liquid, or solid phases, and this is usually expressed by fractionation factor, α, which is defined as

$$\alpha = R_{\text{reactant}}/R_{\text{product}} \tag{2}$$

For example, the exchange between isotopes of the water molecule and the associated fractionation is defined as follows:

$$H_2O_{\text{liquid}} \Leftrightarrow H_2O_{\text{vapor}} \tag{3}$$

$$\alpha_{\text{liquid-vapor}} = (^{2}H/^{1}H)_{\text{liquid}}/(^{2}H/^{1}H)_{\text{vapor}} \tag{4}$$

$$\text{or } \alpha_{\text{liquid-vapor}} = (^{18}O/^{16}O)_{\text{liquid}}/(^{18}O/^{16}O)_{\text{vapor}}$$

Details of the theory and applications of stable isotopic fractionation exist in publications (16,30,34,38–40).

Of major importance in isotope fractionation is "kinetic" separation, which occurs when there is a deficit of moisture in the vapor phase. Kinetic separation results from the differing diffusion constants for the heavy (e.g., ${}^2H_2^{18}O$) and the light (e.g., ${}^1H_2^{16}O$) water molecules: during evaporation the light molecules diffuse faster than the heavy ones through the boundary layer between the water body and the atmosphere (41,42).

Isotopic fractionation is more efficient if the vapor produced in condensation is constantly removed. This leads to the concept of "Rayleigh fractionation," a process in which ${}^{18}O$ or ${}^2H$ is selectively removed from the vapor phase, so that rain becomes progressively lighter in $\delta^{18}O$ and δ^2H, as it falls farther from the ocean. Rayleight fractionation (or distillation, as it is now called) is an exponential function expressed by the relation:

$$R/R_0 = f^{(\alpha-1)} \tag{5}$$

where $R = {}^{18}O/{}^{16}O$ of residual vapor
f = fraction of residual vapor
α = fractionation factor (= 1.009)

For details on Rayleigh processes in hydrogeological applications, see Reference 16. Isotope fractionation can be used to interpret isotopic data from natural settings and is also a useful tool for elucidating and quantifying processes as well as reactions in a hydrogeologic system.

Dependencies of the Isotopic Composition. In environmental isotopic studies, ${}^{18}O$ and ${}^2H$ concentrations in precipitation provide a characteristic input signal that varies regionally and over time. The isotopic signatures encountered in precipitation depend on parameters like temperature, deficit of moisture in the air, and the isotopic ratio of the water vapor source. When these parameters are taken into consideration, the isotopic signatures give information about the origin of vapor, precipitation, and groundwater—and partly about climatic conditions during recharge processes in the past. Based on these interrelations, some generally valid dependencies of the isotopic composition of a groundwater sample can be deduced (41).

The Elevation Effect. During the rise of humid air due to orographic obstacles and successive precipitation, the concentration of heavy isotopes in the precipitation decreases with elevation. The depletion also results from the general decrease of cloud temperatures with elevation. For the elevation effect, the depletion is -1 to $-4‰$ and -0.15 to $-0.5‰$ for δ^2H and $\delta^{18}O$ per 100 m rise. The elevation correction (also known as the altitude or alpine effect) distinguishes groundwater recharged at high altitudes from that of low altitude. Therefore, it turns out to be a useful tool in hydrogeologic studies.

The Continental Effect. During the condensation of atmospheric vapor, the liquid phase (i.e., rain droplets) is isotopically enriched, and the vapor phase is isotopically depleted. However, the amount of vapor in a cloud is limited. As this process continues, the isotopic signature of the vapor and consequently, of the condensed water is continuously changing, which, invariably, leads to a situation in which both the precipitation and groundwater are found depleted with respect to heavy isotopes, as the distance away from the coast increases.

The Effect of Precipitation Rate. This is otherwise known as the amount effect that shows the dependence of the isotopic composition on the amount of rainfall: Heavier rain or greater precipitation amounts result in more negative δ^2H and $\delta^{18}O$ values. As the amount of precipitation increases, depletion in the rain can be observed. During one precipitation, of a significant difference in the isotopic signature is found due to (1) progressive condensation and (2) variations in the intensity of the rain.

The Temperature Effect. The isotopic composition of precipitation depends on the temperature at which oceanic water is evaporated into the air. Seasonal fluctuations of the isotopic composition in local precipitation are influenced by fluctuations in temperature. Rain during winter is isotopically lighter than rain during the summer. In the past, when the climate was significantly different from that of today, then the isotopic signature of groundwater formed in the past differed strongly from that of modern precipitation and modern groundwater.

Moreover, the dependence of isotopic fractionation on temperature and moisture causes an annual fluctuation (seasonal effect) and depletion with latitude (latitude effect). In arid and semiarid zones of low moisture saturation and precipitation amounts, an enrichment of the heavy isotopes in raindrops occurs while they are falling (evaporation effect). Also due to evaporation, surface water in rivers and lakes is isotopically enriched.

Meteoric Water Line. Precipitation in rivers and lakes measured worldwide (35) showed that the delta values of the stable isotopes fit along a straight line on a $\delta^2H-\delta^{18}O$ plot. This line, termed the "global meteoric water line" is characterized by the relation:

$$\delta^2H = 8\delta^{18}O + 10(‰) \tag{6}$$

Craig's global line was later refined from more than a decade of worldwide monitoring of the stable isotopic composition of precipitation [IAEA Global Network of Isotopes in Precipitation—GNIP, reported in (43)] as

$$\delta^2H = 8.13\delta^{18}O + 10.8(‰) \tag{7}$$

From Equation 6, the gradient (s) of the GMWL line is 8, and "d," the intercept on the y axis is 10‰. The value of d, first used by Dansgaard (34) to characterize the deuterium excess in global precipitation, is defined from Equation 6 as

$$d = \delta^2H - 8\delta^{18}O(‰) \tag{8}$$

Evaporation during precipitation changes in the gradient of the straight line to values <8 causes (see Table 3).

Table 3. Examples of Regional Meteoric Lines[a]

Region	Meteoric line (%)
'Global' (meteoric line)	$\delta^2H = 8\delta^{18}O + 10$
Northern Hemisphere (continental)	$\delta^2H = (8.1 \pm 1)\delta^{18}O + (11 \pm 1)$
Mediterranean (or Middle East)	$\delta^2H = 8\delta^{18}O + 22$
Maritime Alps (April 1976)	$\delta^2H = (8.0 \pm 0.1)\delta^{18}O + (12.1 \pm 1.3)$
Maritime Alps (October 1976)	$\delta^2H = (7.9 \pm 0.2)\delta^{18}O + (13.4 \pm 2.6)$
Northeastern Brazil	$\delta^2H = 6.4\delta^{18}O + 5.5$
Northern Chile	$\delta^2H = 7.9\delta^{18}O + 9.5$
Tropical Islands	$\delta^2H = (4.6 \pm 0.4)\delta^{18}O + (0.1 \pm 1.6)$

[a] Ref. 30.

Tritium (^3H)

Tritium, the radioactive isotope of hydrogen, is produced naturally in the upper atmospheric strata by the influence of cosmic radiation on nitrogen atoms:

$$^{14}N + n \Rightarrow {}^{15}N \Rightarrow {}^{12}C + {}^{3}H \tag{9}$$

Tritium, which combines in the atmosphere with oxygen to form water, may precipitate on the earth as rain and thus reach the groundwater. Tritium is usually symbolized as T or simply ^3H. Its concentration in water is expressed in tritium units (TU): 1 TU corresponds to 1 atom ^3H per 10^{18} atoms ^1H. Details of measuring techniques and procedure are fully discussed in Ref. 44.

Tritium decays with a half-life of about 12.35 years to form ^3He. The atmospheric concentration of tritium prior to 1953 was about 3–5 TU. Due to nuclear weapon tests, the concentrations in precipitation up to 1963 reached several thousand TU. Hence, since the early 1960s, the anthropogenic tritium from bombs was used as tracer to study young groundwater. In the meanwhile, however, in Europe, the concentrations have decreased to values <10 TU (45). Measurable tritium in groundwater usually signifies modern recharge. High tritium (>30 TU) indicates recharge in the 1960s, and low values (<1 TU) usually signify paleogroundwater (older groundwater) that has mixed with shallow modern groundwater.

Although, qualitative and quantitative approaches to dating groundwater are also possible for tritium (16), the direct age determination of groundwater accurate to a year is somewhat uncertain partly due to the unknown extent of mixing of each year's recharge with that of the previous year's and partly because of high local and temporal variability of input values in precipitation. However, by measuring ^3H together with its daughter ^3He, true age determination is possible by calculations not based on the complicated tritium input function.

Carbon-14 and Carbon-13

There are three isotopes of carbon in nature: common and stable carbon (^{12}C), rare and stable carbon (^{13}C), and very rare and radioactive carbon (^{14}C). ^{14}C is formed, like tritium, in the upper atmosphere from the impact of neutrons produced by cosmic radiation on nitrogen atoms:

$$^{14}N + n- \Rightarrow {}^{14}C + p \tag{10}$$

where n = neutron and p = proton.

The half-life ($t_{1/2}$) of carbon-14 is 5,730 ± 30 years. The natural ^{14}C-level in the atmosphere corresponds to a ratio $^{14}C/^{12}C$ of 1.18×10^{-12}. The ^{14}C concentration of a sample is given in pmc units (percent modern carbon) as share of the atmosphere value in 1950, which was fixed at 100 pmc. ^{14}C values >100 pmc in the atmosphere and in shallow aquifers document nuclear weapon tests during the 1950s.

The stable isotope ^{13}C is often used to determine the initial content of ^{14}C. The processes of fractionation can reflect themselves in the ratio $^{13}C/^{12}C$. The ^{13}C concentration of a sample is given as deviation in ‰ from a standard. As standard, the ^{13}C value of a marine limestone (Peedee belemnite = PDB) that has the delta value of 0‰ is used. Within the atmosphere, δ values range from −7 to −8‰. Isotopic fractionation is stronger during biological processes. Hence, biological CO_2 has values of about −25 to −15‰ depending on the predominant photosynthesis cycle.

Carbon Dating: Principles and Problems. There are two methods of sampling for ^{14}C: The first is by precipitation of approximately 60 millimoles of total carbon as barium or strontium carbonate at a pH > 9. The second method involves acidification of a water sample, gas stripping the CO_2 with nitrogen, and trapping the evolved CO_2 in a solution of $CO_3{}^{-2}$-free NaOH. ^{14}C is measured by beta counting either in gas or liquid phase or by a more recent method using accelerator mass spectrometry of a graphite target. Radiocarbon activities expressed as percent "modern" carbon (pmc) represent the activity of carbon prior to the dilution by postindustrial 'dead' fossil fuel carbonate. For example, a carbon sample that has 0 pmc is deemed dead or has an age beyond the limit detectable by radiocarbon dating. The age of a given water sample can be calculated from the relation,

$$t = 1/\lambda \ln C/C_0 \tag{11}$$

where t = age (in years), λ = decay constant of ^{14}C, C = measured ^{14}C activity, and C_0 = initial ^{14}C activity.

The age dating of groundwater that contains dissolved, inorganic radioactive carbon (^{14}C) may be used for ages up to 60,000 years, although poor preservation and subsequent contamination of old material now makes the effective dating range shorter. For organic material, the effective range is <50,000 years; for groundwater, the range is limited to 30,000 years or less. The main problems associated with ^{14}C dating are (1) determination of the initial C-14 value, (2) mixtures of waters of different ages, (3) a diffusive admixture of CO_2 from the atmosphere, and (4) dissolution of carbonates. Despite these problems, ^{14}C -age dating is widespread and yields good results in simple situations (16,46).

Correction of the Carbon-14 Age. By various interactions of recent and fossil carbon, an initial ^{14}C value between 50 and 100 pmc results. Other, partly bacterial processes can also influence the isotopic composition of groundwater. During the development of the ^{14}C method, several correction models were set up that reduce the initial activity of samples below 100 pmc. The result is a corrected age. Several correction models exist (46–51). The resulting ages are often compared with conventional ages, which are obtained with initial values of 100 pmc.

OTHER NATURALLY OCCURRING ISOTOPES

Chlorine-36 (^{36}Cl)

Chlorine-36 is a radioactive isotope of chlorine whose application to hydrology has attracted much interest in the last decade. It is naturally produced by cosmic rays interacting with atmospheric argon (^{40}Ar) and finds its way into the hydrologic cycle either as dry fallout or in precipitation. The thermonuclear bomb testing of the 1960s contributed a significant amount of ^{36}Cl, thus elevating its concentrations above the natural atmospheric abundance. ^{36}Cl behaves conservatively in most hydrologic environments, and like bomb tritium, it is useful in delineating recharge rates. However, unlike tritium, its use for dating modern groundwater is unrealistic. But its half-life of 301,000 years makes ^{36}Cl a useful tool in groundwater age determination in the range of 10^5–10^6 years.

Chlorofluorocarbons (CFCs)

Chlorofluorocarbons exist in the atmosphere as CCl_3F and CCl_2F_2 (simply referred to as CFC-11 and CFC-12, respectively). The production of Freons for use as solvents, refrigerants, and propellants has released large quantities of these compounds into the atmosphere. The source of CFCs is mainly anthropogenic, and studies have shown that their concentration in the atmosphere is steadily increasing since the production of Freons started in the mid-1940s. Hydrogeologists have found a use for CFCs, which have accumulated as contaminants in the atmosphere, as tracers like tritium. The analysis of CFC compounds is less complicated than that of tritium. This advantage, coupled with the decreasing concentration of bomb tritium (since the 1990s), is responsible for its increasing applications in hydrogeologic studies. CFC-11 and CFC-12, whose atmospheric residence times are 60 and 120 years, respectively, are not isotopes in themselves but equilibrate with water to form a dating tool for groundwater (<50 years old). They are equally applicable as tracers of groundwater and of sewage contamination in water (16,33).

Uranium Series Isotopes

The radioactive decay of uranium and thorium results in the formation of a series of isotopes, which are in themselves radiogenic. Significant among these are ^{234}U, ^{238}U, ^{226}Ra, and ^{222}Rn. The uranium series displays an enormous array of half-lives (10^5–10^9) and many geochemical distinctive characteristics that make them useful in hydrogeologic applications (16,33):

1. Evaluation of mixing between groundwater bodies can be achieved on a plot of excess ^{234}U versus ^{238}U concentration.
2. The wide range of half-lives is useful in tracing groundwater movement and investigating geochemical processes.
3. Measurement of groundwater–surface water interactions and recharge processes is made possible with ^{222}Rn (half-life $\approx$ 4 days).
4. Uranium activity ratios may provide additional information on the geochemistry of the groundwater system.

Boron Isotopes and Other Pollution Tracers

Natural boron has two stable isotopes, ^{11}B and ^{10}B. Boron is used as tracer in groundwater because of its high solubility in aqueous solution, natural abundance in all waters, and the lack of effects by evaporation, volatilization, and oxidation–reduction reactions. ^{11}B mixing curves enable identification, and in some cases, quantification of contaminants in groundwater (52).

A good number of other isotopes have been employed to trace groundwater pollution. The type of pollutant investigated governs the type of isotope used to trace groundwater pollution. For example, ^{15}N/^{14}N and ^{18}O/^{16}O are used for nitrates in groundwater, ^{34}S/^{32}S for dissolved sulfates, and ^{13}C/^{12}C for dissolved inorganic carbon. ^{11}B (with ^{18}O, ^{87}Sr/^{86}Sr, Br/Cl) is useful in tracing salinity, and ^{13}C/^{12}C, ^{2}H/^{1}H, and ^{37}Cl/^{35}Cl can be used to trace organic carbon pollutants.

SUMMARY OF APPLICATIONS OF ENVIRONMENTAL ISOTOPES

The environmental isotope technique in hydrogeology is based on the principles that stable isotopes and tritium data for groundwater correlate with local precipitation. ^{18}O and ^{2}H concentrations in precipitation provide a characteristic input signal that varies regionally and over time. The isotopic signatures encountered in precipitation depend on parameters like temperature, the deficit of moisture in the air, and the isotopic ratio of the water vapor source. When these parameters are taken into consideration, the isotopic signatures give information about the origin of vapor, precipitation, and groundwater—and partly about the climatic conditions during recharge processes in the past.

Although, qualitative and quantitative approaches to dating groundwater are possible using tritium, the accuracy of this age determination is in question due to the unknown extent of mixing of recharging water with that of the previous year and partly because of high local and temporal variability of input values in precipitation. However, by measuring ^{3}H together with its daughter ^{3}He, true age determination is possible by calculations not based on the complicated tritium input function. Age dating of groundwater with ^{14}C is also widespread in spite of the problems inherent in the method. Stable isotopes of carbon, boron, nitrogen, and sulfur (i.e., ^{13}C/^{12}C^{11}B/^{10}B, ^{15}N/^{14}N, and ^{34}S/^{32}S) can give valuable information about reactions involving these elements and can also serve as pollution tracers. On the other hand, radioactive isotopes of some of these elements decay, providing us with a measure of circulation time and invariably groundwater renewability. In all, environmental isotopes have been applied to a wide spectrum of hydrogeologic problems.

WATER-JETTING DRILLING TECHNOLOGIES FOR WELL INSTALLATION AND *IN SITU* REMEDIATION OF HYDROCARBONS, SOLVENTS, AND METALS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Water-jet drilling or jetting has been used as a drilling method in both the developing world for water supply projects and in the United States for in situ remediation of hydrocarbons, chlorinated solvents, and metals.

Jetting has been documented for installing water supply wells in coarse materials such as boulders in glacial till deposits where the water pressure nozzle can move coarse gravels. This method uses a high-velocity stream of water to advance the borehole. The jet-percussion system is limited to drilling 7 to 10 cm diameter wells to depths of about 60 meters. Drilling tools consist of a chisel-shaped bit attached to the lower end of a piping string. Nozzles on each side of the bit shoot water out at moderate to high pressures. The water keeps the bit clean and lubricated and carries the pulverized drill cuttings in suspension up the annulus. The cuttings settle out by gravity in suspension pits. The water is then picked up by the suction of the mud pump and recirculated through the drill pipe to the nozzles at the bottom of the borehole (1).

As a source of clean water wells for the developing world, such as Africa, well jetting has been successfully designed for the resources, tools, and skills of even the poorest farmers. In the 1980s, George and Richard Cansdale of SWS Filtration developed jetting as a drilling technique that could be used by the developing world to obtain economical and safe supplies of water. The hand pump, called a Rower Pump, is a suction piston pump made by SWS Filtration. The Rower Pump has the entire main pump components such as a foot valve, piston valve, and pump cylinder. The operator holds the T-handle, pulls and pushes directly on the piston rod as the water pours out the top of the well. The manually operated pump pulls water from the 1 to 5 cm diameter wells at a rate of several liters per minute.

Well jetting is particularly suited to unconsolidated sediments such as sandy riverbeds or riverbanks, where water is generally found close to the surface (1 to 5 meters). The jetting technique, which generally does not penetrate more than 10 meters, can be used to drive a pipe and filter into the sandy riverbed of a dry river or wadi, so that subsurface water, close to the surface, can be pumped from below the surface. The jet of water is pushed from a tank through a pump and into a PVC or steel rod, which makes the sand fluid and allows the pipe to slide into the subsurface. On some floodplains, it is possible to jet through more than 30 meters of silt before reaching an underlying sandy aquifer. Small-diameter jetted wells, called "washbores" by local farmers, are used worldwide to irrigate crops during the dry season. Some small-bore jetted wells are used for domestic water supplies. More details are described in Power (2).

Case studies of the jetted wells have been documented in Zambia, Sudan, Nigeria, and Zaire, as well as other countries. For their efforts, the Cansdales were awarded a 1990 IBM Award for Sustainable Development for their well jetting and the muscle-powered Rower Pump. Other low-technology methods for bringing water to the surface through the jetted well include a check ball valve connected to plastic tubing.

Jetting technology can also be used to install small diameter piezometers or well points in sand. The small diameter (1 to 2.5 cm diameter) well pipe with pressure nozzles on the bottom is pushed downward as the water jets advance the borehole in front of the pipe. The well pipe is left in place at the target depth, and the well point is sealed in place at the surface with neat cement grout.

For environmental cleanup projects, jetting technology has been used successfully as a delivery method for treatment chemicals for remediating hydrocarbons, solvents, and metals. Remediation jetting using high-pressure, low to high volume injection of liquids into the subsurface through a small-diameter wand or lance driven into the subsurface has been widely used for several decades. Jetting technology uses tree root feeder systems to inject liquids into the ground. The remediation injection process (RlP®), an updated and more powerful, versatile and adaptable jetting delivery system, has been used efficiently to implement or augment a variety of environmental remediation processes, including chemical oxidation, bioremediation, pH adjustment, and metal stabilization. Handheld RIP® lances have been designed to use high-pressure liquid pumps to increase flow at the tip of the wand at pressures from 20,000–35,000 kilopascals (kPa). High-pressure injection of remediation treatment chemicals can be done in sensitive areas (Fig. 1).

At these pressures, the lances are driven downward at velocities up to 1/3 meter per second. High-pressure

Figure 1. Handheld lances used to perform remediation by jetting technology in a limited-access site (FAST-TEK).

injection points placed on close spacing, such as 0.6 to 1.5 meter centers, allow complete in situ coverage, vertically and laterally. The radius of influence around injection ports exceeds 3 meters (3). Injection port spacing includes overlapping areas (Fig. 2).

Jetting technology is used to remediate areas of limited access such as underneath slabs, railways, and buildings; around tanks, pipelines, and subsurface utilities; and into hillsides, excavation pits, and stockpiles. The flexibility and accuracy of this injection delivery system provides distinct advantages over both conventional in situ and ex situremediation systems. Hot spots can be effectively treated using this technology. As a result, jetting can provide appreciable savings in cost and time over traditional remediation technologies (4).

Jetting uses chemical oxidizers to treat soils rapidly that are contaminated by toxic and persistent organic wastes. The two most common liquid oxidizers used for jetting in soil and groundwater remediation are hydrogen peroxide and potassium permanganate.

Alkalinity, pH, and organic content must be evaluated prior to any in situ metal stabilization project. Injection ports are grouted with bentonite or neat cement. Documented jetting projects include oxidation using hydrogen peroxide and potassium permanganate for both chemical oxidation and aerobic bioremediation of a variety of hydrocarbon contaminants, including gasoline and diesel. Chlorinated solvents have been successfully remediated using chemical oxidation methods. Anaerobic biodegradation of chlorinated solvents combines jetting technology with the injection of carbon sources (molasses, cheese whey, lactic acid, or other chemicals). Metal stabilization uses chemical reductants such as sulfide-based treatments (calcium polysufide, sodium metabisulfite, or ferrous sulfate) with jetting equipment to stabilize various metals successfully, including arsenic, lead, and hexavalent chromium (5–9).

KARST HYDROLOGY

David M. Bednar, Jr.
Michael Baker, Jr. Inc.
Shreveport, Louisiana

The most interesting aspect of a karst landscape is its unique hydrologic system. Karst landscapes are primarily underlain by carbonate, primarily limestone and dolomite, where surface water and groundwater are interconnected to form one functional unit. The end result of this hydrologically integrated flow system is the karst spring. Springs provide substantial quantities of water for human consumption and commercial enterprises. Because karst aquifers provide effective natural cleansing, it is imperative to understand the dynamic flow systems within these aquifers to protect these vulnerable water supplies from contamination.

Karst landscapes occupy 10–20% of the earth's land surface (1). The complex hydrology of karst aquifers has been studied for more than a century, and the understanding of flow patterns has advanced significantly in the last 30 years. Investigative methods used have included spring hydrographs and chemographs, groundwater dye tracing, cave mapping, and computer modeling. However, there is still more to learn about the complex nature of karst groundwater flow systems.

This synopsis includes the terms and concepts developed throughout the last 40 years to characterize the hydrology within karst landscapes. The simultaneous efforts by many researchers throughout Europe, North America, China, and Australia in different karst settings has shaped our understanding of the hydrology of karst landscapes. Excellent sources on karst hydrology are Milanovic (2), Bonacci (3), White (4), Ford and Williams (5), Quinlan et al. (6), and White (7).

GROUNDWATER RECHARGE TO KARST SYSTEMS

Several terms have been developed throughout the years that describe where and how meteoric water enters the subsurface to replenish or recharge underlying aquifers. The first two terms refer to where the recharge waters originate. Jakucs (8) and Pitty (9) recognized allogenic and autogenic recharge. Allogenic recharge is surface water that flows from adjacent nonkarst areas onto to karst. Autogenic recharge refers to water that fall directly onto the karst landscape from precipitation. Gunn (10) proposed four recharge types for conduit flow dominated karst aquifers that combined where and how the water entered the subsurface that included diffuse allogenic, concentrated allogenic, diffuse autogenic, and concentrated autogenic recharge.

The second two terms define how the water moves into the subsurface. Aley (11) used the terms diffuse and discrete recharge. Diffuse recharge falls directly onto the karst landscape and enters the subsurface at a large number of sites where inflow is small. Water infiltrates the soil zone or rock outcrop into the groundwater flow system through joints or fissures in the uppermost layer of the bedrock. Diffuse recharge is relatively slow and can be seen in caves as drip water emerging from cracks in the roof where it deposits secondary carbonates such as dripstone and flowstone (12).

Discrete recharge, also called concentrated recharge, enters the groundwater flow system through localized areas, such as sinking streams or sinkholes. Substantially greater quantities of water per unit area enter the groundwater flow system through discrete recharge areas than through diffuse recharge areas (11). Discrete recharge and diffuse recharge represent the maximum ends of a continuum, and most karst landscapes exhibit both types. Atkinson (13) preferred to use "quickflow" to describe water entering the subsurface through sinking streams and sinkholes, and "baseflow" refers to slow percolation of water into the subsurface through nonlocalized areas.

An argument can be made that the use of any of these eight terms is appropriate and depends on the objective of the study. However, it's the authors opinion that all these terms that have been used to define recharge to karst systems simply leads to confusing terminology for those entering the field of karst science. Palmer (14), Smart and Hobbs (15), and White (12) provide more detailed discussions about recharge in karst systems.

THE EPIKARSTIC ZONE

The epikarstic zone is the uppermost part of the carbonate rock that consists of an integrated system of intersecting dissolution-widened fissures, fractures, cavities, and shafts. The epikarstic zone can vary from zero to 98 feet (16) in thickness, and its development is controlled by such factors as bedrock structure, climate, time since the last glaciation, solubility, vegetal cover, and depth of groundwater circulation. The quantity and depth of solution within the epikarst depends on the quantity of rainfall, its distribution in time, the velocity of recharge water, its composition, and the thickness of the soil and rocks (3). The percentage of bedrock removed by dissolution can range from less than 1% to more than 50% (16). Fissures are considerably widened and observation shows that they decrease rapidly with depth (17) due to the decreased amount of CO^2 in solution as the groundwater approaches equilibrium (18).

Dissolution features in the epikarstic zone are organized to move infiltrating water laterally to localized zones where collector structures, such as shafts, conduct the water farther into the subsurface (19). Water storage in the epikarst generally depends on relief. Areas of gentle topography tend to have higher storage, whereas areas of steeper topography have lower storage. Due to the higher storage capacity in many epikarstic zones, the epikarst serves as a perched aquifer.

Aley (20) divided epikarstic zones into three hydrological types: rapidly draining, seasonally saturated, and perennially saturated. These hydrological types were conceptualized on the basis of dye recovery results where dye was introduced directly into locations of discrete recharge that passed through the epikarst and ultimately discharged at springs. Generally, groundwater travel rates vary in epikarstic systems, and two or more hydrological types may exist. The primary criteria used to distinguish these zones were based on their ability to store water.

Rapidly draining epikarsts are saturated with water for short periods of time especially after major storms that provide little water storage or detainment. Infiltration of fine textured sediment is negligible. Lands commonly characterized by rapidly draining epikarsts include areas of high topographic relief, carbonate bedrock with high solubility, and areas of thin soil and residuum.

Seasonally draining epikarsts store water after major storms lasting for weeks or months or store water on a seasonal basis. Sediment infiltration in voids is greater than that in rapidly draining epikarst. Seasonally saturated epikarsts typically develop in humid areas of moderate relief, appreciable soil and residuum thickness, and at elevations greater than those of local perennial streams. Dye recovery results range from 1–10% for seasonally saturated zones.

Perennially draining epikarsts occur in humid areas of low to moderate relief along perennial streams and are mostly saturated with water. Dye recovery rates are commonly from 0.1–1% for permanently saturated epikarstic zones.

GROUNDWATER TRANSPORT IN KARST SYSTEMS

Before conceptual models of aquifer flow are discussed, one must first define the karst aquifer. The textbook definition of an aquifer does not apply to karst landscapes. Freeze and Cherry (21) define an aquifer as a saturated permeable geologic unit that can transmit significant quantities of water under ordinary hydraulic gradients, which means that most or the entire host rock in the aquifer must be saturated, which is typical in clastic rocks. However, this is not the case in karst areas. Drilling can intercept a water filled conduit that has significant quantities of water in one place, whereas another well drilled 20 feet in any direction may come up dry or provide an inadequate source of water. Furthermore, this definition considers the rock adjacent to a cave stream perched above the water table as an aquifer, even though the rock is not saturated (22), which presents a problem because the entire bedrock unit in karst is not completely saturated, as stated by the textbook definition. Therefore, a more precise definition to satisfy the unique hydrology of karst landscapes was required.

A karst aquifer is an aquifer that contains soluble rocks whose permeability structure is dominated by interconnected conduits dissolved from the host rock which are organized to facilitate the circulation of fluid in a downgradient direction wherein the permeability structure evolved as a consequence of dissolution by the fluid (19). Dissolution of the bedrock increases the permeability of karst aquifers through time. The permeability and preferential pathways created within the karst aquifer are dictated by the hydrodynamic characteristics of the flow system, not the inherited geologic fabric (23). The permeability and hydraulic gradient are the dominant forces that determine the location of conduits where driving force that governs conduit localization is the hydraulic gradient (19,24).

Several terms and analytical methods have been used to conceptualize water movement through karst aquifers. Burdon and Papakis (25) applied the terms diffuse circulation, flow through pores and fractures, and concentrated circulation, flow through larger openings to characterize aquifer flow. Ashton (26) used flood pulse analysis to study the behavior within a karst drainage system. Pitty (9) recognized that karst water exists in discrete systems of fissures. Atkinson (27) separated aquifer flow into three components, diffuse, fissure, and conduit flow. Quinlan and Ewers (28) proposed granular, diffuse, fracture, and conduit flow.

White (29) was the first to develop an oversimplified series of conceptual models for carbonate aquifer flow based on hydrogeology. He proposed two end member aquifer types: conduit flow and diffuse flow. Conduit flow systems form in areas of mature karst and have well-integrated solution channels ranging in size from small pipes to large caves (30). Response to storms is rapid, causes turbulent flow; water can reach velocities of 10^{-3} to 10^{-1} meters per second (22) and has an almost insignificant low-flow hydraulic gradient (31). However, conduit flow represents only a small portion of the aquifer porosity. It has been demonstrated from case studies that enhancement of porosity by dissolution in unconfined carbonate aquifers is relatively minor whereas enhancement of permeability is considerable because dissolution has created an efficient dendritic network of interconnecting channels that can convey 94% or more of the flow in the aquifer (32). Aquifer storage is relatively low in conduit flow systems.

Diffuse flow systems commonly occur in areas of less mature karst. Diffuse flow can occur as fracture flow in dense limestones or intergranular flow in porous limestones. These systems exhibit laminar to slightly turbulent flow through a system of small discrete pathways (widened joints or bedding planes) that are being dissolutionally enlarged extremely slowly (33). Velocities can reach 10^{-8} to 10^{-2} meters per second (22), and response to storms is less than that of conduit flow aquifers. Aquifer storage is higher in diffuse flow systems.

White (34) revised his conceptual model from 1969 to consider the effect of relief, geologic structure, and the aerial extent of the aquifer on its development. The most important conclusion from the study was that recharge was a key factor to differentiate between conduit and diffuse flow aquifers. However, White's conceptual model did not quantify the amount of diffuse and conduit flow in the aquifer. In recognition of this, Atkinson (13) studied the Cheddar Spring catchment within the carboniferous limestone of the Mendip Hills in Great Britain to determine the proportions of conduit flow and diffuse flow within an aquifer. Results indicated that the majority of true groundwater occurs within narrow fissures (diffuse flow), whereas most of the water is transported through the conduits. Recharge to the conduits is derived from quick flow as well as water draining from the diffuse portion of the aquifer. Conduit flow probably accounts for 60–80% of the water transmitted in the aquifer (13).

Quinlan et al. (6) developed a conceptual model that recognized recharge, flow, and storage as the primary components of the classification. They proposed four dominant aquifer types: hypersensitive aquifers, very sensitive aquifers, moderately sensitive aquifers, and slightly sensitive nonkarst aquifers. Each aquifer type describes the aquifer's sensitivity to contamination.

Worthington (35) reported that the threshold passage diameter for conduit flow in a karst aquifer is about 10 mm and that maximum diffuse flow velocities are $<10^{-2}\ \mathrm{m\,s^{-1}}$ and $<10^{-6}\ \mathrm{m^3\,s^{-1}}$ of diffuse flow in a fissure. Because the mean discharges of most karst springs are greater than 10^{-4} $m^3 s^{-1}$, this indicates that these springs are discharging from conduits, that the term diffuse karstic aquifer is a contradiction in terms, and that all karst springs are conduit springs. White (36) agreed with Worthington that the term "diffuse" as applied to spring flow may not be appropriate.

There is agreement among investigators today that karst aquifers consist of a combination of highly anisotropic flow routes and should be classified as triple porosity aquifers (7,37–40). Porosity exists within the rock matrix, in fractures, and in conduits. Matrix porosity refers to water that moves through the intergranular pores in the bedrock. Fracture porosity refers to water movement through fractures and bedding plane partings with the bedrock. Dissolution may or may not have taken place. Conduit or channel porosity refers to the movement of water through dissolutionally widened pathways that commonly have greater flow velocities than those of fracture porosity. Water moving through cave streams is an example of channel porosity.

Worthington et al. (32,38) provided credible support for a triple porosity model in unconfined carbonate aquifers. Case studies were examined in four contrasting carbonate aquifers in the Lower Paleozoic dolostone of Ontario, Canada; the Upper Paleozoic limestone of the Mammoth Cave area in Kentucky in the United States; the English chalk of Great Britain; and the Cenozoic limestone of the Yucatan Peninsula in Mexico. Results demonstrated that at least 96% of the storage in all four aquifers was in the matrix portion of the rock (32) and 94% or more of the flow was through the interconnected network of channels (conduits) within the aquifers.

GROUNDWATER STORAGE IN KARST SYSTEMS

The volume of water within a karst aquifer is commonly defined as storage. Because the karst aquifer is considered to have triple porosity, water in storage can be found in the rock matrix, within fractures that have undergone limited dissolution, and in larger channels where significant dissolution has occurred. Storage depends primarily on such factors as hydraulic gradient, bedrock composition, and the degree of karstification within the flow system. Just like recharge and flow, aquifer storage falls within a continuum. The following studies represent the various conceptual models proposed to characterize karst aquifer storage.

Aley (11) developed a predictive hydrologic model to evaluate the effects of land use and management on the quantity and quality of water from Ozark springs. The model was the result of a study conducted in the Hurricane Creek topographic basin in southern Missouri. Aley stressed that groundwater movement in karst areas cannot be compared to water movement in nonkarst areas. Typical groundwater movement in nonkarst areas is less that 10 feet per year and under such conditions it seems proper to view groundwater as water in storage (11). However, water movement in karst, as substantiated by numerous dye traces, can be several orders of magnitude greater than that in nonkarst areas; flow rates are up to 1 mile per day through conduits and cave streams. As a result, Aley divided groundwater movement into two components within a continuum. Water moving at rates greater than 1 foot per hour was considered "water in transit," while water moving less than 1 foot per hour was "water in storage."

Gunn (41) summarized the work of previous researchers that characterized karst aquifer storage. All studies relied on the importance of storage in the unsaturated zone and recognized four major areas of storage or stores: the soil and superficial deposits, the epikarst, water filled conduits in the phreatic zone along with associated solutionally enlarged fissures and bedding planes, and the saturated rock mass.

Smart and Hobbs (15) proposed that storage, just like recharge and flow type, fell within a continuum that has two end members: unsaturated storage and permanently saturated storage, where a seasonally saturated storage component is the central zone. The model was developed to conceptualize aquifer flow within the unsaturated and saturated zones. Two dominant types of storage were recognized in the saturated zone: dynamic storage and perennial storage. Dynamic storage occurs above base level in unconfined aquifers and flows under gravity to provide discharge at springs; storage is relatively low due to steeper hydraulic gradients. Perennial storage occurs below base level in unconfined aquifers and has a greater volume of water than dynamic storage. Due to the lower hydraulic gradients in this portion of the aquifer, storage is generally higher.

Quinlan et al. (6) modified the Smart and Hobbs model and proposed three distinct zones of storage within the karst aquifer system. The zone of limited storage, the low-end member, is confined to the soil and epikarstic zone, predominately the unsaturated zone. The second zone is identical to the zone of limited storage but a seasonally saturated zone is added. The high-end member comprises aquifers that have an unsaturated zone, a seasonally inundated saturated zone, and either perennial storage in a confined aquifer or a water table aquifer that extends well below spring level (6).

GROUNDWATER DISCHARGE FROM KARST SYSTEMS

Springs represent the pulse of a karst aquifer. For many years, investigators wrestled to find the mechanism that causes variations in spring chemistry. Analysis of spring flow and water chemistry have been the primary techniques used for karst aquifer characterization. Jakucs (8) suggested that recharge type was an important factor that influenced spring chemistry variation; springs that had high chemical variation were related to autogenic percolation recharge, whereas springs that had low chemical variation were associated with concentrated allogenic recharge. Pitty (9) stressed that the percentage of different recharge waters (allogenic recharge via sinking streams and autogenic recharge via percolation) influenced spring chemistry variation. Newson (42) recognized a linear correlation between the percentage of allogenic recharge in a spring's catchment to the coefficient of variation (COV) of hardness at springs; as the percentage of allogenic recharge increased, so did the COV of hardness at the springs. Additionally, Newson found that spring total hardness could be expressed in terms of a simple two-component mixing model (35). From the study of total hardness of springs, cave streams, and percolation water in the Mendip Hills of England, he determined the percentage of allogenic and autogenic recharge received at local springs.

Shuster and White (33) conducted a study within the folded Ordovician dolomites and limestones of central Pennsylvania using 14 springs. They suggested that flow type within the aquifer controlled the chemical character of the springs and used the COV of hardness as the principal statistical parameter. The first group of springs that discharged from fractured dolomites had a constant hardness and a COV of less than 5%, displayed a nearly constant chemical character regardless of season or storm, was recharged by diffuse infiltration, and they called them diffuse flow springs. The second group of springs discharged from karstic limestones with internal recharge from sinkholes. Hardness was very variable throughout the year and had a COV greater than 10%; they called these conduit flow springs. Jacobson and Langmuir (43) produced similar results for chemical variation at carbonate springs.

The conduit flow springs were generally undersaturated with respect to calcite. Springs that discharge from conduit flow systems are flashy based on the high ratios between maximum discharge and base flow discharge. Flow is turbulent, whereas water hardness is low at a mean of 100 ppm, but highly variable. The COV of hardness ranges from 10 to 25% or more (28,44). Groundwater flow velocities are commonly rapid, and water can travel up to a mile per day. Conduit flow springs were considered outlets from conduit flow systems and are described by pipe and channel equations (45).

The diffuse flow springs were generally saturated with respect to calcite. Turbidity is low, but water hardness may exceed 300 ppm; the COV of hardness is typically less than 5% (28). Discharge is nonflashy, groundwater flow is much slower, and water can take months to travel short distances. Diffuse flow springs were considered outlets from diffuse flow systems.

The use of hardness variation to distinguish between flow types appeared to work well for the study conducted by White for small drainage basins in temperate climates. However, larger drainage basins show less variation when springs are fed by conduits (4). It is likely that this is due to longer residence times and the contribution of other waters whose chemistry is different from that of other parts of the basin. Subsequent studies found that the binary classification developed by Shuster and White (33) was not applicable to all karst settings.

Aley (11) applied different terms to Missouri springs. As previously discussed, he divided groundwater in storage into transit water and storage water, which resulted in two spring classifications: high transit springs and high storage springs. High transit springs are similar to conduit flow springs; water is derived from areas of discrete recharge. High storage springs are similar to diffuse flow springs; water is derived from areas of diffuse recharge.

Smart and Hobbs (15) recognized that flow type alone is not responsible for the chemical variation at springs and incorporated recharge and storage components into a simple conceptual model. From this model, it is possible to map the different types of carbonate aquifers. Scanlon and Thrailkill (46) conducted a study in the relatively flat limestones and shales of the Inner Bluegrass karst region of central Kentucky. The physical and chemical characteristics of springs from the Inner Bluegrass were compared with those from the study conducted by Schuster and White (33). Results from their study showed that seasonal water chemistry variation in major low level springs and local high level springs did not correspond with the physical characteristics of the springs over time. Chemical similarities were attributed to the mode of recharge. The difference in bedrock types and structure between the two studies was considered a control factor for the relationships between the physical and chemical attributes of the springs.

Worthington et al. (47) performed a statistical analysis using data from 39 springs in six countries using temperate climates taken from the literature. Results from their study demonstrated no evidence that hardness variation was an indicator of flow conditions within an aquifer, as suggested by Schuster and White, and that greater than 75% of hardness variation was explained by recharge type. Currently, it is recognized that recharge type and storage both play an integral role in the chemical variations at karst springs.

SPRING HYDROGRAPHS AND CHEMOGRAPHS

Spring hydrograph and chemograph analysis have been widely used in concert to gain insight into the hydraulics of the karst groundwater system. A hydrograph is a time series plot of spring discharge versus time. Discharge is plotted on the vertical axis and time on the horizontal axis. The shape of the hydrograph recorded at a spring is a unique reflection of the response of the aquifer to recharge (3,5). A spring hydrograph is divided into three main responses to a discharge event: lag time, the rising limb, and the falling limb. Each of these three components is shown in Fig. 1. The lag time shows the spring discharge before the recharge reaches the spring. The rising limb represents the first arrival and increase of discharge at the spring. The peak of the graph indicates the maximum amount of spring discharge from the storm. The water that flows at the spring at this time does not reflect recharge water; it is older water in the most downstream part of the aquifer that is displaced from storage (49), which represents the pulse-through event, the arrival of energy at the spring from the storm. The falling limb, more commonly called the recession curve, shows the spring discharge as it returns to prestorm conditions.

The recession limb typically consists of a fast response segment and a slow response segment, as shown when the recession limb is plotted on semilogarithmic paper. The fast response segment can be assigned to the conduit portion of the aquifer that drains rapidly when the storm input ceases; the slow response segment can be assigned

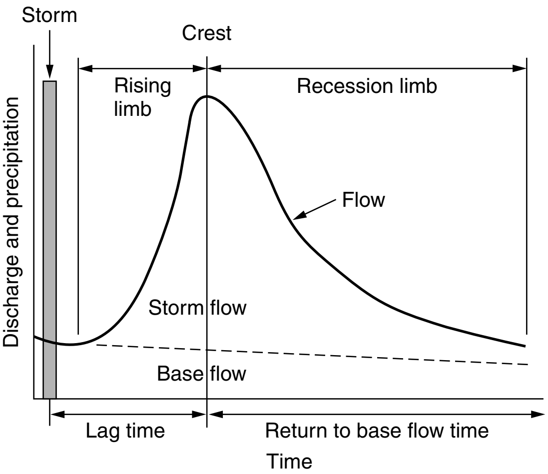

Figure 1. Example of a hypothetical hydrograph (taken from Ref. 48).

to the draining of the fracture system into the conduit after the conduit has emptied (7).

Chemographs show measured concentrations of dissolved chemical parameters in spring water over time. Although many parameters can be used to characterize the chemistry at karst springs, common parameters include turbidity, dissolved oxygen, hardness, stable isotopes, specific conductance, and temperature (5). Figure 2 shows a hydrograph and chemograph from Komlos spring in Hungary. The graph generally shows the increase in parameter concentration after the arrival of the storm pulse wave. Thus, spring hydrographs show a pattern composed of sequential and sometimes superimposed pulses of water of different quality and quantity from different stores and tributary inputs (5).

GROUNDWATER TRACING THROUGH KARST SYSTEMS

Water tracing in karst landscapes has proven to be an effective tool for aquifer characterization. A variety of tracing agents have been used throughout the years to trace and estimate groundwater flow velocities from discrete recharge areas to springs. Tracing agents used include bacteria, surfactants (wetting agents), salts, ions in solution, radioactive isotopes, environmental isotopes, club moss spores, nonfluorescent dyes, and fluorescent dyes (50). Although all agents have been widely used to trace water through karst systems, the following discussion focuses on the use of fluorescent dyes.

Tracing groundwater flow routes with fluorescent dyes is highly successful because the dyes are easily detected in concentrations that are one to three orders of magnitude less than those at which nonfluorescent dyes can be measured spectrometrically (6). Furthermore, fluorescent dyes perform well in different hydrogeologic settings and can be used effectively to trace water from subsurface to surface water bodies.

Dye tracing has been employed extensively in karst areas for a wide variety of purposes. Some of the uses of dye tracing include delineation of spring recharge areas and subsurface basins, determination of site-specific hydrology, estimation of groundwater flow velocities, detection of leakage from residential sewage disposal systems and dam sites, and identification of sources of potential pollution from hazardous waste sites. Dye tracing has also been used successfully during highway corridor studies to identify areas sensitive to accidental spills (51).

Selection of dye introduction points, the manner in which the dyes are introduced, the sampling strategy employed, and the analytical approach used must be tailored to the hydrogeologic setting and the issues of

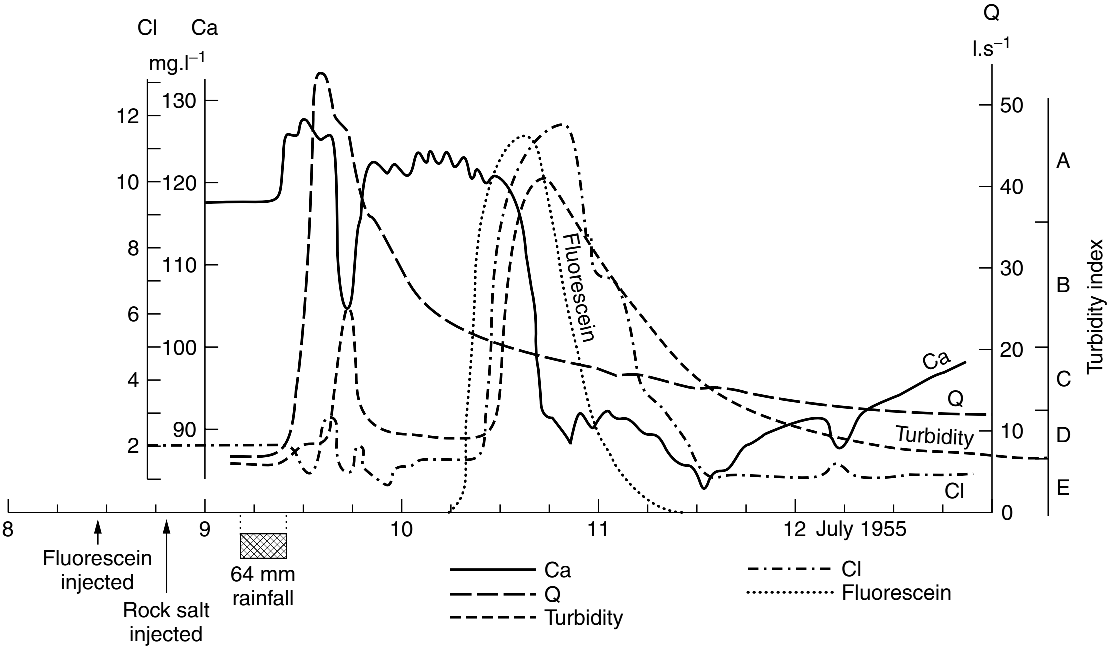

Figure 2. Hydrograph and chemograph of Komlos spring, Hungary (taken from Ref. 8).

concern (52). The amount of dye used for tracing studies is usually based on professional experience because there is no credible standard equation for estimating the dye quantities needed for groundwater tracing. One well-designed dye trace, properly done and correctly interpreted, is worth 1000 expert opinions or 100 computer simulations of groundwater flow (53). Some excellent sources for discussions of groundwater tracing in karst systems include Aley (20,52,54), Smart and Laidlaw (55), Mull et al. (56), Alexander and Quinlan (57), and Kass (50).

VULNERABILITY OF KARST LANDSCAPES

An old adage is that whatever goes up comes down. In karst areas, whatever goes down comes up through a cave, a spring or a well (58). In areas of localized recharge in karst areas, surface water is directly connected to the groundwater flow system. Karst aquifers are highly vulnerable to contamination because they commonly transport water at rates several orders of magnitude greater than those encountered in nonkarst groundwater systems, provide minimum adsorption or other natural cleansing processes, commonly support flow in the turbulent regime, and are too large to provide effective filtration for most pathogens (16). Another concern regarding contamination in karst landscapes is that contamination can enter the subsurface through one location and discharge at multiple spring locations miles apart from each other. Improved adaptation to karst conditions requires that land use and land management decisions simultaneously consider both surface and subsurface resources and conditions (59). Unfortunately, development on karst will continue, but with the implementation of proper land use strategies impacts to this vulnerable landscape can be avoided or at best minimized.

Spores can be dyed various colors and injected into different discrete recharge areas at the same time. Once collected, samples are detected with a microscope. Analysis and preparation techniques require skilled personnel and considerable care (59). An advantage to using spores rather than dyes is that they can be injected in up to six input sites and traced simultaneously, whereas only three sites can be used using during fluorescent dye traces (5).

KARST MODELING

Karst modeling involves developing of methods for reproducing karst processes in the laboratory, so that the natural phenomena can be understood better (60). Karst modeling can include interpretation of several aspects of the karst environment; some of them include groundwater geochemistry and flow patterns, distribution of porosity and permeability in the karst aquifer, fate and transport of contaminants, and groundwater monitoring and remediation strategies. Conceptual, analytical, digital, statistical, and scale models have been used to understand the nature of karst processes better.

Conceptual models are built on ideas based on field observation along with an understanding of relevant physical and chemical characteristics of the system. For a conceptual model to be sound, it must stand alone without quantitative support (60). Analytical models use mathematical equations based on physical laws to model natural phenomena. Equations of fluid flow, chemical kinetics, and conservation of mass are commonly used. When analytical models begin to approach the complexity of real systems, the only way to solve them quantitatively is to break the model into discrete space and time increments so that each increment can then be solved simultaneously (60).

Digital models come in two formats: commercial software for interpreting groundwater flow patterns and chemical equilibria and specialized numerical models designed to investigate complex physical relationships, for example, in the evolution of karst conduits (1). Statistical models are based on measured field data. A hypothesis is developed, and a statistical analysis is conducted to use the model to predict or extrapolate the occurrence of karst features or processes. Scale modeling refers to the actual construction of a model to evaluate physical processes. Sources that discuss karst modeling include White (29), Curl (61), Mangin (62,63), Gunn (64), Clemens et al. (65), and Palmer (60).

KARST TOPOGRAPHY

DAVID M. BEDNAR, JR.
Michael Baker, Jr. Inc.
Shreveport, Louisiana

Karst is an irregularly shaped area of land where underground drainage dominates and has resulted in dissolving the bedrock to form distinctive surface and subsurface features. Karst predominately develops on lands underlain by soluble bedrock such as limestone and dolomite, but can also form in marble, gypsum, and halite. Due to differences in climate, cover, rock type, hydrology, and geologic structure, some areas show significant expression of karst development at the surface, and others show no obvious signs at all. Chemical solution of the bedrock by groundwater leads to the formation of open passageways into and through the subsurface. The degree of development of these features varies greatly from one region to another (1).

The term karst is derived from a plateau region located along the northeastern shore of the Adriatic Sea between Slovenia and Italy. Karst topography, it is estimated, covers about 20% of the earth's surface and can be found in the United States, Russia, the Baltic Republics, Great Britain, Japan, China, Vietnam, Australia, Brazil, and Europe. About 25% of the United States is karst, and it is estimated that 40% of the land east of the Mississippi River is karst. Karst topography occurs in areas of Kentucky, Tennessee, southern Indiana, and central and northern Florida.

BEDROCK DISSOLUTION

The development of karst topography begins with the first drop of precipitation from the atmosphere. Water falls through the atmosphere and reacts with carbon dioxide to produce carbonic acid. As the water infiltrates through the soil horizon, the amount of carbonic acid increases due to reactions with organic matter. Water enters the soluble rock through bedding plains and joints and slowly breaks down and transports dissolved mineral matter into the epikarst.

The epikarst or epikarstic zone (sometimes called the subcutaneous zone) is the dissolutionally weathered upper portion of the bedrock that can vary in thickness from zero to about 100 feet or more (2). Groundwater typically moves horizontally in multiple directions untill it reaches enlarged vertical fissures or shafts where the water moves into deeper portions of the karst aquifer system. Depending on topography, the epikarst can store appreciable amounts of water or transmit water quickly. Water storage is greater in gentle topography as opposed to rapid flow in steeper areas. The intensity of epikarstic development, which can be expressed as a percentage of the bedrock that has been removed by dissolution, is highly variable. This percentage can range from 1 to more than 50% (3). However, many epikarstic zones contain some degree of sedimentation. This can range anywhere from 5 to more than 95%.

Based on the results of about 1,000 positive groundwater trace, Aley (3) divided the epikarst into three hydrological types based on water storage capability. Rapid draining epikarsts are characterized by low water storage and voids that are relatively free of fine textured sediment. These areas typically occur in areas of high relief and where the soluble purity of the bedrock is high. Water that is stored seasonally and after major storms is stored in a seasonally saturated epikarst. In these areas, voids are commonly partially or completely filled with fine textured sediment, occur in humid climate or moderate relief, and the elevation of the epikarst is greater than the elevation of the local perennial streams. Perennial saturated epikarsts contain constant water storage, occur in humid climates and areas of low to moderate relief, and are located along perennial streams. However, all epikarstic zones would more than likely contain a combination of the above.

SURFACE FEATURES IN KARST

Dissolution of the bedrock underground can sometimes produce features that are visible at the surface. Sinkholes are the most common surface features in karst areas. However, the lack of sinkholes at the surface does not indicate a lack of karstification in the subsurface. Sinkholes are bowl-shaped depressions on the surface of the earth that vary in size up to 100 meters deep and 1000 meters in diameter. Subsidence sinkholes form from the gradual movement of soil into the bedrock through solutionally enlarged preferential flow routes in the bedrock (Figs. 1a, 1b, and 1c). As soil moves into the bedrock over time, a circular depression forms at the surface. Collapse sinkholes form when the roof of underlying cavities in the bedrock becomes weak from the weight of the overburden and collapses (Figs. 2a, 2b, and 2c). Caprock protected sinks occur when a sandstone unit located immediately above limestone collapses into the cavernous limestone. The rim of the depression is protected by the sandstone, so that these sinkholes tend to be very deep and steep-sided. Compound sinks form as individual sinkholes grow to form a larger sinkhole that has multiple drainage points.

Karren is another distinctive surface feature. As water flows over soluble rocks on the surface, small-scale dissolution grooves, pits, or channels form. Karren comes in many different patterns and is described in detail by Ford and Williams (4). Additionally, karren can form in the subsurface on bedrock beneath a soil cover.

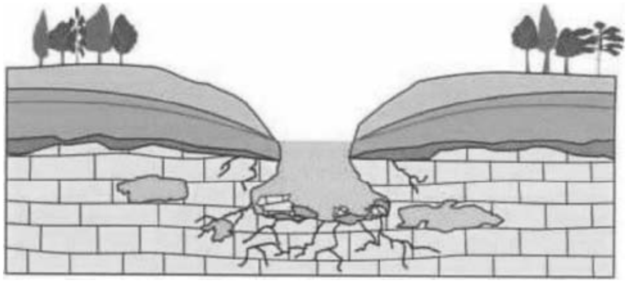

Figure 2(c).

KARST VALLEYS

Three types of distinctive valleys exist in karst areas. Some areas of karst were originally overlain by nonsoluble rocks in topographic valleys. Through time, the overlying rock erodes away by stream action to expose the underlying soluble bedrock in the stream channel. Surface water begins to recharge the groundwater flow system, and the capacity of the groundwater flow system increases to a point where it can handle the entire base flow of the stream. The valley maintains its shape, gradient, and channel, but the discharge from the basin is lost to the groundwater flow system, and it is called a dry valley. Overland flow will occur only during floods. “In some karst river valleys, rivers flow for greater distances before all water is lost to the subsurface at one location. River valleys that end abruptly in this instance are known as blind valleys. The most favorable conditions for the formation of blind valleys are hilly areas of heavy rainfall with well developed streams on impermeable rocks upstream of areas of massive limestone (5).”

Poljes represent another type of karst valley. Meaning “field” in Slovene, poljes are large closed depressions that have well-developed underground drainage systems bounded by steep-sided uplands. Runoff from the surrounding uplands discharges at springs in the polje and forms alluvial streams. These streams sink into caves or swallow holes on the opposite side during periods of low to moderate flow and discharge from them when the groundwater system is at full capacity during periods of high flow.

SPRINGS

Water that disappears into the subsurface in karst areas reappears at the surface at springs. Springs typically discharge along valley floors. Springs can discharge from the contact between two geologic strata, from a solutionally widened opening in the bedrock, or at cave entrances. Quinlan (6) stressed that springs are the pulse of karst aquifers and provide important information about flow regimes. There are two general types of springs in karst areas. Springs that exhibit turbulent flow, respond rapidly to rainfall, and have a highly variable discharge rate are known as diffuse flow springs. Springs that are less turbulent, respond slower to precipitation, and have a low variable discharge rate are called conduit flow springs. However, flow type largely depends on the type of recharge and storage in the karst aquifer as well as the size of the groundwater basin. It must be emphasized that diffuse and conduit flow springs are end members of a continuum and that most springs fall somewhere in the middle (7).

SUBSURFACE FEATURES

Caves and speleothems represent subsurface features in karst areas. A cave is a naturally occurring void in the subsurface that can be easily entered by humans. Caves are formed by the dissolution of the rock along bedding planes and fractures from the circulation of groundwater. Cave formation is affected by such parameters as water quality, tectonics, lithology, topography, geologic structure, climate, and hydrogeologic factors. Additionally, the mode of groundwater recharge helps to enhance cave development.

The shape of cave passageways is dictated by structure and stratigraphy. White (1) placed cave passageways into two broad classes, single conduit and maze passages; each has three distinct geometries. Single conduit caves are classified as those that have linear, angulate, and sinuous passageways. Linear passages are straight without any bends, and the structure of the bedrock controls the path of flow. Angulate passages are characterized by sharp bends and straight segments. Sinuous passages take the pattern of meandering streams, as seen on the surface, that have many curves and few straight segments. Cave patterns found in karst aquifers include branchwork and maze patterns. Sinkholes supply the necessary water flow to form a branchwork (single conduit caves) cave network. In this case, recharge enters the groundwater flow system through several small catchment areas into the subsurface.

Maze-type passages fall into three categories that include network, anastomatic, and spongework mazes. Network mazes consist of intersecting passageways in a uniform grid orientation that are developed by floodwater recharge. This situation is typical where runoff from large areas of insoluble rocks can flow directly into adjacent soluble rocks. The water enters the karst aquifer through a small number of sinking streams each having variable flow. This limited number of input points results in the development of mazes and blind fissures (8). Anastomatic passages look like braided streams on the surface. Spongelike passages are random, interconnected passageways that vary in size and consist of-three-dimensional patterns. The geometry of the cave passage is further dictated by the type of openings through which the water flows, including fractures, bedding plane partings, and intergranular pores.

Speleothems, formerly known as cave formations, form from carbon dioxide rich water that enters the cave atmosphere. Excess carbon dioxide in solution is lost as the groundwater enters the cave atmosphere, and carbonate minerals begin to precipitate out onto the ceiling, walls, or across the floor of the cave. Speleothems are dominantly composed of crystals of calcite and aragonite. Magnesium carbonate deposits are found to a lesser degree. Speleothems are rarely composed of dolomite.

Speleothems are divided into two broad categories, dripstone and flowstone. The common types of dripstones are called stalactites and stalagmites. Stalactites grow as water enters the cave ceiling through joints and bedding-plane partings and slowly drips to the cave floor. Drop by drop, a ring of calcite is deposited to form a hollow tube. Young stalagmites are called soda straws (Fig. 3). Excess water drops onto the floor of the cave and begins to form a mound of calcite known as a stalagmite. Stalagmites form from the cave floor, and successive layers of calcite accumulate upward with time. Sometimes, stalactites and stalagmites come together and form a column. However, this is not always the case. Figure 4 shows an example of a stalactite, stalagmite, and a column.

Figure 3. Soda straws at Mystic Caverns, north central Arkansas.

Figure 4. Stalactite, stalagmites, and a column at Mystic Caverns, north central Arkansas.

Flowstone forms as sheet flows across the cave floor or down the walls of the cave. Draperies (Fig. 5), the most spectacular forms of flowstone, are deposited as water flows over a surface on a cave wall that has an abrupt overhang and deposits in thin trails. Other speleothems within the cave environment include moonmilk, cave coral, rimstone dams, and helictites. Moonmilk is a white unconsolidated deposit of carbonate minerals that resembles cottage cheese when wet (1). Cave coral forms in cave pools when the water becomes oversaturated with calcite and the crystals drop out of solution. Rimstone dams (Fig. 6) are found along the cave floor. These features deposit along the edges of water flowing along the cave floor or at the edges of pools of water where carbon dioxide is lost. Helictites (Fig. 7) are known as eccentric speleothems that defy the law of gravity and grow in any direction from solutions fed along tiny capillaries. They are commonly very short and have a sinuous to curvilinear appearance.

GROUNDWATER RECHARGE

Four dominant types of groundwater recharge are recognized in karst areas. Diffuse recharge enters the groundwater flow system across a broad area. Discrete recharge, also called concentrated recharge, is restricted to small areas, especially through sinkholes or losing streams. Substantially greater quantities of water per unit area enter the groundwater flow system through discrete recharge areas than through diffuse recharge (9). Usually there are several sinking points, or swallow holes, along the course of sinking streams. Surface water is continually lost to the groundwater flow system throughout the year during periods of moderate and high flow. This occurs because the groundwater flow system has reached full capacity and cannot transmit all surface water flow. However, during the summer months, overland flow decreases, and a portion of the stream becomes lost. This water loss through swallow holes or openings in the underlying bedrock eventually reappears at the surface at springs or multiple springs. Surface water that flows from adjacent non-karst areas onto karst is called allogenic recharge. Precipitation that falls directly on the karst that enters the groundwater flow system is known as autogenic recharge. The former two recharge types describe how the water enters the subsurface while the latter two types refer to the where the water originated.

TYPES OF KARST SETTINGS

Quinlan (10,11) noticed that karst settings vary greatly in appearance and classified them into two major types based on cover type. Covered karsts are areas where the bedrock is covered by some material and not exposed at the surface. Four subcategories of covered karst include mantled karst, buried karst, interstratal karst, and subaqueous karst. Mantled karst occurs when a thick layer of unconsolidated sediments partially or wholly covers the bedrock. Buried karst, also know as paleokarst, is an ancient karst landscape that was completely buried by younger rocks. In some instances, soluble rocks are buried beneath less soluble or insoluble bedrock. However, due to circulating groundwater, these rocks are eventually dissolved and are defined as interstratal karst. Karst that forms beneath bodies of water such as river, lakes, or within tidal zones is called subaqueous karst.

Exposed karsts are areas where sediment cover is absent and the rock is exposed at the surface. Four subcategories of exposed karst include naked karst, denuded karst, exhumed karst, and relict karst. Naked karst occurs primarily in alpine regions where soils are poorly developed (1). Denuded karst is interstratal karst that has been exposed at the surface. Karst that was buried by sediment and then later exposed by erosion is called exhumed karst. Relict karst refers to areas where the bedrock has been removed by erosion without any trace of topographic expression.

Additional karst settings identified include deep-seated karst, subjacent karst, and entrenched karst. Deep-seated karst is found buried beneath younger rocks. There is no evidence at the surface, and the soluble rocks are not exposed. Subjacent karst occurs when a portion of the soluble rocks is exposed and surface features are evident. Entrenched karst occurs where the entire thickness of the soluble rock is entrenched along valleys, but the insoluble cap remains over most of the interfluves (7).

VULNERABILITY OF KARST TO CONTAMINATION AND POLLUTION

Karst areas are highly vulnerable to groundwater contamination. Spills that occur on karst can enter the groundwater flow system through discrete recharge zones and travel miles within days or weeks to springs and wells used as sources of water. The high permeability of a karst aquifer provides ineffective natural cleansing of any contaminants transported through it. Contaminated soils have the potential to be washed into the groundwater flow system in diffuse recharge zones without any biological interaction with the soil horizon. Water in storage is more subject to long-term contamination than water in transit (9). Groundwater moves slower under low gradient conditions, and cleanup of contaminated aquifers can last for years.

Keeping vulnerable karst aquifers free of contaminants for water supplies is essential during proper land use planning to minimize impacts to the karst groundwater flow system. In recent years, groundwater dye tracing has proven to be a useful tool for characterizing groundwater flow systems in karst. The delineation of recharge areas for important springs is essential during land use planning.

DETECTING MODERN GROUNDWATERS WITH ^{85}Kr

Craig E. Divine
Geoffrey Thyne
Colorado School of Mines
Golden, Colorado

NATURAL PRODUCTION MECHANISMS AND DECAY BEHAVIOR OF ^{85}Kr

Krypton-85 (^{85}Kr) is a relatively short-lived radioactive isotope of the noble gas krypton (Kr) that is produced naturally in very minor amounts in the atmosphere by spallation reactions (n, γ) with the stable Kr isotope ^{84}Kr. ^{85}Kr decays to rubidium-85 (^{85}Rb) by beta release:

$$^{85}\mathrm{Kr} \longrightarrow {}^{85}\mathrm{Rb} + \beta^- \qquad (1)$$

The decay of ^{85}Kr follows a first-order decay rate given by

$$^{85}\mathrm{Kr_t} = {}^{85}\mathrm{Kr_0}e^{-\lambda t} \qquad (2)$$

where $^{85}\mathrm{Kr_t}$ is the ^{85}Kr concentration at time t (the elapsed time), $^{85}\mathrm{Kr_0}$ is the initial ^{85}Kr concentration, and λ is the ^{85}Kr decay constant (0.06442/yr). The ^{85}Kr half-life ($t_{1/2}$, 10.76 yr) is the time it takes for half of the initial ^{85}Kr to decay to ^{85}Rb and is related to the decay constant by

$$\lambda = \frac{\ln 2}{t_{1/2}} \qquad (3)$$

Krypton is chemically inert, and the only significant sink for atmospheric ^{85}Kr is radioactive decay.

ANTHROPOGENIC SOURCES AND ATMOSPHERIC DISTRIBUTION OF ^{85}Kr

Since the 1950s, anthropogenic contributions of ^{85}Kr to the atmosphere (primarily the result of nuclear weapons testing and nuclear fuel rod reprocessing) have completely overwhelmed natural background concentrations. Worldwide release of ^{85}Kr increased from less than 5 petabecquerels (PBq) per year in 1950 to more than 350 PBq per year in 1986 (1). Although atmospheric ^{85}Kr concentrations vary spatially with strong latitudinal correlation (higher concentrations occur in the Northern Hemisphere due to minimal ^{85}Kr releases in the Southern Hemisphere), the most significant characteristic is the nearly linear increase in concentration (Fig. 1). In contrast with the declining input signal for the tritium groundwater dating method, the increasing ^{85}Kr input signal will facilitate robust apparent age calculations well into the foreseeable future.

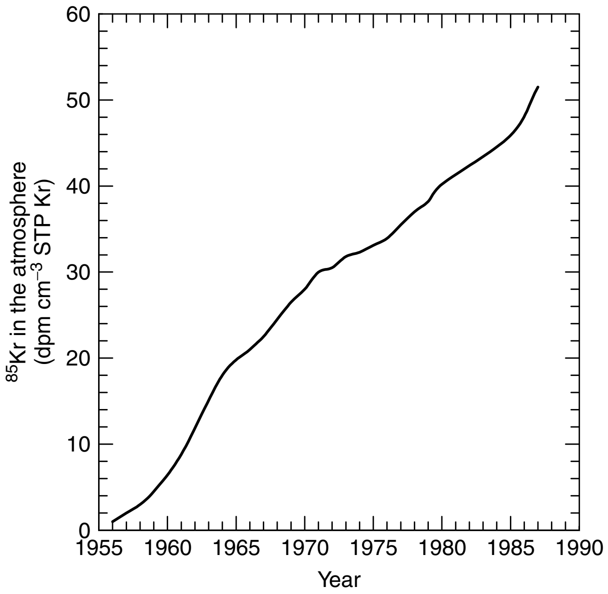

Figure 1. Activity of ^{85}Kr in the atmosphere of the Northern Hemisphere (after Reference 2).

PRINCIPLES, ADVANTAGES, AND DISADVANTAGES OF THE ^{85}Kr DATING METHOD

Anthropogenically related ^{85}Kr overwhelmingly dominates natural background activity in the atmosphere; therefore, the presence of ^{85}Kr in groundwater clearly indicates that the water is relatively young (i.e., recharged after 1950). Furthermore, the relatively simple behavior of the atmospheric concentration history permits estimating exact recharge dates to approximately 1960 by measuring the amount of ^{85}Kr activity in groundwater and accounting for radioactive decay. If dispersion is negligible, an age can be estimated by plotting the measured ^{85}Kr activity in groundwater samples back to an intercept point on the atmospheric ^{85}Kr activity curve (3). Alternatively, a decay-corrected ^{85}Kr activity curve can be plotted for the sample collection date directly relating measured activity to an apparent groundwater age (Fig. 2). For the ^{85}Kr method, the “clock” begins at the seasonal high water table because it is assumed that the ^{85}Kr concentration in the groundwater is in equilibrium with soil gas and the atmosphere (4).

A primary advantage of ^{85}Kr is that it is chemically inert in groundwater and is therefore affected only by the hydraulic properties of the aquifer and radioactive decay (5). Furthermore, age calculations do not require recharge temperature and krypton solubility information because the ^{85}Kr activity is normalized to the total ^{85}Kr present, which also implies that errors from excess air trapped in the aquifer or sample loss are negligible.

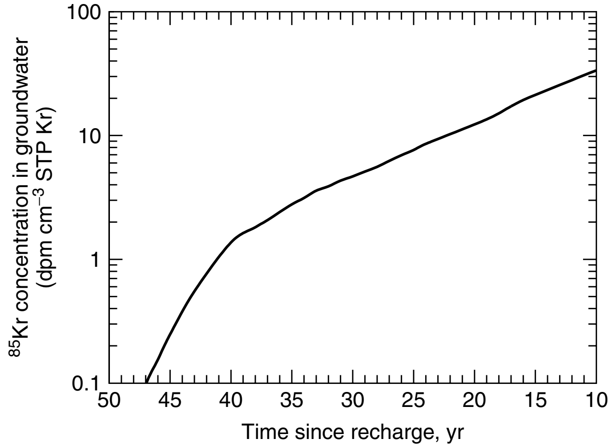

Figure 2. Relationship between apparent age (time since recharge) decay-corrected ^{85}Kr activity for samples collected in 2004 based on the activity of ^{85}Kr in the atmosphere of the Northern Hemisphere (Fig. 1).

However, because of the high current ^{85}Kr activity in the atmosphere, care must be taken to prevent sample contamination during well installation and sample collection. Note that the ^{85}Kr method may overestimate the groundwater age for deep-water tables (greater than 10 meters) due to a time lag through the unsaturated zone (3).

A significant disadvantage of the ^{85}Kr method is the large volume of groundwater required for analysis (~100 L) due to its relatively low aqueous solubility. Furthermore, analytical costs are relatively high: typically \$500–1,500 per sample (4). Water samples must be degassed in the field by vacuum extraction and isolated from the atmosphere. Sampling and analytical methods are discussed by Smethie and Mathieu (6). Ekwurzel et al. (5) report an analytical precision for ^{85}Kr of ±2.9 disintegrations per minute per cubic centimeters of total Kr (dpm cm^{-3} STP Kr).

CASE STUDY: COMPARISON OF THE ^{85}Kr METHOD TO THE ^{3}H–^{3}HE AND CFC DATING METHODS

Ekwurzel et al. (5) compared apparent groundwater ages for several different tracer dating methods, including the ^{85}Kr method, in a study on the Delmarva Peninsula located on the east coast of the United States. The hydrogeology of the area is relatively simple and consists of highly permeable surficial materials and shallow water tables with assumed vertical flow velocities near the water table interface. Discrete groundwater samples were collected in support of tritium–helium (^{3}H–^{3}He) and chlorofluorocarbon (CFC, specifically CFC-11 and CFC-12) dating methods at approximately 30 wells throughout the Delmarva Peninsula. Most wells were screened across less than 1 m of the aquifer and therefore represent relatively discrete intervals of the aquifer. Four ^{85}Kr samples were collected in addition to the other tracers at a local well-characterized flow system within the Delmarva Peninsula (Locust Grove).

Table 1. Comparison of Apparent Groundwater Ages (in years) at Locust Grove, Delmarva Peninsula for Various Dating Methods[a]

	Dating Method			
Well Name	^{85}Kr	^{3}H–^{3}He	CFC-11	CFC-12
KE Be 52	7.7	7.1	8.1	8.4
KE Be 61[b]	14.4	16.7	19.7	20.3
KE Be 62	5.4	3.1	3.2	3.6
KE Be 163	5.7	7.8	9.3	9.2

[a] Reference 5.

[b] Apparent ages are averaged for well KE Be 61 with multiple sampling for the ^{3}H–^{3}He and CFC methods.

The ^{85}Kr method yielded apparent ages that agreed closely (generally within ~30%) with the results of the other dating methods (Table 1). The effect of dispersion on apparent ages was modeled and was relatively insignificant for the ^{85}Kr method for ages younger than 25 years based on site conditions. The investigators also demonstrate that use of multiple methods for groundwater age dating may be advantageous because tracers are affected differently by potential error sources, such as diffusion, dispersion, sorption, degradation, gas entrapment, excess air, recharge temperature, and sampling errors. For additional discussion and case studies on the ^{85}Kr groundwater dating method, see Loosli et al. (7), Loosli (2), Smethie et al. (8), Cook and Solomon (3), Clark and Fritz (9), and Cook and Solomon (4).

LAND USE IMPACTS ON GROUNDWATER QUALITY

Michael D. Trojan
Minnesota Pollution Control Agency
St. Paul, Minnesota

The manner in which humans use land has important consequences for groundwater quality. Using land for waste disposal, recreation, agriculture, residential development, and industry releases different types and quantities of chemicals to the environment. These chemicals often end up in shallow groundwater, where they may impair water quality.

Groundwater impacts from point sources, such as landfills and hazardous waste sites, are well understood. Impacts from "routine" land use, such as residential, commercial, industrial, or agricultural use, are not fully understood or readily apparent. Sources of chemicals from these land uses are called nonpoint or areawide sources. Examples include fertilized urban lawns or all feedlots in an area. This discussion focuses on water quality impacts in shallow groundwater resulting from routine land use.

To assess water quality, we compare chemical concentrations in water to a standard. Most standards are designed to protect human or ecosystem health, but standards also include ambient or natural concentrations of a chemical. For example, a nitrate concentration of 2 mg/L in groundwater under an urban subdivision is well below the drinking water standard of 10 mg/L but may be more than twice the concentration found in areas not impacted by humans.

Resource managers are increasingly concerned about impacts of human activity on groundwater quality. Between 1982 and 1997, the United States population grew about 15%. During that same period, the percentage of developed land, which includes urban land and land used for transportation, increased 34% to just over 98 million acres, which represents 6.6% of the nonfederal land in the United States (1). Urban development is only one of several land use changes that have the potential to impact groundwater quality. Others include changes in agricultural fertilizer and herbicide use, changes in the number of acres under irrigation, and changes in atmospheric deposition resulting from automobile and industrial air emissions. Groundwater impacts from land use are greatest where aquifers are sensitive to contamination. Examples include fractured bedrock or glacial aquifers that are close to the land surface and overlain by permeable geologic material.

UNDEVELOPED AREAS

Undeveloped areas include forested lands, grasslands, wetlands, and other areas not used for urban or agricultural development. These areas are minimally impacted by humans. Water quality from undeveloped areas serves as a benchmark for comparison with other land uses. Typically, pesticides and volatile organic compounds (VOCs) are absent, and concentrations of inorganic chemicals are low unless local geologic deposits are enriched in a particular element (Table 1) (2–5). Variability in chemical concentrations under undeveloped land use is low compared with that of other land uses (6).

Synthetic organic chemicals are occasionally found in undeveloped areas. Chloroform is the most commonly found VOC, atrazine and its primary metabolite, deethylatrazine, are the most common herbicides. These chemicals may be the result of atmospheric deposition (3,7). Chlorinated insecticides, such as dieldrin and DDE, are sometimes detected in groundwater under undeveloped areas and represent historic use of these persistent chemicals (3).

URBAN LAND USE

Urban areas include residential, commercial, and industrial land use. Distinctions between urban land uses are not always clear. Residential areas often include commercial development and may include small tracts of industrial or agricultural land. Residential areas served by municipal sewers (sewered) and septic systems (nonsewered) may be mixed. This intermingling of land uses makes it difficult to associate groundwater quality with a specific land use.

Studies of water quality in urban areas rarely distinguish between different types of urban land use. Consequently, Table 1 shows a wide range in chemical concentrations. Concentrations of major ions, trace elements, pesticides, and VOCs exceed concentrations found in undeveloped areas. Prometon, simazine, dicamba, bromacil, and 2,4-D are the most commonly detected herbicides (7). Prometon, bromacil, and simazine are applied for weed control in rights-of-way, and dicamba and 2,4-D are applied to urban lawns (8). These chemicals are found primarily during the growing season. The organochlorine insecticides, dieldrin and chlordane, are often observed in groundwater beneath urban areas (7,9). Atrazine and deethylatrazine are frequently observed in urban areas (10). Although used on agricultural crops, atrazine is present in precipitation in many areas of the United States (8,11,12). Concentrations of pesticides in urban ground water are typically well below drinking water standards, although standards do not exist for many of the compounds detected (13).

The widespread occurrence of VOCs is the most conspicuous difference between undeveloped and urban areas. Chlorinated hydrocarbons, particularly 1,1,2-trichloroethene (TCE), 1,1,2,2-tetrachloroethene (PCE), and 1,1,1-trichloroethane (TCA), account for the majority of VOC detections. These persistent chemicals were used as degreasers, in dry cleaning, or in septic systems (3,6). Trihalomethanes, particularly chloroform, also occur within urban areas. They are byproducts of disinfection, but other sources include atmospheric deposition and lawn watering with chlorinated water (14). Nonchlorinated hydrocarbons, such as benzene and substituted benzenes, occur in areas where underground fuel tanks have contaminated the groundwater (13).

Table 1. Summary of Median Chemical Concentration, Range in Concentration, and Number of Data Points for Three Land Uses

Chemical[a]	Median			Range			Number of Data Points		
	Und.[b]	Urb.	Agr.	Und.	Urb.	Agr.	Und.	Urb.	Agr.
Major Ions (mg/L)									
Calcium	9	89	60	5–63	20–123	16–92	3	5	5
Chloride	2.4	63	20	1.8–3.0	22–83	10–41	2	4	4
Magnesium	22	26	23	22	18.7–29	22–25	1	3	3
Nitrate	0.6	2.4	4.1	0.5–1.0	1.4–6.1	1.3–15	3	10	11
Potassium	1.1	2.6	2.0	1.1	1–3.2	1.3–5	1	3	3
Sodium	3.3	22	7.4	1–5.6	12–63	4.3–35	2	4	4
Sulfate	8	17	13	3–13	7.1–72	6.3–40	2	4	4
Synthetic Organic Chemicals (% of Samples Detected)									
Total PAHs	0	0	0	0	0–33	0	1	2	2
Total pesticide	4.4	32	86	0–35	0–70	29–100	4	9	8
Total VOCs	4	66	7	0–15	3–100	0–9	3	7	5
Trace Elements (ug/L)									
Arsenic	0.7	1.4	2.9	0.7	0.7–2	0.7–5	1	5	4
Boron	16	56	39	15–17	41–71	21–80	2	3	3
Cadmium	0.1	0.09	2.0	0.1	0.04–1.5	0.04–4	1	5	4
Chromium	1.1	3.1	3.4	1.1	1.1–6	0.59–6	1	5	4
Copper	<5.4	2	5.4	<5.4	2– < 5.4	5.4	1	6	2
Iron	10	34	4.3	10	5.6–63	3.6–4.9	1	3	2
Lead	0.04	0.06	0.027	0.04	0.05–0.07	0.027	1	5	2
Manganese	0.6	5.0	1.7	0.6	0.5–440	0.5–2.6	1	4	2
Zinc	5.9	5.5	6.6	5.9	5.1–9.1	6–7.1	1	4	2

[a] Data are compiled from many sources cited in references.

[b] Und. = undeveloped, urb. = urban, agr. = agriculture.

There are water quality differences between the three urban land uses (Table 2). Nitrate, phosphorus, and boron concentrations are higher in nonsewered areas than in sewered areas (5,15,16). In nonsewered subdivisions that are more than 10 years old and have lot sizes of 1 acre or less, nitrate concentrations often exceed the Maximum Contaminant Level (MCL) in 10% or more of sampled wells (17–20). Manganese concentrations are higher, and VOCs occur more frequently in sewered areas (5). Concentrations of TCE and PCE may exceed drinking water standards in older sewered areas where industries used these chemicals (7).

AGRICULTURAL AREAS

Agriculture includes cropland, pasture, rangeland, and areas managed for silviculture. Cropland can be divided into different cropping types and irrigated or dryland agriculture.

Nitrate concentrations and frequency of herbicide detection in agricultural areas are higher than in undeveloped and urban areas. Concentrations of most other chemicals are higher than concentrations in undeveloped areas but lower than concentrations in urban areas. VOCs are detected less frequently than in urban areas, whereas organochlorine insecticides occur at similar frequencies. DDT, DDE, dieldrin, and heptachlor epoxide are the organochlorine chemicals found most frequently.

Table 2. Summary of Median Chemical Concentrations for Different Urban Land Uses

Chemical[a]	Sewered Residential	Nonsewered Residential	Commercial-Industrial
Major Ions (mg/L)			
Calcium	105	73	74
Chloride	79	83	42
Magnesium	29	19	28
Nitrate	2.4	6.1	2.0
Potassium	2.9	1.0	3.2
Sodium	26	63	17
Sulfate	18	7.1	12
Synthetic Organic Chemicals (% of Samples Detected)			
Total PAHs	0	0	33
Total pesticide	10	0	7.5
Total VOCs	52	3.0	73
Trace Elements (ug/L)			
Arsenic	0.70	0.70	0.49
Boron	41	71	57
Cadmium	0.09	0.04	0.07

Copper	<5.4	<5.4	<5.4
Iron	5.6	<3.1	9.3
Lead	0.07	0.05	0.06
Manganese	8.0	0.45	20
Phosphorus	0.027	0.035	0.020
Zinc	9.1	5.1	7.9

[a] Data from Ref. 5.

Carbamate insecticides occur in areas where they are applied (Table 1) (3,6).

Atrazine, deethylatrazine, and metolachlor are the most commonly observed herbicides in agricultural areas (7,10,21). The presence of other herbicides relates to regional use and includes metribuzin, EPTC, bentazon, diuron, 2,4-D, and dicamba (14,21,22). Recent studies suggest that herbicide metabolites occur at much greater frequency than parent compounds (5). Prometon, simazine, and tebuthiuron are used in road rights-of-way and occur in groundwater from agricultural areas, but at frequencies lower than those in urban areas.

Concentrations of both nitrate and herbicide are directly proportional to the amount of these chemicals applied to cropland (23). Nitrate concentrations are about 1 mg/L under noncropland, 1–3 mg/L under small grains and soybeans, 3–7 mg/L under nonirrigated row crop agriculture, and more than 10 mg/L under irrigated agriculture (5,22,24,25). Nitrate concentrations tend to be lower in areas that have extensive feedlots due to denitrification associated with organic carbon released from the feedlots. Total nitrogen concentrations in these areas, however, may exceed concentrations in areas lacking feedlots (5,24). Herbicides are generally absent under rangeland and forestland used for silviculture; concentrations under irrigated agriculture are about double those under nonirrigated agriculture. Pesticide concentrations typically are lower than drinking water standards, although standards do not exist for many chemicals.

GEOGRAPHIC AND DEPTH RELATIONSHIPS

The land use relationships discussed before are independent of geographic location, except that the chemicals differ locally (6,26). For example,

- Methyl tert-butyl ether (MtBE) is a VOC frequently found in groundwater but only in areas where the chemical is used as an additive in gasoline (7,13).
- Very densely populated urban areas have concentrations of major ions higher than those in less densely populated urban areas (6).
- Local pumping of surficial aquifers induces flow of water from different areas, resulting in a groundwater chemical signature that may not reflect the overlying land use (6).
- Specific synthetic organic compounds are often found in areas where specialty crops are grown. For example, 1,2-dichloropropane was frequently used as a fumigant for potatoes, berries, and other specialty crops. It is found in trace quantities in areas where it was applied to crops (13,22).

Impacts in shallow groundwater do not necessarily relate to water quality deeper in an aquifer. Many aquifers are protected by confining geologic layers or favorable geochemical conditions. Many aquifers, however, do not have adequate protection. Sensitive fractured bedrock aquifers, in particular, are affected by land use.

INFORMATION NEEDS

There are few studies that compare water quality beneath different land uses. Land use studies are complicated by concerns about where in an aquifer to collect samples, well spacing, defining discrete land uses, historical land use, and selection of a parameter list. Data for trace elements are generally lacking, although land use affects concentrations of arsenic, boron, lead, and manganese in ground water (3,5). Recent studies suggest that groundwater may contain chemicals not previously sampled, such as pesticide degradates; chemical additives such as tetrahydrofuran and MtBE; urban insecticides such as diazinon, carbaryl, chlorpyrifos, and malathion; pharmaceuticals; growth hormones; and antibiotics (3,5).

There is also a need for trend information. We do not understand rates of water quality change associated with land use changes. For example, nitrate loss from newly installed lawns is high the first year after establishment, particularly if the lawns are seeded. Other studies show that nitrate loss under established turfgrass is very low (5,27). Rates of change from these two conditions are not known, however. Some trend studies exist for the occurrence of nitrate in groundwater in agricultural and nonsewered residential areas (10,22,28–30). Concentrations of VOCs in urban areas should be decreasing in response to aggressive cleanup and control programs in the last 20 years, but there is limited data to support this assumption.

Finally, we need to understand the effectiveness of management strategies in protecting groundwater quality. For example, studies show that converting land to CRP improves water quality (5). There is less information on the effects of other agricultural BMPs, such as conservation tillage, crop rotation, and nutrient management. In nonsewered urban areas, increasing lot size results in lower nitrate concentrations in groundwater, but increased use of pesticides and fertilizers on larger urban lawns may offset this. In industrial areas, regulatory programs such as the Superfund have resulted in cleanup of soils and groundwater at contaminated sites, but there is limited information on the effectiveness of these cleanups in protecting water quality in aquifers.

SUMMARY

Research consistently shows that chemical concentrations in groundwater increase as the quantity used increases. The type and intensity of land use are thus the most important factors affecting groundwater quality in an area. Water resource managers need to be aware of the potential impacts of different land uses on groundwater quality.

GROUNDWATER CONTAMINATION FROM MUNICIPAL LANDFILLS IN THE USA

David J. Tonjes
Cashin Associates PC
Hauppauge, New York

Groundwater contamination has been a significant environmental impact associated with landfills. Landfilling can affect groundwater quality through leachate releases, landfill gas migration, and runoff. Leachate releases are the most common and serious cause of impacts. Plume chemistry often limits extensive contamination to salts, ammonia, and redox-sensitive metals. Liners and gas control systems are effective in preventing pollution at modern facilities.

INTRODUCTION

Groundwater contamination is often cited as the greatest environmental problem associated with landfills. Municipal solid waste (MSW) landfills are often said to release contaminants such as metals, volatile organic compounds (VOCs) (such as solvents and gasoline constituents), pesticides and herbicides, polychlorinated biphenyls (PCBs), and dioxins and furans to groundwater, often at concentrations associated with human health concerns (1). Additional impacts would occur where contaminated groundwater discharges to surface waters.

Landfilling proponents acknowledge that earlier operational practices at disposal sites caused impacts to ground water (2). Most are now convinced that modern landfill engineering has ended these impacts (3).

Historically, design choices have affected the degree and kind of groundwater contamination. The most important is site location. In addition, the use of active controls can limit groundwater impacts.

Landfills impact groundwater in three ways. The primary concern is leachate releases. Leachate forms within the landfill as a result of precipitation. Precipitation percolates through the fill and dissolves matter from wastes and materials such as cover soils. These liquids foster chemical and biological reactions that liberate various substances. Landfill biota are further known to alter the composition of leachate (4). All of these elements of leachate may react with each other and with landfill features, including the containment liners and associated piping. Leachates undergo alteration in the environment, react with sediments, groundwater, or vadose zone liquids, and undergo additional biological reactions (5).

Contaminants also reach groundwater through gas migration (6). Waste decomposition gases produced within the fill may migrate away, typically through the vadose zone. There, gas may dissolve in recharge to reach groundwater; gas may diffuse at the phreatic zone directly; or, if the pressures from the gas are large, it may bubble into shallow groundwater (enhancing contaminant dissolution). The principal constituents of landfill gas are methane and carbon dioxide, and they are often approximately 50% each by volume. However, chemicals that have high vapor pressures and reactive gases generated by waste reactions also are commonly found in landfill gas (7). VOCs are thus typical gas-generated groundwater contaminants; as metals are not typically found in landfill gas, landfill gas rarely causes any metal contamination of groundwater.

Runoff that was in contact with wastes is another pathway to contaminate ground water (8). Runoff differs from leachate in that liquids do not pass through the waste but have contact with surface or shallow subsurface wastes. The chemistry and biology affecting runoff are different from those generating leachate. The surfaces of landfills tend to be aerobic, whereas fills are anaerobic. Photodegradation is a surface phenomenon, and volatilization is enhanced by wind (albeit interior volatilization is promoted by elevated temperatures). Runoff flowing away from a landfill can percolate through the vadose zone to ground water and may be altered along this pathway.

HISTORICAL FACTORS REGARDING GROUNDWATER CONTAMINATION FROM LANDFILLS

Land disposal has been the most common means of waste management, other than random discards. As municipalities organized waste disposal, locations for discards burial were identified. Lands of little value (such as swamps) or areas needing improvement by fills (quarries, depressions, or shorelines) were used (9).

Early landfills may not have impacted groundwater to the extent that mid twentieth century landfills did. It is clear that cities cause deterioration of underlying groundwater resources through waste disposal. Much of Manhattan's groundwater was unpotable by 1799, for example (10). However, the primary pollutant there and for large third-world cities today appears to be septic wastes (9).

There are few reports of landfill groundwater impacts before the 1960s (11). Many early studies report plume sizes consonant with contamination initiation that coincided with the start of sanitary landfilling (12,13). However, the development of sanitary landfilling occurred when groundwater research became more widespread and as waste disposal rates greatly increased. Sanitary landfills replaced open dumps. Most dumps had small footprints and accepted low volumes of wastes; therefore, relatively small releases of contaminants would be expected. Many dumps were at groundwater discharge zones (shorelines, wetlands, depressions), minimizing impacts to regional resources. In addition, many dumps were managed by burning garbage (a source of noxious air pollution), which reduced labile carbon and formed ashes (14), which may have reduced biological and chemical activity and supported reactions with the remaining wastes or sediment matrices to minimize solubilities.

GEOGRAPHICAL FACTORS REGARDING GROUNDWATER CONTAMINATION FROM LANDFILLS

Three geographical parameters help determine if landfill groundwater contamination may occur and its seriousness. First, there must be groundwater present. Not all of the United States is underlain by aquifers. The absence of significant groundwater resources means there is no resource to impact. Secondly, the resources must be hydraulically connected to the surface. If there is an impermeable barrier (either natural or artificial) between the fill and resource or the distance to the aquifer is too far for the quantity of generated recharge to reach it, then the potential for contamination is very small (4).

Thus, local geology is paramount. In areas of unconsolidated sediments of high permeability, landfill-derived contaminants can reach and impact groundwater but may not in other geological settings (13).

Finally, landfill contamination is driven by precipitation. In desert areas, less leachate, landfill gas, and runoff are generated, compared with landfills in more humid, temperate zones. Therefore, the risk of groundwater impacts from landfills is high on the eastern coastal plain. Rainfall is plentiful, and local geology leads to high-yielding aquifers found near the surface. In the southwest, greater aridity, bedrock outcrops, and large distances to water tables tend to minimize concerns (15).

LEACHATE RELEASES

An early evaluation of landfill leachate contamination of ground water by the U.S. Geological Survey (USGS) occurred on Long Island. Plumes from two, unlined landfills were characterized as extremely salty and enriched in iron and manganese. Other trace metals (except for zinc) were not detectable. The plumes had very low dispersion constants (especially laterally) and tended to sink in the aquifer (13).

The USGS characterized landfill plume chemistry in Delaware, where the plume was delineated by redox zonation. Closest to the landfill was a methanogenic zone. Further from the fill, successive zones marked by iron reduction, manganese reduction, and nitrate reduction (for carbon oxidation by microbes) were observed—the absence of sulfate eliminated sulfate reduction. The work promoted predictions of differential chemical processes in the zones, resulting in differences in plume chemistry (16).

In 1983, a University of Waterloo landfill study was published (19) that established many basic methodologies for acquiring data and generating interpretations of leachate contamination. The discussion of plume geochemistry (18) reinforced the USGS findings and identified cation exchange and other sediment–plume interactions as major controls.

Early modeling efforts found that the leading edge of the plume moved as quickly as groundwater flowed (19), mostly because it was defined by unreactive chloride. Other plume constituents were slowed by reactions, as discussed by Nicholson et al. (18), but, generally, chlorides have defined leachate plumes.

Landfill leachate characterizations are marked by varying concentrations (Table 1), which is true across sites, and even for cells at one landfill. Two leachate samples from different cells of a Long Island landfill had chloride concentrations of 50 mg/L and 58,000 mg/L (8). These variations are generally explicable in terms of different wastes in the cells, but site-specific and time-specific leachate generation processes also cause differences. These variations make it difficult to predict impacts *a priori*, or to determine volumes of releases *post hoc*.

Commonly, it is assumed that the contaminating constituents directly represent disposed waste materials. At an extreme, this resulted in some reports stating that iron, chloride, calcium, and magnesium were dumped as discrete wastes because they were found in plumes at concentrations above drinking water standards (21). Organic compounds cause special problems in this regard. Complex molecules such as DDT or PCBs, if found in a contaminant plume, probably were disposed at the site. Benzene or toluene, however, could have been disposed of as particular solvents, released from petroleum products (22), or even generated as relatively refractory breakdown products as other organic compounds degraded. Once, chlorinated hydrocarbons found in the environment were all thought to be released as solvents. However, now it is known that particular microbes can degrade more complex chlorinated solvents to simpler compounds (23). Additionally, under certain conditions, chlorinated hydrocarbons can be generated *de novo* by environmental bacteria (25).

Table 1. Classic Definitions of Landfill Leachate Quality[a]

Parameter	Range of 20 Samples[b]	Representative Range[c]
Alkalinity	0–20,850	500–10,000
Ammonia	0–1,106	10–1,000
Biological oxygen demand	81–33,360	
Calcium	60–7,200	100–3,000
Chemical oxygen demand	40–89,250	1,000–90,000
Chloride	4.7–2,500	300–3,000
Copper	0–9.9	<10
Iron	0–2,820	1–1000
Lead	<0.1–2	<5
Magnesium	17–15,600	100–1,500
Manganese	0.06–125	0.01–100
Mercury		<0.2
Nickel		0.01–1
Nitrate		0.1–10
Organic nitrogen		10–1,000
Phosphorus as phosphate	0–130	1–100
Potassium	28–3,770	200–1,000
Sodium	0–7,700	200–1,200
Sulfate	1–1,558	10–1,000
Total dissolved solids	584–44,900	5,000–40,000
Total hardness	0–22,800	
Total organic carbon		200–30,000
Total suspended solids	10–26,500	
Zinc	0–370	0.1–100
pH	3.7–8.5	4–8

Efforts to avoid groundwater contamination from landfills often begin by removing hazardous substances from the wastes (1). If landfills actually generate these kinds of compounds, these waste quality improvement programs might not achieve their goal.

A contaminant plume itself can control some pollutants. Research found that iron sulfide complex generation scavenged many free metal molecules, removing the immediate threat of trace metals migrating with the plume (25). In general, microbially mediated reactions together with groundwater–sediment interactions alter a plume substantially, biodegrade and chemically neutralize organic compounds in the near vicinity of many landfills, and limit their mobility in groundwater (26). Thus, leachate plumes at distances from the landfill often are no more than the more unreactive soluble salts (e.g., chloride, sodium, calcium, but not potassium), ammonia (if not nitrified), refractory carbon compounds, and dissolved iron.

LANDFILL GAS MIGRATION

Prior to sanitary landfilling, gas does not seem to have usually been generated in large quantities at most landfills. By the 1960s, landfill gas was a major problem. The most obvious dangers were explosions, especially at structures near landfills, which caused a number of deaths and injuries (27). Health concerns from exposure to the minor constituents of landfill gas also became a concern (28).

By the 1990s, it was becoming more widely known that landfill gas could directly cause groundwater contamination. VOC contamination from gas migration was the major concern (29). Some also noted that, analogous to natural gas impacts (30), redox-sensitive metals (iron and manganese, primarily) could be released from native sediments due to increased microbial activity and associated anoxic groundwater conditions. Methane can even increase alkalinity and therefore bicarbonate concentrations by increasing aqueous carbon (31).

Gas affects groundwater in three ways. It reacts with recharge as the gas migrates through the unsaturated zone away from the landfill (6). Second, as the gas fills the vadose zone, dispersion and surface film reactions can occur at the phreatic surface (32). Finally, if the landfill is producing large amounts of gas, it may increase the pressure gradient enough to infuse gas downward into the shallowest groundwater (33) (this is probably limited to directly beneath or adjacent to the fill), which can introduce gas below the immediate surface layer of the groundwater and allow more complete dissolution of contaminants.

Methane migration thus can cause VOCs and redox-sensitive metals contamination side-gradient and upgradient to overall groundwater flows and may enrich concentrations of these contaminants downgradient in the shallow aquifer. Methane migration cannot cause increases in soluble salts or nonnative metals, as gas cannot transport them. Methane impacts also tend to be restricted to the shallowest groundwater. Thus, impacts from landfill gas can be distinguished from leachate impacts (34).

UNCONTROLLED RUNOFF IMPACTS

There has been little research on runoff impacts from landfills. Modern landfill design intends to minimize and control runoff (35). Also, impacts from these surface flows off the landfill tend to occur very close to the fill, and so may be classed as leachate release impacts. However, where recharge basins are used to collect runoff from the landfill, concentrated impacts away from leachate plumes may occur.

Runoff may encounter only aerobic conditions on the fill, and its chemistry may be determined mostly by dissolution reactions (as is not necessarily so for leachate). Runoff may include high concentrations of particular salts if distinctive materials are found on the landfill surface. One Long Island landfill had unusually high concentrations of calcium and sulfate peripheral to its leachate plume. The landfill used ground construction and demolition debris, rich in gypsum ($CaSO_4$) from wallboard, as daily cover. In addition, organic pollutants (from solvents, for example) and easily dissolved metals may also become entrained in runoff (8).

POLLUTION PREVENTION

Many regulations governing landfills intend to prevent leachate releases. Much of the remaining regulatory effort prescribes extensive groundwater monitoring. Artificial liners evolved from simple sheets of plastics or clay beds pioneered in the 1970s to complex, engineered systems described by voluminous State and Federal regulations, and are required whenever groundwater impacts are possible (2). Early, simple liners had near 100% failure rates, and so now liners made of two separate materials and redundant systems are required in many jurisdictions. Regulations also limit hydraulic head buildup as leachate collects on the liner and require leachate removal off the liner and out of the landfill entirely. New York State, which requires redundant liner systems, has records showing that these modern liner systems can universally prevent all but environmentally unimportant releases to the environment (3). There is also some research that less complex systems, if managed properly, can be effective in controlling leachate releases (36).

Landfills are subject to complex closure procedures when operations cease. The intent is to create a “dry tomb” through continued removal of leachate and installation of an artificial cap on the wastes, so that precipitation cannot percolate in. Thus, the waste mass will be isolated from the environment—swaddled in plastics and/or clays—and leachate releases will be impossible (2). The system is also subject to continued maintenance and monitoring for 30 years, according to current regulations.

Controls on landfill gas migration, primarily through gas collection with combustion, are becoming more prevalent. These systems are usually installed for odor control, greenhouse gas reductions, and explosive gas control, not groundwater quality protection (37). However, the result is to limit groundwater impacts from gas migration directly and also to reduce VOC content in leachate, lessening impacts from leachate releases.

Runoff control for groundwater protection is also not a major concern. Runoff is controlled to reduce erosion and to minimize leachate (38). However, these ends may combine to direct liquids that have long waste contact times to management facilities outside of the leachate system. Most regulations, however, state that all water that comes in contact with wastes, no matter how long or brief the time, should be treated as contaminated leachate.

Tens of thousands of landfills have accepted wastes since 1970. Most have closed, and only approximately 2150 sites were operating in 2001 (39). However, probably all but several hundred of these landfills were at least partially constructed prior to 1993, and so are not engineered to the high standard required under the Federal Resource Conservation and Recovery Act Subtitle D (40 CFR Part 258) reauthorization. If the landfill is located in an area where impacts to groundwater can occur, a rigorous analysis of water quality near Subtitle D noncompliant sites is likely to find some impacts to groundwater (although the pollution levels may not necessarily exceed water quality standards), which means that old generation landfills comprise one of the major sources of groundwater contamination in the United States.

GROUNDWATER REMEDIATION

Landfill plumes are difficult to clean up (40). They are not single constituent contaminations. Techniques appropriate for certain plume elements may be hindered by other plume constituents. Air stripping towers that work well with solvents are easily plugged by dissolved iron (which precipitates in contact with the atmosphere), for example (41). Ion exchangers do not collect nonpolar compounds such as most chlorinated organics. Many landfill remedial projects, as practical implementations, address only particular plume constituents rather than the entire range of contaminants affecting the groundwater. Source control (such as capping the landfill) remains the most common remediation for a landfill that is causing groundwater contamination.

BIOREACTORS AND THE POTENTIAL FOR GROUNDWATER IMPACTS

A popular, new concept in landfill design is the "bioreactor." It is a lined landfill where the degradation processes are enhanced through the controlled addition of liquids and/or the recirculation of leachates (42). An aim is to degrade labile carbon as quickly as possible, increasing settlement (making more air space available for disposal purposes), and causing biological stabilization of the waste mass. Recirculating leachate may also strip contaminants onto the wastes, decreasing treatment costs for the effluents (43). Bioreactor technology requires increasing the amount of liquids in the wastes and intentionally increasing gas generation (for capture and use for energy generation). Thus, the design seems to increase some of the factors that lead to landfill groundwater contamination. However, the approach relies on the documented success of modern liners to prevent leachate releases as well as active gas collection efforts to minimize environmental impacts.

SUMMARY

Landfills have historically caused extensive groundwater impacts in the United States, through leachate releases, methane migration, and uncontrolled runoff. These problems have been greatest in moist climates where aquifers have high conductivity potentials and are close to the ground surface.

Groundwater contaminated by a landfill is usually discolored and warm and smells bad. It contains high levels of salts, along with dissolved iron and often manganese. VOCs are a general concern in plumes but are not always found at significant concentrations or throughout the contamination. Many landfill plumes have much lower than expected dissolved trace metal levels because of scavenging by iron sulfides and hydroxides in low-redox, anoxic waters.

Modern engineering techniques have largely eliminated the major sources of contaminants. Modern artificial liner systems together with gas collection prevent landfill leachate and gas from carrying contaminants to groundwater. Dry tomb landfill closures isolate fills from the environment after waste disposal ceases.

However, the barriers and processes used to control access of water to wastes cannot be expected to function indefinitely. It is not clear exactly what the pollution potential of dry tomb landfills will be when the liners and caps decay and fail and the wastes are again exposed to the environment, which is an additional impetus for bioreactor research, as the material remaining in a stabilized landfill, it has been hypothesized, would be environmentally benign.

METAL ORGANIC INTERACTIONS IN SUBTITLE D LANDFILL LEACHATES AND ASSOCIATED GROUND WATERS

Mário Abel Gonçalves
Faculdade de Ciências da
Universidade de Lisoba
Lisoba, Portugal

INTRODUCTION

Organic compounds are one of the most important constituents of landfill leachate waters. Their nature and relative amount are dependent on landfill age and evolutionary stage (1). In the early stages of landfills, organic compounds present in the leachate are mostly species with molecular weight (MW) less than 1000 Da, although with a nonnegligible fraction of higher MW species. The leachate pH is typically around 5 in this stage because of the abundance of low molecular weight organic acids. This acidic stage can last for a few years or up to ten years depending on landfills. Gradually, landfill leachates evolve toward the methanogenic stage, attaining pH values around 8, where higher molecular weight organic acids develop, including fulvic- and humic-type compounds, together with the precipitation of sparingly soluble metal phases, which reduces their mobility (2). Organic compounds, with their abundant functional groups, are recognized important metal ligands in this system. Among the different types of compounds, carboxylic acids and phenols are always the most abundant ones (3).

METAL—ORGANIC COMPLEX STABILITY

Metals do not constitute an important component of landfill waters. However, because they are persistent pollutants in the environment, knowing their fate is of utmost importance. Toxicity of metals to living creatures is a well-known issue. Despite such risk, not every chemical form is equally hazardous, one such example is Cr, being an essential component to glucose metabolism, it is also extremely poisonous in the chromate form (Cr(VI)). On the contrary, Cr(III) is not particularly toxic and forms insoluble solids, which reduces its bioavailability. Depending on the speciation and complex formation, metal cations may have different migration velocities in groundwater, which may increase with metal-organic ligand association, and eventually reduce their bioavailability.

Metal-organic interaction in landfill-contaminated waters depends on the stability of complex formation and metal concentration in solution. Classification of metals into hard-sphere (type A) or soft-sphere (type B) cations (4) is helpful in grouping them according to type of complex formation and stability. Hard-sphere cations have noble gas configurations with spherical symmetric orbitals, because of the low polarizability of the electron cloud. These cations form ionic bonds mostly with ligands that have oxygen as a donor atom. Alkali and earth-alkali metals and Al^{3+} are examples in this group. Soft-sphere cations have deformable electron clouds because of their greater polarizability. These metals predominantly form covalent bonds with ligands having S or N as donor atoms. Metal cations in this group include Cu^{+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Pb^{2+}, Sn^{2+}, and Tl^{3+}. Besides, transition metal cations, such as V^{2+}, Cr^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, V^{3+}, Cr^{3+}, Mn^{3+}, Fe^{3+}, and Co^{3+}, also have similar properties (4).

For transition metal cations, a reasonably well-established rule for a sequence of complex stability indicates that the stability increases in the series (known as the Irving–Williams order) $Mn^{2+} < Fe^{2+} < Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$ (4). For hard-sphere cations, complex stability is proportional to the charge/radius ratio of the cation.

Complexes with monodentate ligands are usually less stable than those with multidentate complexes (chelates). Normally, monodentate complexes are easily dissociated at dilute concentrations of the metal cation, which is well illustrated in experiments with monodentate, bidentate, and tertadentate Cu(II) amine complexes. At dilute metal concentrations ($<10^{-4}$ M), where the monodentate complex is fully dissociated, the tertadentate complex remains stable in solution. Thus, even at concentration levels that are likely to be found in leachate-contaminated waters, the complexing effect of monodentate ligands is expected to be negligible. This experimental evidence may justify the verification that the highly abundant monocarboxylic acids on leachate-derived waters had little influence on the adsorption of metals such as Cu and Zn onto solid phases (5,6). Recently, Schilling and Cooper (7) identified that carboxylic groups are the most important binding sites for Cu(II) cations in soil organic matter, and that phenol groups are less important. Increase on metal sorption capacity is also observed with the addition of carboxyl and amino groups to various types of biomass (8).

METAL-ORGANIC INTERACTION IN LANDFILL-POLLUTED ENVIRONMENTS

In spite of such general knowledge about metal-organic complexation stability, it must be stressed that a great deal of experimental studies do not reflect the environment of a landfill-polluted water. Thus, the expected behavior of metals may differ substantially from what may be previously known, and several factors may induce such a view: first, most experimental work deals with manipulated and treated organic compounds; second, very few reported investigations actually dealt with metal-organic complexation in landfill lechate or leachate-polluted groundwater systems; and third, the influence that a high ionic strength environment and the presence of multiple competing ligands has on the ability to form metal-organic complexes is not known. Specific studies on metal-organic complexation associated to landfill leachate waters or leachate-polluted groundwaters are restricted to a few metal cations, most notably Pb, Cd, Ni, Cu, Cr, and Zn (e.g., 9–12).

Despite how scarce and, ultimately, complex these studies may be, it has been possible to gather important knowledge on metal-organic compound interaction. Speciation studies on a landfill leachate based on an exchange procedure with Chelex 100 resin demonstrates that the free or labile complexed fraction is the most important for all the metals studied by Majone at al. (12), increasing from 50% to 80% in the order Cd < Pb < Ni < Cu (≈80%). The slowly enchangeable fraction represents 14% for Cu, 28% for Pb, and 47% for Cd. Ni has the higher relative percentage in the inert or stable complexed fraction (17%). In the case of Cu, this metal becomes complexed either with low molecular weight compounds (<1000 Da, around 47%) or with high molecular weight compounds (>12000 Da, around 45%), these latter corresponding probably to humic acids (12). Overall, these authors concluded that the high MW organic acids have an important influence on metal speciation, and bonding to these substances increases in the rank Ni < Cd < Cu. The work of Jensen and Christensen (11) and Jensen et al. (10) showed that a significant but highly variable fraction of heavy metals have affinity for dissolved or colloidal organic matter. It must also be stressed that the distribution of metals among the different groups considered (dissolved and colloidal forms, organic- or inorganic-associated) varied between samples and between metals within the same sample (10), which demonstrates the heterogeneity of these systems and difficulty in achieving general conclusions. However, in leachates, it has been possible to show that heavy metals, such as Cu, Pb, and Cd, are predominantly associated with organic matter, either in colloidal form or dissolved. A substantial fraction of dissolved metals, such as Zn and Ni, is mostly associated with dissolved inorganic complexes, the remaining are associated with colloidal fractions (either organic or inorganic). The importance that colloidal organic matter has on the speciation and binding of Cu and Pb (10) seems to be the most plausible explanation for the differential partitioning of metals to sediments near the source of spilled landfill leachate to the surface environment (6). Besides, it has also been verified that metals such as Zn and Ni had much less affinity to organic compounds, preferentially forming insoluble sulfide phases, as in the case of Zn. Christensen et al. (9) also verified for Zn and Ni in leachate-contaminated groundwater that at the low concentrations usually observed in the natural system, complex stability decreases significantly.

LEACHING

David W. Kelley
University of St. Thomas
St. Paul, Minnesota

Leaching, sometimes referred to as eluviation, is the phenomenon whereby a liquid, usually water, moves through a matrix from one location to another, dissolving or suspending materials along the way. The matrix must be porous enough to allow fluid movement and is generally soil, but fractured bedrock or unconsolidated mineral or organic (humus) material can also leach liquids. Normally, this occurs under gravity and movement is downward. Occasionally, this movement is lateral when forces such as capillary action, soil matric potential, or confinement pressure draw the liquid to an area of high water tension or push the liquid from an area of high pressure. The liquid that migrates, generally referred to as leachate, contains a mix of dissolved and/or suspended ions or compounds. These materials, either present naturally in the environment or applied to the ground surface, include dissolved salts, fertilizers, soluble minerals, organic material such as humic or fulvic acids, plant nutrients, and natural or synthetic chemicals. Because water is a polar liquid, it can dissolve or transport a wide variety of substances from one location to another. Even nonpolar molecules can form micelles and be moved great distances by leaching.

Leaching is a function of several factors that affect the amount, rate, direction, and quality of the leachate: the hydraulic conductivity of the matrix, impeding layers (aquitards or aquicludes), partitioning coefficients of any chemicals present, antecedent soil water content (saturated vs. unsaturated flow), osmotic or matric potentials, the cation exchange capacity of the soil, the ionic makeup of the dissolved compounds in the percolating fluid, the water-holding capacity of the soil (largely attributable to soil texture), and the macropore flow (a function of soil porosity, structure, disturbance, burrowing animals, and root channels).

If water is applied at a rate slower than the ability of the soil surface to accept it (infiltration rate), water percolates downward once the water holding capacity of soil is exceeded. If water is applied at a faster rate, a portion of the applied water runs off the soil surface (potential erosion). See Table 1.

Most nonindustrial leaching occurs on agricultural land or under antiquated or modern landfills. Leaching rates are highest in humid regions or on land under irrigation and lowest in arid or permanently frozen regions. Leaching is governed by a few basic processes.

Table 1. Water-holding Capacity of Various Soils (Inches of Water Per Inch of Soil Depth)

Textural Class	Capacity
Sand	0.070
Loamy sand	0.065
Sandy loam	0.095
Sandy clay loam	0.150
Loam	0.165
Clay loam	0.185
Silt loam	0.20
Silt	0.23
Silty clay loam	0.25
Silty clay	0.22
Clay	0.20

Mass Flow

This is the dominant leaching process in most systems and accounts for the greatest movement of water and materials, often over large distances. When water infiltrates a dry, permeable soil, a discrete wetting front is formed that has a higher water content (lower tension) above than below. The depth of this wetting front depends on the amount of water added, the permeability of the surface (pore size, volume, and connectivity), and its initial wetness. To a lesser extent, wetting front migration is a response to the rate at which the water is applied. After water is no longer applied, the wetting front moves but at a slower rate due to reduced pressure from above.

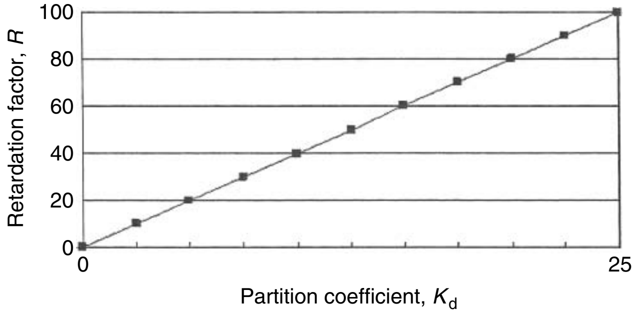
Water infiltrating a dry soil can dissolve and transport salts or chemicals that are not strongly adsorbed on soil solids. Water can also dislodge and transport materials in suspension such as organic colloids or fine clays that are not readily soluble. This dissolved and/or suspended load is transported to depth via the percolating water, but only as far as the wetting front progresses. It can be moved more deeply by subsequent rainfall or irrigation, provided it is of sufficient volume to move percolating water past the previously established wetting front.

If a substance is loosely adsorbed onto solid surfaces in the soil, the depth to which the adsorbed chemical moves is reduced or the rate of movement slowed. This retardation factor, R, is related to the soil-water partition coefficient, K_d, of the particular substance being moved (Fig. 1):

$$R = 1 + \frac{\rho K_\mathrm{d}}{\theta} \tag{1}$$

where ρ is the dry bulk density of the soil and θ is its volumetric water content. The retardation factor varies from a low of 1 for nonadsorbed chemicals to values in excess of 100 for some highly adsorbed ones. The depth to which a substance is leached largely depends on the adsorbent relationship between a substance and the matrix through which it percolates.

The wetting front in an initially dry soil corresponds to the leading edge of the infiltrating liquid. Surfaces that are not initially dry behave similarly except in some soils, where water entering a moist soil can displace water already present and push that water ahead of the front. In such cases, a dissolved or suspended substance would move only to the depth of the infiltrating water, not all the way to the wetting front. Alternatively, because macropore flow (preferential flow paths along cracks in structured soils or fractured rock) is usually present, some water at the wetting front may represent new water. Most likely the situation is a combination of these two mechanisms of water dispersal, which leads to uncertainty in the real location or concentration of a dissolved substance and also suggests that a dissolved chemical is not likely to be concentrated in a sharp pulse but will be more diluted or dispersed.



$$R = 1 + \frac{\rho K_\mathrm{d}}{\theta}$$

Figure 1.

Dispersion

Water moving through soil pores travels at different rates due to porosity, tortuosity, and connectivity differences. A pulse of chemical traveling with the water has its leading and trailing edges spread out, a phenomenon called dispersion. Under natural conditions in the field, water rarely moves through a matrix at a constant rate at all times, even if its physical properties (texture, structure, ionic exchange capacity, etc.) are extremely uniform and water is applied at a constant rate.

Diffusion

Dissolved or suspended substances also move from regions of higher to lower concentration due to osmotic potential referred to as diffusion. Diffusion is usually much less significant than mass flow; it merely spreads the chemical out in an already wetted area. Its influence is generally small and its rate slow due to adsorption (on matrices high in clay and organic matter content).

Sorption

A chemical added to a soil partitions itself between a solution phase and an adsorbed solid phase. When the cation exchange capacity (CEC) of a soil is high (e.g., soils high in smectite clays or organic matter), this bonding is strong because cations are adsorbed to the negatively charged surfaces (Table 2). In other cases (soils with low-CEC clays or lacking clays and organic matter), bonding is quite weak.

Sorption or binding of dissolved chemicals on surfaces is significant because they are not free to move with percolating water. Although sorption retards the rate of

Table 2. Normal Range of CEC Values for Common Soil Groups

Soil Groups	CEC in cmol(+)/kg
Light colored sands	3–5
Dark colored sands	10–20
Light colored loams and silt loams	10–20
Dark colored loams and silt loams	15–25
Dark colored silty clay loams and silty clays	30–40
Organic soils	50–100

chemical movement, it does not necessarily alter the rate of movement of the percolating solution itself.

Substances in a liquid–soil environment tend to establish a balance between the amount on solid surfaces and the amount in solution. Some chemicals exist primarily in the liquid phase; others are strongly adsorbed and exist primarily on solid surfaces. Molecules tend to move from one phase to another to maintain this balance. The manner in which the molecules are partitioned into solid and liquid phases depends on both matrix and chemical properties. These relationships, called sorption isotherms, can be determined experimentally. The center of the chemical pulse on a particular day is greater for substances that have smaller partition coefficients than for those that have larger ones because substances that have smaller partition coefficients are adsorbed less strongly to solid surfaces and can be dislodged and moved more readily by the percolating solution.

Degradation

Chemicals in the environment can undergo biological or chemical transformations, be absorbed by plants, volatilize into the atmosphere, be lost to surface water by surface water flow and erosion, or remain in the surface matrix and be available for leaching to groundwater. The importance of these different processes depends on the unique properties of the substance.

Many natural and synthetic chemicals break down or degrade over time from microbiological and chemical reactions. Substances with low persistence degrade quickly to other products, and highly persistent ones linger. Persistence is usually specified in terms of the degradation half-life, a measure of the time it takes for one-half of the original amount of a substance to be degraded (first-order degradation). Degradation rates are generally temperature and moisture dependent, and most biological breakdown occurs in the root zone of plants because more microbes exist there than elsewhere. Therefore, as compounds are leached to lower depths (below the root zone), they become more persistent and can leach to groundwater before surface organisms have had a chance to degrade them. Typically, root zones can vary from 1 to 6 feet below the surface, depending on the plant and its stage of development.

The chemical makeup of leachate can be altered or its volume reduced through several processes. Roots of actively photosynthesizing plants can scour out essential nutrients or absorb percolating water, denitrification and mineralization can remove or immobilize dissolved nitrogen, chemical alterations such as oxidation to less motile forms can occur (e.g., iron transformed in an oxidizing environment from a mobile, reduced ferrous Fe^{2+} state to an immobile, oxidized ferric Fe^{3+} state), cations (e.g., Na^+, $NH_4{}^+$, Ca^{2+}, Mg^{2+}, etc.) can be adsorbed onto negatively charged surfaces, and shallow subsurface agricultural tile drains can siphon off leachate before it percolates more deeply (into groundwater).

The concern with leaching is that it accounts for the bulk of nonpoint source pollution of groundwater and subsequently to any surface water to which it is hydrologically connected. Any chemicals or suspended solids that are transported to groundwater may impair water quality for aquatic life or render it nonpotable or unfit for human contact (drinking, bathing, swimming). Lawn fertilizers, agricultural chemicals (pesticides, herbicides, fungicides, miticides, etc.), road salts, petrochemical spills, atmospheric particulate fallout (Hg, Pb, oxides of sulfur or nitrogen, etc.) can all end up in groundwater via leaching.

High-risk environments that are of primary concern include

- sandy soils
- shallow-rooted plants
- high rainfall areas or excess irrigation
- shallow unprotected groundwater
- wellhead protection zones
- homesteads with open wells

Leaching affects the receiving waterbody (e.g., a change in the trophic state of a lake receiving discharge from contaminated groundwater), and also in agricultural systems, represents a two-pronged economic loss: fertilizer purchases go wasted if nutrients end up in places other than the root zone, and plant nutrients made unavailable by leaching result in lower harvests. Essential plant nutrients, naturally occurring or supplemented by fertilizers, that are lost by leaching include

- *Calcium (Ca)*: ion generally in the largest concentration in leachate
- *Magnesium (Mg), Sulfur (S), Potassium (K)*: next highest concentrations, depending on soil composition and acidity of leachate
- *Nitrogen (N)*: ranges from high (recent fertilizer application on porous soil prior to intense rainfall) to low (natural systems with no disturbance or low precipitation), depending on plant growing conditions and natural soil fertility
- *Phosphorus (P)*: limited concentration in leachate due to low solubility and high affinity for sorption onto soil particles

The U.S. Environmental Protection Agency (EPA) regulates several pollutants that routinely make their way into drinking water supplies and pose health risks for consumers in the United States. For example, the EPA currently stipulates that drinking water cannot exceed 10 mg per liter (ppm) nitrate ($NO_3{}^-$); this poses significant problems for drinking water suppliers in rural areas that rely on aquifers under agricultural fields for their water source (Fig. 2). The EPA limits lead (Pb) in drinking water to 15 μg per liter (ppb), a challenge in older urban areas that still have lead service pipes as part of their underground water systems. Recently, the EPA issued guidelines for arsenic (Ar) in drinking water; the standard was lowered to a maximum of 10 ppb beginning January 23, 2006. In addition to these specific thresholds for drinking water, the EPA also regulates waterbodies (surface, groundwater, drinking water aquifers) for dissolved salts, fecal coliform

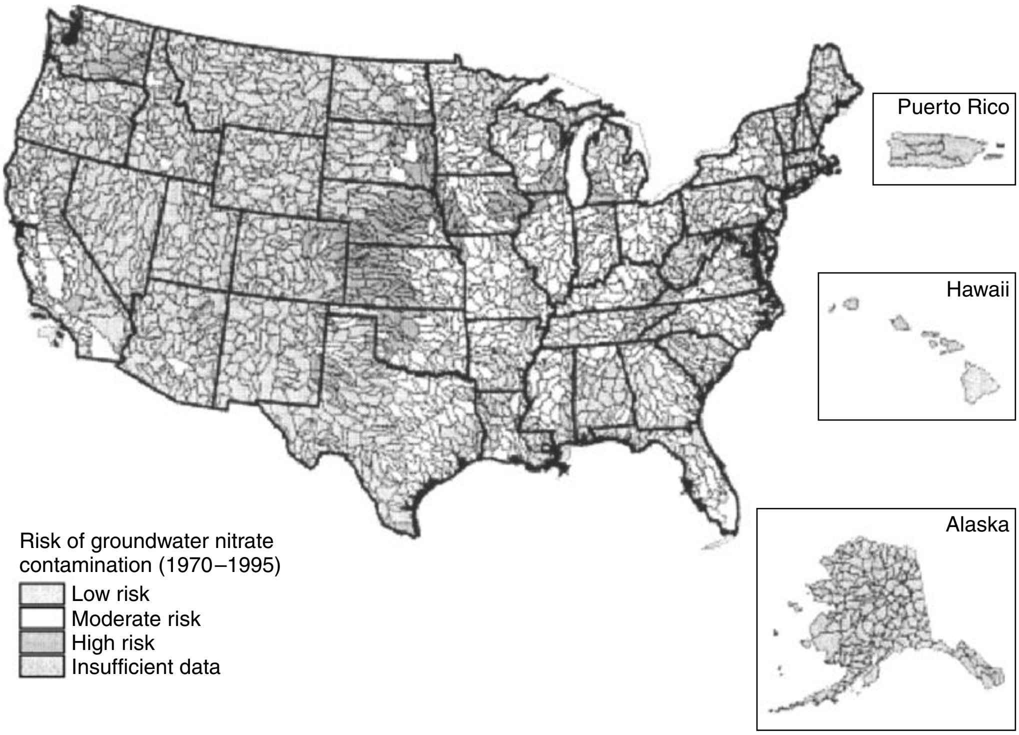


Figure 2. Risk of groundwater nitrate contamination.

bacteria, harmful chemicals, and more, some of which are attributable to leaching processes.

WELL MAINTENANCE

Stuart A. Smith
Smith-Comeskey GroundWater
Science LLC
Upper Sandusky, Ohio

PREDICTIVE AND PREVENTIVE MAINTENANCE

Well maintenance consists of two overall problem-preventing scopes of work: predictive and preventive maintenance (together comprising PM). Predictive maintenance involves tasks such as monitoring water quality, power, and other indicator data to detect evidence of deterioration prior to a fault and making necessary repairs. Preventive maintenance includes tasks such as maintaining lubrication, replacing components, and preventive well treatments conducted prior to deterioration of performance. By contrast, reactive maintenance repairs deteriorated components and performance conditions.

PM GOALS

PM activities are intended to prevent or significantly slow performance deterioration and lengthen intervals between equipment replacements and service events. PM begins with design. In any engineered system, including water works and water wells, prevention of adverse water quality and performance problems begins with appropriate planning and design. These activities include

1. identifying potential problems
2. designing a system to minimize these problems
3. allowing for effective restoration.

Where industry-recommended design parameters (1,2) are followed and materials selected for resistance to deterioration due to water quality, deterioration can be slowed and prevented. These conditions are site-specific, and design is based on investigation and testing.

ANALYSES RELEVANT TO PM

PM of wells depends on analysis of water quality and well performance. The analyses performed necessarily depend on the resources available and also on the environmental difficulties posed by the well environment and the well's purpose and use. Table 1 lists relevant parameters for commercially significant wells (e.g., public and industrial water supply, irrigation).

Data collection may be greatly simplified for wells in very low-demand environments or for low-impact use (campgrounds, low-volume domestic wells). However, some data collection should be performed systematically to avoid "run to failure" typical of such wells.

RECORDS

Records are important in establishing trends that show patterns in performance, including indication of deterioration. Records should include the following:

1. Physical locations and as-built descriptions of the wells and their equipment. The geographic location of well should include reference to fixed landmarks and coordinates.
2. As-built diagram of the well's construction, with any modifications over time.
3. Any lithologic and well construction log information.
4. Records of pumping tests and geophysical, borehole flow meter, etc. tests of the completed well over time.
5. Dates of replacement of components, manufacturer and type of component, if known, and length of service, if known. Include itemized invoices with costs. Take photos or videotapes of deteriorated components for future reference and include descriptions. Include copies of product owner operation and service literature. Document any contractor service personnel.
6. Color borehole TV survey video records: Take at any zero point, before and after well rehabilitation measures, and at service intervals. Tapes and CDs may be consolidated as summary CDs of important well features over the years. Label records by well identification and date and store properly in an accessible location. Transfer to improved media as available.

The level of complexity and schedule can vary. At a minimum, for any valuable well under stress or one that is difficult to replace, routine hydrologic performance parameters, water quality, and biofouling indicators should be checked regularly (Table 2).

ADDITIONAL PM INSPECTIONS AND PRECAUTIONS

The capture zones and immediate surroundings of wells should be free of threats to the potable or monitored water quality. The area should be inspected periodically to ensure this condition. Well tops should be securely sealed to prevent contamination and secured against unauthorized entry. However, service access should not be impaired. In some wells, pumps may be pulled, inspected, cleaned, and repaired, as necessary, on a periodic or performance basis.

Table 1. Summary of Methods Relevant to Well Maintenance

Parameter	Indicator
Fe and Mn (total, Fe^{2+}/Fe^{3+}, Fe minerals, Mn^{4+}/Mn^{2+}, Mn minerals and complexes)—sometimes other metals such as Al	Indications of clogging potential, presence of biofouling, E_h shifts. Fe transformations are the most common among redox-sensitive metals in the environment. Mn is less common but locally important.
S (total, $S^{2-}/S^0/SO_4{}^{2-}$, S minerals, and complexes)	Indications of corrosion and clogging potential, presence of biofouling, E_h shifts.
E_h (redox potential):	Direct indication of probable metallic ion states, microbial activity. Usually bulk E_h, which is a composite of microenvironments.
pH	Indication of acidity/basicity and likelihood of corrosion and/or mineral encrustation. Combined with E_h to determine likely metallic mineral states present.
Conductivity	Indication of TDS content and a component of corrosivity assessment.
Major ions, hardness and alkalinity	Carbonate minerals, F, Ca, Mg, Si, Na, Cl determine the types of encrusting minerals that may be present and are used in saturation indexes. Alkalinity used in index and cleaning solution calculations.
Turbidity and particle counts	Indication of suspended particles content, suitable for assessment of relative changes indicating changes in particle pumping or biofouling.
Sand/silt content (v/v, w/v)	Indication of success of development/redevelopment, potential for abrasion and clogging.
Biofouling parameters	Select appropriate methods to permit a complete but convenient assessment of biofouling mechanisms present.
Step-drawdown and specific capacity (Q/s) testing	Flow and drawdown testing conducted periodically. Step tests to calibrate and before and after service events. Q/s testing periodically.
Power and pump performance parameters	Volts, amps, ohms in electrical power both instantaneous and trends, megohm ground leakage, vibration analysis, pressure at various Q to indicate wear.

Table 2. Recommended Data Collection Intervals (Depends on Site Conditions).[a] The Following is for a Difficult Well Situation (Valuable Well) After Its First Year

Type of Inspection	Method	Interval
Physical inspection	Borehole color video	At pump service intervals. Concentrate on screen and other stress points.
	Surface facility inspection	Quarterly
	Examination of pulled components	As needed. Wells should be equipped for easy pulling if at all possible.
Hydraulic performance	Well discharge (flow rate and pressure)	Weekly
	Drawdown	Weekly
	Conduct graphical analysis	Quarterly.
	Specific capacity test (well hydraulic performance).	Annually or at recommended shorter intervals.
	Pump performance: Conduct 5-step "pump" test, compare to "nominal" data	At least annually or at recommended shorter intervals if pump service is severe (Q/s and pump test can be a single operation).
Electrical (power)	System and motor current and load factors	Weekly—recommend installation of current monitors with alarms.
Physicochemistry	Inorganic parameters	At least quarterly using on-site instruments (calibrated) or routine monitoring (laboratory).
	Suspended particulate matter (sand, silt, clay)	Manually at well testing then quarterly.
	Turbidity or particle counting (adds colloidal component)	In-line monitors (continuous).
Biofouling microbial component	BART (or similar) analyses: Wide suite of ecological indicators	Quarterly until patterns develops then drop all but target types.
	Biofilm flow cell for microscopy	Annually on selected wells.
Treatments and service	Well hydraulic improvement and pumping systems	As testing indicates Q/s drops below 90% or pumping system degrades.
	Instrumentation calibration	In accordance with standard protocols.

[a] After Reference 3.

PM TREATMENT

PM well treatments are those applied prophylactically to remove biofouling and clogging prior to impairment of performance, which is a relatively complex and site-specific practice. However, such treatments should be targeted to the clogging conditions, as mild as possible, and capable of being easily applied.

REVIEW AND UPDATE

Methods and experience in PM change and improve over time. Experience in specific well situations also provides the basis for refining practices. Well PM plans should include provision for periodic review and revision of the PM plan and its practices. Also important is a provision for training personnel in new methods and training new employees in PM practices and purpose.

The subject of well maintenance is too complex to consider adequately in a brief article. The following are references used in the preparation of this item and additional recommended sources of information.

MEGAWATERSHEDS

Robert A. Bisson
Alexandria, Virginia

The term "megawatershed" describes deep-seated subsurface aquifer systems that may consist of gravel, fracture-hosted bedrock, and/or sedimentary structures, which are integrated in terms of recharge, storage, transmissivity, and containment. They may not coincide with surface topographic divides and may receive recharge from parts of several surface watersheds including massive amounts of mountain block recharge. "Megawatershed" is a conceptual model, or paradigm, that describes this new class of groundwater domain (Fig. 1). Megawatersheds are formed over geologic time by a combination of factors, including tectonically induced brittle fracturing and displacement of rock facies and strata and solutioning of parent rock facies and regolith by chemically aggressive meteoric and hydrothermal waters. The history and nature of regional tectonic stress fields and principal bounding faults, interacting with lithology and climate, play a major role in determining the geometry and extent of megawatershed boundaries.

Megawatersheds often transcend surface topographic divides and may receive recharge from parts of several surface watersheds. Similarly, as a structurally contained water resource, wells drilled into multiple aquifers in a single megawatershed may produce water from potentially dissimilar lithologies with common hydraulics related to brittle fracturing and gravity-fed contributions from adjacent and overlying unconsolidated sediments. Megawatersheds often occupy diverse host environments exhibiting both primary (continuous) and secondary (fracture) porosities with flow systems delineated by fracture systems, faulted and/or weathered lithologic contacts, and igneous intrusions (e.g., dikes), overlying or adjoining weathered rock and overlying porous unconsolidated sediments. This model supersedes the traditional watershed and aquifer models, which describe topographically controlled, functionally two-dimensional drainages and incorrectly depict most deep groundwater resources as static, poorly recharged artifacts of surface flow, confined to local discrete bedrock or alluvial units.

The megawatershed concept operates effectively and has scientific validity and economic and management utility on a scale of 10s to 1000s of square kilometers. Studies have documented megawatershed environments in Africa, Asia, the Middle East, Europe, North America, South America, and the Caribbean.

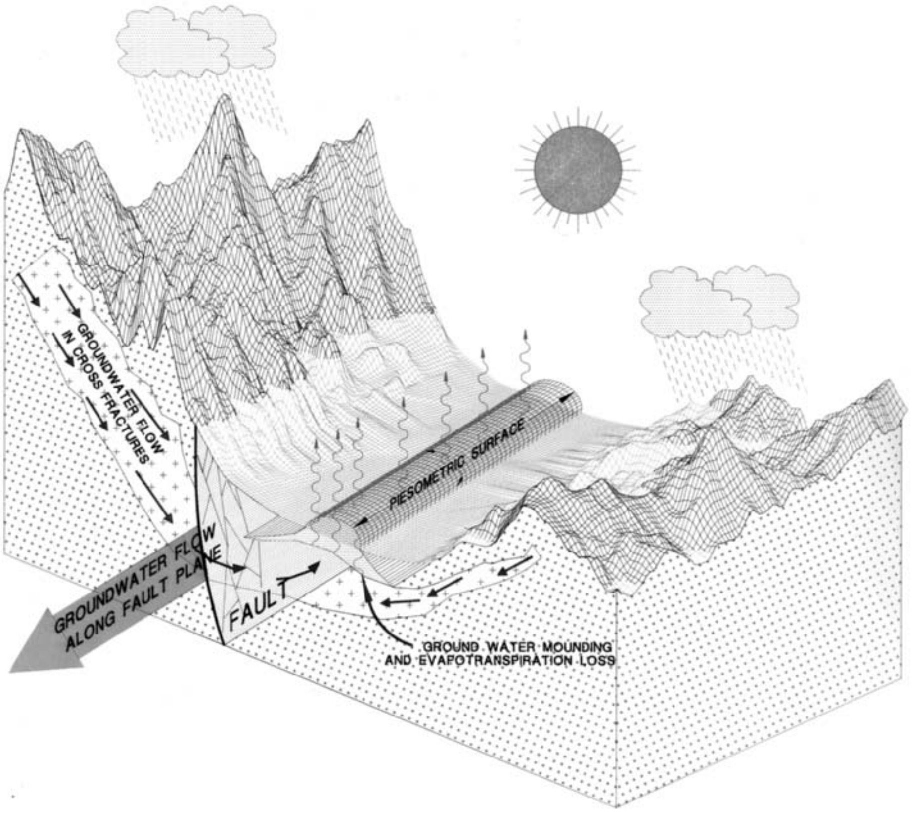

Figure 1. Megawatershed conceptual model indicating the roles of mountain block recharge and interbasin deep groundwater transfers within megawatersheds developed by Bisson Exploration Services Co. and CAD illustration by Summit Engineering, 1992.

HISTORY OF DISCOVERY

The space age has induced quantum leaps in geologic theory, and comparable advances in geophysical instrumentation and interpretive methods have permitted scientists to discover new information about the genesis, composition, and structure of the earth's crust and the internal dynamics of the many fluids, (e.g., magma, oil, water) contained within it. Equally important, the perfecting of computer-based geographic information systems (GIS) allowed skilled explorationists to combine and analyze many different types of data quickly and accurately, leading to major discoveries of oil, gas, minerals and, more recently, to breakthroughs in the understanding the nature and extent of groundwater resources, including the discovery of complex aquifer systems coined "megawatersheds" by the explorers who first documented the phenomenon, circa 1987, in the Great Rift systems of East Africa, where mountain block recharge from mountains and highlands in Ethiopia, Sudan, Kenya, and Chád remains largely untapped.

MEGAWATERSHEDS EXPLORATION PROGRAM

When the megawatershed paradigm is used as a groundwater exploration model, the result is greatly improved understanding of groundwater environments, permitting accurate, comprehensive assessments of "safe yield" from local, countrywide, or regional water resources. The megawatershed paradigm actually provides a template for measurement of all facets of the hydrologic cycle in reality-based natural hydrogeological catchments, including rainfall, evapotranspiration, surface and subsurface inflow and outflow interactions with surface water, shallow aquifers, deep fractured bedrock, and deep alluvial aquifers.

Modern explorationists employ current geologic theory, state-of-the-art exploration technologies, and interpretive methods adapted to the oil, gas, and mineral industries but rarely used in the groundwater field (Fig. 2). The "megawatersheds" paradigm of groundwater occurrence is the template the exploration program follows.

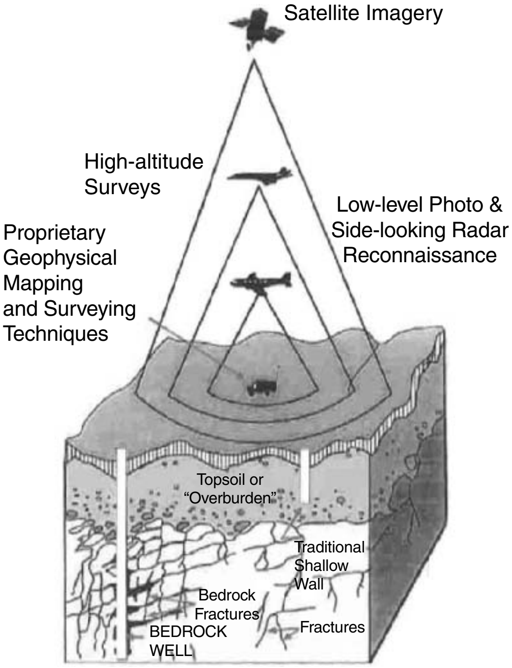

Figure 2. Illustration of megawatershed exploration program.

Case Studies

Two examples of megawatershed environments discovered using modern groundwater exploration methods are summarized here, one in the arid northwest region of Somaliland (1984–86) and the other in the humid small island developing state (SIDS) of Trinidad and Tobago, West Indies (1999–2002). These summaries are extracted from case studies included in Bisson and Lehr's book *Modern Groundwater Exploration: Discovering New Water Resources in Consolidated Rocks Using Innovative Hydrogeologic Concepts, Exploration, Drilling, Aquifer Testing and Management Methods*.

Somalia Case Study. In 1984, the Horn of Africa was experiencing a particularly brutal famine, brought about by the coincidence of periodic drought and regional and civil wars. America's ally, Somalia, was at war with the Soviet Union's ally, Ethiopia. At the same time, Somalia was mired in a bloody civil war, and the most active front for both conflicts was the remote, sparsely populated northwest part of Somalia, 1500 road-kilometers from the capital, Mogadishu, and bordered on the west and south sides by Ethiopia, to the north by the Gulf of Aden, and on the northwest, the last bastion of French colonialism in Africa, Djibouti. Several hundred thousand ethnic Somali refugees had been forced from their ancient tribal lands (annexed to Ethiopia after WWII) in the ongoing war and sought refuge in the arid Woqooyi Galbeed and Tog Dheer provinces of Somalia (Fig. 3). As a result of these circumstances, the socioeconomic fabric of the region was destabilized, cholera and other diseases were rampant in refugee camps located on the outskirts of major urban centers, and virtually no food was being produced locally.

Somalia's new patron, the United States, was working with the UNHCR and USAID to help feed and shelter those desperate people in an arid, undeveloped part of the Horn of Africa with all possible speed. Prior efforts to develop useful quantities of fresh groundwater in water-short areas had failed, and USAID's NGO contractors (New Transcentury Foundation) brought in a firm that pioneered modern groundwater exploration methods and discovered the megawatersheds phenomenon (BCI Geonetics, Inc.) to identify the groundwater resource base of the 35,000 km^2 region and develop emergency water sources for refugee camps and long-term water supplies for new refugee "cities."

Previous water development studies of northwest Somalia by other investigators focused on very limited surface and surficial water sources, but the BCI team focused on the region's bedrock groundwater potential, considering groundwater recharge and storage in unconsolidated overburden only in areas where they represented integral

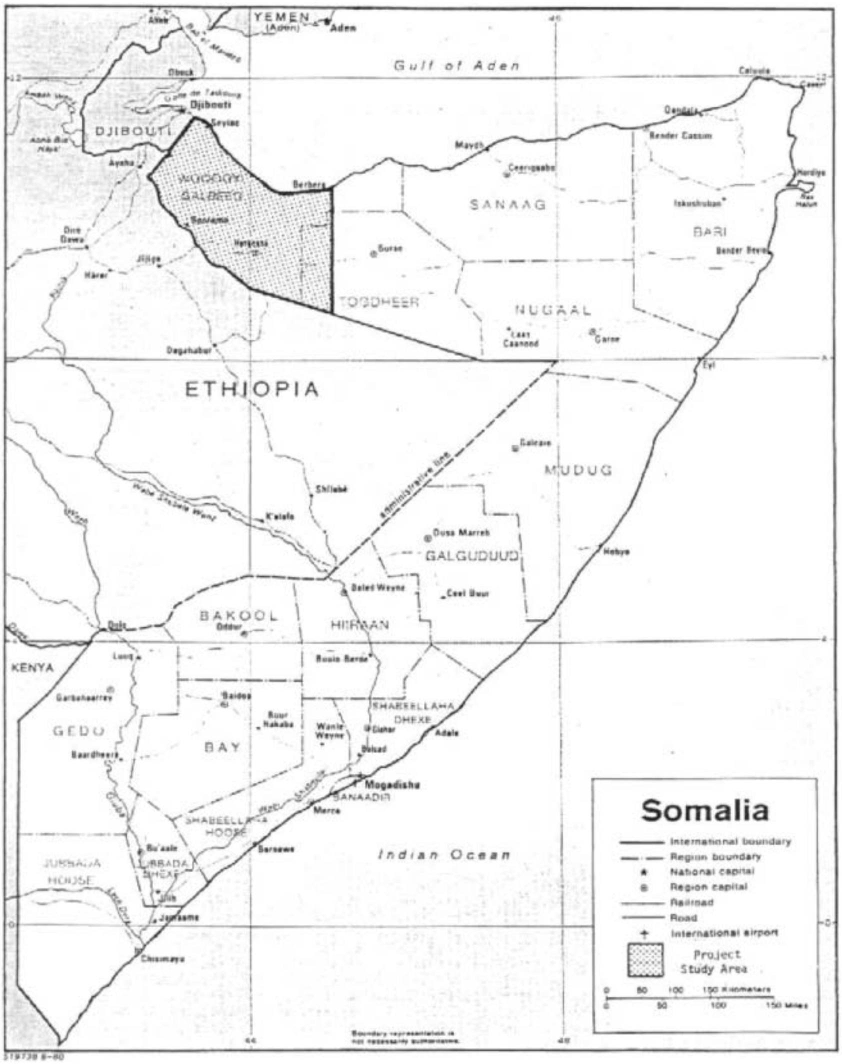

Figure 3. Somalia case study area.

hydrologic parts of deeper, underlying bedrock aquifer systems (megawatersheds).

To carry out their hydrogeologic mapping mission, the field team found only a few contemporary cultural and land-use maps and so augmented older maps with a combination of 1950s-vintage 1:125,000 scale British Ordinance Survey "spot-elevation" maps and RAF aerial photographs, plus 1980s- Tactical Pilotage Charts (TPCs), LandSat Image-maps, and high-resolution Space-Shuttle-borne Large Format Camera (LFC) photographs. The aerial and LFC photos were very useful navigational tools in certain remote areas where there were no roads leading to key bedrock outcrops and to other sites identified by BCI scientists on aerial photographs and satellite images. Thorn-bearing plants and sharp rocks punctured tires and automobile anatomies with great regularity, so undercarriage-armored Land Cruisers imported via neighboring Djibouti were outfitted with 12-ply tires for team expeditions.

The team was tasked to explore the farthest reaches of the county's lawless northwest region, and they often penetrated trackless areas where no vehicle or camel track existed and crossed unmarked borders between Ethiopia and Somalia. They were in constant danger of being captured by Ethiopian troops, strafed by MIGS during daylight, and held up at unmarked roadblocks by Somali bandits, revolutionaries, and government soldiers at night.

The region's wilderness also abounded with nonhuman predators, from hyenas to cobras, poisonous centipedes, and the nightmarish platter-sized, venomous "camel spider." The megawatersheds exploration team in Somalia encountered the most dangerous and difficult field conditions they had experienced to date, including a confrontation with Somali soldiers near the Ethiopian border that very nearly cost the lives of the team's senior scientists. BCI conducted this investigation using an advanced mineral-cum-groundwater exploration method, developed through extensive trial-and-error field-testing in the decade prior to the Somalia project. This systematic, practical approach to quantifying targeted minerals was singularly successful at identifying, drilling, and developing sustainable groundwater sources for nearby consumers in the most economical way.

The premise of the team's modern groundwater exploration program was that groundwater shares and is controlled by the same geologic environments as minerals and is most readily identified and evaluated using modern approaches proven successful in oil, gas, and economical mineral exploration. The successful application of a sophisticated groundwater exploration program required a practiced exploration team of experts in structural geology, remote sensing, surficial geology, exploration geophysics, geochemistry, hydrology, and hydrogeology. Only with an integrated team such as this could the full groundwater potential of the study area be determined.

This was a pioneering, remote-sensing project incorporating LandSat MSS imagery and high-resolution contact prints from the ITEC-built Large Format Camera (LFC), carried aboard NASA's Space Shuttle Challenger in October 1984. NASA supplied stereo-paired photographs of the extreme westernmost part of the study area, and the BCI team used the extraordinary 60,000 square kilometer "footprint", 5-meter resolution, and high planimetric accuracy of enlarged LFC prints both as "ground truth" for BCI's geological interpretations of LandSat MSS image maps and also as road maps, navigating for 2 years through thousands of square kilometers of poorly mapped, highly dangerous terrain in Somalia. The team also integrated specially processed satellite MSS image-data and British Ordinance aerial photographs into its map database for field exploration.

The exploration team's satellite image and aerial photographic analysts first studied the geological history and structural environment of the study area and then focused on identifying true surface expressions of underlying geologic structures consistent with the known tectonic fabric of the region. This work produced accurate working maps of fracture and fault systems on a scale common with other working map products. In the final phase of this part of the analysis, correlations were made between these newly (remote-sensing) interpreted "structural lineaments" and team-constructed tectonic and hydrogeologic models, verified by published geologic maps and field mapping.

In the evaluation and selection process that led to the delineation of favorable zones for further hydrologic analysis and fieldwork, the significance attached to structural lineaments increased with the strength of expression, overall length, and spatial correlation with mapped faults and fractures shown in the fault and brittle feature map—particularly those faults belonging to one of the three major structural trends described in the full report.

An investigative hydrogeologic analytical methodology was established to quantify the amount of active recharge potentially percolating through the vadose zone and available for recharge to deeper alluvial aquifers and conductive fracture zones feeding regional groundwater flow systems in northwest Somalia. The methodology developed synoptically evaluated hydrometeorological data over the study area, including identification of the dominant variables and parameters affecting recharge. Variables evaluated included topography, elevation, slope, evapotranspiration, surface roughness and permeabilities (i.e., caliche layer occurrence), soil infiltration rates and depth, wadi bed characteristics (same as surface and soils), and wadi bed surface area. These variables were investigated using data from previous studies and in the literature, plus results from new fieldwork.

Several reporting stations had documented northwest Somalia's annual precipitation, and rainfall maps of northwest Somalia had previously been published, but meteorological stations were sparse, daily precipitation was not recorded, and the methodology and assumptions on which rainfall maps were based were uncertain. The BCI team therefore sought a means of working with existing data to make it more useful by establishing correlative relationships between documented precipitation and study area topography, thereby generating a rainfall map reflecting statistical correlations of average annual rainfall with elevation. A linear regression was done with rainfall as the dependent variable and elevation as the independent variable.

Wadi beds provide an efficient pathway to the water table and, therefore, a viable mode of recharge. No information on rates of recharge through wadi beds was found. Thus, fieldwork was carried out to estimate recharge through wadi beds. Infiltration rates of the wadi bed surfaces were tested in the field to determine just how quickly storm water would be absorbed. Surface areas of the wadi beds were measured to provide relationships between infiltration rates and volume of recharge.

The slope of the land surface affects the ratio between infiltration and surface runoff. The steeper the slope, the greater the percentage of surface runoff leading to flooding conditions in the wadi beds. Steep slopes also generally have thinner soil cover and exposed bedrock, which increases the chances of groundwater recharge from the infiltration that does take place.

In spite of the early termination of the BCI project due to civil war before large production wells were drilled, the project generated the first-ever strategic groundwater development map for the region, identifying the potential for tens of millions of gallons per day of renewable groundwater available from regional fractured bedrock aquifers (megawatersheds) and solved the water crisis for many refugees and indigenous people by supplying more than 1.5 million gallons per day of fresh, potable water from six test wells. Some of the bedrock test wells reportedly have continued to supply fresh water to Borama's citizens and others for the past 18 years.

Small Island Developing States—Trinidad and Tobago Case Studies. In 1999 and again in 2000, the Water and Sewerage Authority (WASA) of Trinidad and Tobago engaged a team of exploration scientists who utilized the megawatersheds model and modern groundwater exploration technologies in an attempt to gain independence from unreliable surface water sources and to avoid the further expense and environmental impacts of additional dams and desalination plants, especially in the highly sensitive rain forest and coral reefs of Tobago. All previous attempts to find large quantities of naturally recharged and sustainable fresh groundwater using traditional hydrogeologic models and groundwater development methods had failed.

In the quest to accomplish the most comprehensive and accurate groundwater assessment ever implemented anywhere, WASA's contractor implemented data searches on the broadest possible front and applied the most advanced digital, GIS database construction, management, and computer-visualization technologies available, collecting and digitizing diverse data never before pooled; performing analyses of regional tectonic models and satellite remote sensing; digitizing over 15,000 data points from oil and gas seismic lines; carrying out hundreds of line-kilometers of geophysical surveys; interpreting 1600 hundred logs from oil, gas, and water wells; and completing intensive on-ground geologic mapping in prospective megawatersheds.

The exploration team then employed a novel "multiple convergent datasets" method of data processing and integration to produce a working groundwater map of Tobago (Fig. 4) and a state-of-the-art digital hydrogeologic map of Trinidad (Fig. 5). The new maps identified several major new megawatersheds in Tobago and increased the known, sustainable groundwater reserves almost 40-fold, from less than 0.5 million imperial gallons per day (imgd) to 40 imgd.

Subsequent drilling and long-term pumping (>36 months in several cases) confirmed the megawatersheds models and actually developed nearly 5 imgd of new deep bedrock groundwater sources for Tobago for less than US$ 10 million in 1 year, producing an amount of new water equal to a proposed US$ 80 million dam, slated for 5 years of construction in Tobago's protected rainforest.

On the island of Trinidad, modern groundwater exploration methods were successfully employed to identify megawatersheds, bedrock and sedimentary aquifers, and aquifer systems that increased the amount of known, safely extractable groundwater more than 10-fold; the models were validated by test wells and 15.8 imgd of production well long-term pumping [>24 months in several cases to date (Sept.2004)]. Digital copies of the new island-wide maps were provided to WASA for multiagency use within all government ministries.

Trinidad and Tobago is the first country and also the first small island developing state (SIDS) to employ, the megawatersheds paradigm and modern groundwater exploration methods on a national scale, in a highly successful attempt to address short-term water shortages and long-term economic development issues. Within 3 years, Trinidad and Tobago's use of the megawatershed exploration approach resulted in groundwater discoveries in the twin-island state exceeding 300 million US gallons per day, causing a true paradigm shift in the country's vision of its fresh water resources from chronic dependence on unreliable surface water sources to drought- and contamination-resistant, deep, groundwater sources.

The benefits of the Trinidad and Tobago Water Authority's innovative water development program was evident during the 2001 and 2003 dry seasons on the island of Tobago, when surface supplies were severely curtailed and the megawatersheds wells became the primary source of reliable drinking water for the island's indigenous and tourist populations.

EXOHYDROLOGY—IMPLICATIONS OF THE MEGAWATERSHEDS PARADIGM ON MARS

In the 1980s, groundwater investigators hypothesized that the striking similarity of geomorphologies between terrestrial and Martian deserts suggests a comparable geotectonic and hydrometeorological genesis, possibly indicative of paleomegawatershed formations that might retain groundwater in deep bedrock fractures and/or provide bedrock pathways for modern, tectonically induced groundwater flows (see Bisson and El-Baz, 1988).

MASS TRANSPORT IN SATURATED MEDIA

Paul F. Hudak
University of North Texas
Denton, Texas

ADVECTION AND HYDRODYNAMIC DISPERSION

Most of the matter transported by groundwater is in dissolved form, which is referred to as solute. Principally, advection and hydrodynamic dispersion affect the movement of solutes in groundwater. Advection occurs when flowing groundwater carries along dissolved solutes. Hydrodynamic dispersion is the spreading of groundwater and its dissolved constituents by mechanical mixing and diffusion. Mechanical mixing is spreading caused by the aquifer matrix. Diffusion, which can take place in groundwater that is not flowing, is the movement of solutes from areas of high to low concentration. This latter process can be illustrated by placing a drop of dye in a beaker of stagnant water. The dye will spread even though the water is not flowing.

Longitudinal dispersion expresses mixing along flow paths. At the pore scale, mechanical causes of longitudinal dispersion include (1) fluid moving faster in the center of pores than along the edges, (2) some fluid traveling along longer pathways than other fluid, and (3) fluid in larger pores traveling faster than fluid in smaller pores (1).

Transverse dispersion occurs in all directions in a plane perpendicular to groundwater flow. However, studies of mass transport often report only the vertical and horizontal components of transverse dispersion. Bifurcating flow paths cause transverse dispersion (Fig. 1).

Beyond the pore scale, bodies of rock or sediment with different hydraulic conductivity may induce mechanical dispersion within an aquifer. For example, groundwater and dissolved solutes may diverge around a clay lense within a predominantly sandy aquifer. This process is called macrodispersion.

The magnitude of longitudinal dispersion exceeds that of transverse dispersion, as solutes spread more in the direction of groundwater flow than in any direction within a perpendicular plane. Coefficients of longitudinal (subscript L), transverse horizontal (subscript

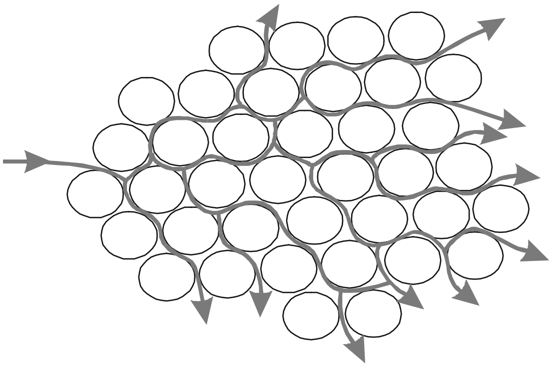

Figure 1. Pore-scale transverse dispersion in groundwater flowing between sand particles.

TH), and transverse vertical (subscript *TV*) hydrodynamic dispersion can be defined as follows:

$$D_L = \alpha_L v + D^* \quad (1)$$

$$D_{TH} = \alpha_{TH} v + D^* \quad (2)$$

$$D_{TV} = \alpha_{TV} v + D^* \quad (3)$$

where α is the dispersivity of the medium and D^* is the effective molecular diffusion coefficient. Dispersivity and the diffusion coefficient have units of length and length-squared/time, respectively. D^* ranges from 10^{-11} to 10^{-8} m^2/s for most ions in groundwater. Table 1 lists diffusion coefficients of several solutes in open water, which should be multiplied by a coefficient (less than one) to account for slower diffusion rates in tortuous, porous media. For unconsolidated media, this coefficient ranges from approximately 0.01 to 0.5 (3).

Dispersivity quantifies the ability of a medium to induce spreading by mechanical means. The magnitude of the mechanical mixing component of hydrodynamic dispersion (first term in Eqs. 1 to 3) usually exceeds molecular diffusion in flowing groundwater. Diffusion is a significant component of Eqs. 1 to 3 only for very slow-moving groundwater.

Dispersivity is a scale-dependent parameter, which attains higher values as the length of the transport domain increases. Laboratory estimates of dispersivity are routinely smaller than are field estimates. In a critical review of dispersivity observations from 59 different field sites, Gelhar et al. (4) found that, for data of high reliability, longitudinal dispersivity ranged from approximately 0.4 to 4 m. Transverse horizontal dispersivity was typically an order of magnitude less than longitudinal dispersivity, and transverse vertical dispersivity was an order of magnitude smaller than transverse horizontal dispersivity.

Table 1. Diffusion Coefficients in Water at 25 °C (2)

Solute	Coefficient (m^2/s)
Na^{+1}	1.33×10^{-9}
K^{+1}	1.96×10^{-9}
Mg^{+2}	7.05×10^{-10}
Ca^{+2}	7.93×10^{-10}
Fe^{+2}	7.19×10^{-10}
F^{-1}	1.46×10^{-9}
Cl^{-1}	2.03×10^{-9}
Br^{-1}	2.01×10^{-9}
$HCO_3{}^{-2}$	1.18×10^{-9}
$SO_4{}^{-2}$	1.07×10^{-9}
$CO_3{}^{-2}$	9.55×10^{-10}

Laboratory sand column experiments demonstrate the process of hydrodynamic dispersion. Distilled water runs through a column at a constant rate. The chloride concentration of the influent is suddenly changed from 0 to C_0 (any arbitrary concentration significantly higher than 0, for example, 1000 mg/L). Chloride concentrations, C, are monitored at the outlet, and the ratio C/C_0 is plotted against time (Fig. 2).

Early on, there are no chloride ions at the outlet; thus C and C/C_0 equal 0. Among the first group of chloride ions entering the tube, some arrive at the outlet ahead of others (because of hydrodynamic dispersion). As more chloride ions reach the outlet, C gradually increases to C_0. Had the solute been transported only by advection, the plotted curve would rise suddenly rather than gradually to C_0. The solute front "breaks through" the outlet when C/C_0 equals 0.5.

REACTIVE SOLUTES

Groundwater transports both chemically conservative and reactive solutes. Conservative solutes do not react with the aquifer medium or groundwater. Examples of conservative solutes are nitrate, chloride, and bromide. Reactive solutes have a tendency to sorb to aquifer media, moving from the liquid to solid phase, and they may go back into solution later on. Many synthetic organic chemicals are reactive, as are many cations. Negatively charged surfaces of clay particles are good sorbing media. If a solute is reactive, it will travel at a slower rate than the groundwater.

The velocity at which a reactive solute travels relative to flowing groundwater depends on both the solute and

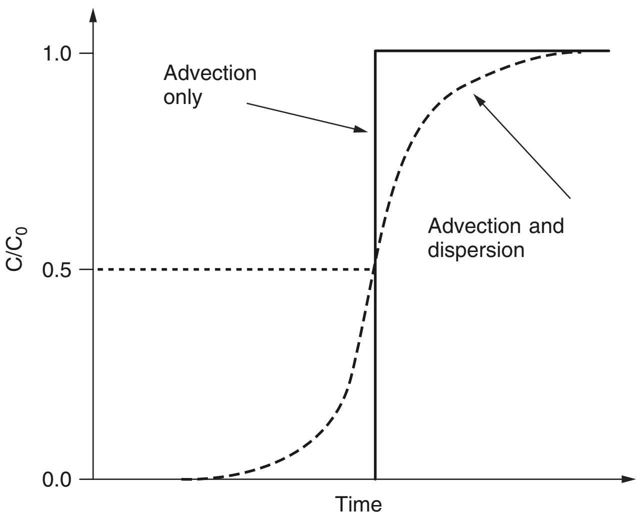

Figure 2. Solute breakthrough curve.

the aquifer material. A retardation factor, R_f, of 2 implies that the reactive solute travels at one half the velocity of groundwater, a factor of 5 implies one-fifth the velocity of groundwater, and so forth. Higher R_f values indicate slower solute transport.

Retardation factors should be carefully considered when delineating contaminant plumes. Multiple contaminants originating from the same source may occupy vastly different volumes in groundwater. Contaminants with higher retardation factors will occupy smaller volumes of aquifer. Conservative contaminants will have migrated further, and they best describe the maximum spatial impact of a leaking source. Chemical transformations and biodegradation, not quantified in R_f, also affect the spatial extent of a contaminant plume.

R_f can be computed as

$$R_f = 1 + \frac{\rho_b}{n} K_d \tag{4}$$

where K_d (commonly mL/g or L/kg) is the distribution coefficient for the solute with the aquifer. K_d can exceed 100 mL/g for reactive solutes and equals 0 for conservative solutes (5).

The distribution coefficient for a compound with a particular soil sample can be determined in a laboratory. An analyst fills jars containing soil with solutions of various contaminant concentrations. Several batches are created in this manner. The concentration of the contaminant in solution and the concentration in sediment are measured for each batch. These data are plotted on a curve (called an isotherm) fitted through the points (Fig. 3). The isotherm can take on different shapes. In the simplest case, it is linear, and K_d is the slope of the line (3). Thus, K_d has units of volume (of solution) per mass (of sediment). Langmuir (5) discusses methods for computing K_d for nonlinear isotherms.

SOIL AND WATER CONTAMINATION BY HEAVY METALS

Kristofor R. Brye
Kenneth F. Steele
University of Arkansas
Fayetteville, Arkansas

Soil and water contamination by heavy metals has a major adverse environmental impact. Concern has long existed over the threat of contamination of soil and water resources by heavy metals but has heightened in recent years as more knowledge has been gained about the negative and potentially serious affects that chronic exposure to heavy metals may have on the health of humans and other living organisms. Long-term exposure to lead affects human cognition; cadmium affects kidney, liver, and gastrointestinal tract functioning; and arsenic affects the skin, kidneys, and central nervous system (1). This article will address terminology, sources, mobility, risk assessment, and management and remediation alternatives for heavy metals in the environment that may contaminate soil and water resources.

TERMINOLOGY

Heavy metal is a term used to describe a subset of a large number of metals and metalloids, listed in the periodic table of the elements, which have properties of both metals and nonmetals. In general, heavy metals are elements in which the differentiating electrons are bonding electrons and typically include the top row of transition elements in the periodic table [i.e., scandium (Sc), titanium (Ti), vanadium (V), chromium (Cr), manganese (Mn), iron (Fe), cobalt (Co), nickel (Ni), copper (Cu), zinc (Zn), cadmium (Cd), and mercury (Hg)]. Arsenic (As), selenium (Se), and lead (Pb) may have electrons in outer shells (i.e., d electrons), as the differentiating electrons depending on the charge on the ion and thus are usually considered heavy metals. Heavy metals, except Fe, are also often referred to as trace metals due to their relatively small abundance in the environment.

SOURCES OF HEAVY METALS IN THE ENVIRONMENT

There are a wide variety of natural and anthropogenic sources of heavy metals in the environment that may impact or contaminate soil, surface water, and groundwater resources. Some heavy metals occur naturally in relatively small quantities as constituents of igneous and sedimentary rocks. For example, Fe composes 8.6% of basalt and only 0.38% of limestone. Titanium and Mn are also present in rocks in relatively high concentrations (0.1—1.0% range). The remainder of the heavy metals is present in rocks as trace elements ranging in concentration from 0.05–130 mg kg^{-1} (0.05 to 130 ppm) and typically are present in the 10–100 mg kg^{-1} range. Generally, heavy metals are present in higher concentrations in mafic rocks, such as basalt, and in shale. Mafic refers to igneous rocks that are largely composed of silicate minerals rich in Fe and Mg (ferromagnesium minerals), such as olivine, pyroxene, amphibole, and biotite. Physical and chemical weathering of heavy-metal-containing rocks release heavy metals into the environment. Some heavy metals contained in secondary minerals become part of the silt or clay fractions of soil; other forms of heavy metals may be retained in soil by complexing with soil clays and organic matter.

The former Kesterson Wildlife Refuge is a prime example of how naturally occurring heavy metals can adversely impact the surrounding environment. Selenium occurs naturally in the bedrock and soils of the San Joaquin Valley of central California where the former Kesterson Wildlife Refuge was located. Centuries of bedrock and soil weathering caused increased concentrations of Se in the local groundwater, which was used to irrigate crops in the region. Until 1978, much of the water flowing into the marsh was fresh water. However, the regional hydrology had changed such that by 1981 much of the influent water was from subsurface agricultural drainage water that had elevated concentrations of Se (2). The Se-contaminated marsh water was consumed and Se bioaccumulated in birds and other wildlife causing embryonic mortalities and severe deformities in aquatic birds (3) and the disappearance of most fish species (4). The marsh was ultimately drained in the mid-1980s and capped with noncontaminated soil to mitigate further loss of wildlife. Numerous additional examples exist within the United States and throughout the world of contamination and adverse environmental impacts from naturally occurring heavy metals. Some additional examples are Lake Ontario from Pb and Zn, Lake Cayuga in central New York from Cd, Co, Cu, Pb, and Zn; and Fränkische Saale in Germany from various heavy metals (5). Other natural mechanisms of heavy metal introduction into and transport within the environment include volcanic eruptions and windblown dust. The rate of human-induced heavy metal introduction into the environment has increased exponentially since the Industrial Revolution of the late 1800s.

Anthropogenic sources of heavy metals in the environment generally include atmospheric emissions, land-surface application of various heavy-metal-containing materials, and seepage from damaged or compromised containment structures. Particulate-bound heavy metals are emitted to the atmosphere during various high-temperature processes, such as fossil fuel burning for electric power, smelting of nonferrous ores, melting of ferrous ores, refuse incineration, and kiln operations (6). Due to its volatility, Hg can also be emitted in to the air as a gas and distributed over large areas. This type of transport mechanism is often cited as the source of Hg for methyl mercury contamination of aquatic ecosystems. Atmospheric emissions can be transported long distances and ultimately are deposited and accumulate on the land surface or in surface waters as dry dust particles or as part of precipitation. Heavy-metal-containing residual materials left over from high-temperature industrial processes, such as ashes, and other activities, such as municipal wastewater treatment, are also anthropogenic sources due to their disposal in and discharge to the environment.

A common practice of disposing of some types of industrial by-products is spreading them on the land surface or discharging them to surface waters. These are accepted practices as long as the heavy-metal content does not exceed regulated standards. According to the United States Environmental Protection Agency's Risk Reduction Engineering Laboratory Treatability Database (7,8), industrial sources, such as fabricated metal products except machinery and transportation equipment, chemical and allied products, and electronic and electric equipment, commonly discharge wastewaters containing Cd, Cr, Cu, Ni, and Zn in the range of 10–100 mg L^{-1}. Lead and Hg are also commonly detectable in industrial discharges. Similarly, municipal sewage sludge is often land applied as an organic amendment and fertilizer for agricultural purposes. In 1997, sewage sludge from publicly owned wastewater treatment facilities in Pennsylvania that was disposed of by land spreading contained between 5 and 800 mg kg^{-1} of As, Cd, Cr, Cu Pb, Hg, Ni, Se, and Zn (9). However, the same study also demonstrated that the concentrations of Cd, Cr, Cu, Pb, Ni, and Zn in Pennsylvania sewage sludge decreased significantly between 1978 and 1997 (9).

Aside from industrial sources and sewage sludge, another significant mode for introducing heavy metals into the environment is agriculturally related sources, including fertilizers, liming materials, animal wastes, and pesticides. Heavy metals and other trace metals are important to agriculture because of their essential roles in plant and animal nutrition. Inorganic fertilizers and liming materials are rarely pure substances and often contain other additives, fillers, or impurities that may consist of heavy-metal constituents. For example, some phosphate fertilizers contain Cd and Zn (10). Similarly, heavy metals are often contained in animal wastes (manures and litters) from confined animal feeding operations, such as for dairy, swine, and poultry, due to the use of heavy-metal-containing compounds in feed additives for growth enhancement or disease suppression. Even more so than in industrial by-products or sewage sludge, animal wastes are typically land applied as an organic amendment for agronomic benefit, thus introducing any heavy metals contained in the animal wastes into the environment. For example, poultry litter typically contains notable amounts of heavy metals. On average and depending on production and management practices, poultry litter can contain between 20 and 40 $mg\,kg^{-1}$ of As, Cd, and Pb and between 370 and 660 $mg\,kg^{-1}$ of Cu, Fe, Mn, Se, and Zn (11). Poultry litter in Alabama has also been found to contain relatively high levels of Co, Ti, and V (12). Numerous pesticides used in agronomic crops also contain heavy metals, such as As, Cu, Pb, Hg, and Zn (10).

Landfill leachate is an additional significant source of concentrated heavy metals in the environment. The wide variety of domestic refuse, especially household and unregulated small generator inputs, disposed of in landfills contain and, within the appropriate chemical conditions, may release soluble metal ions (13,14). For example, Cd, Ni, Pb, and Zn can be released from batteries; Cd and Cr can be released from paint residues; and As and Hg can be released from pesticide residues (15). These potentially toxic metals comprise the solutes of leachates produced as water percolates through landfills and discharges eventually into the surrounding soil or groundwater. Landfill leachate also contains a variety of organic compounds that may interact with toxic metal ions and, hence, influence their mobility (13).

HEAVY METAL MOBILITY

The mobility of heavy metals in the environment largely depends on the degree to which the metal is soluble. In turn, heavy metal solubility is governed by the chemical characteristics of the media in which the metal exists and the chemical nature of the metal itself.

Some heavy metals can exist in multiple valence states and in multiple forms or species in soil, such as free ions or complexes. For example, As can exist as the trivalent (As^{3+}) or pentavalent (As^{5+}) ion, Cr can exist as the trivalent (Cr^{3+}) or the hexavalent (Cr^{6+}) ion, and Fe can exist as the divalent (Fe^{2+}) or trivalent (Fe^{3+}) ion. For these metals, speciation is affected by the oxidation–reduction (redox) potential of the surrounding media. The redox potential determines the direction of a redox reaction; this is a reaction in which the complete transfer of electrons from one species to another occurs (16). Depending on the redox potential, certain metal species may be soluble or insoluble, thus affecting their mobility. For example, Fe in the oxidized state (Fe^{3+}) is relatively insoluble and typically exists as an oxide precipitant on surfaces of aggregates in soil, but Fe in the reduced state (Fe^{2+}) is highly soluble and is easily removed as water percolates through the soil. Table 1 lists the dominant chemical species in soil and water and the most toxic species of selected heavy metals.

The mobility of heavy metals in soil is affected by retention and release reactions, which include precipitation–dissolution, ion exchange, and adsorption–desorption reactions (17). Retention and release reactions in turn are affected by numerous soil properties, including pH, organic matter, bulk density, and texture (18).

Precipitation–dissolution reactions are governed by the concentrations of the reactants or solutes and the chemical characteristics of the solvent. Under the proper chemical conditions, some heavy metals may react with other solutes to form precipitates. The reverse reaction is dissolution of a fraction or all of the solid into its ionic components.

Table 1. Dominant Chemical Species in Soil and Water and Most toxic Species for Selected Heavy Metals. Adapted from Table 3 (23)

	Dominant Chemical Species		
Metal	Soil	Water	Most Toxic Species
As	$AsO_4{}^{3-}$	$AsO_4{}^{3-}$, $AsO_3{}^{3-}$	$AsO_4{}^{3-}$
Cd	Cd^{2+}	Cd^{2+}	Cd^{2+}
Co	Co^{2+}	Co^{2+}	Co^{2+}
Cr	Cr^{3+}	Cr^{3+}, Cr^{6+}	Cr^{6+}
Cu	Cu^{2+}	Cu^{2+}-fulvate	Cu^{2+}
Hg	Hg^{2+}, CH_3Hg	$Hg(OH)_2{}^0$, $HgCl_2{}^0$	CH_3Hg
Mn	Mn^{2+}, Mn^{4+}	Mn^{2+}	Mn^{2+}
Ni	Ni^{2+}	Ni^{2+}	Ni^{2+}
Pb	Pb^{2+}	$Pb(OH)^+$	Pb^{2+}
Se	$HSeO_4{}^{3-}$, $SeO_4{}^{2-}$	$SeO_4{}^{2-}$	$SeO_4{}^{2-}$
Zn	Zn^{2+}	Zn^{2+}	Zn^{2+}

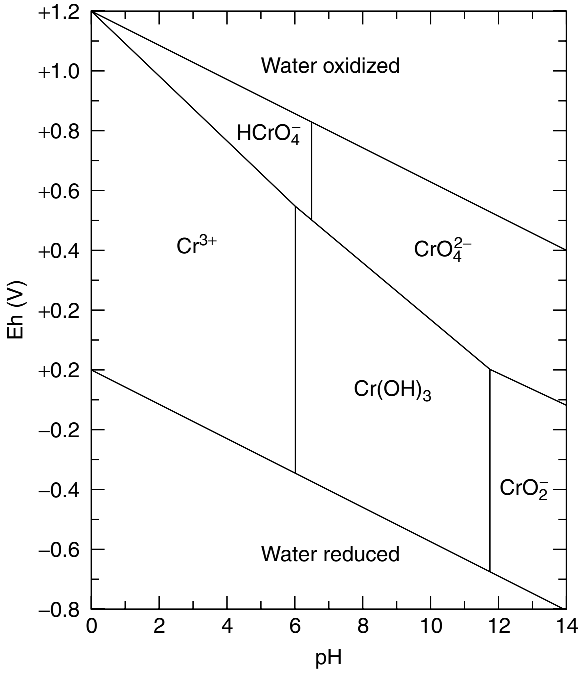

Figure 1. Eh-pH diagram for chromium (Cr) at an activity level of 10^{-6}.

Two of the most important chemical characteristics that influence precipitation–dissolution reactions and general metal speciation are pH and redox potential. The effects of pH and redox potential can best be illustrated using an Eh–pH diagram, where Eh is the reduction/oxidation potential in volts for a redox-influenced heavy metal, for example, Cr (Fig. 1). Depending on the redox conditions and pH, Cr can exist in one of five different forms, ranging from the reduced free ion (Cr^{3+}) at a $pH<6$ and Eh potential between ~ -0.3 and $+1.2$ volts to the chromate ion at a $pH>\sim 6.5$ and Eh potential between ~ -0.12 and

+0.84 volts, where Cr exists as the oxidized (Cr^{6+}) species bound with four oxygen atoms. As the Eh–pH diagram depicts for Cr activity of 10^{-6}, the pH and Eh must be high for Cr to be mobile in natural waters, where the typical pH range is 5.5 to 8.5 and the typical Eh range is 0.1 to 0.45 V (19). pH and Eh affect metal speciation and solubility, so pH and Eh also influence the ability of ionic metals to interact with the surfaces of soil particles.

Due to the presence of many clay particles that have negatively charged surfaces, most soils have some cation exchange capacity (CEC) in which cationic heavy metal species can interact by electrostatic attraction with the surface of these negatively charged clay particles. However, the type of clay minerals present is also important. For example, kaolinite, a 1:1 clay mineral, has a relatively low CEC, typically in the range of 2–5 cmol charge kg^{-1} (20). However, 2:1 clay minerals, such as those in the smectite group (e.g., montmorillonite and vermiculite), have a relatively large CEC typically in the range of 80–180 cmol charge kg^{-1} (20). Humus (organic matter) also has a relatively large CEC, typically in the range of 100–550 cmol charge kg^{-1} (20). The process of ion exchange retains metals in their ionic form in soil and reduces their mobility until the soil–solution concentration of a different cation that has a stronger affinity for the binding site increases enough to replace the cationic metal on the clay surface.

In contrast to ion exchange, adsorption is the process whereby an ionic metal species binds to the surface of a soil particle to form a complex. The degree of adsorption of a metal species depends greatly on the chemical nature of the metal species itself, but also can typically be enhanced by clay and organic matter. Organic matter sometimes acts as a chelating agent. Chelation is the binding of organic chemicals that have multiple functional groups with metals to form ring structures; the end products are organometallic complexes (20).

Many metals form inorganic and organic complexes in soil. Depending on how the metal speciates, some metal complexes, such as complexes containing As^{3+} and As^{5+}, are highly soluble in water (21). Consequently, certain metal species like inorganic As (10), organic complexes of Pb, Zn, and Cr, and oxygen complexes of Cr and Se (22) are considered relatively mobile in soil and pose a health threat when introduced into the environment.

Once in solution, either as free ions or soluble complexes, heavy metals move by mechanisms similar to those of other solutes in the soil or groundwater systems. Diffusion and advection (also called convection) are the two most common mechanisms of solute transport in soil and groundwater. Diffusion is the process by which metals move in response to a concentration gradient; therefore, diffusion occurs relatively slowly. In contrast, advection or mass flow is the process by which metal movement occurs as a result of bulk fluid (i.e., water) movement and typically occurs at a rate much faster than that of diffusion. Some heavy metals may move in the environment via air transport of metal-bound dust particles. Heavy metals may also be transported in the environment in plant tissue after root absorption and translocation to aboveground biomass.

RISK ASSESSMENT

All heavy metals are toxic to some degree when absorbed in excess of an organism's assimilative capacity (23). Once absorbed by plants, animals, or other living organisms, heavy metals can "bioaccumulate" and persist in the organism's system without dissipation. One of the most common pathways of human exposure to heavy metals is by ingestion of either contaminated drinking water or plant or animal tissue. Human exposure to heavy metals can cause a variety of adverse health effects, so acceptable limits have been set for assessing potential human health risks from exposure to heavy metals.

Maximum contaminant limits (MCLs) are standards used to define excessive exposure to metals in drinking water. An MCL is calculated to allow consuming 2 L of water per day that has a concentration up to the MCL for a period of 70 years without increasing the human risk of acquiring cancer to more than 1 in 100,000 people. In addition, the United States Environmental Protection Agency uses oral reference doses for noncarcinogenic and risk-specific doses for carcinogenic metals (24). Table 2 lists the MCLs, potential health risks to humans, common sources of drinking water contamination, and general mammalian toxicity for selected heavy metals.

MANAGEMENT AND REMEDIATION ALTERNATIVES

Prevention of environmental heavy-metal contamination is crucial because the cleanup of contaminated natural resources is difficult, time-consuming, and extremely expensive. Remediation strategies for heavy-metal contaminated soil may be employed *in situ*, where the contaminated material remains in place on-site, or *ex situ*, where the contaminated material is removed and treated off-site. Typically, the first step in the cleanup of contaminated soil is containment, which is only a temporary measure. Traditional *in situ* treatments include high temperature to produce a nonleachable material or the addition of solidifying agents to produce a cement-like material (1). More recent "advancements" in *in situ* remediation of heavy-metal-contaminated soil have included bioremediation and phytoremediation. *Ex situ* treatments most often include excavation followed by landfilling, incineration, repeated washing, incorporation into asphalt mixes, or land farming, a process by which contaminated soil is spread out and actively managed with fertilizers or plants so that degradation processes occur naturally (25).

Remediation of contaminated waters is more difficult than that for contaminated soil partly because the number of potential remediation strategies for contaminated waters is more limited. Removal of contaminated sediments from aquatic ecosystems is difficult. Dredging of contaminated sediments often exacerbates the problem by mixing the sediment with the water. A common remedial activity for groundwater is to pump contaminated water out of the saturated zone followed by treatment and disposal or reinjection into the aquifer (25). Although groundwater can be pumped out and treated, once an aquifer is contaminated, any subsequent flush of water into or through the aquifer will cause the release of more

Table 2. Limits and Potential Health Risks Associated with Selected Heavy Metals (26)

Metal	MCL[a] (mg L^{-1})	MCLG[b] (mg L^{-1})	Potential Health Effects from Exposure Above the MCL	Common Sources of Metal in Drinking Water	Mammalian Toxicity[c]
As	0.01[d]	none	Skin damage, problems with circulatory system, increased risk of contracting cancer	Erosion of natural deposits, runoff from orchards and glass and electronics-production wastes	H
Cd	0.005	0.005	Kidney damage	Corrosion of galvanized pipes, erosion of natural deposits, discharge from metal refineries, runoff from waste batteries and paints	H
Cr	0.1[e]	0.1[e]	Allergic dermatitis	Discharge from steel and pulp mills, erosion of natural deposits	H (Cr^{6+}) M (Cr^{3+})
Cu	1.3[f]	1.3	Gastrointestinal distress, liver or kidney damage	Corrosion of household plumbing systems, erosion of natural deposits	M
Hg	0.002	0.002	Kidney damage	Erosion of natural deposits, discharge from refineries and factories, runoff from landfills and croplands	H
Pb	0.015[f]	0	Delays in physical or mental development, deficits in attention span and learning abaility, kidney problems, high blood pressure	Corrosion of household plumbing systems, erosion of natural deposits	H
Se	0.05	0.05	Hair or fingernail loss, numbness in fingers or toes, circulatory problems,	Discharge from petroleum refineries, erosion of natural deposits, discharge from mines	H

[a] Maximum contaminant level (MCL) is the highest level of a contaminant that is allowed in drinking water and is an enforceable standard.

[b] Maximum contaminant level goal (MCLG) is the level of a contaminant in drinking water below which there are no known or expected health risks. MCLGs are non-enforceable public health goals.

[c] Letters represent the toxicity risk as moderate (M) or high (H); taken from table 9.1 (27).

[d] Effective as of January 23, 2006.

[e] MCL and MCLG are for total Cr.

[f] MCLs for Cu and Pb represent action levels and are based on a treatment technique to control the corrosiveness of the water.

contaminant into solution. Therefore, complete cleanup of groundwater aquifers requires a very long time.

Once the contaminated soil is remediated, several management practices may be used to help immobilize heavy metals in the soil and minimize the potential for transport and adverse environmental effects (1). The soil pH can be adjusted to 6.5 or higher, which will decrease the availability and potential mobility of cationic heavy metals. However, raising the soil pH will generally increase the availability and mobility of anionic heavy-metal complexes (1). Improving soil aeration by draining the soil will sometimes allow heavy metals to oxidize, making most heavy metals less available, except for those that form oxygen complexes (e.g., Cr) and sulfides (e.g., Hg). However, for Cr to exist as $CrO_4{}^{2-}$, requires a dissolved oxygen concentration above that which occurs naturally. Dredging often moves metal sulfides into oxidizing environments where the sulfide can potentially oxidize to sulfate, resulting in release of the metal. The addition of phosphate to a contaminated soil will help reduce the availability of cationic heavy metals due to the high binding affinity of the anionic phosphate ion for cations, but the addition of phosphate would increase the availability of anionic contaminants like As.

The use of plants to extract heavy metals from contaminated soil and water (phytoremediation) is also a very useful and cost-effective remediation strategy. There are three general mechanisms by which plants are used to stabilize or remove metals and other contaminants from soil and water. Phytoextraction is the process of cultivating plants called hyperaccumulators in metal-contaminated soil that have root systems that can absorb and translocate relatively large quantities of metals to their aboveground biomasses. After the plants have been allowed to grow for some time, the plants are harvested and incinerated or composted. There are approximately 400 hyperaccumulating plant species, but determining the appropriate species or group of plants to use depends on the heavy metal contaminant at a site (1). Rhizofiltration is used to remediate contaminated surface waters, whereby plants are initially grown hydroponically in a greenhouse using water from the contaminated site, and are then transplanted at the site. After enough time has elapsed to allow the roots to become saturated with the contaminant by a combination of adsorption and absorption, the plants, including the roots, are harvested and typically incinerated (1). Phytostabilization is a remediation process in which perennial, nonharvested, metal-tolerant plants are used to immobilize soil and water contaminants into roots and aboveground biomass by adsorption, absorption, or precipitation in the rhizosphere and reduce the mobility and bioavailability of some metals (1).

SUMMARY

Soil and water contamination by heavy metals impacts the environment negatively. Scandium, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Hg, as well as As, Se, and Pb, are generally considered heavy metals. There are numerous natural and anthropogenic sources of heavy metals in

the environment. Soil and groundwater properties, such as pH and redox potential, and the characteristics of a particular metal itself affect heavy-metal mobility in the environment. Once in the environment, excessive exposure to heavy metals poses a health risk to any living organism. A wider variety of strategies that can be used to remediate heavy-metal-contaminated soil exists than for remediating contaminated groundwater.

SOURCE, MOBILITY, AND REMEDIATION OF METALS

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

It is estimated that over 60% of CERCLA sites in the United States have contamination because of metals. Similarly, RCRA, general industrial, DOD, and DOE facilities also have problems with metals, which, in conjunction with a paucity of innovative approaches to deal with metal problems, means that metal contamination represents a serious environmental concern and a significant market opportunity for environmental service companies.

Metals (or other inorganics) typically become groundwater problems under the following situations:

- Activities associated with plating shops, where a wide variety of metals are present at high concentrations in forms that are soluble.
- Sites with releases of radionucleides that, because of unique health risks, can have significant impact at very low concentrations. In addition, the use of chelating and complexing agents that make these contaminants mobile in the environment is common during processing of these materials.

Metals and high levels of inorganic Total Dissolved Solids (TDS) are associated with leaks from sanitary, solid waste, and hazardous waste landfills.

High TDS impacts are also associated with salt storage areas and petroleum production activities.

Innovation in the area of hydrocarbon remediation has been significant in the last decade. However, metals may only be mobilized or immobilized, unlike hydrocarbons they cannot be degraded to less innocuous components, such as CO_2 and H_2O, for example. This limited reactivity is one of the reasons that innovative remediation technology has been slow to develop for soils or groundwater contaminated with metals, which will likely change with time, however.

Often particulate metal contamination is confined to the upper few feet of soil beneath a contaminated area. However, instances exist where metal contamination has impacted groundwater. The purpose of this article is to discuss the physical/chemical behavior of metals with a particular focus on conditions that make metals mobile and thus able to impact groundwater. Also evaluated will be remediation alternatives to metal contaminated groundwater.

The important issue with regard to metals is mobility. Specifically, under what conditions are metals mobile and under what conditions are metals immobile? Metals in the environment can take four fundamental forms: (a) raw metallic elements, (b) hydrated ionic salts, (c) covalently bonded molecules termed inorganic complexes, (d) associated with a chelating agent. Elemental metals are generally not highly soluble under normal groundwater conditions. However, naturally occurring elemental metals may cause soil samples to be deemed hazardous using a Toxic Characteristic Leaching Procedure (TCLP) test and guidelines set forth in 40 CFR 261.4. The TCLP test uses strong acids during the laboratory leaching procedure. The TCLP is an EPA SW-846 analytical method (Method 1311) that simulates sanitary landfill contaminant leaching of waste materials, which could include mobilizing naturally occurring metals in the soil sample.

The mobility of metals as hydrated ionic salts is dependent on which metallic element is participating as the positively charged ion (termed the cation) and which anion makes up the negatively charged component of the salt.

Following is a brief summary of cationic/anionic solubility relationships:

- Sodium (Na^+), Potassium (K^+), and Ammonium ($NH_4{}^+$) are cations that form salts that are all soluble.
- All metal salts of the Nitrate ($NO_3{}^-$), Nitrite ($NO_2{}^-$), Acetate ($C_2H_3O_2{}^-$), Permanganate ($MnO_4{}^-$), Perchlorate ($ClO_4{}^-$), and Chlorate ($ClO_3{}^-$) anions are soluble.
- All Chloride (Cl^-), Bromide (Br^-), and Iodide (I^-) salts are soluble except those of Lead (Pb^{2+}), Silver (Ag^+), and Mercury (Hg^{2+}).
- All Sulfate ($SO_4{}^{2-}$) salts are soluble except those of Barium (Ba2+), Strontium (Sr^{2+}), and Lead (Pb^{2+}).
- All Oxides ($O_2{}^-$), Sulfides ($S_2{}^-$), and Hydroxides (OH^-) are insoluble except those of Calcium (Ca^{2+}), Barium (Ba^{2+}), and Strontium (Sr^{2+}).
- With the exception of Sodium (Na^+), Potassium (K^+), and Ammonium ($NH_4{}^+$), all metallic salts are insoluble for anions of Carbonate ($CO_3{}^{2-}$), Phosphate ($PO_4{}^{3-}$), Sulfite ($SO_3{}^{2-}$), Borate ($BO_3{}^{3-}$), Fluoride (F^-), and Silicate ($SiO_3{}^{2-}$).

A covalently bonded inorganic molecule that contains several atoms (one of more of which are metal atoms) is termed an inorganic complex. Of particular interest and environmental concern are a class of inorganic complexes termed oxyanions, which are compounds composed of metal and oxygen atoms forming an entire molecule (rather than just an isolated metal ion) that is capable of forming a hydrated complex charged ion. These oxyanionic complexes are often soluble and, more importantly, have physical/chemical qualities that make them valuable in various industrial processes. In a modern industrial environment, metallic and metalloid oxyanions are not rare substances. The most troublesome and the most common industrial oxyanion is chromate, which contains hexavalent chromium (Cr^{+6}). The chromate molecule, in turn, forms an extremely soluble, anionically charged ion. Contributing to its high mobility in the environment is a property of the chromate ion that allows it to be soluble over the entire range of pH. From acidic to basic conditions, the chromate ion simply changes the overall negative charge it carries, all while staying soluble and not precipitating. This high degree of mobility, in conjunction with its common use, and the fact that it is a known carcinogen, makes it one of the most common problem metals found to contaminate groundwater.

The ability of chromium to form soluble oxyanionic complexes is not unique to it only. Other metals and metalloids exist that form inorganic complexes having more or less the same solubility profiles. This list includes molybdenum, vanadium, tungsten, arsenic, selenium, and tellurium. These compounds are not commonly used by our industrial society. However, arsenic and selenium can have significant groundwater impact around mining areas, irrigation complexes in the west, and, in some moderately common instances, soluble arsenic is a common component in groundwater that flows through arsenic-rich geology (such as volcanics).

Industrial chemistry often makes use of complexing agents with more than one point of attachment to a central metal atom in a complex. This type of complexing agent is termed a polydentate ligand or a chelating agent. Chelating agents form strong bonds with metals and are, in turn, extremely soluble. EDTA (ethylenediaminetetraacetic acid) is a commonly used chelating agent. Chelating agents are used in industrial chemical systems with transition metals, heavy metals, and radionucleides. If released into the groundwater, these metal-bearing chelates are extremely mobile.

It should also be remembered that, under some conditions, metals in groundwater can be mobile as colloidal-sized particles, even though the metal is in an insoluble form. Although not soluble, colloidal particles are so small they may approach within an order of magnitude the size of ionized species. As such, they are transportable in the pore spaces of some aquifer formations.

Last, it is important to understand that metals in groundwater will interact with and adsorb to components of the soil matrix. Clays, other mineral components, and carbonaceous material (especially humic and fulvic substances) can all act in this manner. However, in the case of metals, the dominant adsorptive component of the soil matrix is iron. Iron oxides (particularly of Ferric (Fe^{+3}) iron) have a very high adsorptive affinity and total capacity for metal ions and oxyanionic metal complexes. This capacity is so great that ferric hydroxide is often used in waste water treatment systems to aid in the removal of soluble metallic species such as chromate or arsenic. Knowing the total iron content of the soil matrix is paramount in understanding the fate and transport of metals in groundwater.

METALS AND GROUNDWATER PART II: *IN SITU* BIOREMEDIATION OF METALS CONTAMINATED GROUNDWATER

Significant technical developments have improved our ability to remediate groundwater contaminated with hydrocarbons. There has not been similar growth in treatment alternatives for sites contaminated with metals.

When groundwater is contaminated with metals, remediation alternatives are limited to mobilization or immobilization. Unlike hydrocarbons, biodegradation into innocuous carbon dioxide and water is not possible. Irrespective of the available of *in situ* reactions, the same metal will still ultimately be present.

The choice of mobilization or immobilization is dependent on the hydrogeologic setting of the site, the chemical properties of the metal contaminant, the geochemistry of the site soils and groundwater, and the current and future use of the contaminated groundwater. Generally, it is easier to immobilize a metal than it is to mobilize and recover it. However, an immobilized metal may still be a source of future problems if subsurface ambient conditions change.

MOBILIZATION

Metal mobilization and recovery is vulnerable to the same limitations encountered with pump and treat systems for hydrocarbons. Adsorption to components of the soil matrix can significantly increase the required duration for operation of the recovery system.

Aggressive metal mobilization (beyond that achievable with passive pump and treat) is an approach to be applied only under extreme conditions. However, given proper geochemical conditions, what may be possible is the use of complexing ligands to enhance the mobility of particularly troublesome metal contaminants (such as radionucleides). In such an application, it would be essential to maintain hydraulic control of the site. Injection wells would introduce organic complexing agents (such as gluconate) to mobilize the targeted metals. Groundwater, with the solubilized metals, could then be recovered. Once the metal removal process has been completed, conventional *in situ* bioremediation could be used to degrade the residual concentrations of the organic complexing agent. Another aggressive approach to metal mobilization is methylation. Mercury can be methylated by a number of microorganisms (methanobacterium, for example), resulting in the conversion of Hg^{+2} salts to extremely volatile methylmercury compounds. Arsenic, selenium, and tellurium can undergo similar reactions. Such volatilized methylated metals are very mobile in the subsurface. In addition, the methylated forms of these metals are extremely toxic. The unusual use of this approach would be predicated on a substantial need for total removal of the metal and the ability to exercise complete hydraulic control of groundwater and soil gas at the site.

IMMOBILIZATION

A critical component of applying metal immobilization will be the use of risk assessments to establish the safety of allowing the presence of contaminating metals in an insoluble form within the aquifer matrix.

Mechanisms for microbial mediated metal immobilization can be divided into two categories, active and passive.

Active mechanisms operate directly on the metal and include:

- precipitation;
- intracellular accumulation; and
- oxidation/reduction.

Passive mechanisms act indirectly by modifying the surrounding environment. They include:

- complexing with extracellular biological chelates;
- biosorption to cell surfaces; and
- destruction of complexing ligands.

ACTIVE IMMOBILIZATION

Precipitation

In anaerobic environments, sulfate reducing bacteria, such as Desulfovibrio and Desulfotomaculum, produce hydrogen sulfide by the reaction $SO_4{}^{2-} + 10H = H_2S + 4H_2O$. The hydrogen sulfide reacts with soluble metals forming insoluble metal sulfides. The following solubility products (in parts per billion) illustrate that point:

- Cadmium Sulfide 8.7×10^{-7};
- Copper Sulfide 8.8×10^{-14};
- Lead Sulfide 4.3×10^{-6};
- Mercury Sulfide 1.1×10^{-16}.

Intracellular Accumulation

Intracellular accumulation is a two-stage process. First, metal ions are bound passively to the surface of the bacterial cell wall by physical/chemical processes. Then, the metal ions are transferred to the interior of the cell by microbial energy systems normally associated with magnesium and potassium transport. Pseudomonas and Thiobacillus are examples of common bacterial species that are capable of this process.

Oxidation and Reduction

Many known metal redox reactions mediated by microbes exist. For example, Chromate ions (Cr^{+6}) can be reduced to insoluble trivalent chromium (Cr^{+3}) with soluble reductase enzymes generated by Escherichia coli (E. coli). Soluble uranium ions (U^{+6}) precipitate as the mineral uraninite when reduced to the U^{+4} species. This reduction reaction can be driven by reductase enzymes produced by the bacteria Desulfovibrio vulgaris.

PASSIVE IMMOBILIZATION

Extracellular Complexation

Extracellular complexation occurs from interactions of metals with extracellular polymers excreted by bacteria or from organic matter accumulated from the dead microbes.

Extracellular polymers include:

- polysaccharides,
- proteins, and
- nucleic acids.

Indigenous bacteria can be stimulated to specifically produce extracellular polysaccharides.

Another class of microbial chelating agents are siderophores, which are low-molecular-weight ligands synthesized and excreted by bacteria for capturing and supplying iron to support metabolic activity. Other metals may also complex with these ligands.

Siderophore producers include Psuedomonus, Actinomyces, and Azotobacter.

Cell Wall Binding

Three mechanisms exist for the binding of metals to bacterial cell walls:

1. Ion exchange reactions with peptidoglycan and teichoic acid (important biochemical components of the bacterial cell wall);
2. precipitation through nucleation reactions; and
3. complexation with nitrogen and oxygen ligands.

Gram positive bacteria have high adsorptive capacity, particularly Bacillus, because of the high peptidoglycan and teichoic acid content in their cell walls. In general, gram negative bacterial cell walls are low in these components and exhibit poor metal adsorption.

Destruction of Complexing Ligands

Metals associated with the plating, mining, and nuclear industries are sometimes released into the environment complexed with organic ligands such as EDTA or cyanide. These organic ligands can be biodegraded by conventional *in situ* bioremediation methods to destroy the ligand and immobilize the metal.

CONCLUSION

The use of microbiological methods for environmental remediation is not an entirely new concept. Microbial interactions with metals have long been recognized, and since the 1960s work in the field by biohydrometallurgists and biogeochemists has exploded. Given adequate hydraulic controls, this is a technology that may be easier to physically implement than *in situ* bioremediation of hydrocarbons. The success of the latter has been contingent on the ability to induce adequate mass transfer of oxygen into the impacted zone, which is often difficult. Stimulation of microbes for the manipulation of metals *in situ* is usually dependent on the mass transport of soluble salts, which is a much easier task.

METALS AND GROUNDWATER PART III: REMEDIATION OF METALS CONTAMINATED GROUNDWATER WITH ELECTROCHEMICAL PROCESSES

The remediation of groundwater contaminated with metals is constrained by the fact that metals can only be mobilized or immobilized not destroyed, as with the biodegradation of hydrocarbons. However, the use of electrochemical technology is an approach that is uniquely applicable to metals. What follows is a brief review the application of electrochemical techniques to the remediation of groundwater contaminated with metals.

Introduction to Metal Chemistry

Terminology for the technology includes electrokinetic remediation, electroreclamation, electrokinetic soil processing, and electrochemical decontamination. For purposes of this review, electrochemical remediation processes are broken into two primary areas: electromigration and electroosmosis. Electromigration is used in relatively porous formations that are capable of supporting advective groundwater flow. Electroosmosis is applied to saturated fine-grained formations such as silts or clays.

Electrochemical reactions can be used with any groundwater contaminant that has a charge such as soluble metal ions, other inorganic ions, and organic acids or phenols. Electrochemical reactions are stimulated by placing two or more electrodes in the subsurface that are connected to a direct current power source. The electrode with a positive charge is termed the cathode, and the electrode with a negative charge is formed the anode. Cations migrate toward the negative electrode and anions toward the positive electrode. Power supplies should be capable of delivering currents around one amp per square foot of cross-sectional area between the electrodes and voltage potentials of 10 to 30 volts per foot between electrodes. Estimates for the total power consumption required to treat a cubic yard of saturated soil are in the range of 50 to 250 Kilowatt Hours.

Electromigration is the process of mobilizing metal (or other) ions through an aquifer matrix without advective fluid flow. Mass transport is strictly by ion migration driven by an induced electrical field. The rate of migration for any given ion is dependent on factors that include the concentration of total ions (TDS) in the groundwater and the concentration of individual ions of concern, the charge of those ions, the electrical potential between the electrodes, the mobility of the individual ionic species, and the porosity and tortuosity of the pore spaces in the aquifer. Any groundwater will have multiple soluble ions that make up the TDS. The fraction of the total current carried by a particular ionic species in the TDS is represented by the transference number for that ion. The numerical value of the transference number is dependent on the electromagnetic gradient (the greater the gradient, the higher the mass transport rate) and concentration of the individual ionic species. The dynamics of this system are such that the application of electromigration to metal contaminated groundwater is best suited to conditions in which the metal ion makes up a major component of the TDS. Recovery efficiencies are very low if the metal ion is present at trace levels. One peripheral, but inevitable, process that occurs, and has direct impact on the physical/chemical reactions induced by electromigration, is the electrolytic decomposition of water. Water at the cathode undergoes the following reaction:

$$2H_2O + 2e^- H_2(gas) + 2OH^-$$

Water is oxidized at the anode by the following reaction:

$$2H_2O - 4e^- O_2(gas) + 4H^+$$

Hydrogen ions have an effective ionic mobility 1.8 times greater than that of the hydroxyl ion. Hydrogen ions lower the pH, and their preferential migration through a formation will contribute toward the desorption of metal species from soil particles.

The term electroosmosis refers to a technology that has been used for decades by geotechnical engineers to remove water from clays, silts, and fine sands. The effect was first described in 1809. It has been used by the construction industry to stabilize embankments, dewater foundation soils, and increase the loading capacity of pilings. Electroosmosis is primarily an electrically induced hydraulic flow rather than an ionic flow. Water flows in the same direction as electrons in the electrical field loop, from anode to cathode.

The mechanism inducing the advective flow can be described as follows:

In fine-grained soils, pore space can be visualized as a capillary tube in which the tube walls (clay soil particles) are negatively charged. Water in such a tube exists as a double layer, with an adsorbed layer tightly held directly adjacent to the pore space wall. The water in the center of the pore space and the core of the tube is less strongly held by these attractive forces. The application of an electrical gradient across the tube will cause cations in the tightly adsorbed layer adjacent to the walls of the pore space to migrate toward the cathode, taking the free water in the core of the tube (and between the adsorbed layers) along with it. In contrast, under hydraulic pumping conditions, only the free water in the core of the pore space will flow. Contaminant mass transport is induced through hydraulic flushing, in addition to some electromigration of soluble metal ions.

The finer the grain of the pore space, the greater the significance of the electroosmotic effect. In fine-grained soils, electroosmotic-induced mass transport can be two to three orders of magnitude higher than that capable of being induced hydraulically.

Potential problems in the field application of electrochemical technology include:

- High current densities and subsequent reactions at the anode can cause low pH conditions resulting in corrosion and dissolution of the electrode element.
- Precipitation of metal hydroxides or other TDS components near the cathode can cause pore space blockage.
- If contaminant and general TDS ion concentrations are not favorable, electrical costs can be unreasonably high because all ions (even undesirable ones) participate in the reactions.
- The number and spacing of electrodes can be prohibitive. Subsidence or settlement is a potential under some conditions.

Some of these issues can be addressed through process enhancements, such as using additives to depolarize the cathode and anode. Reactions induced in groundwater under an electric field are complex and will change with time. Low pH, high pH, ion mobilization, precipitation, dissolution, and desorption are all reactions that can take place within different locations in the subsurface electrical cell at different times during the operation of the system. The electrochemistry in such a system evolves with time. The successful use of this technology requires operation of the system to exploit those geochemical changes.

GENETICS OF METAL TOLERANCE AND ACCUMULATION IN HIGHER PLANTS

Rupali Datta
Dibyendu Sarkar
University of Texas at San Antonio
San Antonio, Texas

Phytoremediation of metals is rapidly developing as a cost-effective and environmentally friendly solution for cleaning up heavy-metal-contaminated sites. The most important requirements for effective phytoremediation are fast-growing, high biomass plants that uptake

and accumulate large amounts of toxic metals in their aboveground harvestable parts. A relatively small group of hyperaccumulator plants sequesters metals in their shoot tissues at high concentrations. In recent years, major scientific progress has been made in understanding the physiological mechanisms of metal uptake and transport in these plants. The majority of metal hyperaccumulators are slow growing and typically have low biomass, so bioengineering of nonaccumulators that have high biomass is essential for more effective phytoremediation. Biotechnology offers the opportunity to transfer hyperaccumulator phenotypes into fast-growing, high biomass plants that could be highly effective in phytoremediation. However, comprehensive knowledge of the genetics of metal tolerance and accumulation is essential to design transgenic plants capable of phytoremediation. After an initial focus on plants with an immediate promise of application, research is now being directed at understanding the underlying mechanisms involved in heavy metal hyperaccumulation in plants. Once the rate-limiting steps for uptake, translocation, and detoxification of metals in hyperaccumulator plants are identified, more informed construction of transgenic plants could become rather routine, which will help tremendously in more effective use of phytoremediation technology for cleaning up heavy-metal-contaminated sites.

INTRODUCTION

Mining, manufacturing, and other anthropogenic activities have contributed to extensive soil contamination during the past century, and metals are the main group of inorganic contaminants (1). Several technologies exist for remediating metal-contaminated soils (2) that can be broadly classified into five general categories: isolation, immobilization, toxicity reduction, physical separation, and extraction. Immobilization and extraction by physicochemical techniques can be expensive and are appropriate only where rapid and complete decontamination is required (3). In addition, some of these techniques such as soil washing have an adverse effect on biological activity, soil structure, and fertility. Plants that take up metals from soil offer an alternative and less expensive method of stripping metals directly from soil. The majority of plants have constitutive and adaptive mechanisms for accumulating or tolerating high contaminant concentrations in their rhizospheres. Phytoremediation, the use of such plants to clean up soils and water contaminated with pollutants, is emerging as a new tool for *in situ* metal remediation. Phytoremediation takes advantage of the fact that a living plant is a solar-driven pump that can extract and concentrate certain metals from the environment (4). This remediation method maintains the biological properties and physical structure of soil. The technique is environmentally friendly, cost-effective, visually unobtrusive, and offers the possibility of biorecovery of precious metals.

The majority of phytoremediation-related research to date has focused on hyperacccumulator plants that accumulate metals to concentrations more than 100 times higher than those in nonaccumulators (5). However, metal hyperaccumulation is a relatively rare phenomenon that occurs in only a few terrestrial plants. Only about 400 species have been identified so far as natural metal hyperaccumulators; they represent <0.2% of all angiosperms (6). Threshold values of metal concentrations are used to define metal hyperaccumulation, which varies from element to element, for example, 10,000 mg/kg dry shoot weight for Zn and Mn; 100 mg/kg for Cu, Co, Ni, As, and Se; and 100 mg/kg for Cd (7). The common traits shared by all hyperaccumulators include (1) a bioconcentration factor greater than 1, in some cases as high as 50–100; (2) a shoot-to-root ratio of metal concentration greater than 1, indicating efficient root-to-shoot transport; and (3) enhanced tolerance to metals in the medium and inside plant cells, indicating strong internal detoxification (7). A great deal of research has been conducted to elucidate the physiology and biochemistry of metal hyperaccumulation in plants, but still certain limitations must be overcome for this technology to become efficient and cost-effective on a commercial scale (8). Plants ideal for phytoremediation should be fast growing, have high biomass and extensive root systems, be easy to harvest, and tolerate and accumulate a range of metals in their harvestable parts. No single plant with all these traits has been found so far, but it is possible that high biomass nonaccumulators that are fast growing could be modified using the transgenic approach to achieve some of the properties of hyperaccumulators (9). However, this approach can be used only when the molecular mechanisms of metal uptake, tolerance, accumulation, and translocation are better understood. The primary objective of this article is to evaluate the progress made so far in understanding the physiological and molecular-genetic mechanisms that control uptake and detoxification of metals in plants.

METAL HYPERACCUMULATION IN PLANTS

Hyperaccumulation of metals by higher plants is a complex phenomenon that involves the following steps: (1) transport of metals across the plasma membrane of root cells, (2) xylem loading and translocation, and (3) detoxification and sequestration of metals at the whole plant and cellular levels (10). The term “phytoextraction” describes the use of plants to remove metals from soil by concentrating them in their harvestable parts (11). This process depends on hyperaccumulating plants that can grow naturally on soils rich in metals. The first hyperaccumulators characterized were members of the Brassicaceae and Fabaceae families. About 400 plant species have been reported so far that hyperaccumulate metals (6). Many of the Zn hyperaccumulators identified so far belong to the family Brassicaceae and are in the genus *Thlaspi.* In addition, *Cardaminopsis halleri* and *Viola calaminaria* also hyperaccumulate Zn. Several species of plants that hyperaccumulate Zn have been investigated, but only one Cd hyperaccumulator, *Thlaspi caerulescens,* has been extensively studied. The first indication of the possibility of phytoextraction of Zn was obtained from pot experiments in background and sludge-treated soils using *Thlaspi caerulescens* (12). It was estimated that a crop of *T. caerulescens* could take up 34 kg/ha of Zn and 0.16 kg/ha Cd. Recently, the Chinese brake fern *Pteris vittata* has been found able to hyperaccumulate As from soil (13). It can accumulate up to 22,630 mg As/kg in the shoot (frond) dry weight. Furthermore, the bioconcentration factor, defined as the ratio of shoot As concentration to soil As concentration, was greater than 10 for brake fern. The fern possesses three key features that are typical of metal/metalloid hyperaccumulator plants: an efficient root uptake, efficient root-to-shoot translocation, and much enhanced tolerance to As inside the plant cells (13). After the discovery of this first As hyperaccumulator, several other fern species, including *Pityrogramma calomelanos* (14), *Pteris cretica, Pteris longifolia*, and *Pteris umbrosa* (15) have recently been added to the list of As hyperaccumulators. The hyperaccumulation trait of these ferns may be exploitable in phytoremediation of As contaminated soils.

Several plant species reportedly accumulate Ni, and some of them also accumulate Co and Cu. A few species accumulate Mn and Cd (11). The major disadvantage of the continuous phytoextraction method is that majority of the plants, except for As hyperaccumulating ferns, have low biomass and slow growth rates (11).

MECHANISM OF METAL UPTAKE BY PLANTS

Transport proteins and intracellular high-affinity binding sites mediate the uptake of metals across the plasma membrane in root cells of plants. Several studies have shown that metal hyperaccumulation of Zn and Cd by *T. caerulescens* involves enhanced metal uptake by roots (15,16). Several Zn transporter genes have been cloned recently from *T. caerulescens,* which belong to the ZIP (Zn-regulated transporter/Fe-regulated transporter-like proteins) family (17). These genes, named *ZNT1* and *ZNT2*, are highly expressed in the roots of *T. caerulescens,* but their expression is not responsive to the Zn status of the plant. Through functional complementation in yeast, it was shown that *ZNT1* mediates high-affinity uptake of Zn^{2+} and low-affinity uptake of Cd^{2+} (18). Specific alterations in Zn-responsive elements, such as transcriptional activators, may play an important role in Zn hyperaccumulation in *T. caerulescens* (18). However, increased uptake of Cd by *T. caerulescens* cannot be explained by the Zn transport pathway but may be related to enhanced expression of the *IRT1* gene, which is essential for Fe uptake (10). The *IRT1* gene mediates high-affinity uptake of Cd^{2+} in *A. thaliana* (19,20).

Several classes of proteins are implicated in metal transport in plants, which include the metal (or CPx-type) ATPases that are involved in overall metal ion homeostasis and tolerance in plants, the natural resistance-associated macrophage protein (Nramp) family of proteins, and the cation diffusion facilitator (CDF) family proteins (21). CPx-type metal ATPases have been identified in a wide range of organisms and have been implicated in the transport of essential as well as potentially toxic metals, such as Cu, Zn, Cd, and Pb, across cell membranes (21). These transporters use ATP to pump a variety of charged substrates across cell membranes and are distinguished by the formation of a charged intermediate during the reaction cycle. Metal transporters have been classified as type IB and are called the CPx-ATPases because they share a common feature of a conserved intramembranous cystein-proline-cystein, cystein-proline-histidine, or cystein-proline-serine (CPx) motif, which, it is thought, functions in metal transduction. *Arabidopsis* P-type ATPase (PAA1) was the first CPx-ATPase reported in higher plants (22). Most CPx-type ATPases identified so far have been implicated in Cu or Cd transport. The physiological role of the metal ATPases in higher plants is not known. *Arabidopsis* CPx-ATPases show fairly low similarities to each other, so it is possible that they transport different substrates. They may be present in the plasma membrane and function as efflux pumps removing potentially toxic metals from the cytoplasm or may also be present at various intracellular membranes and be responsible for compartmentalization of metals, for example, sequestration in the vacuoles, Golgi, or endoplasmic reticulum. Intracellular levels of metals must be carefully controlled, so transporters represent good candidates for regulation. How they may be regulated in higher plants is not yet known, which could occur at the transcriptional level (control on initiation rates, mRNA stability, differential mRNA splicing) or at the posttranslational level (targeting, stability), which has been observed in bacteria and yeast (21).

As mentioned earlier, *Nramp* is a novel family of related proteins that has been implicated in the transport of divalent metal ions. The corresponding genes that code for these proteins are called *Nramp* genes. In higher plants, three *Nramp* homologues have been identified in rice (23). Subsequently, two *Arabidopsis* genes showing similarity to *Nramp*s were also been identified (24). Initial results suggest that *Arabidopsis Nramp* homologues encode functional metal transporters (25). Northern blot analysis indicates that the rice *Nramp* gene *OsNramp1* is expressed primarily in the roots, *OsNramp2* in the leaves, and *OsNramp3* in both tissues of rice (23). This distinct pattern of expression could mean that they are regulated differently and have distinct functions in different tissues or that they transport distinct but related ions in different parts of the plant (23).

CDF proteins have been implicated primarily in the transport of Zn, Co, and Cd in bacteria and some eukaryotes. Certain members of CDF have been implicated in Cu or Cd transport. A related Zn transporter (*ZAT1*) from *Arabidopsis* was reported by Van der Zaal et al. (26). This *ZAT1* transporter may have a role in Zn sequestration in plants. Enhanced Zn resistance was observed in transgenic plants that overexpress *ZAT1*, expressed constitutively throughout the plant. High Zn exposure of these plants led to increased Zn content in the roots. Zinc transporter (ZIP) proteins are involved in Zn and Fe uptake (27).

To enhance metal uptake, (1) the number of uptake sites could be increased, (2) the specificity of the uptake proteins could be altered, and (3) the sequestration capacity could be enhanced by increasing the number of intracellular high-affinity binding sites or the rates of transport across organelles. A comprehensive understanding of metal transport processes in plants is essential for formulating effective strategies to develop genetically engineered plants that can accumulate specific metals.

DETOXIFICATION OF METALS IN PLANTS

A general mechanism for detoxification of metals in plants is chelation of the metals by a ligand, followed by sequestration of the metal–ligand complex into the vacuole. Complexation with ligands can be extracellular, for example, the mechanism of Al tolerance by efflux of organic acids such as malate and citrate from roots. Intracellular complexation involves peptide ligands such as metallothioneins (MTs) and phytochelatins (PCs). Metallothioneins are cystein-rich polypeptides, first identified in mammalian tissues as Cd-binding peptides (11). Several MT genes and proteins have been identified in plants. MTs are gene encoded, but PCs are enzymatically synthesized. PCs have been identified in a wide variety of plant species, including angiosperms (both monocots and dicots), gymnosperms, algae (28), fungi (29,30), and marine diatoms (31), but not in animals.

PCs are a family of sulfur-rich peptides that were first identified in yeast. Most of the current knowledge of these peptides has resulted from molecular-genetic studies on yeast and *Arabidopsis* during the last few years. PCs are rapidly induced in cells and tissues exposed to a range of metal ions, such as Cd, Ni, Cu, Zn, Ag, Hg, and Pb, and anions, such as arsenate and selenite (32). PCs consist of only three amino acids, glutamine (Glu), cysteine (Cys) and glycine (Gly). They are structurally related to the tripeptide glutathione (GSH) and are enzymatically synthesized from GSH. PCs form a family of structures with increasing repetitions of the γ-Glu-Cys dipeptide followed by a terminal Gly, (γ-Glu-Cys)n-Gly, where n is generally in the range of 2–5, but could be as high as 11 (33). It was shown that GSH-deficient mutants of *Arabidopsis* are also PC-deficient and Cd-sensitive (34). GSH-dependent PC-synthase activity was identified in cultured cells of *Silene cucubalis* (35). The enzyme is active only in the presence of metal ions such as Cd, Cu, Zn, Ag, Hg, and Pb. Similar activities have been identified in *Arabidopsis* (36), tomato (37), and pea (38). Several studies have suggested that PC-synthase activity is regulated by metal ions at the level of enzyme activation. The fact that PC-synthase activity has an important role in Cd tolerance was shown in *Vigna angularis* (adzuki beans) that are hypersensitive to Cd. Cell-suspension cultures of adzuki bean did not synthesize PCs when challenged with Cd. These cells also lacked PC-synthase activity. Externally applied GSH failed to stimulate PC synthesis or confer Cd tolerance on the cells, which demonstrated the importance of PC synthesis in Cd tolerance in plants (39).

Despite the identification of PC-synthase activity more than a decade ago, the identification of a corresponding gene remained elusive until recently. PC-synthase genes were first isolated almost simultaneously by two research groups. Vatamaniuk et al. (40) identified an *Arabidopsis* cDNA, named *AtPCS1*. The expression of *AtPCS1* protein mediated an increase in Cd accumulation, pointing to a possible role in Cd chelation or sequestration. Clemens et al. (41) identified a wheat cDNA, *TaPCS1*, that increased Cd-resistance in wild-type yeast. Just like *AtPCS1*, the Cd-resistance mediated by *TaPCS1* was associated with an increase in Cd accumulation and was GSH-dependent. Both *AtPCS1* and *TaPCS1* mediated Cd tolerance are GSH-dependent and function in vacuole-deficient mutants, suggesting a cytosolic localization, and mediate *in vivo* PC biosynthesis in yeast. Further evidence of the role of PCs in metal hyperaccumulation comes from the overexpression of a bacterial glutathione synthetase, an enzyme that synthesizes GSH, by Indian mustard plants (42). These transgenic plants have increased GSH and PC concentrations and increased Cd tolerance and accumulation relative to controls. Overexpression of plant PC synthetase in transgenic yeast also increased the tolerance to and the accumulation of Cd (40). These studies show that the manipulation of GSH and PC concentrations has significant potential for increasing the accumulation of metals by plants (43).

Regulation of PC-synthase activity is likely to be the most important regulatory mechanism of the PC biosynthetic pathway. Evidence pointing to the role of posttranslational activation was obtained using plant cell cultures. PC biosynthesis reportedly occurs within minutes of exposure to Cd and is independent of de novo protein synthesis. In *Silene cucubalis* cell cultures (35), tomato (36), and *Arabidopsis* (37), PC-synthase expression is independent of metal exposure. These studies suggest that PC synthase is regulated by enzyme activation by metals. However, there are conflicting reports regarding the induction of transcript levels in response to metal exposure. PC biosynthesis probably varies among different plant species and is regulated at transcriptional and posttranscriptional levels or both, which suggests that PC-synthase activity is regulated differently in different plant species.

PC biosynthesis may also be regulated by the biosynthesis of GSH. In transgenic Indian mustard plants, increases in the expression of enzymes in GSH biosynthetic pathways led to an increase in PC biosynthesis and Cd tolerance (42,44). Wild-type Indian mustard plants respond to increased Cd exposure with increased levels of γ-glutamylcysteine synthatase (γ-*ECS*) transcript, which codes for the first enzyme in the PC biosynthetic pathway (45). Similarly, evidence also exists supporting posttranscriptional regulation of γ-ECS expression (46).

SEQUESTRATION OF METALS IN VACUOLES

Within plant cells, PC–metal complexes accumulate in the vacuole, which appears to be driven by various membrane transporters. Several classes of proteins have been implicated in metal transport, including CPx type ATPases, the Nramp family of proteins, and CDF family proteins. In yeast, PC–Cd complexes are reportedly sequestered in the vacuole. The mutant *hmt1* cannot form the HMW complex on Cd exposure. The *hmt1* gene encodes a member of the ATP-binding cassette (ABC) membrane transport protein that is located in the vacuolar membrane (47). The transport of PCs and PC–Cd complexes across the vacuolar membrane was not dependent on the proton gradient established across the membrane by vacuolar H^+-ATPase (48). When mesophyll protoplasts from tobacco plants were exposed to Cd, all Cd and PCs accumulated in the vacuole (49). Salt and Rauser (50) also identified an ATP-dependent, but proton gradient-independent activity, capable of transporting both PCs and PC–Cd complexes into tonoplast vesicles from oat roots.

GENETIC ENGINEERING OF PLANTS FOR PHYTOREMEDIATION

Effective phytoextraction of metals depends on the ability of plants to tolerate high levels of toxic metals and also on their ability to take up increased amounts of metals and translocate them to the shoots. Plants that have the ability to translocate metals from roots to shoots at high rates are more effective hyperaccumulators. In nonaccumulators, root concentrations of Zn, Cd, or Ni are ten or more times higher than shoot concentrations, but in hyperaccumulators, shoot metal concentrations can far exceed root levels (51,52). Biotechnology offers the opportunity to transfer hyperaccumulator phenotypes into fast growing, high biomass plants that could be highly effective in phytoextraction. Several recent studies have succeeded in bioengineering plants to hyperaccumulate a variety of toxic metals. Modification or overexpression of the enzymes that are involved in synthesizing glutathione and PCs might be a good approach to enhance metal tolerance and accumulation in plants. Zhu et al. (42) overexpressed the *Escherichia coli* counterparts of γ-ECS and glutathione synthetase in Indian mustard plants that accumulate more Cd than wild-type plants. Rugh et al. (53) modified yellow poplar trees with two bacterial genes, *merA* and *merB*, to detoxify methylmercury from contaminated soil. In transformed plants, *merB* catalyzes the release of Hg^{2+} from methylmercury, which is then converted to Hg^0 by *merA*. Elemental mercury is less toxic and more volatile than the mercuric ion and is released into the atmosphere. Pilon-Smits et al. (54) overexpressed the ATP-sulfurylase (*APS*) gene in Indian mustard. The transgenic plants had fourfold higher APS activity and accumulated three times more Se than wild-type plants. Recently, Dhankar et al. (55) reported a genetics-based strategy to remediate As from contaminated soils. They overexpressed two bacterial genes in *Arabidopsis*. One was the *E. coli arsC* gene encoding arsenate reductase that reduces arsenate to arsenite coupled to a light-induced soybean *rubisco* promoter. The second gene was the *E. coli* γ*-ECS* coupled to a strong constitutive actin promoter. The AsrC protein, expressed strongly in stem and leaves, catalyzes the reduction of arsenate to arsenite, whereas γ-ECS, which is the first enzyme in the PC-biosynthetic pathway, increases the pool of PCs in the plant. The transgenic plants that expressed both AsrC and γ-ECS proteins showed substantially greater As tolerance when grown on As, these plants accumulated 4- to 17-fold greater fresh shoot weight and accumulated two- to threefold more As than wild-type plants.

Most metal hyperaccumulators are slow growing and have low biomass, so bioengineering of nonaccumulators is essential for more effective phytoremediation. Conventional breeding approaches have also been proposed to improve plants for metal extraction. However, the success of this approach is doubtful due to sexual incompatibility between parent lines (56). Biotechnology has the potential of overcoming this limitation. However, a comprehensive knowledge of the genetic basis for hyperaccumulation is essential for effective use of biotechnology to design transgenic plants capable of efficient phytoremediation.

SUMMARY AND FUTURE DIRECTIONS

Phytoremediation as a cleanup process for metal contaminants is very attractive because it is effective, relatively inexpensive, and environmentally friendly. The majority of phytoremediation-related research to date has focused on hyperacccumulator plants that accumulate metals to concentrations more than 100 times higher than those in nonaccumulators. However, most of the known hyperaccumulators are slow growing and have low biomass, which are not ideal traits for optimal metal uptake. Plants ideal for phytoremediation should be fast growing, have high biomass, an extensive root system, be easy to harvest, and tolerate and accumulate a range of metals in their harvestable parts. No single plant that has all these traits have been found so far, but it is possible that nonaccumulators that are fast growing are have high biomass could be modified using the transgenic approach to achieve some of the properties of the hyperaccumulators. However, this approach can be used only when the molecular mechanisms of metal uptake, tolerance, accumulation, and translocation are better understood. Advances have been made in understanding root uptake mechanisms and the identification of transporters that sequester metals in the vacuoles and lead to hyperaccumulation of metals. Once taken up, the general mechanism for detoxification of metals in plants is chelation by a ligand, followed by sequestration of the metal–ligand complex into the vacuole. A lot of work has been done to understand metal tolerance and detoxification, but many questions regarding the genes involved in the processes controlling transport, sequestration, and detoxification of metals still remain. Once the rate-limiting steps for uptake, translocation, and detoxification of metals in hyperaccumulator plants are identified, more informed construction of transgenic plants will help tremendously in improving phytoremediation technology, paving the way for wider application.

IN SITU GROUNDWATER REMEDIATION FOR HEAVY METAL CONTAMINATION

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

THE METALS PROBLEM

Highly toxic and highly soluble heavy metals are contained in numerous waste streams, including those from power, chemical, electronics, and general manufacturing plants, and mining facilities. Heavy metals can create significant health risks to humans.

HISTORY

Arsenic, lead, copper, zinc, cadmium, molybdenum, uranium, and cyanide have been used in a variety of industrial activities such as plating and circuit board manufacturing, and occur in mining and power plant waste streams and from other processes.

Chromium is an example of one metal used by various industries for different purposes. Chromium is used in wood preservation. In that process, copper-chrome-arsenic wood preservatives are used extensively by the timber industry for pressure-treated or green wood. Chromium is also used as a nontarnishing surface coating in the metal plating industry. For making kiln bricks, chromium, due to its large capacity to withstand high temperatures, is used in the refractory industry. Finally, trivalent chromium salts are used widely as a tanning agent transforming animal hides and skins into leather. Chromium is just one heavy metal but illustrates the complexity and variability of industrial uses. With each use comes a series of associated industrial processes, waste streams, recycling programs, fate and transport of the metal in the environment, toxicity to humans, and the various oxidation states of the metal and other factors. All these factors greatly affect the cleanup process.

OVERVIEW OF METAL TREATMENT

Metal remediation has been documented. *In situ* methods using natural systems and enhanced bioremediation have shown promise (1). Various *in situ* treatment technologies, including metal remediation, are described in Nyer et al. (2). Environmental restoration of metal-contaminated soils is described in Ikandar (3). Mining and processing facilities are a source of metal contamination. Remediation of mining wastes is described in Davis et al. (4). Figure 1 shows a conceptual model of metal contaminants moving through the soil and into groundwater.

The success of *in situ* metal remediation requires adequate site characterization of both soil and groundwater zones, good understanding of the valence states of the associated metals and their likely source location, and complete chemical characterization. Chemical analyses include dissolved oxygen (DO), E_h, soil and groundwater

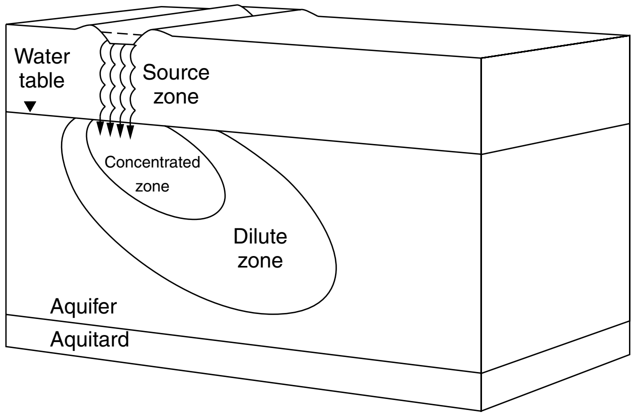

Figure 1. Conceptual model of geochemical zones in a metal contaminant plume (5,6).

pH, total organic carbon (TOC), dissolved organic carbon (DOC), particulate organic carbon (POC), cation exchange capacity (CEC), alkalinity, temperature, specific metals, and other analytes. Bench testing in the laboratory using soil and groundwater from the site allows for optimizing the chemistry in the laboratory prior to a field pilot test and an ultimate full-scale remediation program. Chemical bench tests can range from simple beaker tests where only groundwater is mixed with the reactants to soil column tests. For microbiological testing, heterotrophic count and anaerobic microbes can be evaluated. In addition, microbial bench tests can be performed with soil or groundwater, and microbial colonies can be cultured and evaluated for growth potential in various pH conditions with various bioenhancement chemicals, typically carbon sources such as molasses, cheese whey, sucrose, corn syrup, lactic acid, milk, or propane.

IN SITU TREATMENT TECHNOLOGY

Remediation of heavy metals such as lead, chromium, arsenic, and others in soil and groundwater frequently uses reduction reactions to lower the solubility of an oxidized metal in the higher of two or three valence states to a lower energy and less toxic state. Ultimately, the metal is precipitated as a sulfide or in another immobile and low toxicity form.

The solubilities of arsenic, lead, copper, zinc, cadmium, molybdenum, uranium, and cyanide are pH dependent. Recently, sulfur-based metals treatment technologies have been the focus of an increasing number of research studies and commercial applications for treating metal contamination in soil and groundwater.

Reduction Chemistry

In situ metal remediation by reduction can be either chemical or biological. For chemical reactions, sulfur compounds have been used successfully in a variety of settings. Precipitation of metals in reducing environments as sulfides, hydroxides, and carbonates has been documented as a remediation method. Even zero-valent iron has been used to reduce hexavalent chromium in groundwater through reactive permeable barrier walls, as part of a funnel and gate system. Reactive barriers for *in situ* metal treatment are documented.

Various sulfur-based reductants are available, and the more common ones include metabisulfite, ferrous sulfate, calcium polysulfide, and sodium sulfide. Selected reactions are described below:

Reductant. Metabisulfite ($S_2O_6{}^{2-}$).
In the presence of excess sulfite, Cr(VI) is reduced (7):

$$6H^+ + 2HCrO_4{}^- + 3HSO_3{}^-(\text{excess}) \Longrightarrow 2Cr^{3+} + 2SO_4{}^{2-} + S_2O_6{}^{2-} = 6H_2O$$

In the presence of excess Cr(VI), reduction to Cr(III) by sulfite is performed by this reaction (7):

$$5H^+ + 2HCrO_4{}^-(\text{excess}) + 3HSO_3{}^- \Longrightarrow 2Cr^{3+} + 3SO_4{}^{2-} + 5H_2O$$

Reductant. Ferrous sulfate ($FeSO_4$)
Dissolved Cr(VI) can be precipitated as $Cr(OH)_3$ by injecting ferrous sulfate (1).

$$\text{Acidic conditions: } Cr_2O_7{}^{2-} + 6Fe^{2+} + 14H^+ \Longrightarrow 2Cr^{3+} + 6Fe^{3+} + 7H_2O$$

Neutral or alkaline conditions:

$$CrO_4{}^{2-} + 3Fe^{2+} + 4H_2O \Longrightarrow Cr^{3+} + 3Fe^{3+} + 8OH^-$$

Both Cr(III) and Fe(III) ions are highly insoluble in natural groundwater, and these ions precipitate out as hydroxides as follows (1):

$$Fe^{3+} + 3OH^- \Longrightarrow Fe(OH)_3 \text{ (precip)}$$
$$Cr^{3+} + 3OH^- \Longrightarrow Cr(OH)_3 \text{ (precip)}$$

Reductant. Calcium polysulfide (CaS_5)

$$2CrO_4{}^{2-} + 3CaS_5 + 10H^+ \Longrightarrow 2Cr(OH)_3 + 15S^{\circ} + 3Ca^{2+} + 2H_2O$$

A reductant, such as calcium polysulfide (CaS_4), precipitates the highly soluble metal as a less soluble and nontoxic sulfide (Fig. 2). Metal hydroxides change solubility with changes in pH. Metal sulfides remain insoluble within a pH range of about 5 to 9. Calcium polysufide has a pH of 11.3 to 11.5, a specific gravity of 1.273, and is deep orange-red in solution. The excess calcium precipitates as calcium carbonate, gypsum, or calcium sulfate. Calcium polysulfide is soluble in water and comes as 29% concentration of calcium polysulfide. The extent of metals precipitation is a function of pH.

Delivery System

To deliver sulfur-based chemical reductants into the subsurface, an *in situ* delivery method uses close spacing of high-pressure injection ports, allowing the treatment

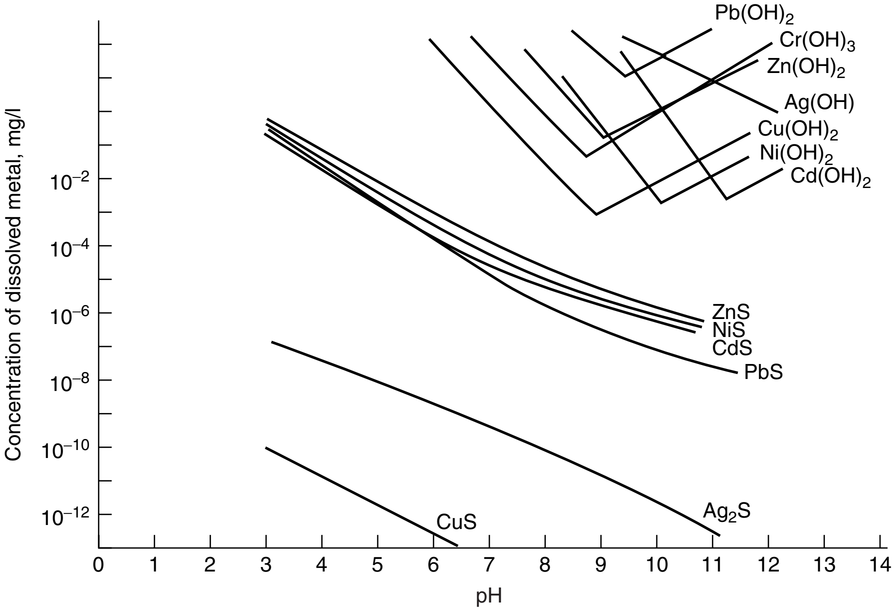

Figure 2. Solubility of metal hydroxides and sulfides as a function of pH (8).

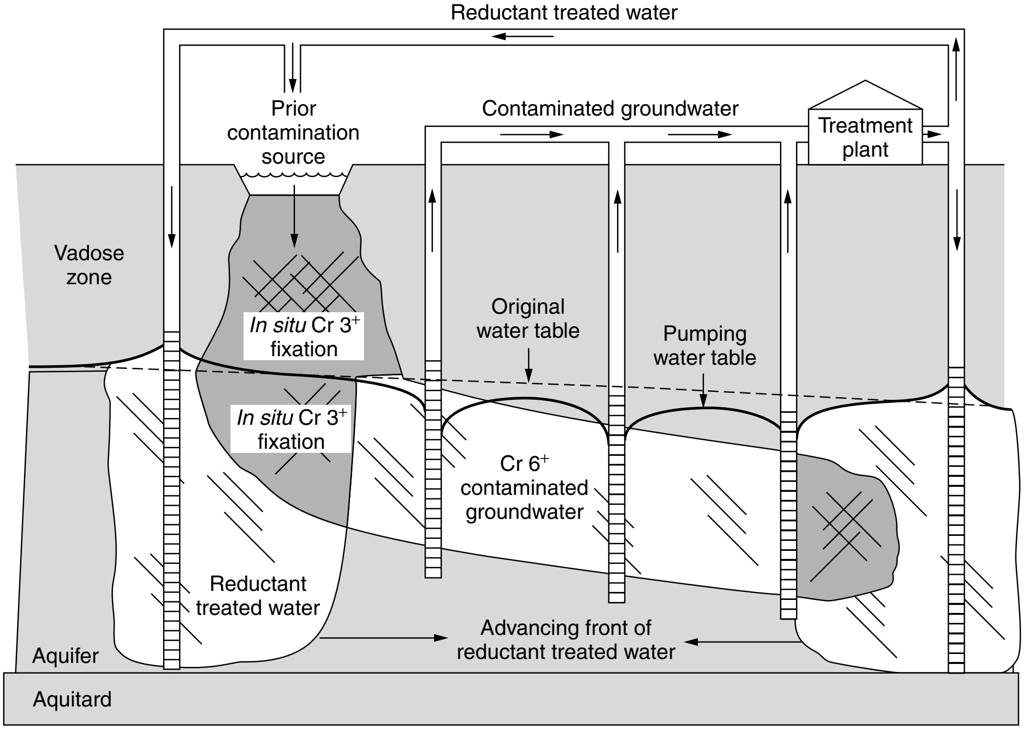

Source: Rouse, 1997

Figure 3. Schematic of an *in situ* chromium remediation process (5,9).

chemicals to contact the contaminant fully. The delivery of the reductant chemicals can be through trenches or wells. A schematic of an *in situ* remediation process for chromium is shown in Fig. 3 (5,6).

In addition, the direct push method allows placing injection ports as well as a specialized lance system to deliver treatment chemicals (10).

Besides sulfur-based reductants, lime [$Ca(OH)_2$] and other alkaline solutions such as potash (KOH) are used for chemical reduction and hydroxide precipitation (Table 1).

BIOLOGICAL METHODS OF *IN SITU* METAL REMEDIATION

Plant-based *in situ* remediation of metals, generically called phytoremediation, can be accomplished using a variety of plants that uptake the metals. An overview

Table 1. ***In situ*** **Metal Remediation**

Metal	Arsenic	Lead	Copper	Zinc
Treatment notes:	Acid medium only	Wide range (pH: 4–9)	Close to neutral (optimal pH: 5–7)	Wide range (pH: 4–9)
Metal	Cadmium	Molybdenum	Uranium	Cyanide
Treatment notes:	Wide range (pH: 4–9)	Wide range (pH: 4–9)	Wide range (pH: 4–9)	Chemical conversion produces thiocyanate[a]

[a] Thiocyanate is treated with lime, producing calcium carbonate, gypsum and ammonia.

Chromium (Cr VI) can be treated with calcium polysulfide, and Cr (VI) is reduced to Cr (III), which is then precipitated as chromium hydroxide.

of phytoremediation and other subcategories is included in Lehr (11).

Microbe-induced reduction of metals has been documented (1). Using chromium as an example, microorganisms may reduce chromium [Cr(VI)] under anaerobic conditions to trivalent chromium [Cr(III)] by exuding reducing agents or by lowering the pH. Other methods can be used to create anaerobic conditions for enhanced bioremediation and consequently reduction of metals. These enhancements use the injection of a carbon source.

PAST REMEDIATION OPTIONS

In the past, conventional remediation of soil and groundwater impacted by heavy metals has relied on soil excavation, which was expensive and disruptive. In addition, moving the soil only moved the problem, without treating the soil or reducing the long-term liability. For groundwater, pump and treat remediation relied on pumps to remove groundwater from the aquifer through a series of extraction wells or trenches. The extracted water was then treated above ground or disposed of off site. Pump and treat methods fail to address the source of the contamination in the vadose zone. Although the construction of passive permeable treatment walls containing zero-valent iron filings can reduce some metals to less toxic varieties, the passive barriers are expensive and do not treat source areas.

The chemical and biological reducing methods of remediating metals *in situ* are technically effective in significantly lowering metals concentrations in 1 to 5 years at reasonable cost. Delivery systems for the chemical reductants and bioenhancements have been developed and used at a variety of sites. The keys to success in most of these projects involve accurate subsurface assessments prior to field remediation, properly designed bench tests to optimize chemistry in the laboratory, realistic regulatory targets for site closure, and a well-designed remediation delivery system.

METHANE IN GROUNDWATER

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

Methane is a colorless, odorless, and tasteless gas, which is produced by biological decay of organic materials or by high temperatures acting on organic materials in unconsolidated and geologically young deposits. These materials include coals, organic rich shales, landfill materials, compost piles, and other accumulations of organic materials both above and underground. For example, a buried oak log, only 1 ft in diameter and 5 ft long, can generate enough methane when it decomposes underground to form an explosive mixture in 400 to 1200 m^3 of air (1).

Methane is produced by biological processes where oxygen is excluded (anaerobic conditions). Methane can be oxidized in water that contains dissolved oxygen, so the amount that reaches the surface depends on the depth of water. Its rate of production generally increases with temperature (2). It is produced only in a strongly reducing medium ($E_h < 100$ mV). Anaerobes that produce methane are called methanogens. Molecular oxygen is very toxic to them. Methane can be produced by fermenting a few simple organic compounds such as acetate, formate, methanol, or methylamines. Molecular hydrogen can also be used to reduce inorganic carbonate to methane (3). During methanogenesis, carbon dioxide is used as an electron acceptor, and methane is produced. The presence of methane in groundwater is indicative of strongly reducing conditions and occurs after oxygen, nitrate, iron, and sulfate have been depleted in the treatment zone.

Methane in water wells becomes a problem when it is allowed to build up in confined spaces. High concentrations of methane can displace oxygen or in the presence of a spark, can explode. Extensive testing for methane in water wells in southwest Colorado has been conducted during the past 10 years. As a result of this testing, many believe that methane concentrations below 1 mg/L are harmless. Methane levels up to 7 mg/L usually are not a concern but should be monitored for changes. Between 7 mg/L and 13 mg/L, additional monitoring and treatment should be considered. Also, care should be taken to ventilate confined spaces where well water is used. When methane levels are 13 mg/L or above, treatment is a must.

Theoretically, water containing as little as 1 to 2 mg/L of methane can produce an explosion in a poorly ventilated air space. Fires and explosions in well pits, basements, and water tanks have occurred from methane emitted by groundwater; safety measures include analysis to detect the presence of the gas, aeration of water before use, and adequate ventilation where the water is being used. There is a danger of people suffocating in dug wells and pump pits where high methane concentrations form (4).

FOSSIL AQUIFERS

Laurel Phoenix
Green Bay, Wisconsin

Fossil aquifers are bodies of very deep aquifers that are disconnected from our contemporary hydrologic cycle. Water in these aquifers can be hundreds to thousands of years old and thousands of feet deep. As they are not recharged by today's precipitation, using them as a water supply is not sustainable. Other deep aquifers may still be connected to surface precipitation, but recharge so slowly relative to human time scales that they can practically be considered nonreplenishable fossil aquifers as well. Not only are these supplies finite, but their depth also makes them more expensive, not only for the initial drilling but also for the increased energy required to pump water from these depths.

WHY DEVELOP AN UNSUSTAINABLE AND EXPENSIVE WATER SUPPLY?

The use of fossil aquifers is a symptom of the larger world water deficit that has developed in recent history. As populations grow, and as cheap fossil fuel encourages overpumping (or mining), accessing fossil water is an easier choice than restricting current water use. Moreover, the increased import/export grain trade has globalized regional water deficits (1). For example, demand to import wheat goes up in water-stressed countries, because it takes roughly 1000 tons of water to produce one ton of wheat. Essentially, importing wheat is a surrogate for importing water, and farmers in other countries that are motivated by the increased world demand for wheat will grow wheat even if they have to pump fossil water to do it.

Fossil aquifers are often accidentally found when drilling for gas and oil, or when communities run out of surface and shallow groundwater supplies and begin exploring for deeper water. Water discovered when drilling for gas and oil has no exploration costs or risks to future water users, because the costs are already borne by the oil exploration. However, when new wells are sunk only to search for fossil water, costs are relatively high because there is no fossil fuel subsidy and some test wells come up dry.

Regions around the world have various reasons to turn to fossil aquifers for more water. Growing populations increase demand for potable water to provide at least the subsistence amounts of water that individuals need. If these populations migrate to cities in search of work, they create an increased localized water demand that may not be satisfied by current water supplies. These growing populations must also be fed, raising demand for agricultural production that requires irrigation water. As 85% of the world's fresh water is used for irrigation, inefficient irrigation methods used in developing countries waste a good deal of their available water. Countries that are recently industrializing also need more water for each new industry that comes online.

New water supplies are also needed when traditional water supplies have become polluted from sewage or industrial effluent. This polluted water essentially removes some accessible water from consideration as a potable water source. For example, in China, there are several rivers whose water is so polluted from industrial waste that the water is dangerous to touch. The famous Ganges River in India is so filled with untreated sewage that its bacterial counts are dangerously high. Some aquifers in India have become so polluted from pesticides that they can no longer be used for drinking water.

INTERNATIONAL EXAMPLES

Developing countries with dry regions, such as China, India, and Mexico, have overpumped their shallow aquifers and have sunk deeper wells to access fossil water. In China's Northern Plain, water tables have dropped 2–3 m per year in some areas (2). Water tables in the agricultural state of Guanajuato, Mexico, have dropped up to 3.3 m/yr. In various regions of India, water tables have fallen from 1 to 3 m/yr.

Countries in the arid climates of northern Africa and the Middle East have been pumping from fossil aquifers for years. Iran, Pakistan, Saudi Arabia, Yemen, Algeria, and Libya, among others, have been relying on these aquifers to provide more potable water that does not cost quite as much as desalinized water. To develop some food independence, Saudi Arabia has used fossil aquifers to support experimental wheat growing in the desert but is now dropping this program after finding it is more practical to import their wheat. Soon, the desert alfalfa fields will also be gone, which will decrease the experimental projects for raising their own milk cows. Sana'a, the capital of Yemen, relies on a fossil aquifer that will run out by 2010, forcing either a mass migration (unlikely) or constructing desalting plants to supply their two million residents. Libya has its famous $27 billion "Great Manmade River," a massive pumping and distribution project to transport fossil water from the Nubian aquifer, underlying Libya, Chad, Egypt, and Sudan, to Libyan cities on the Mediterranean coast (3). This aquifer is large enough to provide Libyans with water for over 100 years, but most of these other countries are using aquifers with a life of perhaps 10–30 years more.

Just as shared shallow aquifers have been sources of conflict between users, pumping from fossil aquifers can generate competition and conflict as well. As more countries move to access fossil aquifers, agreements between countries will have to be crafted to avoid such conflict. Aside from the Nubian aquifer (4) mentioned above, South Africa, Namibia, and Botswana share the Kalahari/Karoo aquifer, and Argentina, Brazil, Paraguay, and Uruguay share the Guarani aquifer. All are looking at how to exploit this resource.

AMERICAN EXAMPLES

In America, two good examples of fossil aquifers are the Ogallala, underlying several states, and numerous smaller aquifers in the dry Southwest. The Ogallala, which consists primarily of fossil water, is shared by eight states where water tables have dropped 100 ft in some areas. This overpumping was primarily driven by irrigation demands. Some areas have been overpumped to the point that deeper drilling has stopped once it becomes economically infeasible, which has caused a depopulation of some High Plains counties as farms go out of business and then towns lose the service jobs that supported the farmers.

The increasing use and/or hunt for fossil aquifers in pockets of the American Southwest has been driven by recent population migration to these warmer cities. Growing cities in arid regions create inevitable water crises. As demand increases and water supply decreases, these cities must either use their current sources more efficiently or continue to hunt for "new" water in competition with other cities doing the same. Reluctant to impose onerous restrictions on residents or scare off industries, these cities then turn to fossil water once surface sources and shallow groundwater sources are fully tapped, often at the expense of other communities. Las Vegas is the most infamous example, as it is now planning to pump fossil water from 28 sparsely populated basins to its west and north and transport this water through pipelines to the city (5).

Globally, more fossil water is being pumped every day. This water is important not so much as an interesting link to the past or a particular challenge to hydrogeologists, but because increasing reliance on these ancient waters in rich and poor countries alike portends an abrupt halt to regional and national economies when the pumps finally run dry.

WHAT IS A HYDROCHEMICAL MODEL?

Kung-Yao Lee
Thomas R. Fisher
Horn Point
Laboratory—UMCES
Solomons, Maryland

INTRODUCTION

A hydrochemical model is a set of mathematical algorithms that calculate water discharge ("hydro") and concentrations of sediment and chemical constituents ("chemical") in a stream or river. The computations are based on adjustable, empirical, or theoretical variables (parameters) and meteorological data for the drainage basin of the river or stream (input data). A variety of hydrochemical models have been employed by researchers, engineers, and environmental planners to predict hydrochemical responses in areas where there are no measurements or in areas where measurements are available but under different management scenarios. In general, a hydrochemical model is calibrated (adjusted to fit) with a set of observations, validated (tested for errors) with a set of reserved observations, and then applied to future or past conditions (forecasting or hindcasting, respectively) to predict watershed responses. From an environmental perspective, a hydrochemical model is a tool to investigate the effects of watershed management (e.g., changes of land use or land cover, human population, etc.) on the hydrology and chemistry of a stream or river.

Generally speaking, a hydrochemical model comprises three simulation submodels (compartments or blocks). Here we use “submodel” to represent a smaller unit or component of a hydrochemical model, and the three major submodels are generally responsible for computing (1) hydrology, (2) soil erosion, and (3) nutrient or metal geochemistry within the drainage basin.

The first submodel estimates the hydrology. This submodel partitions rainfall into physical evaporation, transpiration by plants, surface storage (puddles), overland flow during storms (runoff), and groundwater recharge because of infiltration during storms. Water storage in groundwater slowly flows to streams, creating stream flow (baseflow) between rain events, and overland flow during storms creates stormflow (see Fig. 1). Streamflow is the sum of storm and base flows and is usually integrated over a storm event or a fixed time period such as a day, month, or year.

The hydrology submodel is usually accompanied by an erosion submodel. This model component simulates the export of soil eroded by overland flow generated in the hydrology submodel. The rate of soil erosion is often based on the U.S. Department of Agriculture’s universal soil loss equation (USLE), which uses basin characteristics such as vegetation cover, slope angle and length, cultivation practices, and soil properties such as particle size and density.

Additional geochemical submodels are responsible for the simulation of chemical constituents, which are nutrients such as N, P, or Si, or metals such as Fe, Al, Pb, and so on, from both natural and anthropogenic (manmade) sources. Within the geochemical submodel, these chemical constituents are transported with sediment or in the water flows that are simulated in the first submodel. Despite important differences between hydrochemical models, it is important to realize that the modeling principles developed in a variety of hydrochemical models are similar (2); i.e., the hydrology submodel is developed first and then followed by erosional and geochemical submodels.

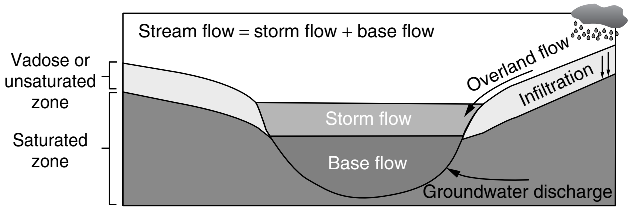

Figure 1. Simplified concept of the hydrological cycle used in hydrochemical models. Stream flow is the sum of storm flow and base flow, as used in GWLF (1) as well as in other models. However, some models may adopt different modeling approaches that differ from this illustration.

Numerous hydrochemical models are freely available. Many can be downloaded from websites or can be requested from the model developers. In Table 1, we list some commonly used hydrochemical models. Each hydrochemical model has its specific designs and limitations, such as model time step (minimum temporal resolution), number of parameters required (internal complexity), or input requirements. For detailed comparisons between these models, see Donigian and Huber (12). Because all models require at least some data input, many hydrochemical models have been ported from their original code (e.g., Fortran or Visual Basic) to more user-friendly windows applications for better visualization or to integrate with a geographic information system (GIS), which provides advanced computing power to manipulate data as subsequent input for the models (see 13–17).

PROPERTIES OF HYDROCHEMICAL MODELS

Hydrochemical models generally can be categorized as lumped-parameter and distributed models. A lumped-parameter model simplifies the watershed properties and ignores the spatial heterogeneity and distributions of these properties, using only the average watershed properties (see 18,19). Although a lumped-parameter model can efficiently generate simulation results, model users cannot spatially identify the locations where problems (e.g., nutrient or metal sources) occur. However, lumped-parameter models linked with a GIS may be applied in spatially contiguous polygons to provide some spatial resolution within a larger watershed (e.g., 15). Conversely, a distributed model can explicitly represent the spatial effects of topography or the spatial variations of properties within a watershed to locate sources; however, a distributed model requires more computer resources because of more intensive computation and more extensive data requirements.

As discussed earlier, a hydrochemical model can be designed either for long-term predictions or as an event simulation tool (or both). Time series of weather data (hourly or daily) are usually required for continuous simulation at hourly, daily, or monthly time steps. Models that predict at longer time steps ($\geq$ monthly; e.g., GWLF) do not resolve individual hydrographs (stream responses to individual storm events; see Fig. 2), whereas models used with shorter time steps (e.g., HSPF) attempt to predict both the timing and magnitude of a watershed’s response to a rain event. The storm usually occurs over hours to days, whereas the watershed response is usually days to weeks, depending on the size of the watershed. Other models (e.g., ANSWERS and AGNPS—earlier versions) have

Table 1. Hydrochemical Models Commonly Used in Watershed Ecology. Figure 2. A hydrograph in response to a storm event that started to occur on 4/26/2004 at the Norwick Creek subwatershed of the Choptank River basin, Maryland. Note that precipitation (cm) was recorded on the daily basis (upper panel), whereas water depth (cm) at the watershed outlet was measured at a 30-min interval (lower panel). Data were compiled from Sutton (20).

been developed for the explicit purpose of predicting short-term hydrograph events such as the observations in Fig. 2.

PARAMETERIZATION OF THE HYDROCHEMICAL MODEL

A hydrochemical model generates a time series of predicted data for a time span defined by the user. To assess the accuracy and precision of the model's behavior, model output is compared on a daily, monthly, or annual basis with observed measurements. Comparisons between model output and model simulations are usually expressed in charts, bar graphs, or as tabular values to assess the model's accuracy (average ability to predict the observations without positive or negative bias, i.e., without underprediction or overprediction over a time interval) and precision (ability to reproduce the observations without scatter). These are often quantified as the cumulative model error over a given time period (model accuracy, e.g., ability to predict the observed annual stream flow for a given year) and root-mean-square (RMS) error at a given time scale (model precision, e.g., the deviations of modeled and observed stream flow at the defined time step). During calibration, model parameters are adjusted to minimize RMS or cumulative errors between the predicted and observed values, and the success of a calibration is then quantified by validation with an independent dataset not used during calibration.

The first comparison of a model's performance is called "Model Calibration." During this process, parameters are adjusted within reasonable ranges to minimize model errors. Model calibration often is a cyclical (21) and time-consuming process to adjust parameter values, although some optimization computer programs are available to automatically calibrate for the most suitable parameters. For example, HSPFEXP is an expert system that can be linked to HSPF to optimize the hydrology parameters (22). Monte Carlo methods (23) can perform statistical probability analyses to obtain the optimal values of variables. The parameter estimation software PEST (24) can also be linked to any existing model for parameter calibration. Despite different approaches to optimize the parameters, it is important to constrain the ranges of model parameters within reported values (14) during model calibration.

The second comparison of model performance is called "Model Verification" or "Model Validation." This process uses the calibrated model parameters with a different set of meteorological data not used in model calibration. In this phase, a similar set of statistical analyses is generated that set the limits of interpretation of model predictions and to investigate the model's ability to simulate natural conditions (25). For example, if validation RMS errors at the daily time scale are ±100%, then only model predictions exceeding this threshold can be considered significantly different. Model verification ensures the validity of calibrated model parameters under the current conditions, and to confirm that the model can predict the stream hydrology and chemistry under different scenarios. Model validation errors are typically large at short time scales (hours-days) and become both more accurate and more precise at longer times scales (years-decades); i.e., it is easier to predict the cumulative discharge or material flux for a given year than it is to predict the daily flow or flux.

MODELING AND REALITY

In most cases, a well-calibrated hydrochemical model can predict water flows and chemistry in situations where no data exist. It is important, however, to remember that models sometimes do not predict well in some areas or under some conditions because model parameters may be difficult to measure (26) or because the model was developed under experimental conditions or with dominant processes that may not fully represent all other cases (27). In this case, a model's predicting performances are substantially affected by these factors when applied elsewhere. For example, AGNPS and ANSWERS are limited to watershed size <200 km^2, whereas SWRRB can be applied to much larger areas (9). In other words, model parameters are often designed for particular geographical areas or watershed sizes. The alpine hydrochemical model (AHM) was, for example, originally developed for the hydrologic and biogeochemical responses of seasonally snow-covered alpine areas (28), and SWMM was mainly designed to perform predictions in urbanized areas, although both can be used elsewhere.

To simplify the natural processes, hydrochemical models often possess unique assumptions. Assumptions may be based on field observations (29) and/or empirically derived functions to simplify the response processes. For example, the Soil Conversation Service (SCS) Curve Number (30) computes direct surface runoff merely based on land use and soil information, which has empirically simplified the estimation of other processes such as interception, depression storage, and infiltration (31). Because of its simplicity, the SCS CN method has been adopted to most hydrochemical models (marked * in Table 1). However, these processes may need to be parameterized for some models, such as HSPF and SWMM.

When rain infiltrates the soil, models often incorporate other empirical assumptions and simplifications borrowed from observations. For example, the soil column above the water table can be separated into two layers—unsaturated and saturated layers (e.g., GWLF). The disadvantage of this simplified approach is reduced model flexibility when applied to other areas. Conversely, SWIM (14) divides the root zone vertically into as many as 10 layers, which increases the model flexibility when applied elsewhere. However, these models require more model variables and intensive input data.

Furthermore, it is often seen that a fixed value is used for a variable throughout all modeling tasks. For example, both GWLF and SWMM use constant values for concentrations of groundwater chemical constituents (e.g., N and P) associated with each land use because both models assume that there are no geochemical interactions for the chemical constituents in the subsurface flow. Also models often assume that the observed chemical measurements in a stream or river have promptly responded to the geochemical reactions that occur in the soil or in the groundwater during a storm event, which is usually not true because groundwater may take years to decades to become the baseflow of streams, and important geochemical reactions may occur at this time scale (29).

Hence, hydrochemical models because of model assumptions and simplifications inevitably produce prediction errors. Those errors are intensified and transferred from the hydrology submodel to the subsequent submodels, which results in decreasing reliability in predictions (32). Therefore, it is important to understand the model assumptions and limitations, and to evaluate the strength and weakness of each hydrochemical model before use in each situation (33).

NON-POINT SOURCE POLLUTION: DEFINITION, SOURCES, SIGNIFICANCE, GLOBAL IMPACT, AND JUSTIFICATION FOR MODELING

Non-point source (NPS) pollutants are defined as "contaminants of [air, and] surface and subsurface soil and water resources that are diffuse in nature and cannot be traced to a point location" (1). Characteristically, NPS pollutants (1) are difficult or impossible to trace to a source; (2) enter the environment over an extensive area; (3) are related, at least in part, to certain uncontrollable meteorological events, and existing geographic and geomorphologic conditions; (4) have the potential for maintaining a relatively long active presence in the global ecosystem; and (5) may result in long-term, chronic effects on human health, and soil-aquatic degradation (2). The most common global NPS pollutants of soil and groundwater resources include biosolids and manure, persistent organic pollutants (POPs), nutrients (e.g., nitrates and phosphates), salinity, toxic heavy metals (e.g., Bi, Co, Sn, Te, Ag, Pt, Tl, Sb, Hg, As, Cd, Pb, Cr, Ni), trace elements (e.g., Se, B, Mo, Cu, Zn), and pathogens.

Often, NPS pollutants occur naturally, such as salts and trace elements in soils, or are the consequence of direct application by humans (e.g., pesticides and fertilizers), but regardless of their source, they are generally the direct consequence of human activities including agriculture, urban runoff, feedlots, hydromodification, and resource extraction (2). Specific sources of NPS pollutants include (1) excess fertilizers, herbicides, and insecticides from agricultural lands and residential areas; (2) oil, grease, and toxic chemicals from urban runoff and energy production; (3) sediment from improperly managed construction sites, crop and forest lands, and eroding stream banks; (4) naturally occurring salts and trace elements from irrigation practices; (5) acid drainage from abandoned mines; (6) pathogens (i.e., viruses and bacteria) and nutrients from livestock, and pet wastes; and (7) atmospheric deposition (2).

The significance of NPS pollutants as an environmental issue stems from their potential global impact and resultant chronic effects on human health. Because of their widespread use and often persistent and mobile nature, NPS pollutants have the capacity not only to injure the surrounding environment and ourselves, but also remote environments and their inhabitants (like the Arctic) and future generations of humans through the buildup of persistent toxic substances that mimic and disrupt human hormone systems (3). The impact of NPS pollutants on soil and water resources extends over millions of hectares of land and billions of liters of water. Throughout the world, 30% to 50% of Earth's land is believed to be affected by NPS pollutant degradation from erosion, fertilizers, pesticides, organic manures, and sewage sludge (4). Worldwide, NPS pollutants are recognized as *the* major contributors to surface and groundwater contamination (5), with agriculture as the single greatest contributor of NPS pollutants (6). Agricultural activities result in the movement of NPS pollutants from the soil surface into rivers and streams via runoff and erosion, and into subsurface soil and groundwater via leaching through the vadose zone (i.e., the portion of the soil extending from the soil surface to the groundwater table). Figure 1 reflects the worldwide extent of human-induced degradation of soil by region and by cause over the period 1945 to the late 1980s.

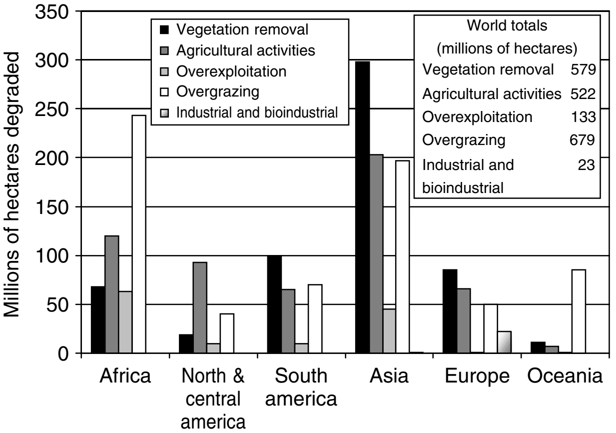

Figure 1. Human-induced soil degradation by region and by cause from 1945 to the late 1980s. *Source:* Ref. 7. With permission.

The world's population has doubled since 1950 and is expected to range from 8 to 12 billion in 2050. Barring unexpected technological breakthroughs, sustainable agriculture is viewed as the most viable means of meeting the food demands of the projected world's population. The concept of sustainable agriculture is predicated on a delicate balance of maximizing crop productivity and maintaining economic stability while minimizing the utilization of finite natural resources and the detrimental environmental impacts of associated NPS pollutants. Assessment of NPS pollutant impacts on soil-groundwater systems at local, regional, and global scales is a key component to achieving sustainable agriculture. Assessment provides the means (1) to establish the true extent of the NPS-pollution problem, (2) to evaluate mitigating management practices and regulatory policies, and (3) to predict future potential problems. The distinct advantage of prediction is that it can alter the occurrence of detrimental conditions before they occur. The reasons for modeling NPS pollutants in the vadose zone are (1) to increase the understanding of cause-and-effect relationships of spatiotemporal processes occurring in soil systems and (2) to provide a cost-effective means of synthesizing the current level of knowledge into a useable form for making environmental policy decisions (8,9).

MULTIDISCIPLINARY NATURE OF MODELING NPS POLLUTANTS IN THE VADOSE ZONE

Modeling NPS pollutants in the vadose zone is a complex environmental problem that requires a multidisciplinary, systems-based approach taken within a spatial context with an awareness of scale (10). The formidable barriers to modeling NPS pollutants are the consequence of the complexities of geographic scale and position; the complexities of the physical, chemical, and biological processes of solute transport in porous media; and the spatial complexities of the soil media's heterogeneity. The knowledge, information, and technology needed to address each of these issues crosses several subdisciplinary lines, including classic and spatial statistics, remote sensing, geographic information systems (GIS), surface and subsurface hydrology, soil science, and space science. Spatial statistics is useful in dealing with the uncertainty and variability of spatial information (11); remote sensing provides measurements of physical, chemical, and biological properties needed in environmental models (12); GIS is a means of organizing, manipulating, storing, and displaying spatial data (13); and water flow and solute transport models developed within soil science and hydrogeology are the tools for simulating future scenarios to assess potential temporal and spatial changes (2,14). Precise geographic location and areal extent are captured with the space science technology of the global positioning system (GPS).

COMPONENTS OF A NPS POLLUTANT MODEL

Modeling the fate and movement of NPS pollutants in the vadose zone is a spatial problem well suited for the integration of a deterministic solute transport model with a GIS. A GIS characteristically provides a means of representing the real world through integrated layers of constituent spatial information. To model NPS pollution within the context of a GIS, each transport parameter or variable of the deterministic transport model is represented by a three-dimensional layer of spatial information. The three-dimensional spatial distribution of each transport parameter/variable must be simulated, measured, or estimated, which creates a tremendous volume of spatial information because of the complex spatial heterogeneity exhibited by the numerous physical, chemical, and biological processes involved in solute transport through the vadose zone. GIS serves as the tool for organizing, manipulating, and visually displaying this information efficiently.

The essential components of modeling NPS pollutants consist of (1) a *model* of solute transport and/or accumulation, (2) input and parameter *dat*a for the model, and (3) a *GIS* to handle the input, manipulation, and output of spatial data. Figure 2 shows the interaction among these three basic components based on flow of information.

Because of the complex spatial heterogeneity of the vadose zone, a variety of sophisticated techniques are useful as tools to deal with the vicissitudes of soil (Fig. 2). Fuzzy logic theory provides a means of handling vague and imprecise data whether as a means to characterize map units or transitional boundaries between map units (16,17). Fractal geometry with its scale independence may offer a means of bridging a variety of gaps related to spatial variability from determining the predictability of complex spatial phenomena such as solute transport to relating difficult-to-measure soil hydraulic properties to other soil variables available from soil surveys (18). Geostatistics is useful in interpolating sparse spatial data and providing associated uncertainty (19). Hierarchical theory establishes an organizational hierarchy of pedogenetic modeling approaches and their appropriate scale of application (20,21). Wavelet analysis provides a means of determining spatial scales and the dominant processes at those scales (22,23). Neural networks and transfer functions provide a means of deriving complex hydraulic parameters from easily measured data (24). Digital terrain or digital elevation models (DEM) provide spatial geomorphologic information. Uncertainty analysis serves as a means of establishing the reliability of simulated model results based on model errors and data uncertainties (25).

Data

The effectiveness of a model to simulate a practical application is highly dependent on how well model inputs and model parameters are identified. Basically, three sources of input and parameter data for NPS pollutant models exist (15): (1) measured data, (2) estimated data, and (3) existing data. Each source of data carries distinct advantages and limitations.

A review of current measurement techniques to determine flow-related properties of subsurface porous media and soil physical properties is provided by Dane and Molz (26) and Topp et al. (27), respectively. Although direct measurement of transport parameters and variables is the most reliable means of obtaining accurate information for modeling purposes, it is also the most labor intensive and costly. A quick and easy means of obtaining these measurements is crucial to the cost-effective modeling of NPS pollutants. Remote sensing and noninvasive measurement techniques have the greatest potential for meeting the thirst for measured spatial data.

Corwin (28) provided a cursory review of some instrumental techniques developed for the remote and noninvasive measurement of variables and parameters found in transport models for the vadose zone. The review covers geophysical resistivity methods, aerial photography, x-ray tomography, ground-penetrating radar, magnetic resonance imaging, microwaves, multispectral imagery, thermal infrared imagery, and advanced very-high-resolution radiometry (AVHRR). Barnes et al. (12) provided a more

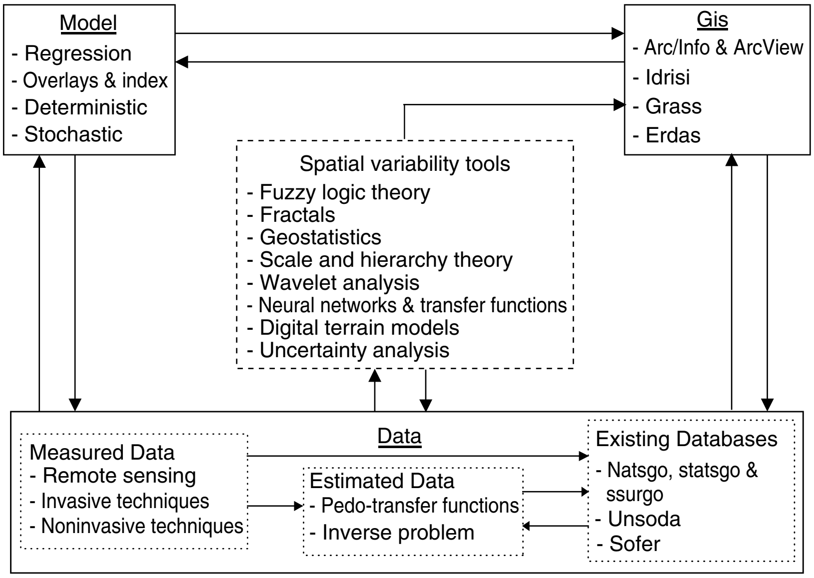

Figure 2. Integrated components of a GIS-based NPS pollutant model system. Arrows show the flow of information. Modified from Ref. 15. With permission.

recent review of remote- and ground-based sensor technology for mapping soil properties.

Even though considerable progress has been made over the past decade, the remote sensing instrumentation needed to measure *all* parameters and variables in even the simplest of transport models, for the vadose zone is not available or even on the drawing board. In most cases, remote sensing provides measurements of only the top few centimeters; consequently, it suffers from a lack *of depth information* needed in modeling the vadose zone. Noninvasive techniques such as electromagnetic induction (EMI) can provide information down to several meters in depth, but these techniques generally require measurements taken at or near the soil surface and their measurement volume is limited to tens of cubic meters or less. Nevertheless, geospatial measurements of apparent soil electrical conductivity (EC_a) with EMI is currently the most widespread and reliable means of characterizing the spatial variability of a variety of physicochemical properties in the vadose zone including salinity, texture, water content, cation exchange capacity (CEC), organic matter (OM), and bulk density (29). Furthermore, in most cases, the parameters measured by remote sensing and noninvasive techniques are often not directly applicable to solute transport models. For instance, the use of EMI to measure soil salinity is not a direct measure of salinity in the soil solution, but rather it measures EC_a, which includes the conductivity of both the solid and liquid phases, thereby requiring ground-truth soil samples for calibration.

The extreme spatiotemporal variability and the nonlinearity of many soil processes make parameterization of landscape-scale models a daunting task. The inability of remote measurement techniques to meet the demand for spatial and temporal parameter and input data has resulted in the development of transport parameter estimation techniques that estimate parameters by fitting data or are based on the formulation of transfer functions. Inverse modeling is a powerful and practical means of estimating flow and transport parameters for landscape-scale solute transport models using advanced optimization algorithms. Transfer functions relate readily-available and easy-to-measure soil properties to more complex transport variables/parameters needed for simulation.

Corwin et al. (15) provide a referenced list of the estimation methods for many common parameters in solute transport models of the vadose zone. The most common transfer function, the pedo-transfer function (PTF), uses particle-size distribution, bulk density, and soil organic-carbon content to yield soil-water retention or unsaturated hydraulic conductivity functions. Rawls et al. (30) provide a review of soil-water retention estimation methods. Reviews of methods of estimating soil hydraulic parameters for unsaturated soils have been written by van Genuchten et al. (31).

In most instances, limited resources do not permit the measurement or even estimation of needed input or parameter data. In these instances, the use of existing data is crucial. Existing soil databases for the United States include SSURGO (State Survey Geographical Database; http://www.ncg.nrcs.usda.gov/ssurgo.html), STATSGO (State Soil Geographical Database; http://www.ncg.nrcs.usda.gov/statsgo.html), and NATSGO (National Soil Geographical Database; http://www.ncg.nrcs.usda.gov/natsgo.html). SSURGO (map scale ranges from 1:12,000 to 1:63,360) is a county-level database, and it is the most detailed GIS database available from NRCS. STATSGO (map scale 1:250,000) is the state-level database designed for state, large watershed, and small river basin purposes. NATSGO (map scale 1:7,500,000) is the national soil database whose map units are defined by major land resource area (MLRA) and land resource region (LRR) boundaries.

The problem with the use of generalized rather than measured data has been associated uncertainties. Loague et al. (32) extensively reviewed the uncertainty associated with the use of an existing database for non-point source groundwater vulnerability and concluded that assessments based on this type of data are relegated to guiding data collection strategies rather than their intended purpose of groundwater vulnerability assessment. Measured input data that captures natural variability both in space and time is essential for diminishing uncertainty in simulations.

GIS

A GIS is defined by Goodchild (33) as a "general-purpose technology for handling geographic data in digital form with the following capabilities: (i) the ability to preprocess data from large stores into a form suitable for analysis (reformatting, change of projection, resampling, and generalization), (ii) direct support for analysis and modeling, and (iii) postprocessing of results (reformatting, tabulation, report generation, and mapping)." In the context of NPS pollutant modeling, a GIS is a tool that characterizes the full information content of the spatially variable data required by solute transport models. The advantages of GIS include (1) ease of data retrieval; (2) ability to discover and display information gained by testing interactions between phenomena; (3) ability to synthesize large amounts of data for spatial examination; (4) ability to make scale and projection changes, remove distortions, and perform coordinate rotation and translation; and (5) capability to discover and display spatial relationships through the application of empirical and statistical models (34). The principal benefit of coupling GIS to subsurface hydrologic models is to enable the models to deal with large volumes of spatial data that geographically anchor many environmental processes.

Model

A review of GIS-based NPS pollutant modeling in the vadose zone has been presented by Corwin et al. (15). To date, most models of NPS pollutants in the vadose zone have used deterministic models of solute transport coupled to a GIS (15,28). However, a growing recognition exists that stochastic approaches may offer the most viable means of modeling an NPS pollution (35).

The use of deterministic transport models with GIS has been justified on practical grounds based on availability, usability, widespread acceptance, and the assumption that a heterogeneous medium macroscopically behaves like a homogeneous medium with properly determined parameters and variables. The philosophy of modeling NPS pollutants in the vadose zone with a one-dimensional deterministic model of solute transport is based on the representation of physical, chemical, and biological properties influencing transport in the vadose zone with a distributed parameter structure. The validity of the assumption that a heterogeneous medium macroscopically behaves like a homogeneous medium depends on whether spatial domains can be defined and characterized that behave as stream tubes or “representative element volumes” (REV).

Three categories of deterministic models have been coupled to GIS to simulate NPS pollution in the vadose zone: regression models, overlay and index models, and transient-state solute transport models (15). Regression models have generally used multiple linear regression techniques to relate various causative factors to the presence of an NPS pollutant. These causative factors have included soil properties or conditions related to groundwater vulnerability or to the accumulation of a solute in the soil root zone. Overlay and index models refer to those models that compute an index of NPS pollutant mobility from a simple functional model of steady-state solute transport. Two types of overlay and index models have been developed: property-based and process-based. Property-based index models are established on a hydrogeologic setting (e.g., DRASTIC) or NPS pollutant properties (e.g., GUS). Process-based index models are founded on the characterization of transport processes (e.g., Rao’s attenuation factor model). Overlay and index models have been used largely to assess groundwater pollution vulnerability to pesticides and nitrates. Transient-state, process-based solute transport models include deterministic models capable of handling the movement of a pollutant in a dynamic flow system. Transient-state, process-based models describe some or all of the processes involved in solute transport in the vadose zone: water flow, solute transport, chemical reactions (adsorption-desorption, exchange, dissolution, precipitation, etc.), root growth, plant-water uptake, vapor phase flow, degradation, and dispersion/diffusion.

Jury (36) pointed out that the difficulty of constructing a three-dimensional model of chemical transport as a consequence of field variability has two significant implications: (1) Any hope of attempting to estimate a continuous spatial pattern of chemical transport must be abandoned; and (2) a possibility exists of extreme deviations from average movement so that significant concentrations of chemical may flow within relatively small fractions of the total cross-sectional area, which may be nearly impossible to detect from point measurements. The latter implication has fostered the development of stochastic solute transport models for the vadose zone as opposed to deterministic models.

Two distinct stochastic approaches are currently in use for dealing with the spatial variability encountered in modeling NPS pollutants in the vadose zone: geometric scaling and regionalized variables. Jury (36) indicates that geometric scaling uses specific “standardized variables to scale the differential equations describing transport and relates the standardized variables to some measurable or definable property of each local site of a heterogeneous field.” Once the variables are defined, the onerous task of characterizing the variability is reduced to determining the statistical and spatial distribution of these scaling parameters. In contrast, Jury (36) explains that the regionalized variable approach regards the “various parameters relevant to a field-wide description of transport as random variables characterized by a mean value and a randomly fluctuating stochastic component.”

In comparison with deterministic models, the coupling of a stochastic solute transport model to GIS is less explored. In a paper discussing the potential compatibility of stochastic transport models with GIS, Jury (35) suggested that stochastic-convective stream tube modeling seems the most compatible with GIS because it “utilizes a relatively simple local process driven by parameters that might be associated with soil morphological features, and could be integrated up to a large scale by simple arithmetic averaging over the local sites.” A stochastic stream tube model is made up of parallel, noninteracting one-dimensional soil columns whose properties are locally homogeneous, but vary from one soil column to the next. The collection of all stream tubes constitutes the field-, basin-, or regional-scale area being represented. This approach is in essence the same approach that has been undertaken in the past where deterministic piston-flow local transport models have been coupled to soil survey information; only now there is an associated stochastic component of information. Jury (35) warns that the challenge of this approach will be “to develop a reasonable local-scale model whose parameters can be related to identifiable local-scale features.”

CONSIDERATION OF SCALE WHEN MODELING NPS POLLUTANTS

Scale, as used in soil science and hydrology, refers to the “characteristic length in the spatial domain” and to the “characteristic time interval in the temporal domain” (37). So, even though space and time are continuous, only a discrete set of scales is of interest based on specific features that make them of particular use or interest (37). The existence of a hierarchy of scales has been postulated to relate to spatial or temporal features of systems of interest (see Fig. 3).

Temporal and spatial scales dictate the general type of model. The consideration of scale in model development requires observed information for the real system being modeled at the spatial and temporal scales of interest, which is to say that microscopic-scale models developed in the laboratory are not appropriate for macroscopic-scale applications, and vise versa.

Models of solute transport in the vadose zone exist at all scales. A hierarchical depiction of the scales from molecular to global showing the relationship between scale and model type is depicted in Fig. 3. An important consideration in model conceptualization is for the model to account for the predominant processes occurring at the

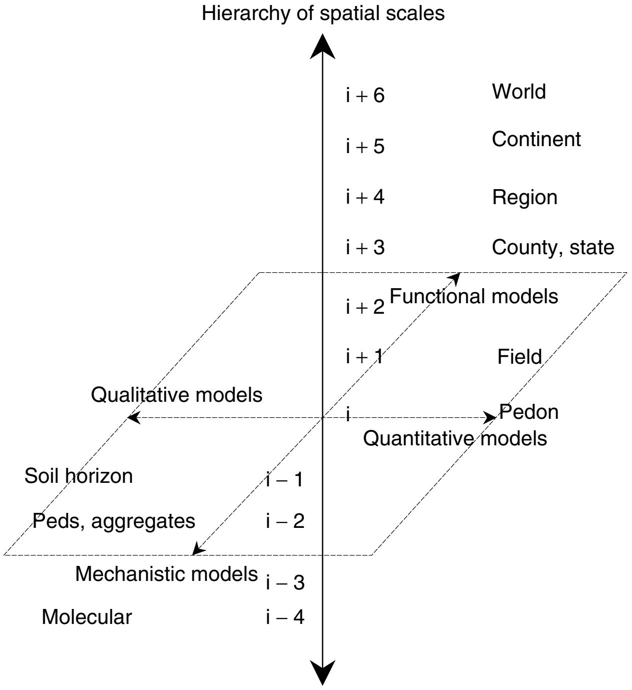

Figure 3. Organizational hierarchy of spatial scales pertinent to NPS pollutant models. *Source:* Ref. 21. With permission.

spatial and temporal scales of interest, which complies with the guideline of parsimony. Qualitatively speaking, as spatial scale increases, the complex local patterns of solute transport are attenuated and dominated by macroscale characteristics. For this reason, mechanistic models are used more frequently at the (i) to (i − 4) scales, whereas functional models are more often applied to scales ranging from (i + 1) to (i + 6). The stochastic application of deterministic models is found at the (i + 1) scale, and stochastic models generally are used at (i + 1) and (i + 2) scales. Statistical models are applied most often at the larger scales, (i + 3) to (i + 6).

The relevance of temporal domain is also a consideration not to be overlooked. Larger spatial scales appear more constant because the rapid dynamics of the lower scales are disregarded (20). For this reason, time steps of functional models can expand over days, such as the time between irrigation or precipitation events, whereas the time steps of mechanistic models characteristically extend over minutes.

The integration of solute transport models of the vadose zone into a GIS provides the ability to dynamically describe NPS pollutant transport at a range of spatial scales allowing the user to rapidly scale "up" and "down." However, this integration introduces incompatibilities between the model and data and raises basic questions regarding (1) the compatibility of the model with input and validation data, and (2) the relevance of the model to the applied spatial scale. Wagenet and Hutson (38) addressed the issue of scale dependency and proposed three scale-related factors to consider when applying GIS-based solute transport models to the simulation of NPS pollutants in soils: (1) the type of model (i.e., functional or mechanistic) must consider the scale of application, and the nature of the available data at that scale; (2) sampling and measurement of input and validation data must be spatially consistent with the model; and (3) measurement and monitoring methods must be relevant at the temporal domain being modeled.

FUTURE DIRECTION

Beven (39) asserts that the real constraint on predictability by landscape-scale environmental models is not the detail of the model structure, but rather the ability to spatially and temporally characterize the variability of model inputs and parameters. Among the various techniques for characterizing the spatial variability of model inputs (e.g., electromagnetic induction, ground penetrating radar, time domain reflectometry, remote imagery, etc.), electromagnetic induction will be the most useful in the short term (29), whereas greater future potential exists for hyperspectral imagery, which is in its infancy for soil and plant science applications.

INTRODUCTION

Groundwater constitutes an important component of water supply systems for domestic use, industry, and agriculture. Due to increased use regularly above sustainable levels, groundwater quality often deteriorates. Contaminants in groundwater systems are introduced by hazardous industrial wastes, leachate from landfills, oil spills, agricultural activities, sites of radioactive waste repositories, and other sources. In most cases, the source of contamination is aboveground, and the contaminants pass through the unsaturated zone on their way to the saturated region.

The fundamental processes that govern solute mobility in groundwater have been studied and reasonably well understood for some time. Solute migration results from a variety of coupled physical, chemical, and biological processes. Owing to the complexities of natural soils and solute–soil–fluid interactions and frequently changing field conditions, modeling solute transport involves some degree of approximation. However, the modeling framework must retain the important aspects of real phenomena. It is also necessary for a reliable/realistic model to answer several relevant questions, such as, what is the purpose of the predictive calculations, what types of environments can be modeled, what level of precision is expected, and what are the advantages and disadvantages of the developed approach. To answer these questions while developing a model for solute movement in the subsurface, many issues must be considered. Table 1 presents some examples of such issues.

Soil is a porous medium, composed of solid and void sections (Fig. 1). The void portion that forms the *effective pore space* is made up of many interconnected channels through which fluid convection takes place. The usual way of modeling solute transport in soil has been to adopt a macroscopic approach where the flow variables are averaged over a *representative elementary volume* (REV) or *representative elementary area* (REA), depending on the dimensionality of the problem domain (1–3). The length scales of REV and REA are selected so that they represent soil heterogeneity. They are much larger than the pore scale but much smaller than the main physical domain. They are determined under the assumption that the solid matrix is distributed uniformly throughout the porous medium domain and is present in each REV or REA. Furthermore, it is assumed that the specific surface of the solid matrix is larger than that of the void portion in a REV or REA.

Convection of a solute in soil takes place due to fluid movement through its pores. As this transport occurs, in most cases, the carrier fluid is a multiphase/multifluid medium (a mixture) that can be miscible or immiscible. If two or more miscible fluids occupy the void space, even if they occupy different regions in the domain initially, they ultimately produce a multicomponent mixture due to gradients (e.g., diffusive and dispersive effects) prevailing over the fluid components. In the case of immiscible fluid flow, distinct layers are observed and interphase mass transfer among the fluid components takes place. Therefore, modeling immiscible multifluid convection of a solute requires more rigorous approaches. Models of single-phase flow can be considered a limiting case of multiphase flow phenomena. The main interest in a single-phase model lies in its simplicity and the methods developed for it which can be extended to multiphase transport mechanisms. Greenkorn (4) and Nield and Bejan (5) have given good descriptions of multicomponent, multiphase flow through porous media. Numerous other studies have also been devoted to modeling two-phase (the simplest multiphase case) or multiphase flow phenomena in soil/porous media (6–9).

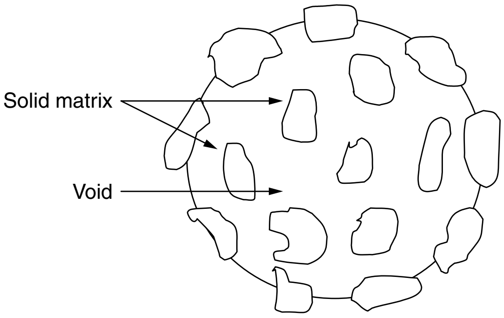

Figure 1. A representative elementary volume (REV) showing solid and void matrices in a porous medium.

Good management of water resources requires the ability to forecast the response of the managed system, for example, an aquifer, to planned operations such as pumping, recharging, and controlling conditions at aquifer boundaries. Any planning of mitigation, cleanup, or control measures requires forecasting the path and fate of contaminants in both the unsaturated and the saturated aquifer. The preferred tool for prediction is a numerical model that simulates the groundwater flow and pollutant movement and any chemical transformation. The construction of good models should be based on a thorough understanding of what happens within the modeled domain and on its boundaries, including chemical and biological processes. We need the ability to express this information as well-posed mathematical statements and, eventually, as a solvable numerical model. The model developed can be solved by employing a suitable numerical technique and appropriate computer programs. Many such programs for flow and solute transport in the subsurface are now available. This article introduces the fundamental concepts for modeling solute transport in groundwater systems. These are particularly useful for developing any remediation method for a contaminated subsurface.

SCALES OF OBSERVATION

Four spatial scales of observation have been suggested for describing solute transport phenomena in the subsurface:

1. The molecular scale, where materials are viewed as a discrete collection of molecules
2. The microscale or pore-scale, which describes solute behavior within a single pore in a porous medium
3. The macroscale or core-scale, where porous medium properties such as porosity, fluid phase saturation, and permeability can be described as continuous functions of space
4. The megascale, which is the scale of a system.

Table 1. Some Important Issues Involved in Solute Mobility in Groundwater Systems

S.N.	Issues	Details	Remarks
1.	Sources of pollutants/chemicals/solute in the ground	1. Hazardous and toxic waste disposal sites 2. Possible leaks in the compartments in ground used for storing toxic chemicals 3. Groundwater movement 4. Interphase mass transfer from air to soil 5. Dry deposition of contaminants from polluted air 6. Wet deposition on land 7. Accidental release of chemicals in the environment	Along with sources of pollutants, the amount of substance available in soil is equally important
2.	Properties of solute	1. Molecular structure 2. Vapor pressure 3. Water solubility 4. Absorption spectra 5. Particle size of particulate matter 6. Rate constants for its various reactions in the aquatic environment 7. Reactive or nonreactive 8. Life of the solute in the environment or its stability 9. Toxicological characteristics of the solute	
3.	Form of the pollutant in the environment	1. Dissolved in water 2. As suspension or colloid 3. As ions 4. As particulate matter	
4.	Direction of flow	1. One-dimensional (1-D) 2. Two-dimensional (2-D) 3. Three-dimensional (3-D)	In almost all cases, flow takes in a three-dimensional domain, but, for ease of modeling, a simpler geometry is often assumed
5.	Nature of transport mechanism	1. Saturated flow (single-phase flow) 2. Unsaturated flow (e.g., vadose zone) 3. Two-phase flow 4. Multiphase flow (more than two phases)	
6.	Soil type	1. Homogeneous soil 2. Heterogeneous soil (e.g., randomly heterogeneous, fractured media) 3. Layered soil and the no. of layers 4. Aggregated soil composed of large lumps	
7.	Soil characteristics	1. Porosity 2. Permeability 3. Dispersibility 4. Tortuosity 5. Density 6. Capillarity 7. Connectivity 8. Moisture content 9. Surface area 10. Depth 11. pH 12. Turbulence 13. Temperature 12. Absorption spectra 13. Proportion of diffusible ion	

Table 1. (*Continued*)

S.N.	Issues	Details	Remarks
8.	Transport and fate mechanisms in the soil	1. Diffusion: random motion of ions, atoms, molecules in all phases 2. Hydrodynamic dispersion: primarily from the complexities of the pore system 3. Adsorption: the passage of chemical species from one bulk phase to the surface of another where it accumulates without penetrating the structure of the second 4. Ion exchange 5. Hydrolysis 6. Photolysis 7. Volatilization 8. Microbial activity in the soil, e.g., anaerobic reaction 9. Relative velocity of a chemical with respect to moving water—sometimes the moving contaminants may be retarded with respect to moving water in soil for the following reasons: (a) ionic exchange reaction (b) precipitation and dissolution reaction (c) generation of insoluble complexes (d) formation of colloids followed by flocculants	
9.	Significance of groundwater	1. Inflow, outflow, downflow, and overflow of water from a control volume of soil 2. Infiltration and percolation of surface water 3. Level of groundwater table rises from rainfall 4. Groundwater draft from pumping of water 5. Carrying capacity of solute in groundwater	

To design soil and groundwater remediation techniques and to make reliable predictions about the efficiency of these techniques, it is necessary to identify and understand flow and transport processes on a smaller (e.g., pore scale) scale and to describe their manifestation on a larger scale (e.g., core scale). The connection of a smaller scale to a larger scale can be understood by a suitable upscaling technique. The choice of an appropriate upscaling method generally depends on the scale of observation because the relative importance of the dominant forces (e.g., capillary, viscous, and gravitational effects) may change with change in the averaging scale.

In principle, the mathematical model that describes the transport of an extensive quantity of a fluid or solid phase through a porous medium (mass balance equations for the transported quantities considered constitutive relations, initial conditions within the phase, and boundary conditions on the surface that bounds that phase) can be stated at every point within the phase considered. This description is said to be on the microscopic level, as we focus our attention on what happens at a (mathematical) point within the phase considered in the domain. Although the transport problem can be stated as a well-posed model, it is difficult to solve on this scale because the detailed geometry of the surface that bounds the phase is not known or is too complex. It is also very difficult to measure the values of variables at points within a phase to validate a flow or transport model and to determine the model parameters. As a consequence, the complete description and solution of a transport problem on a microscopic level is still unavailable.

To circumvent these difficulties, the transport problem is transformed from a microscopic to a macroscopic level, at which the problem is reformulated in terms of average values of the microscopic values. The average values are measurable quantities. We refer to this approach, employed in many branches of science, as the continuum approach.

SUBSURFACE HETEROGENEITY CHARACTERIZATION

The most typical features of groundwater systems are the spatial heterogeneity of the media and the temporal variability of the flow and transport properties. Moreover, these processes occur on multiple of scales. The mathematical descriptions of these processes on different scales are not necessarily similar. Scaling theories have been developed that attempt to quantify the links among process descriptions on various scales. However, due to spatial heterogeneity and temporal variability and the high nonlinearity of hydrologic processes, developing appropriate scaling rules is not trivial. Sometimes, new governing equations and constitutive relations to describe the flow and transport processes in groundwater have to be identified. This may yield a number of upscaled parameters in the governing equations that may have to be measured directly or indirectly. These parameters are either new, meaning they exist on only the larger scale or are averages of small-scale parameters. Questions that may arise in this regard are (1) how can parameter values measured on a small scale (e.g., laboratory experiments) be translated to effective values on a larger scale? (2) how can effective parameters of the larger scale be measured directly? (3) how can small-scale heterogeneities be accounted for in large-scale descriptions of hydrologic systems? (4) how can the large-scale behavior of a system be downscaled to its behavior on a smaller scale?

During the last 60 years, some methods have been developed to describe spatial heterogeneities in the subsurface. These methods cannot generate actual heterogeneity patterns, but they provide a theoretical basis for understanding the effects of heterogeneities and any coupled processes therein on flow and transport processes. Three types of methods have evolved:

1. descriptive methods
2. process-based methods
3. stochastic methods

Each method has its own limitations in theory and application. The descriptive method is limited mostly to large-scale solute transport problems. It cannot describe local variations in hydraulic permeability (K) and is not transferable to deterministic numerical models for flow and transport calculations. Process-based models cannot recreate the depositional faces or the experimental values of hydraulic permeability (K) at observation points. This method also requires data that are often not available, for example, sedimentation and erosion rates, and turbidity factors. Further, process-based models are computationally inefficient in computer time and storage and are highly sensitive to initial and boundary conditions. Interpretation and validation of results are therefore very subjective. Stochastic models are based on the principles of geostatistics and work well in theory. For example, they honor known data and their locations and patterns of spatial variability. Data for these models can be obtained from boreholes, soil survey maps, or any other sampling methods. However, they require an enormous amount of observational data for calculating the spatial statistics of the K distribution, and these data are generally lacking, especially in lateral directions. Therefore, one question that frequently arises in using stochastic models is, how can we estimate spatial variability in three directions from vertical data sets? Therefore, even with available methods, it is still difficult to create a reliable 3-D model that honors the important heterogeneous features at a given location.

An alternative to these approaches for characterizing heterogeneity is to use a Markov-chain approach. This is a hybrid method of deterministic and stochastic models. The earliest attempt to apply Markov chains was used to synthesize stratigraphic sequences in the vertical direction (10). However, the approach was not directed toward extension to multidimensions, and it was not used in real field situations for a long time. Later, a methodology (11) for characterizing subsurface heterogeneity based on a two-dimensional extension of the original one-dimensional Markov chain theory was developed. This model, called the coupled Markov-chain (CMC) model (11), couples two chains for 2-D problems and three chains for 3-D problems. For example, for a 2-D problem, the first chain describes the sequence in lithologies in the vertical direction, and the second chain describes the sequences of variation in the lithological structure in the horizontal direction. The two chains are coupled in the sense that a state of a cell in the domain is dependent on the state of two cells, the one on top and the other on the left of the current cell. This dependence is described in terms of transition probabilities from the two chains. The CMC is a general technique that can produce a variety of heterogeneous patterns that can be stationary or nonstationary in statistical sense.

GOVERNING MODEL EQUATIONS

The equations governing fluid flow and solute transport in groundwater are based on the principles of mass, momentum, and energy conservation. They can be expressed in two different formulations based on the dependent variables used: first, vorticity stream-function equations that are derived by incorporating the definitions of vorticity and stream-functions; second, primitive variable formulations that are expressed in terms of pressure and velocity or mass and momentum of the fluid particles. Furthermore, the governing equations of the fluid flows can be classified mathematically as elliptic, hyperbolic, or parabolic equations. Based on the physical problem under consideration, these model equations can be solved either in rectangular or curvilinear coordinate frameworks.

The use of the vorticity stream-function formulation is most commonly found in one- and two-dimensional cases. Although it is possible to extend vorticity-stream functions to 3-D domains, they give rise to many complications and are not often recommended (12).

Primitive variable formulations can be expressed in either conservative or nonconservative forms, which in turn can be dimensional or nondimensional. The conservative forms of equations derived are based on the assumption that the fluid model is fixed in space. Hence, new fluid particles interact across the domain boundaries as the fluid flows in and out. For nonconservative forms, the observer is assumed to move with the frame of the fluid particles. In other words, the equations are formulated based on a moving coordinate system. Therefore, for a nonconservative system, there is no interaction of fluid elements across boundaries. For a complete discussion of conservative and nonconservative forms of equations, readers are referred to Anderson (13).

Governing equations can also be expressed in either Eulerian or Lagrangian forms. These two formulations are similar to conservative and nonconservative equations, respectively, because they assume that the fluid model is either fixed in space or moving with the flowing fluid. However, as Abbott and Basco (14) have described, important differences exist between Eulerian and conservative forms. Similar differences are also applicable to nonconservative and Lagrangian formulations. An important characteristic of Eulerian equations is that the accelerations of fluid particles form substantial or total derivatives of each velocity component. They are expressed in terms of continuous spatial velocities and pressures. Therefore, when the flow variables are discontinuous, this formulation suffers serious drawbacks. Conservative approaches remove such limitations because they are formulated by assuming mass and momentum of the fluid particles as the dependent variables and as functions of space and time. They are represented as integral forms. This makes any discontinuity of the flow variables irrelevant in the computational domain. Conservative approaches, therefore, provide a more general way of formulating fluid flow phenomena.

The primary issue that comes up in formulating groundwater flow problems is selection of proper mathematical forms for the governing equations. Solute transport in porous domains can be represented by the convective dispersion equation (Eq. 1). The velocity profiles can be obtained by solving a suitable flow equation, for example, the Darcy or Brinkman equation. Equation 1 does not include any source/sink terms, which might become evident if there are any reactions in subsurface flow problems.

Solute Transport Equation

$$\text{Convective dispersion equation: } \frac{\partial C}{\partial t} + \overline{\nabla}.(C\mathrm{v}) = \overline{\nabla}.(D\overline{\nabla}\overline{v}) \tag{1}$$

D in Eq. 1 is the dispersion coefficient tensor and can be represented as

$$D = \begin{bmatrix} D_{xx} & 0 & 0 \\ 0 & D_{yy} & 0 \\ 0 & 0 & D_{zz} \end{bmatrix} \tag{2}$$

where D_{xx}, D_{yy}, and D_{zz} are the principal components of the dispersion coefficient tensor in the x, y, and z directions.

Flow Equations

Various linear and nonlinear relationships describe flow behavior in the subsurface (5). The two most popular flow equations are the Darcy (Eq. 3) and the Brinkman (Eq. 4) equations.

Assuming that the fluid is incompressible and neglecting any body forces, the governing momentum balance equations can be written as

$$\text{Darcy's equation:} \qquad \overline{\nabla}P = -\frac{\mu}{\overline{K}}\overline{v} \tag{3}$$

$$\text{Brinkman equation:} \qquad \overline{\nabla}P = -\frac{\mu}{\overline{K}}\overline{v} + \mu'\overline{\nabla}^2\overline{v} \tag{4}$$

K in Eqs. 3 and 4 represents anisotropic soil permeability and is a second-order tensor that can be represented as

$$K = \begin{bmatrix} K_{xx} & 0 & 0 \\ 0 & K_{yy} & 0 \\ 0 & 0 & K_{zz} \end{bmatrix} \tag{5}$$

where K_{xx}, K_{yy}, and K_{zz} are the principal components of the permeability tensor in the x, y, and z directions. Hence, the diagonal form of the anisotropic permeability is a special case which occurs when the coordinate axes coincide with the normal axes of K. In general, these components are functions of the fluid and material properties. Due to the varying range of particle sizes and shapes and complex fluid–solid interactions in field conditions, there is a lack of theoretical corelations for estimating the permeability in the subsurface.

If the soil is isotropic, then,

$$K_{xx} = K_{yy} = K_{zz}$$

Equations 3 and 4 are coupled with the continuity equation (Eq. 6), and then solved to determine the unknown field variables, velocities and pressures.

For an incompressible fluid and nondeformable porous medium, the continuity equation for conservation of mass can be written as

$$\text{Continuity equation:} \qquad \overline{\nabla}.\overline{v} = 0 \tag{6}$$

NUMERICAL TECHNIQUES FOR SOLVING GOVERNING MODEL EQUATIONS

There are mainly five different numerical approaches for modeling solute transport problems in groundwater: the finite-difference, finite-element, finite-volume, boundary-element, and spectral-expansion. They have been employed for solving many different complex fluid problems with reasonably good success (15–19). Each method was developed to handle a specific problem, to eliminate the limitations of an existing technique, or simply, as a variant form. For example, the finite-element method was developed mainly because of its ability to cope with complex geometry. Similarly, the spectral method was developed as a variant of the finite-element method (15) to enhance the accuracy of solutions. The techniques have their own advantages and disadvantages, and many similarities and dissimilarities exist among their concepts and procedures. Comparison among these methods has been made by Hirsch (16), Versteeg and Malalasekera (17), Comini et al. (18) and Garg (19), among many other authors. The choice of the technique to be used in modeling depends on all these criteria, apart from its applicability to the particular problem.

Finite-Difference Method

The procedure for deriving finite-difference equations consists of approximating the derivatives in the differential equations via a truncated Taylor series expansion. Let us consider the grid points shown in Fig. 2. For grid point

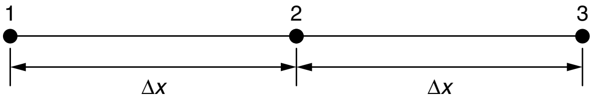

Figure 2. Computational grid for a Taylor series expansion.

2, located midway between grid points 1 and 3 such that $\Delta x = x_2 - x_1 = x_3 - x_2$, the Taylor series expansion gives

$$\varphi_1 = \varphi_2 - \Delta x\left(\frac{d\varphi}{dx}\right)_2 + \frac{1}{2}(\Delta x)^2\left(\frac{d^2\varphi}{dx^2}\right)_2 - \ldots \quad (7)$$

$$\varphi_3 = \varphi_2 + \Delta x\left(\frac{d\varphi}{dx}\right)_2 + \frac{1}{2}(\Delta x)^2\left(\frac{d^2\varphi}{dx^2}\right)_2 + \ldots \quad (8)$$

Truncating the series just after the third term and adding and subtracting the two equations, we obtain

$$\left(\frac{d\varphi}{dx}\right)_2 = \frac{\varphi_3 - \varphi_1}{2\Delta x} \quad (9)$$

$$\left(\frac{d^2\varphi}{dx^2}\right)_2 = \frac{\varphi_1 + \varphi_3 - 2\varphi_2}{(\Delta x)^2} \quad (10)$$

Substituting such expressions in the differential equations leads to a finite-difference equation, which can be cast in matrix notation and then solved using matrix solvers. For advanced literature on finite-difference methods, readers may refer to (20–23).

Finite-Element Method

This method is based on the principles of variational calculus. The differential equation to be solved can be represented as

$$L(\varphi) = 0 \quad (11)$$

Further, we assume an approximate solution for the dependent variable $\overline{\varphi}$ that contains a number of undetermined parameters, such as $a_0, a_1, a_2, \ldots, a_m$:

$$\overline{\varphi} = a_0 + a_1x + a_2x^2 + \ldots\ldots\ldots\ldots\ldots\ldots + a_mx^m \quad (12)$$

Substituting $\overline{\varphi}$ into the differential equation leaves a residual R, defined as

$$R = L(\overline{\varphi}) \quad (13)$$

We wish to make this residual small over the entire computational domain, and hence it can be proposed that

$$\int WR\,dx = 0 \quad (14)$$

where W is a weighting function and the integration is performed over the computational domain. By choosing a succession of weighting functions, we can generate as many equations as are required for evaluating the parameters. For simple regular grids, the equations derived by using the finite-difference and finite-element methods are identical. The computational meshes are generally more refined in the areas of rapid change of dependent variables. For complex problems, the finite-element method has several advantages. First, the boundary conditions are handled naturally by this method in contrast to the finite-difference method, where special formulas must be developed for the boundaries in many instances. Second, inhomogeneities and anisotropies can be taken into account easily. Moreover, the size and shape of the elements can be varied readily, and for curved geometries, the concept of isoparametric mapping can be employed to yield robust solutions. This method, developed by Zienkiewicz (24–27), was applied to structural engineering problems, and later on, was extended to subsurface hydrology.

Finite-Volume Method

The primary steps involved in the finite-volume method are grid generation to divide the domain into discrete control volumes. The governing equations are then integrated over the control volume to yield a set of discretized equation at nodal points. The integral form of the equations allows for discontinuities inside the fixed volume unlike the differential forms of governing equations, which assume that the flow properties are differentiable, hence continuous. This consideration becomes useful when dealing with flow problems that have real discontinuities encountered in subsurface flow. For a detailed text on the finite-volume method, refer to (17).

Boundary-Element Method

The boundary-element method is derived by discretizing an integral equation defined on the boundary of the domain and relates the boundary solution to the solution at points in the domain. The integral equation is commonly referred as the boundary integral equation (BIE) and the method as the boundary-element method (BEM). An integral equation formulated on the boundary can be derived only for certain classes of PDEs. Hence, the BEM is not widely applicable compared to the finite-element and finite-difference methods. The advantages of the boundary-element method are that only the boundary of the domain needs to be discretized. The dimension of the problem is effectively reduced. For example, an equation governing a three-dimensional region is transformed into one over its surface. When the domain is exterior to the boundary, as in potential flow past an obstacle, the extent of the domain is infinite, and the equation governing the infinite domain is reduced to an equation over the boundary. Thus it results in a numerical method that is easier to use and more computationally efficient than the competing methods. One can refer to (28) and (29) for detailed information on the BEM.

Spectral Expansion Method

Spectral methods are algorithms for solving certain classes of PDEs using the fast Fourier transform. Finite-difference, finite-element, and spectral methods can be distinguished on the basis of weighting functions used in the mathematical formulations. In the finite-difference method, the trial functions are polynomials of low order; in the finite-element method, they are local smooth functions (i.e., polynomials of fixed/higher order), whereas in spectral methods, they are global smooth functions such as Fourier series expansions. All spectral methods are based on the complete family of global smooth functions. Detailed discussions on the development of various spectral expansion techniques based on selecting different weighting functions can be found in (30–32).

CONCLUSIONS

The study of solute transport in groundwater systems is a multidisciplinary subject because it integrates the principles of engineering, pure science subjects, for example, applied mathematics, chemistry and physics and, other life science subjects, for example, biology. The physical, chemical, and biological mechanisms that govern solute transport in the subsurface interact in a highly complex manner, and elucidating the important or dominant control mechanisms that govern transport processes can be highly nonintuitive. On the other hand, without thorough knowledge of the governing processes and their interactions, accurate prediction and control of solute migration is severely restricted. For this reason, many experiments on both laboratory and field scales have been attempted. The knowledge gained from such experiments (benefits) is clearly evident in the scientific literature now. However, it is also pivotal to place experimental work within a consistent and coherent theoretical framework to interpret the results obtained and direct further experimental work appropriately. By examining a system in terms of suitable equations with well-defined parameters, a mathematical model can help to provide a route to such a framework.

In the text presented, the important concepts related to modeling solute migration in groundwater systems have been presented. We have discussed the various scales of observation over which solute migration may take place. The ways to characterize the ubiquitous media heterogeneities in the subsurface have been briefly mentioned. Basic equations that govern solute transport behavior in the subsurface and numerical methods to solve them have been presented. These are far from exhaustive analyses. However, it is envisaged that the text gives an overview of various basic underlying concepts for modeling solute transport in groundwater.

NOMENCLATURE

C	Solute concentration
D	Dispersion coefficient tensor
D_{xx}	x component of the dispersion coefficient tensor
D_{yy}	y component of the dispersion coefficient tensor
D_{zz}	z component of the dispersion coefficient tensor
K	Permeability tensor
K_{xx}	x component of the permeability tensor
K_{yy}	y component of the permeability tensor
K_{zz}	z component of the permeability tensor
P	Pressure
t	Dimensional time
v	Velocity vector
xx	x coordinate
yy	y coordintate
zz	z coordinate
Φ	Variable
μ	Fluid viscosity
μ'	Effective fluid viscosity

AMBIENT GROUNDWATER MONITORING NETWORK STRATEGIES AND DESIGN

Douglas C. Towne
Phoenix, Arizona

WHY CREATE AN AMBIENT GROUNDWATER NETWORK?

Expanding populations and associated development are creating greater water demands worldwide. Groundwater is increasingly being used to meet these needs because surface water sources are often over-appropriated, heavily polluted, or are preserved for their ecological benefits. With significant future groundwater withdrawal increases, the long-term sustainability of groundwater resources is a vital issue. Yet even where there appears to be sufficient groundwater supplies to provide for irrigation, municipal, domestic, livestock, industrial, and/or mining purposes, the quality of this resource may limit the applications for which it can be used.

Groundwater quality can be negatively impacted by a variety of physical features and cultural activities that are not always easily discerned by empirical observations. The detection and continued monitoring of groundwater quality constituents and contaminants requires expensive field sampling operations and laboratory analyses. Once deterioration of groundwater quality begins, it may be difficult to reverse, and treating the impacted water can be prohibitively expensive.

Assessing groundwater is a challenging endeavor as the resource resides beneath the land surface, available only for examination at limited sites where wells or springs are located. It is a complex, large-scale, three-dimensional resource that has a high degree of spatial variability (3). To meet these challenges are the benefits supplied by ambient groundwater monitoring, characterization, and assessment networks that address these groundwater quantity and quality concerns. The term “ambient” refers to broad-scale or basinwide conditions not associated with a specific point source, facility, or property. The term “monitoring” refers to point measurement of water level or water quality conditions of groundwater sites, and “characterization” is the description and interpretation of the hydrogeologic setting where the groundwater occurs. Finally, the term “assessment” is used to describe efforts that combine both characterization and monitoring (3).

An ambient network is a proactive strategy that uses groundwater monitoring and characterization along with scientific methods and hydrologic models to assess holistically the groundwater of a given area, usually a defined hydrologic basin. Ambient networks are designed to identify regional changes in groundwater levels and/or degradation of groundwater quality such as occurs from widespread nonpoint sources of pollution or a high density of point sources. Information gleaned from an ambient network includes determining where groundwater levels are fluctuating, locating areas of poor water quality, and identifying spatial and temporal water quality patterns. When correctly designed, the data collected in ambient monitoring programs can be statistically analyzed to make broad statements about the groundwater of a basin that have a known degree of confidence using a relatively small number of investigated sites. Several states such as Arizona and Idaho (1) have redesigned their ambient networks to reflect a statistical, rather than subjective, selection of sites. Others such as Minnesota (2) initiated new ambient networks because the previous design failed to meet objectives.

Although planning and implementing ambient networks is not inexpensive, their costs may be considered relatively minor compared to the hydrologic information they can provide when properly designed and executed. On a regional scale, such networks can determine whether aquifers are in hydrologic equilibrium at current pumping levels, which areas should not be used for municipal or domestic uses without treatment, and whether groundwater quality is being impacted over time by anthropogenic activities. On a more localized scale, networks provide valuable background groundwater level and quality information for site-specific hydrologic studies and projects that may involve remediating contaminated sites or siting production wells. Finally, networks will assist in various surface water investigations because discharges from groundwater systems often sustain river base flow and often directly influence the quality of riparian and wetland ecosystems (3).

OVERVIEW

At their zenith, ambient groundwater networks balance sometime divergent entities such as science and art, theoretical statistical considerations and pragmatic field decisions, and precise analytical laboratory tests and empirical field observations, to assess best the groundwater of a specified area. These networks provide a structured yet flexible framework from which to survey a large basin which, if desired, then can transit into smaller, localized networks to examine groundwater concerns in more specific areas.

CONCEPTUAL STRATEGIES AND DESIGNS—GENERAL OVERVIEW

When creating an ambient groundwater network, attention should focus on adhering to the general principles of probability sampling, so that inferences can then be made about the total population from data collected on the sampled population (4). Thus, statements of the network's goals and methods and which randomized site selection will be used, should be included in the planning. Four different strategies for creating an ambient network are detailed: simple random monitoring, stratified random monitoring, random monitoring within grid cells, and transect monitoring. Each strategy has various strengths and weaknesses but each method should be considered a tool to focus objectives of the study and to minimize potential sources of error rather than to dictate rigid rules blindly (4).

Simple Random monitoring

The easiest method of implementing an ambient groundwater monitoring network is simple random selection of monitoring sites within a basin. This network design is created by random selection, using either a computer or table of random numbers, in which a subset sample of sites is selected for monitoring. This design has the benefit that every potential groundwater monitoring site has an equal chance of being selected for the network. However, this design has the major drawback of being unlikely to achieve a set of monitoring sites that are spatially distributed throughout the basin. Commonly, potential measurement sites are clustered in areas of extensive groundwater development, which may lead to biases in the data.

Stratified Random Monitoring

Stratified random monitoring is a viable alternative to simple random monitoring, particularly where information is available to subdivide a basin into subunits that are likely to be more homogenous than the basin as a whole. The information used to subdivide the basin can be somewhat subjective, though stratification tends to be most effective when the subunits are very dissimilar from one another in combination with minimal variability within each subunit. Stratified random monitoring might be used when, for example, a basin has three distinct physiographic areas, and each has a different land use. These areas include an upland area primarily used for low-intensity grazing, a valley primarily used as farmland irrigated by surface water, and a mesa primarily used for farmland irrigated by groundwater. In this scenario, an important facet of the ambient groundwater monitoring network would be to distinguish water level and quality differences among the areas. Each subunit is then monitored individually by simple random selection, and monitoring sites are equally divided among the subunits. The goal of this monitoring strategy continues to be overall assessment of the basin, but an important factor is the assessment of each individual subunit. Idaho uses stratified random monitoring for its ambient network by dividing the state into 22 subareas characterized by fairly homogenous hydrogeology (1).

Random Monitoring Within Grid Cells

The most common method of implementing an ambient groundwater monitoring network is overlaying a grid on the basin (or other area of hydrologic interest), and randomly monitoring a site within each cell created by the grid. The systematic element requires that the selected sites be spatially distributed throughout the area; the random element ensures that every well within a cell has an equal chance of being monitored. The systematic grid monitoring strategy is especially effective in relatively homogenous areas as a tool to distribute sample sites adequately spatially.

More sophisticated systematic grid monitoring models aided by computer software may divide the basin into equal area cells so that each contains three random sample points (5). The random points are designated primary, secondary, and tertiary, respectively. An appropriate well or spring is then located within a specified radius of the primary sample point to monitor. If no appropriate groundwater sample site can be found near the primary point, a similar process is used for the secondary point and then the tertiary point, if necessary. If no appropriate groundwater sites can be located around any of these three random points, then any appropriate well or spring within the cell can be randomly selected for monitoring.

Random monitoring using grid cells can be adapted to more complex or comprehensive groundwater assessments. Basins that have several overlying aquifers (for example, an upper, unconfined aquifer above a lower, confined aquifer) would require selecting two random sites for monitoring within each cell to characterize each aquifer. One random site should be a deep well screened only in the lower aquifer, and the other site should be a shallow well whose depth does not exceed the upper aquifer's thickness. Wells should be avoided that have the possibility of being screened in both aquifers, as this would provide an unknown mix of groundwater. Even if only a single aquifer is spatially located within a cell, two wells pumping water from different depths (deep and shallow) could be monitored to examine for variability in groundwater levels and constituent concentrations with groundwater depth. In the perfect scenario, the shallow well could be pumping water from just below the water table to provide data on the water quality of the recharge percolating through the vadose zone.

Transect Monitoring

Transect monitoring is an especially useful design in basins that consist of steep river valleys. Most water development in these basins occurs along the flat river floodplain; minimal groundwater monitoring opportunities lie in the surrounding uplands. Transect monitoring requires selecting sites from each aquifer along, as close as possible, a straight line perpendicular to the river valley. For example, sites could be monitored at high elevation mountain hardrock, in the upland basin-fill aquifer, and finally along the floodplain aquifer. Each of these transects would allow the opportunity to examine groundwater evolution flow paths from the basin's highest recharge points down to the valley floor. A final groundwater evolution flow path is then examined along the floodplain aquifer from the most upgradient site to the most downgradient site in the basin.

Transitional Subunit Monitoring

Any of the ambient groundwater network designs described can be adjusted to examine for targeted objectives within the basin. A higher density of monitored sites could be established for preselected areas that have, as previously shown in the hydrologic literature, the potential to impact either groundwater levels or quality. Preselected sites include, but are not limited to, clusters of large capacity production wells, confined animal feedlots, mines, landfills, irrigation districts, and residential areas that have a high density of septic systems for wastewater disposal. Other activities that also have a good probability of impacting groundwater may be found in the hydrologic literature. For these targeted subunit studies, care should taken to monitor groundwater at shallow sites both upgradient and downgradient of the preselected site.

Transitional subunit monitoring may also be used to define the extent of sampling sites better in the ambient network that have either dramatic groundwater level changes and/or constituent concentration statistical outliers. This additional monitoring will assist in determining if the randomly selected site is characteristic of the area. A groundwater level outlier might indicate that the well, is tapping a shallow, perched aquifer instead of the regional aquifer. For a constituent concentration outlier, it might indicate that the well is not representative of the area because of construction flaws such as a cracked casing or an improper surface seal that could allow impacted surface flow down the well casing.

MONITORING SITE SELECTION

An important consideration when establishing an ambient network is the type of well to use for monitoring. The preferable option is to construct new wells throughout the system. This allows the major benefit of control over their location, depth, screened opening, pump type, and other characteristics. The downfalls of this option include locating suitable well sites and the major expense of drilling, developing, and the upkeep of the wells. Even if funding allows establishing the wells, finding suitable well sites might not be easy. Preferable sites for wells are public lands, including road rights-of-way to obtain unlimited access. However, it may be difficult to find public lands in all areas where ambient network wells should be established. Selecting groundwater monitoring sites on private property with the land owner's permission allows a wider range of potential well sites. However, this option has the downfall of potentially being denied access to the well at a later date by the present or future, property owner.

Using preexisting private wells also has a number of advantages and disadvantages; the major factor is significantly less initial cost to establish an ambient monitoring network. No well drilling, development, or upkeep costs are required because wells are already in place, maintained by an outside party. The disadvantages are that there is no control over well characteristics. There is also no guarantee that the well will continue in operation for monitoring in the future. Even if the current well owner is very positive about involvement in the ambient network, a future property owner could have a different position.

Preexisting wells may generally be divided into two groups. High capacity wells typically consist of those used for municipal, mining, and irrigation purposes. Low capacity wells typically consist of those used for domestic, stock, and monitoring purposes. Other potential groundwater monitoring sites include naturally flowing springs. There are many advantages and disadvantages of using each type of well in an ambient network (Table 1).

In order to minimize potential biases in well selection, the most pragmatic approach for choosing wells for the network is to use a mix of high and low capacity wells that supply groundwater for different purposes. Care should be taken to select wells that are only screened in a single aquifer and have the most complete well characteristic data available. Using both high and low capacity wells should result in a mix of deep and shallow wells that will provide for a more complete assessment of the basin. Generally, public water supply wells are monitored under state and/or federal regulations which may make them generally more amenable to additional sampling. However, other high capacity wells such as which supply irrigation or mining uses or low capacity wells may have never been previously sampled. Selecting these wells could result in obtaining important hydrologic information not previously known about the area of interest.

If some funding is available for well drilling, very shallow monitoring wells often are a good choice to construct for several reasons. Foremost, such wells would indicate what type of impacts the aquifer might be receiving from recharge through the vadose zone. Because they are screened near the top of the water table. Also, because of their shallow depth and associated lesser cost, more monitoring wells could be drilled than other types of deeper wells.

MONITORING SITE INVENTORY

A site inventory is created to collect and document information for each well or spring selected or constructed for the ambient network. The site inventory contains important hydrologic information including, but not limited to, well location, owner, water use, well depth, screened interval, pumping depth, field measurements (water level and physical parameters such as temperature, pH, and specific conductivity), sampling permission forms, prior sampling measurements, and miscellaneous field activities and observations. A preprinted field sheet should be c-cated on which much of the above information can be added should be created, so that items are not overlooked in the field. Consistent field measurement and sampling protocols must be adhered to.

Table 1. Advantages and Disadvantages of Various Types of Wells for Ambient Groundwater Networks

Well Type	Advantages	Disadvantages
	High-Capacity Production Wells	
All	– easy to purge	– might not have flow rate controls making sampling for volatile constituents difficult
	– provide a more complete measure of groundwater quality throughout depth	– because of high pumping rates may draw water from more than the aquifer the well is screened in
Irrigation	– may pump constantly during the crop's growing season	– might have only seasonal use – turbine pump oil can cause contamination – can cause contamination when used for chemigation without antisiphon devices
Mining	– may pump constantly	
Municipal	– long-term access frequently possible	– wells producing water not meeting standards might be abandoned
	– might have extensive historical water quality data	– must sample before any chlorination
	Low-Capacity Production Wells	
All	– might lack well construction information	– susceptible to local impacts such as septic systems
Domestic	– often are more shallow wells	– may have water taps after storage or pressure tanks
Monitor	– often screened near the water table to investigate aquifer recharge	– may have been originally installed to monitor some sort of contamination
Stock	– often located in areas devoid of other types of wells	– often are windmills which can be difficult to purge adequately in calm weather
	Other Groundwater Sites	
Springs	– often located in mountainous areas devoid of any wells	– may flow only seasonally or during wet periods – may not have a clearly demarcated point of emergence.

MONITORING MEASUREMENTS AND SAMPLES

To determine what measurements and samples to collect for the monitoring network, the cost of each must be weighed against how valuable the information potentially gained from it is. One viewpoint is that much of the cost of an ambient network consists of salaries, travel expenses, and sampling equipment. As such, as wide a variety of groundwater data as possible should be collected at the monitoring site, which is an especially persuasive argument during the initial monitoring, when establishing baseline conditions. However, it might not be fiscally or scientifically prudent to collect certain types of samples where there is an extremely remote possibility of detecting the contaminants. As an example, collecting samples to be analyzed for organic contamination such as pesticides or volatile organic compounds in relatively pristine areas might not be the best use of scarce resources, as these tests are relatively expensive.

Baseline data collected at ambient network sites may include, but are not limited to, the following types of samples: inorganic constituents (physical parameters, major ions, nutrients, and trace elements), isotopes (oxygen, hydrogen, tritium, and others), radiochemistry (especially in areas of granite geology or mining activity), radon gas, volatile organic compounds, and pesticides. In addition, on-site measurements of groundwater depth, temperature, pH, specific conductivity, dissolved oxygen, alkaling and redox can be determined using portable instruments. Bacteria can be sampled but it may be of limited value for long-term trend analyses because microbiological contamination in groundwater is often transient and subject to a variety of changing environmental conditions, including soil moisture and temperature.

During selection of sample types to collect for the ambient network, adequate quality assurance/quality control procedures and samples should be integrated into work plans and activities. Quality assurance data validation tests may include cation–anion balances, specific conductivity–total dissolved solids ratios, hardness (lab-calculated), pH (field-lab), specific conductivity (field-lab), and groundwater temperature–groundwater depth. Quality control samples may include, but should not necessarily be limited to, travel blanks, equipment blanks, replicate samples (both duplicates and splits), and spiked samples.

AMBIENT NETWORK SIZE

The various conceptual designs are efficient methods for characterizing groundwater because they require monitoring relatively few sites to make valid statistical statements with a known degree of confidence about the conditions of a large basin. Each design will characterize the overall basin, though the density of monitoring will depend on scientific and fiscal factors. Obviously, funding has a critical influence on the density of monitoring. When possible, a network size of 30 sites is desired as this is often large enough for a normally distributed population to be recognized as such (4).

Hydrologic factors also provide some measurement of optimal monitoring density. The hydrologic complexity of the basin and the variability of historical groundwater information are important components to consider when planning an ambient network. The hydrologic complexity of a basin is influenced by factors such as the number of aquifers, surface water features such as rivers and lakes, and the presence of high water use activities such as irrigation districts, mining and milling operations, or large urban areas. The variability of historical groundwater data can be judged qualitatively by examining the variation in groundwater levels, the types of dominant water chemistries present, and the number of trace elements detected. More extensive quantitative analyses should also be conducted which can include determining constituent concentration means and standard deviations to gauge the variability of groundwater quality in the basin.

MONITORING FREQUENCY

Once the ambient network has been established and the baseline data have been collected, it should be determined how frequently it will be monitored and what types of data will be collected. Measurement of groundwater levels should be tied to both the overall extent, and to recent changes in, the water development of the basin. Groundwater quality typically varies spatially more than temporally because of the insulating effect of the soil and vadose zone. Therefore, except in very shallow wells, it is typically unnecessary to resample wells frequently because rarely do constituent concentrations change significantly over periods of a few years. A quantitative method of determining the frequency is to examine previous groundwater quality studies in the basin covered by the ambient network. If wells or springs common to both are established, the constituent concentrations can be examined for significant statistical differences that are unlikely to occur by chance. The time period between the previous study and the baseline monitoring of the ambient network can establish the frequency needed for sampling. If new development has occurred in the basin that could potentially impact groundwater, this time period should be shortened to account for these recent influences.

In select areas of very shallow groundwater, monitoring should be seasonal. Particularly susceptible to seasonal fluctuations are perched aquifers of little storage capacity. Impacts such as high runoff from wet winters or irrigation recharge during an agricultural growing season may be reflected in high seasonal variability in both groundwater depth levels and constituent concentrations.

EFFECTIVELY USING DATA FROM AN AMBIENT NETWORK

Hydrologic data obtained from an ambient network should be used for a variety of purposes to make the investment in a program of this type as valuable and cost-effective as possible. If the ambient network is created and data collected without any subsequent assessment, the program should not be considered successful in accomplishing its goals. A common problem is adequately planning, developing, and monitoring an ambient network without the subsequent dedication to analyzing and interpreting the data and producing readable, scientifically valid reports that can be used by hydrologists, planners, and others interested in groundwater information.

Data collected from an ambient network should be used for a multitude of purposes. Most simply, efficient and accessible data storage and retrieval is a necessity for others seeking information from the ambient network, which should be as convenient as possible; potentially the data should be available electronically over the Internet. The potential audience for the ambient network data is wide and includes hydrologists, planners, real estate professionals, and anyone using groundwater.

Data from the ambient network should be examined for both spatial and temporal patterns. Empirical observations and qualitative methods are often successfully used to examine groundwater data. However, so that the hydrologist remains unbiased, statistical methods should also be used to examine the data. Groundwater data can be divided among various components of the basin to examine for statistically significant correlations. Aquifers, geologic types, watersheds, land uses, recharge zones, and fault zones are just some of the potential components used in examining for groundwater quality patterns. The ambient network becomes a powerful predictive tool when significant relationships are revealed between groundwater quality concentrations and physical or cultural features. At this point, the groundwater quality of unmonitored areas is predictable with a known degree of confidence based on statistically significant patterns revealed by the ambient network.

Finally, the data, spatial and temporal patterns and the interpretations of these patterns should be woven into a readable, scientifically valid report. Two versions could be produced: an in-depth report designed for hydrologists who require comprehensive groundwater information on a basin and a short fact sheet designed for a more casually interested audience. Both published reports should be widely disseminated among both the hydrologic community and the area of interest as well as be available on the Internet.

MTBE

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Methyl tertiary-butyl ether (MTBE) is a synthetic compound that was developed as a solution to the problem of air pollution from vehicle emissions. MTBE was originally added to gasoline as a fuel oxygenate in approximately 1979 to reduce air emissions and make the fuel burn cleaner, allowing more complete combustion in internal combustion engines. The concept was to improve air quality by producing fuels that were more readily oxidized and decrease the resulting tropospheric ozone production. In the late 1980s, the U.S. EPA supported the use of fuel oxygenates in reformulated gasoline to achieve air quality goals.

MTBE, a byproduct of gasoline refining, was inexpensive, and readily available nationwide. Ironically, the use of this air-saving gasoline additive has taken its toll on groundwater and surface water resources throughout the nation. Life-cycle studies were not performed on MTBE and ultimately, leaks and spills of gasoline containing MTBE from underground tanks and pipelines have leaked into the groundwater. In addition, incomplete combustion of gasoline containing MTBE by two- and four-stroke engines in water skis and boats has allowed the release of MTBE into surface waters.

MTBE is an ether whose general chemical formula is $C_5H_{12}O$ and structural formula is $CH_3OC(CH_3)_3$ or $(CH3)_3COCH_3$ (1). (See Fig. 1). MTBE is highly soluble in water, more than 75 times more so than many other gasoline compounds. 250,000 MTBE-contaminated sites throughout the nation have been identified. A January 16, 2000, more than airing of the "60 Minutes" television program on MTBE highlighted the problem for a national audience, although the problem of MTBE and water resources had been known for a few years to water professionals and regulators.

PERSISTENCE IN GROUNDWATER

Sampling of groundwater in California and other states has shown that MTBE is more persistent and more mobile than many other fuel compounds.

TASTE AND ODOR

A taste and odor like turpentine has made MTBE-contaminated groundwater sources at levels exceeding the taste and odor threshold unusable for human consumption. Supplying bottled water for impacted areas and/or other large-scale treatment or water importation options will be expensive and will continue into the future. Blending clean water with MTBE-impacted water will also continue.

HEALTH RISK

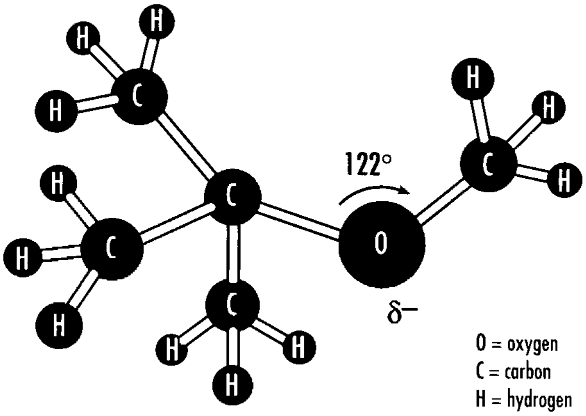

Figure 1.

Although MTBE is considered a potential health risk, there is inadequate evidence that MTBE causes cancer in humans. The strong odor and taste of MTBE at relatively low concentrations would make drinking of large amounts of high-level MTBE contaminated water unlikely, thus reducing the potential for exposure and resulting human health risks from MTBE. MTBE is not listed as a human carcinogen by the U.S. National Toxicology Panel, the California Proposition 65 Committee, or the International Agency for Research on Cancer. Limited evidence from an older Italian MTBE rodent study indicated that MTBE caused cancer in the experimental animals when administered in unrealistic doses hundreds of times greater than probable human exposure. California, a state that has the most MTBE cases, has a primary MCL of 13 μg/L and a secondary MCL (taste and odor threshold) of 5 μg/L (2).

FATE AND TRANSPORT

The MTBE issue is a chemical handling problem associated with gasoline leaking from underground storage tanks, leaking pipelines, and surface spills or from small gasoline engine equipment. Even though the majority of underground tanks in this country have been upgraded, the amount of MTBE already released with gasoline into the environment is so large that the problem of degraded drinking water sources may persist for decades. Compared to other fuel compounds, MTBE adsorbs to soils much less and dissolves in groundwater at much higher concentrations.

Due to these characteristics, MTBE migrates much faster and further in groundwater than equal amounts of other gasoline compounds. According to Wilson (2), MTBE often appears to move out ahead of a BTEX plume. The explanation is based on differences in the extent of adsorption to the aquifer materials. As the fraction of organic carbon in the aquifer sediment increases, benzene and other gasoline compounds adhere more to aquifer sediments than MTBE. Therefore, an aquifer with a high fraction of organic carbon (0.1%) would have a retardation index for MTBE and benzene, at 1.6 and 2.9, respectively (3). These differences help to explain the variations in contaminant transport rates.

GROUNDWATER INVESTIGATION

The investigation of a groundwater resource impacted with MTBE requires more detailed and more rapid sampling of soil and groundwater than other fuel-impacted sites due to the potential for faster and deeper migration of MTBE compared to other gasoline compounds. The presence of other oxygenates should also be tested at all sites containing MTBE. Some brands of gasoline contain tertiary-butyl alcohol (TBA) as an additive. As TBA is a biological breakdown product of MTBE, TBA should also be analyzed at sites containing MTBE.

REMEDIATION

MTBE is an ether compound and was considered very different from gasoline. Some investigators originally thought MTBE was a recalcitrant compound. MTBE remediation has improved after years of research in the laboratory and numerous field case studies. The same technologies that are used to treat fuel hydrocarbons have, in general, been used successfully to treat MTBE. Due to the chemical characteristics of MTBE, the cost of remediation or clean up of the contaminant is equal to or more expensive than that for other gasoline related chemicals, such as benzene, toluene, ethylbenzene, and xylenes. New technologies have improved the remediation efficiency and cost. MTBE remediation has been documented using a variety of *in situ* technologies, including, but not limited to, chemical oxidation (Fenton's chemistry and ozone) and bioremediation. Enhanced *in situ* bioremediation using various delivery systems for oxygen and peroxygens effectively reduce MTBE in groundwater. *Ex situ* technologies include pump and treat systems and soil vapor extraction systems, as well as dual-phase extraction with appropriate surface treatments and destruction. Virgin coconut shell carbon has been documented for MTBE remediation. Due to the high mobility of MTBE in the environment, rapid implementation of source control is the key to remediation of sites impacted with MTBE. More detailed MTBE information and case studies are contained in Moyer and Kostecki (4).

AIR POLLUTION

The effectiveness of MTBE in reducing air pollution in recent years is suggested, but uncertain. Reformulated gasoline containing MTBE may be related to some of the improvement in air quality, however, various conflicting air studies exist. Part of the improvement may be attributable to newer and more efficient vehicle engines with computer-controlled ignition. Replacements for MTBE must be evaluated carefully as to their fate and transport once released into the subsurface. Life-cycle studies focusing on the potential release into the air, soil, and groundwater should be performed prior to introducing any new chemicals into a product as widely used as gasoline.

LIMITING GEOCHEMICAL FACTORS IN REMEDIATION USING MONITORED NATURAL ATTENUATION AND ENHANCED BIOREMEDIATION

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California
David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

In Situ Monitored Natural Attenuation (MNA) and enhanced bioremediation are affected by a variety of limiting factors, including the availability of a terminal electron acceptor (TEA), macronutrients (nitrogen and phosphate), as well as an energy source (carbon). The TEA for aerobic degradation is limited to oxygen. For anaerobic degradation, TEA processes include denitrification using nitrate (NO_3^-), manganese reduction using manganese dioxide (MnO_2), iron reduction using bioavailable iron that includes the hydroxide form ($Fe(OH)_3$), sulfate reduction using the sulfate ion (SO_4^{2-}), and methanogenesis using carbon dioxide (CO_2) (1).

Macronutrients are measured in the laboratory as nitrogen in the form of ammonia or nitrate and orthophosphate. Nutrients, although important, are not as critical as depletion of the TEA. The energy source is the carbon in the hydrocarbons or chlorinated solvents that act as food for the microbes.

Monitored Natural Attenuation occurs when these processes are believed to be occurring on their own without additives. Natural attenuation frequently starts on many hydrocarbon sites, but the aerobic degradation process frequently stops or slows down considerably because of the limiting factors of oxygen and nutrient depletion. Enhanced bioremediation and Monitored Natural Attenuation have been described in detail in numerous volumes, including (1) and (2).

Aerated water at one atmosphere and at room temperature usually has about 8.0 mg/L dissolved oxygen. Although groundwater may have about 8 mg/L near the recharge area, oxygen depletion starts to occur as the oxygen is consumed by the chemical and biological processes that use up the oxygen. To measure these demands, laboratories measure solid or sediment oxygen demand. For dissolved oxygen demand, chemical oxygen demand and a subset, the biological oxygen demand, are typically analyzed. The biological oxygen demand is commonly evaluated as a 5-day analysis originally designed for sewer treatment plants.

To support aerobic biodegradation of petroleum hydrocarbons, aerobic processes are less than optimal when the dissolved oxygen is below 2 to 4 mg/L (3); at this oxygen level, facultative anaerobes may become active. At this stage of oxygen depletion, if a biodegradation process is to be used for the complete remediation of the site, enhanced bioremediation may be used. Enhanced bioremediation is designed wherein oxygen and sometimes nutrients are delivered into the subsurface through wells, well points, borings, or trenches. The delivery of oxygen depends on the oxygen form. Oxygen comes in many forms and can be added using a variety of techniques. Some of the more common forms of oxygen used for enhanced bioremediation include gas phase oxygen (O_2) or ozone (O_3), liquid oxygen sources such as hydrogen peroxide (H_2O_2), and solid oxygen sources including magnesium peroxide (MgO_2) and calcium peroxide (CaO_2). Some of these compounds are chemical oxidizers and, above certain threshold concentrations, can kill microbes in the pore space of the injection area during the process of releasing the contained oxygen. After the reactions occur, microbial populations can increase greatly from populations in more isolated areas of the mineral matrix.

In theory, oxygen levels of at least 3 to 3.5 times that amount of subsurface petroleum mass are required for complete mineralization of the hydrocarbon. Complete mineralization is the converting of the hydrocarbon to carbon dioxide and water:

$$\text{Benzene: } C_6H_6 + 7.5\ O_2 \rightarrow 6\ CO_2 + 3H_2O \ (3.1 \text{ oxygen requirement})$$

For anaerobic TEAs used to treat chlorinated solvents by reductive dehalogenation, one common method of TEA replenishment is to add a carbon source such as liquid molasses, lactic acid, cheese whey, or gases such as propane that also contain a large number of hydrogen atoms. In the process of the biological breakdown of the introduced chemical, hydrogen is liberated in the process. The hydrogen is used as the electron donor and the liberated carbon is used as a food source, along with the carbon-based contaminant. For petroleum hydrocarbons and some xenobiotics, such as MTBE ferric iron or sulfate, salts can be added to stimulate anaerobic biooxidation.

NUTRIENTS

Nutrient levels can be at well below reporting levels. The carbon:nitrogen:phosphorus ratios necessary to enhance biodegradation occur in the optimal range of 100:10:1 to 100:10:0.5, depending on the chemical contaminant, microbes, and other site-specific conditions (3). In some instances, anaerobic biooxidation processes may be inhibited because of the lack of trace nutrients. In these cases, native sulfate will be present in the groundwater and possibly iron. Continued use of these native inorganic TEAs can be stimulated by the addition of critical nitrogen and phosphate as trace nutrients.

SOIL MOISTURE

Soil moisture content in the unsaturated zone may be related to precipitation in the region and the retention capacity of the shallow soil. Soil moisture content of 75 to 90 percent of field capacity is considered optimal for aerobic microbial activity (4).

TEMPERATURE

Temperature has been seen as a limiting factor for biological degradation of hydrocarbons. Microbial growth rate is a function of temperature. Subsurface microbial activity has been shown to decrease significantly at temperatures below 10 °C and essentially to cease activity below 5 °C. From 10 °C to 45 °C, the rate of microbial activity typically doubles for every 10 °C increase in temperature (3). Typical soil microbial activity will slow as the temperatures reach 55 °C and will reach a steady state determined by the capacity to flush heat from the system. In cases where the load of petroleum hydrocarbons is high, the thermodynamics of the heat transport may be the rate-limiting factor rather than any biogeochemical process.

One case adjacent to the Yuba River near Donner Pass in California (7,000 feet above mean sea level) and another at South Lake Tahoe area in Nevada were evaluated for total heterotrophic plate counts and specific hydrocarbon microbial degraders. In both cases, plate counts were well below 100 colony forming units per gram of dry soil. Temperature of the water was seen as the limiting factor.

Assessment procedures must be completed that will, support the reliance on the MNA or enhanced bioremediation process by proving natural attenuation is taking place, defining the site-specific natural attenuation mechanisms, quantifying the kinetics of the process and providing an estimated time for cleanup, and insuring that the site-specific conditions will not allow unacceptable offsite migration of the contaminant plume. Given the above information, a governing regulatory body can support a decision for an MNA solution. The purpose of this article is to examine conditions under which the biological component of natural attenuation is inhibited or terminated, because of toxicity from heavy metals or certain hydrocarbons from the impacting contaminants, other compounds associated with the contaminants (at nonregulated levels), or compounds associated with the native groundwater.

The effect of toxicity on the MNA process is seen in three areas. First is a simple inhibition of activity. The microbial population continues to function, but at a rate that is slower than what would occur under normal conditions.

Second is a complete cessation of biological degradation activity. The bacteria are killed outright or, more commonly, they enter into a vegetative static state in which they are metabolically inactive. However, if the offending toxic material is removed from the system, bioactivity can resume.

Third is interference with degradational activity that is specifically focused on a contaminant of concern, which is more subtle, but particularly important to the MNA process. The overall microbial activity is not inhibited, just degradation of the contaminant. This problem is more often seen in systems where xenobiotic hydrocarbons are the targets of cometabolically generated degradation enzymes. In these cases, it is common for attenuation of the xenobiotic to take place after all of the other “natural” hydrocarbons have been consumed.

To evaluate the impact of toxicity, it is important to understand the mechanisms by which substances are toxic to microorganisms or interfere with the degradation process. The following bacteria cell components or processes are sensitive to toxic effects from the listed compounds:

- The bacterial cell wall can be totally destroyed by heavy metals, phenols, and alcohols.
- The permeability of the cell wall can be fatally increased by phenolic compounds, alcohols, detergents, and quaternary ammonium compounds.
- The alteration of interior proteins (destroying their cellular function) is caused by halogens, phenols, and alcohols.
- Interference with the action of intercellular enzymes will stop metabolic activity. Compounds toxic via this effect include cyanide, strong oxidants (chlorine, etc.), phenols, metals, and metalloids.
- Interference with nucleic acid synthesis can prevent bacterial reproduction; heavy metals can act in this fashion. Environmental conditions also play a role in the impact that toxic materials have, particularly for metals. Toxicity of metals is governed by concentration, chemical form of the metal, pH and Eh of the environment, the type of microbial system involved (i.e., aerobic or anaerobic), and potential for adaptation of the bacteria. Toxic forms of metals include soluble salts and anionic complexes. Insoluble salts, oxides, or even elemental forms are not necessarily toxic. The best method to evaluate groundwater for the presence of potentially toxic metals is to collect and test filtered water samples.

Effect of pH

Bacteria are sensitive to pH conditions. Most bacteria that are indigenous to groundwater systems and functional in the MNA process thrive in the pH range of 6.3 to 7.5. An anthropogenic pH lower than 5.0 is inhibitory or toxic from the pH effects alone. In cases where native groundwater has lower pH, the indigenous bacteria will have likely adapted to that specific condition, which is the case in lignite-rich areas of east Texas where it is common for the native groundwater pH to be as low as 4.5. Lower pH will cause an increase in soluble metal concentrations, including metals that may be native to the aquifer matrix.

REDOX Conditions

Oxidation-reduction (Redox) potential largely impacts the consortia of bacteria that will be active and the electron acceptor available to be used by the system. Almost any range of Eh conditions has the potential to offer effective biodegradation. However, some anaerobic systems are more sensitive to toxic compounds.

Toxicity Issues

Some naturally occurring metals and compounds, as well as man-made pollutants, have contributed to minimizing or stopping *in situ* biodegradation processes. As a general rule, heavy metals in excess of 2,500 mg/L are too toxic for microbial populations (5).

These toxic elements and compounds affect bacteria consortia and bacterial adaptability at the site. There are substances or compounds commonly found at contaminanted sites that have proven to be toxic to microbial populations. In instances where a concentration range is given, the low value represents inhibition of microbial activity, and the high value represents a concentration that will kill or stop microbial activity.

Copper may be the heavy metal with the highest toxicity with regard to the impact on the *in situ* biological degradational process. It is extremely toxic, inhibitory at low concentrations, and can interfere with the cometabolic degradation of chlorinated solvents at the lowest end of this range.

CONCENTRATION RANGES FOR SELECTED TOXIC SUBSTANCES

Copper 0.01 to 20 mg/L
Zinc 0.3 to 10 mg/L
Cadmium 0.1 to 20 mg/L
Chromium 25 mg/L - Inhibition
Nickel 25 mg/L - Inhibition
Lead 900 mg/L - Inhibition
Cobalt 0.3 to 10 mg/L
Mercury 0.01 to 20 mg/L
Methanol 90 mg/L - Inhibition
Isopropanol 55 mg/L - Inhibition
Acetone 75 mg/L - Inhibition
Pentachlorophenol 1 to 200 mg/L
TNT 10 to 100 mg/L
Cyanide 10 to 150 mg/L

Petroleum Hydrocarbons

The components of common petroleum hydrocarbons become inhibitory when soluble concentration ranges reach 200 to 500 mg/L. The upper range for lethal toxicity verges on 50,000 mg/L or free product, in which electron acceptor transport is more an issue than chemical toxicity. Evidence exists that methanogenesis may be inhibited by some constituents in crude oil.

Chlorinated Hydrocarbons

Most chlorinated solvents (also called chlorinated hydrocarbons) become inhibitory to microbes when soluble concentrations of these compounds are in the 100 to 500 mg/L range. They become toxic at concentrations around 1,000 mg/L, because of chemical attack on cell wall lipids. Chlorinated solvent concentrations in excess of 7,000 mg/L are inhibitory or toxic to microbial populations (5).

A baseline of total heterotrophic colony forming units and specific hydrocarbon degraders is useful prior to recommending natural or enhanced bioremediation at appropriate sites. If heterotrophic microbial population count is low (below 1,000 CFU per gram of dry soil), an assessment screen for compounds toxic to bacteria may be useful.

If toxic compounds are found, it may be necessary to perform some level of bench scale testing to quantify the toxic effect of suspect compounds. This assessment process is still a much less expensive procedure than the typical "pump and treat" active groundwater remediation projects. In some situations, pH amendments or other geochemical treatments can modify toxic conditions in the subsurface.

Monitored Natural Attenuation, enhanced aerobic bioremediation, and stimulated anaerobic biooxidation are likely to continue into the future. The first two are commonly used remedial approaches to obtain site closure for hydrocarbon-impacted properties where remediation time can be lengthy, the latter is a rapidly developing new tool for those processes. The costs of bioremediation can be significantly lower than pump and treat or other active and more aggressive remedial approaches. Assessing the limiting factors and performing geochemical studies help set baseline levels and allow for the monitoring of contaminant degradation over time.

Dissolved oxygen and nutrients are commonly depleted early on, so the use of enhancements to optimize subsurface conditions are frequently used. The power of nutrient stimulation to exploit native sulfate and iron for anaerobic biooxidation or the supplement of sulfate or iron salts for further stimulation of anaerobic biooxidation lies in the fact that the amendments are water soluble at relatively high concentrations and, in most instances, are also conservatively transported. They do not react until present with the utilizing bacteria and the impacting hydrocarbon. Sites using MNA as the sole remedial method to obtain site closure to low residual contaminant levels are not that common. Regardless of the biological method used, *in situ* bioremdiation methods are effective, but generally work on a slow time scale, with the results being observed over many months or years.

NITRATE CONTAMINATION OF GROUNDWATER

Ann Azadpour-Keeley
National Risk Management
Research Laboratory
ORD, U.S. EPA
Ada, Oklahoma

Jack Keeley
Environmental Engineer
Ada, Oklahoma

Groundwater supplies drinking water for half of the people in the country and represents the total water supply for many of the western states. Numerous contaminants are anthropogenic, including petroleum products, chlorinated solvents, and pesticides, but nitrate contamination can be either natural or man-made and is one of the most common chemical contaminants of groundwater. Nitrate levels in uncontaminated groundwater are generally less than 2 mg/L, but levels have been increasing during the past five to six decades in areas where contamination has occurred.

Nitrate nitrogen is predominantly the product of the microbial decomposition of nitrogenous material, and almost all nitrogen reactions in soil and groundwater are the result of microorganisms. Through decomposition, nitrogenous matter is converted to ammonia (NH_3) which is first oxidized to nitrite (NO_2^-) followed by further oxidation to the production of nitrate (NO_3^-); both are accompanied by the production of nitrogen gas (N_2). Nitrate serves as a nutrient for the production of plant life that is consumed by living animal matter, which produces wastes products and, upon death, completes the nitrogen cycle by creating nitrogenous matter.

Sodium and calcium nitrate add nitrogen directly to the soil resulting in valuable fertilizers. A large natural deposit of sodium nitrate in Chile served as a major source of nitrogen fertilizer. Geologically deposited nitrate can also be found in the San Joaquin Valley in California, Runnels County, Texas, and shale in Montana and South Dakota.

Although the degradation of plant materials can account for small amounts of nitrate in groundwater, most results from the application of fertilizers to agricultural land, parks, lawns, and golf courses. Other sources include animal wastes, seepage from septic tanks, the application of sewage and sludge to the land, precipitation, geological deposits, and biological fixation. Canter and Knox (1), for example, estimate that one trillion gallons of septic-tank waste are released to the subsurface annually. According to Nolan et al. (2), 11.5 million tons of nitrogen as fertilizer in used in agriculture annually in the United States where the production of commercial fertilizer has increased by a factor of 20 between 1945 and 1985. Manure from farm animals accounts for an estimated 6.5 million tons of nitrate annually, and that from the atmosphere is about 3.2 million tons.

Nitrates are the cause of methemoglobinemia which is also referred to as blue baby disease and nitrate cyanosis in infants. Nitrates are reduced to nitrites in the intestinal tract and absorbed into the blood. The nitrites combine with hemoglobin which deprives organs and tissues of oxygen, resulting in cyanosis which causes a blue color of the skin. Nitrates in drinking water have also been linked to non-Hodgkin's lymphoma. Other health related problems may include impairments to the nervous system and birth defects (3). The U.S. Public Health Service established drinking water standards for nitrate in 1946 at a limit of 10 mg/L expressed as nitrogen and 45 mg/L expressed as nitrate.

Generally, nitrate contamination is pervasive at shallow depths in the vadose zone. For this reason, drinking water from rural water districts or other public water supplies is less likely to contain high nitrate concentrations because of the depth of the wells and steps taken to prevent contamination from sources near the surface such as septic tanks. When water is pumped from greater depths, it is also more likely to have a low oxygen concentration that results in possible denitrification. Rural wells, on the other hand, are usually completed at shallower or depths in areas where sources of contamination, such as septic tanks, fertilizers, or manure from feedlots or holding pens, are more likely. When obtaining water from a domestic well, care should be given to ensure that the screen is placed as deep as is practicable for that location, that the upper casing is properly sealed, and that the wellhead is elevated and protected by a concrete pad and is in a secure enclosure. In a study by Schubert et al. (4), it was found the most likely scenario for exposure to high nitrates in drinking water involved families living on farms supplied by old, shallow wells. In such cases, the water should be tested periodically for nitrates as well as bacteria.

Jason J. Wen
City of Downey
Downey, California

INTRODUCTION

Nitrate is a naturally occurring compound that forms in the soil when nitrogen and oxygen combine. Small amounts of nitrate are normal, but excess amounts can pollute supplies of groundwater.

Drinking water high in nitrate is potentially harmful to human and animal health. Nitrate (NO_3) is a naturally occurring form of nitrogen (N) that is very mobile in water. It is essential for plant growth and is often added to soil to improve productivity. Water moving down through soil after rainfall or irrigation carries dissolved nitrate with it to groundwater. In this way, nitrate enters the water supplies of many homeowners who use wells or springs (1).

Sources of Nitrate Pollution in Water

Common sources of nitrogen in the soil are fertilizers, livestock waste, and septic systems. Excess nitrate in the soil is most often found in rural and agricultural areas. Nitrate travels easily through the soil and is carried by rain or irrigation water into groundwater supplies. Wells that tap groundwater may be affected. Shallow wells, wells in sandy soil, or wells that are improperly constructed or maintained are more likely to have nitrate contamination.

The distribution of nitrate contamination in the United State is widespread. It constitutes the largest amount of pollutant released into the environment. The following references describe the extent of nitrate pollution (1–3).

Agricultural runoff and seepage into the groundwater occurs wherever fertilizer is applied. The denitrification of nitrate effluent into the Mississippi River is what caused the 'dead zone' of the Gulf of Mexico area along the coast of Texas and Louisiana downstream from the Mississippi River estuary. Shallow groundwater in the farming states, Illinois, Ohio, Indiana, Iowa, and Minnesota, is heavily polluted with nitrate. Large cattle feedlots, dairy farms, and orchards in California, Kansas, and Illinois release large amounts of nitrate into shallow groundwater. Nitrate pollution in groundwater is a worldwide problem.

Nitrate Properties in Groundwater

The following references provide in-depth properties of nitrate physical chemistry, natural degradation processes, and migration phenomenon (4–7).

Health Effects of Nitrate/Nitrite in Water

Infants under 6 months of age are susceptible to nitrate poisoning. Bacteria that live in the digestive tracts of newborn babies convert nitrate to nitrite (NO_2). Nitrite then reacts with hemoglobin, which carries oxygen in blood, to form methemoglobin. Methemoglobin cannot carry oxygen, thus the affected baby suffers oxygen deficiency. The resulting condition is referred to as methemoglobinemia, commonly called "*blue baby syndrome*." The most noticeable symptom of nitrate poisoning is a bluish skin coloring, called cyanosis, particularly around the eyes and mouth. A baby with bluish skin should be taken to a medical facility immediately and tested for nitrate poisoning. The blood sample of an affected baby is chocolate brown instead of the normal bright red due to lack of hemoglobin. Methemoglobinemia is relatively simple to treat, and, in most reported cases, the affected baby makes a full recovery. Within several months after birth, the increasing level of hydrochloric acid in a baby's stomach kills most of the bacteria that convert nitrate to nitrite. By the age of 6 months, the digestive system is fully developed, and the risk of nitrate-induced methemoglobinemia is greatly reduced.

Water quality standards for human consumption have been set at 10 milligrams of nitrate-nitrogen per liter of water (10 mg/L NO_3-N). This level of nitrate-nitrogen is equivalent to 45 mg/L of nitrate (NO_3). When reading laboratory reports of water quality, be sure to note whether reported values are for nitrate-nitrogen or nitrate. Note that 1 mg/L equals 1 ppm (parts per million). Most reported cases of blue baby syndrome due to contaminated water have occurred when infant formula was prepared using water that contained more than 40 mg/L NO_3-N. Consumption of high-nitrate water by pregnant women and nursing mothers is not as likely to be harmful to babies as direct consumption. The health effects in these cases are not completely understood, so it is recommended that pregnant women and nursing mothers limit nitrate consumption. Possible connections between nitrate and other health problems such as nervous system disorders, cancer, and heart damage are not well documented and are currently being researched.

Ruminant animals (cattle and sheep) and infant monogastrics (baby pigs and baby chickens) are also susceptible to nitrate poisoning because of bacteria living in their digestive tracts. Horses, even though they are monogastric, are susceptible to nitrate poisoning throughout their lives. Livestock may be exposed to large quantities of nitrate in their feed as well as in contaminated water. Animals that are treated in time can recover fully from nitrate poisoning. Scientific studies indicate that water that contains more than 25 mg/L NO_3-N can be harmful to animals.

Water Use Criteria for NO_3/NO_2 in Water

The U.S. Environmental Protection Agency (EPA) has established the maximum contaminant level (MCL) for nitrate at 10 milligrams per liter (mg/L). In addition, EPA established an MCL for nitrite at 1 mg/L.

Water quality standards for human consumption have been set at 10 milligrams of nitrate-nitrogen per liter of water (10 mg/L NO_3-N). This level of nitrate-nitrogen is equivalent to 45 mg/L of nitrate (NO_3). The presence of high nitrate levels may indicate that other, more serious contaminants may also be entering your water supply. Nitrate and coliform bacteria concentrations are commonly used to indicate well water contamination by surface waters. Water with nitrite (NO_2) levels of 1 ppm or more also is not recommended for human consumption.

These guidelines will help you interpret the results of your water test. Be careful when interpreting different lab results. Nitrate can be measured as NO_3 or as NO_3-N, and the results mean very different things (Table 1).

Nitrate is colorless and odorless. The surest way to tell if you have nitrate in your water is to have it tested. If your water comes from a public water supply, such as a city supplier, it is tested regularly to ensure that it meets safe drinking water standards. If your water comes from a private well, you are responsible for testing it and ensuring that it is safe to drink.

Table 1. Guidelines for Drinking Water

Measured Level (mg/L)	Interpretation NO_3
0–44	Below the drinking water standard. The nitrate level is safe for humans and livestock.
45–176	Higher than the drinking water standard. The water should not be consumed by infants 6 months of age or younger or by pregnant or nursing women. It may be acceptable for adults and livestock, though it is not recommended.
176+	Significantly higher than the drinking water standard. The water should not be consumed. Install a water treatment system or use bottled water for drinking and cooking.
Measured Level (mg/L)	**Interpretation NO_3-N**
0–9	Below the drinking water standard. The nitrate level is safe for humans and livestock.
10–39	Higher than the drinking water standard. The water should not be consumed by infants 6 months of age or younger or by pregnant or nursing women. It may be acceptable for adults and livestock, though it is not recommended.
40+	Significantly higher than the drinking water standard. The water should not be consumed. Install a water treatment system, or use bottled water for drinking and cooking.

Water Testing Frequency

Unfortunately, nitrate is only one of several possible contaminants in well water, which is why water districts recommend that well users conduct comprehensive tests of their water supplies every 1 to 3 years, or more frequently if the taste, odor, or appearance of the water changes, or if you have specific health concerns.

Preventive Measures for Nitrate/Nitrite Pollution

Septic systems, animal waste, and fertilizer are all potential sources of nitrate contamination. Water that comes into contact with a source of nitrate can carry that contamination through the soil and into the groundwater supply. Follow these guidelines to reduce the risk of nitrate contamination:

1. Proper well location: Wells should be located uphill (up-gradient) and at least 100 feet away from septic tanks, leach fields, animal confinement areas, and fertilized areas.
2. Proper well construction: Make sure your well casing extends above the ground, and construct an earth berm around the well to divert surface runoff away from the wellhead. Also, make sure your well has at least a 50 feet deep annular seal (grouting around the outside of the well casing) and an intact concrete slab on the wellhead.
3. Operate your septic system correctly: Maintaining your septic system regularly will help avoid system failure, which can lead to water contamination, the spread of disease, and the need for costly repairs. Follow these guidelines:

Do not run heavy vehicles over the area above your septic tank, drain pipes, or leach field.

Avoid planting trees or shrubs near drain pipes or the leach field. Roots can clog the lines.

Do not dispose of chemicals or nonbiodegradable materials in your toilet or drain.

Conserve water.

Install a lint trap on your washing machine.

Hire a reputable contractor to pump out your septic tank every 2 to 3 years.

If you have two leach fields, switch them every year.

4. Reduce your use of fertilizer: Use lawn and garden fertilizers only when necessary and always according to the manufacturer's instructions. Farmers can use management practices that are both environmentally and economically sound.

BIOLOGICAL DENITRIFICATION

Biodenitrification will probably be a very common technology used to comply with nitrate/nitrite regulation (8).

The demonstration project has developed a two-stage *ex situ* anoxic biofilter biodenitrification process. The process is fixed film bioremediation, using biocarriers and specific bacteria to treat nitrate-contaminated water. Unique to the process is a patented mixed bed reactor that retains the biocarrier within the system, thus minimizing solids carryover. Fixed film treatment allows rapid and compact treatment of nitrate with minimal byproducts. Methanol is added as a source of carbon for cell growth and for metabolic processes that remove free oxygen. The resulting oxygen-deficient environment encourages the bacteria to consume nitrate. Methanol is also important to ensure that conversion of nitrate proceeds to produce nitrogen gas rather than the more toxic nitrite intermediate.

The mechanism for anoxic biodegradation of nitrate consists of two sequential denitrification reactions. Oxygen must be consumed to a dissolved oxygen concentration of <1 mg/L. In the first denitrification step, the bacteria are forced to substitute the nitrate as the electron acceptor and the nitrate is reduced to nitrite. In the second step, the nitrite is further reduced to nitrogen gas. Nitrite production is an intermediate step, and there is no a priori reason to assume that the second reaction is at least as fast and/or favored as the first reaction in the presence of a specific bacterial population. Consequently, any evaluative scheme must establish that there is no buildup of nitrite, particularly because the nitrite-nitrogen maximum contaminant level (MCL) is only 1 mg/L, one-tenth that of nitrate. High concentrations of nitrate and high nitrate/methanol ratios may also affect the concentration of residual nitrite in a particular process configuration.

A simplified process diagram of the treatment system used during the demonstration is composed of two major components: a biodenitrification system and a polishing or posttreatment system. The biodenitrification system is intended to convert nitrates in the groundwater to nitrogen, thus reducing nitrate concentrations. The posttreatment system destroys or removes intermediate compounds generated during the biological breakdown of nitrate and removes bacteria and suspended solids that are not attached to the biocarrier. The posttreatment system can also incorporate treatment for other contaminants, such as VOCs, that may be in the influent.

Biodenitrification is conducted in two reactors, R1 and R2, respectively. The major part of the oxygen removal step is conducted in R1 where aerobic bacteria reduce the dissolved oxygen levels of the influent. Methanol is metered to the tank to encourage the bacteria to begin consuming nitrate. The resulting oxygen-deficient water is pumped from the bottom of R1 to the bottom of R2, which is densely packed with biocarrier media (1 cm) that have the appearance of small foam cubes. A patented mixing apparatus within R2 directs the incoming water into a circular motion, thus ensuring intimate contact with the biocarrier. Within R2, the majority of denitrification occurs by anaerobic bacteria that are continually fed methanol and populate on the large mass of biocarrier media. After a sufficient retention time, depending on concentration and goal, denitrified water drains by gravity to an overflow tank, which allows for continuous and smooth transfer to the posttreatment system and removal of entrained bacteria and media.

Depending on the presence of other contaminants, the posttreatment system consists of a series of varying sized filters downstream of one or more contaminant-specific treatment units. For instance, ozonation may be used to oxidize any residual nitrite to nitrate and to deactivate/destroy all residual biological materials leaving the biodenitrification unit. If VOCs are present, an air stripper and/or carbon adsorption unit can be used. If state regulations require chlorination of drinking water, then chlorine can be added as a posttreatment or directly to the overflow tank immediately following denitrification.

Waste Applicability

Anoxic biodenitrification using one or more biocarriers should be applicable to industrial wastewaters and leachate from commercial, industrial, and hazardous waste sites containing various nitrate concentrations, as well as for treatment of groundwater (the medium treated during the demonstration). The presence of other contaminants could play a significant role in the effectiveness and viability of the overall treatment system. For example, if volatile chlorinated hydrocarbons are present along with nitrate, a postnitrate treatment system (e.g., carbon filters) may be necessary to remove those compounds to acceptable levels.

Demonstration Results

A site demonstration of the biodenitrification system was conducted at the location of a former public water supply well in Bendena, Kansas. This study, from May until December of 1999, was conducted in cooperation with the Kansas Department of Health and Environment (KDHE). The KDHE provided a small building and necessary utilities for the EcoMat systems. In addition, the state is analyzing water samples independently.

The demonstration focused on treating contaminated water from the Bendena Rural Water District No. 2 Public Water Supply (PWS) Well No.1. This former railroad well, constructed in the early 1900s, was at one time the sole source of water for the town of Bendena. The primary contaminant in the water is nitrate from uncertain sources ranging from 20 to 130 mg/L. Low concentrations of VOCs, particularly carbon tetrachloride (CCl_4), in the groundwater, ranging from 2 to 31 g/L, are a secondary problem.

The main goal of the study was to demonstrate that its biodenitrification system could reduce incoming nitrate-N in excess of 20 mg/L to a combined nitrate plus nitrite concentration below 10 mg/L. A second goal of the study was to demonstrate that the posttreatment system used would produce treated water that would meet applicable drinking water standards with respect to nitrate-N and nitrite-N; and that the final effluent would not have turbidity greater than 1 NTU, detectable levels of methanol (1 mg/L), increased levels of biological material or suspended solids, and a pH in the acceptable 6.5 to 8.5 range.

To evaluate both the biodenitrification system and the posttreatment system adequately, water samples were collected from four specific points along the entire process, which were (1) an influent sample point between PWS #1 and R1, (2) a partial treatment sample point between R1 and R2, (3) an intermediate effluent sample point between the biodenitrification system and the posttreatment system, and (4) a final effluent sample point downstream of the posttreatment system. To ensure a statistically adequate number of samples, an average of 30 influent and 30 effluent samples were collected for each of four separate sampling episodes. Over an approximate seven and one-half month period, EcoMat operated its system at a flow between 3 and 8 gallons per minute. Results from the biodenitrification process were encouraging when the entire system was operating at optimal performance. In those instances where the final combined nitrate-nitrite effluent concentration was above the regulatory limit, operating problems (mostly mechanical) were suspected as the primary cause.

REVERSE OSMOSIS TREATMENT

Reverse osmosis (RO) systems can often improve the quality of water. Reverse osmosis water treatment has been used extensively to convert brackish water or seawater to drinking water, to clean up wastewater, and to recover dissolved salts from industrial processes. It is becoming more popular in the home market as homeowners are increasingly concerned about contaminants that affect their health and about nonhazardous chemicals that affect the taste, odor, or color of their drinking water. People considering the installation of a water treatment system to reduce toxic chemicals should first have their water tested to determine how much, if any, hazardous compounds are in the water. Public water supplies are routinely monitored and treated as required under the federal Safe Drinking Water Act and state regulations. Private water systems should be tested at the owner's initiative based on knowledge of land use and contamination incidents in the area (9).

Reducing Contaminants through RO

Reverse osmosis reduces the concentration of **dissolved solids**, including a variety of ions and metals and very fine suspended particles such as asbestos, that may be found in water. An RO device may be installed following a water softener to reduce the concentration of sodium ions exchanged for hardness ions. RO also removes nitrate (NO_3^-), arsenic (As), chromium (Cr), certain organic contaminants, some detergents, and specific pesticides.

The Reverse Osmosis Process

In reverse osmosis, a cellophane-like membrane separates purified water from contaminated water. An understanding of osmosis is needed before further describing RO. Osmosis occurs when two solutions containing different quantities of dissolved chemicals are separated by a semipermeable membrane that allows only some compounds to pass through. Osmotic pressure of the dissolved chemical causes pure water to pass through the membrane from the dilute to the more concentrated solution. In reverse osmosis, water pressure applied to the concentrated side forces the process of osmosis into reverse. Under enough pressure, pure water is "squeezed" through the membrane from the concentrated to the dilute side. Salts dissolved in water as charged ions are repelled by the RO membrane. Treated water is collected in a storage container. The rejected impurities on the concentrated side of the membrane are washed away in a stream of wastewater, not accumulated as on a traditional filter. The RO membrane also functions as an ultrafiltration device, screening out particles, including microorganisms, that are physically too large to pass through the membrane's pores. RO membranes can remove compounds in the 0.0001 to 0.1 micron range (thousands of times smaller than a human hair).

Design of an RO System

Although the reverse osmosis process is simple, a complete water treatment system is often complex, depending on the quality of the incoming water before treatment and the consumer's needs. Most home RO systems are point-of-use (POU) units placed beneath the kitchen sink to treat water used for cooking and drinking. Point-of-entry (POE) systems that treat all the water entering the household are more expensive to purchase and operate than POU systems.

A typical home reverse osmosis system consists of pretreatment and posttreatment filters as well as an RO membrane, flow regulator, storage container for the treated water, and dispensing faucet. The pressure for RO is usually supplied by the feed line pressure of the water system in the home, but a booster pump may be needed to produce an adequate volume of treated water. A sediment prefilter is essential for removing relatively large sand grains and silt that may tear or clog the RO membrane or clog a pump or flow regulator. Water softeners are used in advance of the RO system when household water is excessively hard. If the water is chlorinated or contains other oxidizing chemicals such as bromine, an activated carbon prefilter is needed to protect membranes sensitive to these chemicals.

To remove certain pesticides and organic solvents, activated carbon (AC) posttreatment must be included in the system. A standard AC filter positioned after the storage tank removes compounds that cause unpleasant taste and odors, including those from the tank or plastic tubing, just before water is dispensed. To remove high levels of organic chemicals such as trihalomethanes, volatile organic chemicals, and chloramines, an additional prolonged contact carbon filter (PCCF) is placed between the RO membrane and the storage tank. Combining an activated carbon filter with RO expands the range of chemicals the system can remove. Furthermore, AC treatment is improved because RO removes compounds that adversely affect AC adsorption.

The storage tank, tubing, and dispensing faucet should be made of plastic, stainless steel, or other nontoxic materials. The low pH and mineral content of RO-treated water may corrode copper pipes and allow lead to leach into the drinking water from brass components.

RO Membrane Materials

The most common RO membrane materials are polyamide thin film composites (TFC) or cellulosic types [cellulose acetate (CA), cellulose triacetate (CTA), or blends]. Very thin membranes are made from these synthetic fibers. Membrane material can be spiral-wound around a tube, or hollow fibers can be bundled together, providing a tremendous surface area for water treatment inside a compact cylindrical element (Fig. 1). Hollow fiber membranes have greater surface area (and therefore greater capacity) but are more easily clogged than the spiral-wound membranes commonly used in home RO systems.

The flux, or capacity, of the RO membrane indicates how much treated water it can produce per day. Typically, RO membranes for home systems are rated in the range of 10 to 35 gallons per day. Thus, under standard operating conditions it could take from 2 to 6 hours to fill a two and-a-half-gallon storage tank. CA/CTA membranes have adequate capacity for most households, but TFC membranes should be used if large volumes of treated water are needed.

RO membranes are rated for their ability to reject compounds from contaminated water. A rejection rate (% rejection) is calculated for each specific ion or contaminant as well as for reduction of total dissolved solids (TDS). It is important that consumers know their specific requirements for water quality when buying a system. For example, high rejection rates are essential when high nitrate or lead concentrations in the water must be brought below the EPA maximum contaminant or action levels.

Efficiency of RO Systems

The performance of an RO system depends on membrane type, flow control, feed water quality (e.g., turbidity, TDS, and pH), temperature, and pressure. The standard at which manufacturers rate RO system performance is 77 °F, 60 pounds per square inch (psi), and TDS at 500 parts per million (ppm). Only part of the water that flows into an RO system comes out as treated water. Part of the water fed into the system is used to wash away the rejected compounds and goes down the drain as waste. The recovery rate, or efficiency, of the system is calculated by dividing the volume of treated water produced by the volume of water fed into the system. If not properly designed, RO systems can use large quantities of water to produce relatively little treated water. Most home RO systems are designed for 20 to 30% recovery (i.e., 2–3 gallons of treated water are produced for every 10 gallons put into the system). Home RO systems can operate at higher recovery rates, but doing so may shorten membrane life. The flow regulator on the reject stream must be properly adjusted. If the flow is slow, the recovery rate is high, but RO membranes are easily fouled if concentrated impurities are not washed away quickly enough. If the flow is too fast, the recovery rate is low and too much water goes down the drain. Overall water quality affects the efficiency of an RO system and its ability to remove specific contaminants. The higher the TDS, the lower the recovery rate of treated water. The amount of treated water produced decreases by 1 to 2% for every degree below the standard temperature of 77 °F. An RO system supplied with well water at a temperature of 60 °F produces only three-quarters of the volume it would produce at 77 °F. For an RO system to function properly, there must be enough water pressure. Although most home RO systems are rated at 60 pounds per square inch, the incoming feed line pressure of many private water systems is less than 40 psi. The RO system must work against back pressure created in the storage tank as it fills with water and compresses the air in the tank. The RO device must also overcome osmotic pressure, bonding between water molecules and dissolved impurities; the higher the TDS level, the greater the osmotic pressure. The net water pressure at the RO membrane can be calculated by subtracting back pressure and osmotic pressure from feed line pressure. If the net water pressure at the membrane is lower than 15 psi, treated water production is less efficient and contaminant rejection rates are lower. Auxiliary pumps can be added to the treatment system to boost pressure and improve the quality and quantity of water produced. High-quality RO systems have valves that shut off the flow whenever storage tank pressure reaches two-thirds of the feed pressure; at that point, low net water pressure can result in low rejection rates. In some systems, once the storage tank is filled, surplus treated water is discarded; water loss from such units is frequently excessive. A system that automatically shuts off when the pressure on the tank reaches a given level saves water.

Maintenance of an RO System

An RO system must be well maintained to ensure reliable performance. Clogged RO membranes, filters, or flow controls decrease water flow and system performance. If fouling is detected in early stages, the membrane can often be cleaned and regenerated. The cleaning procedure varies depending on the type of membrane and fouling. Completely clogged or torn RO membranes must be replaced. In addition, pre- or postfilters must be replaced once a year or more often, depending on the volume of water fed through the system and the quality of the feed water. Damage to RO membranes cannot be seen easily. The treated water must be analyzed periodically to determine whether the membrane is intact and doing its job. Many systems now have a built-in continuous monitor that indicates a high TDS level, a sign that the system is not operating properly. It may also be necessary to test regularly for specific health-related contaminants such as nitrates or lead. Microorganisms, dead or alive, can clog RO membranes. To prevent biofouling, RO units must be disinfected periodically with chlorine or other biocides provided by the manufacturer. Continuous chlorination can be used with cellulosic membranes to protect the system from biofouling and eliminate the particle-trapping slime that worsens other forms of fouling such as scaling. Chlorine and other oxidizing disinfectants are harmful to thin film composite membranes. If the feed water is chlorinated, an activated carbon unit must be used to remove the oxidizing chemicals before they reach the TFC membrane. Activated carbon (AC) prefilters should not be used on nonchlorinated water supplies because they provide a place for microorganisms to multiply and lead to increased biofouling of the RO membrane surface. It is important to replace AC filters periodically following the manufacturer's instructions, especially after an extended shutdown period during which microorganisms can flourish.

Choosing an RO System

Homeowners who are thinking about buying reverse osmosis systems should determine their initial water quality and their goals in adding water treatment systems. RO removes many inorganic impurities from drinking water, especially nitrate. Its effectiveness depends not only on the type of membrane but on feed water quality, temperature, pressure, and flow control, as well as the type and concentration of specific contaminants to be removed. A typical RO system consists of a sediment filter, pump, reverse osmosis membrane, flow regulator, storage tank, final activated carbon filter (for taste and odors), and dispensing faucet. An AC prefilter is sometimes needed for dechlorination. RO is commonly used to treat only the water used for drinking and cooking at the point of use rather than at the point of entry for all household use. RO membrane types vary in their ability to reject contaminants and differ in capacity (the volume of treated water produced per day). Water pressure is an important factor in determining the RO system's rejection rate, capacity, and recovery rate (amount of treated water produced per amount of feed water used). Maintenance of an RO system is essential for reliable performance. High levels of TDS and microorganisms in the system are commonly the cause of fouled membranes. Treated water should be monitored for TDS and the level of any specific contaminants that may affect health.

A list of home water treatment devices certified by various state Department of Health Services can be found on their web sites.

INNOVATIVE *IN SITU* TREATMENT

The following are advanced studies for *in situ* groundwater treatment containing nitrate.

Metallic Ion Treatment

Metallic iron was selected as a new reductant for chemically reductive removal of nitrate from water in this study (10). The effect of pH on the reduction rate and products of nitrate was investigated using a fixed dosage of iron powder (size: 80 mesh) of 12 mol-Fe:mol-N^{-1} under acidic ($pH = 2-5$) and aerobic conditions. The reduction of nitrate by metallic iron was a pseudo-first-order reaction under our experimental conditions. The reduction rate of nitrate increased with decreasing pH of the reaction solution, and the pseudo-first-order reaction rate constants were 0.49, 0.40, 0.05, and 0.01 h^{-1} at $pH = 2$, 3, 4, and 5, respectively. The reduction products of nitrate were ammonia and nitrogen gas, and their yields were strongly affected by pH. The yields of nitrogen gas were 30, 31, and 45% at $pH = 3$, 4, and 5, respectively, but no formation of nitrogen was found at $pH = 2$. It was also demonstrated that the indirect reduction of nitrate by hydrogen generated from the reaction between protons and metallic iron may be a major mechanism for the reduction of nitrate under the experimental conditions.

Wetland Treatment

Constructed wetlands have become popular, mainly for polishing wastewater effluent (11). In the arid southwest, where natural wetlands have all but disappeared, constructed wetlands can be a significant wildlife attractant. In our arid climate, wildlife enhancement can be considered an "intermediate" use of wastewater before it is discharged or recharged to aquifers. Despite the widespread popularity of wetlands, our understanding of the biogeochemical transformations occurring in wetlands is lacking. Furthermore, the "black box" design approach commonly used for designing treatment wetlands is archaic.

The C:N Ratio as a Design Guideline. Baker also evaluated the effect of hydraulic loading rate (HLR) and carbon addition (chopped up cattails that were "fed" to the microcosms once a week) on nitrate removal in microcosms that received water containing 30 mg NO_3-N/L. We found that the "critical" C:N ratio for denitrification was 5:1 and that the denitrification rate constant varied linearly with carbon addition.

As wetlands are inherently well suited for nitrate removal (carbon supplied by plants; anoxic mats), potential N removal rates are much higher for wetlands receiving nitrate than for wetlands receiving nonnitrified wastewater. Nitrate treatment wetlands could have broad application for treating irrigation return flow, remediating nitrate-contaminated aquifers, and removing nitrate in nitrified wastewater effluents prior to recharge.

Model of N and C Transformations in Wetlands. During 1996, nitrogen transformations were studied in a wetland receiving lagoon effluent in Kingman, Arizona. In this study, various N species (SON, PON, ammonium, nitrate) were measured for 10 months at 13 locations along the longitudinal axis of the wetland. On average, the wetland removed 75% of input N. Effluent TN levels were consistently <15 mg/L and NO_3-N was always <10 mg/L. In the same study, it was found that effluent DOC concentrations represent the balance between the degradation of DOC in wetland inflow (lagoon effluent) and DOC produced by decomposition of plants.

Low-Tech Wastewater Reuse System. Others have studied the potential for using wetlands as part of a low-tech approach to treat and recharge wastewater in small towns in the United States and Mexico that have limited water supplies and must recycle wastewater if they continue to grow. Proposed systems would treat effluent from an existing aerated lagoon in a wetland; the effluent from the wetland would then be infiltrated through the soil to recharge groundwater. The lagoon would provide most of the BOD and SS removal. Further removal of SS, BOD (and DOC), and most of the N removal would occur in the wetland. Infiltration would remove additional DOC and filter most pathogens. Finally, we developed an integrated design concept that incorporates a "plug flow" component to assure high-level treatment and more natural components (pools; riparian areas) for wildlife habitat.

In Situ Iron Filing Curtain Treatment of Nitrate Contaminated Agricultural Runoff

The common agricultural practice of overapplying slow-release nitrate-based chemical fertilizers, such as ammonium nitrate, and livestock waste disposal practices can result in substantial levels of nitrate (NO_3^-) concentrating in agricultural water runoff that enters streams, rivers, and groundwater aquifers. In many agriculturally intensive regions, the groundwater nitrate concentration exceeds human drinking water standards. These agricultural regions quite often face restricted land development opportunities as strict government nitrate approval criteria are often imposed on developers to ensure that the problem is not worsened by adding new residential and commercial sources of potential nitrate contamination. Beyond the immediate human health impacts, nitrate-laden agricultural runoff that enters rivers and lakes also represents a significant contributor to excessive growth of algae blooms that can negatively impact these ecosystems.

In recognition of these impacts, a passive reactor system for containing and treating nitrate-contaminated agricultural runoff has been developed. Nitrate-laden runoff is gravity conveyed by land drain pipes or ditches to a collection reservoir. The contained runoff is then further gravity fed through a reactor system that is kept under anaerobic conditions and uses a reactive porous carbonaceous medium to convert the nitrates to a less harmful form of nitrogen. In most practical applications of the technology, the low-cost and easily constructed reservoir and reactor system can be passively connected to the end of an existing farm field drainage tile system without any requirement for pumping or chemical addition equipment and without maintenance requirements for many years after installation.

A small-scale field test was completed during June 1991 to May 1992, the results of which were documented in a paper accepted by the *Journal Contaminant Hydrogeology* (7/93). More recently, the technology has been commercially applied at several other sites in Ontario. Canadian patent #2068283 has issued, and the technology is available for licensing in Canada. U.S Patent #5,330,651 has been issued, and the technology is licensed in the U.S to Lombardo Associates Inc. (www.lombardoassociates.com), Contact:

In Situ Electrokinetic Treatment

Electrokinetic treatment of nitrate, chromium, arsenic, and manganese may provide a cost-effective solution (12).

The electrokinetic treatment process involves applying direct current (dc) in a medium (soil and water). The flow of electrons from anode to cathode creates a migration of cations in the medium toward the cathode. The electrolysis of water creates a higher pH and oxidizes the metal or reduces the valence of the metal which renders the metal into a nontoxic form near the cathode. Clayey material may show a dramatic increase in cation exchange capacity under a high pH near the cathode. The proposed electrokinetic process can be applied both *in situ* and *ex situ*. Figure 1 presents a more realistic distribution of the various valence states of metals under the proposed *in situ* electrokinetic influence.

Besides the treatment of the metals, the beneficial side effects of the *in situ* EK treatment are as follows:

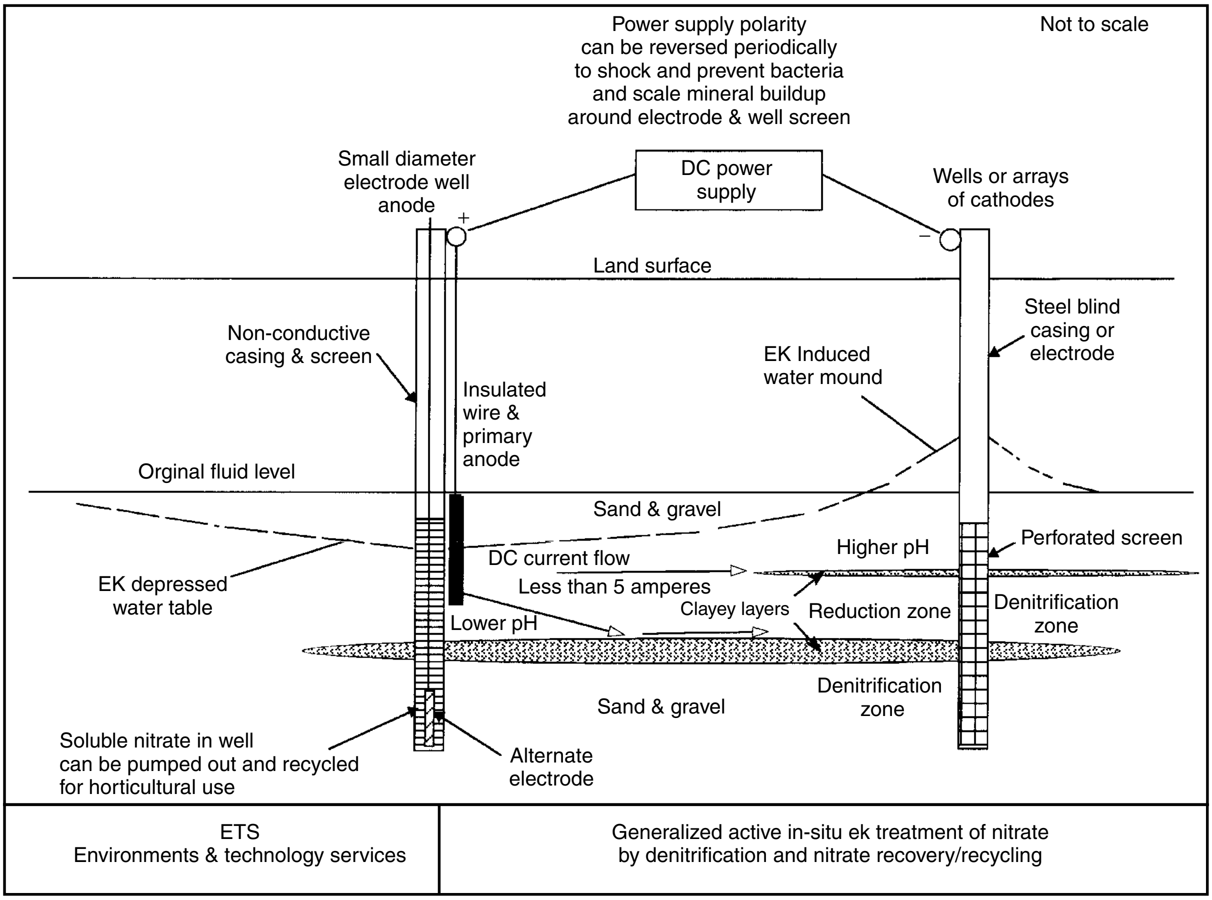

Figure 1. Generalized active *in situ* EK treatment of nitrate by denitrification and nitrate recovery/recycling.

1. The well itself is set up as cathode, so iron bacteria will not live on the surface of the well casing and perforation because of the high pH.
2. The electrokinetically induced water migration toward the cathode (well) may induce an increase in hydraulic head thus increasing well yield.

No large-scale treatment has been tried on nitrate, chromium, arsenic, and manganese in a saturated medium to date. There are many successes of the proposed EK process in the laboratory and in soil. However, we have successfully demonstrated the electrokinetic control of nitrate, selenium, and boron in clayey saturated media at two sites in the Panoche Irrigation District, Central Valley, California. We believe that the same EK control can be applied to nitrate because of the similarity of the electrochemical processes (Fig. 1).

Due to the simplicity of the cathode and anode setup, we believe that the proposed EK processes will prove very cost-effective. In particular, the proposed *in situ* EK treatment (once set up) is permanent. It has a one time capital cost and minimum long-term maintenance costs. The continuous operating electricity demand will not exceed 50 amperes at 30 to 100 Vdc or 1500 w to 5000 watts per site.

NONPOINT SOURCES

Chakresh K. Jain
National Institute of Hydrology
Roorkee, India

In recent years, it is being recognized that the nonpoint sources of water pollution have greater importance than point sources, which is due in part to the continuing efforts to reduce pollution from point sources during the past few decades, as well as recognition that nonpoint sources, such as storm water, may contain harmful contaminants. Modern agriculture has also relied, among other things, on heavy use of fertilizers and pesticides. This has largely occurred without any serious regard to the environmental consequences, especially pollution of both surface and groundwater resources. Chemicals (fertilizers and pesticides) applied in agroecosystems invariably enter the hydrologic cycle and contaminate both surface and groundwater resources. Nutrients and pesticides, particularly, are of major concern because of eutrophication and toxicity. Nutrients and pesticides are transported from cropland either by being absorbed onto eroded soil particles or dissolved in runoff water, which has increased the need to identify and quantify major sources of nutrients and pesticides deposited within river systems. In this article, some basic concepts of nonpoint source pollution, including the effects and extent of pollution in surface and groundwater bodies, pollution control measures, monitoring and modeling approaches, and management options are presented.

INTRODUCTION

The assessment of nonpoint source (NPS) pollution is a perfect example of a spatially and temporally complex, multidisciplinary environmental problem that exists on multiple scales. Nonpoint source pollution accounts for more than 50% of total water quality problems. In many areas, nonpoint source pollution, such as runoffs from cropland, urban storm water, strip mining, and construction sites are becoming major water quality problems (1). Agriculture is often considered the largest contributor to nonpoint source pollution of both surface and subsurface systems. It is mainly responsible for degrading river water quality by generating runoff from animal husbandry units, which contain predominantly organic compounds from the use of mineral fertilizers and chemical pesticides.

The problem of NPS pollution is being recognized and systematically studied in Western countries (2–8) this is not so in developing countries where agricultural pollution is usually complicated by urban and industrial pollution (9). The factors that influence nonpoint source pollution include soil erosion, sedimentation, and erosion of stream banks; washing out nutrients and organic material from livestock wastes and agricultural land; storm runoff from urban areas; and atmospheric deposition. Adsorption to the surface of sediment particles provides a mechanism for transporting many contaminants derived from agricultural fertilizers, pesticides, and industrial wastes. Deposition of sediments carrying such loads in a channel or on a flood plain can have detrimental consequences for ecology and agriculture. The sediment released into a river system can promote channel instability and cause bed degradation.

In most cases, the sources and concentrations of nonpoint source pollutants result from land use interactions with the transport system. It is a source transport problem in which the hydrologic cycle provides the transport processes to move pollutants from the source to groundwater, a stream, or a reservoir. Nonpoint sources can be urban, industrial, or agricultural pollutants that are distributed over the surface. The mode of transport is the flow of water across the soil surface and in stream channels and reservoirs or the flow of water through the soil profile.

The problem of nonpoint source pollution does not involve only the traditional pollution parameters such as suspended sediment, biochemical oxygen demand (BOD), and dissolved oxygen (DO). Some of the most serious nonpoint pollution problems do not have a parallel in the traditional point source oriented environmental pollution control area. These problems include nutrients (nitrogen and phosphorous); PCB (polychlorinated biphenyl) contamination; acid rain; and pesticide contamination of surface water, groundwater bodies, and aquatic biota.

In recent years, exponential growth in population and fragmentation of farm families have caused a reduction in land holding size, consequently forcing the farmers toward intensive cultivation (10) that leads to increased soil and nutrient loss. According to Wollast (11), the increase in the dissolved nitrogen flux in rivers represents 30% of the nitrogen fixed annually by humans in combustion processes and fertilizer production. For phosphorous, the increase is only 15% of the total phosphorous mined annually. The increased biological activity due to the entry of N and P in rivers had led in some cases to anoxia and consequent fish mortality.

To understand the nitrogen and phosphorous concentrations in surface waters, one should always take into account factors such as current and historic nutrient inputs to agricultural land from fertilization and atmospheric deposition, soil type, hydrology, historical landuse, and climatic conditions. Preferential flow also plays an important role in the subsurface losses of nutrients in many soils, especially after longer periods of drought.

Various pathways are involved in transporting N and P into a river system. Depending on the pH and temperature of soils, NH_4^+ and NO_3^- ions are produced in a watershed through ammonification and nitrification of organic matter and are mobilized into rivers through runoffs. The weathering of apatitic rocks is the major natural source of PO_4^{3-}. Rain is a source of dissolved N and S. N, P, and S from fertilizer application, sewage, and nonpoint source runoff contribute significant quantities of dissolved species of N, P, and S near human habitation.

Modern high yielding crops generally require adding fertilizers, which can be inorganic or organic. Annual uptake efficiencies by crops are relatively poor, approximately 50% and 20% for N and P, respectively (12,13). Fertilizer application rates have increased considerably during the last two–three decades (14), which has resulted in the possibility of increased NO_3-N losses from terrestrial systems into watercourses through surface runoff and/or by leaching through the soil profile (15). The relative contribution of individual sources and processes to N and P losses varies spatially and temporally; it is greatly influenced by climatic and management factors.

As per the National Water Quality Inventory Report, nonpoint agricultural pollution significantly affects water quality in 68% of the drainage basins in the United States (16). It has been reported that agricultural pollution contributes 60% of the BOD, 64% of suspended solids, and 76% of total phosphorous discharged into water resources (17).

In the Great Lakes region (18,19), the phosphorous contribution from nonpoint sources represents roughly 50% of the total load to Lakes Superior, Huron, and Erie and exceeds municipal and industrial point sources. The balance is due to atmospheric fallout and shoreline erosion. Phosphorous is the limiting nutrient for controlling eutrophication of most of the Great Lakes. More than 90% of the total loading to Lakes Superior, Michigan, Huron, and Ontario originates from nonpoint sources. In addition, the International Joint Commission research (19) has found that diffuse sources, including atmospheric inputs, account for the major loading of PCBs and organic chemicals to the lakes.

Several articles discuss the urgent need for and the problems of controlling nonpoint sources of water pollution from agriculture, and others evaluated the economic aspects of controlling NPS pollution. Wallace et al. (20) presented an example of a point-NPS trading framework developed to help a discharger comply with load allocation constraints in the Minnesota River. Hoag and Hughes-Popp (21) compared the theory of pollution credit trading and its application in the Tar-Pamlico nutrient-trading program in North Carolina, where point-NPS trading is possible. The article evaluated transaction costs, number and relative discharge of participants, abatement costs, enforcement costs, trading ratio, and loading limits and identified factors that encourage or discourage trades.

SURFACE WATER PROBLEMS

In recent years, it is being recognized that nonpoint sources of water pollution have greater importance than point sources. Several studies on the nutrient levels in surface waters from agricultural watersheds have been conducted in Pennsylvania, Maryland, Delaware, North Carolina, Colorado, Denmark, and Wisconsin (22). Increased nitrogen concentrations were correlated with a greater portion of cropland area in several Chesapeake Bay watersheds (23,24), whereas phosphorus concentrations did not correlate with land use. Sediments in agricultural drainage basins were reportedly enriched with phosphorous in Delaware's Inland Bays (25,26). Deletic and Maksimovic (27) studied the water quality of storm runoff at two experimental catchments in Belgrade, Yugoslavia, and Lund, Sweden. Rai and Sharma (28) made a comparative assessment of runoff characteristics under different land use patterns within a Himalayan watershed and reported that a large quantity of sediments leaves the watershed through its rivers.

Heathwaite and Johnes (29) studied the contribution of nitrogen and phosphorous from agricultural catchments by monitoring the chemical composition of these nutrients in agricultural runoff for both surface and subsurface flow pathways. In another publication, Heathwaite et al. (30) studied the role of nitrogen and phosphorous as key nutrients that determine the trophic status of water bodies. The paper primarily focuses on results from North America and Europe, particularly for the United Kingdom where a wide range of data exists. It is reported that, in general, N and P concentrations have increased dramatically (>20 times background concentrations) in many areas and causes vary considerably, ranging from urbanization to changes in agricultural practices. Johnes and Heathwaite (31) also modeled the impact of agriculture on the nitrogen and phosphorous loading in the surface waters of two contrasting agricultural catchments.

The concentrations of pesticides in surface waters in agricultural watersheds were monitored in Arkansas (32), Nebraska (33), Idaho and Wyoming (34), California (35), and France (36). The pesticides detected include Metolachlor, atrazine, norflurazon, cyanazine, simazine, isoproturon, and organophosphate in varying concentrations. Several studies have also been carried out to evaluate the impact of pesticides on management practices (37–40).

Laroche et al. (41) used model HSPF to study the transport of pesticides on a 78-ha watershed in the province of Quebec, Canada. Pesticide concentrations were measured at the outlet of the watershed from February to November 1993. This short period of time allowed calibrating the pesticide component but precluded verification. Variations of atrazine concentration were well simulated by the Hydrological Simulation Program FORTRAN (HSPF), simulated concentrations were in the same range as observed values, and peak concentrations occurred at the same time.

Surface water-quality impacts of urban and industrial land uses were monitored in Texas (42), Utah (43), North Carolina (44), South Africa (45), and Singapore (46). Results from these studies indicated that urban land uses contribute varying levels of metals, bacteria, sediment, nutrients, and organic chemicals to surface waters. Line et al. (44) showed that metal concentrations in runoff from industrial sites varied significantly for various categories of businesses. Regarding sources of nutrients in urban areas, Linde and Watschke (47) reported that, on average, 11% of applied phosphorus and 2% of applied nitrogen were detected in runoff from turf grass plots, whereas 14% of phosphorus and 3% of nitrogen were detected in leachate.

Bouraoui and Diallaha (48) developed a nonpoint source pollution management model (Answers-2000) to simulate long-term average annual runoff and sediment yield from agricultural watersheds. The model is based on the event-based Answers model and is intended for use without calibration. Wong et al. (49) developed a land use runoff model for Santa Monica Bay using a geographic information system (GIS) coupled with an empirical runoff model. The GIS/model has simple data requirements compared to more complex models that require routing information and is useful for predicting receiving water loading on an annual basis or for single storms.

GROUNDWATER PROBLEMS

There is wide concern in developed countries that groundwater resources are deteriorating in the long term, both in quantity and quality. Groundwater pollution is a major concern mainly because of the implications for human health when it is used for drinking water. Many of the most serious sources of health risk, such as bacterial and viral infection and toxic metals, do not have a specific agricultural origin. However, nitrates, as a cause of methaemoglobinaemia, and pesticides, which have a suspected disturbingly wide array of health effects, have largely agricultural origins and are a major concern.

Concentrations of nitrogen in groundwater are an important concern because a large number of people use groundwater as their drinking water supply. In addition, much of the nitrogen entering our streams and lakes comes from nitrates in groundwater. When urea is applied as a deicing agent during the winter, large concentrations of ammonium are observed at all soil depths; however, over time, the ammonium is oxidized to nitrate, which leaches into the groundwater (50).

Nolan et al. (51) prepared national maps of groundwater vulnerability to nitrate contamination for the United States using different input parameters (population density and the amount of nitrogen contributed by fertilizer, manure, and atmospheric sources) and aquifer vulnerability (soil drainage characteristics and the ratio of woodland acres to cropland acres in agricultural areas). In England and Wales, 125 groundwater sources supplying 1.8 million people had nitrate concentrations exceeding 50 mg/L (52).

Unfortunately, very little has been done in India to carry out well-planned primary field studies to assess the impact of nonpoint source pollution. Agarwal et al. (53) reviewed the status of the diffuse agricultural nitrate pollution of groundwater in India and reported that nitrate levels in groundwater across vast agricultural areas can be correlated with intensive irrigated agriculture, corresponding use of nitrogenous fertilizers, and groundwater development. It is further reported that diffuse agricultural pollution has already endangered the safety of potable groundwater for future generations in both rural and urban areas.

In recent years, there has been a considerable rise in the number of reported incidents of pesticide contamination in groundwater due to excessive use of pesticides in agriculture. Monitoring of pesticides in central South Dakota indicated that the movement of pesticides is controlled primarily by the geological and chemical characteristics of the medium and pesticides (54). Milde et al. (55) reported the occurrence of 22 different pesticides in 34 locations in the United States and Europe. In Britain, the most extensive survey of pesticides in surface waters and groundwaters has taken place in the Anglian region where herbicide usage on cereals has been the greatest.

Milde et al. (55) stated that the main factors influencing the contamination potential of any pesticide are molecular structure, formulation, metabolism, water solubility, adsorption by soil, the retardation factor, and resistance to chemical and biochemical degradation. The time, quantity, and frequency of application, as well as the local hydrogeologic and meteorologic conditions, also affect the quantity of pesticides that reach the water table. Kolpin et al. (56) found that 70% of all 106 municipal wells sampled were contaminated by pesticides and that the different types of aquifers affected pesticide leaching differently.

Numerous workers have studied the processes that affect the movement of pesticides into groundwater. Sorption of pesticides on different types of colloids and subsequent movement of these colloids through the soil profile were studied, and the researchers found almost no increase in the transport of atrazine (57). When fluxes of pesticides from a stream bed were measured, it was found that pesticide fluxes of atrazine were two to five orders of magnitude greater in the stream bed than fluxes of atrazine through agricultural fields (58). Guo et al. (59) found that the concentration of organic matter in the soil profile affects the transport of atrazine through the soil profile. Kolpin (60) studied the effects of land use on concentrations of agricultural chemicals and reported that the concentrations of atrazine and nitrate were positively correlated with the amount of irrigated land area and that alachlor was inversely related to the amount of highly erodible land.

Loague and Corwin (61) presented a regional-scale assessment of nonpoint source groundwater contamination, and Takarate et al. (62) studied the effect of hydrology, vegetation, and substrate on the spatial and temporal variations of nutrient concentrations in the groundwater of a flood plain. It is reported that on the regional scales associated with NPS agrochemical applications, there are staggering data management problems in assessing potential groundwater vulnerability. Geographical information system (GIS) is a timely tool that greatly facilitates the organized characterization of regional-scale variability. The strengths and weakness of using GIS in regional-scale vulnerability assessments (owing to both data and model errors) have also been discussed. A regional GIS-driven integrated assessment approach is discussed, which is based upon cost–benefit analysis and incorporates both physical and economic factors that can be used in a regulatory decision process.

POLLUTION CONTROL MEASURES

Concern for nonpoint source pollution in integrated water quality management has been growing recently. Such sources are likely to be more critical in developing countries, where agriculture and rural habitats are still dominant. The term pollution control refers to regulation of pollutants from individual outfalls or nonpoint sources, including urban developing lands, feedlots, agricultural areas, and other pollution generating land uses. The purpose of all pollution control programs is to protect the capacity of surface waters to assimilate pollution without damage or impairment of their use, to protect shellfish and wildlife, to preserve or restore the aesthetic and recreational values of surface waters, and to protect humans from adverse water quality conditions (63).

Water quality management deals with all aspects of water quality problems for all beneficial uses of water or lands from which pollution originates, whereas pollution control is mostly understood as the safe disposal of wastewater and its treatment. Water quality and pollution are determined by comparing measured physical, chemical, biological, microbiological, and radiological parameters to a set of standards and criteria.

The water quality standards used presently by water pollution engineers and scientists as well as pollution abatement authorities throughout the world are either stream standards or effluent standards. The effluent standards, which determine how much pollution can be discharged from municipal and industrial wastewater sources, are of lesser importance in nonpoint source pollution control and management. Performance standards, the equivalent of effluent standards to control pollution from lands, have been used by some local authorities to control pollution from subdivisions, construction areas, and mining. The stream standards can be related to the protection of aquatic habitat and biota and/or to intended downstream use of water.

Nutrient Control

The control of nutrients is an important issue throughout the world, both from a public health perspective and to keep natural waters free from eutrophication. The most widely used water quality standard for nitrate is the 50 mg/L limit adopted by the WHO as a precautionary level to safeguard babies from the risks of contracting methaemoglobinaemia (64). Most national authorities regard the 50 mg/L concentration as a realistic target in relation to eutrophication and, therefore, programs aimed at controlling eutrophication often use this value as an EQS. Whereas there are techniques available to remove nitrate from drinking water after it has been abstracted, the eutrophication problem is universally dependent on the control of nitrate sources.

An added and unexpected health implication related to eutrophication exists, particularly in lakes. In a number of countries in the world, the phenomenon of excessive growth of blue-green algae has caused concern where recreational pursuits take place on the lakes and also where the water is withdrawn for public supply, which is due to the recognition that such algae produce a number of toxins, which, if ingested, can cause liver damage. There are a number of well-documented cases where animals are known to have died as the result of drinking water heavily laden with these algae and, for this reason alone, nutrient control is justified.

The reduction of nitrogen and phosphorous from agriculture relies upon changes in farming practices because they give rise to diffuse sources. Plowing of grassland and other crops, particularly during autumn, leads to the release of large quantities of soil nitrogen and, therefore, a general move toward permanent pasture regimes assists in lowering nitrate leaching. When this is not possible, the use of short-term rotational crops to take up nitrogen followed by their harvesting and subsequent removal from the catchment is helpful. Animal wastes should be used carefully, avoiding overuse and direct runoff into watercourses, but wherever possible they should be used in place of synthetic fertilizers. Spreading of cattle manure and liquid sludge should be banned when aquifers are being replenished by rains. A manuring season should be prescribed for main crops depending on monsoon and crop patterns in different regions. The use of biofertilizers and green manures should be encouraged, and research needs to be undertaken to improve their quality and efficiency. Use of all types of fertilizers should be carefully controlled and matched to crop requirements.

One of the most important aspects of controlling phosphorous inputs from agriculture is the need to prevent erosion from field surfaces. Phosphates tend to bind to soil particles which, washed from fields into watercourses, become a source of phosphate in suspended form and in deposited sediments. Sediments act as a long-term source of phosphate by releasing it (i.e., by redissolution) under certain environmental conditions. Physical removal of the sediment layer to remove the bound phosphate from the catchment has been tried in a number of locations around the world. Some success has been achieved in lowering phosphate levels in the Norfolk Boards in England by a combination of diverting effluents containing phosphorous out of the area, phosphorous stripping at sewage treatment works, and by dredging 1 m of sediment. Concentrations below the target of $100\,\mu\text{g L}^{-1}$ of phosphorous were reached (65).

In addition to agricultural sources, phosphate occurs in sewage effluents as a result of its use in detergents. Control of phosphate at the source is not yet practiced, and removal relies on stripping of the orthophosphate from the sewage works effluent by chemical treatment. Reductions in the polyphosphate content of some detergents may also help in controlling phosphate.

Pesticide Control

Pesticides represent a particularly difficult area of pollution control, not only because the environmental effects in relation to aquatic flora and fauna are important but because human health issues have a very important bearing on the nature of the control applied. There are several thousand formulations of insecticides, herbicides, and fungicides in common use and, therefore, the potential for water pollution is very high. There are also very stringent limits on pesticides in water used for public supply and, consequently, the control of pollution from pesticides is quite crucial.

Many pesticides in water are derived from agricultural use, and it is therefore difficult to regulate their input to water bodies. Regulation can take place only by prevention, by indirect controls on their manufacture, storage, and use. Approval for the use of pesticides is granted in the United Kingdom by the government, following expert assessment of safety and environmental risks. The active ingredients in pesticides are approved by the European Union and placed on an approved list. This Directive allows authorization provided that the pesticide is not expected to occur in groundwater at concentrations above 0.1 μg/L. Further controls are also placed on products by Directives such as that on Classification, Packaging and Labelling of Dangerous Substances.

WATERSHED MANAGEMENT PLANNING

Watershed management essentially relates to soil and water conservation by proper land use, preventing deterioration of the soil, increasing and maintaining soil fertility, reducing soil erosion, conserving water for drinking and other farm uses, increasing the availability of basic resources, and achieving the optimum productivity of land uses (66). Rai et al. (67) described the traditional conservation practices and relationship to land use in Mamlay watershed in the Sikkim Himalaya. It was observed that the agricultural land area has considerably increased during the past 40 years (66,67). The soil without tree cover on steep upland farming systems associated with more intensive agricultural practices is vulnerable to soil erosion and reduced fertility (10).

In several countries, the process of catchment or watershed planning has been introduced. Catchment management plans are designed to cover the catchment of a river and its tributaries and any associated groundwater flows. Catchment management plans are designed to be strategic in approach and to take into account regional and national policies and all activities likely to have an impact on the watercourse. As a result of the plan, the main polluting sources may be identified and solutions agreed to which can be achieved with available resources and on a timescale agreed to by all concerned.

CONCLUSION

Nonpoint source pollution is a worldwide problem and has been responsible for contamination of both surface as well as groundwater resources. The problem is a complex function of many physical, chemical, and biological interactions in relation to soil type, management practices, and climatic conditions. As progress has been made in reducing pollutant loading from point sources, the relative importance of nonpoint sources has increased. Such sources are likely to be even more critical in developing countries, where agriculture and rural habitats are still dominant. A number of special features need to be considered to tackle the problem of nonpoint source pollution. These include (1) extremely varying rainfall and stream flow pattern; (2) still largely traditional agricultural practices, average application of fertilizers and pesticides, and significant areas under farming or only marginal irrigation; (3) a very large cattle population, where agriculture is almost always linked to animal husbandry; and (4) a culture of living close to the river with dominating in-stream uses of bathing, washing, cattle wading, waste disposal, etc. and large-scale floodplain farming. There is a need to address the problems of nonpoint source pollution and to manage it as carefully as point source pollution. Catchment management plans may be designed to cover catchments of different river systems and their tributaries and associated groundwater flows. The plans should be strategic in approach and should take into account regional and national policies and all other such activities, which are likely to have an impact on the watercourse.

ORGANIC COMPOUNDS IN GROUND WATER

Thomas B. Boving
University of Rhode Island
Kingston, Rhode Island

Virtually all natural waters contain at least some amounts of organic compounds. However, as human impact on the environment increases, the concentration of organic compounds, such as solvents or petroleum products, in the hydrosphere has increased in many places. Consequently, many aquifers experience a degradation of groundwater quality, and there is strong concern how to protect this valuable natural resource effectively from further contamination.

Organic compounds in groundwater can be of natural or anthropogenic origin. Naturally occurring organic compounds in terrestrial water include carbohydrates (sugars and cellulose), lipids (neutral fats), and proteins. The building blocks of proteins are amino acids, whereas functional proteins that act as biological catalysts are enzymes. Proteins are biopolymers that can form complexes with other organic compounds. Such compounds include tannins, which are phenolic compounds that occur naturally in bark, wood, leaves, or roots of many plants. The presence of elevated tannin levels in water results in a yellowish-brown discoloration. The parameter, dissolved organic carbon (DOC), is a commonly used measure for the concentration of organic compounds in aqueous solution. DOC is the fraction of total organic carbon (TOC is all carbon atoms covalently bonded in organic molecules) in water that passes through a 0.45 micron pore-diameter filter. Typical DOC concentrations for groundwater range from a few micrograms to several 10 mg per liter and more. DOC concentrations depend on various factors, such as climate, soil and vegetation coverage, and land use.

Many organic compounds, such as proteins, lignin, or cellulose, are suspended in water. These compounds are solid phase macromolecules. The size of the suspended matter is between that of individual small molecules and macroscopic objects. Particles of this size (ranging from approximately a few nanometer to millimeter are known as colloidal organic matter). The principal source of organic matter in water is from decaying plant material or kerogen, which is the organic matter deposited in the sediments of an aquifer. Organic matter in groundwater is in part made up of humic substances. The humic substances are further subdivided into humic acid and fulvic acids. Humic acid is the fraction of humic substances that is not soluble in water under acidic conditions ($\mathrm{pH} < 2$) but is soluble at higher pH values, whereas fulvic acid is the fraction of humic substances that is soluble in water under all pH conditions. The fraction of humic substances that is not soluble in water at any pH value is referred to as humin. Humic substances are biopolymers that vary in color from light yellow-brown (fulvic acid) to dark brown (humic acid) to black (humin). The carbon based chemical structure of humic substances—especially that of humic acids and humin compounds—is very complex and is characterized by high molecular weight ($\gg$2,000 atomic mass units). The size of the macromolecules can range from 60–500 Å (1). Under the electron microscope, humic substances take the form of rings, chains, and clusters. The polarity of these compounds is intermediate between that of many (hydrophobic or nonpolar) hydrocarbons and that of polar water. For this reason, organic matter is an attractive nonpolar environment for hydrophobic compounds in aqueous solution. The partitioning of hydrophobic organic compounds to organic matter surfaces is referred to as adsorption, whereas partitioning into the organic matter is referred to as absorption. Although sorption to the solid phase of the aquifer would essentially stop or at least retard the movement of hydrophobic compounds, both adsorption and absorption to mobile organic compounds can greatly facilitate their transport in groundwater. Facilitated transport has important implications for assessing the fate and transport of organic contaminants in aqueous solution. The concentration of humic substances in groundwater increases as the DOC concentration increases and typically ranges from about

20 to 66% of the DOC mass (2). Elevated concentrations of organic matter in natural water can cause oxygen depletion, taste and odor problems, and can interfere with the water treatment process (formation of trihalomethanes as disinfection by-products during water chlorination).

Besides naturally occurring organic compounds, many waters contain compounds of anthropogenic origin. Following the definition of Schwarzenbach et al. (3), an anthropogenic compound is one that is introduced into the environment primarily or exclusively as a consequence of human activities. Thus, synthetic compounds, such as chlorinated solvents or most pesticides, as well as naturally occurring compounds, such as petroleum components, can be found in both surface and groundwater. Given the large number of synthetic chemicals and petroleum products used for domestic, industrial, and agricultural applications (including solvents, pharmaceuticals, plastics, dyes, and detergents), a discussion of individual organic compounds in the aquatic system is impractical. Hence, chemicals that share certain structural or chemical similarities are commonly grouped together. For example, those compounds that have two or more fused benzene rings are known as polynuclear aromatic hydrocarbons or polycyclic aromatic hydrocarbons (PAH), and compounds that have several chlorine atoms attached to a central biphenyl structure are called polychlorinated biphenyls (PCB) (Fig. 1). Other grouping criteria are based on (1) a common application, for example, organic compounds that are fungicides, herbicides, or insecticides; (2) a common source of origin, such as petroleum compounds that are lumped together in a group know as total petroleum hydrocarbons (TPH); or (3) similar physical properties, such as volatility. The two most often used volatility based classifications are volatile organic compounds (VOC), which include compounds such as acetone and 1,1,1-trichloroethane, and semivolatile organic compounds (SVOC), such as naphthalene and phenol. Organic compounds that typically co-occur are often discussed together. For example, benzene, toluene, ethylbenzene, and xylenes are commonly referred to as BTEX compounds. These four chemicals are aromatic petroleum hydrocarbons typically found in contaminated groundwater near leaking underground storage tanks. It is possible that a compound can fall in more than one category, for example, naphthalene (Fig. 2) is a PAH but also a common petroleum hydrocarbon and a SVOC. Table 1 provides an overview of the most common classes of anthropogenic organic compounds in the terrestrial aquatic environment.

The physical and chemical properties of many organic compounds are well known and documented. Besides some very well maintained printed data collections (5–7), a number of reputable government and commercial web sites offer information about organic compounds (e.g., www.nedi.gov/NEDI-Catalog or esc.syrres.com/efdb/Chemfate.htm). In addition, there are digital databases, such as the Environmental Fate Database (EFDB) published by United States Environmental Protection Agency (EPA), which contain data or links to data on physical/chemical properties and the environmental fate of several thousand chemicals (16).

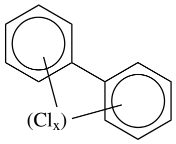

Figure 1. Polychlorinated biphenyls (PCB) are generally a complex mixture of various PCB isomers with different numbers of chlorine atoms (Cl$_x$) substituted onto the biphenyl rings.

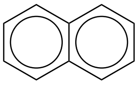

Figure 2. Naphthalene.

Many organic compounds are toxic, and even minute quantities of those chemicals make natural water unfit for human consumption. The EPA has defined threshold values for a number of organic and inorganic compounds. These so-called maximum contaminant levels (MCL) define when water is either of drinking water quality or contaminated. The MCLs and the number of entries changes with time as new scientific evidence emerges about the toxicity of listed and unlisted compounds.

New or improved analytical methods make it possible to detect compounds at lower detection limits. Better analytical resolution has also increased (and will continue to increase) the number of detectable compounds and is helping to identify possible links between the occurrence of negative health effects and the exposure to certain compounds. For example, there is evidence linking the exposure to some synthetic organic chemicals that compete with or disrupt the effects of hormones to reproductive abnormalities in wildlife, with cancer in women, and decreasing sperm counts in men. These so-called hormone or endocrine disrupters are chemicals such as some pesticides, PCBs, nonylphenols (used in surfactants), bisphenol A (a component in epoxy), phthalates (primarily used as plasticizers), and heavy metals.

Some chemicals that had been used on a large scale have been taken off the market after their detrimental biological effects and persistence in the aquatic environment became obvious. Probably the most well-known example is DDT (dichlorodiphenyltrichloroethane) (Fig. 3), which was the first chlorinated organic insecticide synthesized. DDT's effectiveness in fighting malaria and its low cost resulted in worldwide use of large quantities of that compound. In fact, DDT was credited with preventing 500 million human deaths due to malaria in little more than two decades (8). However, DDT in the environment has been linked to cancer in humans. Another organic compound that has received public attention more recently is MtBE (methyl tertiary-butyl ether) (Fig. 4). This compound has been added to gasoline and other petroleum products and has made its way into surface and groundwater. Currently, many states are trying or have already prohibited the use of MtBE as a gasoline additive after possible carcinogenic effects have been reported.

Once an organic compound has been released into the environment, bacterial activity may begin to break it down. This so-called biodegradation process works

Table 1. Important Classes of Anthropogenic Organic Compounds in Natural Waters

Class	Examples	Major uses or sources
Petroleum hydrocarbons	Benzene, toluene, ethylbenzene, xylenes, dodecane, hexane, naphthalene, pyrene	Gasoline, diesel and jet fuel, lubricating and hydraulic oils, grease, waxes
Alcohols, aldehydes, ketones, ethers	Methanol, ethanol, ethylene glycol, formaldehyde, acetone, 1,4-dioxane, tetrahydrofuran, MtBE	Solvents, chemical intermediates, antifreeze, oxygenizers (fuel additives)
Halogenated aliphatic hydrocarbons	Trichloroethene (TCE), tetrachloroethene (PCE), methylene chloride (dichloromethane), chloroform (trichloromethane), trichlorofluoromethane, methylbromide	Solvents, degreasing agents, dry cleaning fluids, refrigerants, pesticides
Polynuclear aromatic hydrocarbons (PAH)	Naphthalene, pyrene, anthracene, phenanthrene, benzo[a]pyrene, chrysene	Expect for naphthalene, there are no commercial uses. Sources: coal tar, crude oil and refined petroleum products, incomplete combustion of hydrocarbons
Polychlorinated biphenyls (PCB)	PCBs are synthetic mixtures of several congeners containing 1 to 10 chloride ions to the biphenyl. PCBs are oily liquids or waxy solids (4). Examples of commercial products containing PCB: Aroclor 1242, Clophen A30, Kenechlor 400.	Due to nonflammability, electrical insulating properties, chemical stability, and high boiling point, PCBs were used in electrical, heat transfer, and hydraulic equipment. Other uses include plasticizers in paints, plastics and rubber products; pigments, dyes, and carbonless copy paper
Substituted aromatics	Phenol, pentachlorophenol, nitrotoluene, 2,4,6-trinitrotoluene (TNT)	Pesticides, explosives, chemical intermediates
Phthalates	Di-*n*-butyl phthalate, dimethylphthlate, bis (2-ethylhexyl) phthalate. Phthalates are esters.	Plasticizers, solvents
Organosulfur and -phosphorus compounds	Malathion, Parathion, Aldicarb	Insecticides, herbicides, fungicides
Surfactants	Group of amphiphilic (partly polar, partly nonpolar) surface active compounds. Examples include alkylbenzenesulfonates (ABS), linear alkylbenzene sulfonates (LAS), fatty alcohol sulfates (FAS), quaternary ammonium chloride.	Soaps, laundry and dishwasher detergents, remediation agents

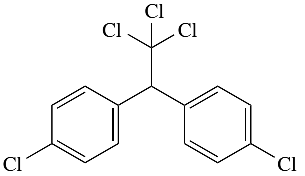

Figure 3. Dichlorodiphenyltrichloroethane (DDT).

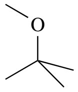

Figure 4. Methyl tertiary-butyl ether (MtBE).

best for those compounds that are naturally occurring or similar to naturally occurring compounds (crude oil and most refined petroleum products). Unfortunately, many synthetic organic chemicals are very resistant to biodegradation and can remain in the environment for a long time. In some cases, the breakdown of a chemical can result in a compound that is even more hazardous. For example, tetrachloroethene (PCE) undergoes a complex biodegradation process during which trichloroethene (TCE), dichloroethenes (DCA), chloroethane, and vinyl chloride are formed (6,7) (Fig. 5). Vinyl chloride is a known carcinogen and even as little as 2 μg/L in water is considered unsafe for human consumption. Some synthetic organic compounds have been used as molecular markers to identify waters influenced by human activity. For example, optical brighteners are synthetic organic compounds that are being added to most laundry detergents. Because these compounds pass through sewage plants or septic tanks systems almost unchanged, they can be detected in many surface and groundwaters (9,10). Other compounds, such as caffeine or the cholesterol breakdown product coprostanol, also have been used as organic tracers (11).

Water contamination from organic compounds is a global problem and is closely related to the recalcitrant nature of many organic chemicals. For example, though the solubility of many organic compounds is very low, (less than a few milligrams per liter), they exceed by far the drinking water limits in most cases.

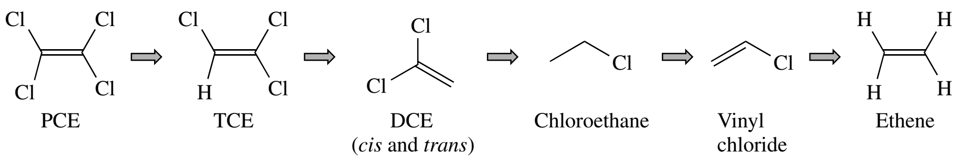

Figure 5. Simplified degradation pathway of tetrachloroethene (PCE), trichloroethene (TCE), *cis*- and *trans*-dichloroethene (DCE), chloroethane, and vinyl chloride to ethene (6).

Hence, even a relatively small spill of a toxic organic compound can contaminate a large volume of water. Many synthetic organic compounds also biodegrade very slowly, attach to organic matter or mineral surfaces, and—in the case of liquid immiscible compounds entering the subsurface—tend to have lower surface tension values than water. Thus, these compounds can enter small pore spaces or fractures from which they are hard to remove. Immiscible organic liquids are known to environmental hydrologists as nonaqueous phase liquids (NAPL). If a NAPL has a density less than that of water, it will float on the water table or the surface of a lake or a river. These compounds are called light nonaqueous phase liquids, (LNAPL). Examples of LNAPLs include gasoline, lubricating oil, and other petroleum products. Conversely, the densities of many NAPLs exceed that of water. These compounds are known as dense nonaqueous phase liquids (DNAPL). Many chlorinated solvents, such as PCE and TCE, are DNAPLs. After a NAPL, especially a DNAPL, has entered the subsurface, it is very difficult to locate and to remediate. Given the large quantities of accidentally released or illegally disposed NAPLs and other organic compounds, it will take decades or even centuries to solve the resulting environmental problems.

A number of analytical methods have been developed to analyze for organic compounds in water, but the methods approved by EPA are usually those that environmental laboratories use most (12). In many cases, the method selected depends on the desired analytical resolution and the instruments available.

Although our knowledge of organic compounds in groundwater has grown significantly during the past decades, there are still many questions to be answered. For instance, there has been a tendency to study the fate and transport of individual organic chemicals, although complex mixtures of organic compounds are much more common. Plenty of evidence now exists that interaction among multiple compounds—either synthetic or natural—results in chemical and physical behaviors distinctively different from those of simple, one-component systems. Further, physical and chemical processes in groundwater tend to be slow, and they very often exceed the length of a typical research project. Consequently, there is a slowly growing body of knowledge about the long-term (several decades) environmental fate of synthetic organic compounds in groundwater. Finally, there are a number of innovative methods under development for remediating contaminated groundwater. The expectation is that these methods will accelerate the removal of contaminants from the subsurface, therefore allowing the reuse of formerly polluted sites and, if possible, the restoration of groundwater to usable levels. Many of these methods, however, need to be tested in the field to explore their capabilities, limitations, and cost-effectiveness.

OVERDRAFT

John E. Moore
USGS (Retired)
Denver, Colorado

Groundwater mining (overdraft) occurs when there is a deliberate or inadvertent extraction of groundwater at a rate so in excess of replenishment that groundwater levels decline persistently and threaten exhaustion of the supply or at least a decline of pumping levels to uneconomic depths (1).

Under natural conditions groundwater moves from areas of recharge to areas of discharge. The water is discharged to springs, lakes, streams, wetlands, and to the ocean. In most cases, equilibrium exists, and long-term recharge of groundwater is balanced by long-term discharge. Water levels in an aquifer fluctuate in response to changes in the rate of recharge and discharge. When discharge exceeds recharge, water is released from storage, and water levels decline. Declines may amount to hundreds of feet in areas where large withdrawals from wells have caused discharge to exceed recharge for long periods of time.

Groundwater in the United States is being increasingly developed for irrigation and municipal supplies. The U.S. Geological Survey has noted that groundwater availability is a significant issue in almost every state (2). The development of groundwater has led to declining water levels in a number of areas. The water table and artesian head declines have resulted in the following:

1. stream flow depletion
2. land subsidence
3. saltwater intrusion
4. increased cost to deepen wells
5. higher costs to pump water
6. decrease in well yield
7. drying up of shallow wells and springs
8. degradation of water quality

Under natural conditions, the largest fluctuations in water levels in unconfined aquifers are seasonal. Short-term fluctuations in confined aquifers commonly occur due to such factors as changes in barometric pressure. In areas where large withdrawals from wells have caused discharge to exceed recharge for long periods of time, declines may amount to tens or even hundreds of feet. These yearly declines may stop if pumpage is reduced so that discharge is equal to or less than discharge.

In a number of areas of the United States, groundwater levels have declined 300 feet or more. Five case studies were selected where groundwater mining has had a major impact: Denver, Tucson, Chicago, California, and Las Vegas. In these areas, groundwater mining has caused land subsidence, stream flow depletion, and increased costs for pumping groundwater (3).

Denver, Colorado

The Denver Basin bedrock aquifer system supplies water to rural and suburban residents of a large area along the eastern front of the Rocky Mountains in northeastern Colorado. The geologic formations that compose the aquifer system are Cretaceous and Tertiary sandstone and conglomerate shale of the Fox Hills Sandstone, Laramie Formation, Arapahoe Formation, Denver Formation, and Dawson Arkose (Fig. 1). In 1985, 12,000 wells withdrew water from these aquifers. A large part of the rapidly growing Denver metropolitan area depends on groundwater from these aquifers. For example, about 70% of the 220,000 residents in the southern metro area obtain water from bedrock aquifers. The bedrock aquifers in the Denver Basin have supplied groundwater to the Denver area for more than 100 years. Groundwater development began in the 1880s with artesian wells in downtown Denver. The artesian pressure was used for decorative fountains, powering elevators, and church organs. The water has been used for domestic, municipal, and industrial purposes. Groundwater withdrawal from the bedrock aquifers has caused water level declines, reduced well yield, and increased pumping costs. Water levels have declined as much as 12 m (40 feet) per year in some areas. In most of the area, the artesian head will be eliminated within the next 10 years. Increased use of groundwater and water level declines has alarmed water districts, government agencies, and water users because of the increased cost and depletion of the supply.

Tucson and Phoenix, Arizona

Large water level declines have caused land subsidence and earth fissures to develop in a 3000 square mile area that includes Tucson and Phoenix. The subsidence is caused by compaction of fine-grained sediments in the basin fill. The sediments deform and compact when water-level declines subject the sediments to additional compression from the weight of the overlying deposits.

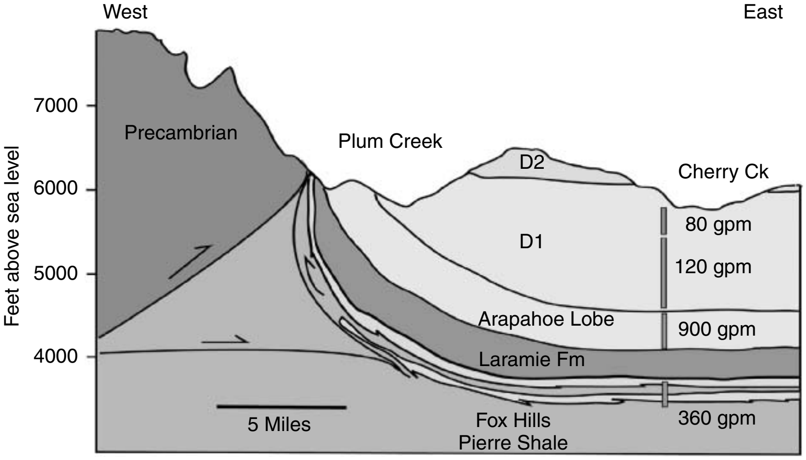

Figure 1. Denver Basin bedrock aquifers (4).

Figure 2. Pima County, Arizona. Sign warning motorists of subsidence hazard was erected after an earth fissure damaged a road in Pima County, Arizona (left photograph). Earth fissure near Picacho, Arizona (right photograph) (photographs by S.R. Anderson, U.S. Geological Survey).

Compaction increases slowly as water levels decline. Land subsidence has exceeded 15 feet since the start of groundwater development. Water levels in the Tucson area have declined 160 feet from 1945 to 1984. Compaction and land subsidence cause cracks (Fig. 2) in the land surface which can extend for hundreds to thousands of feet along the surface and can be hundreds of feet deep (5).

Central Valley, California

The Central Valley of California is one of the most intensively developed areas of irrigated agriculture. The valley is 500 miles long by 50 miles wide, and its total area is about 16,000 square miles. The valley is underlain by a large alluvial aquifer to a depth of 25,000 feet. Fresh groundwater is present to depths of as much as 4000 feet but most well water is less than 1000 feet deep. Significant development of groundwater for irrigation began in the early 1900s. As groundwater withdrawal increased to the point that groundwater withdrawal exceeded recharge, water levels started to decline. The water level declined 260 feet between 1940 and 1963. The groundwater withdrawal caused the compaction of fine-grained sediments (confining beds) which in turn resulted in subsidence of the land surface. Water level declines of 160 feet or more have resulted in land subsidence of about 30 feet in the Los Banos–Kettleman City area (Fig. 3).

Chicago, Illinois

Since 1864, large quantities of groundwater have been withdrawn from glacial drift and bedrock aquifers for municipal and industrial use. In the Chicago area, two Cambrian–Ordovician bedrock aquifers (sandstone and dolomite) supply groundwater. Water use has increased from 9.2–340 million gallons per day from 1864 to 1980. One of the first wells drilled to a depth of 711 flowed at the land surface at a rate of 400 gallons per minute. Groundwater withdrawal from the Cambrian–Ordovician bedrock aquifers (sandstone and dolomite) has caused water level (artesian head) declines of more than 800 feet (Fig. 4). No major land subsidence has been reported as a result of these large withdrawals because the rocks in the area are consolidated and resist compaction. A principal concern has been the possibility of beginning to

Figure 3. Central Valley, California: Land subsidence of 30 feet.

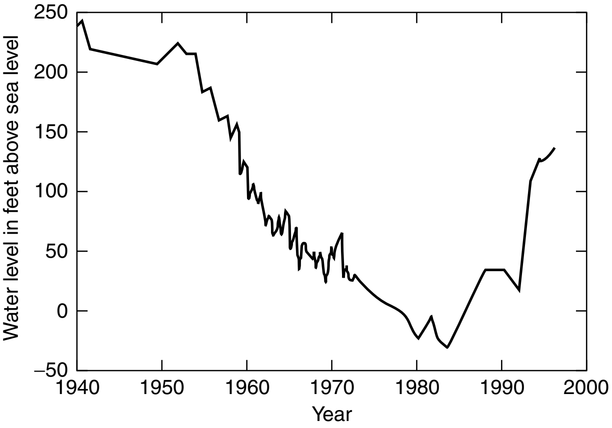

Figure 4. Chicago, hydrograph 1940–1998. (Representative trend of water levels for a deep well in Cook County, Chicago area, since 1940).

dewater the confined aquifer and thus converting it to an unconfined aquifer.

Las Vegas, Nevada

The Las Vegas Valley is the fastest growing metropolitan area in the United States. Water to support this rapid growth is being supplied by imported Colorado River water and local groundwater. Groundwater is pumped from the upper 2000 feet of unconsolidated alluvial sediments. The deeper aquifers called “principal artesian”(below 300 feet) can yield large quantities of groundwater. Overlying the principal aquifers are 100 to 300 foot thick deposits of clay. Since the 1970s, the annual groundwater withdrawal has remained between 60,000 and 90,000 acre feet. Most of the withdrawal is from the northwest area, where declines are more than 300 feet. Areas in central Las Vegas (The Strip) have experienced declines of as much as 200 feet. Since 1935, compaction of the aquifer has caused nearly 6 feet of subsidence and has led to the formation of numerous earth fissures and surface faults. Before groundwater development, the aquifer sustained the flow of many springs that discharged into Las Vegas Wash. Extensive groundwater withdrawal has caused the springs to dry up, and urban runoff has created a reservoir of poorer quality potentially contaminated water that now recharges the principal aquifer (Fig. 5).

Table 1. Subsidence and Groundwater Withdrawal

	Subsidence,		
Locality	Feet	m	Area Affected, km^2
Central Valley, CA	30	9.0	13,500
Houston-Galveston, TX	9.1	2.75	12,170
Eloy, AZ	11.8	3.6	8,700
Tokyo	15.1	4.6	2,400
Po Valley, Italy	9.8	3.0	780
London	1.1	0.35	450
Venice, Italy	0.45	0.14	400
Mexico City	28.5	8.70	225

CONCLUSION

Water level declines and subsidence have been documented in Houston, Beijing, Tokyo, Bangkok, Venice, and Mexico City (Table 1).

Water conservation and regulations should be implemented in areas where groundwater is being mined (6). Some other measures that could be used to sustain the water supply are

- artificial recharge
- water reuse
- conjunctive use of groundwater and surface water
- restrictions on lawn irrigation and other water use.

CHEMICAL OXIDATION TECHNOLOGIES FOR GROUNDWATER REMEDIATION

David B. Vance

Environmental Bio-Systems, Inc.
Mill Valley, California

INTRODUCTION

The use of chemical oxidation for the *in situ* remediation of soils and groundwater impacted with constituents of concern (COC) is a technology that has seen significant development and application in the past decade with numerous site applications in the last eight years. Three chemicals are typically utilized as oxidants:

- Hydrogen peroxide in the form of Fenton's reagent
- Potassium permanganate or sodium permanganate
- Ozone

Each has advantages and disadvantages, as does the use of chemical oxidation technology in general. There are numerous recent reviews of field application of the technology (1,2). Our purpose here is to assess the utilization of *in situ* chemical oxidation in general and the use of these three chemical oxidants in particular. In addition, these are powerful chemicals and care should be taken with their shipping, storage, and use.

Chemical oxidation has had a long history of application in the field of wastewater treatment. Hydrogen peroxide, Fenton's reagent, potassium permanganate, ozone, and combinations of ozone with other oxidants are all chemical oxidation systems that have found application for the treatment of wastewater. One of the key design issues for the application of chemical oxidation to wastewater is the total carbon load or other inorganic constituent that can be oxidized over and beyond that represented by the COC that are targeted in that waste stream. The chemical oxidants will react with and be consumed by all constituents in the wastewater stream not just the COC. In the case of the *in situ* treatment of groundwater, there are also consuming reactions associated with the geologic mineral matrix. In many instances, this adversely impacts the cost of application to the point of being impractical.

The general value of *in situ* chemical oxidation technologies resides in two areas: first, the treatment of residual free product and second, reduction of overall remediation time frames. Specifically, *in situ* oxidation is likely to be selected for difficult applications that include:

- Low permeability soils
- Highly stratified soils
- Low solubility compounds
- High concentrations of highly soluble organics (such as ketones, alcohols, or MTBE) that would be difficult to treat with conventional surface treatment technology (air stripping or activated carbon)
- Gasoline, diesel fuel, chlorinated solvents, polychlorinated biphenyls, organic pesticides, TNT, PBX, and VX
- Target compounds with low *in situ* degradation kinetic constants
- Dense, nonaqueous phase liquids (DNAPLs).

From an economic perspective, chemical oxidants are usually only practical in limited areas, typically near or in source zones. It is important to differentiate types of source zones:

- Primary source zones refer to areas that have been exposed to free phase DNAPLs. Discrete DNAPLs pools, emulsified DNAPLs, and high levels of adsorbed COC are characteristic of such zones.
- Secondary source zones refer to areas that have been exposed to high concentrations of dissolved COC. Elevated levels of adsorbed and dissolved COC are characteristics of these zones.

Chemical oxidation systems have the potential to offer rapid (from a week to a month) removal of COC. In addition, oxidation systems can be applied to dissolved plumes that are above the levels for which natural attenuation mechanisms can be expected to work within the time frames desired for site closure. Treatment of large diffuse dissolved COC plumes is possible with chemical oxidants but often not economically practical due to the effect of side reactions that consume the oxidant reagents.

The most powerful advanced oxidation systems are based on the generation of hydroxyl radicals. The hydroxyl radical is an extremely powerful oxidation agent, second only to fluorine in power. Fenton's reagent, ozone, and sonification are different means of generating those hydroxyl radicals. Each has advantages and disadvantages that can be exploited given the specific setting of a COC impacted site. A less intense, but still applicable, oxidation method involves the use of potassium or sodium permanganate. Following is a listing of common chemical oxidants, placed in the order of their oxidizing strength:

Relative Oxidation Power ($Cl_2 = 1.0$)

Fluorine	2.23
Hydroxyl radical (OH)	2.06
Activated persulfate	1.91
Atomic oxygen (singlet)	1.78
Ozone	1.50
Persulfate	1.48
Hydrogen peroxide	1.31
Perhydroxyl radical (OOH)	1.25
Potassium permanganate	1.24
Chlorine dioxide	1.15
Chlorine	1.00
Bromine	0.80
Iodine	0.54

In addition, the geology must be considered when applying a chemical oxidant *in situ*. Although the first concern is having the liquid reagents reach all of the COC in a heterogeneous situation, the soils themselves can have a significant effect on the reactions. This technology relies on water as a carrier to deliver the chemical oxidant to the COC. The macro- and microgeologic conditions do not always allow for complete contact between the chemical oxidants and the COC present in the vadose or saturated zone.

It is important to understand that COC oxidation occurs only in the aqueous phase, involving dissolved species of both the COC and the oxidant. The solubility of a targeted COC ultimately controls the rate of possible oxidation. There is interface mass transfer and then chemical oxidation. The rate of mass removal is limited by the kinetics of the COC dissolution process rather than those of the chemical oxidation reaction.

In all cases where the final product of the oxidation product is carbon dioxide, there is potential for short-term plugging of the aquifer pore space with carbon dioxide gas bubbles. In the case of Fenton's reagent, oxygen gas will also be generated and contribute to this possible problem.

Lastly, with the exception of some permanganate applications, this technology relies on the total displacement of native groundwater from the treatment zone and replacement with the reagent laden water. In the case of permanganate, the active life is sufficient that at sites with moderate to high groundwater velocities (greater than 30 ft/yr) reagent injection can take place with subsequent reliance on advection and dispersion to mix the oxidation solutions with native groundwater during transport.

CHEMICAL OXIDATION WITH FENTON'S REAGENT

Hydrogen peroxide alone has little effectiveness for the oxidation of chlorinated solvents. Fenton's reaction was first described in 1894. During the 1930s the reaction mechanisms were fully defined. Over the last 15 years commercial reactors have been available for wastewater treatment, and in the 1990s applications for *in situ* groundwater treatment have been developed. Fenton's reagent generates hydroxyl radicals through the reaction of ferrous iron and hydrogen peroxide:

$$Fe^{2+} + H_2O_2 \rightarrow {}^{\bullet}OH + Fe^{3+} + OH^-$$

The process is self-replicating because the reaction of ferric iron with hydrogen peroxide to generate the perhydroxyl radical also occurs:

$$Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + {}^{\bullet}OOH + H^+$$

The perhydroxyl radical is a weaker oxidizer (between hydrogen peroxide and permanganate). But, more importantly, the process generates ferrous ions that in turn stimulate further reaction with hydrogen peroxide to produce more hydroxyl radicals. The hydroxyl radical can react with almost any hydrocarbon to produce carbon dioxide as a final product (and chlorides if a chlorinated hydrocarbon is treated). The key application issues are delivery of the reagents *in situ* and pH control. Optimum pH for the reaction, in the range of 3.0–4.5, is driven by the iron chemistry. It is possible to use iron chelates to get the desired reaction at higher pH values (3). Improper control of the reaction will only generate oxygen and water, not high-intensity oxidation. The technology is ideal for application in source zone areas where there are high concentrations of adsorbed or even interstitial free product. Cost is mostly dependent on the geochemistry of the geologic matrix and control of the iron chemistry. Soil buffering capacity may limit the ability to obtain optimal subsurface pH conditions.

Most of the original utilization of Fenton's reagent was in relatively low concentrations in wastewater applications. The main criteria for wastewater application was to have a sufficient ratio of hydrogen peroxide to the organic chemical that was to be destroyed. The chemical oxidation process is less efficient in the presence of soil. Due to the presence of competing organics and mineral surfaces (4) that are reactive to hydrogen peroxide, and the less than optimal environmental conditions, dosage requirements for *in situ* applications may increase 10–100-fold or more to accomplish the desired oxidation of COC. With regard to the rate of reaction and the degree of completion of the reaction, high concentrations of hydrogen peroxide (10–25%) are preferred. On the other hand, excess consumption of hydrogen peroxide by reactions with the geologic matrix can be controlled by using applications (possibly multiple) at concentrations of 5% or less.

Almost all soils have native iron bearing minerals as part of their geochemical makeup. When soils contain chemically available iron, supplemental iron salts may not be required with the hydrogen peroxide injection solution (5). However, problems may occur when too many iron minerals are present in the soil. If the iron is in a mineralized form not readily available for dissolution under low pH conditions, the natural catalytic activity of the mineralized iron decomposes the hydrogen peroxide to oxygen and water and does not create the hydroxyl radical. A second problem with soil mineralogy comes from soils rich in carbonate minerals or with high alkalinity. These soils produce groundwater with a high pH, which can require unacceptable amounts of acid to buffer the pH down to the required range. Carbonate minerals respond to low pH so rapidly that the geologic matrix itself will consume acid. Lastly, the carbonate ion preferentially scavenges hydroxyl radicals before they have a chance to react with the COC.

The heat generated by exothermic dissociation of hydrogen peroxide promotes contaminant volatilization. Rapid gas generation creates turbulence that further enhances the contact of the oxidant with the targeted COC impacted zones. Concentrations of hydrogen peroxide as low as 11% can cause groundwater to boil. The rate of hydrogen peroxide decomposition doubles with every 10 °C rise in temperature, so the energy release process, once initiated, rapidly accelerates. A pound of hydrogen peroxide can release 1200 BTU of heat energy and up to 6 ft^3 of oxygen gas, which creates volatilization and transport due to the created pressure gradients, which, when exploited in a controlled fashion, can have beneficial effects regarding contact of the oxidant with the COC entrained in the geologic matrix.

For well over a decade, the cost of 50% hydrogen peroxide has been \$3.50 a gallon. Hydrogen peroxide applications are frequently used with sulfuric acid (H_2SO_4) or acetic acid (CH_3CH_2OH) as a pretreatment to optimize the subsurface pH and solubilize the naturally occurring iron as a catalyst for Fenton's reagent. Sometimes ferrous sulfate is added to the hydrogen peroxide as a catalyst if naturally occurring iron is not available. Recently, sodium persulfate ($Na_2S_8O_2$) is being used with hydrogen peroxide for *in situ* oxidation processes. In this case, the heat of reaction from the hydrogen peroxide activates the much longer-lasting sulfate ($S_2O_8{}^{2-}$) radical.

PERMANGANATE

With the permanganate ion, the initial oxidation reactions of COC are independent of pH. For example, the oxidation rate of chlorinated alkenes by potassium permanganate is not affected by pH over a range of 3.0–11.0. However, pH does impact the type of intermediate products produced: At pH 4, formic acid is dominant; at pH 6–8, oxalic and glyoxylic acids dominate. In both cases, the organic acids are subsequently oxidized to carbon dioxide. The conversion of the intermediate oxidation products to carbon dioxide does occur more rapidly under acidic pH conditions. For the initial permanganate oxidation reactions, they can generally be characterized (7) as follows:

- Acid catalyzed reactions at $\text{pH} < 5.0$
- Uncatalyzed reactions at pH 5–9
- Base catalyzed reactions at $\text{pH} > 10$

Potassium permanganate has an affinity for organic compounds containing carbon–carbon double bonds, aldehyde groups, and hydroxyl groups. The permanganate ion borrows electron density from the pi bonds in chlorinated alkenes, which creates a bridged oxygen compound known as the cyclic hypomagnate ester (6). The intermediate ester is unstable and further reacts by a number of mechanisms including hydroxylation, hydrolysis, or cleavage. Under normal pH and temperature conditions, the primary oxidation reactions involve spontaneous cleavage of the carbon–carbon bond. Once the double bond is broken, the highly unstable carbonyl groups are immediately converted to carbon dioxide through either hydrolysis or further oxidation by the permanganate ion.

Manganese dioxide (MnO_2) is the end product of the reduction of the permanganate oxyanion under neutral to basic pH conditions by the following reaction:

$$MnO_4{}^- + 2\,H_2O + 3\,e^- \rightarrow MnO_2 + 4\,OH^-$$

The MnO_2 is insoluble and forms colloids with a typical diameter near 1 μm (8). Plugging of the effective pore space can occur due to the precipitation of MnO_2. The manganese dioxide colloids can also cause problems with surface treatment equipment used as part of oxidation programs that rely on the creation of active circulation cells. The formation of insoluble manganese dioxide reaction products can also form a coating and seal around DNAPL mass, in effect blocking further dissolution and migration of the COC into the adjacent reaction areas (9), which can be a significant problem.

At low pH conditions, the reduction of the permanganate ion proceeds to Mn(II) by the following reaction:

$$MnO_4{}^- + 8\,H^+ + 5e^- \rightarrow Mn^{2+} + 4\,H_2O$$

The Mn(II) cation is soluble in water at concentrations above the regulatory limit (50 ppb) when chloride or sulfate counteranions are present.

Examples of complete reactions of permanganate with CVOCs are as follow:

$$\text{PCE}\ C_2Cl_4 + 2\,MnO_4{}^- \rightarrow 4\,Cl^- + 2\,CO_2 + 2\,MnO_{2(s)}$$

$$\text{TCE}\ C_2HCl_3 + 2\,MnO_4{}^- \rightarrow 3\,Cl^- + 2\,CO_2 + H^+ + 2\,MnO_{2(s)}$$

$$\text{DCE}\ C_2H_2Cl_2 + 2\,MnO_4{}^- \rightarrow 2\,Cl^- + 2\,CO_2 + 2\,H^+ + 2\,MnO_{2(s)}$$

The stochiometry ratios for complete oxidation reactions of permanganate as pounds of the $KMnO_4$ salt required to oxidize 1 pound of CVOC are:

PCE	1.3: 1
TCE	2.4: 1
DCE	4.4: 1
VC	8.5: 1

(The dramatic change in consumption rate is due to the fact that this analysis is on a pound per pound basis, not a molar basis. A pound of vinyl chloride has almost seven times more moles than a pound of PCE due to the loss of three heavy chlorines from the ethene backbone.)

In contrast to Fenton's reagent, the presence of carbonate minerals in the geologic matrix has generally positive effects on permanganate oxidation (10): Mn reduction stops at Mn(IV) (insoluble) rather than proceeding to potentially soluble Mn(II). Trace minerals are coprecipitated and immobilized with the manganese oxide. Consumption of permanganate by reaction with reduced mineral such a magnetite is minimized because the rates of these reactions increase with decreasing pH.

Oxidant demand from the matrix can be attributed to natural organic matter, reduced metals, carbonates, and sulfides. Permanganate demand rates can vary from a few grams of permanganate per kilogram of soil (clean sand with dissolved COC) to as much as several hundred grams of permanganate per kilogram of soil (organic clays with 6% organic carbon content and DNAPLs).

Immobile reduced metals such as chromium, uranium, vanadium, selenium, and molybdenum (all of which are soluble as oxidized oxyanionic complexes) can be oxidized and mobilized by permanganate oxidation.

When the permanganate concentration is 10 times the concentration of the CVOCs, the half-lives of TCE and

DCE range from 24 s to 18 mins; the half-life of PCE is 257 min. Typical dosage range (by weight) is 1.5–5% permanganate in the targeted treatment zone.

The potassium salt has a solubility limit of 65 g/L (6.5%); the sodium salt is significantly more soluble. However, the sodium salt is significantly more reactive. The reactivity difference between the sodium and potassium salt is not significant with regard to COC treatment. It is significant because the increased reactivity of the sodium salt presents greater safety challenges during its shipping, storage, and application.

Potassium permanganate costs $4.75 per pound.

OZONE

Ozone has been used for the treatment of drinking water since 1903. Its oxidizing power and innocuous decay products have made it ideal for that application. Ozone can generate hydroxyl radicals via catalytic decomposition of water. The oxidative power of an ozone generated hydroxyl radical is the same as those generated by Fenton's reagent. It also has specific activity toward alkenes (including chlorinated alkenes) through the attack of the double-bond carbon in a fashion similar to permanganate oxidation. Ozone bridges the carbon–carbon double bond to form unstable ozonide intermediates, which decompose into smaller oxidation species until carbon dioxide and water, or stable refractory compounds, such as acetic acid or oxalic acid, are formed. Ozone does not react well with chlorinated alkanes, particularly chlorinated methanes. Although the fate and reaction mechanisms of ozone in porous geologic media are not completely understood, it is likely that hydroxyl radical production from ozone occurs through catalytic reactions with natural inorganic (probably iron oxides) and organic material.

Ozone is fairly stable in dry air and has a half-life of several hours in low concentration. In water, ozone half-life is several minutes. As ozone is very reactive in an aqueous environment, ozone can oxidize material between 10 and 1000 times faster (11) than most oxidants used in water treatment. As ozone has such a short half-life, it cannot be compressed and stored. Instead, it must be generated on site and used immediately. Electrical generation is the only practical and safe method for large-scale applications of ozone. In practice, ozone concentrations of 1–2% using air and 3–8% using oxygen can be obtained by corona discharge generators. At a production concentration of 1% by weight in air, 650 ft^3 of air is required to produce 1 lb of ozone. As the speed of ozone destruction by decomposition is proportional to the ozone concentration, producing higher ozone concentrations with corona discharge is not feasible.

The decomposition rate of ozone has been shown to be 25 times more rapid in geologic media than in nonreactive media such as glass beads. However, the presence of carbonate ions in the groundwater can provide stabilization and double the half-life of dissolved ozone at a pH of 8.0 (12).

Other species created from ozone include superoxide anion $O_2^{\bullet -}$, which is an intermediate to the hydroxyl radical $^{\bullet}OH$; peroxide anion O_2^{2-}; oxygen atom singlet O; and the oxygen radical anion $O^{\bullet -}$.

At atmospheric pressure, the solubility of ozone is 3.4 mg/L for 1% and 7 mg/L for 2%. Note that solubility is somewhat dependent on the concentration of the ozone in the gas phase. With decreasing temperature, solubility increases. In addition, increasing hydrostatic pressure increases ozone solubility. For example, with a 1% system at 18 psi ozone solubility is 4.2 mg/L; at 25 psi it is 6.3 mg/L; and at 32 psi it is 8 mg/L.

As the TDS of the treated water increases, the solubility decreases. For example, ozone solubility is reduced 30% in seawater (13).

In most applications 1.5–3 lb of ozone is required for each pound of COC to be treated. That consumption rate is based purely on COC degradation requirements; spontaneous decay and ancillary reactions with other groundwater or mineral matrix constituents create an ozone loading requirement over and above those baseline numbers.

The cost for the generation of ozone includes the cost of the equipment: 1 lb/d unit— $7500; 10 lb/d unit— $32,500. Forty percent of the cost is for air pretreatment. The power requirements are in the range of 8–12.6 kW·h per pound of ozone produced.

PRACTICALITY OF APPLICATION

Stoichiometric Cost Comparison

The weight ratio in terms of pounds of oxidant per pound of TCE fully oxidized are 0.8 lb/lb for Fenton's reagent and 2.4 lb/lb for potassium permanganate. The cost for Fenton's regent, including hydrogen peroxide and amendments for pH control and ferrous iron addition, is typically $1.10 per pound and potassium permanganate is $4.75 per pound. So total oxidant cost per pound of TCE destroyed would be $0.88 for Fenton's reagent and $11.40 for potassium permanganate.

Calculation of a similar cost for ozone oxidation is more complicated, involving the capital costs of the equipment, the operational life of the system, electrical efficiency, and electrical costs. Following are assumptions for those key parameters.

A 10 lb/d ozone unit is purchased for $32,000 for a project life of 3 yr, which translates to a capital cost of $2.90 per pound of ozone. It requires 10 kW·h at $ 0.10 per kW·h (or $1.00) for the electrical cost to produce 1 lb of ozone. The total per pound cost for ozone is $3.90 per pound.

It requires 2.25 lb of ozone to oxidize 1 lb of COC, translating into a total cost of $8.75 for the ozone to oxidize 1 lb of COC.

Actual Application Costs

The total costs for the use of these oxidants is not accurately reflected by just the pound per pound cost required for the stochiometric oxidation of the COC. In reality, reactions with native carbon in the geologic matrix, reactions with minerals in the geologic matrix (14), and reactions with native dissolved constituents in the groundwater can increase the consumption rate of the oxidation reagents by orders of magnitude. Fenton's reagent and ozone are particularly susceptible to these effects, potassium permanganate less so.

In practical application, these chemical oxidants are not applied based on the amount of COC present (with the exception of instances when there are significant volumes of DNAPLs present); rather, they are applied to achieve a specific reagent concentration in the treatment zone. Assuming the desired reagent concentration is 5% for Fenton's reagent and permanganate (this argument is not valid for ozone as explained below), following are the per cubic yard costs for one treatment with the respective chemical oxidant:

Fenton's reagent—$21
Potassium permanganate—$115

In practice, it is likely that two to five applications of Fenton's reagent may be required to achieve the remediation goals during a treatment campaign, raising the reagent costs to the range of $42–105. In many instances, one application of potassium permanganate will be adequate for treatment, but in cases where DNAPLs are present two or three applications may be required.

The hydrogen peroxide in Fenton's reagent can have a reaction life (under practical conditions) that ranges from 15 min to several hours. The permanganate ion can remain active in the saturated zone for months or perhaps even a year or more (10). Ozone will decompose in water within minutes, which has significant impact for *in situ* applications: Fenton's reagent can be injected directly into an aquifer, but spacing of the injection points will typically range from 1 to 7 yards. All contact with the COC occurs during advection caused by the injection process, and by mixing caused by heating and gas generation. Groundwater in the treated areas is displaced.

Permanganate salts can be injected *in situ* with the anticipation of further mixing of the reagents with the COC impacted groundwater due to natural flow conditions. Spacing of injection wells can be predicated on the impact of natural groundwater flow over a 6-month to 1-year period. Push–pull circulation systems can also be utilized to decrease the spacing of injection wells, but accommodations must be made for the removal of colloidal manganese dioxide from recovered groundwater. The reaction rate of permanganate also allows it to be applied in conditions where native groundwater flow can provide further advection for transport and dispersion for mixing. Complete displacement of native groundwater is not required.

Ozone is so reactive in water that it cannot be practically injected *in situ*. It can be used as a reactant in the bore of a circulation well or as part of a sparge system. The radius of influence of such systems is limited. As a result, the actual application of ozone as an *in situ* chemical oxidation system has been much more limited than the use of Fenton's reagent or potassium permanganate.

CONCLUSION AND CAUTIONS

A last word of caution. These are powerful chemicals. During shipment, storage, and application of chemical oxidants great care must be taken to maintain safe site conditions with regard to personnel and property.

Health and Safety Precautions for Chemical Oxidants

Hydrogen Peroxide. High strength hydrogen peroxide (greater than 5%) can cause chemical burns to the skin and eyes; lower concentrations will be irritating. In all cases, handling requires protective clothing: face shield, gloves, hard hat, rubber or PVC boots, and a rubber or PVC suit. A shower and eye wash should be available.

Decomposing hydrogen peroxide rapidly generates heat, gas, and pressure. Storage vessels and piping runs that have valve traps should have adequate ventilation and pressure relief systems.

Containers and piping should be free of all contaminants. Contaminants include copper, brass, zinc, mild steel, synthetic rubbers, polypropylene, and organic compounds (especially liquid organics). Acceptable materials for storage include aluminum, stainless steel, glass, ceramics, Teflon, polyethylene, Viton, and (for temporary storage) PVC. All metal components must be properly passivated before use.

Check valves are required to prevent backflow into hydrogen peroxide piping or tanks. Hydrogen peroxide pumps should only be constructed of stainless steel or Teflon.

Hydrogen peroxide can generate enough heat and oxygen to ignite combustible materials. Do not store hydrogen peroxide on wooden pallets or decks. Hydrogen peroxide in the presence of hydrocarbon vapors can cause vapor phase explosions. Every 10 °C increase in temperature doubles the reaction rate of hydrogen peroxide, it must be stored away from heat sources (boilers, steam lines, etc.) and should never be stored in insulated tanks.

Shipment of solutions with a concentration greater than 8% must be done as DOT hazardous.

Hydrogen peroxide is sold as a 50% solution, which is an extremely reactive material. Hydrogen peroxide vendors can readily deliver more dilute solutions. When possible, it is preferable to have the hydrogen peroxide delivered at the concentration at which it will be used for *in situ* chemical oxidization, rather than delivered at 50% and then diluted on site.

Permanganate Salts

Permanganates present a fire and explosion risk when placed in contact with organic materials. Containers of permanganate salts exposed to liquid hydrocarbons may explode. Other materials that exhibit high reactivity include metallic powders, elemental sulfur, hydrochloric acid, hydrazine, hydrogen peroxide, and metal hydrides.

Permanganate salts are irritating to the eyes, skin, respiratory system, and digestive tract from acute exposure. Chronic exposure to the skin can cause defatting and dermatitis. Chronic ingestion can cause central nervous system and kidney damage.

Employee protective equipment should include dust and mist respirator (and or area ventilation), gloves, and safety goggles.

Shipping is regulated under the Transport of Dangerous Goods Act:

TDG Classification: Class 5.1 (9.2) U.N. 1490; Packing group II
WHMIS Classification: C, E
On the DSL list

Ozone. Ozone cannot be shipped; it must be generated at the point of use. Ozone can only be generated at limited concentrations; the chief hazard is exposure to ozone inhalation.

Ozone can be detected by smell at a concentration of 0.01–0.005 ppmv. However, repeated exposure increases the detection level.

For 8 h the exposure limit is 0.1 ppmv; for 10 min the exposure limit is 0.3 ppmv. Ozone equipment and process lines should be in well ventilated areas. Exposure to aqueous ozone solutions can cause skin or eye irritation.

PARTICULATE TRANSPORT IN GROUNDWATER—BACTERIA AND COLLOIDS

David B. Vance
ARCADIS G&M, Inc.
Midland, Texas

James A. Jacobs
Environmental Bio-Systems, Inc.
Mill Valley, California

Enhanced bioremediation via bioaugmentation requires understanding of groundwater flow of both colloids and bacteria.

COLLOID TRANSPORT MECHANISM

Evaluation of mass transport of entrained material in groundwater flow systems is typically focused on two primary areas, dissolved organic or inorganic species, and flowing free phase liquids. However, although generally not as dominant overall, the movement of small particles in groundwater can cause problems at the low concentrations required by regulatory limits. In addition, the proponents of *in situ* bioaugmentation, through injection of bacteria, must rely on successful particulate mass transport through the saturated soil matrix.

Colloids are a special class of material with properties that lie between that of the dissolved state and the solid (or liquid) state. Historically, the term *colloid* is applied to particles with a size range of 0.001 to 1 micron (1 micron is 0.001 millimeter or approximately 0.00004 inches). The surface area per unit mass is very high for colloids, which has a great effect on their mass transport behavior. The sources of colloids in groundwater include the following:

- Detached soil, mineral, or contaminant particles
- Colloids formed from solutes undergoing geochemical precipitation caused by changes in redox conditions from mixing with injected or percolated surface water
- Emulsions of fine droplets from free phase hydrocarbons
- Agglomerations forming micelles seeded by macromolecules such as humic acids.

— Colloids introduced directly into the groundwater from landfills or other surface sources.

On a mass basis, colloid concentrations in groundwater range from 1 to 75 mg/L. Colloid density in natural groundwater systems can range to upper limits of 10^{10} particles per liter in igneous fractures and 10^{12} particles per liter in sandy aquifers.

Contaminants can be transported as colloids resulting in unexpected mobility of low solubility material. Colloids can also act as adsorbents for contaminants that are then transported with the colloid. If contaminants have been adsorbed to colloids, it is important to remember that the transport behavior is determined by the physical/chemical properties of the colloid, not the physical/chemical properties of the contaminant. In cases where colloids are formed *in situ*, contaminants can be incorporated (or occluded) into the colloidal particle as it forms.

MECHANICAL COLLOIDAL PROCESSES

Particles larger than 2 microns in the low-flow conditions common in groundwater systems are subject to removal by sedimentation (settling under the influence of gravity). Below 0.1 microns, the effects of adsorptive process are much more pronounced. As a result, colloids and particles in the range of 0.1 to 2.0 microns are likely to be the most mobile in groundwater. Although particles at the middle of the colloid range are overall more mobile, larger particles may travel through formations more rapidly because of size exclusion. In that process, the particle travels a reduced path length through the soil matrix because it is excluded from the smaller pore spaces. Colloids or other particles can be mechanically removed via filtration by the soil matrix. The key parameter to this process is the pore entrance size, which is a function of grain size. For fine- to coarse-grained silts, pore entrance size ranges from 0.7 to 7 microns, for fine- to coarse-grained sands from 24 to 240 microns, and for fine- to coarse-grained gravels 720 to 7200 microns.

Mechanical removal of particles occurs most often by straining, a process in which particles can enter the matrix, but are caught by the smaller pore spaces as they traverse the matrix. If within the soil matrix there is groundwater flow through heterogeneity, a surface mat may form at the interface when particles are too large to enter the finer grained matrix at all. The best example of this is along the walls of fractures through fine-grained sediments.

ADSORPTIVE COLLOIDAL PROCESSES

The primary forces that influence colloids suspended in a liquid moving through a porous solid matrix include electrostatic repulsion and attraction, London–van der Walls attraction, and brownian motion. Electrostatic charged based forces are familiar. London–van der Walls attraction is a weak (but still effective) form of chemical bonding. Brownian motion is caused by molecular collisions between a particle and the surrounding fluid matrix; it becomes apparent when particle size reaches a few microns. The effect predominates colloids 0.1 microns or smaller; the smaller the size, the higher the velocity that can be imparted because of brownian motion. Adsorptive interactions of colloids may be affected by the ionic strength of the groundwater; specific ionic composition and charge; quantity, nature, and size of the suspended colloids; geologic composition of the soil matrix; and flow velocity of the groundwater.

In most instances, however, the mobility of a colloid is dependent on groundwater chemistry rather than on forces caused by advective flow. Higher mobility occurs at lower overall concentrations of total dissolved solids (TDS). Higher levels of TDS encourage deposition of colloids.

The reasons for this behavior deserves some explanation. Surfaces in an aquifer matrix at normal, near-neutral pH in general have a net negative electrostatic charge because of the predominance of silica in the minerals of the matrix. This charge on the matrix surfaces and the colloids in the groundwater system has a configuration that is described as an electric double layer. The first layer forms because of the collection of positive ions on the exposed negatively charged interfacing surfaces. Anions in solution then form the second diffuse layer around the first to counter the resulting positive surface charge.

As the ionic strength of the groundwater increases, the thickness of the double layer decreases. When a negatively charged colloid approaches a negatively charged grain within the groundwater matrix (both with double electrical layers), mutually repulsive forces increase. Conversely, if the two surfaces can approach past the repulsive maximum, attractive London–van der Waals forces will take over, overcome the repulsive forces, and the colloid is attached to the matrix surface. The high velocities imparted to colloids smaller than 0.1 microns because of brownian motion provides the mechanism for overcoming the electrostatic repulsion of the double layers. The process is delicately balanced such that the reduction of the electrical double layer thickness through increased ionic strength is also required.

The result of this colloidal behavior is beneficial with regard to typical surface contaminant sources such as landfills. The high ionic strength of leachate will serve to provide optimum conditions for the immobilization of entrained colloids. Conversely, the injection of low ionic strength water has the potential to enhance colloid mobility and even mobilize previously adsorbed material.

PARTICULATE TRANSPORT IN GROUNDWATER—BACTERIA

The transport of bacteria in groundwater systems is of concern from both ends of the mobility spectrum. Mobility is essential for the injection of bacteria using the bioaugmentation approach to saturated zone *in situ* bioremediation. Conversely, there is high concern with mobility, and a desire for immobility, with regard to pathogens from septic systems or other sources. Bacteria range in size from 0.2 to 5 microns and viruses from 0.005 to 0.1 microns, which is within the size range considered colloidal. Therefore, bacteria transport is effected by many of the same processes as those for colloids.

As with colloids in groundwater, factors affecting bacteria transport include mechanical and adsorptive processes. However, bacteria are live organisms capable of responding to environmental conditions and have other unique qualities that impact their transport properties. These qualities include surface hydrophobicity, reactive groups on the surface of the bacterial cell wall, and coatings that can be "sticky."

Mechanical Processes

Removal of bacteria can occur solely by straining within the aquifer matrix. The size of the pore space in relation to bacteria size is important enough to repeat: In fine- to coarse-grained silts, pore entrance size ranges from 0.7 to 7 microns; for fine- to coarse-grained sands from 24 to 240 microns; and for fine- to coarse-grained gravels 720 to 7200 microns. As a general rule, bacteria should be half the size of the pore entrance for adequate success in passage, and if the average bacteria size is greater than 5% of the grains (not the pore size) within the porous matrix, straining becomes an important removal mechanism.

In addition to reduction of hydraulic conductivity through the accumulation of bacterial cells, as described above, other processes unique to bacteria can mechanically reduce transport efficiency. Bacteria may excrete extracellular polymers, low solubility metabolic precipitates, or gaseous products (such as nitrogen, methane or carbon dioxide) that can potentially block pore passages.

Adsorption Processes

Increasing ionic strength of groundwater increases the capability of bacteria to adhere to soil surfaces by increasing the availability of ions to act as bridges between the surfaces of the cell and soil particles, and by decreasing the thickness of the electric double layer (a phenomena described above). Increased ionic strength also enhances the ability of bacteria to aggregate, which forms a larger overall particle more likely to be captured in pore spaces. For example, transport efficiency of bacteria through clean sands has been shown to be 2% to 3% in water with 750 ppm of total dissolved solids (TDS) versus 70% to 100% in deionized water.

Bacteria have an overall negative charge on the surface of their cell wall, primarily because of the presence of peptidoglycan, the structural backbone of the bacterial cell wall, which is rich in carboxyl and amino groups. Teichoic acids are a phosphate-rich component of bacterial cell walls, which also help contribute to the presence of a negative charge. So that conversely to the above, bacterial adsorption to positively charged surfaces (such as those presented by iron and other metal oxyhydroxides) is at its maximum under conditions of low ionic strength. In a manner similar to that for inorganic anions, the sorption of bacteria to oxyhydroxides is also pH-dependent. As a consequence, to evaluate bacteria mobility, it is important to know the specific chemical and mineralogical character of the soil matrix. In some circumstances, because of soil chemistry, high levels of bacterial adsorption will occur irrespective of the manipulation of ionic strength in the surrounding groundwater. This news is good for those concerned with septic systems, but bad for those wishing to inject bioaugmentation bacteria.

The bacterial cell wall also contains varying amounts of lipids that are responsible for hydrophobic behavior. Hydrophobic bacteria have the tendency to adsorb to surfaces in the groundwater system because of repulsion from the polar water molecule. The effect of electrostatic repulsive force decreases with increasing hydrophobicity of a bacterial species.

Biological Processes

Attachment of bacteria to a surface is a two-stage process. First, the initial adsorption caused by electrostatic or hydrophobic forces takes place. This adhesion is reversible, given adequate shearing from groundwater flow. The second stage is the irreversible binding through cellular production of exopolymers that anchor the cell to the surface. The production of these exopolymers is stimulated by the initial adsorption and has been observed to increase five-fold once a cell has attached itself to a surface.

Bacterial motility may be important under conditions of static flow or chemotaxis. Motility is the ability of bacteria to move through the use of appendages such as flagella or pili. Chemotaxis is the movement or orientation of bacteria cells along a chemical concentration gradient. By this mechanism, porous media can be penetrated by bacteria that literally grow through the pore space. Growth rates have been observed in cores at ranges up to 0.01 to 0.05 cm/hr. However, pore space is occupied by bacterial biomass, the blockage from which ultimately prevents the transport of required nutrients to the growth area.

Starvation of cells will reduce their size to less than 0.3 microns, therefore reducing overall filtration effects and allowing for penetration of a finer grained matrix. However, in response to the starvation stress, many bacteria will increase the stickiness of their cell walls to improve the chance of adhesion to a surface. In general, bacterial adsorption in uncontaminated water is driven by electrostatic forces. Bacteria adsorption rates are high in groundwater at a pH of 6 or lower. Bacteria transport mobility increases above pH 6.0, significantly so above pH 7.5. In contaminated groundwater, the situation is much more complex and is specific to the site, contaminant properties, and the bacterial species present. In the presence of contamination, bacteria metabolic processes play a much more dominant role in transport properties, overwhelming physical/chemical effects.

Coarse-grained groundwater flow systems or large aperture fracture flow systems (such as karst) have the capacity to support substantial bacterial transport. Bacteria injection is possible, and pathogen transport from septic systems is probable under such conditions. However, bacteria transport in finer grained groundwater systems is more problematic. The high TDS associated with septic systems (or other potential sources of pathogens) will enhance the tendency for immobilization. Bacterial injection for bioaugmentation may be mechanically impossible because of straining and will require careful assessment under marginal porosity conditions.

Bioaugmentation

Bioaugmentation is a technology to enhance bioremediation. One type of bioaugmentation includes culturing indigenous bacteria and reintroducing that population back into the aquifer. A second type of bioaugmentation includes culturing a specific laboratory selected strain of bacteria that has had proven success degrading a specific contaminant and injecting that bacteria into the aquifer. Based on experience, the former is more likely to be successful because the indigenous bacteria are acclimated to the site-specific conditions and food source. Injection pressures for bioaugmentation tend to be 40 psi or less. Pressures approaching 100 psi will get the bacteria further into the aquifer; however, cell walls may start to burst at higher pressures. In addition, injection pressures sufficient to fracture the sediments in an injection zone will induce flow by hydrofracturing, possibly short-circuiting the bulk of a targeted treatment zone. As a rough rule of thumb, injection pressures can increase by 1 psi for each foot of depth. Injections pressures higher than that are likely to stimulate hydrofracturing.

Groundwater flow studies must take into account both colloids and bacteria for successful enhanced bioremediation projects.

PERCHED GROUNDWATER

Leo S. Leonhart
Hargis Associates, Inc.
Tucson, Arizona

.

Perched ground water is subsurface water that forms a saturated horizon within porous media at an elevation higher than the local or regional groundwater table. This condition may result from various field conditions, but the requisite condition is a soil or rock horizon of significantly lower vertical hydraulic conductivity (K_v) (perching unit) amid contrastingly higher K_v strata. Downward movement of infiltrating water through the higher K_v materials is retarded and accumulates above and/or within the perching unit, which typically "mounds" saturated water above the perching unit, leaving an unsaturated (vadose) horizon below the perching unit. The upper limit of saturation in a perched zone is referred to as a perched water table, whereas the lower limit has been defined as an inverted water table.

HYDRAULIC PROPERTIES

K_v contrasts typically of the order of 10 to 20% of the K_v of the overlying materials, are believed to have the potential to produce perched groundwater (Fig. 1) (1,2). Stratigraphically, such contrasts are often conceptualized as fine silty or clayey lenses layered between coarser sediments such as sands or sandy gravels. Equivalent K_v contrasts can result within other stratigraphic analogues such as saprolite or ash horizons between adjacent lava flows, anisotropic fractures patterns in homogeneous crystalline rocks, or intraflow structures within flood basalts. Perching units can vary considerably in areal extent, ranging from extensive, essentially continuous strata to localized, discontinuous lenses.

Porosity within perching and overlying stratigraphic units is typical of the types of materials that comprise these strata. Notably, the porosity of clayey materials is typically higher than that of other granular materials, thereby providing high capacity for storing water but a lesser or slower rate of yield. Secondary porosity of clays, such as fractures, may facilitate downward movement, particularly as water is mounded above the perching unit.

Elastic properties are another potentially important factor in regard to perched groundwater involving clayey units. Specifically, shrinking of the clay lattice may occur upon desiccation, and swelling may occur upon

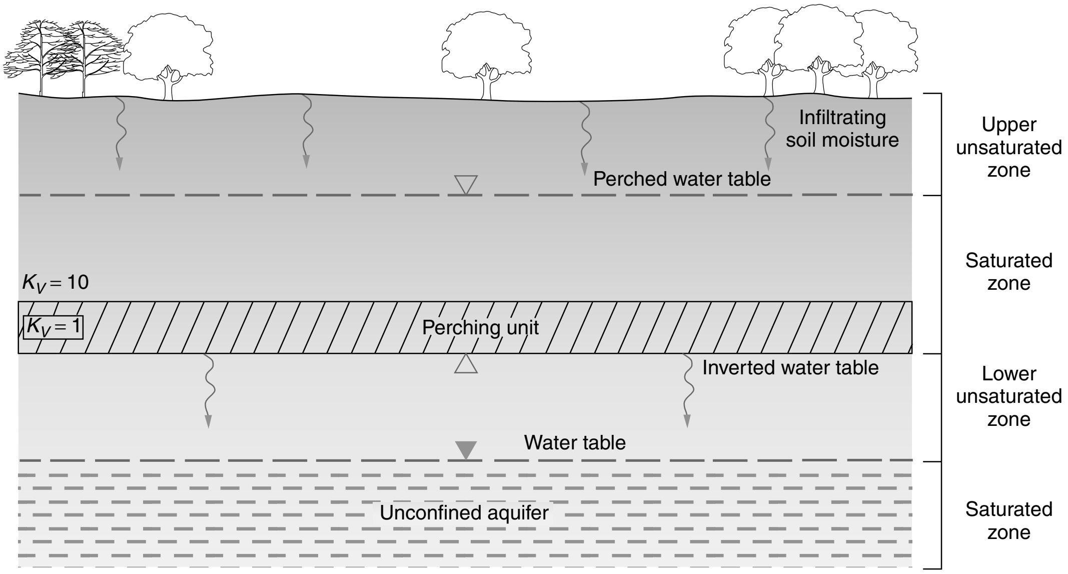

Figure 1. Perched groundwater resulting from hydraulic conductivity contrast and surface infiltration.

wetting, thereby, respectively, enabling greater or lesser rates of water movement through the perching unit. Other rarer forms of secondary porosity may result from certain geochemical interactions, such as dissolution or precipitation of minerals upon wetting.

HYDROLOGIC CONDITIONS

Hydrologic conditions that give rise to perched ground water are variable. Perched groundwater tables have resulted from various high volume natural recharge events, such as flooding or intense and long-term precipitation; artificial recharge resulting from infiltration basins, water line leaks, irrigation, disposal pits, or artificial impoundments; and transient conditions such as falling water tables. In general, all of these mechanisms involve downward movement or drainage of subsurface water. For this reason, perched groundwater is often characterized as transient or ephemeral. However, longer term recharge and discharge may give rise to near steady-state perched groundwater. Wells tapping perched groundwater can have highly variable yields, depending on the specific hydrologic conditions. Generally, however, perched groundwater is not exploited.

Mathematical equations describing the rise and fall of groundwater mounds were developed by Hantush (3) and generally relate to conditions underlying recharge basins. These equations are also applicable to perched groundwater.

Except for perched groundwater resulting from falling water tables, development of a perched groundwater zone can be conceptualized as having three phases: growth, accumulation, and drainage. The perched zone growth phase involves the initial downward movement of subsurface water and its encounter with the perching unit. The downward flux of water must be sufficient to overcome soil moisture tension and is subject to the classical principles of unsaturated flow.

Once a sufficient volume of water encounters the perching unit, accumulation or “mounding” of groundwater begins. Initially, this mounding may be limited to the overlying coarser grained units (or equivalent units in other terrains). As downward flux continues, the mound will accrete both vertically and laterally. As accumulation continues, the added hydraulic head can advance the inverted water table downward into the perching unit. Likewise, lateral movement may continue, potentially extending to the edges of the perching unit, where “spillage” into the underlying unsaturated zone can occur.

The drainage phase represents waning of the perched zone. If the rate of recharge is insufficient to maintain the areal and vertical extent of the perched zone, then it will slowly drain through or off the ends of the perching unit. Another source of discharge may result from evapotranspiration, if the perched groundwater is shallow and within reach of phreatophytes.

Examples of Perched Groundwater

Tucson Basin. The municipality of Tucson, Arizona, relied solely on its underlying aquifer for water supply until the recent delivery of Colorado River water via the Central Arizona Project. As a result of the region’s population growth and associated increases in water demand since the early 1950s, the water table declined more than 200 feet within some areas of the basin. The rapid lowering of the water table that averaged 3 to 4 feet per year from 1950 to 2000 left saturated remnants in several parts of the basin (4). The basin sediments comprise a heterogeneous sequence of unconsolidated to semiconsolidated strata ranging in textures from laterally discontinuous facies of sandy gravels to silty clays. Perched groundwater has reportedly been encountered at depths ranging from 30–85 feet below land surface and ranges in saturated thickness from less than 1 foot to more than 85 feet (5–7). In some places within the basin, the elevation of the perched water table is within the perching unit as opposed to the overlying sediments. In other areas, the perched groundwater is sustained as a result of natural recharge from runoff or artificially from irrigation.

High Volcanic Islands. Perched groundwater is common in high volcanic islands, such as Hawaii and Tahiti, owing to high precipitation upon highland areas and extreme K_v contrasts in layered shield volcanics (8–11). Perched groundwater is often classified as “high level” compared with basal groundwater, which occurs as near or below sea level lenses, “floating” on intruded seawater (Fig. 2). As also seen in the figure, high level water can also result from intrusive dikes, which act as “subsurface dams.” Perching units are generally sedimentary strata, often saprolites, dense lavas, or ash beds interbedded among lava flows. Yields from such perched sources are highly variable; however, exploitation by horizontal wells and tunnels has provided adequate local supplies. As a result of high relief, perched groundwater can often intercept the surface topography and discharge as a spring. Equivalent examples are also found in high-relief fractured crystalline terrains.

Flood Basalts. The hydrogeology of extensive flood basalts such as occur in the Columbia Plateau in parts of Washington, Oregon, and Idaho is controlled largely by the characteristics of intraflow structures. Interflow structures such as those sedimentary interbeds and saprolites described for shield volcanics are also important. In such volcanic terrains, individual lava flows are much thicker than those in shield volcanics, ranging up to 10s to 100s of meters. Intraflow structures from the base to top of an individual flow generally comprise a contact or pillow palagonite, representing a chill zone; a colonnade, consisting of prismatic, hexagonal columns with vertical cooling joints; an entablature, comprising slender, hackly, often-intersecting columns; and a flow top of vesicles and rubbly materials (Fig. 3). From flow to flow, the proportional thicknesses of these structures may vary extensively.

Interflow contacts generally represent zones of higher porosity and permeability than the dense flow interiors. Such zones of comparatively higher porosity preferentially store and transmit higher volumes of water, thereby potentially creating multiple perched horizons. Being

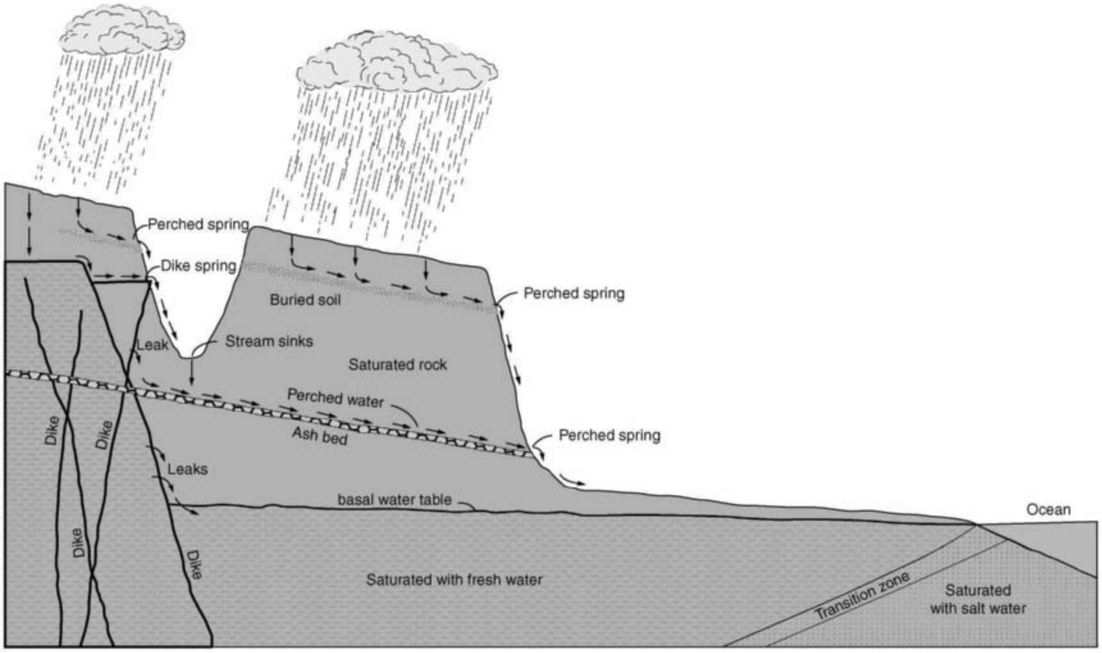

Figure 2. Conceptualization of perching on high volcanic islands (8).

a relatively competent rock, wells completed in basalt are often uncased. This construction often results in the borehole penetrating into several variably saturated horizons. As a result, cascading water from shallower perched zones is common and can be observed in borehole video logs and even heard by listening at the wellhead.

ROLE OF PERCHED GROUNDWATER IN CONTAMINANT MOVEMENT

Considering the position of perched groundwater bodies in relation to the surface, where much contaminant generation occurs, and the groundwater table, it is easy to conceptualize how perched groundwater can play a role in controlling the movement of contaminants in the subsurface. First, perched groundwater may result from artificial recharge due to the handling and disposal of liquids and liquid wastes. Leaky impoundments, such as disposal pits and sumps, underground storage tanks (USTs), pipelines, drywells, landfills, channels and ditches, sewers, and poorly constructed wells can produce reservoirs of contaminated perched groundwater. Similarly, nonpoint sources such as agricultural areas that receive fertilizer and pesticide applications, construction sites, industrial sites, and municipal areas can also constitute sources of liquid contamination.

Such reservoirs of contaminated perched groundwater can act to control the movement and fate of these contaminants within the subsurface. Perched horizons may act as continuing sources, “filters,” vapor reservoirs, or nonaqueous phase liquid (NAPL) reservoirs, depending on both the nature of the contaminant source and the site hydrogeology. At some sites, perching of contaminants may locally prevent contamination of underlying groundwater by intercepting the downward migration of contaminants. On the other hand, this condition may only postpone the inevitable contamination and may prevent earlier detection of sources and incipient problems.

Related Terms & Concepts

Semiperched Groundwater. Semiperched groundwater may be described as a zone of saturation that overlies a semiconfined aquifer. Thus, the perching unit is leaky, and a hydraulic relationship exists between the semiperched aquifer and the underlying semiconfined aquifer and often allows upward migration of water into the semiperched zone. In this case, the saturated zone effectively extends to the top of the semiperched zone, in contrast to the traditional perched zone, which is positioned over an unsaturated zone. Failure to recognize and account for such zones has been identified as a potential issue in interpreting regional groundwater level trends (13).

In another context, semiperched groundwater that occurs among cyclothems in coal regions of Pennsylvania is discussed. Again, the permeability contrasts created in a stratigraphic sequence of alternating lithologies detains or retards the vertical movement of water through the unsaturated zone creating both perched and semiperched groundwater. Depending on topography, these zones may also discharge as springs. Such terrains have been termed “hydrologic islands” and have been related to a hierarchical classification of local, intermediate, and regional groundwater flow (14).

Tension-Saturated Zone. Tension-saturated zone is another term for the capillary fringe overlying the saturated zone wherein pores of the medium are saturated, but the pressure heads are less than atmospheric (15).

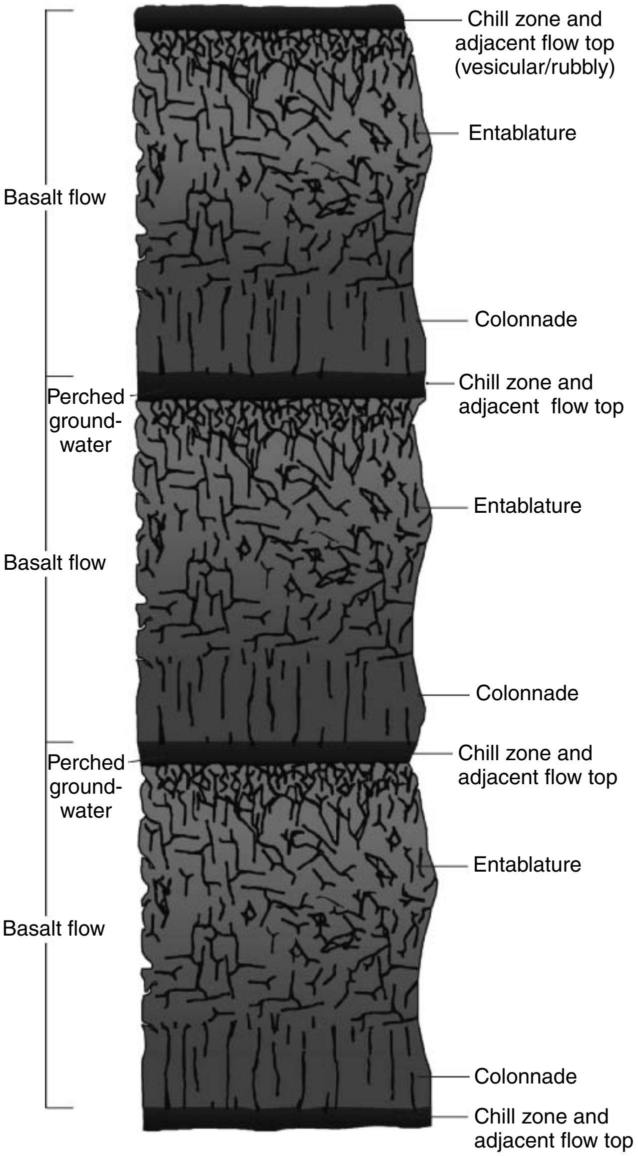

Figure 3. Conceptualized intraflow structures in flood basalts (12).

Temporary Saturated Zones. Perched groundwater may result locally from various ephemeral events as well as in response to surface disturbances. Conditions that lead to sudden recharge are favored by high antecedent moisture conditions; high-intensity rainfall; and various conditions related to storm duration, infiltration, slope, and subsurface strata. Anthropogenic activities such as timber clearing, grading, road construction, and extreme natural events such as flooding and snowmelt may create perched groundwater. In some instances, perched groundwater has been cited as a cause for slope failure (16).

PERMEABILITY

Nitish Priyadarshi
Ranchi University
Ranchi, Jharkhand, India

Permeability is a measure of the ease with which fluids pass through a porous medium. It was established experimentally by Darcy in 1856 that

$$k = (Q/A)n(dp/ds)^{-1}$$

in which k is the permeability, Q is the volume of fluid which passes in unit time through area A in the direction s of the pressure gradient dp/ds, and n is the viscosity of the fluid. The unit of permeability in most common use by geologists and members of the oil industry is the darcy (D), which corresponds to a flow of 1 $\text{cm}^3\,\text{s}^{-1}\,\text{cm}^{-2}$ at a pressure gradient of 1bar cm^{-1}. If the fluid is water, material with a permeability of 1D will pass $10^{-3}\,\text{cm}^3\,\text{s}^{-1}\,\text{cm}^{-1}$ at a pressure gradient of 1 $\text{g}\,\text{cm}^2\,\text{cm}^{-1}$.

A few typical values of permeability for specific rock types are listed in Table 1. The permeability values quoted in Table1 have been determined in experiments in which the rock specimens have usually been subjected to moderate and constant confining pressure.

Permeability is measured in darcys. One darcy is equal to the passage of 1 cm^3 of a fluid with a viscosity of 1 cP (centipoise) in 1 s under a pressure difference of 1 atm through a porous medium having a cross section of 1 cm^2 and length of 1 cm (1). The centipoise is 1/100 of a poise, which is the cgs unit of dynamic viscosity. The poise is equal to $1\,\text{dyn}\,\text{s}\,\text{cm}^{-2} = 0.1\,\text{Pa}\,\text{s}$ (because dynes/square centimeter = pressure). Permeability ranges from 1 to 5 darcy in loose sediments and from 0.05 to 1 darcy in rocks. The lowest value (0.05 darcy) applies to cherts, which are practically impermeable masses of microcrystalline quartz. A rock may have high porosity but no permeability because the holes are not interconnected (e.g., a vesicular lava) or because they are too small (e.g., clay).

Permeability is high where pore spaces are large and numerous and where they are freely intercommunicating. If the pores are large but are not intercommunicating, the rock may have low permeability even though its porosity is high. A rock with pore spaces of given size, abundance, and continuity is more permeable to fluids of low than of high viscosity. Permeability is sometimes called tightness. An oil-bearing rock is tight if it yields its oil with difficulty, and it is open if it yields its oil freely.

In the study of groundwater, the permeability of rocks is of fundamental importance. Generally speaking, highly permeable rocks form good aquifers. Sand and gravel are more permeable than silt and clay. Therefore, gravel and sand constitute a very large proportion of well-developed aquifers. Sandstones generally make good aquifers. Rocks of volcanic origin, such as basalts, make good aquifer materials only if they are fractured, vesicular, and porous. Granite, gneiss, and other crystalline and metamorphic rocks are generally impermeable and hence, do not form good aquifers (3). A geologic formation that is completely impermeable and is devoid of water is called an aquifuge.

Table 1. Typical Values of the Permeability of Some Rock Types[a]

Rock Type	Permeability, k, (D)
Sandstones and limestones	10^0–10^{-2}
	10^{-2}–10^{-5}
Argillaceous	10^{-5}
	10^{-6}–10^{-8}
Halite	$< 10^{-6}$
Marble	$< 10^{-7}$

[a] Reference 2.

When aquifers are confined by an impermeable layer or stratum, the aquifers are called confined aquifers. If the confining unit is relatively impermeable, such as clay, it is called an aquiclude. If, however, the stratum is not completely impermeable, such as sandy clay, then it is called an aquitard. Such poorly permeable strata leak water to adjacent aquifers.

The permeability of rocks depends on

1. The size and shape of the constituent grains. A uniformly coarse-grained gravel forms a highly permeable aquifer, but when the same rock consists of fractions of various sizes, there is a tendency for smaller sediments to get into and fill or block the interstices rendering it less permeable. Rounded fractions result in higher porosity and hence better permeability than angular fractions in the same grain size range (3).
2. Sorting of grains. Well-sorted materials (i.e., where grains of a particular size are in one layer followed by grains of the next size) have higher permeability than ill-sorted or unsorted grains in a rock.
3. Continuity and nature of interstices, especially when they are secondary. The mere presence of cracks or cavities or joints does not make a rock permeable; all openings must also be interconnected or mutually communicating; only then is the flow of water through the rock mass possible.

Permeability Investigation for a Reservoir Site

Many types of rocks may be traversed by a proposed reservoir. For ideal conditions, they should be impervious and impermeable. The main object of permeability investigations is, therefore, to determine the character of the rocks of the reservoir region and locate the "highly permeable" formations that can be treated as most unsuitable for the reservoir or dam site.

For reservoir sites, rocks may be divided into three groups: highly permeable, occasionally permeable, and least permeable. Highly permeable rocks include well-sorted gravel, sand, and coarse sandstone and deposits of glacial origin such as moraines and till. Occasionally permeable includes those rocks that acquire permeability due to secondary features such as cracks, fissures, solution cavities, and gas cavities. Limestone, vesicular basalt, jointed granite, and gneiss are examples of such rocks, which are otherwise impervious but are often rendered unsuitable because of prolific development of the secondary features described. Least permeable are igneous rocks, which are unjointed and thoroughly crystalline; massive limestones and sandstones can generally be considered impermeable.

Relation of Porosity and Permeability

Good correlation if pores are clean (if pore tortuosity is low); poor to no correlation if pore tortuosity is high because of clay cements, etc.

INTRODUCTION

Groundwater contamination is one of the most important environmental quality concerns. The subsurface migration of hazardous wastes from point sources firmly caught the public's attention in 1977 with the well-publicized Love Canal story. Characteristically, point sources are relatively easy to identify and control. Groundwater contamination from nonpoint sources (NPSs) is a greater environmental problem (1). Nonpoint sources, as a result of contaminants entering the environment over an extensive area, are difficult (at best) or impossible to trace to a specific location and have the potential for maintaining a relatively long active presence in entire ecosystems. Historically, point sources have received the greatest attention because of the conspicuous severity of their impacts. In recent years, public, political, and scientific attention have shifted toward NPSs. This shift reflects an awareness of the scope and potential impact of NPS pollution (2,3). Regulation, monitoring, litigation, and remediation have each helped to control or reduce both point and NPSs of groundwater contamination.

The word *pesticide* is a general term used to refer to the chemicals that are employed to control, destroy, mitigate, prevent, or repel pests (plant or animal). There are several classes of pesticides (e.g., algaecides, fungicides, germicides, herbicides, insecticides, miticides, molluskicides, rodenticides, and termiticides). In the United States, the Environmental Protection Agency (EPA) regulates pesticides under the authority of the 1996 amendments to the *Federal Insecticide, Fungicide, and Rodenticide Act* (FIFRA) of 1947. All pesticides must be registered and carry a *label* (providing the rules for application rates and frequencies) approved by the EPA. The distribution and trends of pesticides in the atmosphere (4), groundwater (5), surface water (6), and fluvial sediments and aquatic biota (7) have been carefully assessed. For example, there have been well over 100 monitoring studies in recent years, which quantitatively document the occurrence of pesticides in groundwater (5). The impact of widespread pesticide use, in what Freeze (8) calls *the age of awakening* (i.e., environmental perspective) or *the age of social upheaval* (i.e., new right perspective), was lucidly bought to the public's attention by Rachel Carson in her 1962 book *Silent Spring* (9), which in large part forced the banning of DDT. Barbash and Resek (5) provide a glossary of 600 pesticides that are of interest relative to groundwater impacts. Table 1 identifies 31 pesticides that have received considerable attention.

In many areas of the world, successful agriculture depends on both pesticides and irrigation. The combination of repeated pesticide applications and irrigation over a large NPS area often leads to leaching through the vadose zone and, subsequently, to groundwater contamination. For example, in the semiarid San Joaquin Valley in California, where groundwater contamination concentrations have been among the highest reported, the amount of active pesticide ingredient applied annually is on the order of 50 million kilograms. A spill of concentrated pesticide at a mixing or distribution site is an example of point source pollution. For example, in April 1977, there was an accidental spill of approximately 1900 liters of the pesticide EDB (see Table 1) within approximately 20 meters of a well that provided drinking water to the village of Kunia on the Hawaiian island of Oahu. The area around the spill eventually became a *Superfund* site.

VULNERABILITY ASSESSMENT

Assessment involves determination of the change in some constituent over time. This change can be measured in either real time or simulated by a model. Real-time measurements reflect the activities of the past, whereas simulations can provide useful glimpses into the future. Both means of assessment are valuable. The distinct advantage of simulation is that it can be used to alter the occurrence of detrimental conditions before they occur. It should be pointed out that simulation cannot replace *real* data.

By definition, a model integrates existing knowledge into a framework of rules, equations, and relationships to quantify the way a system behaves. As long as a model is applied over the range of conditions from which they it was initially developed, it serves as a useful tool for prognostication. Models can range in complexity from the simplest empirical equation to complex sets of partial differential equations that are solvable only by numerical approximation techniques.

Table 1. Thirty-One Important Pesticides[a]

Common Name	Chemical Name	Use
1,2-Dichloropropane[b,c]	1,2-Dichloropropane	Nematicide
2,4-D[b]	2,4-Dichlorophenoxy acetic acid	Herbicide
2,4-DP[c]	Butoxyethyl ester of (±) 2-(2,4-dichlorophenoxy)propanoic acid	Herbicide
Alachlor[b]	2-Chloro-*N*-(2,6-diethylphenyl)-*N*-(methoxymethyl)acetamide	Herbicide
Aldicarb[b]	2-Methyl-2-(methylthio)-propionaldehyde *O*-(methylcarbamoyl)oxime	Insecticide
Atrazine[b,c]	2-Chloro-4-ethylamino-6-isopropylamino-*S*-triazine	Herbicide
Bromacil[b]	5-Bromo-3-(*sec*-butyl)-6-methyluracil	Herbicide
Carbaryl[b]	1-Naphthyl-*N*-methylcarbamate	Insecticide
Carbofuran[b]	2,3-Dihydro-2,2-dimethyl-7-benzofuranyl-*n*-methylcarbamate	Insecticide
Carboxin[b]	5,6-Dihydro-2-methyl-1,4-oxathiin-3-carboxanilide	Fungicide
Chlorothalonil[b]	Tetrachloroisophthalonitrile	Fungicide
Cyanazine[b]	2[[4-Chloro-6(ethylamino)-*S*-triazin-2-yl]amino]-2-methylpropionitrile	Herbicide
Dalapon[b,d]	2,2 Dichloropropionic acid (sodium salt)	Herbicide
DBCP[c,d]	1,2-Dibromo-3-chloropropane	Nematicide
DCPA[b]	Dimethyl 2,3,5,6-tetrachloro-1,4-benzenedicarboxylate	Herbicide
Diazinon[b,c]	*O*, *O*-Diethyl-*O*-(2-isopropyl-4-methyl-6-pyrimidinyl)phosphorothiote	Insecticide
Dicamba[b,c]	2-Methoxy-3,6-dichlorobenzoic acid	Herbicide
Dinoseb[b,d]	2-*sec*-Butyl-4,6-dinitrophenol	Herbicide
Diphenamid[b,d]	*N*,*N*-Dimethyl-α -phenylbenzeneacetamide	Herbicide
Disulfoton[b]	*O*,*O*-Diethyl *S*-[2-(ethylthio)ethyl]phosphorodithioate	Insecticide
Diuron[b,c]	3-(3,4-Dichlorophenyl)-1,1-dimethylurea	Herbicide
EDB[c,d]	1,2-Dibromoethane	Insecticide
Methomyl[b]	*S*-Methyl-*N*-(methylcarbamoyl)oxy)-thioacetamidate	Insecticide
Metolachlor[b]	2-Chloro-*N*-(2-ethyl-6-methylphenyl)-*N*-(2-methoxy-1-methylethyl)acetamide	Insecticide
Oxamyl[b]	Methyl 2-(dimethylamino)-*N*-[[(methylamino)carbonyl]oxy]-2-oxoethanimimdothioate	Insecticide
Prometon[c]	6-Methoxy-*N*,*N*′-bis(1-methylethyl)-1,3,5-triazine-2,4-diamine	Herbicide
Prometryn [c]	*N*,*N*′-Bis(1-Methylethyl)-6-(methylthio)-1,3,5-triazine-2,4-diamine	Herbicide
Propazine[c,d]	6-Chloro-*N*,*N*′-*bis*(1-methylethyl)-1,3,5-triazine-2,4-diamine	Herbicide
Simazine[b,c]	2-Chloro-4,6-bis(ethylamino)-s-triazine	Herbicide
Tebuthiuron[b]	*N*-[5-(1,1-Dimethyl)-1,3,4-thiadizol-2-yl]-*N*,*N*′-dimethylurea	Herbicide
Trifluralin[b]	2,6-Dinitro-*N*,*N*-dipropyl-4-(trifluoromethyl)benzenemamine	Herbicide

[a] abstracted from the 341 pesticides in Hornsby et al. (10)

[b] Identified by EPA (11) as high risk for groundwater contamination.

[c] Detected in groundwater in California (12).

[d] Cancelled or severely restricted in the United States.

The use of models to aid in the assessment of groundwater vulnerability is now a well-established tool, employed both in industry and by regulatory agencies. The various mechanisms that facilitate the migration of pesticides from the surface/near surface to the water table and the methods used to simulate these processes have been the subject of considerable review (13–27). In general, subsurface flow and pesticide transport are, respectively, estimated by Richards' equation and the advection–dispersion equation, or simplifications. The processes that are important to consider in assessing groundwater vulnerability to pesticide contamination are advection, diffusion, dispersion, sorption, transformation, and volatilization (28). The increasing availability of geographic information system (GIS) software to those assessing the potential for NPS groundwater contamination from pesticides has resulted in the generation of regional-scale multicolored vulnerability maps for use in decision management (29).

Three categories of models for assessing groundwater vulnerability from pesticides are (1) regression models, (2) index models, and (3) transient-state solute transport models. Regression models generally use multiple linear regressions to relate various causative factors. Index models, which can be property or process based, compute an index of pesticide mobility. Transient-state, process-based models are capable of simulating the concentration/movement of a pesticide in a dynamic flow system.

One of the first and most promoted regional-scale groundwater vulnerability methods for assessing the impact of pesticides was the DRASTIC index (30). The early process-based simulations by Petach et al. (31) were both elegant and ambitious considering the large scale of the pesticide leaching assessments. During the last two decades, a number of process-based models have been developed for assessing the behavior of pesticides in the near surface (e.g., PRZM (32), LEACHM (33), GLEAMS (34), HYDRUS-1D (35), LEACHP (36), RZWQM (37), PRZM-2 (38), PELMO (39), MACRO (40), HYDRUS-2D (41), and PESTLA (42)). Table 2 lists selected pesticide leaching assessments for California, Hawaii, and Tenerife.

UNCERTAINTY

There can be considerable uncertainty in assessments of point and NPS pollution to groundwater from pesticides. Three sources of error inherent in modeling are (1) model error, (2) input error, and (3) parameter error. Model

Table 2. Summary of Selected Pesticide Leaching Assessments in California, Hawaii, and Tenerife

Location	Model Name	Model Category[f]	Reference
San Joaquin Valley, California	PSCLR	R	(43)
	AF[a]	I	(44,45)
	PRZM-2[b]	TSST	(46)
	TTF[c]	TSST	(47)
Oahu, Hawaii	AF	I	(48–56)
	PRZM[d]	TSST	(57–60)
Tenerife, Canary Islands, Spain	AF	I	(61,62)
	Li[e]	I	(63)
	AF, PRZM-2	I, TSST	(64)

[a] Attenuation factor (65).
[b] Pesticide root zone model - Version 2 (37).
[c] Type transfer function model (66).
[d] Pesticide root zone model (31).
[e] Leaching index (67).
[f] R: regression model; I: index model; and TSST: transient-state solute transport model.

error results in the inability of a model to simulate the given process, even with the correct input and parameter estimates. Input error is the result of errors in the source terms. Input error can arise from measurement, juxtaposition, and/or synchronization errors. Parameter error has two possible connotations. For models requiring calibration, parameter error usually is the result of model parameters that are highly interdependent and not unique. For models with physically based parameters, parameter error results from an inability to represent aerial distributions on the basis of a limited number of point measurements. The aggregation of model error, input error, and parameter error is the total (or simulation) error. For multiple-process and comprehensive models, simulation error is complicated further by the propagation of error between model components.

The methods for characterizing uncertainty can, in general, be grouped into three categories (68): (1) first-order analysis, (2) sensitivity analysis, and (3) Monte Carlo analysis. First-order analysis is a simple technique for quantifying the propagation of uncertainty from input parameter to model output. Sensitivity analysis is used to measure the impact that changing one factor has on another. Monte Carlo analysis is a stochastic technique for characterizing the uncertainty in complex hydrologic response model simulations. Loague and Corwin (68) provide examples of first-order uncertainty analysis, sensitivity analysis, and Monte Carlo simulation. Note that most of the groundwater vulnerability assessments listed in Table 2 were designed to identify the uncertainty in the estimates relative to the uncertainty in the chemical, climate, and soil databases.

FRESNO CASE STUDY, AN EXAMPLE

Between the late 1950s and the time of its statewide cancellation in August of 1977, there was widespread use of DBCP (see Table 1) throughout the San Joaquin Valley in California. More than two decades after its cancellation, DBCP-contaminated groundwater persisted as a problem in the San Joaquin Valley. The objective of the Fresno case study (46,69) was to address, from a simulation perspective, if *label recommended* NPS applications were likely to be the principal source of the DBCP groundwater contamination in Fresno County (note that DBCP was a legacy when the study was conducted). The relatively unique characteristic of the Fresno case study is that both the unsaturated near surface and the saturated subsurface were considered for a 2184 km^2 area.

The numerical model used for 1-D simulations (46) of dissolved phase DBCP concentration profiles in the unsaturated zone was PRZM-2 (37). The potential fate and transport of DBCP between the surface and the water table for multiple NPS applications were quantitatively estimated from 1172 separate 35-year simulations. The aggregate of the DBCP concentrations loaded to the water table made up the annual loading files for the 3-D saturated transient transport simulations. The numerical models used for the 3-D simulations (69) of saturated subsurface fluid flow and DBCP transport, for the same 35-year period, are MODFLOW (70) and MT3D (71), respectively. A 76,440-element mesh was used for the saturated simulations.

The simulation results from the Fresno case study lead to several conclusions (46,69): (1) the areas most likely to facilitate DBCP leaching through the entire unsaturated soil profile were targeted; (2) the first appearance of DBCP above the detectable limit at the water table was simulated as most likely to have occurred between 1961 and 1965; (3) the estimated DBCP concentrations reaching the saturated subsurface exceed the maximum contaminant level (MCL) at several locations at different times; (4) the first appearance above the MCL was between 1965 and 1970 (note that by 1990, the concentrations are below the MCL); (5) relative to the size of the study area, the extent and duration of the estimated DBCP contamination was small; (6) DBCP concentrations are a function of spatial and temporal variations in the application rates, the application frequency, the unsaturated profile thickness, the soil-hydraulic properties, and the near-surface sorption; and (7) the DBCP plume evolves (grows and retracts) with time due to the loading rates at the water table. Figure 1 shows 1971 snapshots of the simulated DBCP loading to the water table and the 3-D DBCP plume in the saturated subsurface. Note that the Fresno case study assessments were critically evaluated and extended (72,73).

EPILOGUE

The ethics, efficacy, and economics of widespread pesticide applications have all received considerable attention in recent years. Without question, it is important to assess the vulnerability of groundwater to contamination from widespread applications of pesticides. For more than 10 years, the U.S. Geological Survey's National Water-Quality Assessment (NAWQA) program has played a key role in this assessment; more than 50 major river basins and aquifers were studied (74). The overall picture emerging from the NAWQA program is that pesticides

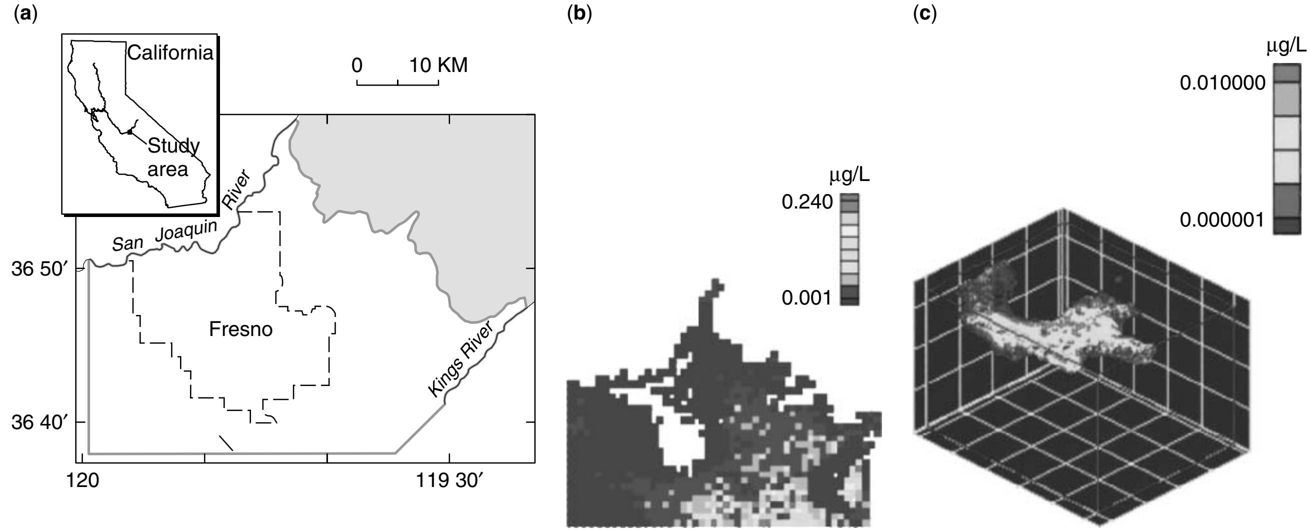

Figure 1. Results from the Fresno case study. (**a**) Location of study area. (**b**) Plan view snapshot of the simulated DBCP concentration loading at the water table for 1971 (46). (**c**) 3-D snapshot of the simulated DBCP concentration plume for 1971 (69).

typically occur at low levels, punctuated by seasonal pulses in concentration (75). Specific to groundwater, pesticides were most frequently found in shallow systems in urban and agricultural areas (74). The patterns of pesticide detection (over space and in time) identify problem areas and chemicals, warn of potential problems, and provide valuable feedback on to improve conditions (75). The use of mathematical models for assessing groundwater vulnerability from pesticides, especially after ground truth comparisons, fills in information gaps, identifies critical areas and chemicals for future monitoring, and provides the "what if" capability needed for both regulation and remediation.

HIGH pH GROUNDWATER—THE EFFECT OF THE DISSOLUTION OF HARDENED CEMENT PASTES

Oak Ridge, Tennessee

INTRODUCTION

Concrete is the most widely used construction material manufactured by mixing together cement, aggregates, water, air, and various admixtures. Conventional hardened concrete comprises approximately 30% by volume of cement paste phase and 18% pore voids. Many concrete structures are built above and below ground, some in contact with surface and/or groundwater. In these cases, pore voids within concrete are filled with water. Groundwater chemistry is affected when brought into contact with or close proximity to such structures since the hydration products of cement can be dissolved and leached into the groundwater.

In fact, groundwater chemistry close to aboveground structures is affected by the rainwater falling on these structures prior to soaking into the ground and becoming groundwater. The composition of groundwater varies widely, depending on the soil or rock with which the water is in equilibrium. Rainwater can be acidic ("acid rain"), which may be quickly consumed. The local soil, rocks, and minerals result in dissolution of some ions into the resulting runoff. For example, acid rain leached aluminum into lakes in the northern United States, killing the local aquatic life in those lakes. Acidic mine runoff is another source for acid groundwater. On the other hand, limestone strata result in hard water with higher pH and seawater results in higher ionic concentrations from dissolved salts. It is well known that some ions in groundwater can migrate into concrete and even deteriorate the integrity of the concrete structures.

The focus here is on how the hydration products of cements affect the pH of groundwater since they have very high equilibrium pH values. To fully evaluate this effect requires knowledge of cement chemistry, the characteristics of hydration products, and the transport of ions in hardened concrete. We first summarize cement chemistry, the effect of supplementary cementing materials on this chemistry, and the dissolution and leaching of hydration products of cement. The last section discusses the interaction with cement and its leached ions. For a given case, the known cement chemistry can be used to project what to expect for the local groundwater in question.

CHARACTERIZATION AND HYDRATION CHEMISTRY OF PORTLAND CEMENT

Portland cement is the most used cementing material in construction. It is a hydraulic cement produced by pulverizing clinker and calcium sulfate (usually gypsum—$CaSO_4 \cdot 2H_2O$) as an interground addition. Cement clinker consists mainly of tricalcium silicate ($3CaO \cdot SiO_2$—C_3S), dicalcium silicate ($2CaO \cdot SiO_2$—C_2S), tricalcium aluminate ($3CaO \cdot Al_2O_3$—C_3A), and tetracalcium aluminoferrite ($4CaO \cdot Al_2O_3 \cdot Fe_2O_3$—$C_4AF$). Different types of Portland cement are manufactured to meet various normal physical and chemical requirements for specific purposes. ASTM C150 specifies five types of common Portland cement produced by adjusting the proportions of their minerals and finenesses.

In the presence of water, C_3S and C_2S in cement hydrate to form calcium silicate hydrate gel (C-S-H gel) and $Ca(OH)_2$. In the presence of calcium sulfate, C_3A hydrates to form calcium trisulfoaluminate hydrate ($3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$—AFt or ettringite), or calcium monosulfoaluminate hydrate ($3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O$—AFm or monosulfate). In the absence of calcium sulfate, C_3A reacts with water and calcium hydroxide to form tetracalcium aluminate hydrate [$3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O$]. C_4AF reacts with water to form calcium aluminoferrite hydrates ($6CaO \cdot Al_2O_3 \cdot Fe_2O_3 \cdot 12H_2O$). These hydration reactions can be expressed as follows:

$$3(3CaO \cdot SiO_2) + 6H_2O \rightarrow 3CaO \cdot 2SiO_2 \cdot 3H_2O + 3Ca(OH)_2 \quad (1)$$

$$2(2CaO \cdot SiO_2) + 4H_2O \rightarrow 3CaO \cdot 2SiO_2 \cdot 3H_2O + Ca(OH)_2 \quad (2)$$

$$3CaO \cdot Al_2O_3 + 3CaSO_4 \cdot 2H_2O + 26H_2O \rightarrow 3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O \quad (3)$$

$$3CaO \cdot Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O + 2(3CaO \cdot Al_2O_3) + 4H_2O \rightarrow 3(3CaO \cdot Al_2O_3 \cdot CaSO_4 \cdot 12H_2O) \quad (4)$$

$$3CaO \cdot Al_2O_3 + 12H_2O + Ca(OH)_2 \rightarrow 3CaO \cdot Al_2O_3 \cdot Ca(OH)_2 \cdot 12H_2O \quad (5)$$

$$4CaO \cdot Al_2O_3 \cdot Fe_2O_3 + 10H_2O + 2Ca(OH)_2 \rightarrow 6CaO \cdot Al_2O_3 \cdot Fe_2O_3 \cdot 12H_2O \quad (6)$$

A hardened cement paste is a heterogeneous multiphase system. At room temperature, a fully hydrated Portland cement paste consists of 50–60% C-S-H gel, 20–25% $Ca(OH)_2$, 15–20% ettringite (or AFt) and AFm by volume. The minor hydration products, such as $Ca(OH)_2$, $3CaO \cdot Al_2O_3 \cdot 6H_2O$, and AFt, form in small quantities depending on the composition of the cementing material and hydration conditions.

Portland cement also contains a small amount of alkalis; but the amount is dependent on the raw materials and production process used. The presence of a small amount of alkalis does not have a significant effect on the hydration process of the cement but may have a significant effect on the pH of the pore solution. Usually, the pH value of the pore solution of a hardened Portland cement is over 12.5 to values as high as 13.5, due to the presence of alkalis.

USE OF SUPPLEMENTARY CEMENTING MATERIALS AS CEMENT REPLACEMENTS

For construction use, supplementary cementing materials, such as granulated/pelletized blast furnace slag, coal fly ash, volcanic ashes, condensed silica fume, rice husk ash, and natural pozzolans, are often used to replace Portland cement to reduce the cost or to improve the performance of concrete.

When Portland pozzolan cement contacts water, Portland cement hydrates first; the lime released from the hydration of Portland cement reacts with pozzolan to form new products depending on the composition of the pozzolan and hydration conditions. The main hydration product in lime–pozzolan mixtures is C-S-H with a C/S ratio less than 1.5, depending on the local concentration of reactants. The aluminate in the pozzolan may yield a variety of hydrates: calcium aluminate hydrate (C_4AH_{19}), gehlenite hydrate (C_2ASH_8), AFt ($C_3A \cdot 3CaSO_4 \cdot 32H_2O$), and AFm ($C_3A \cdot CaSO_4 \cdot 12H_2O$). The pozzolanic reactions can be generally expressed as follows:

$$Ca(OH)_2 + SiO_2 + (n-1)H_2O \rightarrow xCaO \cdot SiO_2 \cdot nH_2O \quad (7)$$

$$Ca(OH)_2 + Al_2O_3 + (n-1)H_2O \rightarrow xCaO \cdot Al_2O_3 \cdot nH_2O \quad (8)$$

$$Ca(OH)_2 + Al_2O_3 + SiO_2 + (n-1)H_2O \rightarrow 3CaO \cdot Al_2O_3 \cdot 2SiO_2 \cdot nH_2O \quad (9)$$

$$(1.5\text{–}2.0)CaO \cdot SiO_2 \cdot aq + SiO_2 \rightarrow (0.8\text{–}1.5)CaO \cdot SiO_2 \cdot aq \quad (10)$$

The relationship between the C/S ratio of C-S-H and equilibrium pH is shown in Fig. 1. There are two plateaus for the equilibrium pH. One corresponds to around pH 12, where the C/S ratio is greater than 1.0. The other plateau corresponds to pH 10, where the C/S ratio of C-S-H varies from 0.05 to 0.6. Typically, the C/S ratio of C-S-H from the hydration of Portland cement ranges from 1.4 to 1.7.

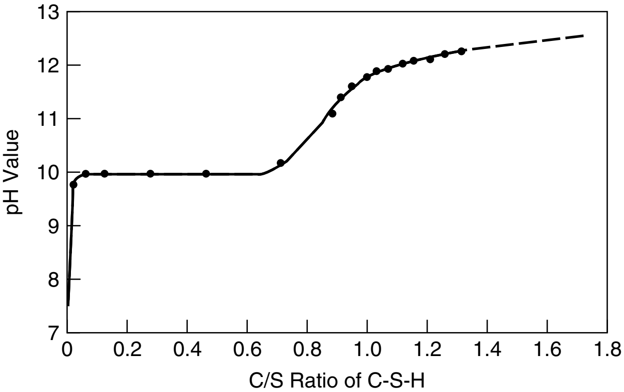

Figure 1. Relationship between C/S ratio of C-S-H and equilibrium pH. (Based on Reference 1).

DISSOLUTION AND LEACHING OF HYDRATION PRODUCTS OF CEMENTS

Table 1 lists the solubility products of common hydration products of hydraulic cements. It can be seen that $Ca(OH)_2$ has the highest solubility among all hydration products. The solubility of C-S-H decreases as its C/S ratio decreases, which means that the use of supplementary cementing materials converts the more soluble $Ca(OH)_2$ into the less soluble C-S-H.

The dissolution of $Ca(OH)_2$ and the decalcification of the C-S-H phase occur so as to maintain the chemical equilibrium of Ca^{2+} between the solid hydrates and the pore solution. Once the concentration of Ca^{2+} in the pore solution of a cement-based material is decreased by diffusion, the dissolution of $Ca(OH)_2$ starts, depleting the $Ca(OH)_2$, followed by the decalcification of the C-S-H phase. The dissolution of $Ca(OH)_2$ and the partial decalcification of C-S-H are given by the following chemical equilibrium equations:

$$Ca(OH)_2 \rightarrow Ca^{2+} + 2OH^- \qquad (11)$$

$$xCaO \cdot SiO_2 \cdot yH_2O \rightarrow (x-m)CaO \cdot (1-n)SiO_2 \cdot (y-m)H_2O + mCa(OH)_2 + nSiO_2 \qquad (12)$$

Chemical equilibrium of the solid cement hydrates and the pore solution with regard to Ca^{2+} is applied according to the model shown in Fig. 2. The initial concentration of Ca^{2+} in the pore solution is approximately 0.02 mol/L of solution and must be maintained as long as the $Ca(OH)_2$ remains in the solid. Subsequently, after all the $Ca(OH)_2$ is dissolved, the decalcification of C-S-H will ensue depending on the concentration of Ca^{2+} with the chemical equilibrium shown in the curved portion of Fig. 2.

Table 1. Solubility Product of Common Hydration Products of Cements

Compound	Solubility Product	Reference
$Ca(OH)_2$	5.5×10^{-6}	2
C-S-H[a]	$1.0 \times 10^{-24 \text{ to } -14}$	3
C_4AH_{13}	3.2×10^{-28}	2
C_2ASH_8	8.1×10^{-52}	4
AFt	1.0×10^{-40}	5
AFm	1.7×10^{-28}	5

[a] The solubility product increases as the C/S ratio of C-S-H decreases.

Table 2. pH Value and Concentrations of Ions in Immersion Water at 12 Weeks

		Ion Concentration (mmol/L)				
W/C	pH	Ca^{2+}	K^+	Na^+	$SO_4{}^{2-}$	Al^{3+}
0.4	12.8	400	110	38	1.9	2.4
0.55	13.0	710	89	33	2.4	2.5
0.7	13.0	760	38	19	2.6	2.6
0.85	13.0	840	32	12	2.7	2.8

Source: Reference 7.

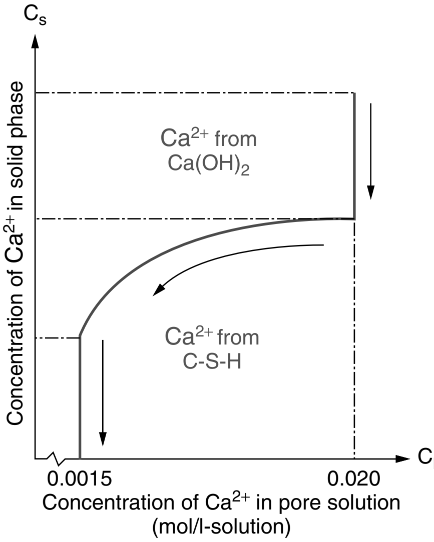

Figure 2. Relationship between Ca^{2+} concentrations in solid and liquid phases (6).

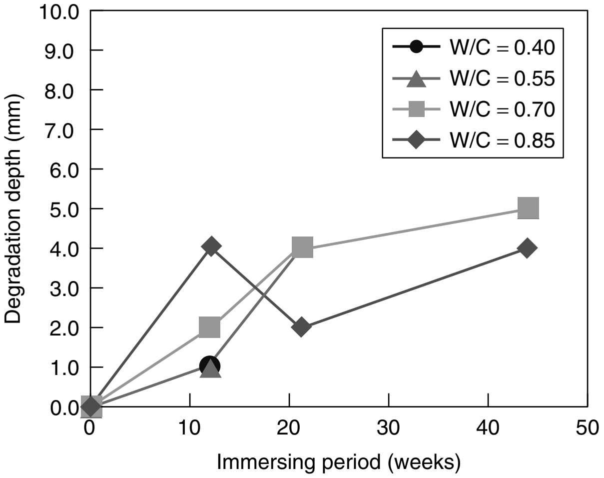

Figure 3. Degraded depths of cement pastes after immersion in water. (Based on Reference 7).

Kosuke Yokozeki et al. (7) investigated the leaching out of ingredients from hardened cement pastes made with different water to cement ratios. They immersed 20 × 20 × 20 mm hardened cement cubes in water with a water to cube (by volume) ratio of 20, then measured the degraded depths of cement paste, as shown in Fig. 3, and pH values and ion concentrations of the immersed water after 12 weeks of immersion, as shown in Table 2.

The results in Fig. 3 indicate that the degradation depth increases with immersion time, but the water to cement ratio does not show an obvious effect. The pH value of immersed water is almost 13 regardless of the water to cement ratio. The Ca^{2+}, K^+, and Na^+ concentrations are high, and the rest are low.

Several researchers (6,8–10) Sugiyama et al. confirmed that hardened cement pastes dissolve and degrade in the following five steps: (1) leaching of calcium hydroxide; (2) decalcification of C-S-H; (3) formation of C-S-H with

C/S ratio or calcium aluminate hydrates; (4) leaching of C-S-H; and (5) leaching of silica gel. As shown in Eq. 11, the initial dissolution and leaching of Ca^{2+} are always associated with hydroxyl ion. Laboratory results clearly indicate a gradual pH drop on the surface of concrete after immersion in water or a solution (11). Once it is controlled by the leaching of C-S-H, the pH of hardened concrete is around 10, as indicated in Fig. 1.

EFFECT OF LEACHING OF HYDRATION PRODUCTS OF CEMENTS ON pH OF GROUNDWATER

In general, the water chemistry is controlled by two large bulk systems: concrete and soil-rock. Both bulk systems are porous with an interfacial transitional zone. Cement chemistry dominates within the bulk of concrete structure and local groundwater chemistry dominates within the bulk of the soil-rock.

As discussed above, the pH of pore solution within concrete is over 12.5 to values as high as 13.5, due to the presence of alkalis, which is significantly higher than groundwater. Hydroxyl ions always transport from concrete to groundwater. Increased pH of groundwater can be expected around the surface of concrete but is not expected to penetrate far into the groundwater matrix, because the transport rate from the concrete is low. A transition zone in the aqueous chemistry exists at the interface between these two bulk systems, as illustrated in Fig. 4.

The width of this transitional zone is controlled mainly by the rate of flow of the groundwater around the surface of the concrete, with higher flows resulting in a narrower zone. For example, a fast-flowing river around a concrete structure makes this zone very thin, or even negligible, sweeping the surface of the concrete clean of ions leached from the concrete and turbulently mixing these ions with the river water. The width of the transitional zone can be significant for concrete sitting in quiescent perched water. Diffusion is very slow, so much so that leaching from a monolithic concrete structure can be dominated by the permeation of water through the porous concrete matrix.

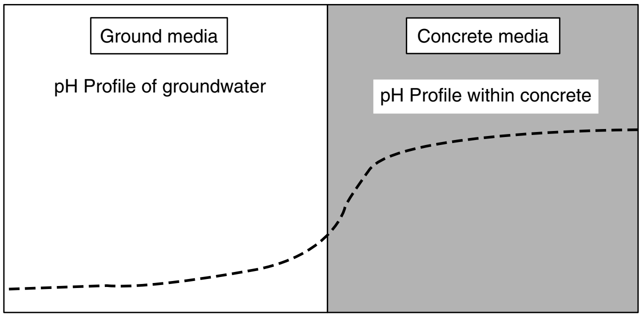

Figure 4. Schematic illustration of pH profiles between groundwater and concrete.

PHYTOEXTRACTION AND PHYTOSTABILIZATION: TECHNICAL, ECONOMIC AND REGULATORY CONSIDERATIONS OF THE SOIL-LEAD ISSUE

Tracey Johnston
Rupali Datta
Dibyendu Sarkar
University of Texas at San Antonio
San Antonio, Texas

Lead is a common environmental contaminant, produced from multiple anthropogenic sources. The cost of traditional remediation techniques for lead-contaminated soils is prohibitive. As a result, new technologies such as phytoextraction, the removal of contaminants from soil and water sources by plants, and phytostabilization, the immobilization of contaminants in the soil, are being examined as remediation alternatives for lead-contaminated soils. Only a few plant species have been identified so far that can tolerate and accumulate lead partly because lead is relatively immobile in soils and has low phytoavailability. However, lowering the pH or the use of soil amendments or chelating agents such as EDTA can enhance the uptake of lead by plants. Lead is already relatively immobile in most soils, so phytostabilization is a promising remediation strategy. However, phytostabilization leaves the contaminant in the soil (albeit in an insoluble form), so long-term monitoring is required to verify that the contaminant does not become soluble again. Although only limited studies on the economic viability of phytoextraction and phytostabilization have been done, the estimated costs are significantly lower than those of traditional methods.

INTRODUCTION

Lead is a bluish-gray heavy metal, which is usually found naturally in soils in levels ranging from 15 to 40 mg/kg. Galena (PbS) is the major mineral source of naturally occurring lead in soils. More than 85% of the lead mined in the United States comes from southeastern Missouri (1). It is common to find lead in soils at levels between 100 and 3000 mg/kg due to the use of lead-based paints, storage batteries, plumbing fixtures, gasoline, explosives, ammunition, and mining and smelting (2,3). According to the Toxic Release Inventory, almost 144 million pounds of lead were released to land and water in the United States between 1987 and 1993, most of which were from lead and copper smelting (1). Lead contamination in soils can lead to many environmental problems, such as lead toxicity in humans, animals, and plants; loss of vegetative cover; and ground water contamination (4). In humans, short-term exposure to lead can interfere with red blood cell activity, cause mental and physical developmental delays in babies and young children, and increase the blood pressure of adults. Long-term exposure to lead has the potential to cause cancer, kidney disease, and stroke in adults (1). Current remediation techniques for lead-contaminated soils include excavation, stabilization, and/or removal to a landfill (3). These techniques are expensive and can result in secondary problems such as human exposure and habitat destruction (3).

PHYTOREMEDIATION

Phytoremediation is the use of plants to remediate contaminated soils, sediments, sludge, ground/surface water, or wastewater (5). Phytoremediation uses a variety of plant biological processes to degrade, remove, or immobilize contaminants (3). Phytoremediation can be an attractive alternative to traditional remediation techniques because it is driven by photosynthesis and is performed on site, reducing costs and human exposure (1). Two specific methods of phytoremediation, phytoextraction and phytostabilization have been used to treat lead-contaminated soils (5,6).

Phytoextraction

Phytoextraction is the uptake of contaminants by a plant, and the toxic substance is then sequestered in the tissues (5). The plants that take up contaminants at the highest rates are called hyperaccumulators (0.1 to 3% of dry biomass) (7). *Brassica juncea* (Indian Mustard), *Helianthus annuus* (common sunflower), *Nicotiana tabacum* (tobacco), and *Zea mays* (corn) have been identified in the literature as hyperaccumulators of lead (2,8). For lead to be taken up by a plant, it must be in an aqueous phase, either in soil solution or in groundwater (9,10). The solubility of lead (in the form of Pb^{2+}) is low at neutral or alkaline pH, so only about 0.1% of the lead in lead-contaminated soils is available for uptake by plants (3). Kumar et al. (2) reported that the ratio of lead in the dry weight of plant to that in soil (called the phytoextraction coefficient) in *B. juncea* was 1.7; in comparison, Cr^{6+} and Cd^{2+} have coefficients over 50. Decreasing the pH of the soil can increase the phytoavailability of lead; however, most plants have an ideal pH range of 5–8 (3,11). Chelating agents, such as EDTA (ethylenediaminetetraacetic acid), increase lead phytoavailability and also increase the amount of lead accumulated in the aboveground biomass (12). However, by making lead more soluble, the danger exists of allowing more lead to enter the food chain or leach into groundwater (13).

Phytostabilization

In phytostabilization, vegetation is used to modify the biological, physical, and chemical properties of soil to reduce the movement of contaminants. *Brassica juncea, Festuca rubra* cv Merlin (red fescue), and *Agrostis tenuis* cv Goginan (colonial bentgrass) have been used to stabilize lead mine wastes (14). One phytostabilization study showed that lead-contaminated soil had 740 mg/kg of lead in the leachate without plant cover, compared with 22 mg/kg with *B. juncea* cover (5). Phytostabilization can be achieved through root absorption, accumulation, and adsorption. Plants may also release exudates in the root zone that could result in precipitation, complexation, or a change in the valence state of a metal contaminant (15). Roots can help precipitate lead in the form of lead phosphate (5). Some grasses, such as ryegrass, have been investigated as possible phytostabilizers due to their extensive roots and widespread growth patterns (14). In addition, plants can prevent wind and water erosion from spreading contaminants to surrounding areas. However, because contaminants are left in the soil in an insoluble form in phytostabilization, the area has to be monitored continuously to verify that they do not become soluble with time (16).

TECHNICAL CONSIDERATIONS

Vegetation

Several plants reportedly accumulate small amounts of lead, but hyperaccumulators are those plants that can take up the metal to tissue concentrations greater than 1000 mg/g (17). For effective phytoextraction, the plant should also be able to translocate lead to aboveground tissues, which allows easier harvesting and helps the next crop of plants to grow quickly due to an already existing root system (16). Depth of roots is an important characteristic of candidate plants for phytoremediation. Most hyperaccumulator plants have shallow root systems; the effective depth is about 12 inches and hence can only take up contaminants from shallow soils (6). Hyperaccumulating plants that have faster growth rates, higher biomass, and an extensive root system would be more effective for phytoremediation (18). Plants used in phytostabilization have to grow and survive long term in contaminated soils. A large root mass would also be advantageous for greater soil–root contact surface area, which would also result in the secretion of larger amounts of enzymes or exudates to immobilize lead. Prospective plants should also be hearty and tolerate the environmental stresses in a given contaminated area (16).

Soil and Lead Chemistry

Soil pH is very important in the solubility of metals such as lead. The solubility of lead is relatively low at neutral or alkaline pH (3). Decreasing the pH of the soil by using soil amendments or acidifiers can increase the solubility and hence the phytoavailability of lead. However, as the pH decreases, aluminum (Al^{3+}), which is ubiquitous in soils and toxic to plants, also becomes more phytoavailable. The optimum pH range for most plants is 5–8, so this would make the optimum pH range for lead uptake between 5 and 6.5 (11). Chelating agents, such as EDTA, have been used to increase solubility and thereby increase plant uptake (13,19). Chelating agents can also increase the translocation of lead into the aboveground biomass (19). On the other hand, by increasing the solubility of lead, there exists the danger of lead entering the food chain or leaching into underground water sources. Strategies for properly using chelating agents include using plants that rapidly take up lead and harvesting them immediately to reduce environmental risks (12).

Soil amendments can also be used to decrease solubility. Increasing the pH of soil via alkalizing agents or mineral oxides increases lead precipitation potential. Organic matter and biosolids have also been used to immobilize lead in soil (20). Phosphates can bind with lead and precipitate it from solution, usually in the form of lead carbonates, hydroxides, and phosphates (21). Therefore, when adding fertilizers to plants involved in phytoextraction, phosphate should be added typically to leaves and not to the soil itself (12). The type of soil and the amount of organic matter present can complicate the uptake of lead. Contaminated areas generally also have multiple contaminants, and there are substantial variations in the concentrations of contaminants at a single site. These scenarios can reduce the effectiveness of any phytoremediation project (16).

Other Considerations

Phytoextraction and phytostabilization use natural plant processes, so it takes longer to remediate contaminated areas using these techniques, compared with traditional methods (5,15). The length of the growing season and rainfall patterns in a contaminated area will also substantially impact the amount of time required for any phytoremediation project. Using plants that have faster growth and high biomass may reduce the time necessary for phytoextraction compared to hyperaccumulators, the majority of which are slow growing and low biomass plants (16). In phytostabilization, selecting plants that produce more exudates or enzymes can speed up the remediation process. Any phytoremediation project requires continuous monitoring of the site. However, a phytostabilization project needs long-term monitoring because of the lead that stays on site. On-site plant tissue sampling to ensure little or no lead uptake and soil and local source water sampling, to ensure that lead remains immobilized may be required for many years (16). Although some herbivorous animals avoid plants with high levels of accumulated metals, it may be necessary to restrict access to hyperaccumulating plants during phytoextraction through fencing, netting, or harvesting before the plants reach the flowering stage to avoid transfer of metals to the food chain (22).

ECONOMIC CONSIDERATIONS

To date, economic viability data for phytoextraction and phytostabilization projects are rather limited. Moreover, the available data are typically gathered from small, pilot-scale studies, which may not accurately reflect the costs and efficiency of large-scale operations (16). The costs of any potential phytoremediation project must consider the initial feasibility studies, which includes site characterization, selecting the most appropriate plants, and determining if soil amendments are necessary (16). Before remediation can begin, site start-up costs may include debris removal, fencing, irrigation systems, and drainage control measures (23). Besides the costs of planting, watering, fertilizing, and pesticide use, project costs must also include periodic monitoring for pH, nutrient levels, and contaminant levels in soils and possibly nearby surface and groundwater sources and disposal of contaminated vegetation (16). Still, estimated costs for most phytoremediation applications are usually 50–80% lower than those of traditional techniques (24). A small-scale study of lead phytoextraction in 1997 predicted that the costs of the phytoextraction project at the Magic Marker site in New Jersey would range from 50–65% of the remediation costs of traditional methods (19). In 1997, another study estimated that the costs for phytoremediating a lead-contaminated area of soil 60 cm deep would be $\$6/m^2$ compared to $\$15–\$730/m^2$ for more traditional remediation techniques (20). One of the disadvantages of using phytoremedation as a cleanup technique is that it can easily take several growing seasons to reduce the lead concentrations to acceptable levels. The cost incurred by not using the land during the period of the phytoremediation project may be a deterrent for a business expecting to make a profit from that land immediately (25). The estimated costs of a typical phytostabilization project may range from $200 to $10,000 per hectare (1 meter root depth) (7). However, the contaminants essentially stay in place in this method, so the costs of long-term monitoring (to verify that the lead has not become soluble again) should be included in any project (7). The number of cost estimates for actual phytoextraction and phytostabilization projects is limited, but there is general agreement that the costs are much lower than those of currently practiced traditional *ex situ* remediation techniques. For phytoextraction, the future recovery and eventual resale of extracted metals has been proposed; however, it is unclear if the technology and markets exist to make such an idea feasible and profitable on a large scale (16).

REGULATORY CONSIDERATIONS

Specific federal regulations for phytoremediation have not yet been developed, but several existing federal acts, statutes, and programs have implications for phytoremediation technologies (26) The Resource and Recovery Act (RCRA) of 1976, an amendment to the Solid Waste Disposal Act, deals with waste management. Two of the sections (Subtitles C - Hazardous Waste Management and D - Solid Waste Management) are most likely to impact phytoremediation projects. Remediation of treatment, storage, or disposal units will fall under the RCRA requirements. These requirements, however, are performance-based and are delegated to the states. It is up to the state authorities to assess the individual site requirements to determine if phytoremediation can be part of a site cleanup. Disposal of plants used in phytoextraction may also be governed by RCRA. The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) was enacted in 1980 to cleanup hazardous waste contaminated sites. The trust fund created by CERCLA provides money for the cleanup of designated hazardous waste sites. Under CERCLA, a feasibility study must be completed to determine if phytoremediation is appropriate for a specific site. Any remediation plan must meet the nine criteria set forth in the National Oil and Hazardous Substances Pollution Contingency Plan (NCP) (27). States may have stricter guidelines for cleanup requirements and remaining material limitations. Any state or federal regulation concerning how much material may be left on site may have important implications for phytostabilization. In addition, the Maximum Contamination Levels (MCLs) put forth by the Safe Drinking Water Act (SDWA) may also apply. Executive Order 13112 signed in 1999 prohibits the use of invasive species unless it can be shown that the benefits of using such species outweigh the potential harm (28). Other regulations and acts that may apply to phytoremediation include the Clean Air Act, Department of Agriculture statutes, and the Toxic Substances Control Act (26).

FUTURE PROSPECTS FOR LEAD PHYTOREMEDIATION

Lead phytoextraction seems to be limited to low to medium lead soil contamination levels and to the root zone of the plants being used, so phytoextraction may emerge as a common polishing step in a multiple step process aimed at total site remediation. For some cleanup projects, traditional remediation techniques could be used to reduce the contamination to plant-tolerant levels followed by phytoextraction to reduce the contamination even further (23). Similarly, appropriate plants can be used to stabilize the remaining pollutants to reduce their bioavailability and potential for leaching as the final remediation step (20). Lead is relatively insoluble in a soil solution, so phytostabilization might be a more promising technique for lead-contaminated soils (2,23). The search for fast-growing and high biomass phytoextracting and phytostabilizing accumulator plants is ongoing (29). Selective breeding and genetic engineering of more suitable plants is a possibility. However, more information on the ecological impact of using genetically modified plants would be needed. The current regulations and the societal view of using genetically modified organisms could also hinder the use of these technologies (23).

PHYTOEXTRACTION OF ZINC AND CADMIUM FROM SOILS USING HYPERACCUMULATOR PLANTS

Rupali Datta
Dibyendu Sarkar
University of Texas at San Antonio
San Antonio, Texas

INTRODUCTION

Mining, manufacturing and various other human activities have contributed to extensive soil contamination during the past century; heavy metals being the main group of inorganic contaminants (1). Accelerated release of metals into ecosystems has resulted in serious environmental problems and poses a threat to human health because most heavy metals are toxic at higher concentrations (2). Heavy metals can cause toxicity for several reasons: (1) by causing oxidative stress; (2) by replacing other essential metals in biomolecules, thereby disrupting their function; and (3) by reacting with thiol groups, thereby interfering with protein structure and function (3).

Zinc and Cd are ubiquitous pollutants that tend to occur together at many contaminated sites (4). Cadmium occurs in natural environments typically in association with Zn ores. Cadmium is emitted into the atmosphere from natural as well as anthropogenic sources. Metal production (drying of Zn concentrates, roasting, smelting and refining of ores) is the largest source of anthropogenic atmospheric Cd emissions, followed by waste incineration, production and disposal of nickel-cadmium batteries, fossil fuel combustion, and generation of dust by industrial processes, such as cement manufacturing (5). In the air, Cd vapor is rapidly oxidized and transferred to the soil by wet or dry deposition.

Most of the commercial production with Zn involves galvanizing iron and manufacturing of brass. Zinc oxide is also used in large quantities as an accelerant in tire vulcanizing. Worn tires are a major contributor to environmental Zn contamination (6). Zinc is also a major effluent from industries, such as soft drink flavoring, fur dressing and dyeing, fish processing, and laundry (7).

Cadmium derives its toxicological properties from its chemical similarity to Zn, which is an essential micronutrient for plants, animals, and humans. In humans, long-term exposure to Cd is associated with renal dysfunction, obstructive lung disease, and bone defects. In Japan, a bone disease called 'itai-itai' has been associated with prolonged exposure to Cd in rice and water (8). Cadmium and Zn are chemical antagonists; Zn deficiency can cause accelerated absorption of Cd (9). Zinc is an essential cofactor in a variety of cellular processes, including DNA synthesis, behavioral responses, reproduction, bone formation, growth, and wound healing. Although humans can handle relatively large quantities of Zn, very high levels of Zn can cause irritation and corrosion of the gastrointestinal tract, renal tubular necrosis, and interstitial nephritis (9).

Conventional soil cleanup methods for heavy-metal-contaminated soils include soil washing, excavation and reburial of soil, and pump and treat systems (10), which are rather expensive techniques. The use of plants for remediating metal-contaminated sites offers an attractive alternative because it is solar-driven and can be carried out *in situ*, minimizing the cost and human exposure (11). It offers a cheaper, safer, and environmentally friendly solution for the cleanup of metal-contaminated soils. The technique of phytoextraction depends on the extent to which plants can take up metals from soils and concentrate them in aboveground tissues (12). Plants that can accumulate metals to exceptionally high concentrations in their shoots are called hyperaccumulators (13).

Hyperaccumulators are an invaluable resource for successful phytoextraction of heavy metals, such as, Zn and Cd, either as phtoremediation crops themselves or as sources of genes for improving other phytoremediation crops (12). In this article, we focus on factors affecting Zn and Cd bioavailability in soils, the mechanism of Zn and Cd hyperaccumulation in plants, and future directions in improving phytoextraction through biotechnology and improved agronomic practices.

FACTORS AFFECTING ZINC AND CADMIUM BIOAVAILABILITY IN SOILS

Zinc

The amount of different Zn forms in soils varies considerably depending on the type and nature of soil constituents. Alkaline soils that are calcareous are generally high in the carbonate form of Zn, whereas soils rich in organic matter are high in organic forms (14). Water-soluble and exchangeable forms of Zn are readily bioavailable to plants; other forms of Zn are either unavailable or not as readily available to plants for uptake. In agriculture agronomic management practices can affect the distribution of metals among soil constituents. In Norwegian soils treated with farmyard manure, rock phosphate, or mixed fertilizers, the majority of the Zn ($\sim$78%) was reportedly associated with the oxides and residual matrices (15). In polluted soils from Poland, the majority of the Zn ($\sim$65%) was found in the oxide and residual fractions (16). The predicted dominant Zn species in soil solution below pH 7.7 is the divalent metal ion, Zn^{2+} (17). Above this pH, $ZnOH^+$ is more dominant (14).

Cadmium

In unpolluted soils, most of the Cd is associated with the residual fraction, which is generally not available for plant uptake (14). In contrast, the greatest amount of Cd ($\sim$37%) in heavily polluted soil in Norway was found in the exchangeable fraction; the oxide and residual fractions accounted for relatively lower concentrations, 23% and 15% of the Cd, respectively (18). Based on several studies, it has become apparent that Cd from mining and smelting activities is likely to be more bioavailable than Cd from unpolluted soil because increasing contamination results in increased amounts of Cd in the labile fractions of the soil (14). Most of the Cd in soil solutions is generally present as Cd^{2+} ions (14).

Cadmium–Zinc Interactions

The close association of Cd and Zn in geologic deposits and the chemical similarity of the two elements carry over into biological systems (14). Cadmium has no known biological function, whereas Zn is an essential nutrient. Cadmium competes with Zn in forming protein complexes, so a negative association between the two can be expected. The interaction between Zn and Cd is either antagonistic or synergistic (14). The addition of Cd-treated sewage sludge to calcareous soil decreased the concentrations of Zn in the shoots of the many plants studied (19). However, at higher levels of Cd, increasing concentrations of Zn increased Cd uptake (20). The variable results are related to the plant species, soil type, Zn/Cd status, source and level of applied Zn or Cd, and the Zn/Cd ratio (14).

PHYTOEXTRACTION OF ZINC AND CADMIUM

Phytoextraction is a term for the process by which plants remove significant quantities of substances from their substrate (21). Generally, the metal phytoextraction protocol consists of the following steps: (1) plant cultivation on a contaminated site, (2) removal of harvested metal-rich biomass, (3) postharvest treatments and subsequent disposal of the biomass as hazardous waste, and (4) eventual recovery of metals from the harvested biomass (22). Metal hyperaccumulation is a relatively rare phenomenon that occurs only in a few terrestrial plants. Only about 400 species have so far been identified as natural metal hyperaccumulators, representing $<0.2\%$ of all angiosperms (13). Threshold values of metal concentrations are used to define metal hyperaccumulation, which varies from element to element, for example, 10,000 mg/kg dry shoot weight for Zn and Mn; 100 mg/kg for Cu, Co, Ni, As, and Se; and 100 mg/kg for Cd (21). These concentrations are two to three orders of magnitude higher than in normal plant species growing on uncontaminated soils. The common traits shared by all hyperaccumulators include (1) a bioconcentration factor greater than 1, in some cases as high as 50–100; (2) a shoot-to-root ratio of metal concentration greater than 1, indicating efficient root to shoot transport; and (3) enhanced tolerance to metals in the medium and inside the plant cells, indicating strong internal detoxification (21).

Several species of plants that hyperaccumulate Zn have been investigated, but only one Cd hyperaccumulator, *Thlaspi caerulescens,* has been extensively studied. Many Zn hyperaccumulators are in the family Brassicaceae and in the genus *Thlaspi.* In addition, *Cardaminopsis halleri* and *Viola calaminaria* also hyperaccumulate Zn. The first indication of the possibility of phytoextraction of Zn was obtained from pot experiments in background and sludge-treated soils using *Thlaspi caerulescens* (23). It was estimated that a crop of *T. caerulescens* could take up 34 kg/ha of Zn and 0.16 kg/ha Cd. McGrath et al. (24) performed a field study on metal-contaminated soil from 20 years of sewage sludge application and reported that hyperaccumulator plants accumulated 10,625 mg/kg of Zn from a soil concentration of 406 mg/kg. McGrath and Dunham (25) reported that *T. caerulescens* and *C. halleri* plants, at field removal rates of 150 and 34 g/ha, could remove 10 years worth of Cd accumulation from agricultural land where P fertilizers added Cd at a rate of 3 g/ha/y. Only the bioavailable fraction of the total metal is of major ecological and human health concern, so it is acknowledged that all the metal need not be removed from the soil, a concept described as 'bioavailable element stripping' (BES). From the study of McGrath and Dunham (25), it is evident that in terms of BES, the bioavailable fraction of Cd can be removed from the soil by *T. caerulescens* in about four harvests.

Brown et al. (26) showed that *T. caerulescens* contained 18,000 mg/kg of Zn and 1,020 mg/kg of Cd in their shoots when grown on contaminated soils, there was no effect on yields, and the result was a in significant reduction in bioavailable metal concentration in the soils. McGrath and Dunham (25) used data from their field experiment to show that *T. caerulescens* and *C. halleri* could remove a maximum of 41 and 0.15 kg/ha/y of Zn and Cd, respectively. It is, however, not known if these extraction rates would decline with time and soil metal concentration.

Although Zn and Cd are chemically similar, as the above case studies illustrate, there are marked differences in their accumulation by hyperaccumulator plants. Cadmium and Zn also differ due to the difference in accumulation and also in relation to their response to concentrations in the soil. McGrath et al. (24) showed that *T. caerulescens* responded to increasing soil Zn concentrations by maintaining consistent hyperaccumulation of the metal. However, Cd accumulation depends much more on soil conditions, especially pH and extractable Cd concentrations (21), which indicates that there are differences in the mechanisms for accumulating the two metals in hyperaccumulators.

MOLECULAR BASIS OF ZINC AND CADMIUM HYPERACCUMULATION

Considerable progress has been made in understanding the molecular basis of metal hyperaccumulation, but the entire picture is far from complete (21). A genetic study using crosses between Zn hyperaccumulator *Arabidopsis halleri* and the nonaccumulator *Arabidopsis petraea* showed that Zn tolerance and hyperaccumulation are independent traits and that tolerance is controlled by a single major gene (27). Several studies have shown that metal hyperaccumulation of Zn and Cd by *T. caerulescens* involves enhanced metal uptake by the roots (4,28). Several Zn transporter genes cloned recently from *T. caerulescens* belong to the ZIP (Zn-regulated transporter/Fe-regulated transporter-like proteins) family (29). These genes, named *ZNT1* and *ZNT2*, are highly expressed in the roots of *T. caerulescens,* but their expression is not responsive to the Zn status of the plant. Through functional complementation in yeast, it was shown that *ZNT1* mediates high-affinity uptake of Zn^{2+} and low-affinity uptake of Cd^{2+} (30). Specific alterations in Zn-responsive elements, such as transcriptional activators, may play an important role in Zn hyperaccumulation in *T. caerulescens* (30). However, increased uptake of Cd by *T. caerulescens* cannot be explained by the Zn transport pathway but may be related to an enhanced expression of the *IRT1* gene, which is essential for Fe uptake (31). The *IRT1* gene, it was shown, can mediate high-affinity uptake of Cd^{2+} in *A. thaliana* (32,33).

Enhanced root-to-shoot transport is another important element of metal hyperaccumulation. Lasat et al. (34) reported that most of the Zn in the nonaccumulator species *T. arvense* was localized in the root cell vacuoles, whereas in the hyperaccumulator *T. caerulescens,* more Zn was transported to the shoot and accumulated in the vacuoles of shoot cells. This pattern of sequestration could be due to tissue-specific expression of transporters responsible for vacuolar Zn sequestration or enhanced xylem loading (12). Very little progress has been made in understanding how hyperaccumulators differ from nonaccumulators in this area (12). Increased metal tolerance is essential for the hyperaccumulation phenotype to occur in majority of natural hyperaccumulator plants (21). Hypertolerance is achieved by internal detoxification and possibly involves compartmentation and complexation. Several studies have reported that metals are sequestered in leaf vacuoles in Zn, Cd, Ni, and As hyperaccumulators (31,35,36). Metal transporter genes encoding putative vacuolar ion transport proteins have been cloned from *T. caerulescens* (*ZPT1*) (37). The *ZTP1* gene belongs to the cation diffusion facilitator (CDF) family and, it was found, is highly expressed, predominantly in *T. caerulescens* leaves. Enhanced tonoplast transport of Zn probably plays an important role in metal tolerance in hyperaccumulator plants. With regard to complexation, Zn was found coordinated with histidine in roots and with organic acids or uncomplexed in shoots of *T. caerulescens* (38).

Phytochelatins (PCs) are small metal-binding peptides whose synthesis from glutathione (39), homo-glutathione, hydroxymethyl-glutathione (40), or γ-glutamylcysteine (41) is catalyzed by a transpeptidase, named phytochelatin synthase (PCS), which is a constitutive enzyme that requires posttranslational activation by heavy metals (39,42). There is strong evidence that phytochelatins are essential for constitutive tolerance to Cd in nonhyperaccumulator plants, but recent reports indicate that in *T. caerulescens,* PCs are not involved in the tolerance of Cd (43). Phytochelatin synthase, it has been shown, is activated by a broad range of metals and metalloids, in particular Cd, Ag, Pb, Cu, Hg, Zn, Sn, Au, and As, both *in vivo* and *in vitro* (42,44). Naturally selected heavy metal hypertolerance, which is commonly found in plant populations from strongly metal-enriched soils, does not seem to be associated with enhanced PC synthesis. De Knecht et al. (45) obtained equal capacities and activation constants for Cd-induced PC synthesis in crude protein extracts prepared from the roots of Cd/Zn-hypertolerant and nonmetallicolous *Silene vulgaris* plants. The root PC concentrations measured *in vivo*, however, were much lower in the hypertolerant plants, even when compared at equal rates of Cd uptake. In the same species, Zn-induced accumulation of PCs in roots were also much higher in nonmetallicolous plants than in Zn-hypertolerant plants when compared at equal metal exposure levels and at equal rates of metal accumulation in the roots (46). Artificial overexpression of enzymes and transporters involved in the PC-based metal sequestration machinery, it has been shown, increases metal tolerance, in general, and Cd tolerance in particular (47–49). Several examples of enhanced PC synthesis in cell lines artificially selected for Cd hypertolerance have also been reported (50). However, there is no evidence of naturally selected enhanced PC synthesis in hypertolerant plant populations from Cd- and Zn-toxic environments (43).

OPTIMIZATION OF PHYTOEXTRACTION WITH AGRONOMIC PRACTICES AND GENETIC ENGINEERING

Successful phytoextraction of heavy metals such as Zn and Cd depends on a number of factors; the most important is the selection of appropriate plant species. The rate of metal removal depends on the biomass of the plant as well as the concentration of metals in the harvested parts. Hyperaccumulator plant species have the capacity to bioconcentrate metals, but their use is limited by their small size and slow growth rate. On the other hand, in nonaccumulator species, low potential for metal bioconcentration could be compensated for by production of a large biomass (51). The benefits of using fast-growing, high biomass nonaccumulators versus slow-growing, low biomass hyperaccumulators for phytoextraction have been debated extensively. Chaney et al. (52) analyzed the rate of Zn and Cd phytoextraction and concluded that nonaccumulator crops do not remove enough metal to support phytoextraction, despite their higher biomass. Moreover, metal phytotoxicity would further reduce their biomass in highly contaminated soils.

Lasat (53) argues that the success of phytoextraction would ultimately depend on agronomic practices applied at the site. Chaney et al. (52) proposed the use of ammonium sulfate as a soil additive to provide nutrients necessary for high plant yield and to acidify soil for greater metal bioavailability. Another important factor that affects biomass production is plant density (53). Other agronomic considerations include the use of crop rotation, weed and pest control and proper irrigation methods (53).

Conventional breeding approaches have also been proposed to overcome the two major disadvantages of using hyperaccumulators for phytoextraction; low biomass and slow growth rates. The success of this approach is limited by sexual incompatibility caused by anatomical differences between parent plants. Biotechnology has the potential to overcome this limitation by allowing direct gene transfer (53). No reports involving the expression of metal hyperaccumulator genes in nonaccumulator species are so far available, but an alternative approach has been used to transfer hyperaccumulation capacity to a nonaccumulating, high biomass plant species. Brewer et al. (54) used somatic hybridization to create a hybrid between *T. caerulescens* and *Brassica napus.* Some of the hybrids had high biomass combined with high metal tolerance and accumulation that make them attractive for metal phytoextraction.

SUMMARY AND FUTURE DIRECTIONS

Phytoextraction is an environmentally friendly approach for remediating metal-contaminated soils that has been widely accepted in recent years. If applied successfully, this technology has the capability to extract metals from large surface areas in a cost-effective manner. The cost of soil cleanup can be less than a quarter of the cost of excavation or *in situ* contaminant fixation (55). On the other hand, phytoextraction technology has the distinct disadvantage of taking much longer to accomplish cleanup goals compared with other conventional treatments. There have also been very few successful demonstrations of phytoextraction under field conditions, which require further optimization of the technique. Successful implementation of this technology is likely to be achieved in the near future as research progresses in the following fields: (1) improved agronomic practices to increase productivity of hyperaccumulators, (2) use of appropriate soil amendments to increase metal availability to plants, (3) development of conventional breeding or tissue culture techniques to improve metal uptake and accumulation capabilities of high biomass nonaccumulators, and (4) use of biotechnology to develop transgenic plants capable of efficient phytoextraction.

PHYTOREMEDIATION ENHANCEMENT OF NATURAL ATTENUATION PROCESSES

David B. Vance

Mill Valley, California

Phytoremediation is a remediation method that uses what is in essence enhanced natural attenuation for cleanup. There are a variety of phytoremediation methods, some having multiple names: phytostabilization, rhizodegradation (phytostimulation, rhizosphere bioremediation, or plant-assisted bioremediation), rhizofiltration (contaminant uptake), phytodegradation (phytotransformation), phytovolatilization, and Phytoaccumulation (phytoextraction or hyperaccumulation). Various types of plants can be used in phytoremediation, including poplar trees, alfalfa, black locust, Indian mustard, fescue grass, crested wheatgrass, and Canada wild rye.

Figure 1 and Tables 1 and 2 summarize the overall concepts of phytoremediation and the types of processes and chemicals that can be treated.

A form of natural attenuation for indigenous plants at a site and enhanced bioremediation for cultivated plants, phytoremediation acts through two fundamental remediation processes: enhancement of saturated zone *in situ* biodegradation and phytoextraction.

The rhizosphere is the zone in the subsurface occupied by the plants' root systems. Root depths of 6–30 ft are common, with some trees and shrubs capable of root penetration to 60 ft. Phreatophytes are deep-rooted plants that draw water from beneath the water table; xerophytes are shallow-rooted and depend more directly on infiltrating rainwater. Depending on site conditions and contaminant distribution, either type of plant can be of value for phytoremediation.

Within the rhizosphere, plants contribute to enhanced *in situ* biodegradation through the supply of carbonaceous substrate and oxygen transfer. Rhizodeposition is partially

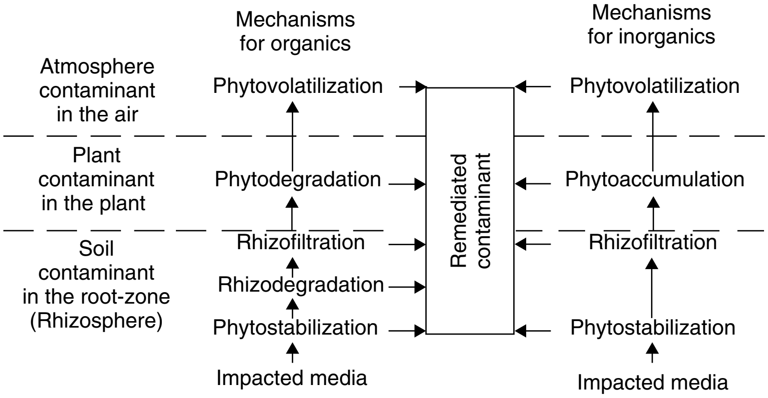

Figure 1. Overview of phytoremediation. (After Ref. 1).

Table 1. Types of Phytoremediation for Organic Constituents

Type of Phytoremediation	Process Involved	Contaminant Treated
Phytostabilization	Plants control pH, soil gases, and redox conditions in soil to immobilize contaminants. Humification of some organic compounds is expected.	Expected for phenols, chlorinated solvents (tetrachloromethane and trichloromethane), and hydrophobic organic compounds
